Patients who develop paraplegia or paraparesis are treated aggressively in an attempt to reverse the deficit. Treatment includes inserting a CSF drain (if not already present), administering steroids and osmotic diuretics, optimizing hemodynamics (including liberalizing blood pressure), correcting anemia, and preventing fever.

Table 54–2.

Results of 2755 Open Descending Thoracic or Thoracoabdominal Aortic Aneurysm Repairs

Extent of repair	No. of patients	30-Day deaths	Paraplegia/paraparesis	Renal failure
DTAA	469	15 (3.2%)	12 (2.6%)	11 (2.3%)
TAAA I	706	35 (5.0%)	23 (3.3%)	19 (2.7%)
TAAA II	762	46 (6.0%)	48 (6.3%)	63 (8.3%)
TAAA III	391	21 (5.4%)	10 (2.6%)	24 (6.1%)
TAAA IV	427	13 (3.0%)	6 (1.4%)	23 (5.4%)
Total	2755	130 (4.7%)	99 (3.6%)	140 (5.1%)

DTAA = descending thoracic aortic aneurysm; TAAA = thoracoabdominal aortic aneurysm.

Vocal cord paralysis can exacerbate respiratory complications and should be suspected in patients with postoperative hoarseness and confirmed by direct examination. Effective treatment can be provided by direct cord medialization (i.e., type 1 thyroplasty) or in higher-risk patients, by polytetrafluoroethylene injection.[103]

Infection of a DTAA or TAAA graft is often fatal. In an effort to minimize this risk, intravenous antibiotics are administered throughout the postoperative course until all drains, chest tubes, and central venous lines have been removed.

SURVEILLANCE FOR ADDITIONAL AORTIC DISEASE

Patients who have undergone DTAA or TAAA repair remain at risk for developing new aneurysms in other aortic segments or in reattachment patches. Progressive weakening of aortic tissue at suture lines can lead to pseudoaneurysm formation. To detect new aortic pathology before life-threatening complications occur, we recommend that all patients undergo annual CT or MRI of the chest and abdomen. This strategy of lifelong surveillance is especially important in patients with connective tissue disorders.[5] Subsequent aortic repairs can be performed with surprisingly low mortality and morbidity, particularly when done in an elective setting.[104]

CHAPTER 55

Endovascular Therapy for the Treatment of Thoracic Aortic Disease

Susan D. Moffatt-Bruce • R. Scott Mitchell

Patients with thoracic aortic disease are a difficult population to treat, as they frequently consist of an aged population with multiple comorbidities. The modern surgical treatment of thoracic aortic diseases began in the 1950s when successful treatment using segmental resection and graft replacement was reported by Swan, Lam, DeBakey, and Etheredge.[1–3] Thereafter, DeBakey and Cooley reported the first successful repair of an ascending aortic aneurysm using cardiopulmonary bypass.[4] Our understanding of the pathophysiology and natural history of thoracic aortic disease has evolved, which has expanded our treatment choices.[5,6] In addition, improvements in diagnostic capabilities, surgical techniques, and perioperative care have resulted in improved outcomes, even as the risk profile has increased. Nonetheless, operative intervention in this patient population frequently results in substantial mortality and long-term morbidity.[7,8] The concept of using an endovascular stent-graft in patients with thoracic aortic disease emerged a decade ago, propelled by the desire to avoid surgical risk as well as to induce reconstructive modeling of the diseased aorta by initiating a natural healing process through exclusion and depressurization of the aneurysmal sac.[9] In an effort to improve outcomes in the treatment of patients with thoracic aortic disease, endovascular stent-graft technology has rapidly followed applications on the abdominal aorta.[10,11] Originally devised for high-risk patients with multiple comorbidities, thoracic stent-graft applications are being expanded to young and old patients with a variety of pathologies, including thoracic aortic aneurysms, aortic dissections, intramural hematomas, penetrating atherosclerotic ulcers, and thoracic aortic trauma.[12–19] Initial reports using these endovascular stent-grafts have been encouraging, but long-term outcomes are unknown, and the necessity for long-term follow-up, with its attendant expense, has raised serious concern.[20–22]

HISTORY

Endovascular stent-graft technology was initially envisioned for use in abdominal aortic aneurysms.[23] Introduced by Parodi, balloon expandable stents attached to the ends of a vascular tube graft were utilized to exclude the aneurysm sac. There were several attractive features of this concept, including the introduction of the device from a peripheral site, eliminating the necessity for an invasive laparotomy, the avoidance of aortic cross-clamping and its requisite physiologic perturbations, and minimizing respiratory complications. Lastly, hospital stay and recovery time could be potentially shortened.

At Stanford University Medical Center, a collaborative effort between interventional radiologists and cardiovascular surgeons proved highly synergistic, and resulted in the manufacture and clinical use of thoracic stent-grafts. Work had commenced years earlier with the use of uncovered stents for the repair of aortic dissections in an animal model. The stent-grafts were manufactured using self-expanding Gianturco Z stents (Cook Co., Bloomington, Ind), which were fastened together and then covered with a woven Dacron graft (Meadox-Boston Scientific, Natick, Mass; Fig. 55-1). Institutional review board (IRB) approval was initially obtained for a high-risk study using endovascular stent-grafts for the treatment of thoracic aortic aneurysms in patients who were deemed not to be surgical candidates.[24] A total of 13 patients underwent transluminal endovascular grafting of thoracic aortic aneurysms with a mean diameter of 6.1 cm. The stent-grafts, custom-designed for each patient, were constructed of self-expanding stainless steel stents covered with woven Dacron grafts. Placement of these stents was successful in all patients with thrombosis of the aneurysm surrounding the stent occurring in 12 of the 13 patients. As reported, at 1 year there were no deaths, paraplegia, stroke, distal embolization, or infection.[24] It was therefore

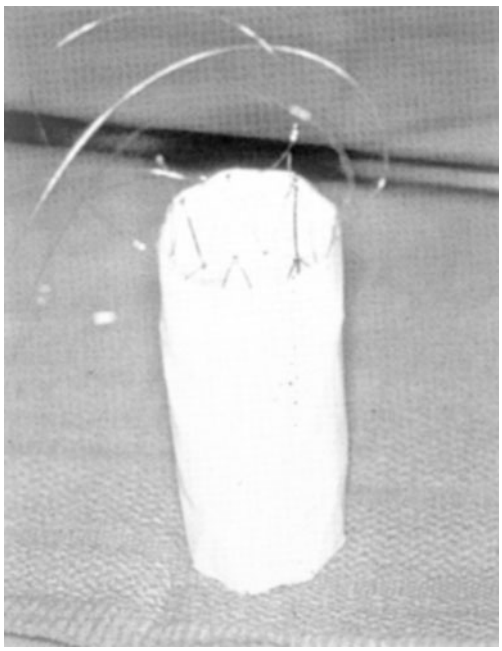

Figure 55-1. First-generation stent-graft assembled from articulated Z stents and covered with a woven Dacron tube graft.

concluded that these preliminary results demonstrated that endovascular stent-graft repair was safe in highly selected patients.

This feasibility trial led to the extension of the IRB approval for the treatment of 103 patients with thoracic aortic aneurysms.[25] Of these 103 patients, 60% were unsuitable candidates for conventional open surgical repair and therefore deemed inoperable. Again, these patients underwent repair of a descending thoracic aortic aneurysm using "home-made" or first-generation stent-grafts fabricated from self-expanding Z stents covered with woven Dacron tube graft. Complete aneurysm thrombosis was achieved in 83% of patients. Early mortality was 9% and was significantly associated with preoperative cerebrovascular accidents and myocardial infarctions. Major perioperative morbidity included paraplegia in 3 patients, cerebrovascular accidents in 7 patients, and respiratory insufficiency in 12 patients. Treatment failure occurred in 38 of the 103 patients, and 5 patients required late operative therapy for endoleaks associated with aneurysm enlargement. Actuarial survival was 81% at 1 year and 73% at 2 years. Given the high-risk nature of this patient population, these first-generation results were deemed satisfactory. It was, however, recognized that mortality and morbidity occurred frequently and that long-term follow-up was necessary to fully define the efficacy of an endovascular approach in thoracic aortic aneurysm therapy. Subsequently, in 2004, midterm results were reported for these 103 patients treated with the first-generation stent-grafts.[26] Overall actuarial survival was dismal; 82%, 49%, and 27% at 1, 5, and 8 years, respectively. However, the survival of the potentially operable candidates was 93% and 78% at 1 and 5 years, respectively, as compared to 74% and 31% at 1 and 5 years, respectively, in those patients designated as inoperable. In patients judged not to be surgical candidates, life expectancy, despite endovascular therapy, was therefore quite bleak, and has raised concerns whether any surgical therapy is appropriate for these patients. Further results revealed that 11 of the 103 patients suffered late aortic rupture at the site of endovascular treatment. This was a very sobering finding considering that open surgical graft replacement has been associated with durable long-term results with only a negligible late hazard of anastomotic problems. However, it must be remembered that this study involved the use of a relatively primitive first-generation device, with a fairly steep learning curve.

Extending the use of the endovascular stent-grafts to the treatment of complicated acute aortic dissections of the descending thoracic aorta, Dake and associates reported their findings in the *New England Journal of Medicine* in 1999.[27] Again these stents were the first-generation "home-made" devices described above. Placement of the stents across the primary entry tears was technically successful in all patients, with correction of malperfusion. Complete thrombosis of the false lumen occurred in 79%. The early mortality rate was 16%, which reflected late referral, with established intestinal gangrene, and another patient with Ehlers-Danlos syndrome, perhaps a poor candidate for endovascular repair. Favorable clinical results persisted out to a mean follow-up of 13 months.

These pioneering efforts at the Stanford University Medical Center established some interesting concepts. Namely, that these were complex patients with complex aortic problems, and that endograft therapy for aneurysmal disease was effective, potentially with reduced morbidity, but with uncertain long-term durability. Improved results could likely be obtained with more sophisticated devices, and endograft repair could effectively reverse malperfusion syndromes in complicated type B aortic dissections.

NATURAL HISTORY AND SURGICAL OUTCOMES OF THORACIC AORTIC DISEASES

Thoracic Aortic Aneurysms

Approximately 50% of all thoracic aortic aneurysms are located in the descending aorta; these aneurysms commonly arise at the level of the left subclavian artery and are often atherosclerotic in nature.[28] The size-rupture correlation has been demonstrated by studying the natural history of these aneurysms as reported by Clouse and associates, using the Olmstead County database, in which thoracic aortic aneurysms have an overall 5-year rupture risk of 30%.[29] The Mount Sinai group has identified clinical variables that determine the risk for rupture, which include increasing age, presence of chronic obstructive pulmonary disease, maximal thoracic and abdominal aneurysm diameter, and the presence

of pain.[30] The Yale Aortic Diseases Group has documented rupture and dissection of ascending or arch aneurysms at a median size of 6 cm and descending or thoracoabdominal aneurysms at a median size of 7.2 cm.[6] Furthermore, the Yale group has reported that the mean rate of rupture or dissection is 2% per year for small aneurysms, 3% for aneurysms 5.0 to 5.9 cm, and 6.9% for aneurysms of 6.0 cm and larger. Using proportional hazards regression, the odds ratio for rupture is more than 25 times higher in patients with aneurysms of 6.0 cm or greater than in those with aneurysms in the range of 4.0 to 4.9 cm.[31]

Open surgical graft replacement is the traditional treatment for these patients. The presence of comorbidities in this specific population increases the surgical risks, especially in the case of emergency intervention. However, with increasing experience, very good surgical morality rates in the 5 to 10% range have been reported from experienced centers.[32–34] Similarly, paraplegia and paraparesis rates range from 3 to 16%, with predictive factors including extent of resection, emergency operation, renal dysfunction, distal circulatory support, and cerebrospinal fluid drainage.[35–37] Nevertheless, 5-year survival rates between 60 and 80% have been achieved in recent surgical series.[32–34]

Thoracic Aortic Dissections

Acute aortic dissection is the most common catastrophe affecting the thoracic aorta, with many more people dying of rupture of dissections than of aneurysms. Although poorly understood, a primary intimal tear allows a high-pressure entry of blood into the subadventitial space, which then rapidly propagates proximally and distally. With the Stanford classification system, type A connotes involvement of the ascending aorta. The high mortality rate of 50% at 48 hours usually mandates emergent surgical repair. Conversely, type B dissections involve the descending thoracic aorta, and are typically managed with anti-impulse therapy, with surgical management reserved for those patients presenting with complications, namely intractable pain, rupture or impending rupture, or visceral or limb malperfusion syndromes.[38–41]

The Stanford group has compared the actual survival of medically and surgically treated type B dissection over a 36-year period. The actuarial survival estimates for all patients were 71%, 60%, 35%, and 17% at 1, 5, 10, and 15 years, respectively, and were similar for the medical and surgical patients.[40] The hope for benefits of avoiding the late complications from false-lumen expansion following surgical repair was not demonstrated in this follow-up.

The utility of thoracic endografts in chronic dissections is even more unclear. Given the multiple septal fenestrations, and the relative immobility of the chronically dissected septum, it seems unlikely that stent-graft insertion could realistically confer any long-term benefits, with the possible exception of a very focal aneurysmal false-lumen dilation distant from septal fenestrations near the level of the diaphragm.

Penetrating Atherosclerotic Ulcers and Intramural Hematomas of the Thoracic Aorta

Penetrating atherosclerotic ulcers (PAUs) and intramural hematomas (IMHs) are distinct pathologic entities now being diagnosed with increasing frequency.[42] PAUs probably represent rupture of an atherosclerotic plaque, with penetration into the internal elastic lamina of the aorta, and may be associated with proximal and distal progression of an intramural hematoma. Conversely, IMH not associated with a penetrating ulcer may result from the spontaneous rupture of aortic vasa vasorum that may initiate hemorrhage into the aortic media, and may progress to an intimal tear and classic aortic dissection.[42]

In the ascending aorta, IMH, with or without PAU, frequently progresses to frank dissection during the acute phase, and thus warrants early ascending aortic replacement. The highest mortality rate among patients with IMH is associated with ascending aortic involvement.[43,44] Experience has therefore suggested that a more aggressive approach with early surgery is warranted in those patients who have ascending aortic involvement or in those who have a coexisting aneurysm with IMH.[44]

In the descending thoracic aorta, pure IMH in the absence of aneurysmal change is usually treated with aggressive control of hypertension. For IMH with PAU, increasing maximal depth and maximal diameter were both associated with disease progression, in addition to persistent pain and increasing pleural effusion.[45] The risk of aortic rupture is higher among patients with PAU by almost 30% than with patients with type A or B dissection.[42] However, the progression of PAU is slow and is associated with a low incidence of acute rupture or other life-threatening events. Among patients with PAU who are not treated surgically, the natural history would indicate that the majority of patients will have aortic enlargement with the formation of saccular or fusiform pseudoaneurysms and intramural thrombus.[43]

Thoracic Aortic Trauma

Trauma is the most common cause of nondegenerative disease affecting the thoracic aorta. According to autopsy series, 36 to 54% of disruptions occur at the aortic isthmus, 8 to 27% involve the ascending aorta, 8 to 18% occur in the arch, and 11 to 21% involve the distal descending aorta.[46] Blunt trauma is commonly a catastrophic injury with only approximately 20% surviving to hospital admission. Mortality following admission ranges from 39 to 73% and is frequently the result of other major injuries.[47] The other multiple injuries a patient may experience almost invariably limit operative approaches and timing. All operations involving the thoracic aorta pose some risk of ischemic injury to the spinal cord, which is a dreaded complication in a predominantly young population. In addition, the immediacy of the operation associated with traumatic injury may require inexperienced surgeons to deal with complex pathology.[46] Fortunately, in the past decade there has been increased understanding, suggesting that for some patients without

radiographic signs of impending rupture, that permissive hypotension may be an effective temporizing strategy, allowing operative intervention after a patient has recovered from serious brain or lung injury that may have compromised immediate operative management.

ENDOVASCULAR THERAPY OF THE THORACIC AORTA

Technical Development

The first stent-grafts used at Stanford were manufactured using 2.5-cm self-expanding Gianturco Z stents (Cook Co., Bloomington, Ind), which were fastened together and then covered with a woven Dacron graft (Meadox-Boston Scientific, Natick, Mass; see Fig. 55-1). These stent-grafts were oversized approximately 10 to 15% above the cross-sectional diameter ascertained by computed tomography (CT) in an effort to obtain sufficient radial force to achieve an endoseal and prevent stent-graft migration. A minimum of 2 cm of normal aorta was required for adequate fixation, otherwise referred to as the "landing zone," both proximally and distally. The covered stent was loaded into a delivery capsule which required femoral and iliac arteries greater than 8 mm to allow the introduction of a 28 F delivery sheath. This dilator contained a sheath that had been previously placed over a super-stiff guidewire and was positioned proximal to the point of deployment. Once this was achieved, the compressed stent-graft was advanced into the sheath and deployed by using a "pusher" rod. Devices were limited to a maximal diameter of 40 mm in that aortas larger than 37 mm in diameter were themselves aneurysmal and unlikely to serve as stable attachment zones. Other anatomic constraints of these early "home-made" or first-generation stent-grafts that precluded secure fixation included acute angulation at the distal arch, and severe sigmoid-like tortuosity coursing through the diaphragmatic crura, reflecting the relative inflexibility of these early delivery systems.

The advent of this new stent-graft technology required a new terminology for endoleaks that allowed blood to leak around or through the stent-graft, thus allowing the aneurysmal sac to remain pressurized. Type I endoleaks occur at the proximal or distal attachment sites, and signify a failure to achieve a hemostatic seal at these implantation sites.[14,24,25] Type II endoleaks denote a communication between a branch vessel and the excluded aneurysm sac. These usually occur from a back-bleeding inferior mesenteric artery in the abdomen, or intercostal artery in the chest. Type III endoleaks originate from the middle graft sections, and are usually caused by disruption of graft-to-graft overlaps, or by leakage through the graft itself. Type IV endoleaks are characterized by an increase in size of the aneurysm sac in the absence of an identifiable patent branch vessel, variously referred to as "endotension."

Years of experience with endovascular abdominal aorta repair and follow-up of thoracic aortic repairs has yielded important information for improved stent-graft technology.[11,48,49] Commercially produced second- and third-generation stent-grafts are more flexible and have a lower profile, and thereby allow use of a smaller introducer sheath in the femoral vessels. Experience has shown that tapered, flexible, over-the-wire delivery systems that are less than 20F in diameter rarely fail to traverse tortuous femoral or iliac arteries. Hooks at the proximal end of the stent-graft appear to provide the most secure means of attachment, but may be suboptimal for treating patients with acute dissections. It is likely that different grafts may be developed for different pathologies, with devices for dissections being devoid of hooks or uncovered metal components. For traumatic aortic lacerations, smaller device sizes are necessary, as these are usually nonatherosclerotic normal-sized aortas with small access vessels. Ideal device components have been broken down into three categories: delivery system, graft material, and metal frame.[50] The delivery system should be of low profile, flexible for maneuverability, rigid enough to resist kinking, and hemostatic during use. The graft material should also be of low profile, strong and durable, and reasonably thin. The graft metal frame should provide high column strength and ductility, be compression and kink resistant from external forces, radiopaque, and corrosion and fatigue resistant. Nitinol is now used for the stent material in the majority of grafts and the graft material is usually polytetrafluoroethylene (PTFE) or polyester.

Currently, the Gore Excluder TAG system (W. L. Gore, Sunnyvale, Calif) is the only Food and Drug Administration (FDA)-approved graft. However, the Talent and Valiant systems (Medtronic, Sunrise, Fla) and the Zenith system (Cook-Cardiovascular, Bloomington, Ind) are being used with special release consents required (Fig. 55-2). These second- and third-generation endoprostheses are more flexible

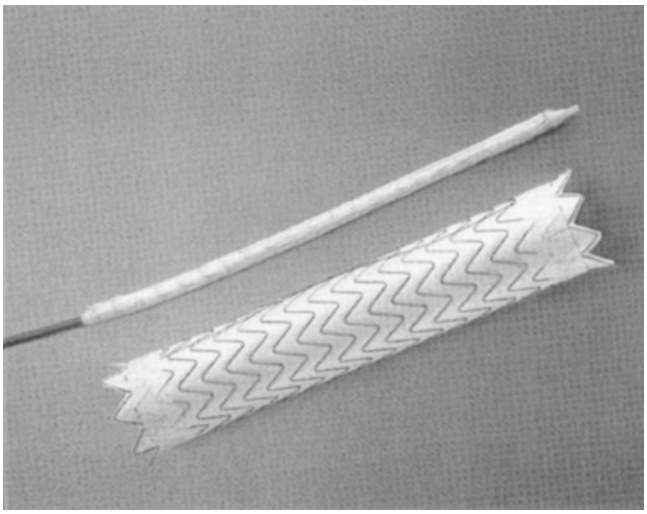

Figure 55-2. Second-generation commercially manufactured thoracic aortic stent-graft. The thoracic Excluder TAG system by W. L. Gore contains a thin-walled PTFE graft covered by a nitinol exoskeleton.

and have a lower profile with smaller delivery systems that can be inserted easily to treat a number of thoracic aortic pathologies.

Clinical Results Using Endovascular Stents for Thoracic Aortic Disease

Thoracic aortic aneurysms

The Stanford group originally reported their outcomes of endovascular stent-graft placement in 13 patients back in 1994.[24] These preliminary results demonstrated that endovascular stent-graft repair was safe in highly selected patients with descending thoracic aneurysms (Fig. 55-3). This paper was followed by a report of 103 patients treated with endovascular stent-graft technology as part of a 5-year clinical trial. Using first-generation "home-made" stent-grafts, early mortality was reported as 9%, but a stroke rate of 7% and paraplegia rate of 3% were also reported. More recently, the Stanford group has reported 5- and 10-year results and has identified risk factors for adverse late outcomes.[26] Overall survival was 82%, 49%, and 27% at 1, 5, and 8 years. This included patients who were deemed both operable and inoperable. In the group of patients who were deemed operable and could have undergone open repair of their descending thoracic aneurysms, the survival was 93% and 78% at 1 and 5 years, compared with 74% and 31% in those deemed inoperable. Independent risk factors for death were older age, previous stroke, and designation as a nonoperative candidate. Freedom from aortic reintervention and treatment failure at 8 years was only 70% and 39%, respectively. Ultimately these findings suggested that by using the first-generation stent-grafts, good operative candidates had satisfactory outcomes. Conversely, those deemed inoperable had bleak outcomes, perhaps no better than if they had not been treated at all. Therefore the question of intervening at all in this cohort of patients comes into question, with many questions concerning resources and quality of life being asked. This study also revealed that late aortic complications were detected in nearly 30% of patients, which re-emphasizes the importance of follow-up serial imaging surveillance.

In January 2005 the phase II multicenter trial of the Gore Excluder TAG thoracic endoprosthesis results were reported.[51] This multicenter prospective nonrandomized trial was conducted at 17 sites and compared results of stent-graft repair of descending thoracic aortic aneurysms in 140 patients with results of open repair in 94 patients. Strict inclusion and exclusion criteria attempted to ensure comparability of both groups. Follow-up CT scans were obtained at 1, 6, 12, and 24 months. For stent-graft patients, operative blood loss, renal failure, paraplegia, and mortality rates were all significantly less than for the open repair group. Interestingly, stroke rates were about equal in both groups. ICU stay and total hospital stay, and time to return to normal activity were 50% shorter for the stent-graft group than for those with open repair. Although stent-graft patients maintained an advantage from aneurysm-related mortality out to 2 years (97 versus 90%), interestingly, all-cause mortality was similar between groups at 2 years, which is similar to results of recent randomized trials in abdominal aortic aneurysm stent-graft trials.[52]

Ricco and colleagues have most recently reported on an independent nationwide study in France using a variety of endovascular devices to treat descending thoracic aortic aneurysms in the majority of cases.[53] The Gore Excluder TAG (Gore) and Talent (Medtronic) devices were used in 84% of patients and an operative mortality of 10% was reported. A complication rate of 21% was reported, which included endoleaks in 16% of patients that were fatal in three patients. The 6-month survival rate was 86% and freedom from other complications (other than endoleak) was only 63% at 6 months. This study, involving 166 stent-graft repairs, performed in 29 centers and using 6 different types of endoprostheses, demonstrated that stent-graft repair of thoracic aortic disease could be performed with acceptable morbidity and mortality, at short-term follow-up. They do, however, qualify their conclusions by stating that endograft

treatment of thoracic aortic aneurysms should continue to be used in an investigative setting.

Thoracic aortic dissection

For dissections originating distal to the origin of the left subclavian artery, referred to as Stanford type B dissections, aggressive antihypertensive therapy has been the mainstay of treatment.[40] For complicated dissections, however, including rupture, impending rupture, intractable pain, rapid expansion, or malperfusion syndromes, surgical intervention is indicated. In these instances, however, surgical mortality has been reported to be as high as 50 to 60%. Endograft coverage of the primary intimal tear, redirecting flow into the true lumen, would appear to be an ideal application of this endograft technology. The Stanford group, with their colleagues in Mie University in Japan, reported the use of the first-generation stent-grafts in 19 patients with complicated type B aortic dissections. Placement was successful in all patients, and revascularization of ischemic branch vessels occurred in 76% of cases. There were three hospital deaths, two of which resulted from late referral, and one in a patient with Ehlers-Danlos syndrome who was perhaps untreatable by any modality. Although the follow-up was short, there were no incidences of aortic rupture or aneurysm formation, and a single-lumen aorta to the level of the stent-graft was achieved in the majority of patients[27] (Fig. 55-4).

More recently, Kato and associates reported their use of endovascular stent-grafts for the treatment of aortic dissections, both acute and chronic.[54] Significant findings were that although 2 of the 38 treated patients died early, there were no late deaths during a mean follow-up of 27 months. Furthermore, early and late complication rates were 33% and 36%, respectively, in patients with acute dissections, whereas rates were 4% and 0%, respectively, in patients with chronic dissections. These complications included endoleak and aneurysmal degeneration of the aorta in 25% of patients. Only one case of paraplegia was reported. This group therefore concluded that acute dissections could be treated with endovascular stent-grafts but that stent-graft repair should be delayed for acute Stanford type B dissections without complications.

Currently, a randomized trial is underway to compare the 2-year outcome of uncomplicated Stanford type B aortic dissections treated by endovascular implantation of a Medtronic Talent stent-graft to best medical treatment. This trial, referred to as the INSTEAD trial (*IN*vestigation of *STE*nt in patients with type B *A*ortic *D*issection) will measure all-cause mortality as the primary outcome; secondary outcome variables will include conversion to stent and/or surgery, thrombosis of the false lumen, cardiovascular morbidity, aortic expansion, quality of life, and hospital stay. Given the relatively low 1-year mortality for uncomplicated type B dissections, the benefit for any interventional strategy may be difficult to prove. Results should be available in late 2006.[55]

(C) CT scan of the abdomen and (D) angiogram of the descending thoracic aorta after stent-graft implantation into the true lumen in the proximal descending thoracic aorta.

Penetrating atherosclerotic ulcers and intramural hematomas

IMH of the aorta is attracting growing interest as a variant of aortic dissection.[44] The evolution from IMH to overt dissection or rupture is not well understood and currently pure IMH of the descending thoracic aorta is not amenable to stent-graft repair. IMH of the ascending aorta is currently a surgically treatable disease with early intervention being warranted.[43,44] IMH, however, is often associated with or even precipitated by PAUs of the descending thoracic aorta.[42] Therefore, covering the PAU with a stent-graft may limit the progression of the IMH and allow healing to occur.[19,42] Unfortunately, even with successful stent-graft implantation using both first- and second-generation grafts, retrograde aortic dissection, new ulcer formation, and endoleaks have been noted in a significant percentage of patients, emphasizing the diffuse and severe nature of this disease.[56–59]

The Stanford group has reported their mid-term results treating PAU of the descending thoracic aorta, with an average of 51 months of follow-up[19] (Fig. 55-5). Using both first-generation and second-generation commercial devices, 26 patients were treated, 14 of whom were deemed nonoperative candidates. The primary success rate was 92% with actuarial survival estimates of 85%, 76%, and 70% at 1, 3, and 5 years, respectively. Perioperative mortality was 12%. Increasing aortic diameter and female gender were determinants of treatment failure. These risk factors reflect the importance of careful patient selection based on anatomic criteria and clinical factors. In addition, long-term follow-up with serial CT angiography is necessary to detect late complications.

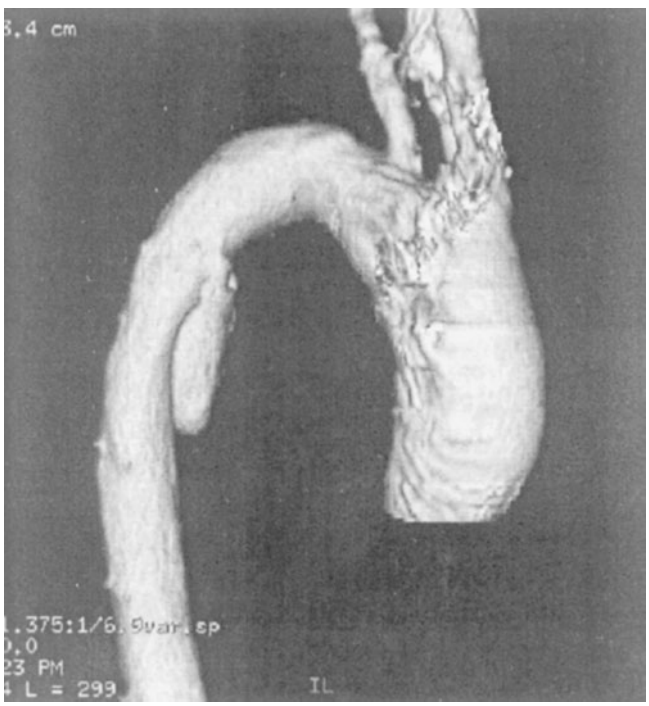

Figure 55-5. Three-dimensional CT scan of a giant penetrating ulcer involving the descending thoracic aorta that is perfectly suited to treatment with a thoracic stent-graft.

Thoracic aortic trauma

Aortic injuries secondary to nonpenetrating trauma are lethal lesions, with 80 to 90% of patients dying in the hour following the accident.[60] Urgent surgical graft replacement of the aorta is the standard treatment, but these patients frequently have other major injuries, including closed head injuries, pulmonary contusions, and other solid organ injuries that limit open surgical repair. Several authors have reported the improved results of stent-grafts over open repair for these acute injuries.[61,62] Although long-term durability may be a concern, there appear to be significant short-term benefits.[62,63] The major difficulty at present is the absence of thoracic stent-grafts sufficiently small in diameter as to be appropriate for these relatively normal-sized aortas, frequently less than 20 to 22 mm in diameter. Because of these limitations, our current strategy is to allow permissive hypotension, intervening only for those patients with signs of impending rupture, those with increasing mediastinal hematoma or hemothorax, or persistent pain. For these patients, conventional repair is preferred, using heparin-bonded circuits, unless closed head injury or pulmonary contusions contradict. Stent-graft repair is utilized for those patients in whom a conventional repair could not be tolerated.

The Stanford group has reported on their mid-term results of stent-graft repair of chronic traumatic aneurysm of the descending thoracic aorta[64] (Fig. 55-6). Among 15 patients treated with either first- or second-generation stent-grafts, deployment was successful in all patients without need for surgical conversion. No neurologic complications were reported. Actuarial survival estimates at 1 and 6 years were 93% and 85%. Freedom from reintervention on the descending thoracic aorta was 93% and 70% at 1 and 6 years, respectively. Freedom from treatment failure at 1 and 6 years was 87% and 51%, respectively. They therefore concluded that stent-grafts are safe in patients with chronic traumatic aneurysms, and are associated with satisfactory but not optimal mid-term durability. They state that younger, low-risk patients should be offered conventional, open surgery and stent-grafting should be reserved for those patients who are at prohibitive operative risk.[64]

CONCLUSIONS

Despite the many advances in the field of endovascular surgery, stent-grafting the thoracic aorta remains in a developmental phase.[20,65] This evolving technology has been applied to the treatment of thoracic aortic aneurysms, aortic dissections, IMHs, and PAUs, and traumatic injuries. The early outcomes are encouraging but middle- and long-term outcomes are a concern. Although device technology has certainly improved over the past 20 years, all devices are limited

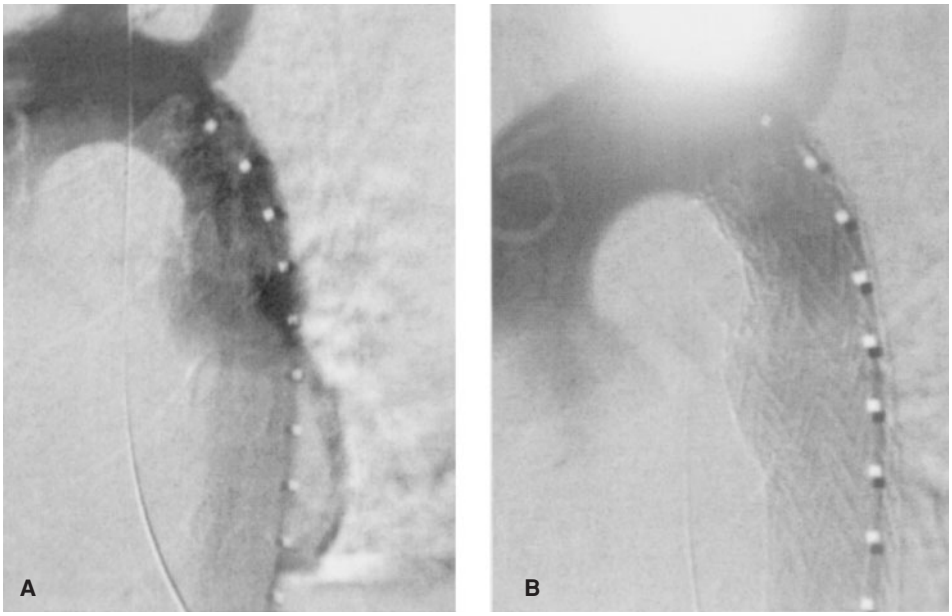

Figure 55-6. (A) Thoracic angiogram demonstrating a contained rupture of the descending thoracic aorta in a trauma victim. (B) Thoracic angiogram revealing repair of the aortic rupture with a thoracic stent-graft.

by their own structural flaws, lack of conformability, limited array of sizes, length of landing zones necessary to allow secure fixation, and structural integrity to withstand the severe physiologic milieu present in the thoracic aorta. Given the variable pathologies, it is likely that many different stent-graft configurations will be necessary for the various clinical indications.

Of utmost importance in the treatment of thoracic aortic pathology with stent-grafts is strict and dedicated follow-up. Patients need to be seen on a routine basis and new symptoms or findings need to be investigated. Serial CT angiography is an excellent tool to follow the areas of the thoracic aorta treated with the endograft, as well as to follow the evolution of the untreated portions of the aorta. Follow-up will allow endoleaks and device migration to be detected, and may further define the natural history of endovascular treatment strategies.

Diseases of the thoracic aorta pose a significant challenge to the surgeon because of the complexity of the disease and the characteristics of the patient population. Current literature supports the early advantage of endovascular technology in well-suited patients, but longer follow-up and results of ongoing trials will help define the indications for their use in the future.

CHAPTER 56

Pulmonary Embolism and Pulmonary Thromboendarterectomy

Michael M. Madani • Stuart W. Jamieson

Pulmonary thromboendarterectomy (PTE) is the definitive treatment for chronic pulmonary hypertension as the result of thromboembolic disease. Although pulmonary embolism (PE) is one of the more common cardiovascular diseases affecting Americans, PTE remains an uncommon procedure, primarily because this form of chronic pulmonary hypertension remains an underdiagnosed condition. Patients affected by chronic thromboembolic pulmonary hypertension (CTEPH) may present with a variety of debilitating cardiopulmonary symptoms. However, once diagnosed, there is no curative role for medical management, and surgery remains the only option.

The exact incidence of PE remains unknown, but there are some valid estimates. Acute PE is the third most common cause of death (after heart disease and cancer). Approximately 75% of autopsy-proven PEs are not detected clinically.[1] Dalen and Alpert[2] calculated that PE results in 630,000 symptomatic episodes in the United States yearly, making it about half as common as acute myocardial infarctions, and three times as common as cerebrovascular accidents. This is, however, a low estimate, since in 70 to 80% of the patients in whom the primary cause of death was PE, premortem diagnosis was completely unsuspected.[3,4] The disease is particularly common in hospitalized elderly patients. Of all hospitalized patients who develop PE, 12 to 21% will die in the hospital, and another 24 to 39% die within 12 months.[5–7] Thus approximately 36 to 60% of the patients who survive the initial episode live beyond 12 months and may present later in life with a wide variety of symptoms.

More than 90% of clinically detected pulmonary emboli are associated with lower extremity deep vein thrombosis (DVT), but in two-thirds of patients with DVT and PE, the DVT is asymptomatic.[8,9] Greenfield estimates that approximately 2.5 million Americans develop DVT each year.[10]

For the most part, DVT and acute PEs are managed medically. Cardiac surgeons rarely become involved in management of acute PE, unless it is in a hospitalized patient who survives a massive embolus that causes life-threatening acute right heart failure with low cardiac output, with a large clot burden. Conversely, the mainstay of treatment for patients with chronic pulmonary thromboembolic disease is the surgical removal of the disease by means of pulmonary thromboendarterectomy. Medical management is only palliative, and transplantation surgery is an inappropriate use of resources with less than satisfactory results.

The prognosis for patients with pulmonary hypertension is poor, and it is worse for those who do not have intracardiac shunts. Thus patients with primary pulmonary hypertension and those with pulmonary hypertension due to pulmonary emboli fall into a higher risk category than those with Eisenmenger syndrome and encounter a higher mortality rate. In fact, once the mean pulmonary pressure in patients with thromboembolic disease reaches 50 mm Hg or more, the 3-year mortality approaches 90%.[11]

Surgical options are dependent on both the primary disease process and the reversibility of the pulmonary hypertension. With the exception of thromboembolic pulmonary hypertension, lung transplantation is the only effective therapy for patients with pulmonary hypertension when the disease reaches end stage. Pulmonary transplantation is also still used in some centers as the treatment of choice for those with thromboembolic disease. However, a true assessment of the effectiveness of any therapy should take into account the total mortality once the patient has been accepted and put on the waiting list. Thus the mortality for transplantation (and especially double-lung or heart-lung transplantation) as a therapeutic strategy is much higher than is generally appreciated because of the significant loss of patients awaiting donors. Considering also the long-term use of antirejection medications and their associated side effects, the higher

operative morbidity and mortality, the long waiting time, and inferior prognosis even after transplantation, transplantation is clearly an inferior option to pulmonary thromboendarterectomy. We consider it to be inappropriate therapy for this disease, leaving pulmonary thromboendarterectomy as the only curative option for patients with CTEPH.

DEEP VENOUS THROMBOSIS

DVT primarily affects the veins of the lower extremity or pelvis and rarely affects the venous system elsewhere. The process may involve superficial as well as deep veins, but superficial venous thrombosis does not generally propagate beyond the saphenofemoral junction and therefore very rarely causes PE.[9,12] Venous thrombosis of the upper extremity is almost always associated with trauma, indwelling catheters, or other pathologic states and is an uncommon cause of PE, but can be fatal. Pulmonary emboli that do not originate from the deep venous system of the legs and pelvis are thought to come from a diseased right atrium or ventricle or from retroperitoneal and hepatic systems.[12,13]

DVT is most common in hospitalized patients but may occur in ambulatory patients outside the hospital. In recent years improved understanding of the pathogenesis of the disease and better diagnostic tests have identified patients at risk, improved prophylaxis, and increased the percentages of patients who are diagnosed and treated.

Pathology

In careful autopsy studies microscopic thrombi may be found in the pockets of venous valve cusps, in vein saccules, and at vein junctions of pelvic, thigh, and calf veins.[12,14] Calf vein thrombi are most common, and multiple and bilateral thrombi at independent sites within the lower body venous system can occur simultaneously.[12] The initial thrombus grows by accretion of platelets, fibrin, and enmeshed red cells and may detach at any time. Six primary sites of origin of DVT are described: external iliac, common femoral, termination of either the superficial or deep femoral, popliteal, posterior tibial, and intramuscular calf veins.[12] Most calf vein thrombi either do not embolize or produce small, often asymptomatic emboli of little clinical significance. However, somewhere between 20 and 30% of calf vein thrombi propagate proximally into upper thigh veins.[9,15] The majority of PEs originate in thigh and pelvic veins.

Thrombi are composed of fibrin, platelets, and usually large numbers of red cells that may form lakes within the clot. In clots that do not embolize, the fibrinolytic system usually dissolves the thrombus. Incomplete dissolution results in the formation of granulation tissue at sites where the thrombus attaches to the vein wall. The organizing thrombus becomes incorporated into the vein wall, and usually destroys the adjacent valve as proliferating vascular channels and fibroblasts invade the site.[14,15]

Pathogenesis

In 1856 Rudolf Virchow made the association between DVT and PE and suggested that the causes of DVT were related to venous stasis, vein wall injury, and hypercoagulopathy. This triad of etiologic factors remains relevant today and is supported by an ever-growing body of evidence.

Injections of contrast material in foot veins require up to 1 hour to clear from venous valves in the soleus muscle of immobilized patients.[16] Venous stasis is also produced by mechanical obstruction of proximal veins, by low cardiac output, by venous dilatation, and by increased blood viscosity.[17] Some pelvic tumors, bulky inguinal adenopathy, the gravid uterus, previous caval or iliac venous disease, and elevated central venous pressures from cardiac causes also enhance venous stasis. Tourniquets, anesthetic agents, pregnancy, high-dose estrogens, and increasing age produce venous dilatation. Polycythemia, hyperfibrinogenemia, and some abnormal protein diseases increase the viscosity of blood.[17] It is not clear whether or not superficial varicosities increase the likelihood of DVT in deep veins. However, immobilization is by far the most important cause of venous stasis in hospitalized patients.

The role of vein wall injury is less clear since DVT often begins in the absence of mechanical trauma. Recent work shows that subtle vein wall injuries may occur during surgery in veins remote from the operative field.[18,19] In animals, endothelial cell tears have been found at junctions of small veins with larger veins at remote sites during hip replacement (Fig. 56-1). The mechanism is thought to be

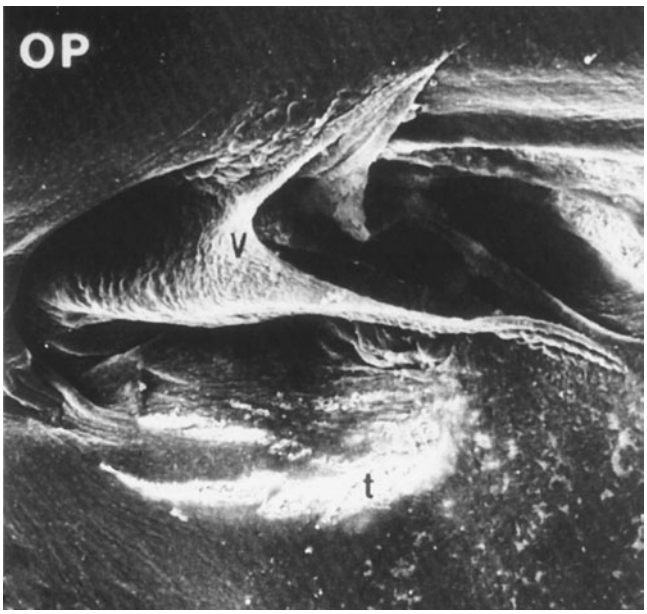

Figure 56-1. Scanning electron photomicrograph of a canine jugular vein after total hip replacement with significant operative venous dilatation. An endothelial cell tear (t) is visible near a valve cusp (V). *(Reproduced with permission from Comerota AJ, Stewart GJ, White JV: Combined dihydroergotamine and heparin prophylaxis of postoperative deep vein thrombosis: Proposed mechanism of action. Am J Surg 1985; 150:39.)*

venous dilatation mediated by the production of circulating vasoactive substances, including histamines, bradykinin, activated complement, and the leukotrienes during surgery.[20] Exposure of subendothelial tissue factor provides a powerful procoagulant stimulus by activating factor VII and the extrinsic coagulation pathway.[21] The cytokines interleukin-1 and tumor necrosis factor, produced by macrophages and other cells in various pathologic conditions, stimulate procoagulant activity of endothelial cells. In ways that are still not clear these processes may combine with venous stasis, microscopic endothelial tears, and blood procoagulant activity to localize the formation of the initial thrombus to venous saccules and valve pockets of the deep leg veins.

Simultaneous maintenance of the fluidity of blood and the integrity of the vascular system requires a balance between blood pro- and anticoagulants. Some patients with DVT have deficiencies in natural anticoagulants. Three uncommon familial deficiencies associated with venous thrombosis are in antithrombin, protein C, and protein S. Antithrombin is a natural plasma protease that inhibits thrombin after it is formed, and to a lesser extent before it is formed. Antithrombin is also the cofactor that is accelerated 1000-fold by heparin. Protein C is a potent inhibitor of factor V and platelet-bound factor VII and requires protein S as a cofactor for anticoagulant activity. Both protein C and S are vitamin-K–dependent zymogens that are activated by thrombin and accelerated by thrombomodulin produced by endothelial cells.

A much more common coagulation deficiency, resulting from a mutation of factor V (factor V Leiden) that prevents its degradation by protein C, has been described and is present in approximately 6 to 7% of study populations of Swedes and North American males.[22–24] Both the homozygous and heterozygous mutants are strongly associated with venous thrombosis and pulmonary embolism but are not associated with stroke, myocardial infarction, and other manifestations of arterial thrombosis.[24,25]

The presence of the lupus anticoagulant, which is an acquired IgG or IgM antibody against prothrombinase, increases the likelihood of venous thrombosis by poorly understood mechanisms.[25] The disease may be associated with lupus-like syndromes, immunosuppression, or intake of specific drugs, such as procainamide.

In addition to the three classic risk factors described above, decreased fibrinolytic activity in blood may also contribute to the development of DVT. Fibrinolytic activity is less in leg veins than in arm veins, particularly in older patients.[26] Decreased fibrinolytic activity may be due to decreased production of tissue plasminogen activator or increased concentrations of plasminogen-activator inhibitor-1.[27]

Risk Factors for DVT

The presence of major risk factors increases the likelihood of venous thromboembolism in proportion to the number of risk factors present. In patients with clinically suspected DVT, 50% of patients with three risk factors will have a proven diagnosis of DVT; however, without any risk factors DVT is proven in only 11%.[28] The rationale for aggressive prophylactic therapy against the disease is based on the strong association between major risk factors and venous thromboembolism.

Table 56–1.

Major Risk Factors for Venous Thromboembolism

Previous venous thromboembolism	Age over 4 years
Major hip or knee surgery	Bedrest 7 days or longer
Recent major surgery	Cancer
Congestive heart failure	Paralysis of lower extremity
Pelvis, hip, or leg fracture	Multiple trauma
High-dose estrogen therapy	

Table 56-1 presents a list of major risk factors for the development of DVT or PE. Previous thromboembolism, older age, immobilization for more than 1 week, orthopedic surgery of the hip or knee, recent surgery, multiple trauma, and cancer are strong risk factors. In patients with a history of venous thromboembolism the risk of developing a new episode during hospitalization is nearly eight times that of someone without a history.[9,29] Up to 10% of patients with a first episode of DVT or PE and up to 20% of those with a recurrent event develop a new episode of venous thromboembolism within 6 months.[30]

The incidence of DVT and PE increases exponentially with age (Fig. 56-2). Patients in the seventh and eighth decades of life are 200 times more likely to develop venous thromboembolism than patients below age 40. Males are at greater risk than females. Immobility from any cause and prolonged bedrest are major risk factors. Although usually other risk factors are present, the incidence of autopsy-proven venous thrombosis rises from 15 to 80% in patients at bedrest for more than 1 week.[30,31]

Surgeries, particularly orthopedic and abdominal, and multiple trauma are associated with a significant incidence of DVT and PE. Without prophylaxis the risk of DVT and PE after major abdominal surgery is approximately 25% and 2%, respectively.[8,31] The risk of venous embolism is also increased following urologic surgery and operations for gynecologic cancer.[9] After multiple trauma the risk of DVT and PE is over 50% in patients with pelvic, thigh, or leg injuries.

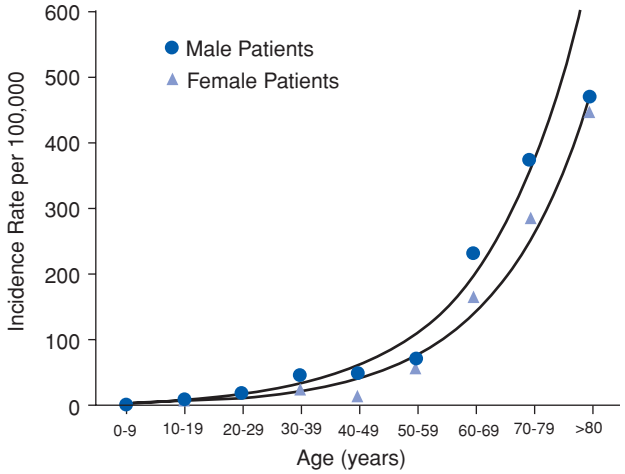

Figure 56-2. Annual incidence of venous thromboembolism in the United States stratified for age. Males have a significantly higher incidence rate of venous thromboembolism than females. Both curves fit an exponential function. *(Reproduced with permission from Anderson FA Jr, Wheeler HB, Goldberg RJ, et al: A population based perspective of the hospital incidence and case fatality rates of deep vein thrombosis and pulmonary embolism: The Worcester DVT study. Arch Intern Med 1991; 151:933.)*

The incidence of venous thromboembolism increases threefold in patients who have operations for cancer.[9] The incidence is highest in patients with advanced or metastatic disease and may be related to the production of procoagulant material or suppression of fibrinolytic activity by some tumors.[9] Patients with congestive heart failure are at higher risk of venous thromboembolism because of venous stasis and higher venous pressures, and if PE occurs are more likely to die because of reduced cardiac reserve. Acute myocardial infarction may be an independent risk factor for PE, but this is not clear because other risk factors usually are present.[9]

Although the risk of PE is low, women who have just given birth are at higher risk of PE than during pregnancy, and PE remains a major cause of maternal mortality.[17] High-dose estrogen given to treat some malignancies is associated with an increased risk of venous thromboembolism. It is not clear whether or not oral estrogen contraceptives increase the risk of thromboembolism. Low-dose estrogens, obesity, and varicose veins are probably not independent risk factors for DVT or PE but may be additive.[9]

Of particular interest to cardiac surgeons and cardiologists is the recent observation that clinically silent DVT develops during hospitalization in nearly 50% of patients after myocardial revascularization.[32] Nearly all of the thrombi occur in calf veins and are distributed equally between the saphenous vein donor leg and the opposite extremity. Patients are asymptomatic for DVT, there are no physical clues, but all thrombi in this small series were proven by duplex scanning.[32]

A follow-up study[33] found that the incidence of PE in hospital after coronary artery bypass operations was 3.2%. Risk factors included prolonged postoperative recovery, previous venous thromboembolism, obesity, and hyperlipidemia. Hospital mortality in patients with PE was 18.7%. Interestingly, valvular surgery was not associated with the development of PE. In a retrospective study of 5694 patients who had open heart surgery, Gillinov and colleagues found the risk of PE proven by ventilation-perfusion scan (20 patients), angiography (4 patients), or autopsy (8 patients) was 0.56% within 60 days. However, the mortality was 34% in patients with PE.[34]

Diagnosis

Approximately two-thirds of patients with DVT do not have clinical symptoms[9] and thus the diagnosis depends on a high degree of clinical suspicion and a variety of objective diagnostic tests. Venography remains the most reliable test for detecting thrombus in calf veins but competes with noninvasive tests for detecting DVT in thigh and pelvic veins. Venography, however, is invasive, not suitable for serial studies, and the contrast material may be thrombogenic if allowed to remain within the deep venous system.[10] With advances in technology and the accuracy of the noninvasive diagnostic tests that are widely accessible, venographies are very rarely performed.

The most popular noninvasive test, which can be done at the bedside, is a combination of ultrasound and color flow Doppler mapping, widely referred to as *duplex scanning*. The method does not detect fresh thrombi directly but infers the presence of clot by flow patterns and the inability to compress the vessel in specific locations.[10] In the hands of skilled examiners duplex scanning is highly accurate for the detection of thrombus in popliteal, deep femoral, and superficial femoral veins and has a sensitivity between 89 and 100% against venography in symptomatic patients. Diagnostic accuracy is much lower in asymptomatic patients for thrombi in these locations, and specificity is nearly 100% in both symptomatic and asymptomatic patients.[10,35] Against magnetic resonance imaging (MRI), duplex scanning has a sensitivity of 70% for pelvic veins and a specificity of nearly 100%.[35] The test is less accurate in the calf and also in patients suspected of recurrent DVT. MRI is a noninvasive method that can image the entire venous system, including upper extremity veins and mediastinum.[36] The method detects flow within the venous system and reliably separates flowing blood from stagnant blood or thrombus.

Impedance plethysmography assesses volume changes in the leg after occlusion of the vein with calf electrodes and a thigh cuff. It is clinically useful in symptomatic patients but has relatively low sensitivity and specificity in asymptomatic patients and calf thrombosis.[35] Injection of iodine 125–labeled fibrinogen with subsequent leg scanning is a sensitive test for detecting calf vein thrombus but does not detect iliofemoral vein thrombosis. The combination of these two tests improves sensitivity and specificity, but in most hospitals duplex scanning, venography, and MRI have superseded both tests.

Prophylaxis

The prevalence of DVT, its strong association with PE, and the identification of risk factors in the pathogenesis of the disease provide the basis and rationale for prophylactic measures that are recommended in patients with two or more major risk factors, such as age over 40 years and major surgery.[9] Innocuous measures such as compression stockings probably should be prescribed more often and be used in most nonambulating patients in the hospital. Intermittent pneumatic compression is more expensive and more cumbersome but is effective. Both methods reduce the incidence of DVT after general surgery to approximately 40% of that of control patients.[9] Low-dose subcutaneous heparin or low-molecular-weight heparin given once per day reduce the incidence of DVT to approximately 35% and 18% of controls, respectively.[9,31,37] The reduction in PE with subcutaneous standard heparin or low-molecular-weight heparin is similar.[31,37]

Calf vein DVT that does not propagate has a low risk of PE, and controversy exists as to whether or not these patients should be anticoagulated.[13] Of patients who have DVT diagnosed in hospital without PE, the probability of clinically diagnosed PE within the next 12 months is 1.7%.[5] If PE occurs, the probability of recurrent PE is 8.0%.[5] Six months of warfarin anticoagulation is recommended for patients who have DVT with or without PE as prophylaxis against recurrent disease.[38]

PULMONARY EMBOLISM

Pathology and Pathogenesis

Partial or complete occlusion of calf or thigh veins reduces the velocity of flow in the more proximal femoral and iliac veins, and enhances the propagation of thrombus toward the direction of the flow. The thrombus is attached to the vein wall at the site of origin, usually does not develop other sites of attachment immediately,[26] and may grow to fill most of the lumen of the vein and extend into the vena cava. The only firm attachment is at the site of origin, usually a venous saccule or venous valve pocket. The degree of organization within the thrombus varies, but recent clots are more likely to migrate than older thrombi that are more firmly attached to the vessel wall.

Detached venous thrombi are carried in the bloodstream through the right heart into the pulmonary circulation. Large thrombi may float as a single embolus or fragment into smaller clots along the way. In autopsy series the percentage of emboli that obstruct two or more lobar arteries (major) ranges between 25 and 67% of all emboli,[39] but this percentage varies with the thoroughness of the examination. In clinical trials based on angiographic data the percentage of major emboli is similar and ranges from 30 to 64%.[40] The majority of pulmonary emboli lodge in the lower lobes[12] and are slightly more common in the right lung than in the left. Soon after reaching the lungs emboli become coated with a layer of platelets and fibrin.[12]

Simple mechanical obstruction of one or more pulmonary arteries does not entirely explain the often devastating hemodynamic consequences of major or massive emboli. Humoral factors, specifically serotonin, adenosine diphosphate, platelet-derived growth factor, thromboxane from platelets coating the thrombus, platelet-activating factor, and leukotrienes from neutrophils are also involved.[41] In animal and early clinical studies serotonin inhibitors, cyproheptadine, and ketanserin partially block constriction of both pulmonary arteries and bronchi associated with PE.[42] Anoxia and tissue ischemia downstream to emboli inhibit endothelium-derived relaxing factor production and enhance release of superoxide anions by activated neutrophils. The combination of these effects contributes to enhanced pulmonary vasoconstriction.[41]

Natural History

The mortality of untreated PE is 18 to 33% but can be reduced to about 8% if diagnosed and treated.[7,43,44] Seventy-five to ninety percent of patients who die of pulmonary emboli do so within the first few hours of the primary event.[45] It is possible that those who die later do so of recurrent PE. In patients who have sufficient cardiopulmonary reserve and right ventricular strength to survive the initial few hours, autolysis of emboli occurs over the next few days and weeks.[46] On average, approximately 20% of the clot disappears by 7 days, and complete resolution may occur by 14 days.[44,46,47] For many patients, up to 30 days are needed to dissolve small emboli and up to 60 days for massive clots.[48] As the natural fibrinolytic system dissolves the embolic mass, the available cross-sectional area of the pulmonary arterial tree progressively increases, and pulmonary vascular resistance and right ventricular afterload decrease. In the vast majority of patients, pulmonary emboli continue to resolve and thus an immediate interventional therapy, particularly surgical embolectomy, is not necessary for survival except in a minority of patients.

In an unknown but small percentage of patients with acute PE the clot will not lyse, and chronic thromboembolic obstruction of the pulmonary vasculature develops. The reasons for failure of emboli to dissolve are unknown. Patients often are asymptomatic until symptoms of dyspnea, exercise intolerance, or right heart failure develop, mostly secondary to the pulmonary hypertension that ensues. Asymptomatic patients may have partial or complete chronic thrombotic occlusion of one or more segmental or lobar arteries. Symptomatic patients usually have over 40% of their pulmonary vasculature obstructed by organized and fresh thrombi; however, significant pulmonary hypertension can develop in patients despite lesser degrees of vascular obstruction.

ACUTE PULMONARY EMBOLISM

Clinical Presentation

Acute PE usually presents suddenly. Symptoms and signs vary with the extent of blockage, the magnitude of the humoral response, and the pre-embolus reserve of the cardiac and pulmonary systems of the patient.[49] Symptoms and signs vary widely, but the clinical diagnosis is often missed or falsely made. Most pulmonary emboli occur without sufficient clinical findings to suggest the diagnosis, and in autopsy series of proven emboli only 16 to 38% of patients were diagnosed during life.[39]

The acute disease is conveniently stratified into minor, major (submassive), or massive embolism on the basis of hemodynamic stability, arterial blood gases, and lung scan or angiographic assessment of the percentage of blocked pulmonary arteries.[40,49,50] Most pulmonary emboli are minor. These patients present with sudden, unexplained anxiety, tachypnea or dyspnea, pleuritic chest pain, cough, and occasionally streak hemoptysis.[39,45,50] Examination may reveal tachycardia, rales, low-grade fever, and sometimes a pleural rub. Heart sounds and systemic blood pressure are often normal; sometimes the pulmonary second sound is increased. Interestingly, less than one-third of patients will have evidence of clinical DVT.[39] Room air arterial blood gases indicate an arterial partial oxygen pressure (Pa_{O_2}) between 65 and 80 torr and a normal arterial partial carbon dioxide pressure (Pa_{CO_2}) around 35 torr.[45] Pulmonary angiograms show less than 30% occlusion of the pulmonary arterial vasculature.

Major PE is associated with dyspnea, tachypnea, dull chest pain, and some degree of hemodynamic instability manifested by tachycardia, mild to moderate hypotension, and elevation of the central venous pressure.[45,50] Some patients may present with syncope rather than dyspnea or chest pain. In contrast to massive PE, patients with major embolism (at least two lobar pulmonary arteries obstructed) are hemodynamically stable and have adequate cardiac output.[40] Room air blood gases reveal moderate hypoxia (Pa_{O_2} <65 and >50 torr) and mild hypocarbia (Pa_{CO_2} <30 torr).[50] Echocardiograms may show right ventricular dilatation. Pulmonary angiograms indicate that 30 to 50% of the pulmonary vasculature is blocked; however, in patients with pre-existing cardiopulmonary disorders, lesser degrees of vascular obstruction may produce similarly alarming symptoms.

Massive PE is truly life-threatening and is defined as a PE that causes hemodynamic instability.[40] It is sometimes associated with occlusion of more than 50% of the pulmonary vasculature but may occur with much smaller occlusions, particularly in patients with pre-existing cardiac or pulmonary disease. The diagnosis is clinical, not anatomic. Patients develop acute dyspnea, tachypnea, tachycardia, and diaphoresis and sometimes may lose consciousness. Both hypotension and low cardiac output (<1.8 L/m^2/per minute) are present. Cardiac arrest may occur. Neck veins are distended, central venous pressure is elevated, and a right ventricular impulse may be present. Room air blood gases show severe hypoxia (Pa_{O_2} <50 torr), hypocarbia (Pa_{CO_2} <30 torr), and sometimes acidosis.[40,45,50] Urine output falls; peripheral pulses and perfusion are poor.

Diagnosis

The clinical diagnosis of acute major or massive PE is unreliable and is wrong in 70 to 80% of patients who have angiography subsequently.[49,51] Even in postoperative patients and those with additional major risk factors for DVT, differentiation of major or massive PE from acute myocardial infarction, aortic dissection, septic shock, and other catastrophic states is difficult and uncertain. A plain chest x-ray, an electrocardiogram (ECG), and insertion of a bedside Swan-Ganz catheter may add confirmatory information but might not necessarily prove the diagnosis.

The chest film may be normal but usually shows some combination of parenchymal infiltrate, atelectasis, and pleural effusion. A zone of hypovascularity or a wedge-shaped pleural-based density raises the possibility of PE. In patients with massive PE and hemodynamic compromise the chest x-ray may actually appear normal. Usually the ECG shows nonspecific T-wave or RS-T segment changes with PE. A minority of patients with massive embolism (26%) may show evidence of cor pulmonale, right-axis deviation, or right bundle-branch block.[49] An echocardiogram showing right heart dilatation raises the possibility of major or massive PE. A Swan-Ganz catheter generally shows pulmonary arterial desaturation (Pa_{O_2} <25 torr) but usually does not show pulmonary hypertension over 40 mm Hg because of low cardiac output and cor pulmonale (the unprepared right ventricle cannot generate pulmonary hypertension).

Ventilation-perfusion (V/Q) scans will provide confirmatory evidence, but these studies may be unreliable, since pneumonia, atelectasis, previous pulmonary emboli, and other conditions may cause a mismatch in ventilation and perfusion and mimic positive results. In general, negative V/Q scans essentially exclude the diagnosis of clinically significant PE. V/Q scans usually are interpreted as high, intermediate, or low probability of PE to emphasize the lack of specificity but high sensitivity of the test (Fig. 56-3). Pulmonary angiograms provide the most definitive diagnosis, but collapse of the circulation may not allow time for this procedure, and pulmonary angiograms should not be performed if the patient's circulation cannot be stabilized by pharmacologic or mechanical means. In stable patients, angiograms are associated with a mortality of 0.2%, but similar to a V/Q scan, a normal angiogram will rule out a clinically significant PE.[52,53]

MRI and computed tomography angiographies are better noninvasive methods for the diagnosis of pulmonary emboli and provide specific information regarding flow within the pulmonary vasculature.[54] Unfortunately, these methods are expensive, somewhat time consuming, and not

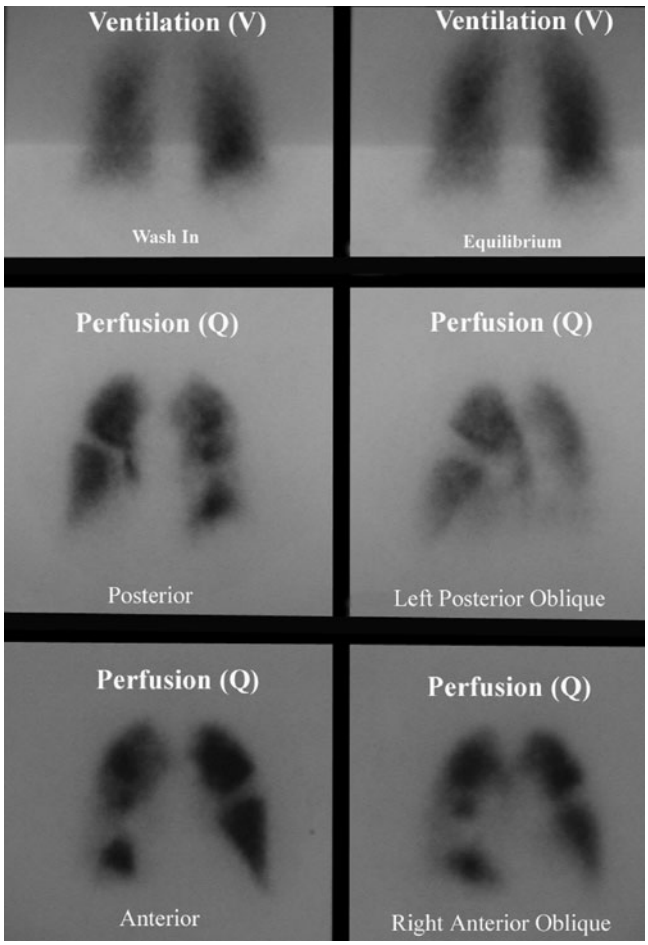

Figure 56-3. Anterior and posterior views from a radionuclide perfusion scan in a patient with chronic thromboembolic disease. Note the large punched-out defects.

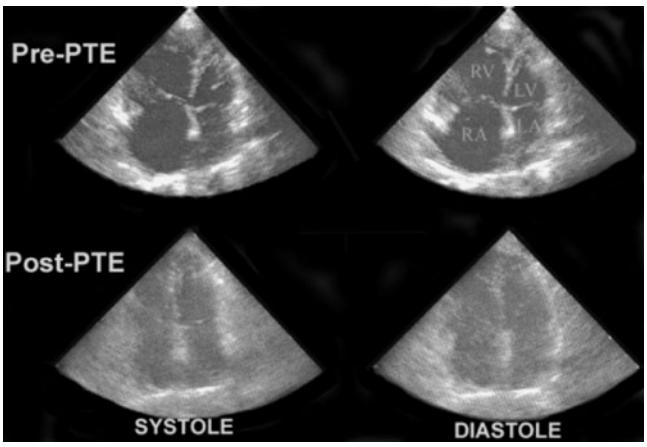

Figure 56-4. Appearance of echocardiography before and after the operation. The top images represent pre-PTE and the bottom images represent post-PTE. Note the shift of the intraventricular septum toward the left in the systole before the operation, together with the relatively small left atrial and left ventricular chambers. After the operation, the septum has normalized, and the right-sided chambers are no longer massively enlarged. LA = left atrium; LV = left ventricle; PTE = pulmonary thromboendarterectomy; RA = right atrium; RV = right ventricle.

widely available. Furthermore, they are not generally suitable for hemodynamically unstable patients. Transthoracic or transesophageal echocardiography with color flow Doppler mapping can provide reliable information about the presence or absence of major thrombi obstructing right-sided chambers or the main pulmonary artery. More than 80% of patients with clinically significant PE have abnormalities of right ventricular volume or contractility, or acute tricuspid regurgitation by transthoracic echocardiography (Fig. 56-4).[55] In some patients abnormal flow patterns can be discerned in major pulmonary arteries during transesophageal echocardiography.

Management of Acute Pulmonary Embolism

For the purposes of this chapter major or submassive PE is defined as an acute episode that causes hypoxia and mild hypotension (systolic arterial pressure >90 mm Hg), but that does not cause cardiac arrest or sustained low cardiac output and cardiogenic shock. By definition there is sufficient time in these patients to definitively establish the diagnosis and to attempt pharmacologic therapy and possibly removal of embolic material by catheter suction.

The first priority after sudden collapse of any patient is to establish adequate ventilation and circulation. The first may require intubation and mechanical ventilation. Pharmacologic agents, including cardiovascular pressors and vasoactive agents, are then used to help stabilize the patient's hemodynamics. Once the circulation has been stabilized, both arterial and central venous catheters are placed for access and for continuous pressure monitoring. Usually a Swan-Ganz catheter is also placed to monitor cardiac output and pulmonary arterial oxygen saturation. The ECG is monitored, a Foley catheter is placed for recording urine output, and blood gases are obtained.

If the patient's circulation can be stabilized, intravenous heparin is started with an initial bolus dose of 70 U/kg followed by 18 to 20 U/kg/per hour if there are no contraindications to heparin. Heparin will prevent propagation and formation of new thromboemboli, but does not dissolve the existing clot. In most instances the patient's own fibrinolytic system lyses fresh thrombi over a period of days or weeks.[46] Heparin is monitored by measurement of activated partial thromboplastin times, which are maintained between 51 and 68 seconds (twice control), every 6 to 8 hours. Platelet counts should be obtained at the beginning of heparin therapy and every 2 to 3 days to detect the presence or appearance of heparin-induced thrombocytopenia. Prothrombin times also are obtained at baseline to prepare for long-term anticoagulation with warfarin later.

The addition of lytic therapy (i.e., streptokinase, urokinase, or recombinant tissue plasminogen activator) increases the rate of lysis of fresh thrombi and is recommended in patients with a stable circulation and no contraindications.

Thrombolytic therapy increases the rate of lysis of fresh pulmonary clots over that of heparin alone during treatment,[56] but there is little difference in the amount of residual thrombus between the two treatments at 5 days or thereafter.[57–60] There is also no statistical difference in mortality or in the incidence of recurrent PE, but more recent experience shows a trend toward better results with thrombolytic therapy because of a more rapid reduction in right ventricular afterload and dysfunction.[56] Furthermore, there are no data that indicate that thrombolysis reduces the subsequent development of chronic pulmonary thromboembolism and pulmonary hypertension. Compared to heparin therapy alone, thrombolytic agents carry a higher risk of bleeding complications. Despite precautions, bleeding complications occur in approximately 20% of patients.[61,62] Contraindications to the use of these agents include patients with fresh surgical wounds, recent stroke, peptic ulcer, or bleeding disorders. Thrombolytics are also contraindicated in severely anemic patients and patients with potential sources of catastrophic intracranial, retroperitoneal, or gastrointestinal bleeding.[56]

Mechanical removal of pulmonary thrombi is possible by using a catheter device inserted under local anesthesia into the femoral (preferred) or jugular vein.[50,63,64,67,69] The catheter, which has a small terminal cup, is steered into the pulmonary artery using fluoroscopy for guidance. Syringe suction is applied to the cup as a thrombus is engaged, and the whole assembly is removed through the venotomy. The procedure may be repeated. Successful extraction of clot with meaningful reduction in pulmonary arterial pressure varies between 61 and 84%.[64,69]

Management of Massive Pulmonary Embolism

If the circulation cannot be stabilized at survival levels within several minutes or if cardiac arrest occurs after a massive PE, time becomes of paramount importance. Most deaths from acute PE occur before effective treatment is instituted, often as a result of failure of diagnosis. Eleven percent of patients with fatal PE die within the first hour, 43 to 80% within 2 hours, and 85% within 6 hours.[65] To a great extent, circumstances and the timely availability of necessary equipment and personnel determine therapeutic options. Mitigating factors such as advanced age, irreversible underlying health problems, and the likelihood of brain damage also enter into decision making. A decision to treat medically in an effort to stabilize the circulation at a survival level may preempt lifesaving surgery, but also may make surgery unnecessary. For many reasons retrospective studies are of limited relevance for this decision. Sometimes surgical treatment is not available immediately; at other times deteriorating patients are referred to surgery too late after failing medical therapy. The relative infrequency of treatment opportunities in massive PE, mitigating factors, and the lack of clear criteria for prescribing medical or surgical therapy leave the management of massive PE unsettled.

Better understanding of the condition and newer technology offer a reasonable, if untried, algorithm for dealing with "probable massive pulmonary embolism with life-threatening hemodynamic instability" in hospitalized patients. In otherwise healthy patients in whom surgery poses little risk or morbidity, emergency thromboembolectomy with preoperative confirmation of the diagnosis in the operating room by transesophageal echocardiography offers the best chance of survival, even though an occasional patient may undergo an unnecessary operation. When surgery is not immediately available or in patients who may not be surgical candidates, or in whom an alternate diagnosis seems more likely, emergency extracorporeal life support (ECLS) using peripheral cannulation is an attractive alternative.[72,73] In prepared institutions ECLS can be instituted rapidly outside the operating room. ECLS compensates for acute cor pulmonale and hypoxia and sustains the circulation until the clot partially lyses, pulmonary vascular resistance falls, and pulmonary blood flow becomes adequate.

Emergency Pulmonary Thromboembolectomy

Emergency pulmonary thromboembolectomy is indicated for suitable patients with life-threatening circulatory insufficiency as discussed earlier, but should not be done without a definitive diagnosis. A clinical diagnosis of PE is often wrong.[47,58,66,67] If a patient has been taken directly to the operating room without a definitive diagnosis, transesophageal echocardiography and color Doppler mapping can confirm or refute the diagnosis in the operating room. Transesophageal echocardiography permits good assessment of right ventricular volume, contractility, and tricuspid regurgitation, which are strongly associated with massive PE and acute cor pulmonale.[68] Echocardiographic detection of a large clot trapped within the right atrium or ventricle in a hemodynamically compromised patient with massive acute PE is another indication for emergency pulmonary thromboembolectomy.[74,75,77]

A midline sternotomy incision is used. The ascending aorta and both cavae are cannulated after full heparinization, and cardiopulmonary bypass is initiated. The heart may be electrically fibrillated or arrested with cold cardioplegic solution. Significant hypothermia may not be necessary since only a short period of complete bypass is needed. The main pulmonary artery is then opened 1 to 2 cm downstream to the valve, and the incision is extended into the proximal left pulmonary artery. Forceps and suction catheters remove the clot from the left pulmonary artery and behind the aorta to the right pulmonary artery. The right pulmonary artery can also be exposed and opened between the aorta and superior vena cava to allow better exposure in the distal segments, if necessary. If a sterile pediatric bronchoscope is available, the surgeon can use this instrument to locate and remove thrombi in tertiary and quaternary pulmonary vessels. Alternatively, pleural spaces are entered, and each lung is gently compressed to dislodge small clots into larger vessels and the clots are suctioned out. The pulmonary arteriotomy is then closed with a fine running suture (e.g., 6-0 polypropylene). After restarting the heart, the patient is weaned from bypass,

decannulated, and closed. Greenfield recommends placement of an inferior vena caval filter before closing the chest.[10,69,70,79] European surgeons generally clip the intrapericardial vena cava at the end of pulmonary thromboembolectomy to prevent migration of large clots into the pulmonary circulation.[77] This clip increases venous pressure and stagnant flow in the lower half of the body and causes considerable morbidity in over 60% of patients.[70,74,77]

Although recurrent PE is always a threat, the likelihood of this during the immediate postoperative period is statistically small. We feel that the diagnosis of proximal DVT, knowledge of risk factors, and efficacy of anticoagulant therapy permit brief deferral of the decision to place a filter. Anticoagulation for 6 months is recommended for most patients with PE, but an inferior vena caval filter is recommended for patients with contraindications to anticoagulation or with recurrent PE, or those who will require pulmonary thromboendarterectomy. The cone-shaped Greenfield filter is most widely used and is associated with a lifetime recurrent embolism rate of 5% and has 97% patency rate.[71]

Extracorporeal Life Support

The wider availability of long-term extracorporeal perfusion (termed extracorporeal life support, or ECLS) using peripheral vessel cannulation to stabilize the circulation offers a compromise position since most massive pulmonary emboli will dissolve in time. ECLS can be implemented outside the operating room, but extensive preparations must be made before ECLS is available for emergency therapy. An emergency team must be assembled and trained, and needed equipment and supplies must be collected. ECLS can be implemented within 15 to 30 minutes by an equipped team of trained personnel.[72]

The femoral vein and artery are rapidly cannulated under sterile conditions using local anesthesia. If the circulation is reasonably stable, both vessels can be cannulated over guidewires inserted via no. 16 angiographic needle punctures. A small skin incision is made to accommodate the cannulae, and after giving a bolus of heparin (1 mg/kg) first dilators and then cannulas are inserted. Alternatively, surgical cutdown and then cannulation using guidewires under direct vision can expose both femoral vessels. If pulses are absent or weak, a cutdown is usually faster; however, since patients need heparin and possibly fibrinolytic drugs, a minimal wound is preferred. The tip of the venous catheter is advanced into the right atrium to obtain flow rates of 2.5 to 4 L/min using an emergency pump-oxygenator circuit primed with crystalloid.[73] The perfusion circuit consists of a small venous reservoir with intravenous access tubes, a centrifugal pump, and membrane oxygenator. An arterial filter is not needed; and an electromagnetic flowmeter is usually placed on the arterial line. During ECLS, heparin is infused to maintain activated clotting times between 150 and 180 seconds. Activated clotting times are measured every 30 minutes initially and every hour thereafter.

Although the groin wound is minimal, some bleeding occurs. Usually the amount of bleeding is small, but it is often persistent. Theoretically, the addition of thrombolytic drugs accelerates clot lysis and may decrease the duration of ECLS; however, these drugs are likely to increase bleeding complications and are not needed once the circulation is stabilized. An alternative is to give low-dose fibrinolytic therapy directly into the thrombus via a pulmonary arterial catheter. ECLS should not be needed beyond a few hours or 1 to 2 days since clot lysis proceeds rapidly. Once pulmonary vascular resistance is adequately reduced, femoral cannulation sites should be closed surgically because of the need for heparin and long-term anticoagulation. ECLS should be discontinued in the operating room since vessels will need to be sutured closed because of the need for heparin and long-term anticoagulation.

Postoperative Care

Postoperative care is no different from care for other patients who require open cardiac surgery. Cardiac output is maintained by pharmacologic means and is usually adequate if the patient can be weaned from cardiopulmonary bypass and has not suffered irreversible myocardial damage. Reperfusion pulmonary edema is not a problem, but renal failure and ischemic brain damage from preoperative periods of inadequate circulation may become apparent. Antibiotics are required, particularly if sterile conditions were compromised in the resuscitation effort.

Results

Mortality rates for emergency pulmonary thromboembolectomy vary widely between 40 and 92%.[66,70,74–77] Results are best if cardiopulmonary bypass is used to support the circulation during pulmonary arteriotomy.[75] The eventual outcome depends largely on the preoperative condition and circulatory status of the patient. If cardiac arrest occurs and external massage cannot be stopped without ECLS, mortality ranges between 45 and 75%, and without cardiac arrest mortality ranges between 8 and 36%.[74,70,77] ECLS instituted during cardiac resuscitation is associated with survival rates between 43 and 56%.[74,66] Primary causes of death include brain damage, cardiac failure, bleeding complications, and sepsis. Recurrent embolism is uncommon,[70,78] but approximately 80% of survivors maintain normal pulmonary arterial pressures and exercise tolerance. In these patients postoperative angiograms are normal or show less than 10% obstructed vessels. A minority of patients have 40 to 50% of pulmonary vessels obstructed and have significantly reduced exercise tolerance and pulmonary function.[78]

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Incidence

The incidence of pulmonary hypertension caused by chronic PE is even more difficult to determine than that of acute PE.

There are more than 500,000 survivors per year of acute symptomatic episodes of acute pulmonary embolization.[79,80] The incidence of chronic thrombotic occlusion in the population depends on what percentage of patients fail to resolve acute embolic material. One estimate is that chronic thromboembolic disease develops in only 0.5% of patients with a clinically recognized acute PE.[79] If these figures are correct and counting only patients with symptomatic acute pulmonary emboli, approximately 2500 individuals would progress to chronic thromboembolic pulmonary hypertension in the United States each year. However, because most patients diagnosed with chronic thromboembolic disease have no antecedent history of acute embolism, the true incidence of this disorder is probably much higher, and in the range of 5 to 10 times our estimate.

Regardless of the exact incidence or the circumstances, acute embolism and its chronic relation, fixed chronic thromboembolic occlusive disease, clearly are much more common than generally appreciated and are seriously underdiagnosed. Houk and colleagues[81] in 1963 reviewed 240 reported cases of chronic thromboembolic obstruction of major pulmonary arteries but found that only 6 cases had been diagnosed correctly before death. Calculations extrapolated from mortality rates and the random incidence of major thrombotic occlusion found at autopsy support a postulate that more than 100,000 people in the United States currently have pulmonary hypertension that could be relieved by surgery.

Pathology and Pathogenesis

Although most individuals with chronic pulmonary thromboembolic disease are unaware of a past thromboembolic event and give no history of DVT, the origin of most cases of unresolved pulmonary emboli is from acute embolic episodes. Why some patients have unresolved emboli is not certain, but a variety of factors must play a role, alone or in combination.

The volume of acute embolic material may simply overwhelm the lytic mechanisms. The total occlusion of a major arterial branch may prevent lytic material from reaching, and therefore dissolving, the embolus completely. Repetitive emboli may not be able to be resolved. The emboli may be made of substances that cannot be resolved by normal mechanisms (already well-organized fibrous thrombus, fat, or tumor). The lytic mechanisms themselves may be abnormal, or some patients may actually have a propensity for thrombus or a hypercoagulable state. After the clot becomes wedged in the pulmonary artery, one of two processes occurs:[82]

1. The organization of the clot proceeds to canalization, producing multiple small endothelialized channels separated by fibrous septa (i.e., bands and webs), or
2. Complete fibrous organization of the fibrin clot without canalization may result, leading to a solid mass of dense fibrous connective tissue totally obstructing the arterial lumen.

In addition, there are other special circumstances. Chronic indwelling central venous catheters and pacemaker leads are sometimes associated with pulmonary emboli. More rare causes include tumor emboli; tumor fragments from stomach, breast, and kidney malignancies have also been demonstrated to cause chronic pulmonary arterial occlusion. Right atrial myxomas may also fragment and embolize.

As previously described and discussed, in addition to the embolic material, a propensity for thrombosis or a hypercoagulable state may be present in a few patients. This abnormality may result in spontaneous thrombosis within the pulmonary vascular bed, encourage embolization, or be responsible for proximal propagation of thrombus after an embolus. But, whatever the predisposing factors to residual thrombus within the vessels, the final genesis of the resultant pulmonary vascular hypertension may be complex. With the passage of time, the increased pressure and flow as a result of redirected pulmonary blood flow in the previously normal pulmonary vascular bed can create a vasculopathy in the small precapillary blood vessels similar to Eisenmenger syndrome.

Factors other than the simple hemodynamic consequences of redirected blood flow are probably also involved in this process. For example, after a pneumonectomy, 100% of the right ventricular output flows to one lung, yet little increase in pulmonary pressure occurs, even with follow-up to 11 years.[83] In patients with thromboembolic disease, however, we frequently detect pulmonary hypertension even when less than 50% of the vascular bed is occluded by thrombus. It thus appears that sympathetic neural connections, hormonal changes, or both, might initiate pulmonary hypertension in the initially unaffected pulmonary vascular bed. This process can occur with the initial occlusion either being in the same or the contralateral lung.

Regardless of the cause, the evolution of pulmonary hypertension as a result of changes in the previously unobstructed bed is serious, because this process may lead to an inoperable situation. Consequently, with our accumulating experience in patients with thrombotic pulmonary hypertension, we have increasingly been inclined toward early operation so as to avoid these changes.

Clinical Presentation

Chronic thromboembolic pulmonary hypertension is an uncommon and frequently underrecognized, but treatable cause of pulmonary hypertension. There are no signs or symptoms specific for chronic thromboembolism. The most common symptom associated with thromboembolic pulmonary hypertension, as with all other causes of pulmonary hypertension, is exertional dyspnea. This dyspnea is out of proportion to any abnormalities found on clinical examination. Like complaints of easy fatigability, dyspnea that initially occurs only with exertion is often attributed to anxiety or being "out of shape." Syncope, or presyncope (light-headedness during exertion) is another common symptom in pulmonary hypertension. Generally, it occurs in

patients with more advanced disease and higher pulmonary arterial pressures.

Nonspecific chest pains or tightness occur in approximately 50% of patients with more severe pulmonary hypertension. Hemoptysis can occur in all forms of pulmonary hypertension and probably results from abnormally dilated vessels distended by increased intravascular pressures. Peripheral edema, early satiety, and epigastric or right upper quadrant fullness or discomfort may develop as the right heart fails (cor pulmonale). Some patients with chronic pulmonary thromboembolic disease present after a small acute pulmonary embolus that may produce acute symptoms of right heart failure. A careful history brings out symptoms of dyspnea on minimal exertion, easy fatigability, diminishing activities, and episodes of angina-like pain or light-headedness. Further examination reveals the signs of pulmonary hypertension.

The physical signs of pulmonary hypertension are the same no matter what the underlying pathophysiology. Initially the jugular venous pulse is characterized by a large A wave. As the right heart fails, the V wave becomes predominant. The right ventricle is usually palpable near the lower left sternal border, and pulmonary valve closure may be audible in the second intercostal space. Occasional patients with advanced disease are hypoxic and slightly cyanotic. Clubbing is an uncommon finding.

The second heart sound is often narrowly split and varies normally with respiration; P_2 is accentuated. A sharp systolic ejection click may be heard over the pulmonary artery. As the right heart fails, a right atrial gallop is usually present, and tricuspid insufficiency develops. Because of the large pressure gradient across the tricuspid valve in pulmonary hypertension, the murmur is high pitched and may not exhibit respiratory variation. These findings are quite different from those usually observed in tricuspid valvular disease. A murmur of pulmonic regurgitation may also be detected.

Pulmonary function tests reveal minimal changes in lung volume and ventilation; patients generally have normal or slightly restricted pulmonary mechanics. Diffusing capacity is often reduced and may be the only abnormality on pulmonary function testing. Pulmonary arterial pressures are elevated and suprasystemic pulmonary pressures are not uncommon. Resting cardiac outputs are lower than the normal range, and pulmonary arterial oxygen saturations are reduced. Most patients are hypoxic; room air arterial oxygen tension ranges between 50 and 83 torr, the average being 65 torr.[84] CO_2 tension is slightly reduced and is compensated by reduced bicarbonate. Dead space ventilation is increased. Ventilation-perfusion studies show moderate mismatch with some heterogeneity among various respirator units within the lung and correlate poorly with the degree of pulmonary obstruction.[85]

Diagnosis

To ensure diagnosis in patients with chronic pulmonary thromboembolism, a standardized evaluation is recommended for all patients who present with unexplained pulmonary hypertension. This work-up includes a chest radiograph, which may show either apparent vessel cutoffs of the lobar or segmental pulmonary arteries, or regions of oligemia suggesting vascular occlusion. Central pulmonary arteries are enlarged, and the right ventricle may also be enlarged without enlargement of the left atrium or ventricle (Fig. 56-5). However, one should keep in mind that despite these classic findings, a large number of patients might present with a relatively normal chest radiograph, even in the setting of high degrees of pulmonary hypertension. The electrocardiogram demonstrates findings of right ventricular hypertrophy (right-axis deviation and a dominant R wave in V_1). Pulmonary function tests are necessary to exclude obstructive or restrictive intrinsic pulmonary parenchymal disease as the cause of pulmonary hypertension.

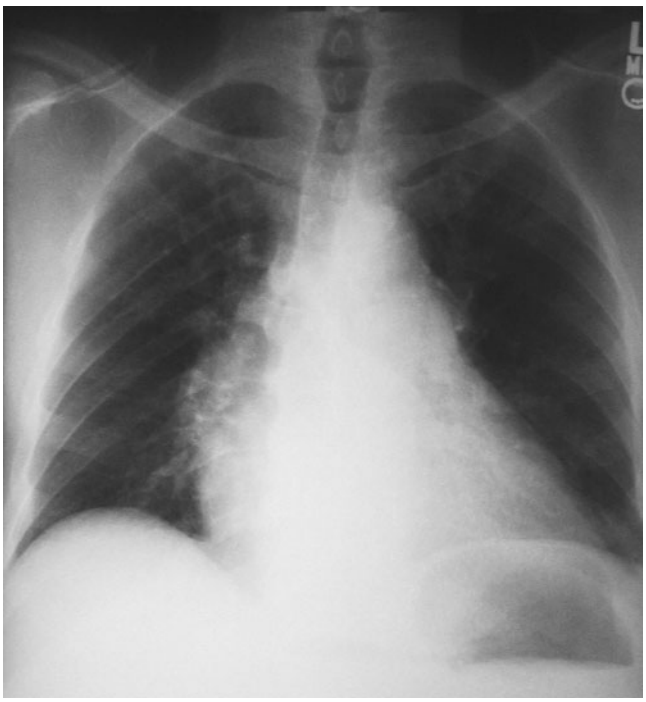

Figure 56-5. Chest radiograph of a patient with chronic thromboembolic pulmonary disease and evidence of pulmonary hypertension. Note the enlarged right atrium and right ventricle, disparity of size between the left and right pulmonary arteries, and the hypoperfusion in several areas of the lung fields.

The ventilation-perfusion lung scan is the essential test for establishing the diagnosis of unresolved pulmonary thromboembolism. An entirely normal lung scan excludes the diagnosis of both acute or chronic unresolved thromboembolism. The usual lung scan pattern in most patients with pulmonary hypertension either is relatively normal or shows a diffuse nonuniform perfusion.[84,85–87] When subsegmental or larger perfusion defects are noted on the scan, even when matched with ventilatory defects, pulmonary angiography is appropriate to confirm or rule out thromboembolic disease.

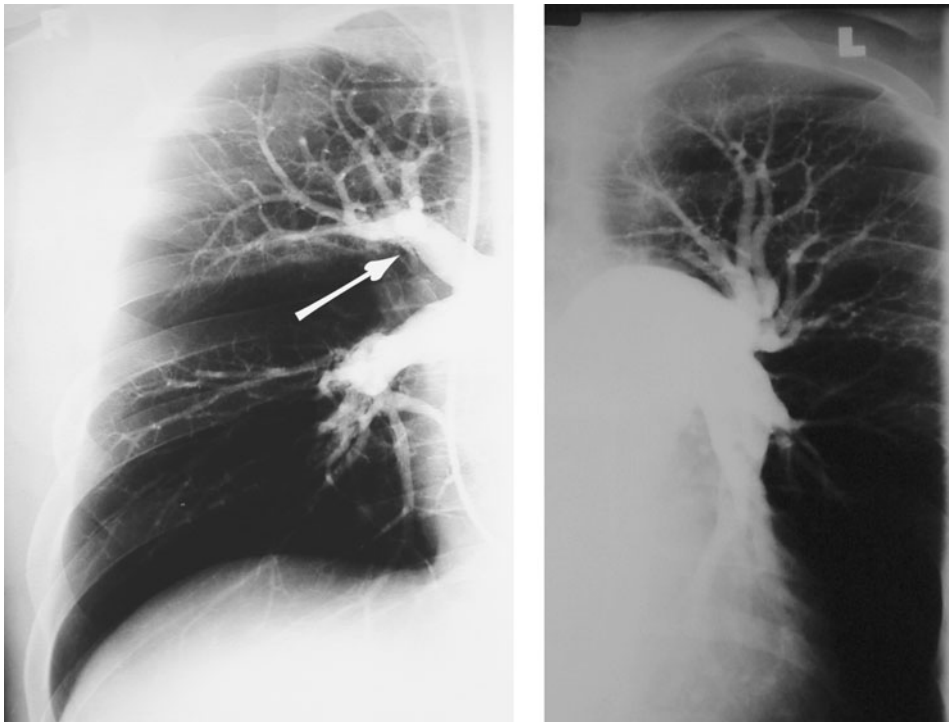

Figure 56-6. Right and left pulmonary angiograms demonstrate enlarged pulmonary arteries, poststenotic dilatation of vessels, lack of filling to the periphery in many areas, and abrupt cutoffs of branches. The arrow points to intraluminal filling defects representative of a web or band.

Currently, pulmonary angiography remains the gold standard for diagnosis of CTEPH. Organized thromboembolic lesions do not have the appearance of the intravascular filling defects seen with acute pulmonary emboli, and experience is essential for the proper interpretation of pulmonary angiograms in patients with unresolved, chronic embolic disease. Organized thrombi appear as unusual filling defects, webs, or bands, or completely thrombosed vessels that may resemble congenital absence of the vessel[87] (Fig. 56-6). Organized material along a vascular wall of a recanalized vessel produces a scalloped or serrated luminal edge. Because of both vessel-wall thickening and dilatation of proximal vessels, the contrast-filled lumen may appear relatively normal in diameter. Distal vessels demonstrate the rapid tapering and pruning characteristic of pulmonary hypertension (see Fig. 56-6).

Although some risk remains, the benefit of establishing the presence of a treatable cause of the hypertension far outweighs the small risk, and pulmonary angiography should be performed whenever there is a possibility that chronic thromboembolism is the etiology of pulmonary hypertension. Historically, angiography in those with pulmonary hypertension has been thought to carry disproportionate risk. We have found that not to be the case, and at our institution pulmonary angiographies are performed daily in these patients with minimal associated risks. Several thousand angiograms in pulmonary hypertensive patients have now been performed at our institution without mortality.

In addition to pulmonary angiography, patients over 40 undergo coronary arteriography and other cardiac investigation as necessary. If significant disease is found, additional cardiac surgery is performed at the time of pulmonary thromboendarterectomy.

In approximately 15% of cases, the differential diagnosis between primary pulmonary hypertension and distal and small-vessel pulmonary thromboembolic disease remains unclear and hard to establish. In these patients, pulmonary angioscopy is often helpful. The pulmonary angioscope is a fiberoptic telescope that is placed through a central line into the pulmonary artery. The tip contains a balloon that is then filled with saline and pushed against the vessel wall. A bloodless field can thus be obtained to view the pulmonary artery wall. The classic appearance of chronic pulmonary thromboembolic disease by angioscopy consists of intimal thickening, with intimal irregularity and scarring, and webs across small vessels. These webs are thought to be the residue of resolved occluding thrombi of small vessels, but are important diagnostic findings. The presence of embolic disease, occlusion of vessels, or the presence of thrombotic material is diagnostic.

Medical Treatment

Chronic anticoagulation represents the mainstay of the medical regimen. Anticoagulation is primarily used to prevent future embolic episodes, but it also serves to limit the development of thrombus in regions of low flow within the pulmonary vasculature. Inferior vena caval filters are used routinely to prevent recurrent embolization. If caval filtration and anticoagulation fail to prevent recurrent emboli, immediate thrombolysis

may be beneficial, but lytic agents are incapable of altering the chronic component of the disease.

Right ventricular failure is treated with diuretics and vasodilators, and although some improvement may result, the effect is generally transient because the failure is due to a mechanical obstruction and will not resolve until the obstruction is removed. Similarly, the prognosis is unaffected by medical therapy,[88,89] which should be regarded as only supportive. Because of the bronchial circulation, pulmonary embolization seldom results in tissue necrosis. Surgical endarterectomy therefore will allow distal pulmonary tissue to be used once more in gas exchange.

The only other surgical option for these patients is transplantation. However, we consider transplantation not to be appropriate for this disease because of the mortality and morbidity rates of patients on the waiting list, the higher risk of the operation, and the lower survival rate (approximately 80% at 1 year at experienced centers for transplantation versus 95% for pulmonary endarterectomy). Furthermore, pulmonary endarterectomy appears to be permanently curative, and the continuing risk of rejection and immunosuppression are absent.

Natural History

The natural history of chronic thromboembolic pulmonary hypertension is dismal, and nearly all patients die of progressive right heart failure.[11] Because of the insidious onset, the diagnosis is usually made relatively late in the progression of the disease when dyspnea and/or early symptoms of right heart failure develop and pulmonary hypertension is severe (>40 mm Hg mean). In the series of Riedel and associates of 13 patients, 9 died a mean of 28 months after the diagnosis of right heart failure.[11] Seven of the 13 had recurrent episodes of fresh emboli demonstrated by new perfusion defects or by autopsy. The severity of pulmonary hypertension at the time of diagnosis inversely correlates with duration of survival.[11]

Pulmonary Thromboendarterectomy

Although there were previous attempts, Allison and colleagues[90] did the first successful pulmonary "thromboendarterectomy" through a sternotomy using surface hypothermia, but only fresh clots were removed. The operation was 12 days after a thigh injury that led to PE, and there was no endarterectomy. Since then, there have been many occasional reports of the surgical treatment of chronic pulmonary thromboembolism,[91–94] but most of the surgical experience in pulmonary endarterectomy has been reported from the University of California, San Diego (UCSD) Medical Center. Braunwald commenced the UCSD experience with this operation in 1970, which now totals more than 2000 cases. The operation described below, using deep hypothermia and circulatory arrest, is the standard procedure.

Indications

When the diagnosis of thromboembolic pulmonary hypertension has been firmly established, the decision for operation is made based on the severity of symptoms and the general condition of the patient. Early in the pulmonary endarterectomy experience, Moser and colleagues[92] pointed out that there were three major reasons for considering thromboendarterectomy: hemodynamic, alveolorespiratory, and prophylactic. The hemodynamic goal is to prevent or ameliorate right ventricular compromise caused by pulmonary hypertension. The respiratory objective is to improve respiratory function by the removal of a large ventilated but unperfused physiologic dead space, regardless of the severity of pulmonary hypertension. The prophylactic goal is to prevent progressive right ventricular dysfunction or retrograde extension of the obstruction, which might result in further cardiorespiratory deterioration or death.[92] Our subsequent experience has added another prophylactic goal: the prevention of secondary arteriopathic changes in the remaining patent vessels.

Most patients who undergo surgery are classified as New York Heart Association (NYHA) class III or IV. The ages of the patients in our series have ranged from 7 to 85 years. A typical patient will have a severely elevated pulmonary vascular resistance (PVR) level at rest, the absence of significant comorbid disease unrelated to right heart failure, and the appearance of chronic thrombi on angiogram that appear to be relatively in balance with the measured PVR level. Exceptions to this general rule, of course, occur.

Although most patients have a PVR level in the range of 800 dynes/sec/cm^{-5} and pulmonary artery pressures less than systemic, the hypertrophy of the right ventricle that occurs over time makes pulmonary hypertension to suprasystemic levels possible. Therefore many patients (approximately 20% in our practice) have a level of PVR in excess of 1000 dynes/sec/cm^{-5} and suprasystemic pulmonary artery pressures. There is no upper limit of PVR level, pulmonary artery pressure, or degree of right ventricular dysfunction that excludes patients from operation.

We have become increasingly aware of the changes that can occur in the remaining patent (unaffected by clot) pulmonary vascular bed subjected to the higher pressures and flow that result from obstruction in other areas. Therefore, with the increasing experience and safety of the operation, we are tending to offer surgery to symptomatic patients whenever the angiogram demonstrates thromboembolic disease. A rare patient might have a PVR level that is normal at rest, although elevated with minimal exercise. This is usually a young patient with total unilateral pulmonary artery occlusion and unacceptable exertional dyspnea because of an elevation in dead space ventilation. Operation in this circumstance is performed not only to reperfuse lung tissue, but to re-establish a more normal ventilation-perfusion relationship (thereby reducing minute ventilatory requirements during rest and exercise), and also to preserve the integrity of the contralateral circulation and prevent chronic arterial changes associated with long-term exposure to pulmonary hypertension.

If not previously implanted, an inferior vena caval filter is routinely placed several days in advance of the operation.

Operation

PRINCIPLES: There are several guiding principles for the operation. Surgical treatment and endarterectomy must be bilateral, because this is a bilateral disease in the vast majority of our patients. Furthermore, for pulmonary hypertension to be a major factor, both pulmonary vasculatures must be substantially involved. The only reasonable approach to both pulmonary arteries is through a median sternotomy incision. Historically, there were many reports of unilateral operation, and occasionally this is still performed in inexperienced centers through a thoracotomy. However, the unilateral approach ignores the disease on the contralateral side, subjects the patient to hemodynamic jeopardy during the clamping of the pulmonary artery, does not allow good visibility because of the continued presence of bronchial blood flow, and exposes the patient to a repeat operation on the contralateral side. In addition, collateral channels develop in chronic thrombotic hypertension, not only through the bronchial arteries but also from diaphragmatic, intercostal, and pleural vessels. The dissection of the lung in the pleural space via a thoracotomy incision can therefore be extremely bloody. The median sternotomy incision, apart from providing bilateral access, avoids entry into the pleural cavities and allows the ready institution of cardiopulmonary bypass.

Cardiopulmonary bypass is essential to ensure cardiovascular stability when the operation is performed and to cool the patient to allow circulatory arrest. Excellent visibility is required, in a bloodless field, to define an adequate endarterectomy plane and to then follow the pulmonary endarterectomy specimen deep into the subsegmental vessels. Because of the copious bronchial blood flow usually present in these cases, periods of circulatory arrest are necessary to ensure perfect visibility. Again, there have been sporadic reports of the performance of this operation without circulatory arrest. However, it should be emphasized that although endarterectomy is possible without circulatory arrest, a complete endarterectomy is not. We always initiate the procedure without circulatory arrest, and a variable amount of dissection is possible before the circulation is stopped, but never complete dissection. The circulatory arrest periods are limited to 20 minutes, with restoration of flow between each arrest. With experience, the endarterectomy usually can be performed with a single period of circulatory arrest on each side.

A true endarterectomy in the plane of the media must be accomplished. It is essential to appreciate that the removal of visible thrombus is largely incidental to this operation. Indeed, in most patients, no free thrombus is present, and on initial direct examination, the pulmonary vascular bed may appear normal. The early literature on this procedure indicates that thrombectomy was often performed without endarterectomy, and in these cases the pulmonary artery pressures did not improve, often with the resultant death of the patient.

PREPARATION AND ANESTHETIC CONSIDERATIONS: Much of the preoperative preparation is common to any open-heart procedure. Routine monitoring for anesthetic induction includes a surface electrocardiogram, cutaneous oximetry, and radial and pulmonary artery pressures. After anesthetic induction a femoral artery catheter, in addition to a radial arterial line, is also placed. This provides more accurate measurements during rewarming and on discontinuation of cardiopulmonary bypass because of the peripheral vasoconstriction that occurs after hypothermic circulatory arrest. It is generally removed in the intensive care unit when the two readings correlate.

Electroencephalographic recording is performed to ensure the absence of cerebral activity before circulatory arrest is induced. The patient's head is enveloped in a cooling jacket, and cerebral cooling is begun after the initiation of bypass. Temperature measurements are made of the esophagus, tympanic membrane, urinary catheter, rectum, and blood (through the Swan-Ganz catheter). If the patient's condition is stable after the induction of anesthesia, up to 500 mL of autologous whole blood is withdrawn for later use, and the volume deficit is replaced with crystalloid solution.

SURGICAL TECHNIQUE: After a median sternotomy incision is made, the pericardium is incised longitudinally and attached to the wound edges. Typically the right heart is enlarged, with a tense right atrium and a variable degree of tricuspid regurgitation. There is usually severe right ventricular hypertrophy, and with critical degrees of obstruction, the patient's condition may become unstable with the manipulation of the heart.

Anticoagulation is achieved with the use of beef-lung heparin sodium (400 U/kg, intravenously) administered to prolong the activated clotting time beyond 400 s. Full cardiopulmonary bypass is instituted with high ascending aortic cannulation and two caval cannulas. These cannulas must be inserted into the superior and inferior vena cavae sufficiently to enable subsequent opening of the right atrium. The heart is emptied on bypass, and a temporary pulmonary artery vent is placed in the midline of the main pulmonary artery 1 cm distal to the pulmonary valve. This will mark the beginning of the left pulmonary arteriotomy.

When cardiopulmonary bypass is initiated, surface cooling with both the head jacket and the cooling blanket is begun. The blood is cooled with the pump-oxygenator. During cooling a 10°C gradient between arterial blood and bladder or rectal temperature is maintained.[93] Cooling generally takes 45 minutes to an hour. When ventricular fibrillation occurs, an additional vent is placed in the left atrium through the right superior pulmonary vein. This prevents atrial and ventricular distension from the large amount of bronchial arterial blood flow that is common with these patients.

It is most convenient for the primary surgeon to stand initially on the patient's left side. During the cooling period, some preliminary dissection can be performed, with full mobilization of the right pulmonary artery from the ascending aorta. The superior vena cava is also fully mobilized. The approach to the right pulmonary artery is made medial, not

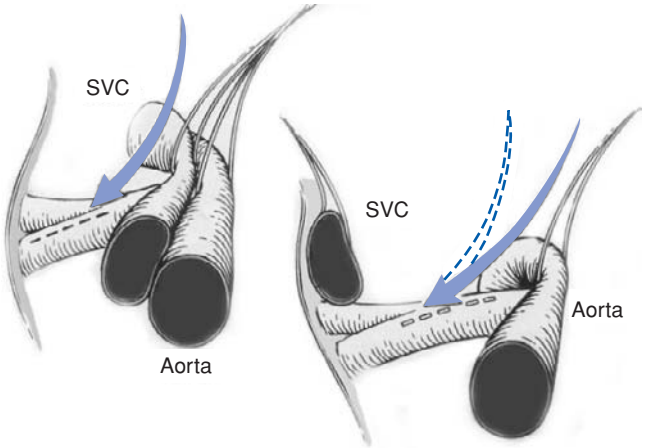

Figure 56-7. Recommended surgical approach on the right side. This approach, medial to the superior vena cava (SVC), between the superior vena cava and aorta, provides a direct view into the right pulmonary artery. Note that an approach on the lateral side of the superior vena cava will only provide a restricted view and should be avoided.

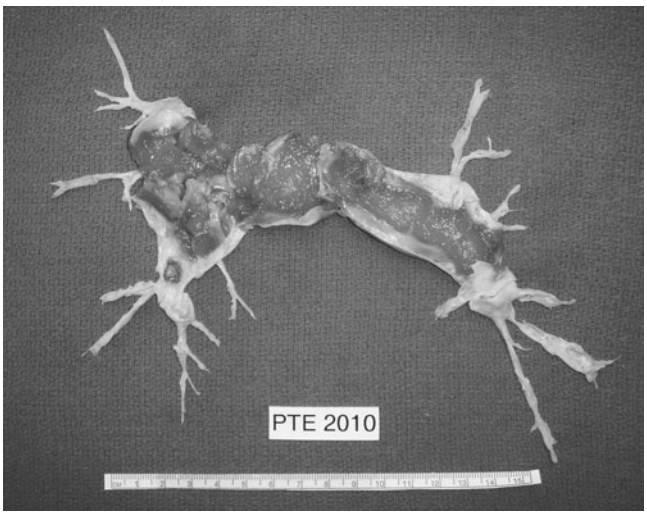

Figure 56-8. Surgical specimen removed from a patient showing evidence of some fresh and some old thrombus in the main and both right and left pulmonary arteries. Note that simple removal of the gross disease initially encountered upon pulmonary arteriotomy will not be therapeutic, and any meaningful outcome involves a full endarterectomy into all the distal segments.

lateral, to the superior vena cava. All dissection of the pulmonary arteries takes place intrapericardially, and neither pleural cavity should be entered. An incision is then made in the right pulmonary artery from beneath the ascending aorta out under the superior vena cava and entering the lower lobe branch of the pulmonary artery just after the takeoff of the middle lobe artery (Fig. 56-7). It is important that the incision stays in the center of the vessel and continues into the lower, rather than the middle lobe artery.

Any loose thrombus, if present, is now removed. This is necessary to obtain good visualization. It is most important to recognize, however, that first, an embolectomy without subsequent endarterectomy is quite ineffective, and second, that in most patients with chronic thromboembolic hypertension, direct examination of the pulmonary vascular bed at operation generally shows no obvious embolic material. Therefore, to the inexperienced or cursory glance, the pulmonary vascular bed may well appear normal even in patients with severe chronic embolic pulmonary hypertension.

If the bronchial circulation is not excessive, the endarterectomy plane can be found during this early dissection. However, although a small amount of dissection can be performed before the initiation of circulatory arrest, it is unwise to proceed unless perfect visibility is obtained because the development of a correct plane is essential.

There are four broad types of pulmonary occlusive disease related to thrombus that can be appreciated, and we use the following classification:[87,94] type I disease (approximately 10% of cases of thromboembolic pulmonary hypertension; Fig. 56-8) refers to the situation in which major vessel clot is present and readily visible upon opening the pulmonary arteries. As mentioned earlier, all central thrombotic material has to be completely removed before the endarterectomy. In type II disease (approximately 70% of cases; Fig. 56-9), no major vessel thrombus can be appreciated. In these cases only thickened intima can be seen, occasionally with webs, and the endarterectomy plane is raised in the main, lobar, or segmental vessels. Type III disease (approximately 20% of cases; Fig. 56-10) presents the most challenging surgical situation. The disease is very distal and confined to the segmental and subsegmental branches. No occlusion of vessels can be seen initially. The endarterectomy plane must be carefully and painstakingly raised in each segmental and subsegmental branch. Type III disease is most often associated with presumed repetitive thrombi from indwelling catheters (such as pacemaker wires) or ventriculoatrial shunts. Type IV disease (Fig. 56-11) does not represent primary thromboembolic pulmonary hypertension and is inoperable. In this entity there is intrinsic small-vessel disease, although secondary thrombus may occur as a result of stasis. Small-vessel disease may be unrelated to thromboembolic events ("primary" pulmonary hypertension) or occur in relation to thromboembolic hypertension as a result of a high-flow or high-pressure state in previously unaffected vessels similar to the generation of Eisenmenger syndrome. We believe that there may also be sympathetic "cross-talk" from an affected contralateral side or stenotic areas in the same lung.

When the patient's temperature reaches 20°C, the aorta is cross-clamped and a single dose of cold cardioplegic solution (1 L) is administered. Additional myocardial protection is obtained by the use of a cooling jacket. The entire procedure is now performed with a single aortic cross-clamp period with no further administration of cardioplegic solution.

A modified cerebellar retractor is placed between the aorta and superior vena cava. When blood obscures direct

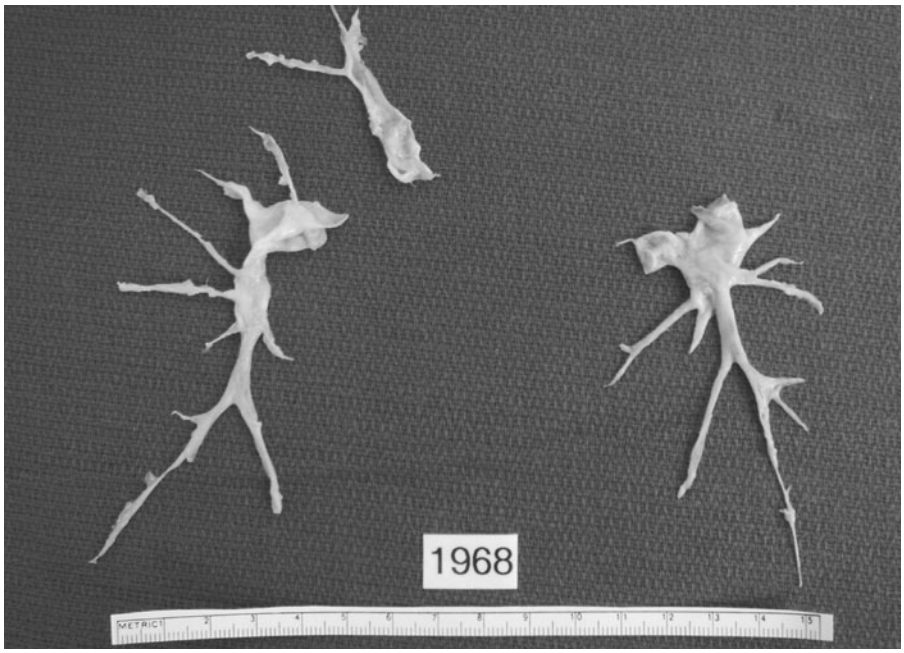

Figure 56-9. Specimen removed in a patient with type II disease. Both pulmonary arteries have evidence of chronic thromboembolic material. Note the distal tails of the specimen in each branch. Full resolution of pulmonary hypertension is dependent on complete removal of all the distal tails.

vision of the pulmonary vascular bed, thiopental is administered (500 mg to 1 g) until the electroencephalogram becomes isoelectric. Circulatory arrest is then initiated, and the patient undergoes exsanguination. All monitoring lines to the patient are turned off to prevent the aspiration of air. Snares are tightened around the cannulas in the superior and inferior vena cavae. It is rare that one 20-minute period for each side is exceeded. Although retrograde cerebral perfusion has been advocated for total circulatory arrest in other procedures, it is not helpful in this operation because it does

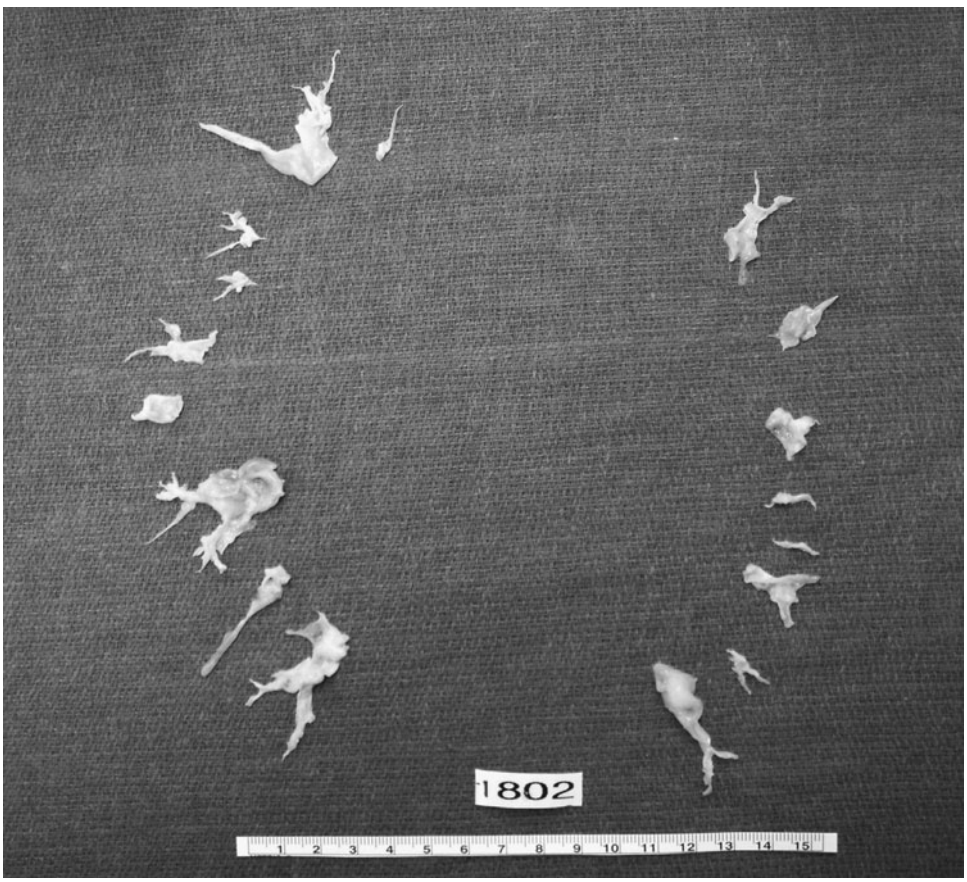

Figure 56-10. Specimen removed from a patient with type III disease. Note that the disease is distal, and the plane was raised at each segmental level.

Figure 56-11. Note the absence of distal "tails" in this specimen removed from a patient with surgical classification type IV. All "tails" are replaced by "trousers." No clinical benefit was obtained from this procedure and the patient's postoperative hemodynamics were not improved, despite what appears to be an impressive endarterectomy specimen. The patient had primary pulmonary hypertension.

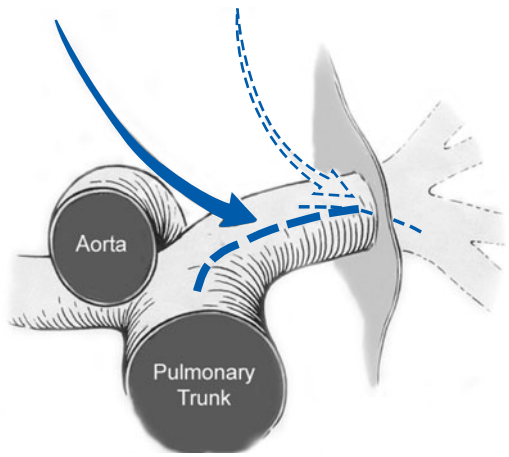

Figure 56-12. Surgical approach on the left side. The incision in the left pulmonary artery begins in the midpoint of the main pulmonary trunk, at the insertion site of the pulmonary artery vent. This incision provides better visibility than a more distal approach (dotted line and arrow). Care must be taken to avoid injury to the phrenic nerve.

not allow a completely bloodless field, and with the short arrest times that can be achieved with experience, it is not necessary.

Any residual loose thrombotic debris encountered is removed. Then a microtome knife is used to develop the endarterectomy plane posteriorly, because any inadvertent egress in this site could be repaired readily or simply left alone. Dissection in the correct plane is critical because if the plane is too deep the pulmonary artery may perforate, with fatal results, and if the dissection plane is not deep enough, inadequate amounts of the chronically thromboembolic material will be removed.

When the proper plane is entered, the layer will strip easily, and the material left with the outer layers of the pulmonary artery will appear somewhat yellow. The ideal layer is marked with a pearly white plane, which strips easily. There should be no residual yellow plaque. If the dissection is too deep, a reddish or pinkish color indicates that the adventitia has been reached. A more superficial plane should be sought immediately.

Once the plane is correctly developed, a full-thickness layer is left in the region of the incision to ease subsequent repair. The endarterectomy is then performed with an eversion technique. Because the vessel is everted and subsegmental branches are being worked on, a perforation here will become completely inaccessible and invisible later. This is why the absolute visualization in a completely bloodless field provided by circulatory arrest is essential. It is important that each subsegmental branch is followed and freed individually until it ends in a "tail," beyond which there is no further obstruction. Residual material should never be cut free; the entire specimen should "tail off" and come free spontaneously.

Once the right-sided endarterectomy is completed, circulation is restarted, and the arteriotomy is repaired with a continuous 6-0 polypropylene suture. The hemostatic nature of this closure is aided by the nature of the initial dissection, with the full thickness of the pulmonary artery being preserved immediately adjacent to the incision.

After the completion of the repair of the right arteriotomy, the surgeon moves to the patient's right side. The pulmonary vent catheter is withdrawn, and an arteriotomy is made from the site of the pulmonary vent hole laterally to the pericardial reflection, avoiding entry into the left pleural space. Additional lateral dissection does not enhance intraluminal visibility, may endanger the left phrenic nerve, and makes subsequent repair of the left pulmonary artery more difficult (Fig. 56-12).

The left-sided dissection is virtually analogous in all respects to that accomplished on the right. The duration of circulatory arrest intervals during the performance of the left-sided dissection is subject to the same restriction as the right.

After the completion of the endarterectomy, cardiopulmonary bypass is reinstituted and warming is commenced. Methylprednisolone (500 mg intravenously) and mannitol (12.5 g intravenously) are administered, and during warming a 10°C temperature gradient is maintained between the perfusate and body temperature, with a maximum perfusate temperature of 37°C. If the systemic vascular resistance level is high, nitroprusside is administered to promote vasodilatation and warming. The rewarming period generally takes approximately 90 to 120 minutes but varies according to the body mass of the patient.

When the left pulmonary arteriotomy has been repaired, the pulmonary artery vent is replaced at the top of the incision. The heart is retracted upward and to the left, and a posterior pericardial window is made between the

aorta and the left phrenic nerve. Alternatively, prior to closure a posterior pericardial drain can be placed and removed once drainage has substantially decreased.

The right atrium is then opened and examined. Any intra-atrial communication is closed. Although tricuspid valve regurgitation is invariable in these patients and is often severe, tricuspid valve repair is not performed. Right ventricular remodeling occurs within a few days, with the return of tricuspid competence. If other cardiac procedures are required, such as coronary artery or mitral or aortic valve surgery, these are conveniently performed during the systemic rewarming period. Myocardial cooling is discontinued once all cardiac procedures have been concluded. The left atrial vent is removed, and the vent site is repaired. All air is removed from the heart, and the aortic cross-clamp is removed.

When the patient has rewarmed, cardiopulmonary bypass is discontinued. Dopamine hydrochloride is routinely administered at renal doses, and other inotropic agents and vasodilators are titrated as necessary to sustain acceptable hemodynamics. The cardiac output is generally high, with a low systemic vascular resistance. Temporary atrial and ventricular epicardial pacing wires are placed.

Despite the duration of extracorporeal circulation, hemostasis is readily achieved, and the administration of platelets or coagulation factors is generally unnecessary. Wound closure is routine. A vigorous diuresis is usual for the next few hours, also a result of the previous systemic hypothermia.

Postoperative care

Meticulous postoperative management is essential to the success of this operation. All patients are mechanically ventilated for at least 24 hours, and all patients are subjected to a maintained diuresis with the goal of reaching the patient's preoperative weight within 24 hours. Although much of the postoperative care is common to more ordinary open-heart surgery patients, there are some important differences.

The electrocardiogram, systemic and pulmonary arterial and central venous pressures, temperature, urine output, arterial oxygen saturation, chest tube drainage, and fluid balance are monitored. A pulse oximeter is used to continuously monitor peripheral oxygen saturation. Management of cardiac arrhythmias and output and treatment of wound bleeding are identical to those used for other open-heart operations. In addition, a higher minute ventilation is often required early after the operation to compensate for the temporary metabolic acidosis that develops after the long period of circulatory arrest, hypothermia, and cardiopulmonary bypass. Tidal volumes higher than those normally recommended after cardiac surgery are therefore generally used to obtain optimal gas exchange. The maximum inspiratory pressure is maintained below 30 cm H_2O if possible.

Although we used to believe that prolonged sedation and ventilation were beneficial and led to less pulmonary edema, subsequent experience has shown this not to be so. Extubation should be performed on the first postoperative day, whenever possible.

DIURESIS: Patients have considerable positive fluid balance after operation. After hypothermic circulatory arrest, patients initiate an early spontaneous aggressive diuresis for unknown reasons, but this may in part be related to the increased cardiac output related to a now lower PVR level, and improved right ventricular function. This should be augmented with diuretics, however, with the aim of returning the patient to the preoperative fluid balance within 24 hours of operation. Because of the increased cardiac output, some degree of systemic hypotension is readily tolerated. Fluid administration is minimized, and the patient's hematocrit level should be maintained above 30% to increase oxygen-carrying capacity and mitigate against the pulmonary reperfusion phenomenon.

ARRHYTHMIAS: The development of atrial arrhythmias, at approximately 10%, is no more common than that encountered in patients who undergo other types of nonvalvular heart surgery. The small, inferior atrial incision, away from the conduction system of the atrium or its blood supply, may be helpful in the reduction of the incidence of these arrhythmias.

TRANSFUSION: Despite the requirement for the maintenance of an adequate hematocrit level, with careful blood conservation techniques used during operation, transfusion is required in only a few patients.

INFERIOR VENA CAVAL FILTER AND ANTICOAGULATION: A Greenfield filter is usually inserted before operation, to minimize recurrent pulmonary embolism after pulmonary endarterectomy. However, if this is not possible, it can also be inserted at the time of operation. If the device is to be placed at operation, radiopaque markers should be placed over the spine that correspond to the location of the renal veins to allow correct positioning. Postoperative venous thrombosis prophylaxis with intermittent pneumatic compression devices is used, and the use of subcutaneous heparin is begun on the evening of surgery. Anticoagulation with warfarin is begun as soon as the pacing wires and mediastinal drainage tubes are removed, with a target International Normalized Ratio of 2.5 to 3.

Complications

Patients are subject to all complications associated with open-heart and major lung surgery (e.g., arrhythmias, atelectasis, wound infection, pneumonia, and mediastinal bleeding) but also may develop complications specific to this operation. These include persistent pulmonary hypertension, reperfusion pulmonary response, and neurologic disorders related to deep hypothermia.

PERSISTENT PULMONARY HYPERTENSION: The decrease in PVR level usually results in an immediate and sustained restoration of pulmonary artery pressures to normal levels, with a marked increase in cardiac output. In a few patients, an

immediately normal pulmonary vascular tone is not achieved, but an additional substantial reduction may occur over the next few days because of the subsequent relaxation of small vessels and the resolution of intraoperative factors such as pulmonary edema. In such patients, it is usual to see a large pulmonary artery pulse pressure, the low diastolic pressure indicating good runoff, yet persistent pulmonary arterial inflexibility still resulting in a high systolic pressure.

There are a few patients in whom the pulmonary artery pressures do not resolve substantially. We do operate on some patients with severe pulmonary hypertension but equivocal embolic disease. Despite the considerable risk of attempted endarterectomy in these patients, since transplantation is the only other avenue of therapy, there may be a point at which it is unlikely that a patient will survive until a donor is found. In our most recent 500 patients, more than one-third of perioperative deaths were directly attributable to the problem of inadequate relief of pulmonary artery hypertension. This was a diagnostic rather than an operative technical problem. Attempts at pharmacologic manipulation of high residual PVR levels with sodium nitroprusside, epoprostenol sodium, or inhaled nitric oxide are generally not effective. Because the residual hypertensive defect is fixed, it is not appropriate to use mechanical circulatory support or extracorporeal membrane oxygenation in these patients if they deteriorate subsequently.

THE "REPERFUSION RESPONSE": A specific complication that occurs in most patients to some degree is localized pulmonary edema, or the "reperfusion response." Reperfusion response or reperfusion injury is defined as a radiologic opacity seen in the lungs within 72 hours of pulmonary endarterectomy. This unfortunately loose definition may therefore encompass many causes, such as fluid overload and infection.

True reperfusion injury that directly adversely impacts the clinical course of the patient now occurs in approximately 10% of patients. In its most dramatic form, it occurs soon after operation (within a few hours) and is associated with profound desaturation. Edema-like fluid, sometimes with a bloody tinge, is suctioned from the endotracheal tube.[95] Frank blood from the endotracheal tube, however, signifies a mechanical violation of the blood-airway barrier that has occurred at operation and stems from a technical error. This complication should be managed, if possible, by identification of the affected area by bronchoscopy and balloon occlusion of the affected lobe until coagulation can be normalized.

One common cause of the reperfusion pulmonary edema is persistent high pulmonary artery pressures after operation when a thorough endarterectomy has been performed in certain areas, but there remains a large part of the pulmonary vascular bed affected by type IV change. However, the reperfusion phenomenon is often encountered in patients after a seemingly technically perfect operation with complete resolution of high pulmonary artery pressures. In these cases the response may be one of reactive hyperemia, after the revascularization of segments of the pulmonary arterial bed that have long experienced no flow. Other contributing factors may include perioperative pulmonary ischemia and conditions associated with high permeability lung injury in the area of the now denuded endothelium. Fortunately, the incidence of this complication is much less common now in our series, probably as a result of the more complete and expeditious removal of the endarterectomy specimen that has come with the large experience over the last decade.

MANAGEMENT OF THE "REPERFUSION RESPONSE": Early measures should be taken to minimize the development of pulmonary edema with diuresis, maintenance of the hematocrit levels, and the early use of peak end-expiratory pressure. Once the capillary leak has been established, treatment is supportive because reperfusion pulmonary edema will eventually resolve if satisfactory hemodynamics and oxygenation can be maintained. Careful management of ventilation and fluid balance is required. The hematocrit is kept high (32 to 36%), and the patient undergoes aggressive diuresis, even if this requires ultrafiltration. The patient's ventilatory status may be dramatically position sensitive. The fraction of inspired oxygen level is kept as low as is compatible with an oxygen saturation of 90%. A careful titration of positive end-expiratory pressure is carried out, with a progressive transition from volume-limited to pressure-limited inverse ratio ventilation and the acceptance of moderate hypercapnia.[95] The use of steroids is discouraged because they are generally ineffective and may lead to infection. Infrequently, inhaled nitric oxide at 20 to 40 ppm can improve the gas exchange. On occasion we have used extracorporeal perfusion support (an extracorporeal membrane oxygenator or extracorporeal carbon dioxide removal) until ventilation can be resumed satisfactorily, usually after 7 to 10 days. However, their use is limited to patients who have benefited from hemodynamic improvement but are suffering from significant reperfusion response. Extracorporeal devices should not be used if there is no evidence or hope of subsequent hemodynamic improvement, since they carry mortality close to 100%, and will not play a role in improving irreversible pulmonary pressures.

DELIRIUM: Early in the pulmonary endarterectomy experience (before 1990), there was a substantial incidence of postoperative delirium. A study of 28 patients who underwent pulmonary endarterectomy showed that 77% experienced the development of this complication.[96,97] Delirium appeared to be related to an accumulated duration of circulatory arrest time of more than 55 minutes; the incidence fell to 11% with significantly shorter periods of arrest time.[96–98] With the more expeditious operation that has come with our increased experience, postoperative confusion is now encountered no more commonly than with ordinary open-heart surgery.

PERICARDIAL EFFUSION: Probably because of the lymphatic tissue that is encountered during the dissection of the hilum

and the mobilization of the superior vena cava, possibly combined with the diminution of cardiac size that occurs immediately after the operation, we have encountered significant pericardial effusions in several patients. It is now our practice to either create a posterior pericardial window at the end of the operation or place a posterior pericardial drain, which we usually keep longer. These techniques have essentially eliminated the problem, and in general it is much easier to treat the pleural effusion on the left side in the occasional patient who may develop this complication.

Results

More than 2000 pulmonary thromboendarterectomies have been performed at UCSD Medical Center since 1970. Most of these cases (over 1800) have been completed since 1990, when the surgical procedure was modified as described earlier in this chapter. The mean patient age in our group is about 52 years, with a range of 7 to 85 years. There is a very slight male predominance. In nearly one-third of the cases, at least one additional cardiac procedure was performed at the time of operation. Most commonly, the adjunct procedure was closure of a persistent foramen ovale or atrial septal defect (26%) or coronary artery bypass grafting (8%).[87]

HEMODYNAMIC RESULTS: A reduction in pulmonary pressures and resistance to normal levels and a corresponding improvement in pulmonary blood flow and cardiac output are generally immediate and sustained.[98,99] In general, these changes can be assumed to be permanent. Whereas before the operation, more than 95% of the patients are in NYHA functional class III or IV, at 1 year after the operation, 95% of patients remain in NYHA functional class I or II.[99,100] In addition, echocardiographic studies have demonstrated that, with the elimination of chronic pressure overload, right ventricular geometry rapidly reverts toward normal. Right atrial and right ventricular enlargement regress. Tricuspid valve function returns to normal within a few days as a result of restoration of tricuspid annular geometry after the remodeling of the right ventricle, and tricuspid repair is not therefore part of the operation.

OPERATIVE MORBIDITY: Severe reperfusion injury was the single most frequent complication in the UCSD series, occurring in 10% of patients. Some of these patients did not survive, and other patients required prolonged mechanical ventilatory support. A few patients were salvaged only by the use of extracorporeal support and blood carbon dioxide removal. Neurologic complications from circulatory arrest appear to have been eliminated, probably as a result of the shorter circulatory arrest periods now experienced, and perioperative confusion and stroke are now no more frequent than with conventional open-heart surgery. Early postoperative hemorrhage required re-exploration in 2.5% of patients, and only 50% of patients required intra- or postoperative blood transfusion. Despite the prolonged operation, wound infections are relatively infrequent. Only 1.8% experienced the development of sternal wound complications, including sterile dehiscence or mediastinitis.

DEATHS: In our experience, the overall mortality rate (at 30 days or in-hospital if the hospital course is prolonged) is about 7% for the entire patient group, which encompasses a time span of over 35 years. The mortality rate was 9.4% in 1989 and has been about 5 to 6% for the more than 1800 patients who have undergone the operation since 1990. Looking at our most recent experience over the last 5 years, the mortality rate has been about 4.5%. We generally quote an operative risk of less than 5%, but some patients predictably fall within a much higher-risk group. With our increasing experience and many referrals, we continue to accept some patients who, in retrospect, were unsuitable candidates for the procedure (type IV disease). We also accept patients in whom we know that the entire degree of pulmonary hypertension cannot be explained by the occlusive disease detected by angiography, but feel that they will be benefited by operation, albeit at higher risk. Residual causes of death are operation on patients in whom thromboembolic disease was not the cause of the pulmonary hypertension (50%) and the rare case of reperfusion pulmonary edema that progresses to a respiratory distress syndrome of long standing, which is not reversible (25%).

Late follow-up

A survey of the surviving patients who underwent pulmonary endarterectomy surgery at UCSD between 1970 and 1995 formally evaluated the long-term outcome.[100] Questionnaires were mailed to 420 patients who were more than 1 year after operation. Responses were obtained from 308 patients. Survival, functional status, quality of life, and the subsequent use of medical help were assessed. Survival after pulmonary thromboendarterectomy was 75% at 6 years or more. Ninety-three percent of the patients were found to be in NYHA class I or II, compared to about 95% of the patients being in NYHA class II or IV preoperatively. Of the working population, 62% of patients who were unemployed before operation returned to work. Patients who had undergone pulmonary endarterectomy scored several quality-of-life components just slightly lower than normal individuals, but significantly higher than the patients before endarterectomy. Only 10% of patients used oxygen, and in response to the question, "How do you feel about the quality of your life since your surgery?" 77% replied much improved, and 20% replied improved. These data appear to confirm that pulmonary endarterectomy offers substantial improvement in survival, function, and quality of life, with minimal later health care requirements.[100]

CONCLUSION

It is increasingly apparent that pulmonary hypertension caused by chronic PE is a condition which carries a poor prognosis. Medical therapy is ineffective in prolonging life and only transiently improves the symptoms. The only therapeutic alternative to pulmonary thromboendarterectomy is lung transplantation. The advantages of thromboendarterectomy

include a lower operative mortality rate and excellent long-term results without the risks associated with chronic immunosuppression and chronic allograft rejection. The mortality for thromboendarterectomy at our institution is now in the range of 4.5%, with sustained benefit. These results are clearly superior to those for transplantation both in the short and long term.

Although PTE is technically demanding for the surgeon and requires careful dissection of the pulmonary artery planes and the use of circulatory arrest, excellent short- and long-term results can be achieved. It is the successive improvements in operative technique developed over the last four decades which now allow pulmonary endarterectomy to be offered to patients with an acceptable mortality rate and excellent anticipation of clinical improvement. With this growing experience, it has also become clear that unilateral operation is obsolete and that circulatory arrest is essential.

The primary problem remains that this is an underrecognized condition. Increased awareness of both the prevalence of this condition and the possibility of a surgical cure should avail more patients of the opportunity for relief from this debilitating and ultimately fatal disease.

CHAPTER 57

Trauma to the Great Vessels

Thomas G. Gleason • Joseph E. Bavaria

Vesalius was the first to report on a traumatic injury to the aorta manifesting as a posttraumatic aortic aneurysm in 1557.[1,2] Aortic rupture was a very uncommon injury until the latter half of the 20th century as travel by motor vehicles increased. Based on limited epidemiologic data, 85% of traumatic injuries to the great vessels in civilian practices were previously attributed to penetrating trauma with 57% caused by gunshot wounds and 25% by stab wounds.[3–6] A more recent Scottish population-based study suggests that over 70% of thoracic aortic trauma is caused by blunt trauma.[7] One percent of blunt chest trauma patients will have an aortic injury.[8–10]

TRAUMATIC AORTIC DISRUPTION

Epidemiology

Blunt aortic injury remains the second leading cause of death from vehicular trauma, representing 15% of motor vehicle–caused deaths.[11–13] Death occurs at the accident scene in 75 to 90% of cases.[1,11–14] Approximately 8% of patients survive more than 4 hours.[1] Those who survive aortic transection typically have two other associated serious injuries, while those who die have four or more serious injuries.[1,13] According to Parmley's landmark report published in 1958, 42% of patients with lethal aortic rupture had an associated cardiac injury.[1] The short duration of postaccident survival and the high incidence of fatal associated injuries preclude recovery in most of these patients. Recovery of the select few who survive the first few hours after aortic rupture depends on how they are managed in the hospital.

The true incidence of blunt aortic rupture is not known, but based on autopsy series aortic rupture occurs in 12 to 23% of deaths from blunt trauma.[1,15–18] According to national vehicular crash databases in the United States and the United Kingdom, the incidence of thoracic aortic injury among motor vehicle crash victims is 1.5% and 1.9%, respectively.[19] Seventy-three to 92% of all traumatic aortic disruptions involve motor vehicle drivers, passengers, or pedestrians hit by vehicles.[1,13,15,17,18] Alcohol or other substance abuse is involved in over 40% of these motor vehicle accidents.[15,17] Ejection from a vehicle doubles the risk of aortic rupture, and seat belt restraint reduces mortality risk by a factor of four.[15] Data confirm that active restraints (seat belts) are more effective than passive restraints (air bags) in preventing traumatic aortic injury.[20] Aortic rupture of both the ascending and descending aorta has been attributed to the deployment of an air bag, in some cases with cars going less than 10 mph.[21–24] The risk of an aortic injury is at least three times higher among unbelted than belted motor vehicle occupants.[19] Frontal and side impact crashes, regardless of the side of impact, have the highest risk.[14,19] Accidental or suicidal falls, crush injuries, airplane accidents, and rare cave-ins are among the other causes of aortic rupture.[1,13,16,25–27] Falls causing aortic rupture typically occur from heights greater than 3 meters.[1,25,26,28]

Seventy to eighty percent of these injuries occur in males with an average age of 36 to 40 years.[7,13,29,30] Seventy-five percent of patients with traumatic aortic rupture who make it to the hospital alive are initially hemodynamically stable,[13] but up to 50% die prior to definitive surgery.[29,31] Compared to autopsy series, patients who reach the hospital alive have fewer severe associated injuries.[1,12,13,16] Forty to 92% of patients are transferred from a hospital to a level I trauma center.[13,32,33]

Table 57-1 lists the frequency of associated injuries from data accrued throughout the 1970s into the late 1990s.[13,26,34–37] The most robust database was gathered prospectively from 50 trauma centers throughout the United States and Canada (American Association for the

Surgery of Trauma [AAST] trial).[13] Fifty-one percent of patients have an associated closed head injury. Forty-six percent have multiple rib fractures, and 38% have pulmonary contusions. Compared to older autopsy series, which had demonstrated that the majority of patients have associated cardiac contusion, recent data suggest that the incidence is only 4%.[13] Orthopedic injuries remain common, occurring in 20 to 35% of cases. Mean injury severity score in the AAST trial was 42.1, which is significantly higher than that seen in older retrospective reports, implying that significantly more patients with these types of serious injuries make it to the hospital and are saved in the modern era.[13]

Pathology

Aortic disruptions occur in all aortic segments including, rarely, the abdominal aorta, but the most common site among patients who survive is at the aortic isthmus (Fig. 57-1). According to autopsy series, 36 to 54% occur at the aortic isthmus, 8 to 27% involve the ascending aorta, 8 to 18% occur in the arch, and 11 to 21% involve the distal descending aorta.[1,16,38,39] Alternatively, surgical series demonstrate that 84 to 97% of ruptures occur at the isthmus, while 3 to 10% occur in the ascending, arch, or distal descending aorta.[12,13,32,35,36,40–42] Among patients who survive, it is evident that the periadventitial tissues around the isthmus provide some protection against free rupture that allows for short-term survival and transfer to a hospital. The aorta is typically transected in a transverse fashion involving all three layers of the aortic wall with the edges often separated by several centimeters[1,16] (Fig. 57-2). Non-circumferential and partial aortic wall disruptions do occur and can vary from only a few millimeters to several centimeters.[1,16,43,44] Spiral lacerations or longitudinal extensions are uncommon. Intramural hematomas and focal dissections occur with partial-thickness disruptions but not transections.[1] Partial tears tend to occur posteriorly, involving the intima and media. Aortic wall structure at and around the transection does not differ from nearby uninvolved aorta, and atherosclerotic disease is generally not present.[1,15,16] The aortic adventitia provides the majority of its tensile strength, but there is no evidence to suggest that the adventitia at the aortic isthmus is any weaker than any other part of the aorta.[45,46]

Blunt trauma can also produce trauma to the other great vessels. Aortic disruption at the base of the innominate

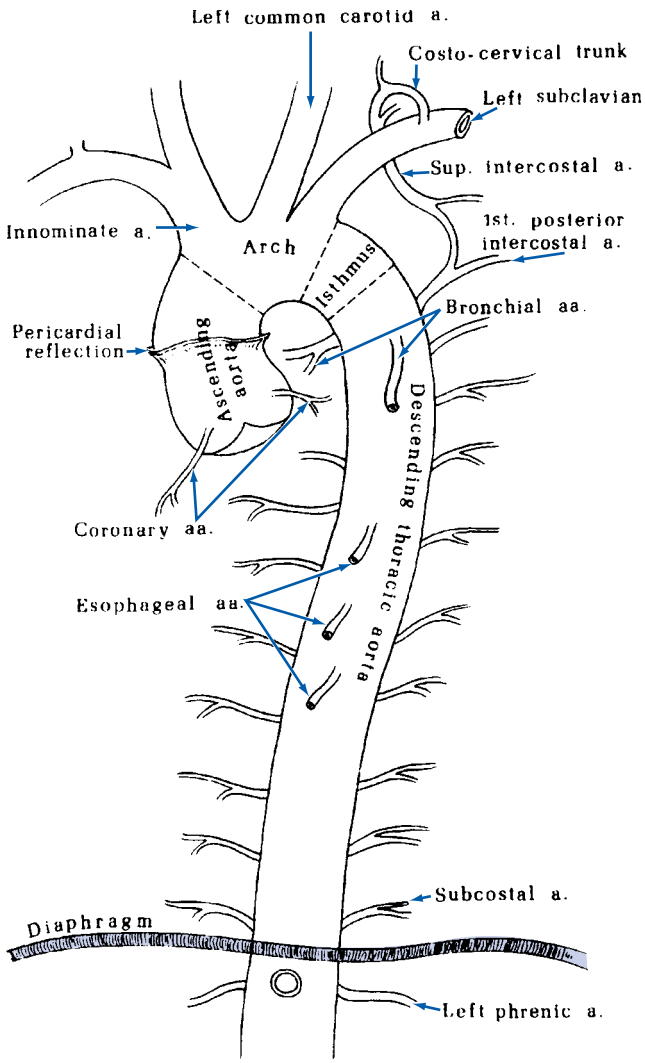

Figure 57-1. Anatomic diagram of the thoracic aorta and its major branches.

artery is the most common site of injury after the isthmus, followed by the base of the left subclavian artery, and then the base of the left carotid.[47] Central venous injuries are rarely injured with blunt trauma,[5] but they do occur with penetrating trauma.[48]

Approximately 2 to 5% of patients with aortic disruptions survive without operation, or even detection, to form chronic false aneurysms.[49] Little is known of the natural history of these chronic pseudoaneurysms because many go undetected. It is likely that an initial false aneurysm with blood flow partially thromboses and organizes to form a fibrous wall. This wall tends to calcify.[49–51] It can evolve into a saccular or fusiform aneurysm and late expansion or even rupture can occur. Ninety percent involve the aortic isthmus, again presumably reflective of the inherent protection afforded to this area by mediastinal periadventitial tissues around the isthmus.[52–54] The patients who develop chronic pseudoaneurysms have fewer associated injuries at the time of the traumatic event.[52–54] In fact, 35% have no other injuries, and 50% have only one.[50]

Pathogenesis of Blunt Aortic Injury

Despite extensive investigation, analysis, and debate, no consensus or unified understanding of the pathogenesis of aortic transection has emerged. Popular opinion has employed the "whiplash" theory posing that a combination of traction, torsion, shear, bending, and bursting forces secondary to differential deceleration of tissues within the mediastinum cause an appropriate stress to rupture the aorta at specific sites—the isthmus being the most common.[15,45,46,55–62] The ligamentum arteriosum, the left main stem bronchus, and the paired intercostal arteries limit the mobility of the aorta at the isthmus and just distal to it.

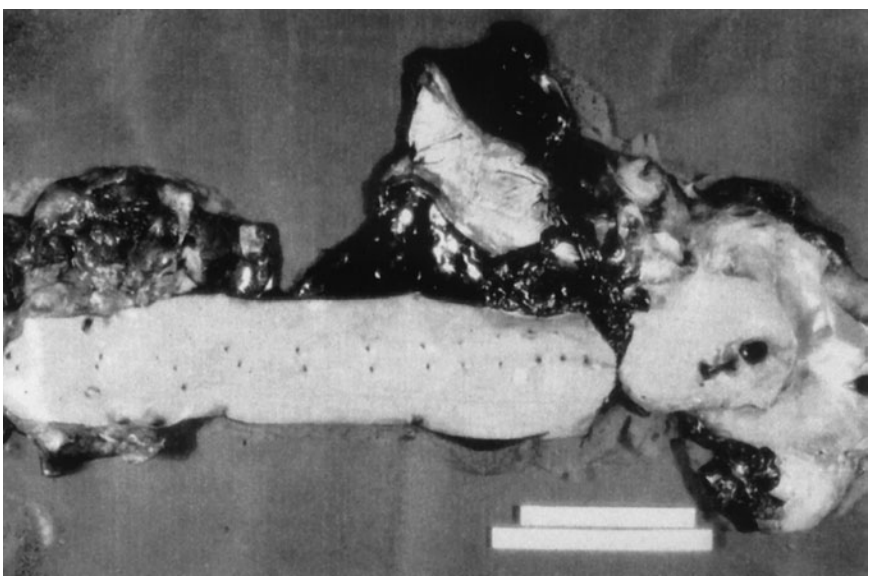

Figure 57-2. Photograph of a traumatic aortic disruption at the isthmus. (*Reproduced with permission from Strassman.*[44])

Experiments have suggested that the aorta can be displaced in a longitudinal (cranial or caudal) direction sufficient to cause traction tears at the isthmus.[57,59] It has also been apparently recognized that deceleration forces can reach several hundred times the force of gravity, producing injury without any direct impact on the chest.[55,56] Alternatively, a "shoveling mechanism" has been postulated to explain cranially directed traction stresses in drivers and front seat passengers in motor vehicle accidents.[63]

Contrarily, Crass and associates argue that the forces of differential deceleration, torsion, or hydrostatics alone have inadequate magnitude in vehicular accidents to result in aortic tearing given the inherent properties of the aorta.[64–66] Several studies have demonstrated that the gravitational forces of vehicular trauma do not approach the tensile strength of the aorta. Oppenheim and Zehnder showed that a normal aorta can withstand a 2000-mm Hg pressure before bursting.[67,68] Crass proposed a new mechanism he coined "the osseous pinch" based on thoracic compression that he tested in the laboratory. The hypothesis was that anterior thoracic osseous structures (manubrium, first rib, and clavicular heads) rotate posteriorly and inferiorly about the axes of the posterior rib attachments. When the force is large enough these anterior bony structures impact the vertebral column, and the portion of the aorta fixed overlying the spine (the isthmus and proximal descending aorta) is pinched between the bones. This causes a direct shearing of the aorta. Crass' group demonstrated in a canine model that a blunt force as small as 20,000 N transected the intima and media of the aorta.[64] In comparison, a 38-mph collision produces a force of 198,000 N in a normal-sized adult.[64] Some clinical data support the osseous pinch mechanism.[69]

Other forces may be important in ascending aortic injuries. The anterior location of the ascending aorta and the weight and ease of displacement of the heart downward and to the left facilitate traction stress on and above the aortic root.[59] Hyperextension of the spine and consequent shearing forces may play a role in the distal descending aorta.[64]

It is likely that the majority of victims of motor vehicle accidents experience some combination of differential deceleration forces and thoracic compression forces, causing aortic disruption.[70] It is clear that many different mechanisms of trauma (i.e., front impact, side impact, falls, crushing injury, and blasts) have caused aortic disruption. Each of these situations affords different circumstances and different forces, making it difficult to isolate a specific mechanism.

Natural History

The natural history of aortic transection in a given patient is dependent on many factors, not the least of which is how quickly a diagnosis is made. Our understanding of survival rates is based on data drawn from autopsy series and operative series. Autopsy studies tend to underestimate the rate of long-term survival, while operative studies tend to overestimate it. Parmley and associates observed that 86% of patients die at the scene, and 11% survive longer than 6 hours.[1] The only survivors in the Parmley series were in fact operated on. Mortality rates in most recent surgical series range from 0 to 50% variably dependent on the size of the series, although the attributable-mortality rates are not clearly defined.[12,13,25,29–32,71–75] Several groups have reported selective nonoperative or delayed operative management with aggressive antiimpulse therapy (beta-blockade) in patients deemed unsuitable candidates for surgery or in cases of apparent minimal aortic injury.[8,29,30,71,76–82] Those initially unsuitable for surgery in these series were elderly and morbid or had too severe associated injuries to tolerate operative repair and thus underwent delayed repair. When surgery has been delayed for stabilization of other injuries, the interim mortality rate prior to definitive repair appears to be between 30 and 50%, with the majority of deaths being attributed to head trauma or other complications.[79,81,83] Delays of up to 4 months prior to repair have been reported.[78,84–90] We conclude that aortic transection can be treated nonoperatively or with operative delay in carefully selected patients with severe associated injuries or significant comorbidities.

Numerous anecdotal reports confirm long-term survival in self-selected patients who were not diagnosed at the time of injury.[51,54,91–96] A review of the literature by Finkelmeier and colleagues demonstrated that among survivors like these, over 70% survive more than 5 years from the time of the injury.[50] The inherent survival bias of this group of patients is evident, but it does confirm that some patients can survive long-term without surgery. In Finkelmeier's review, the 60 patients who did not have operations for chronic traumatic aortic aneurysms had 5-year, 10-year, and 20-year survival rates of 71, 66, and 62%, respectively. Ninety-four percent of chronic traumatic aortic aneurysms were located at the aortic isthmus. Rarely, the arch and ascending aorta were involved.[50]

Clinical Presentation

The presentation of aortic rupture is protean. Aortic rupture itself manifests in the form of specific signs or symptoms in less than 50% of cases.[18,97–100] Patients may develop dyspnea, back pain, or differential hypertension in the lower as compared to the upper extremities.[66,97,98,100–104] Aortic injuries are more commonly identified in the backdrop of a multitrauma patient, and the diagnosis is made only if it is suspected. Consequently, aortic injury can easily be missed if patients are not appropriately screened. Identifying the character and mechanism of trauma is the critical first step in making the diagnosis of aortic disruption. If speeds or distances fallen suggest severe impact or significant deceleration forces, the possibility of aortic rupture exists, and it should

be ruled out. In all cases of motor vehicle crashes, falls, blasts, crush injuries, or other deceleration forces, aortic rupture should be considered.[8,11,25,77,105–108]

The initial management of a multitrauma patient is uniform regardless of whether aortic disruption is suspected. The patient's airway, breathing, and circulation are addressed first. Primary and secondary surveys are completed, and appropriate venous access is obtained concomitant with initial laboratory and radiographic studies. Priority of injury is based largely on the acute lethal potential of an injury. Exsanguinating hemorrhage in any body compartment, perforated viscus, or central neurologic injury take the usual priority. Most patients with aortic disruption also have one or more bone fractures. Fractures should be stabilized but not definitively treated prior to excluding the diagnosis or treating an aortic rupture. There are often clues evident in the initial evaluation of a trauma patient that suggest aortic disruption (Table 57-2). In the majority of trauma cases, a supine chest radiograph is obtained as part of the initial evaluation, and the constellation of grossly widened mediastinum, hemothorax, and transient hemodynamic instability upon arrival appear to be predictive of early in-hospital death from blunt thoracic aortic injury.[109]

Table 57–2.

Clues that Suggest Aortic Disruption

History
Motor vehicle crash >50 km/h
Motor vehicle crash into fixed barrier
No seat belt
Ejection from vehicle
Broken steering wheel
Motorcycle or airplane crash
Pedestrian hit by motor vehicle
Falls greater than 3 meters
Crush or cave-in injuries
Loss of consciousness
Physical signs
Hemodynamic shock (systolic blood pressure <90 mm Hg)
Fracture of sternum, first rib, clavicle, scapula, or multiple ribs
Steering wheel imprint on chest
Cardiac murmurs
Hoarseness
Dyspnea
Back pain
Hemothorax
Unequal extremity blood pressures
Paraplegia or paraparesis

Diagnostic Studies

Chest radiograph

A standard supine anteroposterior chest x-ray does not provide the diagnostic sensitivity to rule out aortic injury.[8,10,25,110] Nine to 40% of patients with aortic rupture have chest x-ray findings interpreted as normal at the time of initial evaluation in major trauma centers.[8,10,25,99,110–117] At least fifteen distinct signs on a standard anteroposterior chest x-ray are associated with blunt aortic injury or rupture (Table 57-3).[110] Unfortunately, none of these signs are sufficiently sensitive, specific, or predictive of aortic rupture. In a series of 188 consecutively evaluated multitrauma patients, 10 blunt aortic injuries were identified, and the sensitivities of these plain radiographic findings ranged from 0 to 90%.[110] The specificities ranged from 6 to 93%.[110] In lieu of obtaining an upright chest x-ray which is typically not possible in a multitrauma patient, reverse Trendelenburg 45° anteroposterior chest x-rays have been suggested to be more accurate than supine films at evaluating the mediastinum.[118]

Table 57–3.

Chest X-Ray Findings Associated with Blunt Aortic Disruption

Widened mediastinum (>8.0 cm)
Mediastinum-to-chest width ratio >0.25
Tracheal shift to the patient's right
Blurred aortic contour
Irregularity or loss of the aortic knob
Left apical cap
Depression of the left main bronchus
Opacification of the aortopulmonary window
Right deviation of the nasogastric tube
Wide paraspinal lines
First rib fracture
Any other rib fracture
Clavicle fracture
Pulmonary contusion
Thoracic spine fracture

Computed tomography

Volumetric helical or spiral computed tomography (CT) has become the standard screening tool to rule out aortic disruption, with sensitivity and negative predictive values of 100%.[8,10,25,116,119–121] The technology was introduced in the early 1990s, and since that time it has become the screening modality used in most institutions.[8–10,25,28,76,88,112,116,117,119,121–132] Its advantages over other sophisticated imaging techniques (e.g., transesophageal echocardiography, magnetic resonance imaging, or aortography) include its wide availability, its speed, its sensitivity, its reasonable cost, and its ease of interpretation.

Nonionic contrast media is typically used, and 50 to 150 images with slice thicknesses of 3 to 5 mm are acquired in less than 1.5 minutes.[10] Normal aorta is depicted with homogeneous enhancement. Several findings are indicative of aortic disruption, including wall thickening, extravasation of contrast, filling defects, para-aortic hematoma, intimal flaps, mural thrombi, pseudoaneurysm, or pseudocoarctation (Fig. 57-3).[10]

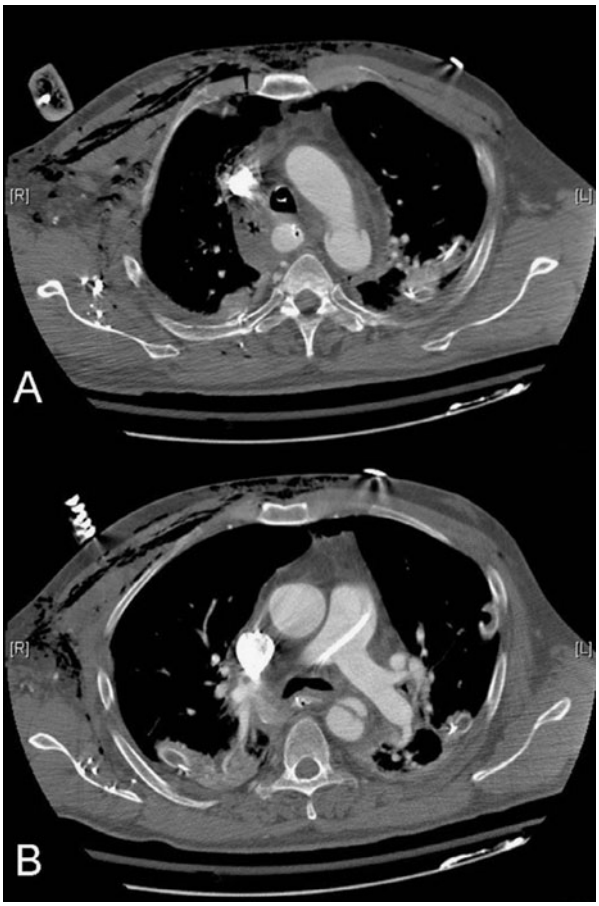

Figure 57-3. Helical computed tomography scan of the chest in a 30-year-old male after a high-speed motor vehicle accident. Slice A demonstrates circumferential disruption of the aortic wall just beyond the left subclavian. Slice B demonstrates an intimal flap in the proximal descending thoracic aorta. Both slices demonstrate periaortic hematoma.

Approximately 1% of blunt trauma patients have a thoracic aortic injury identified by helical CT.[8,123] False-positive CT studies do occur. The specificity, accuracy, and positive predictive value of helical CT range from 50 to 89%.[8,25,116,120] One uncommon finding that mimics aortic injury is a ductus diverticulum remnant.[10] Unlike an aortic injury, a ductus diverticulum will have no intimal irregularity or mediastinal hematoma. When there is a luminal or mural aortic irregularity without evidence of a periaortic hematoma, or when there is periaortic hematoma without obvious aortic luminal or mural irregularity, additional aortic imaging should be considered prior to intervention. Minimal aortic injuries (defined as small, less than 1-cm, intimal flaps) are being identified at an increasing rate because of the improved resolution of CT imaging and its widespread use.[8,10,76] These minimal injuries pose a management dilemma. Many of these minor aortic injuries can and probably should be managed medically with antiimpulse therapy.[76]

Transesophageal echocardiography

The development of multiplanar transesophageal echocardiography (TEE) has revolutionized cardiothoracic surgery such that its use is now necessary to plan and facilitate intraoperative management in most cardiothoracic surgical procedures. Its use in cases of aortic transection is no exception. TEE reliably images the entire thoracic aorta except the distal ascending aorta and proximal aortic arch, which can be obscured by tracheal and bronchial air artifact. Contrarily, transthoracic echocardiography cannot accurately evaluate the descending aorta. The accuracy of TEE for diagnosing aortic injury is operator-dependent. Some report its sensitivity and specificity to be approaching 100%,[120,133,134] while others demonstrate a sensitivity and specificity as low as 63 and 84%, respectively.[135] A recent prospective comparison of the use of helical CT to TEE in evaluating blunt aortic injury in 110 consecutive patients demonstrated a sensitivity, specificity, negative predictive value, and positive predictive value of 93, 100, 99, and 100%, respectively, for TEE compared to 73, 100, 95, and 100% for helical CT.[120]

A major advantage of TEE is its portability. The hemodynamically unstable patient who is taken to the operating room immediately can undergo exploratory laparotomy or other procedures while simultaneously being evaluated by TEE. The major disadvantage of TEE is that it requires an experienced operator. The risk of TEE is low.[120,133] It is contraindicated in cases of concomitant cervical spine, oropharyngeal, esophageal, or severe maxillofacial injury, or in patients with esophageal or pharyngeal lesions that would impede or complicate passage of the probe.

Multiplanar TEE probes permit acquisition of cross-sectional images at different angles along a single rotational axis (Fig. 57-4). The typical 5- or 7-MHz transducer permits adequate resolution of structures as small as 1 to 2 mm.

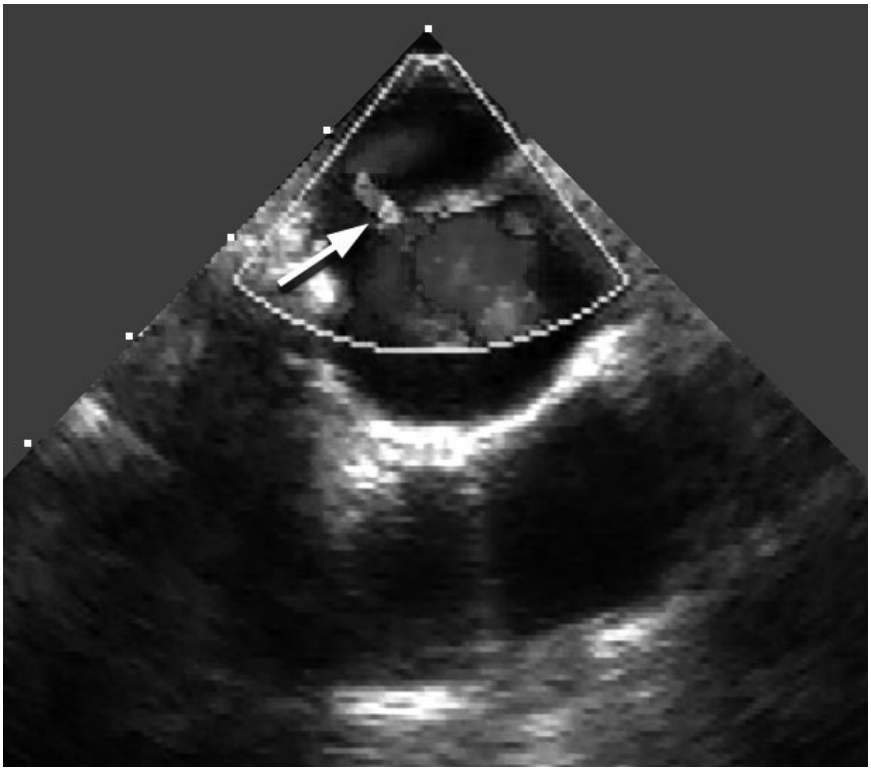

Figure 57-4. Transesophageal echocardiographic cross-sectional image in the short-axis with color flow Doppler depicting transection of the aortic isthmus. The transection appears as two distinct lumens, the "double-barrel" sign, and there is flow between the separated aorta. (*Courtesy of B. Milas, University of Pennsylvania.*)

Time-resolved imaging allows evaluation of the movement of anatomic structures and enhances the ability to determine the physiologic consequences of structural abnormalities. Doppler echocardiography is used to evaluate abnormal blood flow patterns which can aid in identifying intimal flaps.

The most common feature of aortic injury identified by TEE is a mural flap. Thickening of the vessel wall can represent a contained rupture or a mural thrombus. Color Doppler flow mapping can demonstrate alterations in flow patterns including turbulence at the site of injury. Chronic atheromatous changes can produce false-positive signs of intimal disruption. When aortic disruption is suspected on TEE there usually is a surrounding mediastinal hematoma, and its absence should prompt skepticism of the diagnosis.

Aortography

Aortography is the imaging modality by which all other techniques have been previously compared for evaluation of aortic injury. Its technique and role in evaluating aortic injuries or other vascular injuries was established long before any of the other sophisticated imaging methodologies. In experienced hands its sensitivity and specificity both approach 100%.[136] Its major disadvantages are that its use requires a highly skilled interventional radiology team, and it is time consuming, rendering the patient inaccessible during the time of the study. Rates of exsanguination and death of up to 10% in the angiography suite have been reported.[104,137,138] Complication rates attributed directly to aortography are low. Contrast reactions, renal insufficiency secondary to contrast material and groin hematomas or pseudoaneurysms do occur. In the pre–helical CT era, 85 to 95% of aortograms were negative, calling into question the cost- and time-effectiveness of the technique.[28,98,104,131,136,138] False-positive studies are usually attributed to atheromata or ductal diverticula. Though now only rarely used for diagnosis, aortography is becoming routine to facilitate endovascular stent grafting (EVSG) for traumatic disruptions (Fig. 57-5).

The technique of intra-arterial digital subtraction angiography is used by most groups and allows for faster generation of images. Intravenous digital subtraction angiography was used in the past by some as an even more rapid means of evaluating the aorta in the angiography suite.[138] This technique employs IV contrast instillation with time-delayed images of the arch and descending aorta. The time of a study can be reduced by up to fourfold when compared to conventional biplanar angiography. Unfortunately, the diagnostic quality of intravenous digital subtraction angiography is less than 70%,[138] and consequently with the near uniform availability of helical CT, the technique has become obsolete.

Magnetic resonance angiography

Magnetic resonance angiography provides excellent images of vascular structures, particularly the thoracic aorta, and its utility in the diagnosis and follow-up of complex aortic disease including aortic dissections and aneurysms is firmly established.[139–142] However, its use in

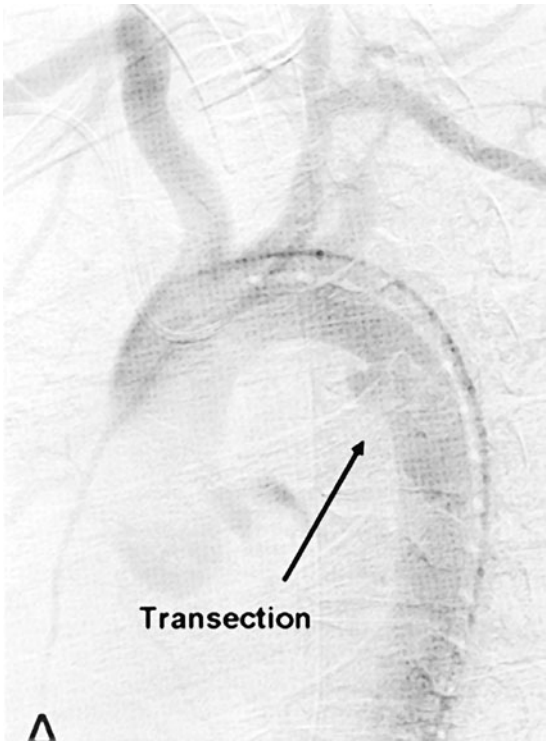

Figure 57-5. Intra-arterial digital subtraction angiogram of an acute traumatic aortic disruption near the isthmus. The left subclavian artery was transposed to the left common carotid artery prior to deployment of a stent graft.

the acute trauma patient has not been broadly justified. The time required to attain images and the confining nature of the scanners preclude its use in this patient population. If in the future magnetic resonance data acquisition time decreases and patient accessibility within a scanner increases, there may be a role for magnetic resonance angiography in acute trauma settings. Alternatively, it is reasonable to use magnetic resonance angiography for posttherapeutic surveillance of traumatic aortic injuries, particularly in those patients with minimal aortic injury who are treated nonoperatively.

Patient Assessment

Initial evaluation

Ninety-five percent of patients with aortic disruption have associated injuries, and consequently it is imperative that a comprehensive trauma evaluation occur prior to definitive imaging to rule out aortic injury.[12,13,77] However, the leading cause of death in patients with aortic injury who make it to the hospital remains exsanguinating aortic rupture, which occurs in at least 20% of patients.[13] Among patients who present hemodynamically stable with aortic injury, 4% die in the hospital of aortic rupture prior to surgical repair.[13] These data emphasize that a careful, planned, and expeditious team approach is mandatory in order to save as many of these patients as possible. The first steps include primary and secondary physical examinations with control of the airway, respiration, and hemodynamics. Intubation, cardiovascular resuscitation, chest x-ray, insertion of thoracostomy tubes, and identification and stabilization of head injuries take priority. Patients with nonlethal associated injuries who are hemodynamically stable should be diverted toward exclusion of aortic injury, and patients who are unstable require immediate direction toward life-saving operative intervention (e.g., laparotomy or thoracotomy), bypassing all time-consuming tests, in order to achieve the best chance of survival.

After initial trauma evaluation, a head CT should be obtained prior to any planned aortic operation in all patients with signs of an open- or closed-head injury. Relief of intracranial space-occupying lesions takes priority over nonbleeding aortic injuries. Hemodynamically unstable patients with signs of exsanguinating hemorrhage should go directly to the operating room for control of hemorrhage, and TEE should be used to evaluate for aortic injury. Identification of blunt aortic injuries in hemodynamically stable patients should be done in the most efficient manner for a given institution, depending on availability of experienced imaging diagnosticians and equipment, and should be coordinated with the evaluation of other life-threatening injuries. The usual scenario of a hemodynamically stable blunt trauma patient dictates leaving the emergency department to undergo head and abdominopelvic CT scan for identification of closed head injury and intra-abdominal injury. Patients with either an abnormal chest x-ray or a mechanism of injury that poses significant risk of aortic injury (e.g., falls greater than 3 m, motor vehicle crashes of greater than 50 km/h, or pedestrians hit by automobiles) should undergo simultaneous helical chest CT at the time of head and/or abdominopelvic CT. In most institutions, aortography is now reserved for use in patients with equivocal helical CT or TEE results or in patients with complex aortic injuries which cannot be accurately defined by these other imaging techniques. Occasionally thoracoscopy has been used to evaluate traumatic hemothoraces.[143] However, there is little role for thoracoscopy in the diagnosis of aortic disruption, because in experienced hands, the sensitivity and specificity of intraoperative TEE is so good.

In the preoperative period, patients with aortic injury should receive anti-impulse therapy for control of aortic wall tension and blood pressure.[8,77] Reduction of the change in pressure over the change in time ($\Delta P/\Delta t$) reduces wall stress significantly.[144] These measures have been shown to reduce in-hospital aortic rupture rates without adversely affecting the outcome of other injuries.[8] These control measures should be employed in patients going to the operating room and in patients undergoing delayed aortic repair for the treatment of other life-threatening injuries.

Timing of operation

Immediate aortic repair is recommended once the diagnosis of aortic injury is made in hemodynamically stable patients without severe associated injuries that require emergent laparotomy, craniotomy, or pelvic stabilization. Intracranial bleeding causing mass effect, and significant thoracic, abdominal, pelvic, or retroperitoneal hemorrhage should all be addressed prior to thoracotomy or stent grafting for contained aortic injury.[84,145] Contained aortic injuries should be aggressively managed with anti-impulse therapy if delayed aortic management is planned in order to address other life-threatening injuries. Delayed management may be appropriate in carefully selected patients with severe associated injuries or severe comorbidity.[29–31,71,79-83,146] Presentation of aortic disruption with ongoing aortic bleeding or signs of impending rupture requires immediate surgical intervention. Aortic injuries should be monitored by TEE during the surgical treatment of intracranial, thoracic, or abdominopelvic injuries. Treatment of all non–life-threatening injuries should be delayed until after definitive aortic repair.

Hemodynamically unstable patients should be taken to the operating room immediately, prior to definitive testing. Laparotomy or even thoracotomy may be required to locate and control ongoing hemorrhage. Patients with instability secondary to associated trauma who require laparotomy or thoracotomy for damage control to establish hemodynamic stability may be better served by subsequent immediate transfer to the intensive care unit for further resuscitation prior to definitive repair of contained aortic rupture until complete resuscitation and hemodynamic stability are achieved. Once stabilized, anti-impulse therapy with short-acting beta-blockade should be instituted and aggressively applied to reduce aortic wall stress.[8] Determining the optimal extent of delay for definitive aortic repair in patients with severe associated injuries is not clear. In rare cases, particularly extremely comorbid patients, nonoperative management has been extended for long periods of time with acceptable mortality.[82,83]

Operative Strategies

Conventional open repair of traumatic aortic disruption via interposition grafting for replacement of the injured segment is safe, effective, and durable. Historically, open repair via thoracotomy is the standard to which all other management strategies must be compared. However, as endovascular strategies for treating abdominal and more recently thoracic aortic pathology have evolved, there is growing enthusiasm for endovascular stent grafting (EVSG) of traumatic disruption because of its relative ease, reduced operative time required, and potentially reduced complication rate compared to conventional open repair. Consequently, but despite a lack of prospective clinical trials, recent trends around the world demonstrate a more liberal use of EVSG for acute traumatic aortic disruption, particularly for complicated cases with severe associated injuries. Retrospective reviews of single institutional experiences have demonstrated favorable short-term outcomes with endovascular strategies; however, the reported series are small, ranging from 5 to 29 cases per report.[29,30,72,73,80,147–151] Currently there are ongoing clinical trials of the use of new EVSG repair for traumatic aortic disruption, but these trials are not randomizing patients to open repair. An important limitation of the use of EVSG for traumatic transection is that the currently available thoracic aortic stent grafts were designed to treat aneurysmal disease, not traumatic disruption. Unlike aneurysms, aortic transection typically occurs in younger patients (average age 36 to 40 years)[7,29,30,152] with normal-caliber descending aortas in the range of 18 to 24 mm. The currently available stent grafts are not optimally suited for this size thoracic aorta. Consequently, groups have often resorted to the use of homemade or improvised materials that were originally designed for other purposes like extension cuffs of abdominal stent grafts. The long-term durability of these rudimentary, rigged devices or even the newest available devices designed for the thoracic aorta is not known. Despite these limitations, it is becoming clearer that EVSG can safely be used in a significant percentage of trauma patients. In many cases, simply bridging a patient with a stent graft to a more stable, chronic pseudoaneurysm may have an advantage over thoracotomy in a multitrauma patient. Because EVSG techniques continue to evolve and are not uniformly applicable, surgeons treating thoracic aortic disruption must be comfortable with conventional open repair techniques.

Open repair

The technical aspects of repairing aortic disruptions are straightforward. Although no one method of repair of aortic transection has been proven superior, standards are established. There remains some controversy surrounding the issue of spinal cord protection and what means of protection are optimal.[12,13,32,36,40,42,66,77,86,88,99,108,115,153–161] There are two general perspectives: (1) that "clamp-and-sew" techniques are sufficiently safe, and (2) that some form of lower body perfusion provides added spinal cord and visceral protection against the ischemia of the aortic cross-clamp. Paraplegia has historically occurred at an overall rate of approximately 10%.[12,40,42,99,152,162] More recently, data from multiple institutions demonstrate a marked reduction in paraplegia rates with the use of adjuvant perfusion techniques.[8,13,25,77,163]

SPINAL CORD PROTECTION: The spinal cord is supplied blood flow by anterior and posterior spinal arteries that consist of anatomic vascular chains that run the length of the cord.[164] The anterior spinal artery supplies the anterior two-thirds of the cord and is well developed in the upper thorax. Collateral arterial vessels also feed off of the left subclavian

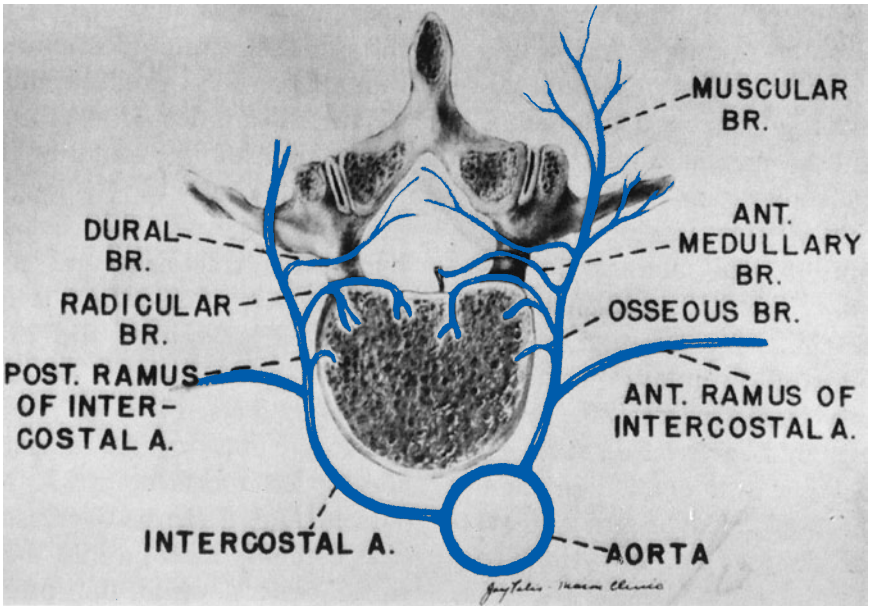

Figure 57-6. Cross-sectional diagram showing a medullary (radicular) arterial branch to the anterior spinal artery.

artery, including the vertebral artery, and consequently its occlusion during repair may have added implications toward a heightened risk of spinal cord ischemia. In the lower thorax and upper abdomen the anterior spinal artery is less developed and relies on segmental branches from intercostal and lumbar arteries. The anterior artery is supplied by 7 to 10 unpaired anterior medullary branches that vary in location along the cord (Fig. 57-6). Usually at least two anterior medullary vessels supply the cervical cord, two or three supply the thoracic cord, and two supply the lumbar cord. At the level of the first lumbar vertebra (variations T8 to L4) the anterior spinal artery receives the arteria radicularis magna (or artery of Adamkiewicz), which is essential for cord blood supply in this zone in at least 25% of patients.[164,165]

Aortic cross-clamping near the aortic isthmus produces profound hypotension to the lower body and spinal cord below this region, and spinal cord injury is proportional to aortic cross-clamp time (Fig. 57-7).[166] Clamping the aorta above the takeoff of the left subclavian artery may increase the risk of paraplegia since the collateral vessels fed by the internal thoracic, vertebral, and subscapular vessels all emanate from the subclavian.[167] Paraplegia has occurred after only 9 minutes of aortic cross-clamping without extracorporeal perfusion of the lower body.[168]

Several adjuncts have been proposed to reduce the risk of paraplegia in cases of elective repair of thoracic or thoracoabdominal aneurysms, but many of these techniques are not practical in the trauma patient requiring repair of aortic

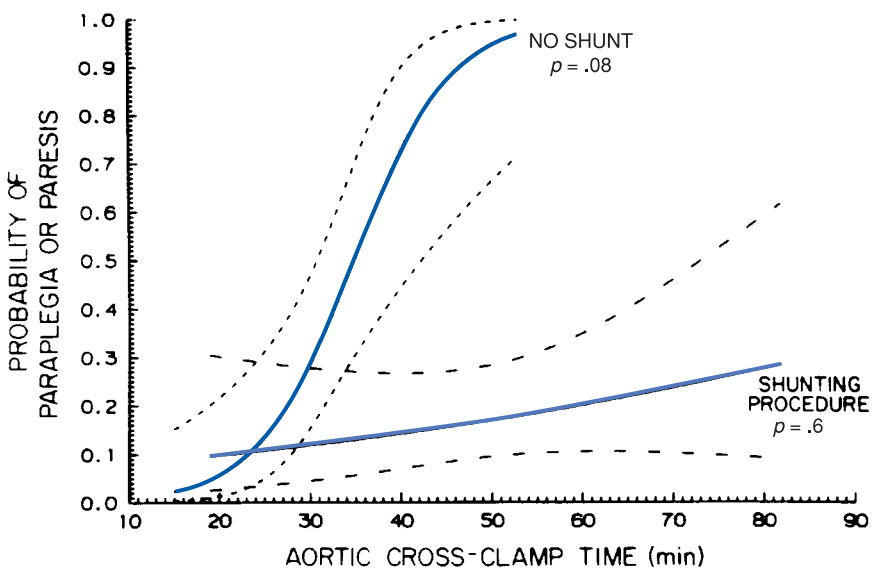

Figure 57-7. Probability of paraplegia in relation to aortic cross-clamp time with and without lower body perfusion in patients with traumatic aortic disruption at the isthmus. (*Reproduced with permission from Katz et al.*[166])

transection. These include monitoring of somatosensory evoked potentials and lumbar cerebrospinal fluid drainage, both of which require added time and expertise in the preoperative setting which is often not available to trauma patients.[162,169–175] Hypothermia, while attractive as a means of spinal cord protection, is not practical in partial bypass systems which rely on the heart to perfuse the upper body. On rare occasions when aortic injury involves the aortic arch, hypothermic circulatory arrest techniques are required for repair and may actually offer added spinal cord protection.[176–179] Selective retrograde spinal cord hypothermia and perfusion has been studied in the laboratory, but to date these techniques have not been employed in humans.[180,181] Epidural cooling has been used for thoracoabdominal aortic resections, but is not practical in trauma patients.[182] Experience with theoretical neuroprotective pharmaceuticals like steroids, lidocaine, or magnesium have not been thoroughly studied in this patient population.

Based on the currently available data from the surgical community as a whole, it appears that cross-clamp times exceeding 30 minutes and utilization of the "clamp-and-sew" technique alone yield higher rates of paraplegia than techniques that include extracorporeal lower body perfusion (Tables 57-4 and 57-5).[152,162,163] Certainly there are groups that have had success with low paraplegia rates using exclusively a simple cross-clamping technique,[12,32] but these results have not been reproducible throughout many institutions, and their results rely on short cross-clamp times (average 20 to 25 minutes) with little margin for difficult cases. Recent data suggest that the paraplegia rate approaches zero when cross-clamp times are short (less than 30 minutes) *and* lower body perfusion techniques are employed.[13,156,162] We have employed some form of lower body perfusion, typically left heart bypass, during aortic cross-clamping for these injuries since 1994. In our experience, there have been no cases of paraplegia with open repair since this strategy was implemented (over 50 patients, unpublished data).

SIMPLE AORTIC CROSS-CLAMPING: Simple aortic cross-clamping probably still has a role in the management of traumatic aortic rupture. The only advantage to this technique is its simplicity. In particular, it may be useful to the general, vascular, or trauma surgeon who is not experienced in the utilization of extracorporeal perfusion circuits or the cannulation of cardiac chambers or great vessels when thoracic surgical expertise is unavailable. It may also be useful in unstable patients who are actively bleeding from the aortic tear; in these patients there may be no time to employ a distal aortic perfusion system.

When aortic cross-clamp times are less than 25 to 30 minutes, low paraplegia rates have been achieved.[12,13,32] However, the average cross-clamp time reported in the literature is 41.0 minutes.[40] Many cases of aortic transection require more than 30 minutes to repair because of extravasated blood, fragility of the aorta, and difficulty in identifying local anatomy within a large hematoma. This is especially true if the tear extends proximally to involve the orifice of the left subclavian artery. These patients require clamping the aorta proximal to the left subclavian artery,

which may increase the incidence of paraplegia in the absence of distal aortic perfusion.

ADJUVANT PERFUSION METHODS: Optimally, both right radial and femoral arterial catheters should be in place to allow for monitoring of upper and lower body perfusion. Both active and passive shunting systems have been successful with both full systemic heparinization and no heparinization.[13,32,34,36,108,153–155,157,158,160,169,183–185] Despite the theoretical risk of bleeding with heparinization in the trauma setting, most groups, including our own, that employ active partial left heart bypass techniques use full systemic heparinization and have not seen bleeding complications.[8,13,75] Pulmonary venous cannulation near its confluence with the left atrium has a lower complication rate than cannulation of the left atrial appendage.[186] It is important to be well versed in the various lower body perfusion systems because distinct circumstances may require alterations in routine practice.

The system used by any one group should be simply applied, and reliable and routine for that group. Distal perfusion pressure should be maintained at 60 to 70 mm Hg.[158] Full heparinization is relatively contraindicated in cases of intracranial hemorrhage and severe lung injury, but is otherwise safely used by many groups.[12,13,40,75,99,158,183,187] Use of a centrifugal pump with heparin-bonded tubing and active partial left heart bypass or use of a heparin-bonded passive shunt is an option that does not require systemic heparinization.[154,158,185,187] It is helpful to employ the use of a heat exchanger within extracorporeal circuits in order to maintain core temperatures above 35°C in these patients that cool quickly.

PARTIAL LEFT HEART BYPASS: A small single- or dual-stage cannula is placed into the left atrium through the left inferior pulmonary vein to provide inflow to the pump (Fig. 57-8). Arterial cannulation size is determined by body size and site of cannulation. We preferably use a high-flow, atraumatic, aortic cannula in the distal descending aorta or less commonly place a femoral arterial cannula. Distal aortic cannulation has the advantage of convenience and speed. Partial left heart bypass serves several purposes: (1) to unload the left heart and control proximal hypertension at the time of cross-clamping, (2) to maintain lower body perfusion, (3) to allow rapid infusion of volume, and (4) to control (remove) intravascular volume. The lower body is perfused at a flow rate of 2 to 3 L/min with lower body mean arterial pressure of 60 to 70 mm Hg while maintaining an upper body mean arterial pressure of 70 to 80 mm Hg. All field blood is returned to the circuit via a pump reservoir or is accumulated and returned by cell saver.

Ventricular arrhythmias pose a major risk since the native heart perfuses the upper body. Single-lung ventilation does not increase postoperative pulmonary problems

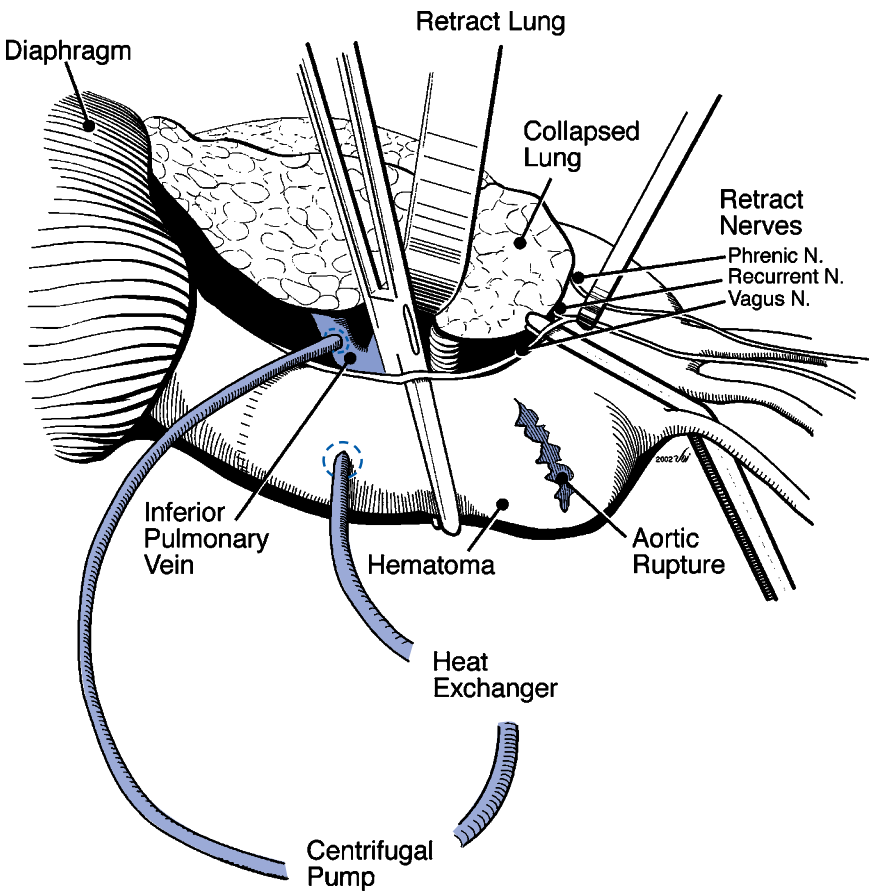

Figure 57-8. Diagram showing a typical setup for partial left heart bypass in a patient with aortic disruption at the isthmus.

after left heart bypass. If the system is used without systemic heparinization, heat exchangers and oxygenators should be removed from the circuit to minimize surface area and thrombotic risks, but in doing so great care must be taken to reduce heat losses and maintain near-normal temperatures.

FULL OR PARTIAL CARDIOPULMONARY BYPASS: Direct right atrial cannulation at the inferior vena cava–right atrial junction from a left thoracotomy by simple, transverse, inferior pericardiotomy below the left phrenic nerve is straightforward and provides excellent venous drainage. Alternatively, a long venous catheter with multiple side holes via the left common femoral vein into the right atrium can be placed with a guidewire. Right atrial–femoral arterial bypass has been used with or without an oxygenator like partial left heart bypass. When no oxygenator is used blood is returned with a partial arterial oxygen pressure of approximately 40 mm Hg (saturation 45 to 65%), and this has been shown to be adequate for lower body tissue oxygen needs provided the hemoglobin concentration is maintained above 10 g/dL.[169,188] Full cardiopulmonary bypass support is most useful in cases in which the aortic arch is involved in the injury to allow for systemic cooling.[189,190]

Right femoral venous to arterial bypass has the distinct advantage of allowing for establishment of partial or complete bypass prior to entering the chest. This technique may be preferred when there is concomitant right lung contusion in order to ensure adequate tissue oxygenation during repair. Rarely, there may be a need to perform a proximal anastomosis under deep hypothermic circulatory arrest (HCA) because an injury involves the mid-aortic arch. In cases of aortic arch transection in proximity to the innominate or left common carotid, anterior exposure via sternotomy or thoracosternotomy may offer better exposure for total arch replacement.[189,190] Use of HCA in trauma patients should proceed with caution and only after other serious associated injuries have been addressed to avoid bleeding complications. If HCA is required, it is essential to confirm the lack of significant aortic valvular insufficiency. When HCA is utilized within the left chest, the left ventricle should be vented, and we typically do this via the left atrium.

PASSIVE (GOTT) SHUNT: Of predominantly historical interest, this technique shunts blood from the proximal aorta to the distal aorta with a tapered, heparin-coated polyvinyl tube.[154] The proximal end is placed in the ascending or arch of the aorta or the left subclavian artery and the distal end is placed in the descending aorta or femoral artery. Ventricular cannulation had been used in the past; however, it was abandoned due to a high rate of ventricular dysrhythmias, reduced shunt flows, and a higher rate of paraplegia.[34,154,155,184,191,192] The diameter of the shunt is obviously fixed, and therefore flow is passive, unmonitored, and dependent on a pressure gradient. Femoral arterial monitoring, as with all of these techniques, is recommended.[184] The Gott shunt is easy to use, although it requires a more extensive dissection of either the aortic arch or ascending aorta. It offers no left ventricular unloading or loading advantage that partial bypass systems do, and therefore blood pressure control is left to pharmacology alone.

OPERATIVE TECHNIQUES: A standard fourth interspace posterolateral thoracotomy with or without fifth rib notching usually provides excellent exposure to the aortic isthmus and proximal descending aorta. The incision should be long enough to facilitate dissection of the descending aorta below the level of the inferior pulmonary vein and dissection of the arch of the aorta between the left common carotid and left subclavian arteries. Dissection near the isthmus or tear should be avoided until both proximal and distal aortic control is established. Depending on the stability of the patient, lower body perfusion can be established prior to aortic exposure by gaining access to the left groin.

If cannulation is planned in the chest, proximal and distal aortic control is established first. The left inferior pulmonary vein–left atrial junction is dissected after gaining aortic control when using left heart bypass. Excessive compression or traction of the lung should be avoided, particularly when dissecting out the aortic arch, because the left pulmonary artery may be easily disrupted at this location (see Fig. 57-8).

The mediastinal pleura is incised along the anterior surface of the proximal left subclavian artery. The subclavian artery is isolated. The pleura overlying the distal aortic arch is incised lateral to the vagus nerve. Great care is taken to avoid injury to either the phrenic or vagus nerves as they pass over the aortic arch, which can be difficult since they are often obscured by the hematoma. They should be reflected off the aorta with the overlying pleura and retracted medially by attaching stay sutures to the pleura just lateral to the vagus nerve. Loops around the nerves themselves should be avoided, as even stretch of these nerves can result in paresis. This reflection exposes the arch of the aorta between the left common carotid and left subclavian arteries, which is the point needed for proximal aortic control in the majority of cases. Inferiorly, the vagus nerve and its branching left recurrent laryngeal nerve are reflected medially as well. This exposes the ligamentum arteriosum which can be sharply divided. The aortic arch between the left carotid and subclavian artery superiorly and medial to the ligamentum inferiorly is encircled with a tape after establishing a plane between the posterior arch and the trachea using a combination of sharp and gentle finger dissection. There should be no dissection distal to either the left subclavian or the ligamentum in order to avoid free disruption of the hematoma.

Distal aortic control is established at an adequate distance from the aortic injury to facilitate repair. The overlying pleura is incised, and the aorta isolated. The left inferior pulmonary vein is dissected out anteriorly. Opening the pericardium just anterior to the vein allows better exposure and a better site of pulmonary venous cannulation. Heparin, if employed, is given. We establish arterial cannulation first. Distal aortic purse-string sutures are fashioned below the

distal clamp site, or the femoral artery is cannulated by Seldinger technique with serial dilatation to the desired cannula size. The inferior pulmonary vein is then cannulated with a dual-stage catheter. The circuit for left heart bypass is de-aired and connected. Lower body perfusion is initiated, and once systemic blood pressure is stabilized the left subclavian artery is clamped followed by the proximal aorta, then the distal aorta. We prefer to always clamp the proximal aorta *between* the left common carotid artery and the left subclavian artery because the tear frequently extends quite close to the ostium of the left subclavian artery. Upper and lower body pressures are stabilized with the bypass circuit to maintain upper body mean arterial pressures of 70 to 80 mm Hg and a lower body pressure of 60 to 70 mm Hg with flows of 2 to 3 L/min (see Fig. 57-8).

The periaortic hematoma is then entered, and the edges of the transected aorta identified. Usually the aorta is completely transected, and the edges are separated by 2 to 4 cm.[1,16] Less frequently the transection is partial. Some authors advocate primary repair at this point;[34,193] however, we advocate placing a short interposition graft after débridement of the torn edges.[12,13,32,35,42,103,155,157,159–161] Collagen-coated woven polyester grafts or gelatin-impregnated grafts are used most commonly. Use of intraluminal prostheses has been abandoned by most groups.[194] Grafts are sewn using a running polypropylene suture with the proximal anastomosis performed first, followed by the distal. Generous amounts of adventitial tissue are included in each bite. If the proximal anastomosis is done under HCA, cardiopulmonary bypass and reperfusion of the arch should be reinstituted immediately after completion of the proximal anastomosis for optimal neurocerebral protection. This requires cannulation of the graft just beyond the proximal anastomosis, and then the distal anastomosis is completed using a dual arterial-inflow perfusion setup perfusing the arch and lower body simultaneously. The left subclavian can either be incorporated into the proximal anastomosis or grafted separately as appropriate.

If the aorta is already ruptured with bleeding into the hemithorax, proximal aortic dissection between the left carotid and subclavian arteries is rapidly performed, and a cross-clamp quickly applied. The descending aorta is then clamped below the injury, and the hematoma opened. No attempt is made to establish lower body perfusion, but every attempt is made at maintaining adequate mean arterial pressure during clamping. The aortic repair is done as expeditiously as possible to minimize clamp time. Repair sutures are placed accordingly after clamps are removed. Hemostasis is achieved after continuity of the aorta is reestablished.

SPECIAL CONSIDERATIONS

PREVIOUS LEFT THORACOTOMY: Emergency department thoracotomies are usually done in haste by inexperienced nonthoracic surgeons and are often placed at sites too inferior to effectively repair an aortic transection. Given this situation it is usually best to enter the chest through a fourth interspace thoracotomy even if this means creating a second intercostal incision (using the same skin incision). When a patient with a history of prior left thoracotomy presents with an aortic injury the associated scarring offers both an advantage and disadvantage to the patient. The adhesions between the lung and mediastinum help contain the rupture making it less likely to exsanguinate, but the adhesions also make the dissection considerably more difficult and time consuming. Optimally, dissection in these cases should be done prior to heparinization.

EXTENSION OF THE TEAR INTO THE LEFT SUBCLAVIAN ARTERY: Traumatic aortic disruptions that occur in close proximity (<1 cm) from the left subclavian artery portend a higher mortality risk and greater operative difficulty than injuries further away from the left subclavian ostium.[195] We recommend routinely placing the proximal aortic clamp proximal to the left subclavian artery since most aortic ruptures tear close to it. This allows for an easier, more precise proximal anastomosis. The subclavian should also be controlled by encircling it with a tape just distal to its origin. Occasionally, the aortic tear will extend into the left subclavian orifice, and in this case the proximal clamp may have to partially or totally occlude the left common carotid. The left subclavian can then be completely detached from the aorta, the proximal anastomosis completed, and the clamp then moved distally onto the graft. The left subclavian is then reattached to the aortic graft with an interposition graft after completing the distal aortic anastomosis. The left common carotid artery will usually tolerate occlusion for 10 to 15 minutes without sequelae. The left subclavian interposition graft is fashioned with an end-to-end anastomosis distally and an end-to-side anastomosis proximally.

Endovascular stent grafting (EVSG)

There are now many reports of the efficacy of EVSG in the setting of acute traumatic aortic disruption.[29–31,72,73,80,147–151,196–199] Most groups placing EVS grafts for aortic disruption are doing so selectively based on the prediction of higher risk with conventional repair due to severity of illness, age, comorbidity, or associated injuries. Open- or closed-head injury, bleeding abdominal visceral injury, retroperitoneal bleeding, and pulmonary contusions are commonly cited factors that may favor an EVSG approach.[29–31,72,73,80,149]

EVSG for traumatic aortic disruption should be performed in either a hybrid operating room/angiosuite with a fluoroscopy unit designed for endovascular surgery or a conventional operating room with a portable C-arm fluoroscopy unit. The rate of conversion from EVSG to open repair is higher with management of aortic disruption than aneurysms,[72] and the operative team involved must be ready and capable of making the conversion immediately. General anesthesia is used most commonly. Aortic access is retrograde via either the femoral or iliac artery. Percutaneous and femoral arterial cutdown or direct iliac arterial puncture or iliac access via a silo graft sewn to the iliac artery have all been used. One theoretical advantage of an endovascular approach may be the use of a very low dose or no heparin in trauma patients. A floppy J-tipped wire is advanced under

fluoroscopic and/or TEE guidance, and an aortogram is performed using steep anterior oblique projection with a marked catheter to accurately assess and measure the aortic arch anatomy relative to the site of transection. *Diameter* of the prosthesis used should be based on aortic measurements obtained preoperatively by CT angiography. *Length* of graft coverage should be based on intraoperative angiographic measurements. Intravascular ultrasound is likely to improve our ability to accurately determine the extent of coverage and the size of grafts needed in the operating room.[200,201] Based on the proximity to the aortic injury, the left subclavian artery may need to be covered, and if covered, it may need to be embolized and bypassed or transposed to the left common carotid artery in order to ensure a proximal EVS graft seal and avoid problems of ischemia to the left arm or vertebrobasilar system (see Fig. 57-5).[202–205]

Stent graft collapse is a problem that can occur in nearly any setting, but EVSG for transection may be particularly prone because of the fact that the available grafts may be relatively oversized for the normal-sized aorta adjacent to an injured segment. There are several unpublished reports of EVS graft collapse during or immediately after deployment for transection including events from our own institutions. Idu and colleagues reported a case of delayed EVS graft collapse that was identified on CT angiogram 3 months after repair of a traumatic transection.[206]

There is little doubt that as devices are designed better and more suitably for aortic transection, EVSG will become part of the standard of care. Currently we employ a selective strategy whereby most patients that are young and have limited associated injuries are treated by conventional open grafting, recognizing the durability of this approach. Alternatively, elderly, comorbid patients or those with severe associated injuries are treated with EVSG.

Nonisthmic Aortic/Arterial Disruptions

The incidence of acute rupture of the ascending aorta among motor vehicular or other trauma patients is not known, as most of these patients do not survive beyond the site of the accident. However, there are reports of successful repairs of these injuries.[22,33,207] Most commonly the proximal ascending aorta at or just above the sinotubular junction is involved.[33] There are a few case reports of ascending aortic ruptures associated with the deployment of air bags.[22,23] Ascending aortic ruptures require full heparinization and cardiopulmonary bypass for repair. These injuries are approached through a median sternotomy. The survival among cases reported in the literature of those undergoing repair is about 85%.[33] They have been repaired either primarily or with an interposition graft. Rarely, a concomitant aortic valve replacement is required.[33]

Lacerations to the base of the innominate or left common carotid arteries should be approached through a median sternotomy and may require cardiopulmonary bypass depending on the degree of aortic involvement.[47] Extension of the incision into the right or left neck including detachment of the sternocleidomastoid from the sternum is usually helpful in obtaining adequate exposure. When the base of the left carotid or innominate is injured, the safest option is to oversew the base and create an interposition graft to the ascending aorta in an end-to-side fashion.[108,208,209] Injury to the base of the left subclavian artery can be approached either by sternotomy or left posterolateral thoracotomy, the latter of which typically provides better exposure.[208] Alternatively, when injuries extend out onto either the left or right subclavian artery a thoracosternotomy, cervicosternotomy, or cervicosternothoracotomy "trap door" incision provides good exposure depending on the level of the injury.[5] Finally, the transverse anterior thoracosternotomy, "clam-shell" incision provides good exposure to the mediastinal structures and both hemithoraces when multiple injuries require repair.[5]

Aortic injuries of the descending aorta distal to the isthmus to the level of T8 should be approached through a posterolateral thoracotomy in the fourth, fifth, or sixth interspace, depending on the level of injury. These types of aortic injuries from blunt trauma are rare. More commonly, this segment of aorta is injured by penetrating trauma. These patients rarely make it to the hospital alive. When the distal thoracoabdominal aorta is injured below T8, it should be approached by thoracoabdominal incision. This can be done either retroperitoneally or intraperitoneally. An intraperitoneal approach offers the advantage of allowing for abdominal exploration; however, retraction of the abdominal contents with a thoracoabdominal incision and a violated peritoneum can be cumbersome. We use partial left heart bypass with left atrial to femoral arterial or distal aortic cannulation for all thoracoabdominal aortic procedures unless active bleeding precludes its setup, or there is an absolute contraindication to heparinization.

Postoperative Care

Postoperative care after aortic repair is similar to that given patients who have other major cardiothoracic surgery. Immediately following aortic repair in the operating room, patients should undergo flexible bronchoscopy for evacuation of bloody secretions to avoid plugging and atelectasis of the left lung. Respiratory function, ventricular filling pressures, blood pressure, cardiac output, renal function, chest tube output, nasogastric drainage, body temperature, neurologic status, and coagulation function should be monitored closely. Pulmonary toilet is extraordinarily important, and once clinically stable an epidural catheter may be advantageous to facilitate good pulmonary recovery. Antibiotics are given in a standard prophylactic fashion. Patients are extubated as soon as is clinically indicated. Chest tubes are removed when any air leak has stopped and drainage is less than 150 to 200 mL of serous fluid per day.

Complications

Complications after aortic repair occur at a rate of 40 to 50%.[13,34,36,42,108] Pneumonia is the most common complication and occurs at a rate of 17 to 34%.[13,34,36,42,108] Other complications include bacteremia, renal insufficiency, and paraplegia. Rates of frequency for several series are listed in

Table 57–6.

Major Postoperative Complications

	Schmidt et al[34] n = 73, %	Cowley et al[42] n = 51, %	Kodali et al[108] n = 50, %	Fabian et al[13] n = 207, %
Paraplegia	5.4%	19.6	10	8.7
Renal failure	9.6	9.8	4	8.7
Sepsis	13.7	9.8	—	—

Left phrenic nerve palsy	1.4	5.9	—	—
Stroke	2.7	—	4	—
Re-exploration for bleeding	1.4	9.8	4.0	—
Pulmonary embolism	1.4	3.9	—	—
Deep vein thrombosis	2.7	—	—	—
Empyema	—	—	—	1.9
Wound infection	—	3.9	—	—
Chylothorax	—	3.9	—	—
Deaths	8.8	43.1	28.0	14 (31.3)*

ARDS = acute respiratory distress syndrome.

**Twenty-nine deaths (14%) occurred among the 207 patients who presented in stable condition. An additional 46 patients presented either in extremis or with free rupture, and all of these patients died in the hospital. All told there were 86 deaths among 274 patients included in the AAST trial (31.3%).*

Table 57-6.[13,34,36,42,108] Left vocal cord paralysis has been reported to occur at a rate of 4 to 14% percent, although recurrent nerve injuries are probably underreported. Late complications are rare in these patients. Aortobronchial fistula following repair of transection has been reported.[210,211]

Patients who survive an undiagnosed aortic injury may develop a chronic traumatic aortic aneurysm.[26,49–54,92–96] Among those patients with initial pseudoaneurysm formation, most develop progressive dilation with symptoms of pain referable to aneurysmal expansion. Other symptoms include dyspnea or cough secondary to compression of the left main stem bronchus, hoarseness due to stretching of the recurrent nerve, hemoptysis, or dysphagia. These chronic traumatic aortic aneurysms, once discovered, should be repaired regardless of size unless there are contraindications due to age or comorbidity.

Results

The mortality rate of patients with aortic rupture who reach the hospital ranges from 7 to 65% depending on whether or not the injury is repaired.[12,13,29–32,40] The large discrepancy is likely due to underreporting of patients who make it to the hospital but not to the operating room, as most series only report operative results. Among hemodynamically stable patients undergoing open repair or EVSG repair, the hospital mortality rate ranges from 0 to 20% in the modern era (Tables 57-6 and 57-7).[13,29,30,80,163] The mortality rate of nonoperative patients with associated injuries precluding initial aortic repair was 55% in the AAST trial.[13] All patients who either presented in extremis or with free rupture died of aortic rupture. A few small series have demonstrated acceptable survival rates of 67 to 72% in select, high-risk patients treated nonoperatively.[82,83] In his meta-analysis of 1492 patients, Von Opell reported an average of 7.8% of patients dying during aortic repair, and 13.5% dying in the postoperative period.[40]

Paraplegia or paraparesis occurred in an average of 9.9% of patients in the meta-analysis.[40] However, paraplegia rates vary widely depending on the operative technique utilized, with a range of 0 to 20% (see Tables 57-4 and 57-7).[12,13,29–32,40,42,72,73,80,86,108,147,149,163,198] Although there are several groups that have reported very low paraplegia rates

Table 57–7.

Results of Endovascular Stent Grafting (EVSG) for Aortic Transection (with Comparison to Open Repair)

using the "clamp-and-sew" technique, these results have not been widely reproduced.[13,32] It is clear that increasing cross-clamp time, particularly beyond 30 minutes, increases the rate of paraplegia.[13,166] Alternatively, use of extracorporeal lower body perfusion systems have facilitated low rates of paraplegia.[13,163] Our own institutional data similarly demonstrate that since the practice of partial left heart bypass for all open repairs of aortic transection was instituted in 1994 (over 50 patients), there have been no cases of paraplegia (unpublished data). The preponderance of data suggests that the combination of partial left heart bypass for lower body perfusion with short, less than 30 minutes, cross-clamp time affords the lowest rate of paraplegia.[13,40] The early results of EVSG repair suggest that it may reduce the risk of paraplegia further (see Table 57-7), although to date the data are limited and comparisons are retrospective.

NONAORTIC GREAT VESSEL INJURY

The majority of injuries to the great venous structures and the pulmonary arteries are a result of penetrating trauma. Blunt trauma to these structures is rare, presumably because of their distensibility and low pressure. The incidence of injury to the nonaortic great vessels among cases of penetrating thoracic trauma is not known; however, the overall incidence of great vessel injury with thoracic gunshot wounds is approximately 5% and with stab wounds is 2%.[212] Wounds penetrating the thoracic "box" bordered by the midclavicular lines, the thoracic outlet, and xiphoid process should be explored operatively. Chest tubes should be inserted as a diagnostic and therapeutic measure, and an echocardiogram or a subxiphoid pericardial window performed to rule out hemopericardium. Patients with a high index of suspicion of mediastinal great vessel injury or with a confirmed hemopericardium should undergo sternotomy. Patients with central venous or pulmonary arterial rupture will decompensate from pericardial tamponade. Expeditious pericardial decompression will often provide enough stability to facilitate definitive repair. Exsanguination from a venous or pulmonary arterial injury into one of the hemithoraces requires immediate massive volume resuscitation and transfer to the operating room. Choice of incision should be made based on clinical suspicion of site of injury or objective data (arteriography, chest radiograph, or bleeding site). When the site of injury is not clear, median sternotomy provides excellent access to the heart and great vessels, and it can be extended across a hemithorax or up the neck along either sternocleidomastoid to facilitate exposure of any vascular structure in the chest. Most venous injuries and pulmonary arterial injuries when localized and simple can be repaired without cardiopulmonary bypass. Large or complex venous, and particularly pulmonary arterial, injuries are often more easily repaired on full cardiopulmonary

bypass with a decompressed heart. When repairing pulmonary venous injuries it is important to safeguard against air embolus, the result of which can be devastating. Therefore, complex pulmonary venous injury may require aortic cross-clamping with cardioplegia to prevent embolus to the brain.

Surgery for Cardiac Arrhythmias

This page intentionally left blank

CHAPTER 58

Interventional Therapy for Atrial and Ventricular Arrhythmias

Robert E. Eckart • Laurence M. Epstein

Therapy available for the treatment of heart rhythm disorders has gone through significant evolution. Although previously limited to pharmacologic therapy, the transformation and adaptation of surgical procedures to a minimally invasive catheter-based approach, and subsequent hybridization of the approach has led to new possibilities in arrhythmia management. A fundamental understanding of the invasive diagnostic and therapeutic strategy for treating heart rhythm disorders is critical to surgical specialties exposed to these rhythm disorders. This chapter will focus on catheter-based ablation, predominantly radiofrequency (RF) ablation, the most common type, but will also briefly explore alternative energy sources. It will also review diagnostic strategies and localization of specific tachyarrhythmias to appropriately target the energy delivery.

HISTORICAL EVOLUTION

The recording of intracardiac signals through electrodes, and subsequent stimulation of the cardiac tissue using these same electrodes, allowed for development of the concept of ablation. In 1967, Durrer and associates first described reproducible initiation and termination of tachycardia in a patient with atrioventricular re-entrant tachycardia (AVRT) using a bypass tract.[1] In 1969, the His bundle was first reproducibly recorded using a transvenous electrode catheter.[2] The continued advancements allowing localization of intracardiac signals led to the study of a variety of tachyarrhythmias.

The idea emerged that critical regions of cardiac tissue were necessary for the initiation and propagation of tachyarrhythmias. If these regions could be interrupted, the tachyarrhythmia could then be clinically cured. Once catheter mapping could localize arrhythmogenic foci, surgical excision was contemplated. In 1968, a description of such a surgical procedure for the elimination of an accessory pathway was first published.[3] This heralded an era of nonpharmacologic treatment of tachyarrhythmias.

Surgical Ablation

A variety of arrhythmogenic foci and circuits were successfully mapped and ablated using surgical techniques in the 1970s. Resection of an atrial focus felt to be responsible for an atrial tachycardia was reported in 1973.[4] Identification of re-entry circuits within the atrioventricular (AV) node allowed surgical dissection to treat AV nodal re-entrant tachycardia (AVNRT) without causing complete heart block.[5] Although surgical ablation was therapeutic for a variety of tachyarrhythmias, the morbidity and mortality associated with thoracotomy and open-heart surgery limited its application. Because most supraventricular tachycardias (SVTs) are not life-threatening, the risk of the procedure was hard to justify. Rather, ablation procedures were an option of last resort in highly symptomatic patients refractory to medical therapy. With these limitations of the surgical approach, catheter-based ablation procedures were explored.

Catheter Ablation

In attempts to minimize the morbidity associated with ablation, a method of using a catheter to delivery energy to cardiac tissue to achieve local tissue injury was sought. In 1981, Scheinman and colleagues reported the first catheter-based ablation procedure, describing the ablation of the His bundle in dogs.[6] This same group, in March 1981, performed the first closed-chest ablation procedure in a human. A patient with atrial fibrillation and rate control refractory to medical therapy was placed under general anesthesia and a catheter was advanced to the His bundle region. Using a standard external direct-current (DC) defibrillator, they attached one of the defibrillator pads to the intracardiac catheter and used the second defibrillator pad as a cutaneous grounding pad. A

series of DC shocks was delivered between the two pads and complete heart block, and thereby rate control, was achieved.[7]

This closed-chest catheter-based procedure was quickly adopted to treat a variety of SVTs dependent on the AV node.[8] However, to restore quality of life, these patients undergoing AV node ablation frequently required pacemakers, which at the time were not the small devices we are accustomed to today. As experience was gained and specific catheters were developed, energy could be more precisely directed to allow ablation of accessory pathways, atrial tachycardia, single limb of AVNRT, and ventricular tachycardia.

Although DC shock ablation allowed for the initiation of catheter-based ablation, it had its own limitations. The mechanism for DC shock ablation is such that a high-energy discharge from the catheter tip is developed. This results in the formation of a plasma ball at the distal electrode and subsequent "explosion" at the electrode tip. Because energy delivery was not titratable, such treatment had variable outcomes, including cardiac rupture and perforation. Since DC energy was delivered from the intracardiac electrode toward a cutaneous site, general anesthesia was required.

The introduction of RF energy as an ablative energy source heralded a new era in the nonpharmacologic, nonsurgical treatment of arrhythmias. RF energy had been used for decades by surgeons for surgical cutting and cautery and had a long history of safety and efficacy. Animal studies using RF energy were first described in 1987.[9] Intracardiac RF energy produces controlled lesions at the catheter tip over a period of 40 to 120 seconds. The improved safety and efficacy of RF catheter-based ablation procedures quickly replaced DC shock ablation techniques.

BIOPHYSICS OF ABLATION

Ablation using RF as an energy source involves the delivery of sinusoidal alternating current between the catheter tip at the endocardial surface and a large grounding pad on the skin. The current has a frequency of 350 to 700 kHz. The principal method of tissue injury with RF delivery is thermal. As the RF energy passes through the tissue at the distal electrode of the ablation catheter, resistive heating produces coagulation necrosis. The lesions produced are well demarcated and are 5 to 6 mm wide by 2 to 3 mm deep when a standard catheter tip is used. To achieve irreversible tissue injury, a tissue temperature of about 55° to 58°C is required.[10] At temperatures above 100°C, plasma reaches the boiling point and coagulates on the catheter tip. Coagulum and desiccated tissue act as an insulating barrier to energy delivery, resulting in a rise in impedance and the prevention of tissue heating. If subendocardial tissue temperature exceeds 100°C, steam may be formed within the tissue, resulting in a rapid expansion and crater formation and an audible "pop" during ablation. Much like DC shocks, such steam "pops" can cause unpredictable injury (e.g., to surrounding normal conduction tissue) as well as rupture of thin-walled structures. Thus it is important to regulate the temperature of the catheter-tissue interface by regulating the energy delivered. Contemporary RF ablation catheters have a thermistor or thermocouple that allows for automatic adjustment of the temperature at the electrode tip–tissue interface through adjustment of power. This allows the maximal energy delivery without the buildup of excessive temperature that results in coagulum and increases in impedance.

A limitation in lesion size places some epicardial foci and arrhythmia circuits out of reach of endocardial ablations. One method to increase lesion size and depth uses the principle of limiting coagulum size by increasing the electrode-tissue interface by increasing tip size. In vitro studies have shown that 8-mm catheter tips produced lesions that are twice as deep and four times larger than lesions produced by standard 4-mm tips.[11] A limitation of larger catheter tips is that the larger surface area makes it difficult to regulate power delivery and achieve even temperatures. High current densities develop at the edges of the electrode resulting in higher temperatures and coagulum formation. The larger catheter tips have been shown clinically to significantly reduce procedural and fluoroscopy time for some types of ablation.[12]

Cooling the ablation catheter tip with saline irrigation, either through the catheter or external to the catheter, can also prevent coagulum formation at the tissue interface. This prevents a rise in impedance and allows for more energy delivery deep into the tissue, resulting in deeper and larger lesions.[13] Irrigated RF catheters bathe the catheter tip internally using recirculating saline (Chilli II, Boston-Scientific, Natick, Mass) or externally through a porous electrode tip (Navistar Thermocool, Biosense-Webster, Inc., Diamond Bar, Calif). These catheters continue to utilize RF as an energy source; however, maximization of power delivery has demonstrated deeper lesions with a greater volume than with standard RF.[14]

Since the effects of RF ablation are usually irreversible, some ablations, such as for AVNRT, carry a 1% risk of complete heart block. Because of this concern, alternative energy sources have been developed that allow for reversible tissue injury prior to placement of permanent lesions.

One such catheter system (Freezor MAX, CryoCath, Montreal, Quebec, Canada) relies on gradual cooling of tissue to allow for an estimation of injury effect, and can be followed up by a more permanent cryoablation. Hypothermia has been the preferred method of delivering linear lesions in surgical ablation. This technique utilizes pressurized nitrogen or nitrogen oxide flow through a catheter tip nozzle. As the gas expands beyond the obstruction, there is a temperature drop to as much as –90°C. The advantage to the system rests entirely in its ability to deliver both transient and permanent injury to the tissue. The "cooling" phase (CryoMapping) allows one to assess not only the impact on pathologic tissue (e.g., anteroseptal accessory pathways, the slow limb of a dual AV node), but also to assess the impact of potential lesion placement on surrounding normal

conduction tissue.[15] If the CryoMapping phase yields desirable results, then the temperature is lowered even further to a "freezing" stage. Of interest is that during the "cooling" phase, an ice ball actually forms on the tip of the catheter and becomes mildly adherent to the tissue. This enhances stability of the catheter despite cardiac motion. The ability to deliver reversible injury and catheter stabilization has made CryoCath increasingly popular in those cases in which the pathologic lesion is in close proximity to the AV node and in younger patients in whom a pacemaker would be less than desirable.[16]

A second potential disadvantage to RF as an energy source is the risk of extracardiac tissue injury. Although constantly evolving, the inclusion of pulmonary vein (PV) isolation for treatment of atrial fibrillation is increasingly common.[17] There were early reports of PV stenosis following PV ostial RF ablation and concerns about atrioesophageal fistula following RF ablation in the left atrium.[18,19] Interestingly, the rate of intraoperative atrioesophageal perforation was as high as 1.3% in one open-chest series of patients undergoing linear lesions between PV ostia, to include the posterior wall overlaying the esophagus.[20,21] This has led to less anatomic, more functional, approaches in some centers, with the intent of avoiding extracardiac structures placed at risk by older techniques.[22,23]

The complexity of a nonanatomic approach to atrial fibrillation ablation has left many in search of alternatives allowing for PV isolation without risk of damage to extracardiac structures. One such approach may be through the use of energy-delivering balloons. Previous work with RF in delivery of linear ablations was limited by the exponential increase in the power supply necessary with increasing electrode length. However, the placement of a cryothermy balloon in a pulmonary vein ostium has been shown to cause a significant transmural lesion, without extracardiac injury.[24] However, the means by which extracardiac tissue is left uninjured is also a minor setback for this technology. The placement of a lesion is only in those areas with direct contact with the energy source. Since the target is unlikely to be the perfect circular shape built into a balloon, any flow around the balloon will be an area in which there will be no injury, and therefore acts as a potential source for continued atrial-PV electrical connectivity. Recent European approval and ongoing clinical trials in the United States of an endocardial deflectable catheter-based high-intensity focused ultrasound balloon (ProRhythm, Ronkonkoma, NY) may allow for the placement of transmural linear lesions without the need for direct tissue contact, and animal trials into the use of laser balloon therapy are ongoing.[25]

ELECTROPHYSIOLOGY STUDY PROCEDURAL PROTOCOL

Catheter ablation of tachyarrhythmias is typically an elective procedure with the patient presenting on an outpatient basis. As with any invasive procedure, patients need to be thoroughly evaluated and informed of the risks, benefits, and alternatives regarding the specific planned procedure. Occasionally, electrophysiology procedures are performed on an emergency basis in patients with recurrent or incessant hemodynamically unstable arrhythmias (e.g., ventricular tachycardia or atrial fibrillation with a rapidly conducting accessory bypass tract) that are refractory to drugs or overdrive suppression through a temporary wire.

Electrocardiographic (ECG) recording of the clinical tachyarrhythmia is crucial to planning the procedure. In the absence of hemodynamic instability, every attempt should be made to obtain an ECG prior to pharmacologic arrhythmia suppression. A patient may present to a physician's office or to an emergency department with the tachyarrhythmia, allowing the recording of a 12-lead ECG. A loop recorder or 24-hour Holter monitor is sometimes helpful to record symptomatic tachyarrhythmias.[26] The recording of onset and termination of the tachyarrhythmia, either spontaneously, with vagal maneuvers, or with drugs, is also very helpful in determining the mechanism of the tachycardia.[27–29]

Additional studies to be considered when evaluating the patient with a known or suspected arrhythmia include an echocardiogram to identify the presence of structural heart disease; a graded exercise test to determine catecholamine sensitivity with possible imaging to assess for ischemic burden; and right heart and left heart catheterization and coronary angiography to assess for stability of known disease, or to further seek etiology of a new arrhythmia. Because a diagnostic study can invoke hemodynamically unstable arrhythmias, it is important to know beforehand if there is myocardium at risk for either demand-related ischemia or for low-flow conditions.

All antiarrhythmic medications are usually discontinued at least four half-lives prior to the procedure to allow for induction of tachyarrhythmias. In most cases, AV nodal–blocking medications (commonly beta blockers and nondihydropyridine calcium channel blockers like diltiazem and verapamil) should also be stopped when the AV node may be involved in the re-entrant circuit. Anticoagulation medications should also be stopped, and depending on the indication, the patient may be bridged for the procedure with subcutaneous low molecular weight heparin or admitted to the hospital for intravenous heparin. Because of the need for systemic anticoagulation for ablative procedures that require left heart access, premenopausal women should avoid scheduling procedures that conflict with the first day of menses. Routine complete blood count, electrolyte status, and coagulation profile should be obtained before undergoing the elective procedure. Additional laboratory tests that are sometimes useful are thyroid function tests in patients with a history suggestive of hyperthyroid state, and a pregnancy test in women of childbearing age.

Patients should present on the day of the procedure in a fasting state in preparation for intravenous conscious sedation. Drugs typically used include short-acting benzodiazepines and narcotics in combination (e.g., midazolam and

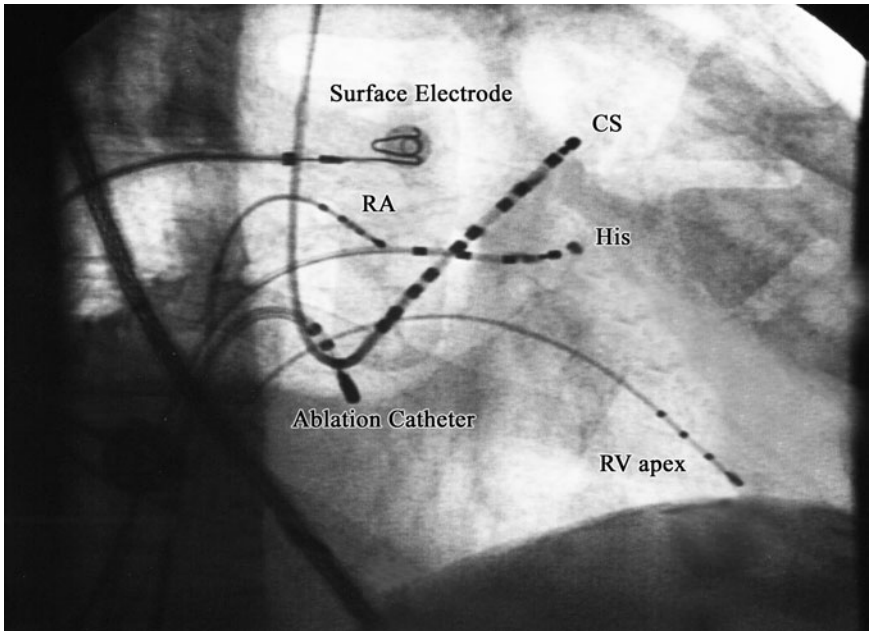

Figure 58-1. Radiograph in the right anterior oblique projection showing catheters positioned for a standard diagnostic electrophysiology procedure. Three nonsteerable diagnostic catheters are introduced from the inferior vena cava into the right heart. Two 4F catheters with four electrodes are positioned in the region of the right atrial appendage (RA) and right ventricular apex (RV apex). A 5F catheter with six electrodes is positioned across the tricuspid annulus to obtain a His bundle recording (His). A nonsteerable 6F catheter is introduced via the right internal jugular vein into the coronary sinus (CS) to obtain left atrial and ventricular recordings. Finally, a deflatable 7F ablation catheter is positioned in the region of the low right atrium.

fentanyl). Because sedation may suppress arrhythmias, or alter the conduction properties of the heart, administration of these agents should be at the discretion of the electrophysiologist. Although general anesthesia is rarely required, it may be used in those undergoing prolonged procedures or in high-risk unstable patients.

Patient Monitoring

Continuous monitoring is performed using surface ECG, noninvasive or invasive blood pressure monitoring, continuous pulse oximetry, and capnography. An external defibrillator is available and attached to the patient with "hands-free" patches throughout the procedure. Intubation and resuscitation supplies should be readily available. Electrophysiologic procedures are typically divided into diagnostic and ablative phases. The diagnostic phase involves obtaining venous access, passage of multiple catheters into the heart to record intracardiac electrograms, and induction and mapping of tachyarrhythmias. Only after mechanistic determination of a tachyarrhythmia is ablation considered.

Diagnostic Electrophysiology Study

Diagnostic localization of tachyarrhythmias involves positioning catheters in strategic locations within the heart to obtain intracardiac recordings from all four chambers of the heart as well as from the His bundle. Venous access is typically obtained in the bilateral groins via the right and left femoral veins. Catheters of 4F to 6F in size are passed into the right atrium and right ventricle as well as positioned just across the tricuspid valve to obtain His bundle recordings under fluoroscopic guidance. To obtain recordings of the left atrium and ventricle, a catheter is guided into the coronary sinus, which passes posteriorly in the AV groove and drains into the right atrium. Because of the angle of the entrance into the coronary sinus, cannulation is easier via the superior vena cava and thus previously venous access has been obtained from the right internal jugular, left subclavian, or left antecubital vein. However, steerable catheters allow for reliable access from the inferior approach and are now being used more frequently (Fig. 58-1).

Anticoagulation and Electrophysiology Studies

Direct recordings of the left heart are sometimes necessary and accomplished either by transseptal cannulation via the intra-atrial septum from the right atrium, or via a retrograde approach from the femoral artery and across the aortic valve. Systemic anticoagulation with heparin is maintained during catheter manipulation in the left heart because of the risk of thromboembolic events. Animal models have determined that mural thrombus is evident in up to 50% of cases immediately following RF ablation.[9,30] The Multicentre European Radiofrequency Survey conducted from 1987 until 1992 revealed that 84% of institutions used unfractionated heparin during the procedure, and 56% used either postprocedural heparin for a mean of 3.4 $\pm$ 2.8 days, or warfarin for a mean of 29 $\pm$ 11 days following ablation.[31] In addition to the risk of mural thrombus at the site of ablation, there is mounting evidence of a systemic prothrombotic condition following RF ablation.[32,33]

Once diagnostic catheters are positioned, programmed electrical stimulation is performed to induce and study the tachyarrhythmia. Sometimes modulation of the autonomic nervous system is required to induce tachyarrhythmias with the infusion of atropine or isoproterenol.[34] As will be described later, there are specific pacing maneuvers to initiate and evaluate the mechanism of a variety of

tachyarrhythmias. Once an optimal site for ablation is determined, steerable ablation catheters are positioned at the target site. These catheters come with a variety of curvatures. Specifically shaped long vascular sheaths may also be used to direct catheters. Once RF energy is delivered to the target site, re-induction of the tachycardia is attempted.

At the end of the procedure, all catheters and sheaths are removed and manual pressure held to achieve hemostasis. If the patient was heparinized for the procedure, sheath removal is delayed until anticoagulation reverses. The patient is placed on bedrest for 4 or more hours. During this recovery period, the patient is monitored for hemodynamic stability and recovery from sedation, and to assess for bleeding from puncture sites. The patient may be discharged to home the same day or be observed overnight in the hospital. Routine follow-up studies are not warranted unless required to assess for a complication. As mentioned previously, because of the risk of thromboembolic events, patients are frequently sent home on aspirin, thienopyridines, low molecular weight heparin, warfarin, or a combination of risk-appropriate antithrombotic therapies.

Complications Associated with Electrophysiology Studies

In referring patients for catheter ablation, it is important to weigh the risks and benefits of the procedure for the individual patient. Most tachyarrhythmias, although causing a variety of symptoms, are generally hemodynamically well tolerated and are not life-threatening. Thus an awareness of the potential complications of catheter ablation is necessary prior to referring a patient. Complications can be divided into those involving access, catheter manipulation within the heart, and ablation.

Access-related complications include pain, adverse drug reaction from anesthesia and sedation, infection, thrombophlebitis, and bleeding at the site of access. Complications associated with bleeding include hematoma or arteriovenous fistula formation. Arterial damage or dissection may also result. Systemic or pulmonary thromboembolism can occur, most seriously resulting in transient ischemic attack or stroke.

Complications associated with placement of intracardiac catheters can be more life-threatening. These include trauma of a cardiac chamber or the coronary sinus resulting in myocardial infarction, perforation, hemopericardium, and cardiac tamponade. Programmed electrical stimulation can result in the induction of life-threatening tachyarrhythmias such as ventricular tachycardia or fibrillation. Catheter manipulation can also result in usually transient but sometimes permanent damage to valvular apparatus or to the conduction of the right or left bundle branches due to mechanical trauma.

RF delivery within cardiac structures carries with it its own set of risks as alluded to previously. Inadvertent ablation of the normal conduction system could result in complete heart block requiring permanent pacing. Perforation of a cardiac chamber or vascular structure can also occur with RF delivery. Collateral damage to coronary circulation could result in myocardial infarction, heart failure, or cardiogenic shock. Phrenic nerve paralysis can occur. Ablation near the pulmonary veins within the left atrium can result in venous stenosis and pulmonary hypertension. Finally, new tachyarrhythmias can arise over the next 1 to 2 months due to what is likely a profound inflammatory process at the site of ablation, as well as from the scars induced by RF ablation.

An 8-year prospective study of 3966 procedures found an overall complication rate of 3.1% for ablative and 1.1% for diagnostic procedures. Complications are more likely to occur in elderly patients and those with systemic disease.[35] No deaths were reported in this series and other studies have shown very low mortality rates directly attributable to the electrophysiology study. Body dosimetry studies have shown that the lifetime excess risk per 60 minutes of fluoroscopy exposure is 294 per million cases or 0.03% per patient. The risk is higher for obese patients and the lungs are the most susceptible organs.[36]

DIAGNOSTIC ELECTROPHYSIOLOGY TECHNIQUES

A variety of techniques have been developed to elucidate the origin and mechanism of tachyarrhythmia propagation. These techniques are necessary to reveal targets for ablation. They involve pacing in a specific chamber at particular intervals to initiate a tachyarrhythmia, assess its response to pacing maneuvers, or terminate it.[37] Thus some of these techniques involve pacing in sinus rhythm while others are performed during the tachyarrhythmia.

Activation Mapping

Activation mapping is a technique of localizing focal tachycardias and accessory pathways. It involves positioning the mapping/ablation catheter during the tachyarrhythmia in such a way that activation at the catheter electrode tip precedes any other intracardiac activation or corresponding surface P wave or QRS. The earliest site of activation during a focal tachycardia must by definition be the source of the tachycardia.[38,39] The use of electroanatomic mapping systems allows for logging of local activation times in a three-dimensional model.[40] Earliest activation can then be easily relocated for stable re-entrant rhythms.

Accessory pathways can also be mapped using this technique by tracing the tricuspid and mitral annulus with the ablation catheter. The atrial insertion can be localized by determining the earliest site of retrograde atrial activation during AVRT or in sinus rhythm during ventricular pacing. The ventricular insertion can be localized in patients with preexcitation by determining the site of earliest ventricular activation during sinus rhythm.

Pace Mapping

Pace mapping is performed during sinus rhythm after obtaining a 12-lead surface ECG during tachycardia. By pacing at different sites and comparing the resulting paced ECG to the tachycardia ECG, the disparity can be assessed and the catheter can be repositioned until a perfect 12-lead match is obtained.[41] These sites are then the targets for ablation. This technique is typically used for focal ventricular tachycardias, especially those of right ventricular outflow origin.[42]

Mapping of local electrogram potentials requires recording an intracardiac signal from the structure targeted for ablation. For instance, to achieve complete heart block, the His bundle is the target and the ablation catheter is positioned such that the distal tip is recording a His bundle potential. Similarly for bundle-branch re-entry, the right bundle potential is used to target the right bundle to achieve right bundle-branch block. Sometimes an accessory pathway potential can be recorded and used to localize a target for ablation.[43]

Anatomic Mapping

Anatomic mapping is yet another way to localize potential targets for ablation by using fluoroscopy to localize anatomic landmarks for ablation. Catheters placed through the inferior vena cava into the coronary sinus and across the tricuspid valve delineate these structures. In typical atrial flutter that is dependent on the cavotricuspid isthmus, anatomic landmarks are used for the delivery of a line of lesions to prevent conduction across this isthmus. Bidirectional conduction block across this isthmus terminates flutter and prevents its reinitiation.[44]

Entrainment Mapping

Entrainment mapping is a technique of localizing re-entrant circuits for ablation. It involves positioning the catheter in a region thought to be involved in a re-entrant tachycardia. This is confirmed by pacing during the tachycardia slightly faster than the tachycardia rate. If the pacing site is within the circuit, then activation should proceed orthodromically, or in the same direction as the tachycardia, around the circuit resulting in an identical activation pattern. The resultant QRS or P wave should match that of the tachycardia. At the termination of the pacing the activation wavefront proceeds around the circuit. Therefore, if pacing was in the circuit, the first beat should be close to the cycle length of the tachycardia.

In clinical situations a combination of these mapping techniques is used to localize an arrhythmia for ablation. Usually an anatomic approach is used to find the general region and then more precise mapping is used to specifically localize the focal arrhythmia or re-entrant circuit.

Advanced Mapping Techniques

The success of ablation is very much dependent on localization of arrhythmogenic foci and circuits. The previously mentioned mapping techniques are useful for arrhythmias that originate from specific anatomic locations or have characteristic endocardial electrograms. Conventional fluoroscopy and the use of a single roving mapping catheter have limited success in ablation of complex arrhythmias that may originate from sites without characteristic fluoroscopic landmarks or have variable electrograms as recorded from the catheter tip. Advanced mapping techniques have been developed as adjuncts to conventional methods to improve the efficacy of catheter ablation for arrhythmias that are transient, focal, or hemodynamically unstable and thus require rapid mapping.

The multielectrode "basket" catheter (Constellation, Boston-Scientific, Natick, Mass) is a system with eight splines each with eight electrodes. The splines expand within a cardiac chamber to provide recordings from all 64 electrodes simultaneously to enable reconstruction of activation maps such that a single ectopic beat can be mapped online rapidly. Although these catheters are still fluoroscopically guided, multiple data points are acquired simultaneously, limiting procedure times, especially in patients with hemodynamically unstable arrhythmias.[45] Low spatial resolution limits this technology to larger macro re-entrant arrhythmias.

An electroanatomic mapping system (CARTO, Biosense, Diamond Bar, Calif) uses a magnetic field to localize the mapping catheter tip in three-dimensional space. Three coils in a locator pad located beneath the patient's chest generate ultra-low-intensity magnetic fields in the form of a sphere that decays in strength. A sensor in the catheter tip measures the relative strength and hence the distance from each of the coils. This allows for the recording of the spatial and temporal location of the catheter. Electrodes at the catheter tip record local electrograms, and this information is displayed on screen as a three-dimensional map of the local activation times relative to a reference catheter in a color-coded fashion. Data from multiple single mapping points acquired during tachycardia can be reconstructed to show animated sequences of arrhythmia propagation. Voltage maps can be obtained to delineate regions of scar and diseased myocardium.[46]

A similar endocardial mapping system (EnSite NavX, St. Jude Medical, St. Paul, Minn) consists of a catheter with a woven braid of 64 insulated 0.003-mm-diameter wires with 0.025-mm breaks in the insulation that serve as electrodes. A locator signal is generated between the array and a standard mapping catheter to permit nonfluoroscopic localization of the catheter to regions of interest. The position of the roving catheter is acquired over time to construct a three-dimensional map of the endocardial surface. The woven braid also acts to obtain and then reconstruct a virtual electrogram of the chamber of interest. Over 3360 virtual electrograms are simultaneously acquired by this system, allowing high-density maps to be acquired from a single beat. Thus this system is very useful for mapping in unstable or transient, nonsustained arrhythmias.[47]

The largest advantages to these mapping systems are the increase in patient and operator safety through the reduction of fluoroscopy while preserving precise localization of the catheter tip. In addition, recordings of catheter position allow for the repositioning of the catheter to previously mapped sites of interest.

Intracardiac echocardiography (ICE) has extended the principles of intravascular ultrasound (IVUS) for electrophysiologic use.[48] In contrast to IVUS catheters, ICE catheters use lower-frequency (5.5 to 10 MHz) transducers to extend the imaging range. Newer ICE catheters are steerable and have Doppler capability (Acuson, Mountain View, Calif), allowing for hemodynamic evaluation of intracardiac structures. For electrophysiologic use, ICE catheters are useful for visualization of endocardial structures such as the fossa ovalis and for guiding transseptal catheterization.[49–51] As the recognition of the importance of anatomy in the genesis of arrhythmias has grown, so has the importance of imaging. ICE catheters allow the accurate targeting of anatomic sites such as the crista terminalis and pulmonary vein ostia.[52] They are useful for imaging diagnostic and ablation catheter positions and visualization of tissue contact for optimal ablation. Through visualization of pericardial effusions, rapid diagnosis of perforation and other complications is feasible.

CLINICAL APPLICATIONS

Using the techniques described above, a variety of tachyarrhythmias can be targeted for percutaneous catheter-based ablation, including both atrial and ventricular arrhythmias that are either focal or that utilize re-entrant circuits.

Atrioventricular Nodal Re-entrant Tachycardia

The most common SVT is AVNRT.[53] Of patients with SVT, AVNRT represents up to 60% of cases that present to tertiary centers for electrophysiologic studies. This tachycardia can present at any age, although most patients who present for medical attention are in their 40s and the majority are female.[54,55] Advances in RF catheter ablation of this tachycardia has made it a first-line therapy for those symptomatic patients not wishing to take medications.[56]

This tachycardia has a re-entrant mechanism utilizing two pathways within the AV nodal tissue. The pathways are known as the "slow pathway" and "fast pathway" based on their relative conduction velocities. The anatomic location of these pathways is variable but generally located within the triangle of Koch. The Koch triangle is bounded by the tricuspid annulus and the tendon of Todaro with the coronary sinus at the base. The apex of the triangle is the His bundle at the membranous septum where it passes through the central fibrous body. The anterior third of the triangle contains the compact AV node and the fast pathway, and the middle and posterior portion, near the coronary sinus os, contains the slow pathway (Fig. 58-2).[57]

In the typical form of AVNRT, antegrade conduction from the atrium to the ventricle occurs over the slow pathway, and the retrograde conduction from the ventricle to the atrium occurs over the fast pathway. Since conduction in the

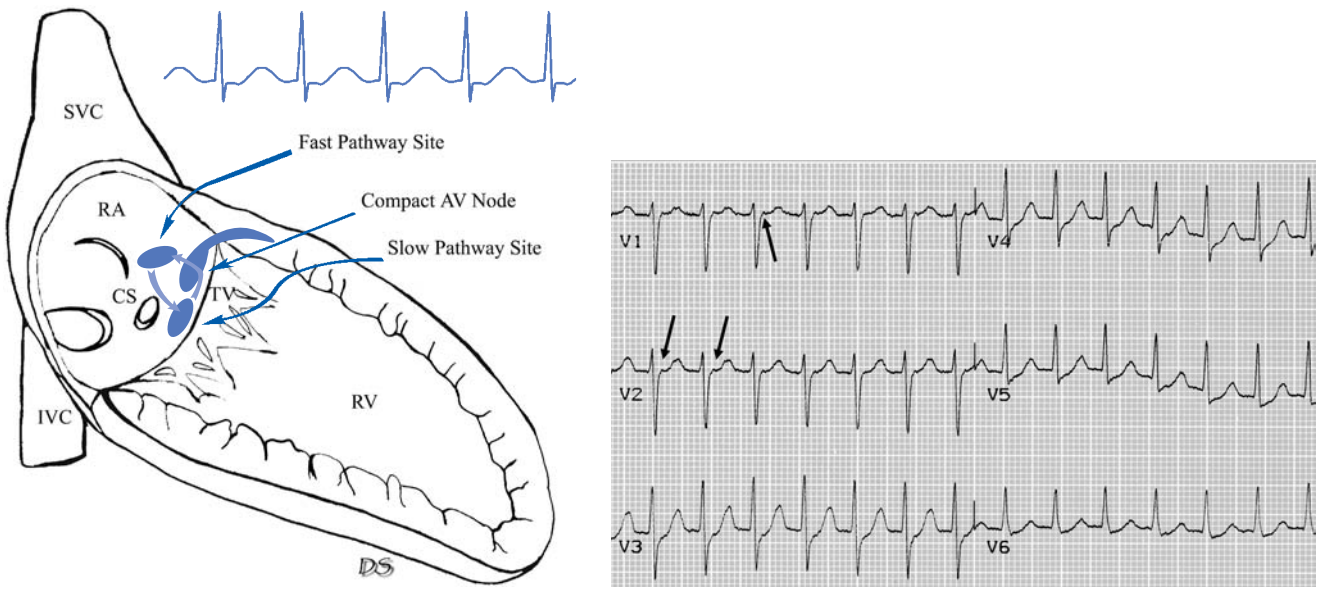

Figure 58-2. (A) Diagrammatic representation of typical atrioventricular nodal re-entrant tachycardia. Surface ECG shows narrow complex tachycardia with no clear P waves. The re-entrant circuit (gray arrows) consists of the posterior slow pathway region acting as the antegrade limb, and the anterior fast pathway region acting as the retrograde limb. The slow pathway target site is located between the coronary sinus os (CS) and the tricuspid valve annulus (TV). IVC = inferior vena cava; RA = right atrium; RV = right ventricle; SVC = superior vena cava. (B) Surface ECG showing precordial leads in AVNRT. This demonstrates that the retrograde P waves are barely discernible in some leads. In V_1, it forms a pseudo r′ wave (arrow). P waves are also visible in the terminal portions of QRS complexes in V_2 and V_3 but not in the lateral leads.

retrograde direction is fast, the atria and ventricle are depolarized almost simultaneously. Thus the electrocardiographic feature of this tachycardia is P waves that are inscribed within the QRS and thus not seen or barely discernible at the termination of the QRS complex.[58]

In less than 10% of cases, the circuit is reversed. In *atypical* AVNRT, antegrade conduction occurs over the fast pathway and retrograde conduction occurs over the slow pathway. Thus the ECG of this tachycardia shows inverted P waves in the inferior leads denoting retrograde activation of the atria with short PR segment due to rapid antegrade conduction.[59]

In the early days of catheter ablation therapy, highly symptomatic patients who had failed drug therapy underwent AV junctional ablation utilizing DC shocks with the insertion of a permanent pacemaker. While this greatly improved quality of life, it made patients pacemaker-dependent. Initial attempts to selectively eliminate AVNRT while leaving antegrade AV nodal conduction intact were performed with DC energy.[60] While selective pathway DC shocks were being studied, RF as an energy source was developed and quickly replaced DC shocks as a mode of therapy.

Early procedures utilizing RF energy targeted the fast pathway. While successful in up to 90% of patients, there was still a 5 to 10% incidence of inadvertent complete heart block.[61] In addition, ablation of the fast pathway left the patients with prolonged AV conduction (a long PR interval). In some, this led to symptomatic atrial contraction during ventricular contraction (pseudopacemaker syndrome), especially during sinus tachycardia when they were unable to shorten the AV conduction interval. Subsequently it was determined that the slow pathway could instead be reliably targeted in the posterior triangle of Koch.[62]

Slow pathway ablation has a high degree of success with a recurrence rate in the range of 2 to 7%, with the complication of complete AV block occurring about 1% (range 0 to 3%) of the time.[63] The North American Society of Pacing and Electrophysiology (NASPE) self-reported surveys on 4249 patients who underwent slow pathway ablations had success rates of $>96\%$ and complication rates of $<1\%$.[64,65]

Pilot trials have demonstrated a similar immediate success rate but a higher recurrence rate in those treated with cryoablation as compared with RF ablation in patients with AVNRT.[66] This particular pilot trial was underpowered to show increased safety profile with cryoablation, but the European Multicenter Study RF Versus Cryo in AVNRT with 500 anticipated enrollees with 6-month follow-up may be able to provide us with a more definitive answer as to its superiority.

Atrioventricular Re-entrant Tachycardia

The next most common type of SVT is AVRT.[53] About 30% of SVTs are due to AVRT. This is a re-entrant tachycardia utilizing the AV node and an accessory pathway (AP). These APs are remnants of conductive tissue from embryonic development that span the normally electrically inert tricuspid and mitral valve annulus and provide an independent path of conduction outside the AV node between the atria and the ventricles. The most common form of AVRT is part of the Wolff-Parkinson-White (WPW) syndrome of ventricular pre(mature)-excitation and symptomatic arrhythmias. The most common APs connect the atrium to the ventricle. Other APs may connect the atria or AV node to the His-Purkinje system. In sinus rhythm, antegrade conduction over the AP results in pre-excitation of the ventricles through conduction by other than the AV node, and is manifested by a short PR segment and slurring of the onset of the QRS, the delta wave. Absence of these findings does not exclude an AP, as the degree of pre-excitation may vary or conduction may only occur in the retrograde direction (~30% of APs).

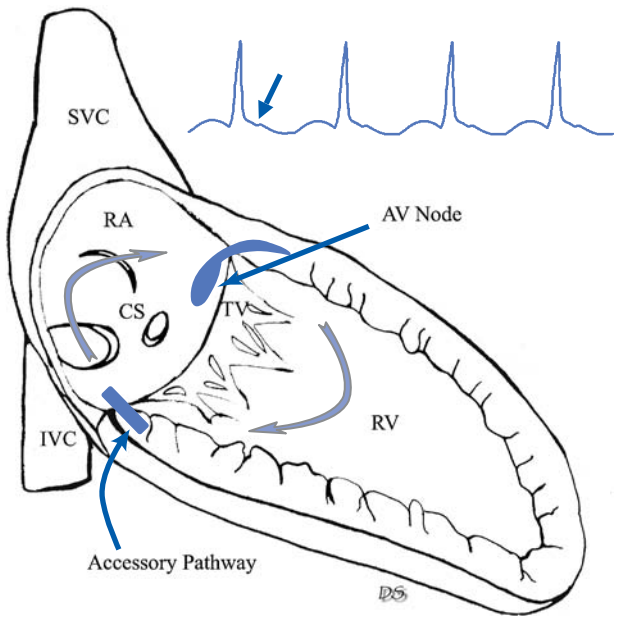
Patients with WPW typically present with palpitations due to rapid heart rate. This may be the result of AVRT or due to any SVT with resulting rapid AV conduction via the AP. Associated symptoms may be mild such as palpitations and shortness of breath, or as severe as syncope and sudden death.[67] Sudden death may be due to ventricular fibrillation resulting from the extremely rapid ventricular activation over the AP during atrial fibrillation in some patients.

Indications for ablation of APs include patients with symptomatic AVRT or those with atrial tachyarrhythmias with rapid ventricular conduction who fail or do not wish to undergo medical therapy. Relative indications for ablations include asymptomatic patients in high-risk professions, those with family history of sudden death, or those mentally distraught over their condition.[53]

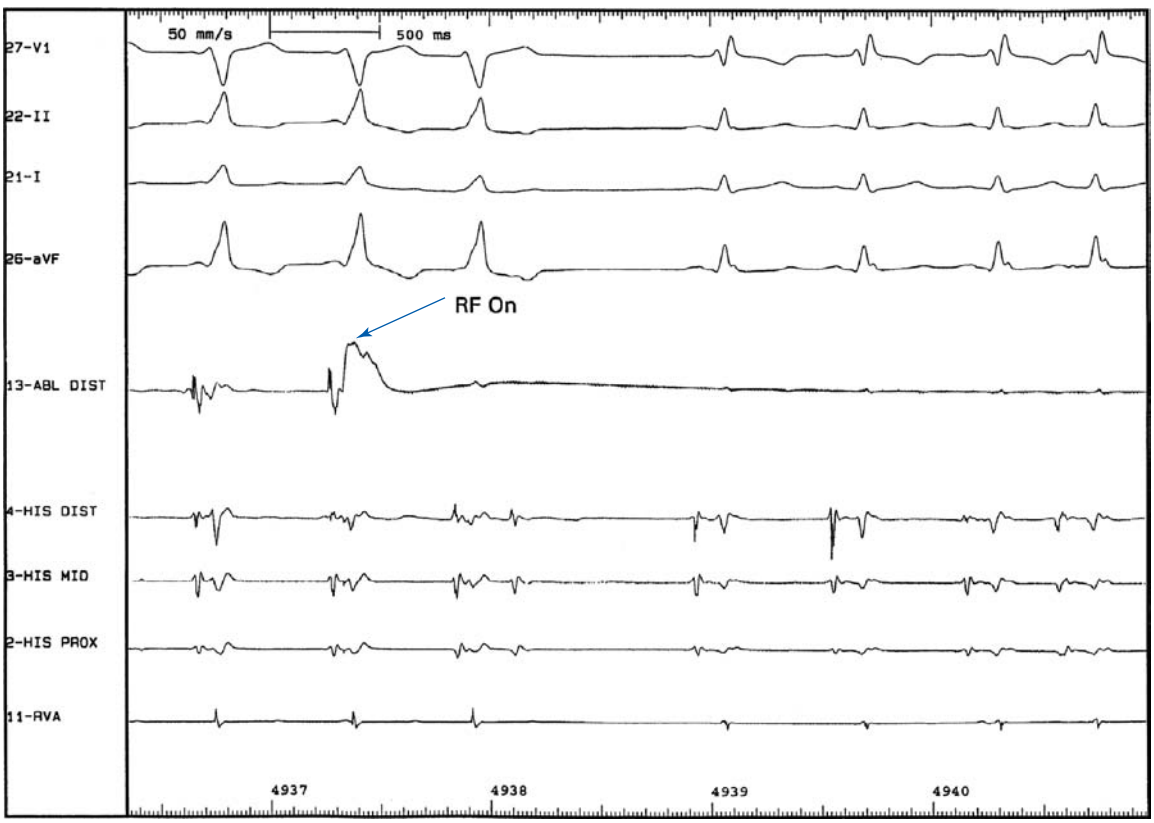
In the typical or orthodromic form of AVRT, antegrade conduction from the atrium to the ventricle occurs over the AV node and retrograde conduction occurs over the AP. In this form of AVRT, the P wave in the tachycardia closely follows the preceding QRS complex with a long PR segment (Fig. 58-3). In the rare antidromic form of AVRT, antegrade conduction occurs over the AP with retrograde conduction over the AV node. This results in eccentric depolarization of the ventricle, producing a wide complex tachycardia with retrograde P waves that can be easily mistaken for ventricular tachycardia with one-to-one ventriculoatrial conduction.

Patients with highly symptomatic WPW syndrome or asymptomatic patients in high-risk professions who had failed medical therapy were the initial population to undergo surgical interruption of APs. Although this procedure evolved with success rates near 100% and mortality rates of 1%, it still involved a major surgical procedure.[68] Catheter-based ablation of accessory pathways has success rates approaching those of surgical ablation and have lower morbidity and mortality rates.

The first catheter ablation procedures were performed with DC energy in patients with posteroseptal accessory pathways.[69] With the development of RF energy for ablation, APs in all locations could be treated.



A



B

Figure 58-3. (A) Diagrammatic representation of atrioventricular re-entrant tachycardia. This macro re-entrant circuit (gray arrows) utilizes the AV node and an accessory pathway (AP), in this case a right lateral pathway. In orthodromic AVRT, antegrade conduction occurs over the AV node and retrograde conduction occurs over the AP. Because of the conduction delay from the His-Purkinje system through the ventricular myocardium to reach the AP, retrograde P waves are discernible after the QRS complexes (arrow). In antidromic AVRT, the re-entrant circuit is reversed and surface ECG shows P waves that closely precede the QRS complexes. CS = coronary sinus; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; SVC = superior vena cava; TV = tricuspid valve. (B) Intracardiac recording of atrioventricular re-entrant tachycardia with termination of eccentric conduction over the accessory pathway during RF ablation. The tracing at 50-mm-per-second speed shows four surface leads (VI, II, I, and aVF) and intracardiac recording from catheters: ablation (ABL); His distal, mid, and proximal; as well as right ventricular apex (RVA). The first three beats of the tracing show evidence of eccentric conduction over an accessory pathway: short PR segment and delta wave. With onset of RF energy (RF On) from the ablation catheter positioned in the region of shortest AV conduction, conduction becomes normal within two beats, with normalization of the PR segment and loss of the delta wave.

Ablation of a right-sided AP is performed by accessing the right heart via the femoral vein or occasionally via the antecubital, subclavian, or internal jugular veins. Left-sided APs are ablated via a transseptal approach or via a retrograde approach from the femoral artery. The initial procedures to ablate leftsided accessory pathways were via a retrograde aortic approach. While successful in more than 95% of patients, there was a small risk of aortic valve perforation or dissection of a coronary artery.[70] Most centers now perform ablation of left-sided accessory pathways via a transseptal approach.

Rarely, left-sided APs can be ablated from within the coronary sinus if they are on the epicardial surface, which is unusual. Due to the more sloping architecture of the tricuspid annulus, it is more difficult to achieve a stable catheter position for right-sided pathways. While the use of long curved vascular sheaths may be helpful, the success rates for right free wall APs may be lower than for other locations.

The major challenge that remains is the ablation of APs near the normal conduction system and those that are epicardial in location. Ablation of pathways that are anteroseptal and midseptal in location carries a high risk of causing complete heart block. It is hoped that newer ablative energy sources such as cryoablation, although found to be effective, may offer a safer alternative.[15] Recently, elimination of epicardial accessory pathways via a pericardial approach has been attempted.[71]

Unusual accessory pathways include atriofascicular (Mahaim) pathways. These show decremental conduction and the atrial insertion is typically located in the right free wall. These can often be successfully ablated via an endocardial catheter approach.[72] The 1998 NASPE prospective catheter ablation registry reported on 654 patients with a 94% success rate.[65] Success rates are lower (in the range of 84 to 88%) for septal and right free wall pathways. Other pathways have success rates in the range of 90 to 95%.[43,73,74]

Complications associated with ablation of accessory pathways include those associated with any ablation procedure. A specific complication associated with transseptal catheterization may be persistent intra-atrial shunt. Although acute shunt may be present in up to 50% of patients, long-term sequelae and persistence beyond 3 weeks are rare.[75,76] Mortality rates are less than 1% and nonfatal complications are about 4%.[65]

Atrial Tachycardia

Atrial tachycardias depend wholly on atrial tissue for initiation and maintenance of the tachycardia. Ectopic atrial tachycardia, sinoatrial nodal re-entrant tachycardia, inappropriate sinus tachycardia, atrial flutter, and atrial fibrillation can all be considered atrial tachycardias. Focal atrial tachycardias, a less common type of SVT, form about 10% of all SVTs referred for electrophysiologic studies.[53] Multifocal atrial tachycardia is due to multiple foci of abnormal automaticity or triggered activity and is not amenable to catheter ablation.[77]

Patients with atrial tachycardia present with palpitations and associated symptoms may include chest discomfort, shortness of breath, and dizziness. Symptoms most often are benign and not life-threatening. These arrhythmias are more common in patients with structural heart disease. Indications for ablation include failure or intolerance of medical therapy. Rarely, incessant tachycardias can lead to cardiomyopathy. With ablation and control of heart rate, myocardial dysfunction can be reversed, although there may be a delayed risk of sudden death that necessitates use of a defibrillator.[78–80]

Surface ECG features of atrial tachycardia include abnormal P-wave morphology or axes that are close to the following QRS complexes. Mapping and ablation of atrial tachycardias can be more difficult, as they can originate from anywhere within the right or left atrium. But there are specific anatomic regions that have a high incidence of foci and serve as primary targets. They include the crista terminalis, atrial appendages, valve annulus, and pulmonary ostia.[81] Intracardiac echocardiography has been used to localize these anatomic regions of interest.[82,83] Mapping can be facilitated by techniques previously mentioned and reviewed here.

Activation mapping by means of a roving mapping catheter is used to localize a region of earliest activation. Successful targets for ablation usually have intracardiac activation 30 ms or more prior to any surface P wave. Sometimes two catheters are used to triangulate a target by moving one catheter at a time toward sites of earlier activation. A caveat to this mapping technique is that an early right atrial activation site may in fact originate from the left atrium, as the posterior septum of the right atrium overlies the left atrium.[84] Other techniques that have aided focal ablation are the use of noncontact and electroanatomic mapping systems.[85,86] These newer mapping catheters have increased the success rate of ablation of focal tachycardias, especially in patients with altered atrial anatomy such as those with congenital anomalies and post–atrial surgery.[87–89]

Inappropriate sinus tachycardia and sinoatrial nodal re-entry tachycardias occur more infrequently and experience with catheter ablation of these tachycardias is more limited. Inappropriate sinus tachycardia is also difficult to ablate due to the variability and diffuse location of sinoatrial tissue.[90] Medical therapy is the preferred method of therapy and catheter ablation is attempted only after drug failure. Catheter ablation may result in complete loss of sinoatrial node function and resulting junctional rhythm, requiring insertion of a pacemaker. Even if the resting heart rate is reduced with nodal modification, symptoms may continue with episodes of tachycardia. Sinoatrial nodal re-entrant tachycardia is targeted for ablation using techniques similar to those used for other atrial tachycardias.

Success with ablation of atrial tachycardia is quite variable depending on the location of the arrhythmogenic foci and the experience of the operator. The 1998 NASPE survey showed a success rate of 80% for right-sided versus 72% for left-sided versus 52% for septal foci in 216 cases of atrial

tachycardia ablation.[65] Another large review examined the frequency of arrhythmias as a predictor of success. In 105 patients, the overall initial success rate was 77%, and 10% had recurrence over a 33-month follow-up period. There was an 88% success rate for the paroxysmal form versus 71% for permanent and 41% for repetitive forms of atrial tachycardia.[91]

Atrial Flutter

Atrial flutter is a type of atrial tachycardia that utilizes a macro re-entrant circuit contained within the atria. A variety of natural and surgical barriers to conduction can create a re-entrant circuit within the atria. Typical atrial flutter is due to a right atrial circuit, bound anteriorly by the tricuspid valve (TV) annulus. Posteriorly, it is confined by the superior vena cava, crista terminalis, inferior vena cava (IVC), eustachian ridge, and coronary sinus (CS)[92] (Fig. 58-4).

In the typical and more common form of atrial flutter, the circuit transverses the right atrium in a counterclockwise manner in the frontal plane. In the inferior leads, the P waves are negative and have a sawtooth appearance. In V_1, the P wave is usually upright and in V_6 it is inverted. Clockwise flutter utilizes the same circuit but in a reversed manner. The ECG also shows a reversed pattern. In the inferior leads the P waves are upright, with inverted P waves in V_1 and upright in V_6. This surface ECG morphology is suggestive of the circuit but needs intracardiac confirmation.[93] These two forms of atrial flutter have been termed "isthmus dependent" due to the use of the IVC-tricuspid annular isthmus. Other types of atrial flutter are called "atypical."

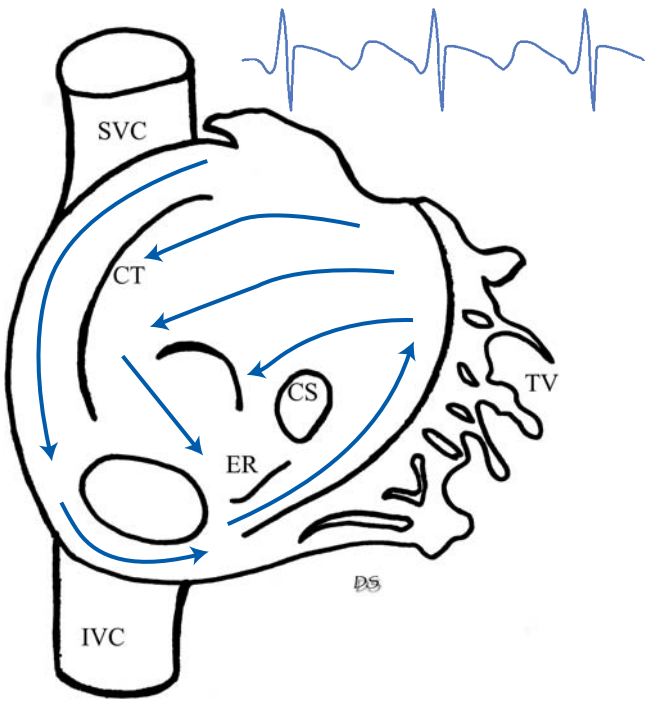


Figure 58-4. Diagrammatic representation of typical or counterclockwise right atrial flutter. Surface ECG shows large inverted P waves in the inferior leads. Lead III above shows 2:1 AV conduction with "sawtooth" flutter waves. The re-entrant circuit (gray arrows) is confined to the right atrium by the tricuspid valve annulus (TV) and barriers to conduction within the right atrium. These include the superior vena cava (SVC), crista terminalis (CT), inferior vena cava (IVC), eustachian ridge (ER), and coronary sinus (CS). The isthmus between the IVC and TV is the preferred target for ablation.

A macro re-entrant circuit can be cured by lesions that transect the circuit between two anatomic barriers. In the case of isthmus-dependent flutter, the target for ablation is the isthmus between the IVC and TV. This is a relatively narrow target and easily reachable by ablation catheters introduced from the IVC. Success rates for ablation of this form of atrial flutter are high. Initial success rates are up to 90% with recurrence rates of 10 to 15%.[94,95] Given these results, ablation has become the first line of therapy for recurrent isthmus-dependent atrial flutter.[53] In addition, studies have shown that the incidence of atrial fibrillation is markedly reduced in patients with atrial flutter treated with ablation as compared to medications.[96]

In some patients with atrial fibrillation, treatment with class IC antiarrhythmics or amiodarone results in the development of typical atrial flutter. A hybrid approach using ablation of the IVC-TV isthmus and continued use of the antiarrhythmic medication has been shown to be highly successful in reducing the incidence of atrial fibrillation.[97]

While the right atrial circuit described above is the most common, a variety of other circuits in the right and left atrium are possible. These are more common in patients with underlying heart disease. Although initially thought not to be amenable to ablative therapy, mapping and ablation of these arrhythmias are now routinely performed. However, the success rate is somewhat lower than that for typical isthmus-dependent atrial flutter. An electroanatomic map of a patient with left atrial flutter can be seen in Fig. 58-5. Ablation in the isthmus between these scars resulted in termination of the flutter.

Surgical Scar–Related Atrial Arrhythmias

Incisional scars from prior cardiac surgery can be the substrate for re-entrant atrial arrhythmias.[87–89] The most common is an atypical atrial flutter related to a lateral right atrial incision. Mapping demonstrates a circuit circling the incision. Ablation from the end of the incision to either the superior vena cava or more commonly the inferior vena cava is often curative.[98]

It had been thought that there was conduction block between the donor and recipient atria in patients who have undergone heart transplantation. Recent reports have demonstrated re-entrant arrhythmias due to donor-recipient atrial conduction. Mapping the connection between the atria can successfully ablate these arrhythmias.[99–101] Atrial arrhythmias have also been reported in a number of patients who have undergone the surgical Maze procedure for atrial fibrillation. These treatment failures are most often due to

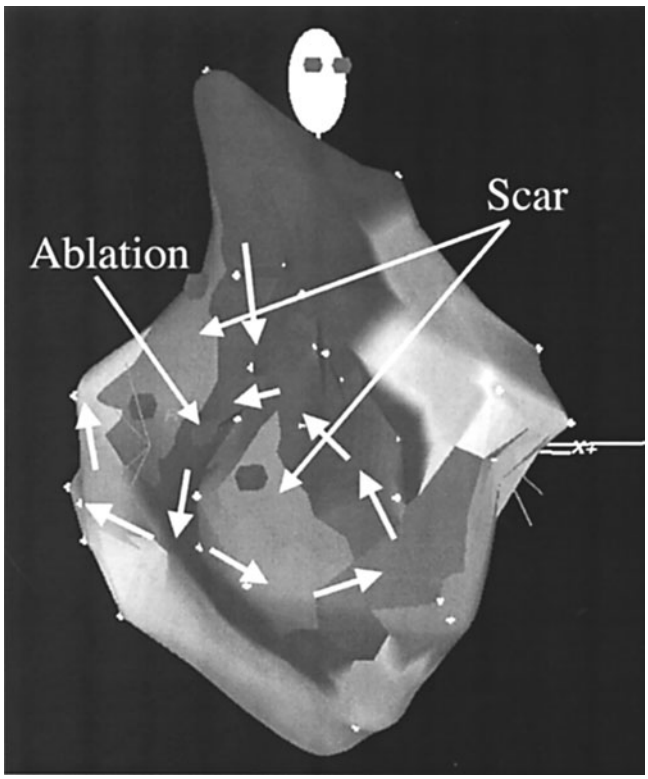

Figure 58-5. An electroanatomic map of a patient with left atrial flutter is shown in the right anterior oblique projection. Two large areas of scar can be seen in gray. Gradation in color shows activation sequence, with lighter being the earliest and darker being late in relation to a reference catheter, in this case positioned in the coronary sinus. The circulating wavefronts describe a figure-eight pattern around these two areas of scar but are confined by the narrow region (isthmus) between them. Ablation in the isthmus resulted in termination of the flutter.

re-entrant circuits involving gaps in the Maze lesion or through alternative pathways such as the musculature surrounding the coronary sinus.[102] These arrhythmias can now be successfully mapped and ablated. Mapping systems are useful in improving success of these ablations. The principle of interrupting these circuits by placing lesions to connect conduction barriers remains the same.[103]

Atrial Fibrillation

Atrial fibrillation is another difficult-to-treat atrial tachycardia with variable targets for ablation. Atrial fibrillation is often symptomatic for patients due to irregular and/or rapid ventricular rates. Patients can also be completely asymptomatic and present with stroke or be diagnosed on routine examination. Medical therapy for atrial fibrillation is of limited efficacy and pharmacologic control of atrial fibrillation may be associated with increased mortality in large trials.[104–106] In addition, sustained rapid ventricular rates can lead to a tachycardia-related cardiomyopathy.[80] When medical therapy aimed at maintaining sinus rhythm or blocking AV nodal conduction to slow ventricular response fails, ablation can be considered.[53]

In the past, AV nodal or His ablation, with placement of a permanent pacemaker, was considered in patients with difficult-to-control ventricular rates and symptomatic palpitations. The advantages of the approach are the relative ease and speed of the procedure. The downside is that it renders the patient pacemaker-dependent. Success rates of this procedure are nearly 100%.[53,107] Complications of this procedure include the same complications as those seen in other ablation procedures. A unique complication associated with creation of complete heart block is bradycardia-related ventricular tachycardia (torsades de pointes).[108] The incidence of this complication is reduced with high-rate atrial pacing at 80 to 90 bpm for up to a month following ablation. In highly symptomatic patients, this approach to the treatment of atrial fibrillation has been associated with improvement in quality of life and left ventricular function, and with a reduction in hospitalizations.[109] With up to 3 years of follow-up, no long-term sequelae have been noted.[110] Patients with congestive heart failure and atrial fibrillation may particularly benefit from this approach, and in some cases restoration of function will return as tachycardia slows; but in many cases it may be more beneficial to proceed directly with implantation of a cardiac resynchronization device.[111,112]

Surgical experience with the Maze procedure to create lines of conduction block in the atrium has led the way for catheter-based ablation procedures to treat atrial fibrillation. Studies have attempted to replicate the success of the surgical procedure using a catheter-based approach. Atrial fibrillation consists of multiple re-entrant circuits within the atrium; around the vena cava, pulmonary veins, and appendages; and around areas of functional block.[113] Creation of multiple lines of block between these nonconducting structures may prevent propagation of arrhythmic circuits.

A variety of catheter techniques have been employed including a "point-by-point" approach, a "drag" approach, and a multielectrode approach. Right atrial lesions alone were shown to be ineffective.[114] Attempts at left atrial or biatrial lesions have met with limited success due to the prolonged procedure times, high risk of complications, and limited efficacy.[115,116] There is also concern about reduced mechanical function of the atria following extensive ablation. This limits the hemodynamic benefit of the restored sinus rhythm. As understanding of the mechanism of atrial fibrillation has evolved, attempts to block propagation of atrial fibrillatory circuits have been abandoned in favor of attempted ablation of the fibrillatory triggers.

Data suggest that atrial fibrillation may in some cases be triggered by an organized SVT. About 12% of patients with AVNRT or AVRT will develop symptomatic atrial fibrillation in 1 year of follow-up.[117] Thus ablation of the initiating trigger arrhythmia may prevent atrial fibrillation. In a series of patients undergoing a left-sided catheter Maze procedure, it was discovered that rapidly firing premature atrial contractions arising from the musculature of the pulmonary veins were triggering atrial fibrillation.[118] Ablation of these foci eliminated atrial fibrillation in some patients. This procedure

has evolved to empiric electrical isolation of the pulmonary veins. One approach is the complete encircling of the pulmonary veins (i.e., wide area circumferential ablation).[119] Another approach is segmental isolation of each vein by mapping the location of the connecting fibers.[120] The encircling and nonencircling procedures have shown to be equally efficacious in 6-month follow-up. The advantage to the nonencircling method, whereby the focus is on pulmonary vein exit block, is the ability to avoid a posterior wall line. The placement of posterior wall lines is thought to be responsible for the finding of atrioesophageal fistula postoperatively. Electroanatomic mapping and intracardiac echocardiography have been employed to facilitate ablation.[121] Data on the long-term efficacy and complications of this procedure are limited and it is still considered to be a procedure in evolution. In one series of 251 patients, the short-term success over 10.4 months of follow-up was 80%. There was an 85% success rate in those with paroxysmal and 68% success in those with permanent atrial fibrillation. There was a continued need for antiarrhythmic medications in some patients.[122]

A major complication of ablation *within* the pulmonary veins was focal pulmonary vein stenosis. In 102 patients undergoing pulmonary vein focal ablation, 39% with right upper vein ablation and 23% with left vein ablation developed focal pulmonary vein stenosis by transesophageal echocardiography 3 days after the procedure.[123] In this series, only three patients experienced symptoms of dyspnea on exertion and only one had a mild increase in pulmonary pressure. Although most cases are asymptomatic, severe cases have been reported that progress to pulmonary hypertension and lung transplant. Changes to prevent this complication include limiting ablation to the vein ostia, limiting power, and using ultrasound imaging during ablation. Since its recognition as a possible adverse event, the occurrence postprocedurally should now be considered rare.

In some patients, triggering foci arise from outside the pulmonary veins. Reported sites have included the superior vena cava, ligament of Marshall, crista terminalis, posterior wall of the left atrium, tricuspid/mitral valve annulus, and limbus of the fossa ovalis. Pulmonary vein isolation failures in some cases may be due to the triggers from these alternative sites. In patients with persistent and/or chronic atrial fibrillation, there may be a combination of triggers and substrate responsible. Successful ablation may require elimination of triggers combined with modification of substrate.[22] The future of ablation for atrial fibrillation has been driving the future for electrophysiology.

Ventricular Tachycardia

Ablation techniques can also target ventricular tachycardia (VT). Over 90% of life-threatening ventricular arrhythmias originate from myocardium with structural abnormalities. Regions of scarred or aneurysmal myocardium create channels for re-entrant circuits. Initial successes with resection of ventricular arrhythmogenic foci and re-entrant circuits surgically have led to advancements in catheter-based ablation techniques. Beginning with DC ablation, techniques have advanced with the use of RF ablation catheters and electroanatomic mapping systems. Despite these advances, ablation for VT in patients with coronary artery disease has a secondary role. Given the life-threatening potential of VT in patients with structural heart disease, even a single recurrence can be disastrous. Therefore implantable cardiac defibrillators have become the primary therapy. Indications for ablation in this population are failure of antiarrhythmic medication to suppress symptomatic, sustained monomorphic VT, or more often frequent shocks from an implanted defibrillator despite optimal medical therapy.

There are several factors limiting the role of catheter ablation of ischemic VT. The hemodynamic instability of patients with coronary artery disease and depressed left ventricular function limits mapping during the tachycardia. A patient may have multiple re-entrant circuits, not all of which are clinically significant. The VT re-entrant circuits involve scarred myocardium or can be epicardial in locations that may be out of reach for RF energy to penetrate. Finally, short-term success may be eclipsed by development of new VTs with further myocardial injury.

Success of ischemic VT ablation is variable due to the heterogeneity of the population. Reported studies have shown efficacy in the range of 60 to 90% using the criteria of reduced defibrillator shocks and decreased need for antiarrhythmic medications. The recurrence rate is as high as 40%. Recently, success has been reported with an approach employing "substrate mapping." This technique defines the potential arrhythmic substrate using electroanatomic voltage maps. Ablation is targeted to eliminate potential re-entrant circuits. Complications are in the range of 2%, with concern for perforation and cardiac tamponade due to the thin, scarred ventricles that are the substrates for ablation and thromboembolic events in those undergoing extensive ablation.[124–126] One reason for failure of ischemic VT ablation is the deep or epicardial location of circuits. Catheter ablation has been directed at these epicardial circuits using a pericardial approach with some success.[127]

In patients with dilated cardiomyopathy and His-Purkinje system disease, sustained monomorphic VT can occur due to a macro re-entrant circuit using the bundle branches. Patients typically present with syncope or sudden death or can present with palpitations. The most common circuit is down the right bundle branch and up the left bundle branch resulting in a wide complex tachycardia with a left bundle-branch block pattern. Treatment involves ablation of one of the fascicles involved in the re-entrant circuit. The right bundle is most commonly targeted to interrupt the re-entrant circuit. Long-term success is good for prevention of recurrent bundle branch re-entry. Due to intrinsic conduction disease, patients may develop heart block. Patients may also develop other VTs due to other structural abnormalities, requiring further ablation, antiarrhythmic therapy, or defibrillator implantation.[128,129]

Other cardiac disorders can be associated with VT and are potential candidates for catheter ablation. These include right ventricular dysplasia,[130] infiltrative disorders (sarcoid), and tumors. As in patients with atrial arrhythmias due to surgical incisions, patients with prior ventricular surgery can develop incision-related VT. This has occurred most often in patients who have undergone repair of congenital abnormalities such as tetralogy of Fallot.

Ventricular tachycardia that presents in patients with no structural heart disease is termed idiopathic and represents up to 10% of all VTs that present to tertiary referral centers. Patients may be asymptomatic or present with palpitations, dizziness, or syncope. Idiopathic VT may be focal or a micro–re-entrant circuit utilizing the Purkinje fibers.

Focal VT can originate from either the right or left ventricle. Right ventricular tachycardia typically originates from the outflow tract, on the septal or free wall sites. It has typical left bundle-branch morphology with leftward, inferior axis. This occurs more often in women than men, and patients typically present in their 30s to 50s. Idiopathic left ventricular tachycardia typically originates from the left posterior fascicle. It has a right bundle-branch morphology with rightward, superior axis, and may be verapamil sensitive. It occurs more often in men. These VTs are localized by activation or pace mapping. Ablation is facilitated by the lack of other cardiac pathology and the presence of only one VT. Success rates for idiopathic VT are in the range of 70 to 90% with recurrence rates in the range of 15%. Complication rates are consistent with those of other ablative procedures.[131,132]

Cost-Effectiveness

Several studies have shown the cost-effectiveness of catheter ablation compared to medical therapy and surgical ablation. Catheter ablation has lower procedural costs than surgical ablation and reduces the need for further medical care and emergency department visits in comparison to drug therapy. Studies from both the United States and from Australia have shown both cost savings and improvement in quality of life for those undergoing catheter-based ablation compared to medical management.[133–135]

FUTURE DIRECTIONS

After the advent of steerable catheters, newer imaging techniques have been the most useful in directing the positioning of catheters to specific areas of interest within the heart. The techniques of nonfluoroscopic mapping discussed above have extended the efficacy of catheter-based ablation. Newer imaging techniques are in development that will continue to push the field of electrophysiology. The Niobe system (Steroetaxis, Inc., St. Louis, Mo) is a magnetic navigation system that uses two externally located magnets to create a steerable field that can be used to affect the magnetically active catheter tip. For advancing and retracting, the unit can be completely controlled remotely through a small motor. The entire system can be controlled from a shielded room by joystick and touch-screen monitors to allow for catheter manipulation through hands-free robotic catheter control. The ability to perform an entire ablative procedure with the primary operator behind a glass in a lead-lined room may be the next step in development of electrophysiologic treatment. One novel technology in development is the use of magnetic resonance imaging that would allow high-resolution three-dimensional mapping of the heart and localization of catheters in three-dimensional space in real time without radiation.[136] Magnetic resonance imaging would also allow for the visualization of any tissue injury due to attempted ablation in real time.

CONCLUSION

The past 35 years have seen the development of intracardiac recording, programmed stimulation, and catheter ablation. The field of interventional electrophysiology is relatively young. Over the past two decades, great advances have been seen in the interventional management of atrial and VTs. Where the surgeons have gone with their scalpels, electrophysiologists have followed with their catheters. Transvenous RF ablation, once the standard of care for the treatment of many arrhythmias, may be phased out in preference of alternative energy sources. These procedures have been proven to be safe and efficacious. Improved treatments for arrhythmias such as atrial fibrillation and VT will come with further understanding of the mechanisms underlying these arrhythmias. Future advances in catheter design, energy delivery, and imaging techniques will continue to advance the field of electrophysiology.

CHAPTER 59

Surgical Treatment of Atrial Fibrillation

Rochus K. Voeller • Richard B. Schuessler • Ralph J. Damiano, Jr.

ATRIAL FIBRILLATION

Atrial fibrillation (AF) is present in up to 2% of the general population and in approximately 10% of patients over the age 60, making it the most common form of sustained cardiac arrhythmia.[1–5] The actual incidence and prevalence of AF may be substantially higher, due to undetected asymptomatic AF and undersampling in patients with paroxysmal AF. With the increasing age of the population in North America, there is no question that the prevalence will continue to rise.[6] Health care costs related to AF have increased significantly. Admissions for inpatient care in which AF was a factor tripled between 1985 and 1999 in the United States, rising from 787,750 to almost 2.3 million.[7] Similarly, inpatient hospitalizations with the primary diagnosis of AF increased from 154,086 to 376,487 during the same period.[7] At this rate, experts predict that the number of AF-related hospitalizations will increase to over 3.3 million by 2025 in the United States.[7] It is not an exaggeration to state that AF is a growing epidemic in this country.[8]

AF is undoubtedly a costly public health issue. Unfortunately, the actual numeric data on the economic burden of AF are sparse compared to those on other significant cardiac disease states such as stroke and congestive heart failure. A recent study in the United Kingdom, however, estimated a 50% increase in health care expenditures on AF from 1995 to 2000.[9] Stewart and associates further stated that AF consumes around 1% of all health care expenditures and indirectly contributes to an additional 2% of the health care costs in the UK.[9]

Although AF is often considered to be an innocuous arrhythmia, it is associated with serious morbidity and mortality due to its three detrimental sequelae: (1) palpitations, resulting in patient discomfort and anxiety; (2) loss of synchronous atrioventricular (AV) contraction, which compromises cardiac hemodynamics, resulting in varying degrees of ventricular dysfunction or congestive heart failure; and (3) stasis of blood flow in the left atrium, which increases the risk of thromboembolism and stroke.[10–14] It has been estimated that AF results in a three- to fivefold increase in a patient's risk of stroke.[15] Twenty to 30% of all acute stroke patients are found to be in AF.[16–18] AF has been the attributed cause of stroke in one-quarter of patients over 80 years of age.[19] AF also independently increases mortality rates. Using the data from the Framingham Heart Study, Benjamin and associates established the risk factor–adjusted odds ratio for death in men and women with AF as 1.5 and 1.9, respectively.[20]

Unfortunately, the results with medical therapy for AF have been disappointing. Antiarrhythmic drugs have limited long-term efficacy in converting AF to normal sinus rhythm and have significant and sometimes fatal side effects.[21–26] The goal of pharmacotherapy is therefore often shifted from the ideal *rhythm* control to *rate* control (i.e., slowing the ventricular response rate to AF and avoiding the development of rate-related cardiomyopathy due to prolonged rapid ventricular response). The Atrial Fibrillation Follow-Up Investigation of Rhythm Management (AFFIRM) Study[27,28] showed that management with rhythm control did not have any survival benefit over a rate control strategy in anticoagulated patients with AF.[29,30] Furthermore, a rate control strategy may potentially have advantages over rhythm control, such as lower risk for adverse side effects that can be seen with aggressive rhythm control.[29]

Despite the results from the AFFIRM trial supporting no difference in long-term outcome between rhythm control versus rate control in anticoagulated patients with AF, some patients may have clinically meaningful advantages from being in normal sinus rhythm. These advantages include increased exercise tolerance, decreased palpitations, and prevention of atrial remodeling.[28,31] Most importantly, in the AFFIRM trial, the presence of sinus rhythm was associated with a significantly decreased risk of death (hazard ratio = 0.53, $p < .0001$).[32] The conclusion to be drawn from the

AFFIRM study is that antiarrhythmic drugs are detrimental, but normal sinus rhythm is beneficial in this patient population.

Rate control alone clearly has its disadvantages. Although the ventricular response rate can often be controlled pharmacologically with rate control, the atria are still in fibrillation. With persistent AF, three of the detrimental sequelae associated with AF persist. In patients with baseline cardiac dysfunction, the absence of atrial "kick" often can result in worsening symptoms of congestive heart failure. Most importantly, patients with chronic AF are at a risk for developing thromboembolism, requiring indefinite anticoagulation with warfarin. The use of warfarin itself is associated with significant morbidity, with a major complication rate of approximately 2% per year.[33–35]

PHYSIOLOGIC BASIS

AF is characterized by the irregular activation of the atria and an irregular ventricular response. Activation of the atria during AF exhibits two different patterns. One pattern is a stable source, focal or small reentrant circuit, with fibrillatory conduction away from the source. The other pattern is characterized by multiple changing sources or reentrant circuits. These sources can be stable for short periods of time, spawning one or more sources, that then assume dominance. For either pattern of activation there are four substrates that determine whether or not AF is initiated and sustained. They are: (1) a trigger, usually a premature depolarization or runs of focal ectopic depolarizations; (2) refractory period, both the magnitude and spatial distribution; (3) conduction velocity, including the magnitude and anisotropic spread; and (4) geometry or anatomy, both macroscopic and microscopic. Whatever the pathology, whether it be valvular disease, heart failure, ischemia, tachycardia, pericarditis, or inflammation, the changes that occur in the atrial myocardial structure and physiology affect one or more of these four factors.[36]

The surgical treatment of AF is directed at altering the geometry and anatomy needed to support AF. Non-reentrant mechanisms, such as abnormal automaticity or triggered activity, are important for the generation of premature beats, which act as a trigger for reentry, but may also be involved in maintaining AF. The premature beats interact with the underlying distribution of refractory periods. As the distribution becomes more inhomogeneous, unidirectional block can occur. This is a necessary condition for the initiation of reentry. When unidirectional block occurs, reentrant arrhythmia will occur only if a critical mass of tissue is present. The critical mass is the interaction of the tissue geometry, the magnitude of refractory periods, and the magnitude of conduction velocity. As the atrial size increases, or the conduction velocity is slowed, or the refractory period is decreased, the probability of initiating and sustaining AF increases. Although numerous nonpharmacologic approaches to treating AF have involved altering one of these substrates, like isolating triggers, it must be remembered that the other substrates can be affected, too. Incisions or ablations affect conduction, alter the geometry, and can denervate regions of the atria, altering refractory periods.

There are several systems of classifying AF. These include the historic paroxysmal and chronic AF. The classification system published jointly by the American Heart Association, American College of Cardiology, and the Heart Rhythm Society is the most widely used.[37] This system defines AF as either paroxysmal, persistent, or permanent. When a patient has had two or more episodes, AF is considered recurrent. If recurrent AF terminates by itself, it is designated paroxysmal; but if it does not, it is termed persistent. Termination by pharmacologic therapy or electrical cardioversion before expected spontaneous termination does not change the designation of paroxysmal. Permanent AF includes cases of long-standing AF (>1 year), in which cardioversion has not been indicated or has failed to convert the arrhythmia. This terminology applies to episodes of AF that last more than 30 seconds and that are unrelated to a reversible cause. Recently, Cox has offered a new system, defining intermittent and continuous AF.[38–40] In this system, the patient is either in AF all the time (continuous) or not (intermittent). This has not been widely accepted by professional organizations.

Recently, there has been a great deal of emphasis placed on the role of the pulmonary veins (PVs) in AF. Paroxysmal AF often originates in the PVs.[41] In humans, the anatomy of the PVs is variable, with electrically excitable cardiac muscle extending 1 to 4 cm beyond the ostium of the veins.[42] The cardiac muscle is insulated from the smooth muscle of the veins by connective tissue. The muscle fiber orientation is complex, spiraling perpendicularly around the vein with other fibers running parallel to the vein. There is an increase in connective tissue going from the proximal to the distal end of that portion of the vein composed of cardiac muscle.[43] Developmental biology data suggest that pacemaker tissue may be present in the PVs. During the development of human embryos, HNK-1 antigen, a specific marker of the developing specialized conduction system, is seen not only in the sinus and AV node regions, but also in the regions superior and inferior to the sinoatrial (SA) node, the coronary sinus, the lower septum, and the PVs.[44]

In studies in the guinea pig, normal and abnormal automaticity have been observed in the PVs.[45] However, no pacemaker tissue has been found within the veins of humans or animals. Another potential mechanism of focal activation is afterdepolarizations. Studies in animal models have also shown that these can be evoked from the PVs in animal models.[45] Intraoperative mapping studies in humans have shown ectopic atrial beats originating from the region of the PVs.[36] Biatrial mapping studies by Schmitt and colleagues have shown that the premature beats that trigger AF were located in the PVs 53% of the time.[46]

Arora and coworkers have shown in the canine atria that action potential durations are longer but more inhomogeneous in the PVs than adjacent muscle.[47] Recent studies by

Cha and associates, also in the dog, show exactly the opposite data with shorter action potential duration in the PVs than the body of the left atrium.[48] However, in atria that have remodeled as a result of a fast rate, the PVs no longer have a shorter refractory period than the surrounding tissue. In this model, removal of the PVs did not prevent the initiation or maintenance of AF. Jais and colleagues have shown in humans that refractory periods are longer in the PVs than adjacent muscle.[49]

Conduction velocities within the PVs are 0.3 m/s compared to surrounding left atrial tissue with velocities of 0.9 m/s.[47] The complex fiber orientation and the lack of Cx40 in the veins, a major determinant of conduction velocity in the atria, probably contribute to this slower conduction.[43] The slow conduction properties are particularly manifested during premature depolarizations that occur in the veins. Mapping studies in animal models have shown conduction to be decremental and highly anisotropic.[47] Arora and colleagues have demonstrated reentry within the veins with a circuit size of 1 to 2 cm.[47] Without adequate spatial resolution, such small circuits would appear focal. Most intraoperative and catheter mapping systems do not have the spatial resolution within the PVs to separate reentrant from non-reentrant mechanisms. So even though "focal" fibrillation may be reported, it is important to realize that this does not rule out reentry as a mechanism underlying the arrhythmia.

What is the significance of these data to the diagnosis and treatment of AF in patients? First, the mapping studies of Schmitt and associates suggest that the trigger for initiating AF is in the PVs slightly over 50% of the time.[46] Likewise, if the triggers were outside the PVs, but the other substrates were within the veins, the AF would be prevented. This logic assumes that there is only one driver of the AF. As shown by the low success of curing AF by isolating a single vein, this is not true for most patients. Nitta and coworkers have also observed concurrent drivers of AF by using intraoperative mapping in patients with mitral valve disease.[50] In our experience, the driver of AF moved during the short period in which we intraoperatively map (~10 minutes) in about 50% of patients. These data suggest that many patients have multiple potential drivers of AF. Furthermore, caution should be taken in interpreting various interventional studies, whether catheter ablation or surgery, about the underlying mechanisms involved in a patient's AF. In very few studies are only the PVs isolated. In some studies, all the PVs, adjacent atrial muscle, and the muscle in the oblique sinus between the veins are isolated. This represents about one-third of the left atrium. Some ablation devices extend beyond the PVs, further increasing the amount of left atrium that is isolated. This substantially reduces the critical mass needed to sustain AF and may incorporate other non-PV substrates.

It should be pointed out that the definitions of paroxysmal, continuous, persistent, chronic, and permanent AF do not imply a specific mechanism. Even though some data would suggest that in paroxysmal AF patients PV isolation is effective 70 to 80% of the time, it is clear that 20 to 30% of the time the PVs are not involved. Likewise, in persistent AF, where PV isolation alone has a much lower success rate, the definition of AF does not implicate a mechanistic substrate. The PVs have the substrates needed to initiate and maintain AF in some patients; however, they are not the only regions within the atria that can initiate and maintain AF, and present diagnostic technologies rarely allow for a preoperative delineation of mechanism.

HISTORICAL ASPECTS

Because of the inadequacy of medical therapy for AF, there has been strong interest in the nonpharmacologic treatment of AF, which led to the development of various catheter-based and surgical techniques in the 1980s and 1990s. Unfortunately, many of them were not successful in addressing all of the detrimental sequelae associated with AF. Nevertheless, they helped physicians gain fundamental knowledge regarding the mechanism of AF and laid a foundation for the development of the Cox-Maze procedure. The Cox-Maze procedure today is recognized as the gold standard for surgically curing AF. The next section of this chapter will briefly describe these various surgical procedures developed in an attempt to cure AF.

The Left Atrial Isolation Procedure

In 1980, Williams and colleagues developed the *left atrial isolation procedure*, which was successful in confining AF to the left atrium and restoring the remainder of the heart to normal sinus rhythm.[51] This procedure was important because it restored normal ventricular rhythm without requiring a permanent pacemaker. Since the sinoatrial node, AV node, and internodal conduction pathways are located in the right atrium and interatrial septum, the left atrial isolation procedure did not interfere with normal AV conduction.

Electrically isolating the left atrium also unexpectedly restored normal cardiac hemodynamics. This occurred because the right atrium and the right ventricle contracted in synchrony following the procedure, providing a normal right-sided cardiac output that was then delivered to the left side of the heart. Although the left atrium was isolated, the left ventricle adapted immediately to the normal right-sided cardiac output and delivered a normal forward cardiac output.

By confining AF to the left atrium only, the left atrial isolation procedure eliminated two of the three detrimental sequelae of AF: irregular heartbeat and compromised cardiac hemodynamics. However, since the electrically isolated left atrium remained in AF, this procedure did not eliminate the risk of thromboembolism.

Catheter Ablation of the Atrioventricular Node-His Bundle Complex

In 1982, Scheinman and associates described the *catheter fulguration of the His bundle*, which controlled the irregular

cardiac rhythm associated with AF and other refractory supraventricular arrhythmias.[52] Similar to the left atrial isolation procedure, this procedure electrically isolated the arrhythmia to the atria. However, ablating the His bundle necessitated the implantation of a permanent ventricular pacemaker to restore normal ventricular rhythm.

Unfortunately, His bundle ablation only eliminated the irregular heartbeat. Both atria still remained in fibrillation, and the vulnerability to thromboembolism was unaffected. AV contraction remained desynchronized, compromising cardiac hemodynamics. Despite its drawbacks, this remains a common current treatment of medically refractory AF.

The Corridor Procedure

In 1985, Guiraudon and coworkers introduced the *corridor procedure* for the treatment of AF.[53] This was an operation that isolated a strip of atrial septum harboring both the SA node and the AV node, thereby allowing the SA node to drive the ventricles. This procedure corrected the irregular heartbeat associated with AF, but both atria either remained in fibrillation or developed their own asynchronous intrinsic rhythm because they were isolated from the septal "corridor." In addition, the atria were also isolated from their respective ventricles, thereby precluding the possibility of AV synchrony. The corridor procedure was soon abandoned because neither the hemodynamic compromise nor the risk of thromboembolism associated with AF was addressed.

The Atrial Transection Procedure

All three surgical procedures developed in the early 1980s described above had attempted to isolate and confine AF to a certain region of the atria, stopping it from propagating its effects on the ventricles. None of the aforementioned procedures were targeted to cure the AF itself.

In 1985, Cox's group described for the first time a series of experiments that attempted to cure AF in a canine model.[54] After a number of experiments, it was found that a single long incision across both atria and down into the septum cured AF (Fig. 59-1). This "atrial transection" procedure prevented the induction and maintenance of AF or atrial flutter in every canine receiving the procedure.[55]

Unfortunately, this procedure was effective but not curative in its clinical application. It soon became apparent that the surgical cure of AF would require a more complete understanding of the fundamental electrophysiologic mechanisms of AF.

DEVELOPMENT OF THE COX-MAZE PROCEDURE

Extensive experimental investigation at Washington University in St. Louis under the leadership of James L. Cox led to the introduction of the Maze procedure in 1987.[55–57] The

Cox-Maze procedure was designed to interrupt any and all macro-reentrant circuits that might potentially develop in the atria, thereby precluding the ability of the atrium to flutter or fibrillate (Fig. 59-2). In contrast to the previous procedures, the Maze procedure successfully restored both AV synchrony and a regular heartbeat, thus significantly decreasing the risk of thromboembolism and stroke.[58] The operation involved creating a myriad of incisions across both the right and left atria. The surgical incisions were placed so that the SA node could "direct" the propagation of the sinus impulse throughout both atria. It also allowed

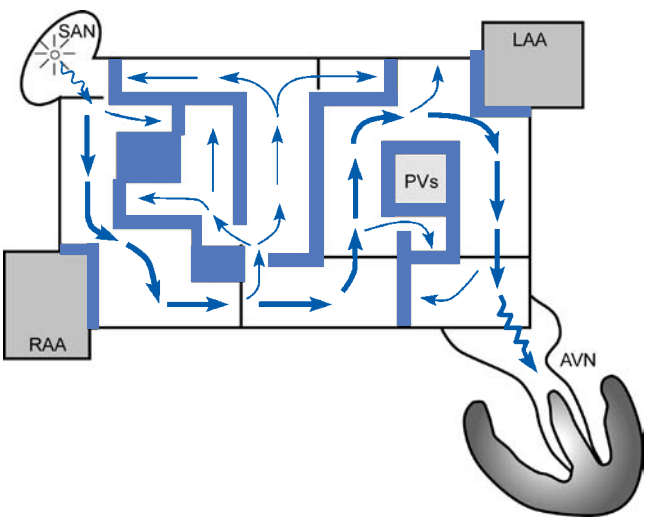

Figure 59-2. By creating a myriad of surgical incisions in the atria, the Maze procedure is designed to preclude the ability of the atria to fibrillate. AVN = atrioventricular node; LAA = left atrial appendage; PVs = pulmonary veins; RAA = right atrial appendage; SAN = sinoatrial node. (*Reprinted with permission from Cox et al.*[55])

all of the atrial myocardium to be activated, resulting in preservation of atrial transport function in most patients.[59]

The original technique, the Maze-I procedure, was introduced in 1991, only to be soon modified to become the Maze-II procedure because of late chronotropic incompetence and a high incidence of pacemaker implantations. The Maze-II procedure, however, proved to be extremely technically difficult to perform. It was therefore modified again to become the Maze-III procedure, also known as the Cox-Maze III procedure today[60,61] (Fig. 59-3).

Over the last decade, the Cox-Maze procedure has become the gold standard for the surgical treatment of AF. In a long-term study of patients who had the Cox-Maze procedure, 97% of the patients at late follow-up were free of AF.[62] These superb results have been reproduced by other institutions around the world.[63–65]

NEW SURGICAL ABLATION TECHNOLOGY

Despite its proven efficacy, the Cox-Maze III procedure did not gain widespread acceptance. Few cardiac surgeons were willing to add the procedure to a coronary revascularization or valve procedure due to its complexity and technical difficulty. In an attempt to simplify the operation and make it more accessible to the average surgeon, groups around the world have replaced the incisions of the traditional cut-and-sew Cox-Maze III procedure with linear lines of ablation.[66] These linear lines of ablation are created using a variety of energy sources, including radiofrequency energy, microwave, cryoablation, laser, and high-frequency ultrasound.

The development of these new ablation technologies has revolutionized the surgical treatment of AF by taking a technically difficult and time-consuming operation and making it easy for all cardiac surgeons to perform. Today, most patients undergoing open heart surgery who have chronic AF are offered concomitant AF surgery. Another advantage of ablation technologies is the promise for the development of less-invasive procedures for AF performed via a small incision or port. A beating heart procedure with high efficacy is the ultimate goal of these efforts. With the availability of easy-to-use ablation devices, numerous groups around the world have also introduced a variety of new procedures for AF involving more limited sets of atrial lesions. Some groups are currently performing only the left atrial lesions, while others are advocating PV isolation alone. Results with these new procedures will be discussed in a later section.

For ablation technology to reliably replace the incision in AF surgery, it must meet several important criteria. First, it must reliably produce bidirectional conduction block. This is the mechanism by which incisions prevent AF, by either blocking macro- or micro-reentrant circuits or by isolating trigger foci. In order to do this with certainty, an ablation device must have the capability to reliably make transmural lesions on the arrested heart from either the epicardial or endocardial surface.

The second crucial characteristic of the ablation device is its safety. This requires a precise definition of dose-response curves to limit excessive or inadequate ablation. The surgeon also must have knowledge of the effect of the specific ablation technology on surrounding vital cardiac structures, such as the coronary sinus, coronary arteries, and valves.

Third, a device should make AF surgery simpler and require less time to perform. This would require features such as rapidity of lesion formation, simplicity of use, and adequate length and flexibility.

Finally, the device ideally would have to be adaptable to a minimally invasive approach. This would require the ability to insert the device through minimal access incisions or ports. It would also require the device to be capable of creating epicardial transmural lesions on the beating heart. The following sections will briefly introduce the current ablation technologies, with their potential advantages and disadvantages.

Cryoablation

There are currently two commercially available sources of cryothermal energy that are being used in cardiac surgery. The older technology utilizes nitrous oxide and is manufactured by Cooper Surgical (Trumbull, Conn). The nitrous oxide devices use rigid reusable electrodes. More recently, CryoCath Technologies (Montreal, Quebec, Canada) has developed a device using argon. This device uses a disposable flexible catheter that has a 6-cm ablation electrode. At 1 atmosphere of pressure, nitrous oxide is capable of cooling tissue to –89.5°C, while argon has a minimum temperature of –185.7°C.

The size and depth of cryolesions are determined by numerous factors, including probe temperature, tissue temperature, probe size, the duration and number of ablations, and the particular liquid used as the cooling agent.[67] With

conventional nitrous oxide, 2- to 3-minute ablations have been shown to reliably create transmural lesions on both the right and left atrium. Because of the heat sink provided by circulating endocardial blood, epicardial cryolesions on the beating heart made with nitrous oxide have not been transmural.

There are few data available regarding dose-response curves or efficacy for cryoablation with argon. There has been one published study on epicardial cryoablation using the argon device in a sheep model.[68] In the animal study, they examined epicardial cryoablation for 2 minutes at –160°C on the beating heart. They were able to create transmural lesions 62% of the time around the PVs. Five of six lesions on the right atrial appendage were transmural, but only two of eight (25%) on the left atrial appendage were transmural. Thus, this device appears to be capable of creating transmural epicardial lesions, but not in a reliable fashion.

Cryoablation has the benefit of preserving the fibrous skeleton of the heart and thus is one of the safest of the technologies available. Nitrous oxide cryoablation has extensive clinical use and has an excellent safety profile. While cryothermal energy appears to have no permanent effects on valvular tissue or the coronary sinus, experimental studies have shown late minimal hyperplasia of coronary arteries and these structures should be avoided.[69–72] In the report by Doll and colleagues, they were able to create mild esophageal lesions in seven of the eight cases with epicardial cryoablation.[68]

In summary, cryoablation is unique among the currently available ablation technologies in that it destroys tissue by freezing rather than heating. The important advantage is its ability to preserve tissue architecture. The nitrous oxide technology has a well-defined efficacy and safety profile and is generally safe except around the coronary arteries. The potential disadvantages of cryoablation technology include the relatively long time necessary to create a lesion (1 to 3 minutes). There is also difficulty in creating lesions on the beating heart due to the "heat sink" of the circulating blood volume. Furthermore, if blood is frozen during epicardial ablation on the beating heart, it coagulates, creating a potential thromboembolism risk.

Radiofrequency Energy

Radiofrequency (RF) energy has been used for cardiac ablation for many years in the electrophysiology laboratory.[73] It was one of the first energy sources to be used in the operating room for AF ablation. RF energy can be delivered by either unipolar or bipolar electrodes, and the electrodes can be either dry or irrigated.

There are numerous unipolar RF devices available for ablation. Boston Scientific (Natick, Mass) has marketed the Cobra catheter, a dry unipolar catheter that is a segmented, flexible device with variable lesion lengths of 10 to 95 mm. It has seven electrodes, which can be individually selected and temperature controlled. The more recent Cobra Cooled surgical probe is the same size, but has an irrigated tip that allows for better heat transfer. Medtronic (Minneapolis, Minn) has developed a unipolar RF device, the Cardioblate catheter. This is an irrigated unipolar RF catheter used to make point-by-point ablations by dragging it across tissue to make a linear lesion.

Bipolar RF is similar to unipolar energy except that two electrodes, instead of one, are used to focus the path of energy. This allows for faster ablation (usually less than 10 seconds), while limiting destruction to tissue that is in close proximity to the electrodes. For bipolar RF, the electrodes are clamped over the targeted atrial tissue. The first bipolar RF device was introduced by AtriCure, Inc.(Cincinnati, Ohio). The Isolator was a specially designed clamp with 1-mm wide, 5-cm long electrodes embedded in the jaws. The device was unique in that it had an online measurement of lesion transmurality. The conductance between the electrodes was measured during ablation. When the conductance dropped to a stable minimum level, this correlated well both experimentally and clinically to histologically transmural lesions.[74–76] Two other bipolar ablation devices have since been released by Medtronic and Boston Scientific.[77,78] The Medtronic bipolar device, the Cardioblate BP, has an irrigated, flexible jaw along with an articulating head, with 5 cm-long electrodes.

RF energy uses an alternating current in the range of 100 to 1000 KHz. This frequency is high enough to prevent rapid myocardial depolarization and the induction of ventricular fibrillation, yet low enough to prevent tissue vaporization and perforation. Resistive heating occurs only within a narrow rim of tissue in direct contact with the electrode, usually less than 1 mm. The deeper tissue heating occurs via passive conduction. With unipolar catheters, the energy is dispersed between the electrode tip and an indifferent electrode, usually the grounding pad applied to the patient. In the bipolar clamp devices, alternating current is generated between two closely approximated electrodes. This results in a focused ablation. The lesion size depends on electrode-tissue contact area, the interface temperature, the current and voltage (power), and the duration of delivery. The depth of the lesion can be limited by char formation and the tissue-electrode interface. To resolve this problem, irrigated catheters were developed; this reduced char formation by keeping temperatures cooler at the tissue interface. These irrigated catheters have been shown to create larger-volume lesions than dry RF devices.[79,80]

Dose-response curves for unipolar RF have been described.[81–83] Although unipolar RF has been shown to create transmural lesions on the arrested heart in animals with sufficiently long ablation times (60 to 120 seconds), there have been problems in humans. After 2-minute endocardial ablations during mitral valve surgery, only 20% of the in vivo lesions were transmural.[82] Epicardial ablation has been even more difficult. Animal studies have consistently shown that unipolar RF is incapable of creating epicardial transmural lesions on the beating heart.[83,84] A recent clinical study has confirmed this problem. Epicardial RF ablation in humans resulted in only 7% of lesions being transmural despite

electrode temperatures of up to 90°C.[85] Bipolar RF ablation, on the other hand, has been shown to be capable of creating transmural lesions on the beating heart both in animals and humans with average ablation times between 5 and 10 seconds.[74,75,86]

Because RF ablation is a well-developed technology, much is known about its safety profile. A number of clinical complications of unipolar RF devices have been described, including coronary artery injuries, cerebrovascular accidents, and the devastating creation of esophageal perforation leading to atrioesophageal fistula.[87–90] Use of the bipolar RF devices has eliminated most of the collateral damage that is created with the unipolar devices, and there have been no injuries described with these devices.

Unipolar RF ablation has been shown to be able to create endocardial transmural lesions most of the time, but is incapable of creating epicardial transmural lesions on the beating heart. As with all unipolar energy sources, it radiates unfocused heat, and this can cause collateral injury if not used carefully. On the other hand, bipolar RF ablation has the advantage of focused and discrete lesions that can be made in a fraction of the time of unipolar ablation. Furthermore, by using a conductance algorithm, bipolar RF ablation is capable of creating reliable transmural lesions. However, bipolar RF ablation has the disadvantage that it can only ablate tissue that can be clamped and is difficult to use in proximity to valve tissue.

Microwave Energy

Microwave ablation uses dielectric heating created by electromagnetic waves emitted from an antenna. The field that is created causes oscillation of molecular dipoles, generating heat and an area of ablated tissue. This technology produces efficient and uniform penetration without overheating and does not cause char formation.[91,92]

Guidant Corporation, Inc. (Indianapolis, Ind) has developed the only microwave catheters available in the United States, the Flex 4 and Flex 10. The former has a flexible 4-cm long sheath and is able to ablate in increments of 2 cm; the latter device is 20 cm long and also ablates in 2-cm increments. Both probes consist of a flexible and malleable sheath containing a 2-cm microwave antenna that emits microwave radiation at 2450 Hz. The Flex 10 design allows for placement of the sheath around the heart and then positioning of the antenna within the sheath in 2-cm increments to create a continuous linear lesion up to 20 cm in length. Minimally invasive techniques with the Flex 10 catheter have been described.[93,94]

Microwave energy encompasses electromagnetic waves between 30 and 3000 MHz; 915 MHz or 2450 MHz is used in ablation catheters. Microwave devices radiate an electromagnetic field into the surrounding tissue. The energy is independent of current flow from ablation catheter to tissue. As a result, catheter contact pressure, orientation, and tissue desiccation do not limit lesion formation. In vitro as well as in vivo studies of the bovine heart show that lesion size depends on the power, duration of delivery, and antenna length and width. The depth is dependent on power and duration.[91,95]

Dose-response curves for microwave ablation have been developed on the arrested heart.[91,92] In our laboratory, both the Flex 4 and Flex 10 devices created uniformly transmural lesions on cardioplegic-arrested porcine atrial tissue after 90 seconds of ablation.[92] Thus, this energy source appears capable of creating endocardial transmural lesions on the arrested heart. However, there is controversy regarding its ability to create transmural lesions on the beating heart.

In a recent canine study, the Flex 10 device was evaluated. The histology showed full circumferential lesions after 1 to 3 weeks; however, they were not fully transmural.[96] In our laboratory, the Flex 10 device has been incapable of creating reliable transmural lesions on the beating heart in an acute porcine model.[92]

Microwave technology ablates tissue using heat, and is therefore potentially susceptible to complications of collateral damage. There are reports of coronary artery stenosis after microwave ablation.[97] Concern for esophageal injury exists, although there are no published reports of such injury from this modality. Reports of over 600 patients from several clinical trials have not mentioned complications attributable to the microwave device, lending confidence in its safe use.[98]

Microwave ablation has an advantage over RF ablation in that the device is less likely to create char formation, and is less sensitive to electrode positioning. Microwave ablation can reliably create endocardial lesions, but there is some question of whether it is capable of creating epicardial lesions on the beating heart. Microwaves are still an unfocused source of heat energy with the potential to cause collateral injury. A disadvantage of this technology is that there is no way to judge the transmurality of ablation during surgery.

Laser Energy

A laser energy device consists of a power source, a laser medium (usually crystal or gas), and two mirrors, one at each end of the medium; one is fully and the other is partially reflective. Lasers boost the energy state of the medium to a higher level, and then the device allows energy to be emitted when the medium drops back to its lower state. This mechanism allows controlled direction of energy output. Lasers produce narrow, deep lesions in a short amount of time, making this an attractive power source for ablation.[99]

Edwards Lifesciences (Irvine, Calif) has developed the Optiwave 980, an endocardial device with a malleable shaft and a 5-cm diffuser that allows creation of linear ablation lines. Two forms of light are carried from the source via fiber-optics to the treatment site: visible red light to allow targeting of tissue, and invisible 980-nm–wavelength laser energy that induces the destruction of tissue. The light is scattered within the tip and a diffuser disperses the infrared laser energy perpendicular to the shaft.

The lesion created is a direct result of tissue heating, termed photocoagulation. Laser beam power decreases within tissue in an exponential decay manner, and absorption is tissue-dependent. Because adipose tissue and cardiac muscle each has its own specific extinction coefficient (the amount of scattering and absorption), the infrared laser is able to penetrate myocardial tissue independent of overlying fat.

Laser energy produces no surface charring, and direct heating of the tissue by the laser is accompanied by conductive heating that allows penetration. The lesion size depends on the amount of energy delivered, the level of tissue heating, and the amount of scatter, transmission, reflection, and absorption.

The ability of laser to create transmural lesions in atrial tissue has been investigated in a small number of studies.[99–104] Keane and Ruskin demonstrated the ability of the diode laser to create transmural, linear, continuous atrial lesions in a goat model.[101] In a study by Thomas and associates, narrow, transmural lesions were successfully created in the myocardium using a laser catheter.[99] Reddy and colleagues used laser ablation for PV isolation in a goat model, demonstrating successful creation of transmural lesions.[100] Lemery and coworkers showed similar results in a pig model.[103] Linear transmural lesions in canine myocardium were successfully created using laser radiation by Fried and colleagues as well.[102,104] Clinical trials with humans have been encouraging, but results are few.[105]

Laser ablation is a promising technology that may have some advantages over other energy sources. The energy is focused, unaffected by overlying fat, and may have enhanced penetration. A disadvantage of this technology is that the energy delivery is unconfined and thus could cause collateral damage. Another problem is that at present, there is no way to judge transmurality of the ablation during procedures.

High-Intensity Focused Ultrasound

Although the interaction between ultrasound energy and biologic tissue has been a subject of interest for decades, its application with cardiac tissue has only been recently studied.[106–112] Ablation using ultrasound in the surgical treatment of AF is currently the newest modality being tested clinically. Ultrasound effectively ablates tissue via mechanical hyperthermia.[113] When ultrasound waves are emitted from the transducer, the resulting wave travels through the tissue causing compression, refraction, and particle movement. This translates into kinetic energy and ultimately thermal coagulative tissue necrosis.

Ultrasound can either be utilized in a focused (HIFU; high-intensity focused ultrasound) or nonfocused form. HIFU produces rapid, high-concentration energy in a focused area, and is able to create transmural epicardial lesions through epicardial fat in less than 2 seconds.[114] Nonfocused ultrasound, although it has a simpler transducer system and more flexibility, requires more time to create transmural lesions.

Over recent years, HIFU has become an increasingly attractive possible modality for cardiac ablation for several reasons. HIFU is unique in its ability to create noninvasive, non-contact focal ablation in three-dimensional volume without affecting intervening and surrounding tissue. HIFU utilizes ultrasound beams in the frequency range of 1 to 5 MHz or higher, creating focused lesions quickly by rapidly raising the temperature of the targeted tissue to above 80°C, effectively killing the cells.[115] There is a steep temperature gradient between the focus and collateral tissue, demonstrated by the sharp demarcation seen between the volume of necrotic tissue and normal surrounding cells on histology.[116] By using focused ultrasound waves, HIFU is able to create targeted thermal coagulation of tissue at a very well-defined focus without harming intervening tissue with very limited collateral damage.

Another advantage of HIFU is its mechanism of thermal ablation. Most other energy sources heat or cool tissue by thermal conduction, thereby creating a graded response depending on the distance from the energy source. Since the mechanism of thermal conduction in these energy sources is relatively slow, they may be particularly susceptible to cooling near blood vessels or "heat sink."[117,118] HIFU, on the other hand, ablates tissue by directly heating the tissue in the acoustic focal volume and is affected much less by the "heat sink."[119]

Since ultrasound can be collimated through fluid media, it is ideal for application with a balloon delivery system. Saliba and associates evaluated the use of an 8-MHz HIFU transducer mounted in a saline-filled balloon designed for pulmonary vein isolation (PVI) for the treatment of AF. Unfortunately, only 30% of 33 patients who underwent PVI were cured of AF in late follow-up. The variability of the PV anatomy was the main reason for the poor results, often requiring several applications to achieve PVI during the procedure.[109,110]

Because of its ability to focus the target of ablation at specific depths, epicardial surgical ablation using HIFU has recently gained interest. In a recent study by Ninet and colleagues, 103 patients with AF underwent beating-heart PV isolation procedures with concomitant cardiac procedures.[120] At 6-months' follow-up, the freedom from AF was 85%.[120] Epicardial approaches using HIFU for the ablation of AF allow for the possible development of minimally invasive techniques.

In summary, each ablation technology has its own advantages and disadvantages. In the future, it will be imperative to develop a more complete understanding of the effects of each surgical ablation technology on atrial hemodynamics, function, and electrophysiology.

ELECTROPHYSIOLOGIC EVALUATION

Initial experimental electrophysiologic studies showed that AF was much more complex than other arrhythmias previously treated with surgery.[57] The traditional algorithm of

obtaining pre- and postoperative mapping data and applying this information to guide the specific surgical technique, as was done with arrhythmias such as Wolff-Parkinson-White and ventricular tachycardia, was not feasible. AF is complex and requires a high density of closely placed electrodes as well as a sophisticated mapping and signal processing system to define the particular mechanism in each individual patient.

Although it was previously thought that AF was maintained by multiple macro-reentrant circuits, there is evidence that focal triggers can be responsible for the initiation of paroxysmal AF.[41,121] Therefore, preoperative mapping data may allow surgeons to identify the particular triggers of AF in individual patients. Unfortunately, the analysis of multiple atrial electrograms over long periods of time has been difficult. Thus, it usually is not possible to locate the precise focal point of origin responsible for the initiation or maintenance of AF in the majority of patients.

For the reasons mentioned above, preoperative mapping is not routinely performed on patients prior to undergoing the Cox-Maze procedure. Furthermore, the traditional activation sequence is difficult and time-consuming and is not suitable to provide useful real-time information during the procedure. Improvements in technology and further experimentation may provide the means for faster data analysis and a map-directed approach may be feasible in the future. Recent studies have shown the possibilities of determining the location that has the highest frequency of activation from multiple sites in the left or right atrium. This may allow for designing a more directed and limited set of lesions. Although still investigational, these new techniques may eventually allow us to customize the incision set to the specific underlying mechanism.[50,122,123]

SURGICAL INDICATIONS

Lone Atrial Fibrillation

The main indication for the surgical treatment of AF is intolerance of the arrhythmia in patients who have failed medical therapy. Patients with paroxysmal atrial flutter or fibrillation are usually more symptomatic than those with continuous or permanent AF. Major symptoms include dyspnea on exertion, easy fatigability, lethargy, malaise, and a general sense of uneasiness. Patients with lone AF should receive a trial of medical therapy prior to surgery. A significant number of patients with AF are referred to surgery because of significant side effects or intolerance to antiarrhythmic drugs.

The development of tachycardia-induced cardiomyopathy (TIC) in patients with AF is another important indication for surgery. TIC is a condition characterized by atrial or ventricular dysfunction resulting directly from increased heart rates in an otherwise structurally normal heart.[124] Untreated TIC can lead to heart failure. It is extremely important to recognize this condition in patients with uncontrolled AF, since TIC is reversible if normal sinus rhythm is restored surgically.[125]

Another important indication for surgery is in patients who develop a contraindication to long-term anticoagulation, such as patients who have suffered intracranial hemorrhage while on warfarin. Up to one-third of patients screened for participation in prior clinical trials of the use of warfarin in AF were deemed ineligible for chronic anticoagulation, primarily because of a high perceived risk for bleeding.[126,127] Patients taking warfarin have twice the rate of intracerebral hemorrhage mortality in a dose-dependent manner.[128] In a recent study, the annual rate for major bleeding in anticoagulated patients with AF was 2.3% per year, and the rate for intracranial hemorrhage was 0.9% per year.[127]

In addition, patients with chronic AF who suffer from cerebrovascular accidents despite adequate anticoagulation should be considered for surgical treatment. Anticoagulation with warfarin reduces the risk of ischemic and hemorrhagic stroke by over 60% in patients with AF, but does not eliminate this dreaded complication.[18,129] Approximately 20% of patients who underwent the Cox-Maze III procedure at our institution had experienced at last one episode of cerebral thromboembolism that resulted in a significant temporary or permanent neurologic deficit prior to having the procedure.[62]

Concomitant Atrial Fibrillation

Virtually all patients with AF who undergo elective cardiac surgery (i.e., coronary artery bypass grafting or valve repair or replacement) should be strongly considered for a concomitant Cox-Maze procedure. Recent studies have shown that adding a Maze procedure can decrease the late risk of cardiac- and stroke-related deaths in these patients.[130,131] The only contraindication to the Maze procedure would be in high-risk patients who have tolerated their AF well and have not had problems with anticoagulation.

SURGICAL TECHNIQUE: THE COX-MAZE IV PROCEDURE

The final version of the standard cut-and-sew technique to cure AF was the Cox-Maze III procedure.[55,123,132,133] However, only a handful of cardiac surgeons still perform this operation. At most centers, many of the surgical incisions have been replaced with linear lines of ablation using different energy sources. At Washington University, bipolar RF energy has been used successfully to replace most of the surgical incisions of the Cox-Maze III procedure. Our current procedure incorporates the identical lesions as the Cox-Maze III procedure and has been named the Cox-Maze IV[134] (Fig. 59-4). Our clinical data have shown that this modified operation has significantly shortened the operative time while maintaining the high success rate of the traditional cut-and-sew Cox-Maze III procedure.[135]

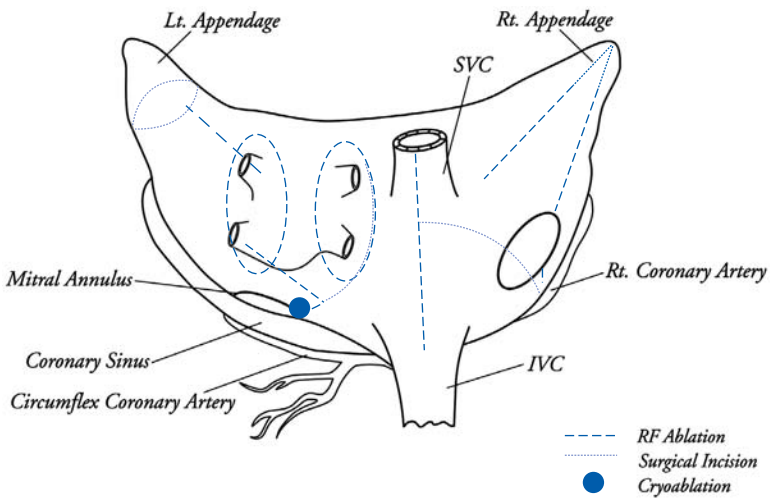

Figure 59-4. The Cox-Maze IV lesion sets. IVC = inferior vena cava; RF = radiofrequency; SVC = superior vena cava. (*Adapted with permission from Gaynor et al.*[86])

Bipolar RF ablation was chosen for the Cox-Maze IV procedure over other potential energy sources for several reasons. First, the device allows for the online determination of lesion transmurality by measuring the conductance between the two electrodes. Second, the bipolar RF device has extremely short ablation times, with 5- to 6-cm long transmural ablations performed in 5 to 15 seconds. Third, the lesions are narrow (2 to 3 mm in width) and tissue injury is confined to within the clamp. This virtually eliminates the possibility of unwanted collateral injury.[88,136–138]

The Cox-Maze IV procedure is performed with the patient on cardiopulmonary bypass using bicaval cannulation. Initially, the heart is perfused at normothermia to maintain sinus rhythm and allow for accurate determination of pacing thresholds. The right and left PVs are bluntly dissected. If the patient is in AF, an intravenous bolus of amiodarone is given and the patient is cardioverted. The ablations are performed on the cuff of atrial tissue surrounding the right and left PVs (Fig. 59-5). Proof of electrical isolation is confirmed after ablation by pacing from both the superior and inferior PVs.

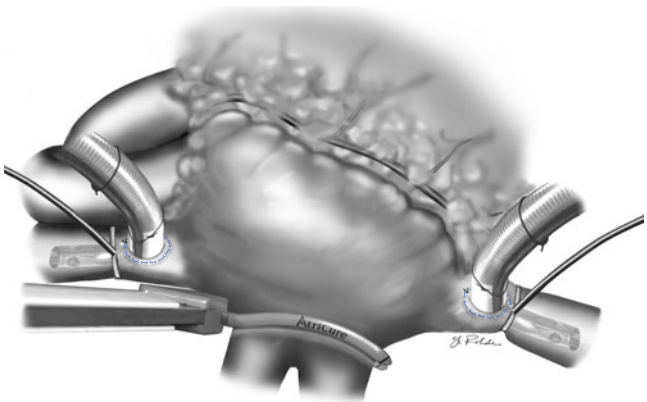

Figure 59-5. The right and left PVs are isolated using the bipolar RF device. (*Reprinted with permission from Damiano et al.*[134])

The right atrial lesions are performed with the heart beating. A small, 1-cm atriotomy is created in the right atrial appendage (Fig. 59-6). The bipolar device is placed through this incision to create the right atrial free wall lesion. A 2-cm gap is left between this ablation and a vertical atriotomy that extends from the crista terminalis to the AV groove approximately at the acute margin of the right ventricle. After bluntly dissecting the AV groove fat pad, the bipolar RF device is placed across the anterior tricuspid annulus and extended slightly onto the valvular tissue at approximately the 10 o'clock position. Occasionally, a cryolesion is needed to complete this ablation line so that it extends onto the valvular tissue. A similar lesion is created to the posterior tricuspid valve annulus at the 2 o'clock position. To complete the right-sided lesions, the RF clamp is placed up to the

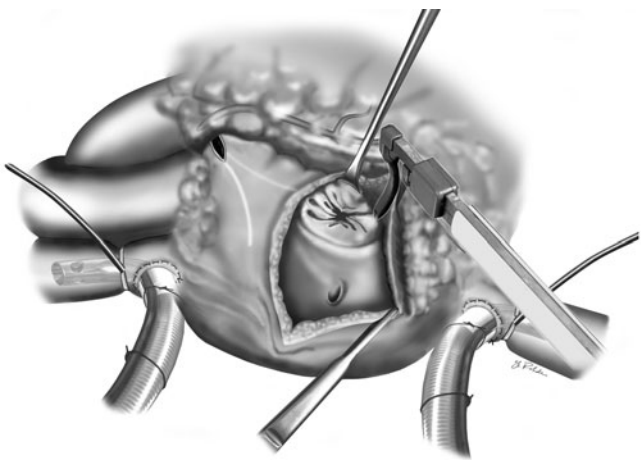

Figure 59-6. The right vertical atriotomy is created down to the tricuspid valve annulus. The bipolar RF clamp is advanced with one arm inside the right atrium and the other outside the atrium down to the tricuspid annulus. An ablation is performed with care being taken to ensure that the jaws of the clamp extend onto the tricuspid valve. (*Reprinted with permission from Damiano et al.*[134])

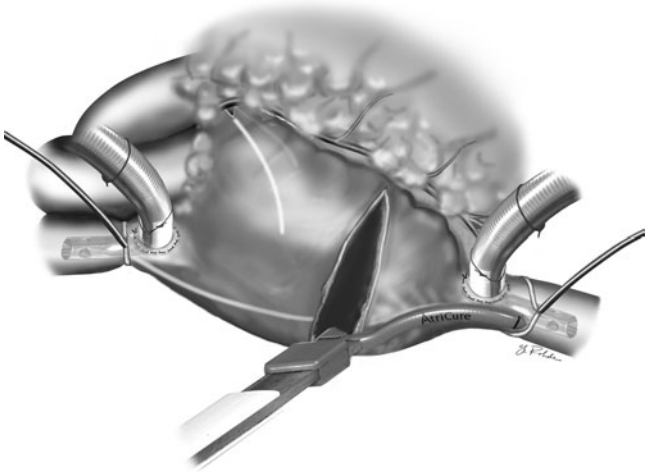

Figure 59-7. From the inferior aspect of the vertical right atriotomy, the bipolar RF clamp is placed up to the superior vena cava, extending the ablation onto caval tissue. The clamp is then rotated 180° and extended in a similar fashion onto the inferior vena cava to create the ablation. (*Reprinted with permission from Damiano et al.*[134])

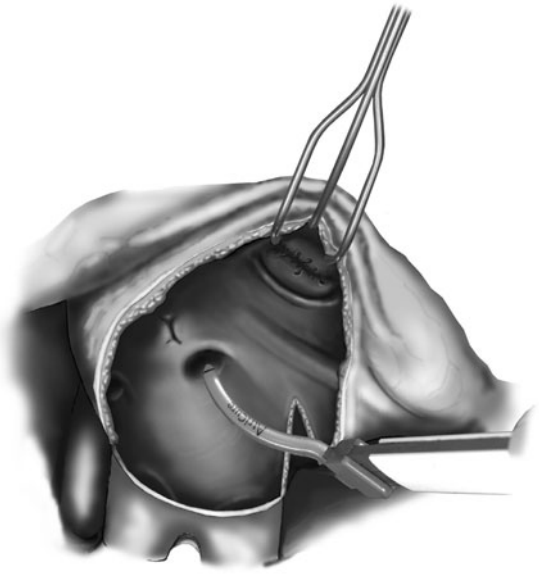

Figure 59-9. A standard left atriotomy is performed below the interatrial groove and extended inferiorly around the right inferior PV. The bipolar RF clamp is used to create a lesion connecting the left atrial incision inferiorly to the ablation line encircling the left PVs. (*Adapted with permission from Damiano et al.*[134])

superior vena cava and then rotated 180° and extended down onto the inferior vena cava (Fig. 59-7).

The left-sided lesions are performed through a standard left atriotomy with the heart arrested (Fig. 59-8). This incision is extended inferiorly around the right inferior PV and superiorly onto the dome of the left atrium. The incision is made such that it connects to the right PV ablation lesion. A lesion is made with the bipolar RF device connecting the left atrial incision inferiorly to the ablation line encircling the left PVs (Fig. 59-9). If the left atrium is greater than 5 cm in size, another lesion is performed from the superior aspect of the left atriotomy, across the dome of the left atrium and into the left superior PV. A lesion is then created up to the mitral valve annulus, usually with the bipolar RF device. This lesion is performed from the inferior aspect of the left atrial incision across the posterior left atrium, AV groove, and the coronary sinus. The ablation is performed in the space between the circumflex and right coronary artery circulation in order to avoid damage to the coronary arteries. If the patient has a left dominant circulation, this lesion is usually created surgically in order to identify and spare the circumflex artery. A cryolesion is placed at the mitral valve annulus using a 15-mm bell cryoprobe cooled to –60°C for 2 to 3 minutes. The left atrial appendage is amputated and a final ablation is performed through the amputated left atrial appendage onto the left superior PV (Fig. 59-10). The left atrial appendage is oversewn, the aorta is unclamped, and the right atrial incision is closed during the rewarming period.

In patients undergoing a mitral valve replacement, it is recommended to amputate the left atrial appendage prior to performing the other left atrial lesions to avoid excessive traction. Pacing wires are left in place for control of postoperative arrhythmias.

SURGICAL TECHNIQUE: OTHER ATRIAL FIBRILLATION PROCEDURES

There have been a number of new surgical procedures introduced in an attempt to cure AF. This plethora of procedures

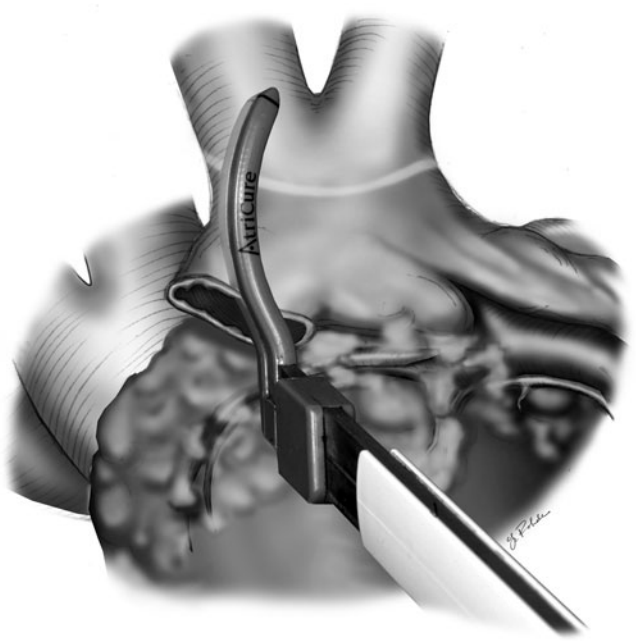

Figure 59-10. The bipolar RF clamp is placed through the amputated appendage down into the left superior PV with one jaw inside and the other outside the atrium. This ablation should overlap the previously performed encircling ablation of the left PVs. (*Reprinted with permission from Damiano et al.*[134])

can be divided into two groups. The first group comprises operations including only left atrial lesions to cure AF. These procedures typically involve isolating the PVs, either as a box or separately with a connecting lesion. Most surgeons also advocate creating a lesion to the mitral annulus from the PV isolation and amputation of the left atrial appendage.[87,139–147]

The second group includes those who advocate only isolating the PVs for curing AF.[94,148,149] These procedures involve either isolating the PVs as a box, or separately (Fig. 59-11). Different devices have been developed to create these lesions, including laser, microwave energy, and high-frequency ultrasound.

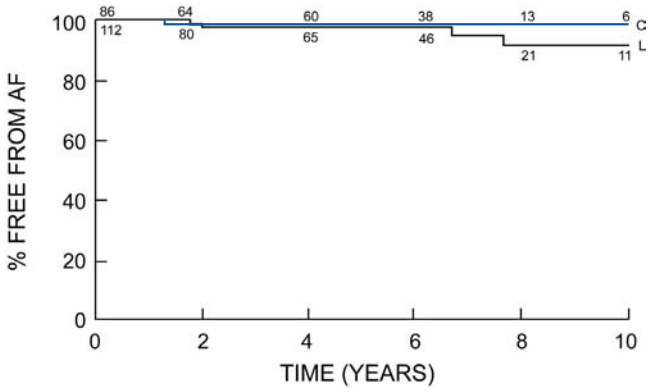

Figure 59-12. Kaplan-Meier survival analysis of freedom from recurrent AF. The numbers on each line indicate the number of patients at risk. There was no difference in the long-term estimate of freedom from AF between the lone Cox-Maze group (L) and the concomitant group (C; $p = 0.64$). (*Reprinted with permission from Prasad et al.*[62])

SURGICAL RESULTS: THE COX-MAZE PROCEDURE

The Cox-Maze III procedure has excellent long-term results. In our series at Washington University, of 198 consecutive patients undergoing the procedure, 97% of all patients at a mean follow-up of 5.4 years were in sinus rhythm (Fig. 59-12). There was no statistical difference in cure rates between patients undergoing a lone Cox-Maze procedure and those also undergoing concomitant procedures. The cure rate off all antiarrhythmic medications was 80% and 73%, respectively, in patients undergoing lone and concomitant Cox-Maze procedures at late follow-up.[62] Similar results have been obtained from other centers around the world (Table 59-1) with the traditional cut-and-sew technique (Cox-Maze III).[63,65,150]

Early results from patients who underwent the Cox-Maze IV procedure have been encouraging as well. In a prospective, single-center trial from our institution, 91% of patients at 6 months' follow-up were free from AF. The new procedure was also safe, as its operative mortality in this

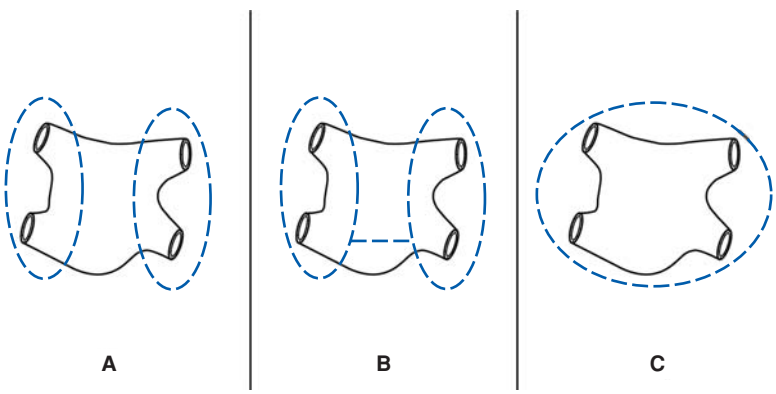

Figure 59-11. Pulmonary vein isolation is performed either separately or as a box. (A) illustrates pulmonary vein isolation separately. (B) illustrates pulmonary vein isolation separately plus an ablation line connecting the inferior aspect of the two isolated islands. (C) illustrates the isolation of all four pulmonary veins as a box.

Results of the Cut-and-Sew Cox-Maze III Procedure

Study	No. of patients	Mean follow-up in years	Overall freedom from AF (%)	Drug-free freedom from AF (%)
Prasad et al[62]	198	5.4 ± 2.9	97	80
Schaff et al[65]	221	2	85–90	N/A
McCarthy et al[63]	100	3	91	N/A
Arcidi et al[150]	99	N/A	97	N/A

AF = atrial fibrillation.

series was 0%.[86] A multicenter trial of the Cox-Maze IV procedure had similar results.[135] In this study, 96% of patients were free of AF at 6 months, and there was no operative mortality in this group of 30 patients.[58]

The Cox-Maze IV procedure has significantly shortened the mean cross-clamp times for a lone Cox-Maze from 93 ± 34 minutes for the Cox-Maze III procedure to 54 ± 27 minutes for the Cox-Maze IV ($p < .001$), and from 123 ± 36 minutes for the Cox-Maze III procedure alone to 99 ± 30 minutes ($p < .005$) in those undergoing the Cox-Maze III procedure concomitantly with another cardiac operation.[86]

The Cox-Maze III procedure also has been effective at decreasing the risk of late stroke in this high-risk patient population.[151] In Cox's experience in over 300 patients, there were only two perioperative strokes (0.7%) and only one minor stroke during long-term follow-up (11.5 years; mean 3.9 ± 2.7 years). The long-term stroke rate after the Cox-Maze III procedure was 0.1% per year, despite the fact that the vast majority of patients were off all anticoagulation at last follow-up.[58]

In a series from Japan that examined the effect of mitral valve replacement on stroke rates, the Cox-Maze procedure was found to significantly decrease the incidence of late stroke, even in those patients already receiving anticoagulation for mechanical mitral valves. Patients who underwent a concomitant Cox-Maze procedure with their mitral valve replacement were 99% stroke-free at 8-years of follow-up, while the group with lone mitral valve replacement only had an 89% stroke-free rate.[152]

While the efficacy of the Cox-Maze procedure has been established, there are only a few studies examining the benefit of adding the operation during concomitant cardiac surgery in patients with chronic AF. Bando and associates[131] reported on 363 patients with nonischemic, noncardiomyopathy mitral regurgitation with preoperative AF undergoing either mitral valve repair alone or mitral valve repair with a concomitant Cox-Maze procedure. At late follow-up, adding a Cox-Maze procedure significantly improved the freedom from cardiovascular-related death (97% versus 82%; $p < .001$) and freedom from stroke (98% versus 83%; $p < .001$). Adding a Cox-Maze procedure also improved late left ventricular function as measured by left ventricular end-systolic dimension.[131]

SURGICAL RESULTS: OTHER ATRIAL FIBRILLATION PROCEDURES

A number of centers around the world have suggested performing ablation only in the left atrium to successfully cure AF. This concept is supported by the fact that the majority of paroxysmal AF appears to originate around the PVs and the posterior left atrium. The success rates from these procedures have varied between 58% and 95% at different follow-up periods[87,139,143,146,147,153–165] (Table 59-2). One of the complications from performing surgery only on the left atrial lesions is postoperative atrial flutter. In a series by Golovchiner and associates from Tel Aviv that evaluated a group of 50 patients who underwent left atrial ablation, 13% of patients developed atrial flutter at a 15-month follow-up. Left atrial flutter was present in four of the six patients.[165] In a similar series from Japan, 21% (5 of 24) patients developed recurrent atrial flutter or tachycardia during follow-up (36.9 ± 14.1 months) after left atrial ablation.[146]

Other surgeons have proposed only isolating the PVs. These procedures have had mixed results. In studies evaluating patients undergoing concomitant procedures (particularly mitral valve surgery), the outcomes have been poor. At Washington University, 23 patients with AF (12 with paroxysmal AF and 11 with permanent AF) underwent PVI only during concomitant mitral valve surgery or coronary revascularization. The average duration of AF in 12 patients was 6.7 ± 14.2 years. At a mean follow-up of 57 ± 37 months, only 50% of patients were free from AF.

In a larger series, Gaita and colleagues[139] evaluated 105 patients who underwent AF and valve surgery by assigning them randomly to three groups. Two groups included patients who underwent left atrial ablation using two different patterns. The third group was composed of patients who

Table 59–2.

Results Of Left Atrial Lesions Only

Study	No. of patients	Energy source	Removal of LAA	Mean follow-up in months	Overall freedom from AF
Gaita et al[139]	70	Cryoablation	No	41 ± 17	90% (at 24 mo)
Benussi et al[143]	132	RF ablation	Yes*	16.9 ± 14.2	77% (at 36 mo)

had PVI-alone. Only 29% of patients in the PVI-only group were free from AF at last follow-up. In contrast, 76% of patients who had more extensive left atrial lesions were free from AF.[139]

In another series, Isobe and coworkers evaluated a group of 101 patients who underwent PVI with cryoablation concomitantly with mitral valve surgery. In this series, 53% of patients were free from AF at last follow-up.[166] Without antiarrhythmics, only 24% of the patients were free from AF.

Finally, in another study from Japan, 66 patients with mitral valve disease and chronic AF underwent pulmonary vein cryoablation. At late follow-up, 61% of patients were free from AF, but only 17% of patients were free from AF without antiarrhythmics.[148] Compared to the 97% rate of freedom from AF at late follow-up seen in mitral valve patients undergoing the Cox-Maze III procedure at Washington University, these results compare very unfavorably.[62]

Some groups around the world have suggested performing endoscopic or limited-access beating-heart PVI in patients with lone AF. Although there have been some promising early results, the series are too small with too short of a follow-up to evaluate their efficacy.[93,94,167,168] In a series by Wolf and associates, 27 patients underwent video-assisted bilateral PVI and left atrial appendage exclusion for AF.

Bipolar RF energy was used and patients underwent bilateral thoracotomies. Ninety-one percent of patients were free from AF without antiarrhythmics postoperatively.[168] However, the average postoperative follow-up was only 6 months. Similarly, Salenger and associates published a series of 14 patients who underwent completely thoracoscopic PVI and amputation of the left atrial appendage. Microwave energy was used for epicardial ablation. Only 67% of patients were free from AF at 12 months follow-up.[94]

In summary, there have been exciting recent advances in the surgical treatment of AF. The use of ablation devices has widely expanded the number of patients undergoing arrhythmia surgery. At present, virtually all patients undergoing concomitant cardiac surgery with chronic AF should undergo a curative procedure for their AF. Ablation technology has also simplified the operation to the point that minimal access procedures are a reality for the treatment of lone AF. In the coming years, it is likely that there will be continuing progress in this area, and that a beating-heart, limited-access procedure with high efficacy will be developed.

CHAPTER 60

Surgical Implantation of Pacemakers and Automatic Defibrillators

Henry M. Spotnitz • George H. Humphreys, II

Pacemaker and defibrillator management is increasingly complex and is the subject of comprehensive reviews.[1–3] In 2760 procedures in the authors' experience at New York Presbyterian Hospital, 23% of pacemaker recipients and 5% of implantable cardioverter defibrillator (ICD) recipients were octogenarians. The 80- to 90-year-old age group accounted for 22% of pacemaker generator replacements and 5% of ICD generator replacements. The incidence of pacemaker insertion in patients older than 75 was 2.6% in a recent survey of noninstitutionalized adults. The high pacemaker efficacy and cost-effectiveness in late middle-aged and younger elderly patients are widely accepted,[4] but the appropriate role for ICD insertion in much older patients is still in evolution. Application of pacemaker and ICD technology is now feasible across the entire span of human age, and the technology continues to expand into pacing for heart failure and prophylaxis against lethal arrhythmias. Arrhythmia control devices are increasingly becoming part of the purview of the electrophysiologist. Thoracic surgeons are being progressively excluded from ICD insertion and endocardial biventricular pacemaker insertion due to lack of interest, as well as referral patterns and recommendations of cardiology groups. However, because some aspects of pacemaker/ICD insertion still require thoracotomy, it is likely that thoracic surgeons will continue to play an important role both as implanters and consultants for complex or complicated cases. This chapter presents an overview of practical information related to pacemaker and ICD insertion and management.

PACEMAKERS

History

The early history of cardiac surgery was complicated by iatrogenic heart block, which was lethal. Transthoracic pacing was implemented with Zoll cutaneous electrodes.[5] Percutaneous endocardial pacing was described in 1959.[6] A "permanent" pacemaker using epicardial electrodes was described in 1960.[7] Pacemakers and implantation techniques have progressed rapidly since the 1960s, reflecting advances in bioengineering and technology. Persistent problems include lead durability, chronic inflammatory responses to pacemaker materials, infection, device size, programmer compatibility, and expense.

Anatomy of Surgical Heart Block

The conduction system is vulnerable to injury during heart surgery. Complete heart block can occur as a result of suture placement during aortic, mitral, or tricuspid valve surgery, or during closure of septal defects or during myotomy for idiopathic hypertrophic subaortic stenosis. The sites of these lesions are indicated schematically in Fig. 60-1. Occlusion of the blood supply to the conduction system or incomplete myocardial protection can also result in surgical heart block.

Device Description

A permanent pacemaker consists of pacing leads[8] and a pacemaker generator. The generator contains a battery, a telemetry antenna, and integrated circuits. The power source is generally lithium iodide, but rechargeable and nuclear batteries have been used. The integrated circuits include programmable microprocessors, oscillators, amplifiers, and sensing circuits.[9] The integrated circuits employ CMOS (complementary metal-oxide semiconductor) technology, which is subject to damage by ionizing radiation.[10] Current pacemakers can store and monitor their internal status, the condition of their external connections, their programmed settings, recent activity, and notable arrhythmias. Unfortunately, each device responds only to the programmer of its manufacturer.

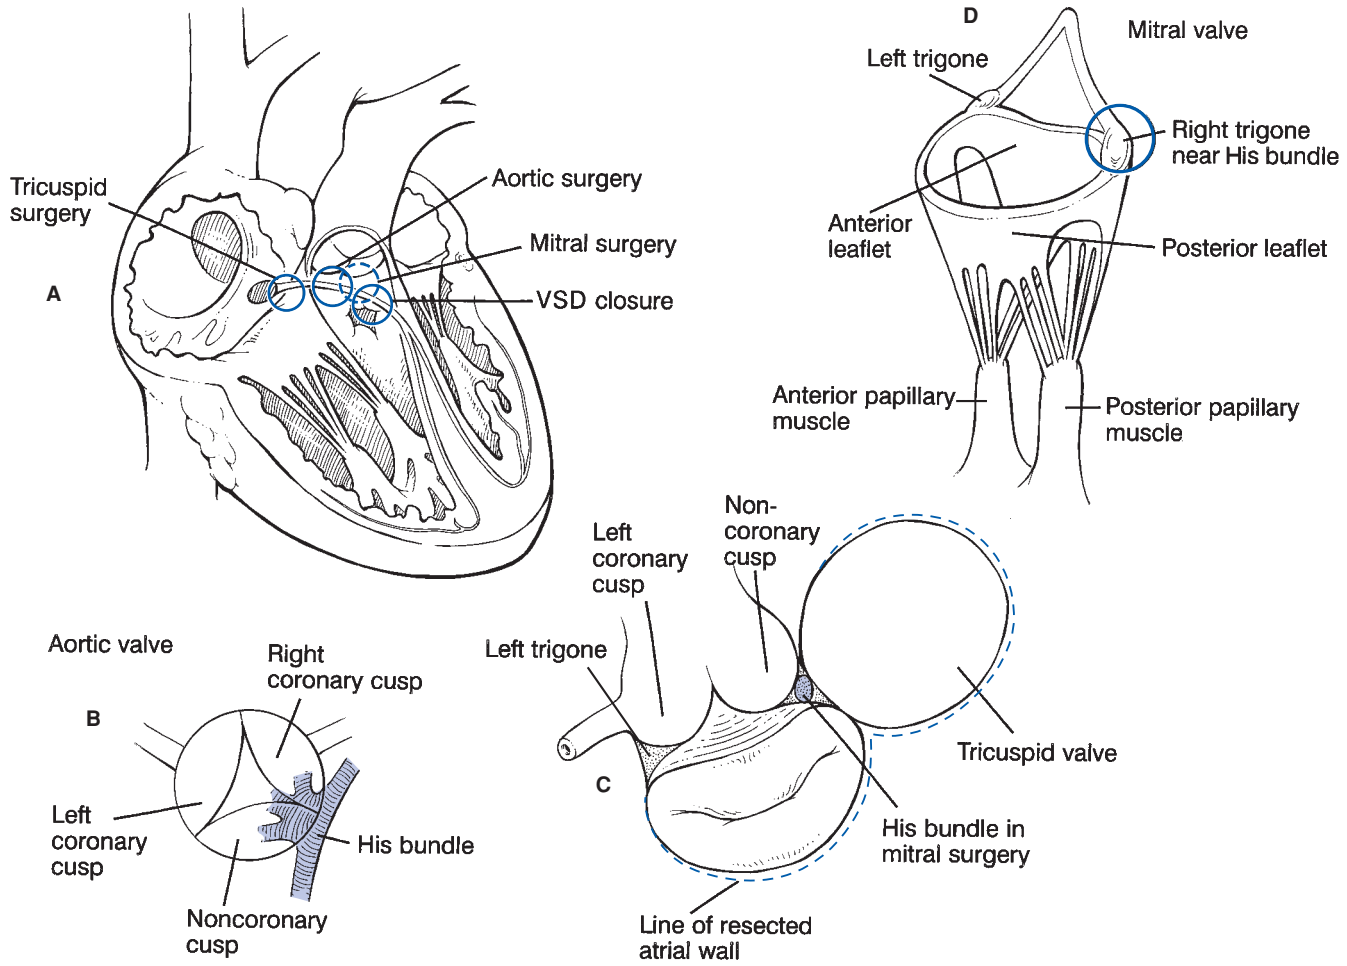

Figure 60-1. Anatomy of iatrogenic complete heart block. (A) The His bundle and nearby cardiac structures are illustrated. Common sites of injury are indicated. (B) The His bundle lies within the ventricular septum, just below the commissure between the noncoronary and right coronary aortic cusps. (C) During mitral valve surgery, the His bundle is on the ventricular septum anteromedial to the posterior commissure and right fibrous trigone (D). VSD = ventricular septal defect.

International Pacemaker Code

A five-letter code describes pacemaker function.[11] Three letters are in common usage (Table 60-1). The first letter is the chamber paced and the second is the chamber sensed. The third letter describes the algorithm used to integrate pacing and sensing functions. Thus, fixed-rate ventricular and atrial pacemakers are VOO and AOO, respectively. Demand (rate-inhibited) pacers for the same chambers would be VVI and AAI. VDD refers to a pacemaker that paces the ventricle only, but senses both the atrium and the ventricle.[12] DVI involves atrial and the ventricular pacing, but only ventricular sensing. DDD is the most flexible of current designs. The suffix R added to the three-letter code indicates rate responsiveness, discussed below.

Cellular Electrophysiology

Cellular membrane depolarization and repolarization provide a mechanism for automaticity of the cardiac chambers and the conduction system. In the resting state, the outer surface of the cell is positive, and the interior of the cell is negative. Applying a negative current to the outside of the cell theoretically produces a greater potential difference and would be expected to be more successful in depolarizing the cell than a positive current. Empirically, this is correct—unipolar pacing thresholds are lowest when the negative terminal (cathode) of a pacing system is connected to the heart and the positive terminal (anode) is connected to ground.[13] Electrogram amplitude is not substantially affected by polarity.

Rhythm Disorders

Indications for pacemaker insertion

Concern about indiscriminant referral for pacemaker insertion led to Medicare guidelines (Table 60-2). Supporting documentation may be required for billing. There are three categories: accepted, controversial, and not warranted.

Table 60–1.

International Pacemaker Code

I chamber paced	II chamber sensed	III pacing algorithm
A	A	T
V	V	I
D	D	D
O	O	O
S	S	—

A = Atrium; D = Dual (both triggered and inhibited); I = Inhibited; O = None; S = Single; T = Triggered; V = Ventricle.

Table 60–2.

Medicare Guidelines for Cardiac Pacemaker Implantation (Pre-2002)

Accepted, in symptomatic patients with chronic conditions
- Atrioventricular block
  - Complete (third-degree)
  - Incomplete (second-degree)
    - Mobitz I
    - Mobitz II
  - Incomplete with 2:1 or 3:1 block
- Sinus node dysfunction (symptomatic)
  - Sinus bradycardia, sinoatrial block, sinus arrest
  - Bradycardia-tachycardia syndrome

Controversial
- In symptomatic patients
  - Bifascicular/trifascicular intraventricular block
  - Hypersensitive carotid sinus syndrome
- In asymptomatic patients
  - Third-degree block
  - Mobitz II
  - Mobitz II atrioventricular block following myocardial infarction
  - Congenital atrioventricular block
  - Sinus bradycardia <40 bpm with long-term necessary drug therapy
  - Overdrive pacing for ventricular tachycardia

Not warranted
- Syncope of undetermined cause
- In asymptomatic patients
  - Sinus bradycardia, sinoatrial block, or sinus arrest
  - Bundle-branch blocks
    - Mobitz I

Source: Modified from AMA Council on Scientific Affairs: The use of cardiac pacemakers in medical practice. Excerpts from the report of the Advisory Panel. JAMA 1985; 254: 1952; superseded by Gregoratos et al.[15]

Symptomatic third- or second-degree heart block or profound sinus bradycardia is an accepted indication for pacemaker insertion if adequately documented. Sinus bradycardia may justify pacemaker insertion if symptoms can be causally related to the underlying bradyarrhythmia. Documentation often requires Holter monitoring. Pacemakers may be allowed for bradycardia <40 bpm in support of long-term necessary drug therapy for medical conditions such as supraventricular arrhythmias, ventricular tachycardia, hypertension, and angina. While novel indications for pacemaker therapy may be supported by clinical research, recognition of such advances by the Food and Drug Administration and insurance carriers is often slow. Electrophysiology studies are often helpful in defining proper treatment.[14] In 2002, an American College of Cardiology/American Heart Association/North American Society for Pacing and Electrophysiology (ACC/AHA/NASPE) task force released revised recommendations for pacemaker and ICD insertion that expand and detail the indications for device insertion. Any practitioner who implants arrhythmia control devices should be familiar with these guidelines.[15]

Atrioventricular block

First-degree block refers to prolongation of the P-R interval beyond 200 ms. First-degree block, at a low atrial rate, may progress to Wenckebach as the atrial rate is increased. Second-degree block involves incomplete dissociation of the atria and ventricles, which results in either progressive P-R prolongation and dropped beats (Wenckebach and Mobitz I, usually atrioventricular nodal block), or frequently dropped beats without prior progression of the P-R interval (Mobitz II, usually in the His-Purkinje system[16]). Third-degree block is complete atrioventricular (AV) dissociation, the atrial rate usually exceeding the ventricular rate. Left and right bundle-branch blocks and left anterior and posterior hemiblocks are partial conduction system blocks recognizable by electrocardiogram. The etiology of AV block includes ischemic heart disease, idiopathic fibrosis, cardiomyopathy, iatrogenic damage, AV node ablation, Lyme disease, bacterial endocarditis, systemic lupus erythematosus, and congenital heart disease.

Sinus node dysfunction

Whether sinus node dysfunction warrants pacemaker insertion depends on whether it is symptomatic and whether symptomatic bradycardia is caused by administration of drugs required for treatment of ancillary conditions. Causes of sinus node dysfunction include coronary artery disease, cardiomyopathy, and reflex influences.

Reflex problems include carotid sinus hypersensitivity, vasovagal syncope, and oddities like micturition-induced and deglutition syncope.[17] Both cardioinhibitory (asystole >3 s) and vasodepressor (marked fall in blood pressure despite adequate heart rate) components of reflex-mediated syncope are recognized. Whether pacemaker insertion is indicated is determined by symptoms and clinical judgment based on the duration of asystole. Tilt table testing provides objective data. Current trends favor pacemaker insertion for asystolic intervals >3 s medical therapy is favored for vasodepressor syncope even with substantial sinus bradycardia.[18] Dual-chamber (DDD or VDD) pacing is favored for this population because of beneficial effects of AV synchrony on stroke volume and symptomatology.

Features of Permanent Pacing

Dual-chamber pacing and atrioventricular synchrony

AV synchrony is important for maintenance of ventricular filling and stroke volume. In the normal heart, stroke volume is augmented 5 to 15% by AV synchrony versus the asynchronous state.[19,20] Left ventricular hypertrophy, decreased diastolic compliance, and heart failure increase the quantitative importance of AV synchrony.[21] Apical pacing of the right ventricle disrupts the normal sequence of activation, because depolarization spreads slowly and progressively over the ventricular walls rather than spreading rapidly and symmetrically through the conduction system.

The hypothesis that abnormalities of the sequence of activation can impair mechanical performance of the left ventricle has been established experimentally, and recent experience has demonstrated clinical relevance. Thus, disruption of the activation sequence is believed to explain why the ventricular-aortic gradient in idiopathic hypertrophic subaortic stenosis can be reduced in some patients by DDD pacing.[22–24] Furthermore, right ventricular outflow tract pacing may improve stroke volume when compared to apical pacing because of favorable effects on activation sequence.[25] Biventricular pacing via the right ventricular apex and coronary sinus in patients with advanced cardiomyopathy and an intraventricular conduction defect improves left ventricular function by restoring simultaneous contraction of the septum and free wall, "ventricular resynchronization."[26,27] Single-site, epicardial left ventricular pacing may provide similar benefits in some patients. For temporary epicardial DDD pacing in postoperative heart block, biventricular pacing is superior to right ventricular pacing[27] and may prove useful for treatment of left ventricular dysfunction after cardiac surgery.

Dual-chamber pacing algorithm

DDD pacemaker programming includes the lower rate, the upper rate, and the AV delay.[28] When the intrinsic atrial rate is between the upper and lower rate limits, the pacemaker tracks the atrium to maintain a 1:1 response between the right atrium and right ventricle. If the atrial rate falls to the lower rate limit, the pacemaker adds atrial pacing at the lower rate limit. If the atrial rate exceeds the upper rate limit, the ventricle is paced at the upper rate limit with loss of AV synchrony, resembling a Wenckebach effect.

The programmable AV delay defines the allowable interval between atrial and ventricular contraction. Timing starts with the atrial electrogram or pacing stimulus and continues until the allowed AV delay has elapsed. If no ventricular depolarization is detected during the delay, the ventricle is then paced. When the atrium is being paced because of low intrinsic rate, the actual P wave may be delayed 100 ms or more after the atrial pacing artifact. Thus, a longer AV delay is needed during atrial pacing than during atrial tracking, so these delays are programmable to different values.

Rate response to increased metabolic demand

During high metabolic demand, cardiac output is potentiated physiologically by increases in ventricular contractility, venous return, and heart rate. In patients with heart block and a normal sinus node response to exercise, dual-chamber pacing restores both AV synchrony and a physiologic rate response. However, with sinus node incompetence (no atrial rate increase with exercise) or with single-chamber ventricular (VVI) pacing, alternate methods of increasing heart rate with exercise are needed. Pacemakers with this capability are identified by the letter "R" (for "rate responsive") added to the three-letter pacemaker code. When the response of the sensor indicates increased metabolic demand, the lower rate of the pacemaker increases within a programmed range. Body vibration[29] or respiratory rate[30] is commonly employed to estimate demand in these pacemakers. Other indicators under evaluation include body temperature,[31] venous oxygen saturation,[32] QT interval,[33] right ventricular systolic pressure,[34] and right ventricular stroke volume.[35] All proposed and implemented indicators can produce aberrant increases in heart rate.[36] For example, a pacemaker that senses body vibration may cause tachycardia during a bumpy car ride. Elderly patients with sedentary life styles are not likely to benefit substantially from rate responsive pacing, and adverse effects can result from elevated heart rates in patients with evolving coronary disease.

Choice of pacing technique

Dual-chamber pacing has become a standard, with the exception of chronic atrial fibrillation. Paroxysmal atrial fibrillation is usually well handled by mode switching, and sinus rhythm apparently is better maintained by atrial than ventricular pacing.[37] Benefits of dual-chamber pacing in reflex-mediated syncope with cardioinhibitory features have been reported.[18] Whether the additional complexity of dual-chamber pacing is warranted in elderly patients who do not suffer from pacemaker syndrome is debatable. VVI or VVIR pacing is most appropriate for patients with bradycardia in chronic atrial fibrillation. AAIR is appropriate for cardiac allograft recipients with sinus arrest or sinus bradycardia.[38]

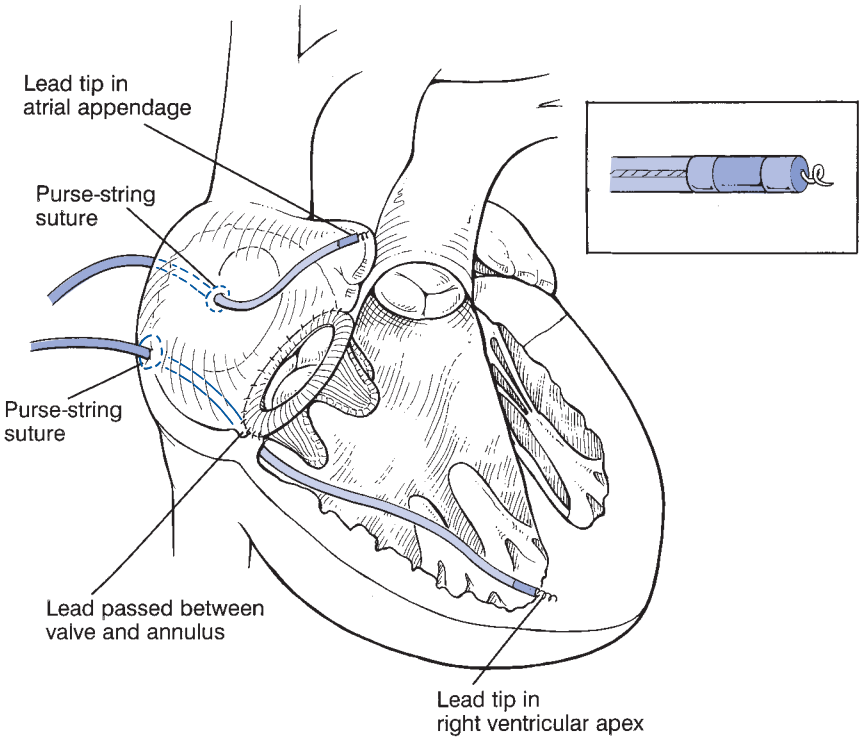

Figure 60-2. Endocardial pacing from an epicardial approach during cardiac surgery. Purse-string sutures in the atrium provide access; leads are advanced and screwed into position with the aid of introducers or by manual palpation. The ventricular lead is shown traversing the tricuspid plane between the valve prosthesis and the annulus. The inset shows the tip of the endocardial screw-in lead.

Biventricular pacing using an endocardial coronary sinus lead is recommended for symptomatic heart failure in patients with an ejection fraction below 36%, and QRS prolongation beyond 120 ms.[39]

Pacemaker Technology

Epicardial versus endocardial leads

Epicardial leads are generally inferior to endocardial leads in electrical characteristics and stress-related fractures.[40,41] Steroid-eluting tips and low-threshold designs with small contact surfaces have recently been developed for epicardial leads.[8] Fibrosis and trauma make epicardial pacing more difficult at reoperative cardiac surgery. Infected epicardial leads require a thoracotomy for lead removal. The epicardial approach is thus best reserved for congenital heart disease, tricuspid obstruction by mechanical valves, or venous thrombosis/occlusion. At thoracotomy, the option of inserting endocardial leads through an atrial purse-string is useful.[42] Left ventricular pacing is more easily achieved with epicardial than coronary sinus leads. A technical failure rate of 5 to 10% for coronary sinus lead insertion is stimulating development of minimal access approaches to biventricular pacing. Epicardial pacing avoids problems with coronary sinus entry and lead security while allowing many lead locations to be tested for efficacy.[43]

A preferred approach to DDD pacemaker insertion during open-heart surgery is indicated in Fig. 60-2. Endocardial atrial and ventricular fixed-screw, positive fixation leads are introduced into the heart through small atrial punctures and passed to the cardiac chambers. They are fixed into position by axial rotation, tested, and secured with purse-string sutures. When a tricuspid prosthesis or ring is being inserted, an option is to pass the right ventricular lead between the sutures securing the prosthetic ring and the valve annulus. A method for epicardial atrial application of endocardial pacing leads is illustrated in Fig. 60-3. Additional approaches to the patient with limited venous access are described below.

Unipolar versus bipolar

Bipolar leads include two conductors electrically separated by insulation. In unipolar systems, the patient's body is the

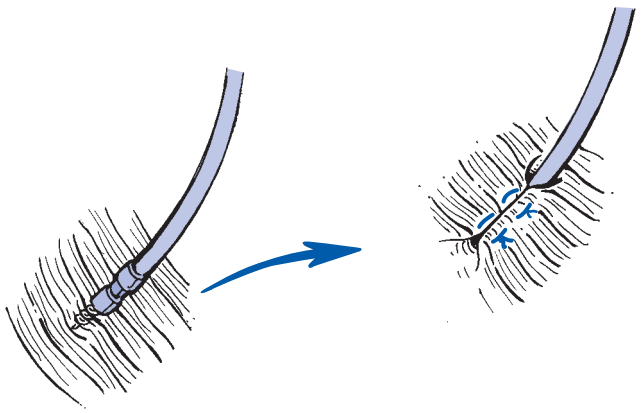

Figure 60-3. Permanent epicardial atrial pacing with an endocardial screw-in lead. The tip is screwed into the atrial myocardium, and atrial myocardium is then overlapped over the electrode with 6-0 monofilament suture.

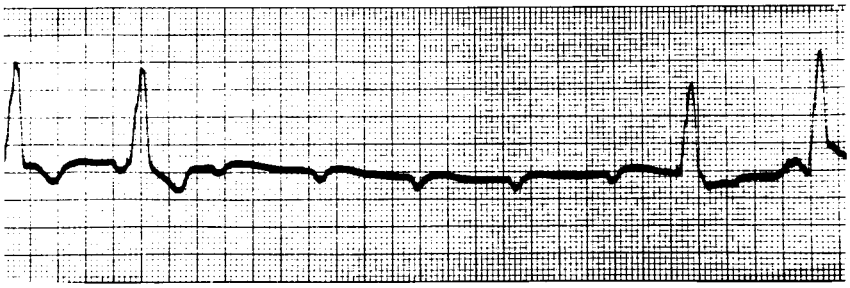

Figure 60-4. Telemetry from a patient with presyncopal episodes, third-degree heart block, poor escape rhythm, and a bipolar VVI pacemaker. The differential diagnosis of oversensing versus failure to capture was resolved when programming to VOO mode eliminated pauses. The patient underwent successful lead replacement and was discharged the next day. This is a life-threatening effect of oversensing. This older model pacemaker was not capable of monitoring electrograms to confirm the diagnosis.

second (anodal) conductor; a single conductor in the lead carries the negative current to the heart. Bipolar pacing systems reduce electrical noise (oversensing) and adventitious pacing of the diaphragm or chest wall. These advantages are offset by increased engineering complexity. Bipolar leads historically were prone to breakdowns of insulation or conductors. This could severely compromise sensing, pacing, or both[8,44] (Fig. 60-4). Early bipolar leads were thicker, stiffer, and less maneuverable than unipolar leads. Flexibility facilitates J bends and loops (Fig. 60-5) and reduces the chance of perforation through the right ventricular apex. Recent bipolar leads are much improved and similar in dimensions and handling to unipolar leads (Fig. 60-6). Short-term durability is improved, but durability of these leads beyond 10 years of service remains to be confirmed. The choice of endocardial leads for infants and small children is presently rather limited, but this is likely to improve in parallel with new technology for coronary sinus leads.

Lead fixation

We prefer positive fixation techniques, particularly in locations with sparse trabeculation. A small wire spiral or screw holds the lead in place (see Fig. 60-6G). In designs with extended screws, a soluble coating on the tip promotes venous passage. In retractable screw designs (Bisping), extension/retraction is accomplished by rotation of the pin at the lead tip. Axial clockwise rotation of these screw-in leads during fixation provides tactile feedback on the firmness and security of the attachment. Lead impedance provides feedback on the adequacy of tip extension in retractable screw designs.

Tined leads use miniature anchors in a variety of shapes and sizes to secure the lead tip between myocardial trabeculae (see Fig. 60-6A). Tined leads require a larger introducer than screw-in leads and are not as secure in smooth-walled (i.e., atria or ventricles in corrected transposition of the great vessels) or dilated chambers. Nevertheless, many physicians report excellent results with these leads.[45,46]

Temporary Pacing

Acute bradycardia can be treated with transthoracic pacing, temporary endocardial pacing, or chronotropic drugs including atropine, dobutamine, or isoproterenol. Right ventricular perforation has become less prevalent with current temporary endocardial leads but must be borne in mind if hypotension develops acutely after removal of temporary wires.

Bradycardia after cardiac surgery is commonly treated with pacing via temporary atrial and ventricular epicardial wires. Problems may include unfavorable evolution of right atrial or right ventricular thresholds and right atrial sensing. Atrial undersensing and pacemaker competition can precipitate atrial fibrillation or atrial flutter. If atrial sensing is not adequate, overdriving the atrium faster than the intrinsic

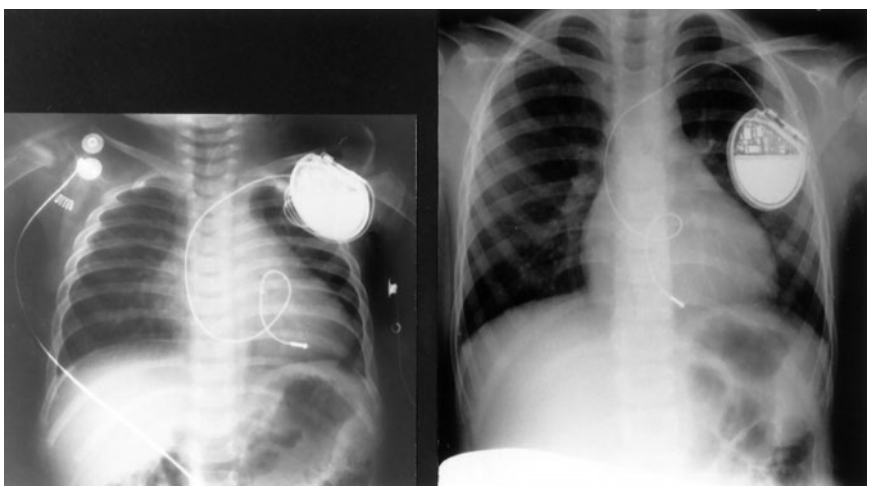

Figure 60-5. Excellent fixation and flexibility of small-diameter, positive fixation leads is illustrated in these x-rays, demonstrating the stability of a transvenous pacing lead with an intracardiac lead loop over 4 years of growth in a patient from age 1 (left) to age 5 years (right).

rate can prevent competition. Reversing polarity or inserting an independent ground wire in the skin under local anesthesia may alleviate problems with pacing threshold. The output of the external generator in volts or milliamps should be left at least twice as high as the threshold, and be measured daily. Ventricular undersensing in critically ill patients is hazardous, as pacing during the vulnerable period can precipitate ventricular tachycardia or fibrillation.

Cardiac output and pacing rate

For patients with hemodynamic compromise following cardiac surgery, pacing rate and AV delay can affect hemodynamics. Mechanisms include effects on valve leaks or fixed stroke volume. Mean arterial pressure can be used to estimate cardiac output, if systemic resistance is constant. Rate and timing adjustments should be assessed over intervals of less than 20 s to minimize reflex effects. The settings producing the highest sustained mean arterial pressure should also produce the highest cardiac output.

Pacemaker Insertion

Environment and anesthesia

Pacemaker and ICD surgery is increasingly performed in electrophysiology (EP) laboratories.[47] Whether in the operating room or EP lab, properly functioning equipment is essential. Infection control is critical;[48] operating room standards for air quality should be enforced. Pacemakers can be inserted in an EP laboratory by one skilled surgeon and one skilled circulating nurse. This is satisfactory until a problem like angina, transient ischemic attack, patient disorientation, or lidocaine toxicity arises. Also, certain patients are simply too unstable because of dementia, myocardial ischemia, heart failure, anxiety, or ventricular tachycardia to undergo pacemaker insertion without an anesthesiologist. Vancomycin reactions (red man syndrome), pacing-induced ventricular fibrillation, air embolism, and Stokes-Adams attacks are rare emergencies that are less problematic if considered in advance. Intraoperative death can occur due to hemorrhage, tamponade, or myocardial infarction. Good clinical judgment about when an anesthesiologist is essential is important. If English is not the patient's first language, a translator is helpful.

Monitoring

R-wave detection by an electrocardiogram (ECG) monitor is inadequate for pacemaker insertion, because pacing artifacts that fail to capture may not be distinguished from those that do. Thus, subthreshold pacing can elicit regular beeping from the monitor in an asystolic patient. Oxygen saturation monitors are preferable, as they beep only during blood flow. Pulse oximeters should not be placed on the same extremity as a blood pressure cuff. When monitors are unreliable, palpation by an anesthesiologist or nurse of the temporal, facial, or radial artery pulse can detect asystole.

Venous access strategy

Choices include which side will be employed and whether a cutdown or percutaneous venipuncture will be used. Cutdown approaches to the cephalic, subclavian, external jugular, and internal jugular system have been described.[49] Subclavian vein anatomy has been analyzed[44,50] in an effort to reduce the frequency of subclavian crush (Fig. 60-7). Subclavian puncture is associated with an apparently unavoidable but low incidence of pneumothorax, hemothorax, and major venous injury. Ultrasonic vessel locators may further reduce the frequency of injury during deep vein puncture.

Venous access is effectively impossible in superior vena cava syndrome or subclavian/innominate vein obstruction or thrombosis (e.g., with chronic dialysis, mediastinal tracheostomy, or multiple pacemaker leads). Access from below

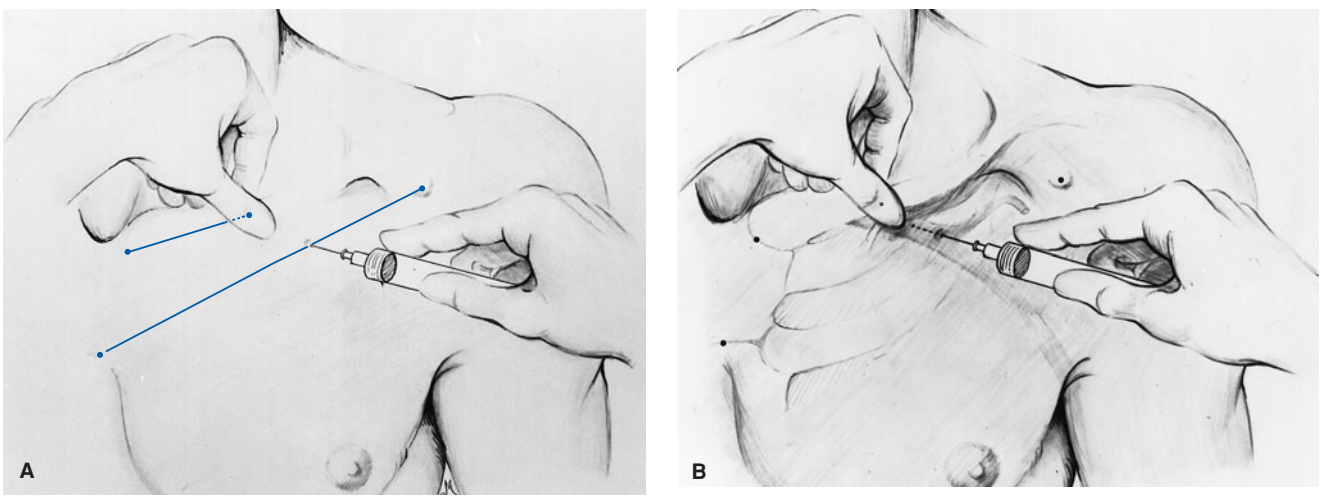

Figure 60-7. Landmarks for subclavian vein puncture. Potential complications of this procedure include pneumothorax, hemothorax, and lead damage due to subclavian crush injury. (*Reproduced with permission from Magney et al.*[44])

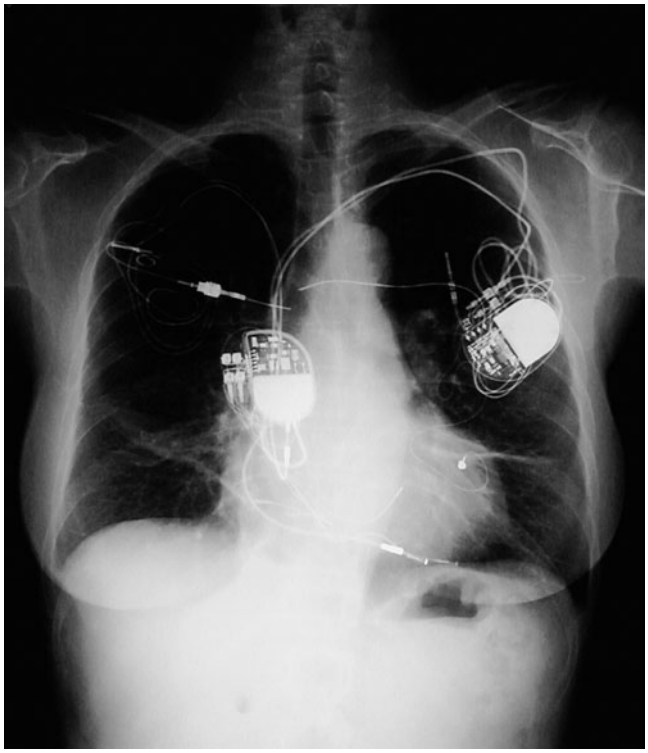

Figure 60-8. X-ray of a patient with very poor escape rhythm, bilateral venous obstruction, and severe exit block. A new pacing system was inserted through the right atrial appendage via right parasternal mediastinotomy. Her old pacemaker was programmed to back-up mode and scheduled for removal at a later date.

or even transhepatically is possible,[49,51] but the potential for bleeding, venous thrombosis, and pulmonary embolism are concerns. Right parasternal mediastinotomy exposure of the right atrium and a Seldinger approach with small introducers and atrial purse-string sutures can be useful in difficult cases[42] (Fig. 60-8).

Antibiotic prophylaxis

Antibiotic prophylaxis is indicated before insertion of a prosthetic device.[48] We prefer 1 g of intravenous cefazolin. We also irrigate the operative field with a portion of a solution of 1 g of cefazolin in a liter of warm saline. Patients who have a valve prosthesis or who have a penicillin or cefazolin allergy receive vancomycin (500 mg) and gentamycin (1 mg/kg).

Pacing systems analyzer

Pacing thresholds and electrogram amplitudes are measured with a pacing systems analyzer. Electrogram characteristics and slew rate can be examined with many current analyzers, and electrogram telemetry is available from most current pacemakers. The analyzer must function properly, and should be serviced and tested periodically. The batteries must be checked and replaced when depleted. Any discrepancies between measurements by the analyzer and the pacemaker should be noted and related functions of the analyzer rechecked.

A skilled operator is needed to run the analyzer and record the results. Alternatively, the analyzer can be placed in a sterile bag and operated from the surgical field. Manufacturer's representatives, an increasing presence in the operating room and EP lab, are skilled in operation of these analyzers.

Cables

The cables connecting the analyzer to the leads are the patient's lifeline. Even with excellent quality control, cables with open or reversed connections may be delivered to the surgical field. Errors can also occur in connecting the cables to the analyzer. A routine for testing the cables and the integrity of their connections is therefore recommended. After passing the cables from the operating table, pacing is initiated from the analyzer at 5-V output. The alligator connectors are then briefly touched to the subcutaneous tissue, with caution to minimize inhibition of the permanent pacemaker. The current measured in the analyzer should rise to 300 to 1000 ohms. If impedance is more than 5000 ohms, the circuit is faulty. The operation should not proceed until the problem is corrected, as the analyzer-cable circuit is defective. Connections to the analyzer should also be checked, since inadvertent reversal of polarity can make measured pacing thresholds inappropriately high. Even disposable leads with polarized connectors can be manufactured with the connectors reversed.

Fluoroscopy

Fluoroscopy is essential for transvenous device implantation, and operating room personnel need to be familiar with the equipment. Distracting problems with image orientation, rebooting, timers, brakes, and locks can be avoided by a knowledgeable team. Sudden failure of fluoroscopy at a critical point happens to every pacemaker surgeon with a large enough clinical volume. If a back-up unit is not available, the options include "blind" endocardial lead insertion, epicardial insertion, or postponement of the procedure. Overheating is an issue when fluoroscopy is prolonged, as may occur during biventricular pacemaker insertion. The use of low-dose and pulsed image options is desirable when prolonged use of the fluoroscope is planned.

Surgical approach

We approach the patient from the left when feasible. The fluoroscope, on the patient's right, is positioned carefully to allow visualization of the apex, right atrium, and deltopectoral groove. The right arm is extended to the right on an arm board. The drapes are suspended from IV poles. One pole is caudad to the arm board. Careful positioning allows the left clavicular region to be exposed while leaving the patient adequate light and air. After skin preparation, towels are aligned with the deltopectoral groove and clavicle to define the essential landmarks. The region of the incision and generator is infiltrated with 1% lidocaine to produce a field block. A 5- to 6-cm horizontal incision is created 4 cm beneath the clavicle, the lateral extent of the incision just reaching the deltopectoral

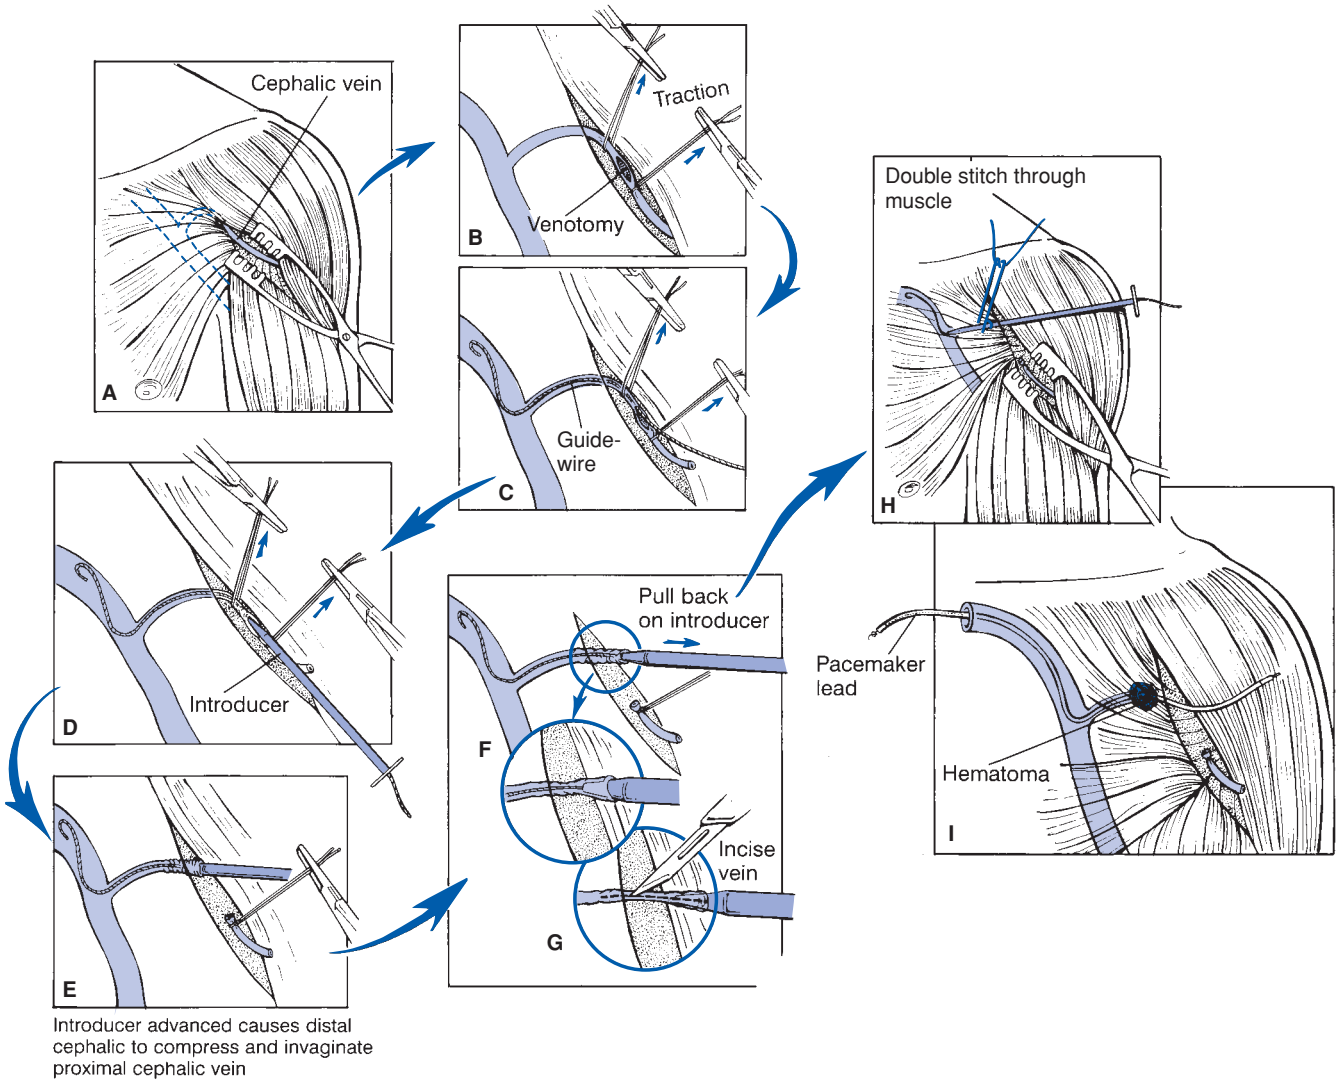

Figure 60-9. Cephalic cutdown approach to small veins that pass a guidewire, but not an introducer, to the central veins. Resistance results from entrapment of the introducer tip and inversion of the vein; the introducer advances by turning the vein outside-in. Fortunately, this entrapment can be put to good use. After the guidewire is advanced (C), a no. 18 Angiocath is passed over the guidewire to dilate the vein (not shown). This allows the introducer tip to enter the vein (D), but if the vein does not split, the introducer cannot be advanced (E). The impaled vein is exposed by gently withdrawing the introducer (F). The adherent, exposed segment of vein is then split longitudinally with a no. 11 blade (G). The procedure can be repeated, if necessary, to advance the introducer centrally. A purse-string suture approximates soft tissue around the path of the introducer to achieve hemostasis (H, I).

groove. This allows the generator to be positioned away from the deltopectoral groove and axilla, avoiding interference with motion of the left arm at the shoulder. An alternate incision directly over the deltopectoral groove facilitates exposure of the cephalic vein; this is particularly valuable in obese patients or elderly patients with atretic veins.

Venous access

When the deltopectoral groove has been exposed, additional anesthesia is infiltrated into the lateral margin of the pectoralis and laterally into the deltoid. The dissection proceeds into the deltopectoral groove, following the lateral edge of the pectoralis, until the cephalic vein or another venous branch is exposed. Failure to find a vein may mean the incision is too far cephalad or caudad or not lateral enough. The incision can be deepened into the subpectoral fat if necessary. If the vein is too small to pass a pacemaker lead, the curved end of the guidewire for a 7F introducer is passed centrally. The ability to manually stiffen and extend the curve by central manipulation of the tension in the guidewire is an important technical aid in tortuous veins. The method illustrated in Fig. 60-9 can be used to dilate the vein. If the guidewire will not pass centrally, a no. 18 Angiocath is advanced over the guidewire and used to inject a small amount of iodinated contrast to visualize the venous system fluoroscopically. If the cutdown approach must be

abandoned, precise localization of the subclavian vein by venogram reduces the risk of injury during subclavian puncture. If dual-chamber pacing is planned, the guidewire should be reinserted through the introducer before the introducer is stripped away. This provides venous access for the duration of the procedure.[52,53] A purse-string suture in the muscle usually provides adequate control of bleeding and allows stabilization of the lead(s).[54,55] Ultrasonic localizers may be useful at this stage, with appropriate sterile precautions.

Right ventricular lead insertion

From the patient's left, a gentle spiral in the distal 10 cm of the stylet will guide the lead toward the tricuspid valve, right ventricle, and pulmonary artery. Advancing the lead into the pulmonary artery outside the cardiac silhouette confirms that the lead is not in the coronary sinus. For fixed-screw positive fixation leads, withdrawing the stylet 3 to 5 cm minimizes the risk of apical perforation while screwing the lead tip into the myocardium with axial clockwise rotation. Reverse torque that develops as the lead is rotated should be noted; this torque is a guide to the security and safety of fixation. We fix the lead with three consecutive 360° clockwise rotations of the lead shaft and then release the torque. This fixation sequence is repeated as many times as is necessary, until the lead is secure, with substantial reverse torque after the first 360° rotation. No more than three complete axial rotations are employed in any sequence. A rare problem that can develop with screw-in leads is undetected ventricular perforation. The lead tip should be watched during the fixation process to look for sudden extra-anatomic movement, with the lead tip following the cardiac silhouette around the apex and then cephalad. If this happens, the lead should be withdrawn and repositioned. An echocardiogram should be obtained and the patient carefully monitored for tamponade.

When the lead tip has been properly positioned, the stylet should be withdrawn and thresholds tested. The patient is asked to hyperventilate and cough to confirm fixation. The ventricular pacing threshold should be less than 0.7 V, and R-wave amplitude should be more than 5 mV. For unipolar leads, impedance should be 400 to 1000 ohms, depending on lead design. There should be no diaphragmatic pacing at an output of 10 V.

If the lead is dislodged by hyperventilation and coughing, or if thresholds are not adequate, the lead should be repositioned. A positive fixation lead can be unscrewed by counterclockwise axial rotation until it floats free. Positive fixation leads can be secured almost anywhere along the margins of the right ventricular silhouette (Fig. 60-10), including the right ventricular outflow tract (Fig. 60-11[56]). In difficult cases, we have relocated leads as many as 15 times. The geographic center of the right ventricular silhouette is not a desirable location, as it can lead to entanglement of the lead in the chordae tendineae (see Fig. 60-10).

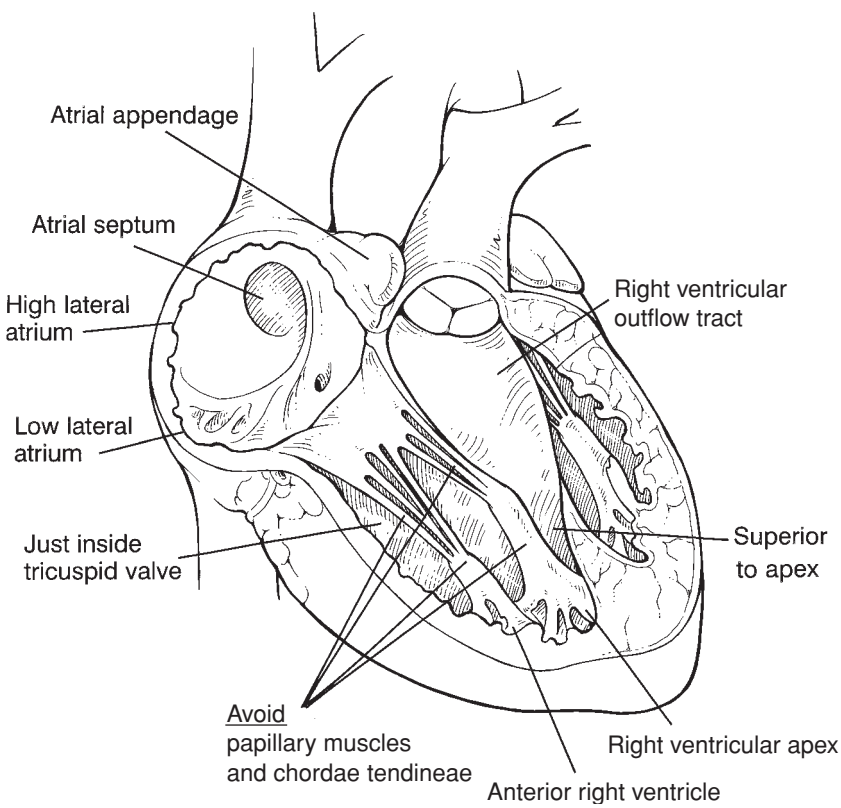

Figure 60-10. Useful sites for transvenous atrial and ventricular pacing using fixed-screw unipolar leads. The geographic center of the right ventricle (RV) should be avoided; screwing leads into this location can result in lead entrapment in the chordae tendineae, which may necessitate lead abandonment.

Figure 60-11. Screw-in lead in the right ventricular outflow tract of a patient with complete heart block after tricuspid valve replacement for Ebstein anomaly.

Coronary sinus lead insertion

Left ventricular pacing via the coronary sinus (CS) is a desirable skill as a result of the MIRACLE trial and subsequent studies indicating that biventricular pacing can improve the symptoms of heart failure and also may reduce the mortality of dilated cardiomyopathy.[26,27,39] Electrophysiologists are familiar with CS entry for arrhythmia mapping, with steerable mapping catheters and biplane fluoroscopy being important tools. However, most clinical trials of biventricular pacing for heart failure indicate a technical failure rate of CS lead insertion of 5 to 10%.[26,39] The CS is a posterior structure near the caudal aspect of the tricuspid valve (Fig. 60-12). Locating the os in heart failure patients is difficult because the CS is angulated and distorted by enlargement of the right ventricle and right atrium. Transesophageal echocardiography and venography can be helpful in locating the os. Biventricular pacing candidates are prone to ventricular arrhythmias, making rapid defibrillation capability desirable. Even experienced operators may require hours to insert a CS lead with present methods, although technology for both endocardial and epicardial left ventricular lead placement is improving. Over-the-wire lead designs are the most successful. We prefer to do the CS lead first via the cephalic approach, with right atrial and right ventricular leads following via subclavian puncture. Lead insertion involves insertion of an angled catheter into the CS, CS venography, and lead insertion through the cannula into a lateral branch of the CS. The CS cannula must then be removed and stripped off without dislodging the lead. Positive fixation leads are not available. The large selection of angled CS cannulas, steerable probes, and lead designs testifies to the technical challenge. The difficulty of CS lead insertion in heart failure patients should not be underestimated; special training by an experienced preceptor is definitely worthwhile.

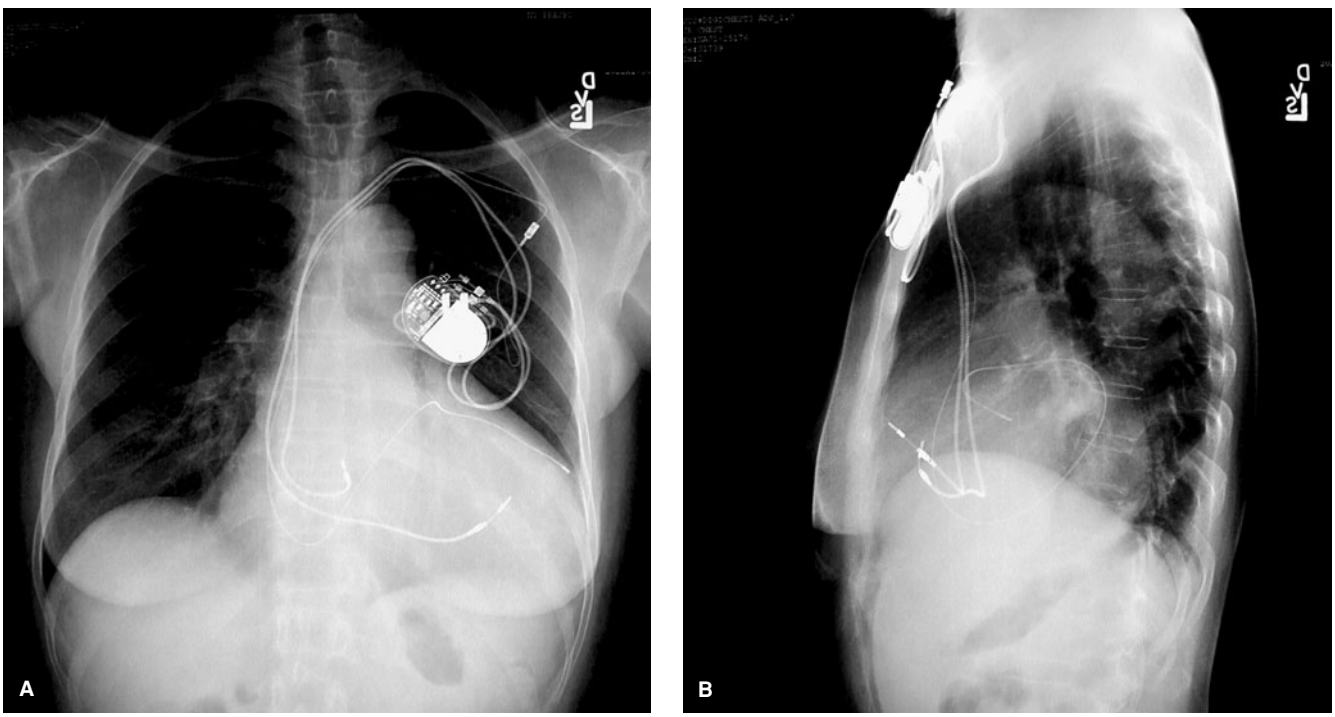

Figure 60-12. (A) Biventricular, dual-chamber pacemaker with endocardial leads in the right atrium, right ventricle, and lateral branch of the coronary sinus (left ventricle). This patient was relieved of dobutamine dependence by addition of the left ventricular lead. (B) Lateral x-ray of the same patient. The posterior course of the coronary sinus is apparent.

Length adjustment

Lead length must be adjusted between "too short," in which a deep breath results in lead displacement, and "too long," in which a cough results in formation of a loop that effectively shortens the lead, also causing displacement. Maximal inspiration and expiration under fluoroscopy helps judge length. Vigorous coughing tests the security of lead tip fixation. This valuable feedback is lost if the patient is heavily sedated or cannot cooperate. Pacemaker syndrome also can be detected immediately during VVI pacing in conscious patients.

Atrial lead insertion

For dual-chamber pacing, the atrial lead is introduced last. A "J" or "S" stylet shape is best for finding the atrial appendage from the left side.[55] The "S" shape is also useful for passing a positive fixation lead to the right margin of the atrium near the junction of the right atrium and inferior vena cava (Fig. 60-13). P-wave amplitude is often best in this location. The atrial pacing threshold should be less than 2 V. In the presence of complete heart block, it may be difficult to confirm atrial capture from the surface ECG. Pacing the atrium at 150 bpm results in rapid oscillation of the lead tip. If this is apparent fluoroscopically, lead oscillation can be used to determine the atrial pacing threshold. This technique should only be used if the high atrial rate is not conducted to the ventricle. High-output atrial pacing can inhibit whatever temporary VVI pacing is supporting the patient, resulting in asystole.

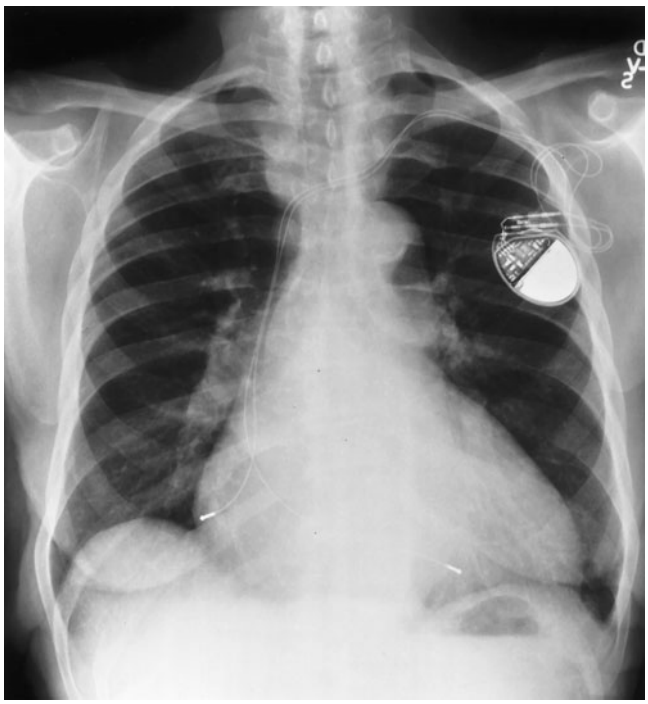

Figure 60-13. Dual-chamber pacemaker illustrates low, right lateral atrial lead placement. This location, particularly advantageous after obliteration of the atrial appendage at heart surgery, requires a positive fixation lead. P-wave amplitude in this location is often acceptable when other sites fail. If phrenic nerve stimulation is observed with 10-V stimulation, however, the lead tip should be repositioned.

The P-wave electrogram is the Achilles heel of dual-chamber pacing. If atrial sensing is not satisfactory, a DDD pacemaker will not function properly. The P-wave amplitude should ideally be greater than 2 mV. Measurement of P-wave amplitude with unipolar leads can be confusing. Crosstalk or far-field sensing of ventricular depolarization from the atrial lead can occur, so that the signal measured through a pacemaker analyzer is not the P wave but the QRS complex. Simultaneous measurement and display of atrial and ventricular electrograms as well as the surface ECG can resolve this. An alternate solution involves programming the generator as a P-wave detector: The lower rate is set below the patient's intrinsic atrial rate, the AV delay is set shorter than the patient's PR interval, and atrial sensitivity is set at 2 mV. When the generator is connected to the atrial and ventricular leads, every P wave will be followed immediately by a ventricular pacing spike if P-wave amplitude is greater than 2 mV. The pacemaker must be reprogrammed to clinically appropriate settings at the conclusion of surgery.

Telemetry of atrial and ventricular electrograms by pacemakers is a valuable source of EP data. For example, inability to pace the atrium or to measure atrial electrograms in the operating room may indicate low-amplitude atrial fibrillation or supraventricular tachycardia; this may be invisible on the surface ECG but may be detectable as electrogram activity. Electrogram telemetry provides valuable confirmation of proper DDD pacing (Fig. 60-14).

Generator location

We utilize a watertight, three-layer skin closure for primary implants, three layers in generator replacements. Cosmetic appearance is important to many patients, and in others technique is critical to optimize healing. Past injury to the chest wall or surgery/radiotherapy for breast cancer can present formidable technical problems. The use of bipolar systems facilitates generator placement behind the pectoralis or inside the rectus sheath. Diminutive generators are available, but battery life is reduced. Innovative locations for pacemaker generators include axillary, retromammary, intrathoracic, and preperitoneal sites. These approaches are rarely indicated with present generator designs.

Length of Stay After Pacemaker Implantation

Ambulatory surgery

Same-day hospital discharge after pacemaker insertion is feasible in patients who have an adequate escape rhythm. Positive fixation leads are preferred. After monitoring and recovery from sedation, patients are ambulated and instructed in range of motion exercises for the shoulder. A chest x-ray is obtained to document lead position and rule out hemothorax or pneumothorax or pericardial enlargement.

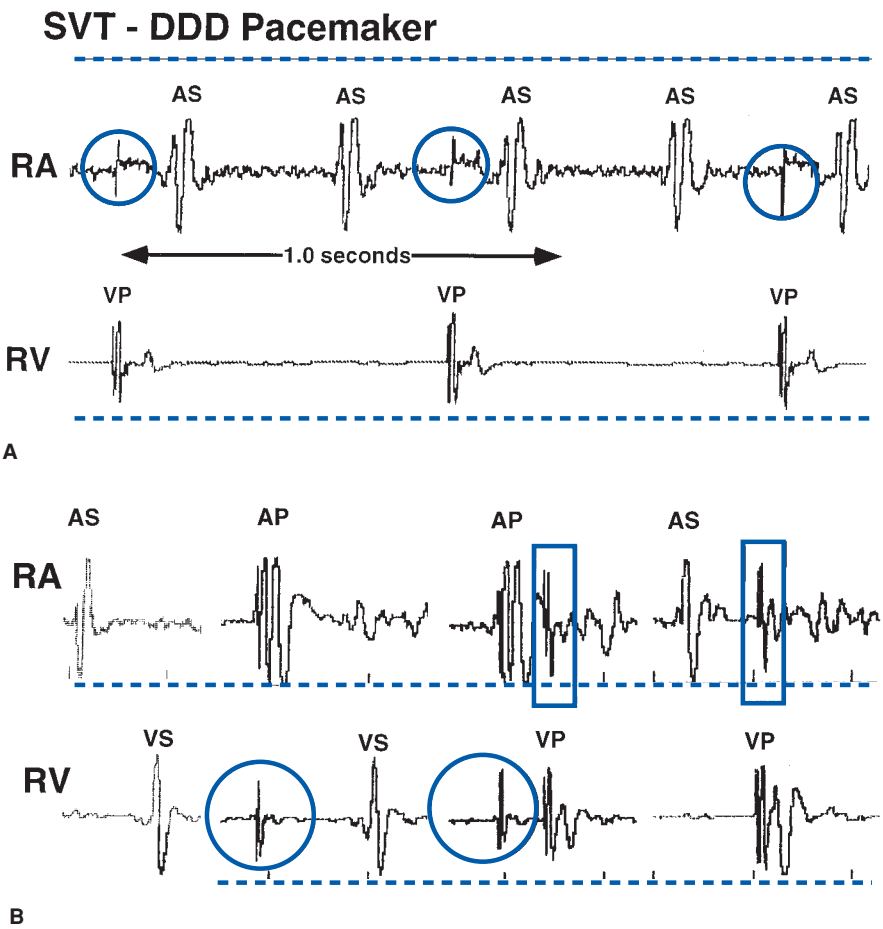

Figure 60-14. Right atrial (RA) and right ventricular (RV) electrograms from a unipolar DDD pacemaker during supraventricular tachycardia (SVT). Regular atrial depolarizations appear (AS) at a rate of 160 bpm. The pacemaker paces the ventricle (VP) at 80 bpm, because alternate P waves fall inside the postventricular atrial refractory period and are not detected. The circles illustrate far-field sensing of the RV pacing artifact in the RA lead. The SVT was not detected preoperatively. Once this recording was obtained, overdrive atrial pacing from the pacemaker converted the SVT to normal sinus rhythm, and normal pacemaker function returned.

Pacemaker-dependent patients

Lead displacement can be result from technical error, to struggling of demented patients, and other factors. Since a small percentage of lead displacement is probably unavoidable,[45,46,57,58] patients who might suffer death or injury in the event of abrupt pacemaker failure should be observed in the hospital overnight on telemetry. However, lead displacement in our experience in ambulatory patients has not been more frequent than in hospitalized patients.

Pacemaker Generator Replacement

Planning

Fifteen percent of functioning pacemakers were replacements in a recent survey.[59] Complications of pacemaker generator replacement include infection, lead damage, connector problems, and asystole during the transition from the old generator to the new. Relative pacemaker independence at the time of initial pacemaker implant may progress to severe pacemaker dependence by the time of generator replacement. Ambulatory surgery is common. As a practical matter, we no longer reverse warfarin for pacemaker generator replacement unless lead replacement is expected.[60] Patients with leads more than 10 years old should be carefully evaluated for pacemaker dysfunction prior to generator replacement; a Holter monitor should be obtained if lead dysfunction is suspected. Rising pacing threshold may indicate impending lead failure. The possibility of unexpected lead replacement should be discussed with the patient in advance.

Back-up pacing

Some practitioners insert a temporary transvenous pacing wire during pacemaker generator replacement, but this is rarely necessary. The output of the replacement unit must be high enough to match the pacing threshold of a chronically implanted lead. This can be problematic if the generator is an older type with a fixed output of 5.4 V. Lack of programmability prevents preoperative threshold testing, and the 5.4-V output is considerably higher than nominal for most current generators. The standard approach with newer generators is to test the pacing threshold with a pacemaker analyzer and program the replacement to appropriate output before connecting it. Before disconnecting the old generator, be sure that the pacemaker analyzer, cables, and connections are intact and that personnel in the operating room are aware of where the cables run. Some place the analyzer in a sterile bag on the operative field. With many generators, an Allen wrench placed in the header establishes electrical continuity with the

ventricular lead; the pacing threshold can then be established before disconnecting the old generator. The old generator should be kept within reach as a back-up in case of trouble with the new generator, the analyzer, or the connectors.

Lead sizes

The three common sizes of lead connector for permanent pacing are 6 mm, 5 mm, and 3.5 mm (VS-1 or IS-1). The new generator should be an exact match for the patient's lead size, but a selection of step-up and step-down adapters can be helpful. The contacts do not always line up correctly across VS-1 and IS-1 connectors, even though the connector diameter is the same. It is important to determine in advance whether connections can safely be made across the VS-1/IS-1 interface.

Postoperative Care

Wound care

Patients are instructed to keep implant wounds dry until an office visit 7 to 10 days postoperatively. Any wound drainage at the postoperative visit is cultured, and prophylactic antibiotics are started until culture results are available. We have abandoned aspiration of the rare postoperative hematoma in favor of close observation, unless infection is an issue or spontaneous drainage occurs or appears imminent.

Antibiotic prophylaxis

Routine use of prophylactic antibiotics before dental work and other invasive procedures in pacemaker or ICD recipients is not recommended under AHA/ACC guidelines. We recommend prophylaxis for 3 months after device insertion, allowing time for the pacing leads to become endothelialized.

Testing and Follow-Up

Office/clinic versus telephone

Pacemakers require periodic testing to confirm sensing and pacing function and detect battery depletion. Current standards involve testing these functions at 1- to 3-month intervals. Whether follow-up should be done by transtelephonic monitoring or clinic or office visits is in dispute.[61–63] Transtelephonic monitoring alleviates transportation issues for elderly patients, but some are too anxious or debilitated to manage the process. In addition to reducing patient travel and strain on office resources, many commercial services provide emergency monitoring on a 24-hour basis, an important advantage in managing apprehensive or incapacitated patients.

Pacemaker programming

Programming can be done in an office setting by trained, experienced personnel. In some situations, a manufacturer's representative may provide valuable help. Transtelephonic programming is not currently available.

DDD pacemaker programming allows adjustment of electrogram sensitivity as well as pacing stimulus amplitude/pulse width for both the atrium and ventricle. Lower rate, upper rate, atrioventricular delay, and refractory periods for atrial and ventricular sensing are programmable. Rate responsiveness, unipolar/bipolar configuration, and many other options are also adjustable noninvasively.

We initially program newly inserted pacemakers to stimulation amplitude and pulse width higher than nominal. At the initial office visit, pacing thresholds are retested and amplitude and pulse width are adjusted to nominal levels if pacing thresholds are low. The use of high initial output is less important with steroid-eluting leads. Details of pacemaker programming have been described elsewhere.[63,64] Some current pacemakers are capable of automated threshold adjustment.

Programming allows most problems detected by transtelephonic or Holter monitoring to be corrected. The etiology of symptoms can often be elicited from real-time electrograms or stored data. Adjustments may include not only sensitivity or pacing output but also pacing mode for new-onset atrial fibrillation[65] (Fig. 60-15A) or sinus node incompetence related to medication changes (Fig. 60-15B). Problems that may require reoperation include lead displacement, lead fracture (Fig. 60-16), insulation degradation (see Fig. 60-4), and exit block[57,58] (Fig. 60-17).

Pacemaker interrogation should begin with a printout of the initial settings, which is an invaluable reference after involved programming. Telemetry should be examined to determine time-related variation in heart rate, percentage of beats sensed and paced, the quality of the electrograms, lead impedance, and battery voltage.

The pacing amplitude and pulse width are finely tuned at the 1-year follow-up visit. We generally provide at least 100% safety margin on pulse width threshold. Pacing mode, rates, refractory periods, rate response, and delays are adjusted to optimize patient comfort and battery life. For example, some pacemakers allow programmed reduction of a lower rate at night, eliminating unnecessary pacing during sleep. A very long atrioventricular delay can eliminate ventricular pacing in some patients with first-degree block, but a reduction in the upper rate limit to 105 bpm may be necessary to achieve this.

Complications of Pacemaker Insertion

Mortality

Death is a rare complication of pacemaker implantation.[57,58,66] Lethal problems can include lead displacement, venous or cardiac perforation, air embolism, and ventricular tachycardia or fibrillation.[57,58] A review of 650 pacemaker insertions by the author between January 1984 and April 1993 revealed one perioperative death due to heart failure induced by general anesthesia in a child with congenital heart disease (Table 60-3).

Incidence of complications

The incidence of early complications in one recent published series was 6.7%, with 4.9% requiring reoperation.[57] For

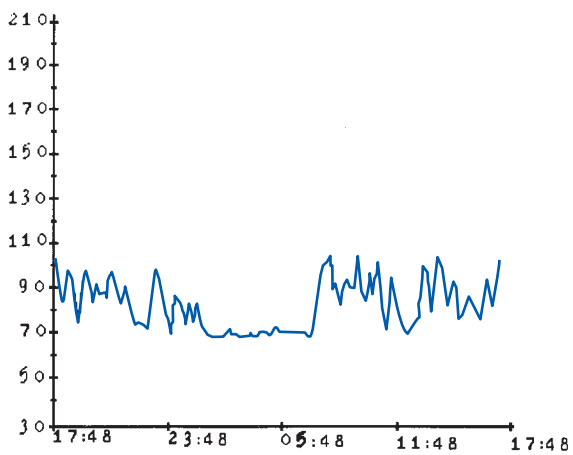
B



C

Figure 60-15. (A) Atrial (upper, RA) and ventricular (lower, RV) electrograms from a unipolar DDD pacemaker during atrial fibrillation (AF). The AF appears as rapid atrial depolarizations (AS). The upper rate limit and postventricular atrial refractory period of the pacemaker determine the rate at which the pacemaker stimulates the ventricle (VP). (B and C) Average heart rate over 24 hours recorded by memory circuits in a DDD pacemaker. The initial tracing (B) reveals sinus node incompetence, which developed during amiodarone therapy for paroxysmal atrial fibrillation. More normal rate variation resulted from activation of the rate-responsive feature of the generator (C), and the patient reported improved exercise tolerance.

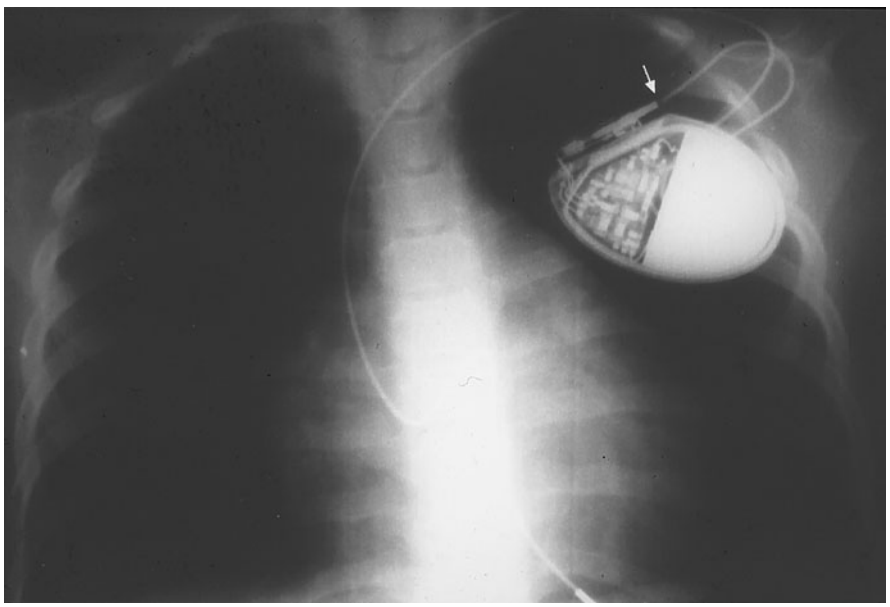


Figure 60-16. Unipolar lead fracture in a 3-year-old with complete heart block as revealed by x-ray. The patient underwent successful lead replacement.

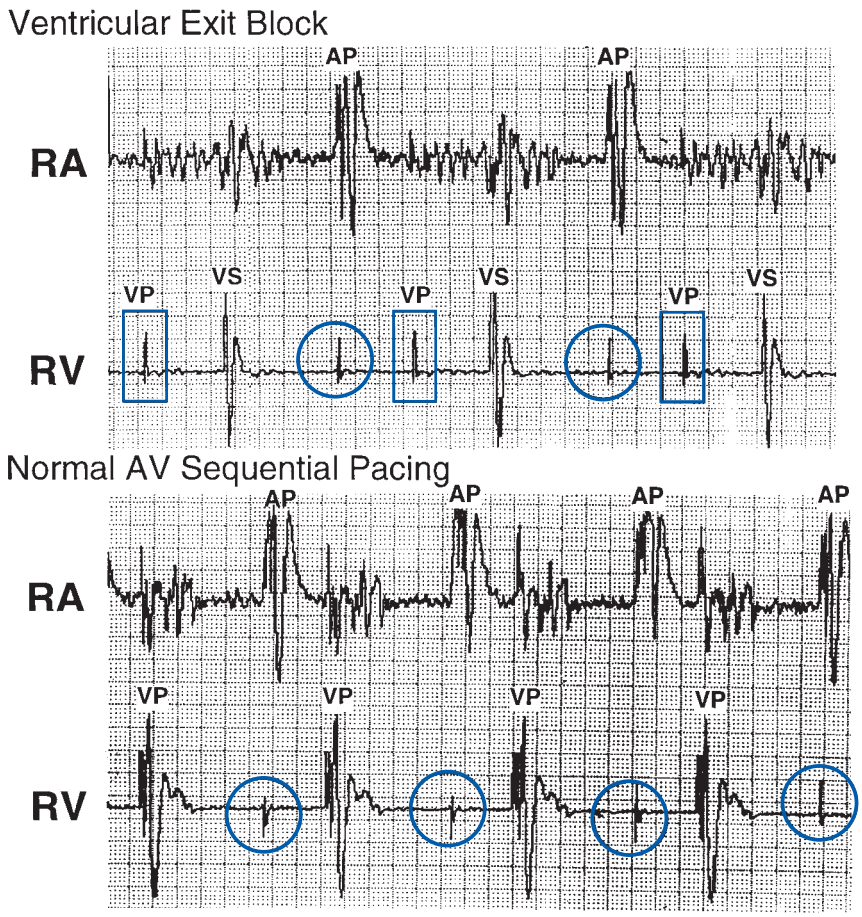

Figure 60-17. Right atrial (RA) and right ventricular (RV) unipolar electrograms in right ventricular exit block (above). Atrial (AP) and ventricular (VP) pacing are required for sinus arrest and marked first-degree atrioventricular block. Right ventricular capture is restored after RV pacing amplitude is programmed from 3.5 (above) to 5.4 V (below). Ventricular capture increases the effective heart rate, because the late, conducted ventricular electrograms (VS) in the upper tracing are sensed by the pacemaker and used to begin a new cardiac timing cycle. The circles indicate far-field sensing of the RA pacing artifact in the RV lead.

patients over 65, comparable figures were 6.1% and 4.4%, respectively.[58] Lead displacement, pneumothorax, and cardiac perforation were the most common complications. The reported incidence of late complications was 7.2%.[57] Reoperation in the authors' series was required in 4.0% of 480 patients with long-term follow-up (see Table 60-3).

Lead displacemkent

The incidence of endocardial lead displacement with early lead designs was more than 10%.[58] With tined and positive fixation leads this has fallen to the range of 2%.[8,45,46,57,58,66–68] The overall incidence of this complication was 1.5% for both atrial and ventricular leads in all locations in a recent review (see Table 60-3). Secure placement of pacemaker leads is a learned skill, and relevant technical issues have been described above. We have found that positive fixation leads can be applied in a variety of unusual locations with essentially no penalty in terms of lead displacement (Table 60-4).

Myocardial infarction

Pacemaker insertion may be indicated as an adjunct to medical therapy of angina in patients with inoperable coronary artery disease. However, increased heart rate can be detrimental if control of ischemia is marginal. Angina, myocardial infarction, or death can result from pacemaker-induced increases in heart rate of as few as 10 bpm.

Hemopneumothorax

Hemopneumothorax and pericardial tamponade can result from injury to the heart or arterial or venous system. Errors with the Seldinger technique can lead to such injuries. In patients over 65, pneumothorax has been related to subclavian puncture.[58] In our experience with pacemaker insertion in more than 1000 patients by cephalic cutdown, hemopneumothorax did not occur. In contrast, a recent review of 1088 consecutive implants by subclavian puncture revealed a 1.8% incidence of pneumothorax.[58]

Pacemaker syndrome

Loss of atrioventricular synchrony produces symptoms related to contraction of the atria against closed AV valves and reflex effects. The resulting constellation of symptoms is known as pacemaker syndrome.[69] These symptoms are quite variable, but severely affected patients may refuse pacemaker magnet testing. Symptoms are relieved immediately by conversion from VVI to dual-chamber pacing.

Lead entrapment

Entanglement of a pacemaker lead in the chordae tendineae can lead to firm entrapment. Options under these circumstances include further escalation of force, application of lead extraction techniques,[70,71] or an open procedure. Our experience with this involved three firmly entangled leads in 1000

Table 60–3.

Results of Pacemaker Implantation, Columbia-Presbyterian Medical Center 1984 to 1993*

Surgical mortality	1/616 (general anesthesia–related)
Mean follow-up	884 ± 675 (SD) days (n = 480 patients, 679 leads)
Morbidity	19 reoperations (4.0% of 480) 4 Infections (0.8%) 7 Lead displacements (1.5%) 4 Exit block (0.8%) 4 Undersensing (0.8%) 5 Suspected right ventricular perforations 2 Leads abandnoed (chordal entrapment) 41 Reprogrammed for dysfunction 0 Hemothorax 0 Pneumothorax 1 Procedure abandoned for thoracotomy (newborn)
Characteristics at generator replacement (n = 40, 75 ± 31 months after implant)	
Pacing threshold	1.3 ± 0.5 V 3.0 ± 1.3 mA
R-wave amplitude	8.9 ± 4.3 mV
Long-term DDD pacing	89% (1109 ± 34 days follow-up)
Causes of DDD failure	8.4% Atrial fibrillation 2.4% Lead dysfunction

lead implants. These leads were capped and abandoned rather than escalate the risk of the procedure. There were no untoward consequences of abandoning these leads. This experience taught us to avoid the anatomic center of the right ventricle when implanting positive fixation leads. This problem has not recurred in more than 750 subsequent pacemaker implants.

Infection and erosion

Pacemaker infection appears as frank sepsis, intermittent fever with vegetations or inflammation, and purulence or drainage at the pacemaker pocket. Established infection in implanted prosthetic devices can be suppressed but rarely eliminated by antibiotics. Antibiotic suppression may result in temporary resolution of signs of infection in a pacemaker or ICD pocket, but the problem usually recurs several months later.[69,70] Negative cultures from a pacemaker erosion may encourage the clinician to move the generator to a fresh, adjacent site, but the erosion usually recurs. Clinical resolution of recurrent device erosion in such individuals almost always requires removal of all hardware and insertion of a new device in a fresh site.[72,73] The incidence of erosions, infections, hematoma, and lead displacement early after pacemaker implantation is increased by operator inexperience.[68]

Pacemaker dysfunction

Mechanical defects in leads, lead displacement, or errors in connecting the lead and generator can cause pacemaker dysfunction. Most commonly, lead dysfunction represents scarring at the lead-myocardial interface, changes in myocardial properties due to tissue necrosis or drug effects, or a poor initial choice of lead position.

Generator dysfunction

Electrical component failures are rare. Three pacemaker or ICD generator failures have required urgent device replacement over the past 10 years at our center. New pacemaker and lead designs may contain flaws that do not become apparent for many years.[8,74]

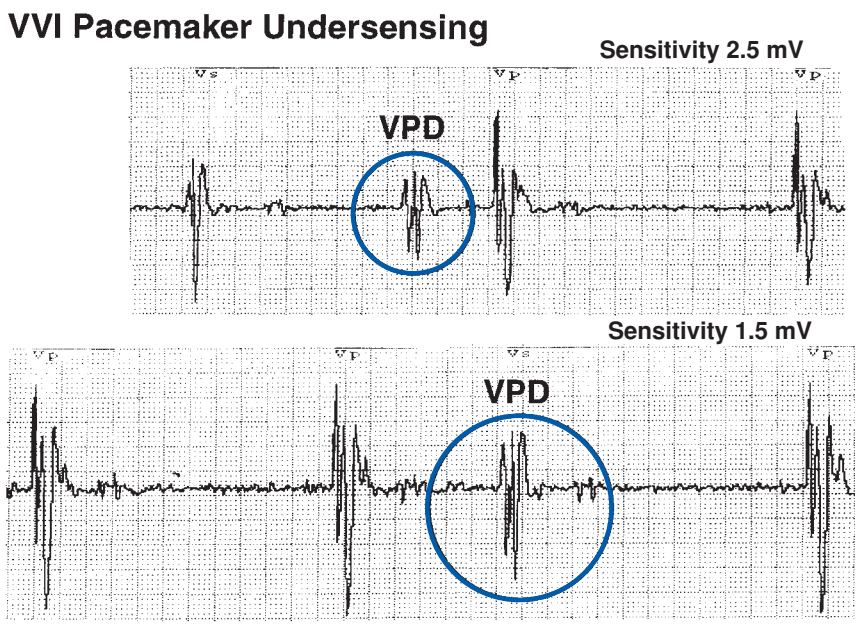

Figure 60-18. Undersensing of ventricular premature depolarizations (VPD) illustrated in the upper panel of electrograms obtained by telemetry from a VVI pacemaker. The amplitude of the electrograms increases, and sensing is corrected after reprogramming to increase sensitivity to P waves from 2.5 mV (above) to 1.5 mV (below).

Undersensing

This is failure to sense atrial or ventricular electrograms. The result is an atrial or ventricular pacing artifact that should have been inhibited by the preceding (unsensed) beat. In a dual-chamber pacemaker, undersensing may also cause failure to pace the ventricle after an atrial P wave. Undersensing can often be corrected by programming increased generator sensitivity, but this can also lead to oversensing. The latitude for reprogramming can be estimated by examining telemetered electrograms[61–64] (Figs. 60-18 and 60-19).

Oversensing

Inappropriate pacemaker inhibition or triggering in unipolar systems may result from detection of myopotentials (muscular activity). This is more common in unipolar systems and may be correctable by programming reduced pacemaker sensitivity. Oversensing in bipolar systems may indicate breakdown of lead insulation (see Fig. 60-4).

Crosstalk and far-field sensing

A deflection on the ventricular lead immediately after the atrial pacing artifact could be either premature ventricular contraction or far-field sensing of an atrial depolarization (see Fig. 60-14). Many pacemakers deal with this ambiguity by pacing the ventricle at a short (100-ms) atrioventricular delay. This short AV delay, known as "safety pacing," indicates that the pacemaker is detecting an ambiguous signal during the AV delay.[28]

Complexities of dual-chamber pacemaker programming involve blanking and refractory periods used to compensate for crosstalk or to prevent retrograde AV conduction from producing pacemaker-mediated tachycardia (see below). Crosstalk is ameliorated by bipolar lead systems.

Exit block

This is rising pacing threshold due to edema or scarring at the lead tip–myocardial interface. Pacing threshold com-

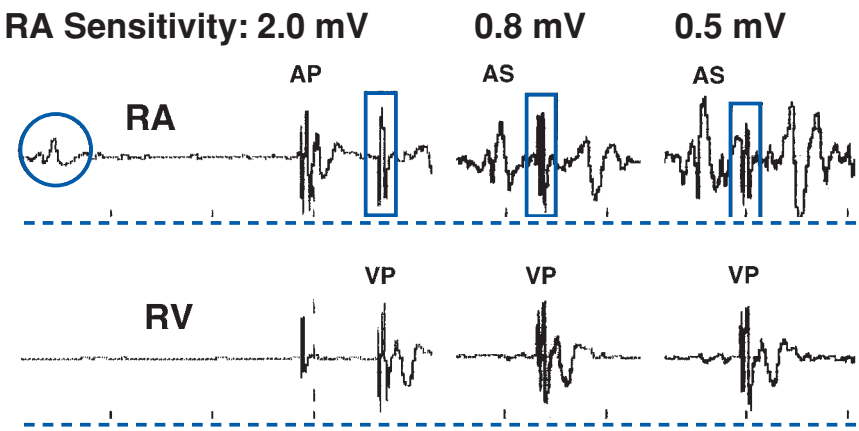

Figure 60-19. Right atrial (RA) and right ventricular (RV) electrograms telemetered from a DDD pacemaker during correction of atrial undersensing. The amplitude of the RA electrogram increases after atrial sensitivity is increased from 2.0 mV (left) to 0.8 (center) to 0.5 mV (right). The P-wave electrogram (circled) is not sensed at 2.0 mV, resulting in unnecessary atrial pacing (AP). Proper sensing is restored and the size of the electrogram increases (AS) as sensitivity is increased. VP indicates ventricular pacing. The rectangles in the RA tracing identify far-field sensing of the ventricular pacing artifact.

monly increases over 7 to 14 days after lead insertion and stabilizes at about 6 weeks. This phenomenon, which is related to inflammatory changes at the lead tip, is ameliorated by steroid-eluting leads.[8,75] Exit block may be corrected by programming increased amplitude or pulse width, but this shortens battery life. In unipolar systems, pacing of the chest wall and/or diaphragm may result from high generator output.

Lead fracture

Lead fracture, whether due to insulation or conductor breaks, is often demonstrable by chest x-ray (see Fig. 60-16). Lead impedance less than 300 ohms suggests an insulation break, while high lead impedance, more than 1000 ohms, suggests conductor problems, a loose set screw, or improperly connected lead. High impedance also can indicate incomplete extension of a loose set screw, or a bad generator connection. Office examination may detect impending lead fracture as electrical noise on telemetered electrograms when the patient hyperventilates, coughs, bends, or swings the arms. Oversensing related to body movement usually mandates lead replacement or repair.

At reoperation, dysfunctional leads can be capped or removed. Removal of chronically implanted leads is potentially hazardous and results in endothelial venous damage even when successful. Lead removal probably should be deferred unless mandated by infection or mechanical problems. The probability of lead fracture has been promoted historically by design errors, bipolar construction, certain forms of polyurethane insulation, and epicardial insertion.[64] Technical factors in fracture include tight ligatures applied to the lead without an anchoring sleeve, kinking, lead angulation, vigorous exercise programs, and subclavian crush.[8,44,51]

Subclavian crush

This refers to entrapment of a pacemaker lead between the clavicle and first rib in the costoclavicular ligament. The lead is believed to be subjected to unusual stress during body movement, resulting in early lead failure. This problem pertains to leads implanted by percutaneous puncture of the subclavian vein and may be avoided with cephalic cutdown. Techniques to minimize this problem have been described (see Fig. 60-7).[8,44,51]

Pacemaker-mediated tachycardia

DDD pacemakers can inadvertently cause a reentrant arrhythmia, pacemaker-mediated tachycardia.[64] This includes retrograde conduction through the atrioventricular node, possibly triggered by a premature ventricular depolarization. If the pacemaker senses the resulting atrial depolarization and paces the ventricle, a repetitive cycle is set up that could continue indefinitely at the upper rate limit of the pacemaker. This problem can be minimized by avoiding high upper rate limits in patients with retrograde conduction and by adjusting the postventricular atrial refractory period so that the pacemaker will ignore atrial depolarizations for 300 to 350 ms after the QRS complex. Current pacemaker circuits also have built-in safeguards that attempt to break reentrant arrhythmias by periodic interruption of continuous high-rate pacing. In addition, pacemaker interrogation provides notification of high-rate pacing suspicious of pacemaker-mediated tachycardia.

Innovations and Special Problems

Pacemaker lead extraction

Indications for lead extraction include chronic infection or life-threatening mechanical defects.[76–78] Some recommend that any dysfunctional pacemaker lead should be removed. Until recently, the techniques for extraction of a transvenous lead were external traction or thoracotomy/cardiotomy employing inflow occlusion or cardiopulmonary bypass. Chronically implanted leads can be densely fibrosed to the right ventricular myocardium, vena cava, or innominate and subclavian veins.

Lead extraction has been advanced by techniques described by Byrd.[70,71] A locking stylet is passed inside the central channel to the tip of the lead where it uncoils, allowing traction to be applied to the lead tip. Telescopic Teflon, plastic, or metal sheaths slightly larger than the pacing lead are passed over the lead to mobilize it. When the long sheath reaches the lead tip, countertraction is applied to the myocardium with the sheath while traction is applied to the lead tip with the locking stylet (Fig. 60-20). Success with this technique has been >90%, with a 3% chance of serious morbidity or death. Laser-based systems have also been used.[79] Technical details have been described.[70,71] Extraction of leads implanted for more than 10 years is difficult and tedious.

Accufix lead

An unusual form of lead fracture affected the Telectronics Accufix lead, a bipolar, Bisping type atrial screw-in lead.[76–78] A J-shape was integrated into this lead to direct the tip to the atrial appendage. A curved retention wire was welded to the indifferent ring electrode near the tip and then was bonded to the lead body with polyurethane. This retention wire proved susceptible to fracture and extrusion (Fig. 60-21). Deaths were reported from cardiac tamponade, possibly related to puncture of the atrium or aorta by protruding wire. More than 45,000 of these leads were implanted, and many were surgically extracted. Because some morbidity and mortality occurred during extraction of this lead, the manufacturer recommended conservative management.

Atrial fibrillation and mode switching

Many DDD pacemaker recipients suffer from both sinus bradycardia and intermittent, paroxysmal atrial fibrillation (sick sinus syndrome). A standard DDD pacemaker responds to atrial fibrillation by pacing at the upper rate limit. While DDD pacing was initially felt to be contraindicated in atrial fibrillation, the current view is that atrial

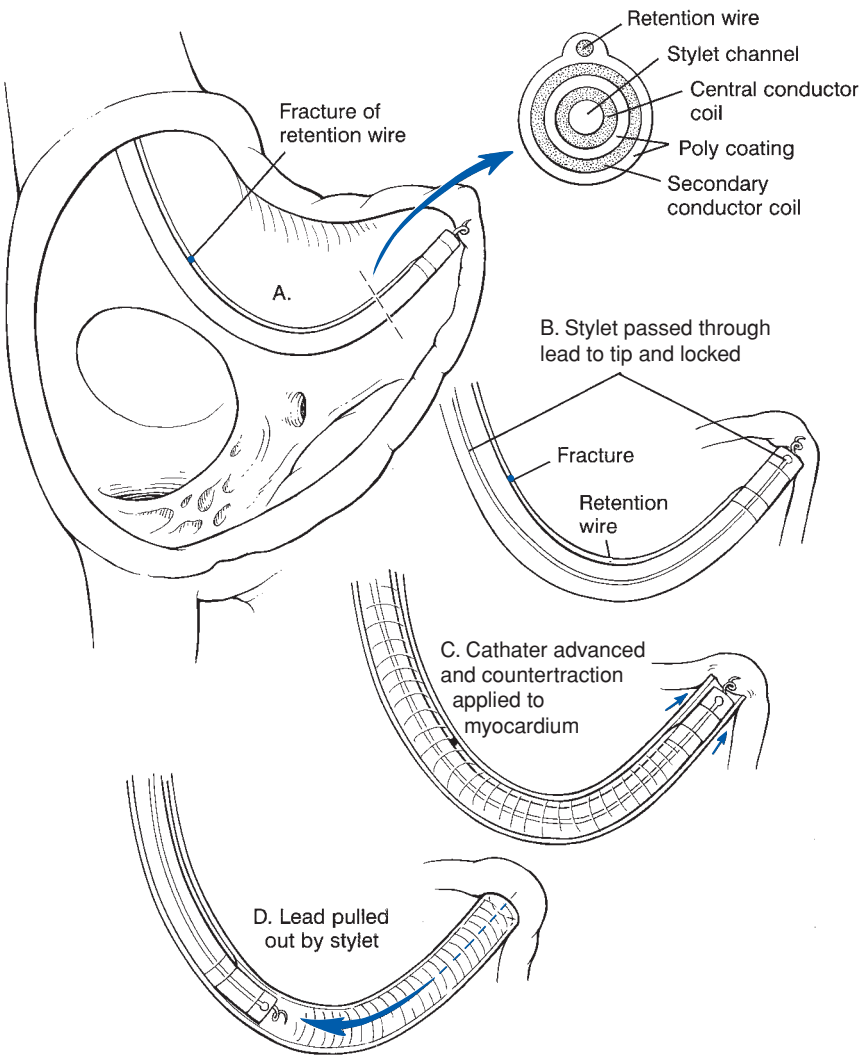

Figure 60-20. Byrd method of lead extraction using Cook catheters. Drawings illustrate successful removal of a Telectronics Accufix J-lead with a fractured retention wire.

pacing may decrease the frequency of paroxysmal atrial fibrillation. Mode switching[80] achieves a useful compromise. Mode switching can be triggered by a programmed upper rate limit or by comparing the observed atrial rate to predictions based on the patient's activity level. If an atrial tachyarrhythmia is detected, the pacemaker switches to VVIR pacing until the atrial rate again appears appropriate. Successful mode switching requires bipolar leads and high sensitivity in patients with low-amplitude atrial fibrillation. Management of atrial fibrillation in the elderly may involve fewer medications and interventions than in younger patients.[65]

Database support

Pacemaker- and ICD-related data include information for billing, for generating operative notes, serial numbers of leads and generators, records of programming, and management of follow-up visits and monitoring and patient education. A large amount of data should be available at a moment's notice in the event of a query related to device malfunction. For this purpose, a multi-user relational data-

The region of the fracture appears relatively benign in the upper lead.The lower lead illustrates retention wire extrusion after percutaneous extraction. Mechanical characteristics of the extruded wire resemble those of a safety pin.

base, allowing simultaneous access by multiple users, is particularly valuable. A variety of commercial and home-grown software packages are helpful for this purpose.

General surgery and pacemakers

General surgery in a pacemaker-dependent patient presents a serious problem,[81] especially for major surgery that requires unipolar cautery. Preparations should include (1) identify the manufacturer and model of the pacemaker, using the pacemaker ID card, monitoring service, medical record, or x-ray appearance;[81–84] (2) determine magnet mode (see below) and any peculiarities related to impedance sensing monitors; (3) obtain a programmer for the pacemaker; (4) interrogate the pacemaker to determine operating mode, programmed parameters, polarity, battery life, and lead characteristics; (5) determine pacemaker dependence[81] (if the electrocardiogram reveals 100% pacing, programmed reduction of the pacing rate or output with ECG monitoring should be used preoperatively to determine whether the patient has an escape rhythm; pacemaker dependence can increase during anesthesia, because of withdrawal of sympathetic stimulation); (6) implement a back-up plan (transthoracic pacing or chronotropic agents) if the patient is pacemaker-dependent; (7) program the pacemaker to VOO, DOO, or VVT mode intraoperatively and program rate response off to prevent inhibition[81] or pacemaker acceleration[82] by electromagnetic interference (EMI); (8) identify a physician responsible for dealing with any intraoperative pacemaker problem; (9) interrogate the pacemaker postoperatively to confirm thresholds and function and restore programming to appropriate values.

Electrocautery

Manufacturers recommend that electrocautery should not be employed in pacemaker patients because of the danger of EMI or pacemaker damage. If electrocautery must be used, unipolar cautery is far more likely to cause EMI than bipolar cautery. Unipolar pacemakers are also more susceptible to EMI than bipolar pacemakers. At a minimum, EMI from the electrocautery may be misinterpreted by pacemaker sensing circuits as a rapid heart rate, resulting in pacemaker inhibition. This inhibition reverses when the EMI stops. Cautery can also cause pacemaker reprogramming, acceleration of impedance-sensing pacemakers to the upper rate limit,[82] or reversion of the pacemaker to a "back-up mode" or "magnet mode" (see below). Finally, electrocautery can cause complete and permanent loss of pacing, although this is rare.[81]

One approach to avoiding pacemaker inhibition by EMI is to program sensing off and to increase the rate to minimize competition with the intrinsic heart rate. However, competition with spontaneous beats can occur, creating a risk of induction of atrial fibrillation or ventricular tachycardia in susceptible patients. In view of this, the pacemaker should be returned to an appropriate sensing mode as soon as possible after the completion of surgery.

Magnet mode

A permanent magnet placed over a pacemaker closes a magnetic reed switch and converts the pacemaker to "magnet mode." Magnet mode is not the same for all pacemakers. In some, a magnet initiates VOO mode, making the pacemaker insensitive to EMI. Other pacemakers will convert to VOO for a few beats and then revert to the underlying program. Most current generators perform a threshold margin test under the influence of a magnet; this investigates the adequacy of the pacing margin by decreasing the pulse width in a predictable pattern.

Steroid-eluting leads

A promising approach to the problem of fibrosis at the lead-myocardial interface involves incorporation of a pellet of dexamethasone at the lead tip. This improves early pacing thresholds compared to conventional leads.[75] The long-term (>1 year) advantage of steroid-eluting leads remains to be defined.

Adults with congenital heart disease

Congenital heart disease presents special challenges. A persistent left superior vena cava draining to the coronary sinus favors a right-sided approach, although the left side can be used with special techniques.[54,55] Preoperative echo Doppler or angiographic studies can define caval and coronary sinus anatomy. Persistent left superior vena cava may displace the subclavian vein, increasing the hazards of percutaneous subclavian vein puncture. High priority should be placed on the cephalic cutdown approach in patients with congenital heart disease.[54] Situs inversus and corrected transposition can be particularly confusing in the operating room if undetected prior to pacemaker insertion.

Positive fixation leads are particularly useful for atrial pacing after a Mustard operation or a caval-pulmonary anastomosis and for pacing the smooth-walled "right" ventricle in corrected transposition of the great arteries.[54] A coronary sinus lead can provide ventricular pacing in some patients after Fontan surgery (Fig. 60-22). We have also found ventricular pacing via the coronary sinus to be advantageous in patients with a mechanical tricuspid valve.

Pacing in infants and children

Transvenous pacing can be facilitated in this population by leaving an intracardiac loop to allow for growth (see Fig. 60-5). Unipolar, positive fixation leads are ideal for this purpose[54,55] but other approaches have been described.[85] We prefer a cephalic vein cutdown, with optical magnification if needed. A flexible guidewire is passed centrally and a 7F introducer is used to introduce the lead. A longitudinal split of the cephalic vein facilitates advancing the introducer (see Fig. 60-9). In very small infants, the external jugular vein at the thoracic inlet may be useful. Others prefer a subclavian vein puncture guided by a catheter introduced via the femoral vein.[85] Thoracotomy provides a third option.[42] Infants under

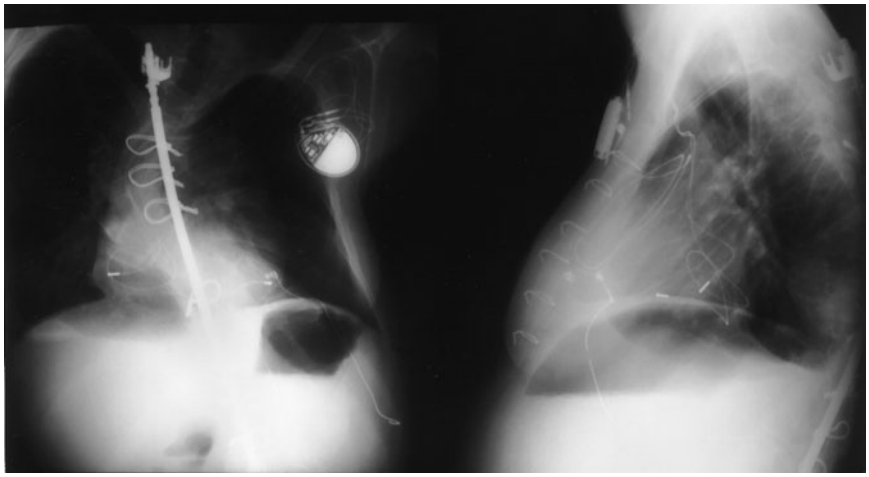

Figure 60-22. X-ray of a dual-chamber pacing system illustrates ventricular pacing via the coronary sinus after Fontan surgery. This system functioned successfully for nearly 5 years and was replaced at the time of Fontan revision. An epicardial pacing wire, which failed due to exit block, is also illustrated.

6 months of age are suboptimal candidates for transvenous pacing because of limited long-term lead utility. Generators should be placed beneath the pectoralis in children under 6 years old if possible, to reduce infection risk.

Dementia

Dementia is problematic for surgery under local anesthesia. Sedation can make dementia worse and exaggerates bradycardia. The patient's arms should be secured to prevent groping for the surgical wound. Postoperative confusion with thrashing can cause pacemaker lead displacement. A family member at the bedside may palliate this problem. Every effort should be made to anticipate and avoid such problems.

Atrioventricular node ablation

AV node ablation controls ventricular rate in refractory atrial fibrillation but leads to permanent heart block. Historically, the AV node was ablated first. Temporary pacing supported heart rate until a permanent pacemaker was inserted. Ventricular escape rhythm was often poor in these patients, favoring positive fixation leads, overnight observation on telemetry, and high pacemaker output. Alternatively, the pacemaker can be inserted and allowed to heal prior to ablation, reducing the risk of lead displacement and avoiding the need for overnight hospitalization.

Transplant recipients

The most common indication for pacemaker insertion in cardiac transplant recipients is sinus bradycardia or sinus arrest, which can be managed successfully by AAIR pacing.[38,86] In our experience, most outgrow the need for pacing within 2 years.[38,86] The surface ECG can be quite misleading, with the two sources of P waves—the atria of the donor and the recipient—suggesting heart block. Need for ventricular pacing can be evaluated by pacing the atrium at a rate of 150 bpm. If a 1:1 response of the ventricle is observed, the AV node is essentially normal. The location of the atrial appendage is more medial than usual in these patients, and positive fixation leads are preferable (Fig. 60-23).

Implantable cardioverter defibrillator recipients

Before integrated devices were available, transvenous pacing in ICD recipients had stringent requirements for lead performance. Crosstalk between devices could result in inappropriate ICD shocks or failure of the ICD to detect and correct lethal ventricular arrhythmias. While independent implantation of pacemakers and ICDs has been described,[87] ICDs with integrated DDD pacemakers render this technique superfluous.

Long QT syndrome

This is a genetically determined repolarization abnormality that is associated with a high incidence of sudden death.

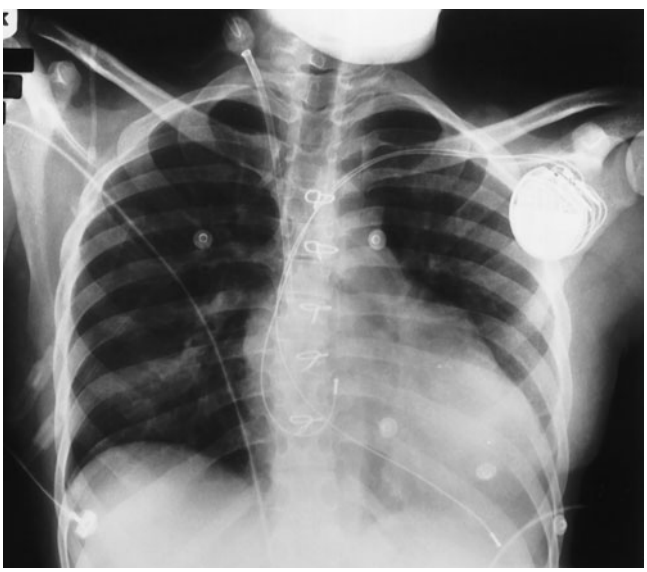

Figure 60-23. DDDR pacing system in a cardiac allograft recipient illustrates the shift of the atrial appendage toward the midline that is characteristic of these patients.

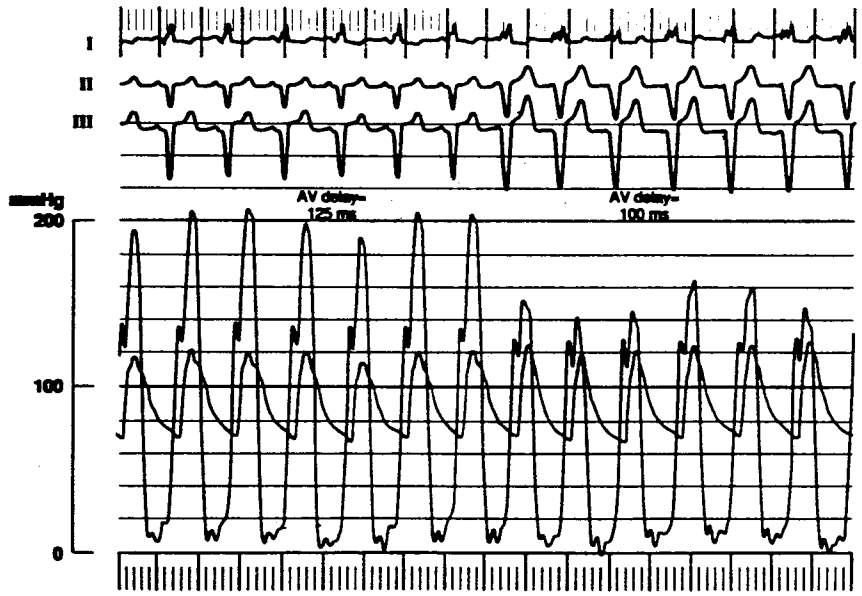
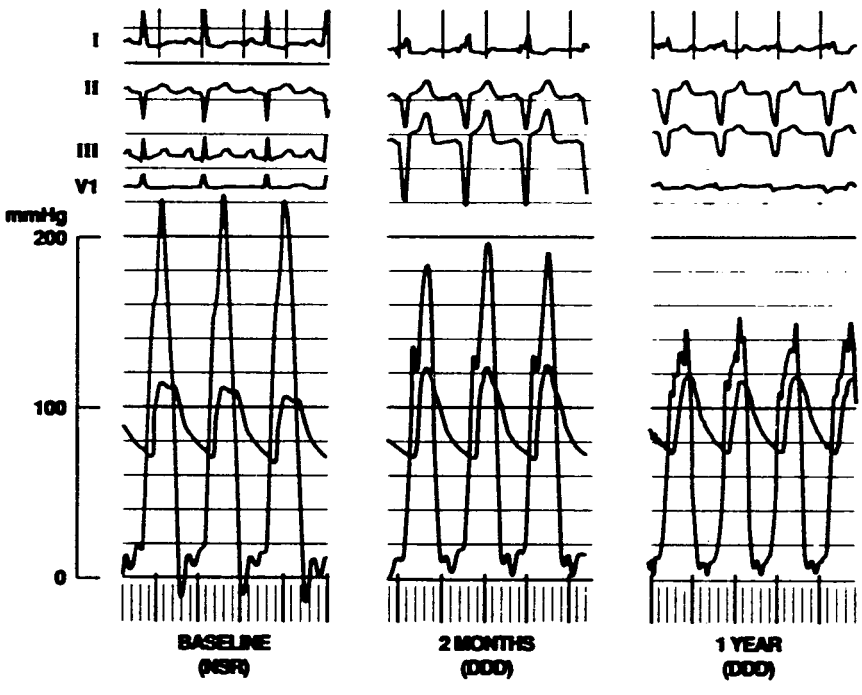


A



B

Figure 60-24. (A) Effect of reducing AV delay in DDD pacing from 125 ms (left tracings) to 100 ms (right tracings) on left ventricular outflow tract gradient in idiopathic hypertrophic subaortic stenosis. (B) Effect of time and DDD pacing on left ventricular outflow tract gradient in idiopathic hypertrophic subaortic stenosis. (*Reproduced with permission from Fananapazir et al.*[22])

Recommended therapy includes stellate ganglionectomy and/or adrenergic blockade.[88,89] In severe cases, the pacing threshold may be too high for ventricular pacing, and atrial pacing may be preferable.[88] ICD therapy is increasingly common for this condition.[85]

Idiopathic hypertrophic subaortic stenosis

Idiopathic hypertrophic subaortic stenosis or obstructive cardiomyopathy can cause left ventricular outflow obstruction with angina and/or syncope. Permanent right ventricular pacing at short atrioventricular intervals pre-excites the right ventricle and decreases outflow gradients in some patients[22–24] (Fig. 60-24). A reduction in the incidence of sudden death has also been claimed with this approach in patients with a history of syncope, but ICD therapy has been increasing.[88]

Biventricular pacing

End-stage cardiomyopathy and heart failure tend to progress with advancing age. Advanced therapies like cardiac transplantation or left ventricular assist devices are appropriate for some patients, but biventricular pacing is widely

applicable at a lower cost. Clinical trials demonstrate modest subjective and objective improvement in dilated cardiomyopathy with left ventricular ejection fraction <36% and QRS intervals >120 ms.[26,27,90] Marked clinical improvement is seen in some patients (see Fig. 60-13).

Atrial and ventricular tachyarrhythmias

Overdrive pacing techniques can be effective for ventricular tachyarrhythmia, Wolff-Parkinson-White syndrome, or atrial flutter.[88] Implantable defibrillators are under development for atrial fibrillation. Anti-tachycardia ventricular pacing for ventricular tachyarrhythmia has been integrated into ICD therapy.

Environmental Issues

Electromagnetic interference

EMI can be caused by electrocautery, cellular telephones, magnetic resonance imagers,[91] microwaves, diathermy, arc welders, powerful radar or radio transmitters, and theft detectors in retail stores. Any defective, sparking electrical appliance or motor, electric razor, lawn mower, or electric light can be problematic. The importance of EMI is related to pacemaker dependence. Most pacemaker recipients are not pacemaker-dependent, so a brief period of pacemaker dysfunction will not result in loss of consciousness. Patients who are pacemaker-dependent and work in electrically noisy environments may benefit from the added protection of bipolar pacing systems. Cellular telephones should be separated by several inches from pacemaker generators, preferably on the contralateral side.[92]

Mechanical interference

Lithotripsy, trauma, dental equipment, and even bumpy roads can affect pacemakers. Automobile accidents have caused pacemaker damage and disruption of pacemaker wounds.[93] Vibration in subways or automobiles causes inappropriately high heart rates in rate-responsive units. Patients with poor escape rhythms should be discouraged from exposure to deceleration injury, as in traditional contact sports as well as basketball, handball, downhill skiing, surfing, diving, mountain climbing, and gymnastics. Participants in these activities should realize that abrupt pacemaker failure could occur in the event of lead displacement related to trauma.

Radioactivity

The integrated circuits of current pacemakers can be damaged by radiotherapy. If the pacemaker cannot be adequately shielded from the radiation field, it may be necessary to remove and replace it or move the pacing system to a remote site.

Quality of life

In contrast to ICD recipients, quality of life is not a major concern for most pacemaker recipients. While many clinics require periodic visits, the model of transtelephonic monitoring with office visits only for problems is highly acceptable to most patients. This latter system involves a preoperative visit, a 10-day postoperative visit, a 1-year visit to adjust output, and no additional visits unless functional problems or impending battery depletion are detected. Some recipients are never happy with their pacemakers because of body image problems, vague symptoms, or concern that life will be artificially prolonged. The value of generator replacement in patients with advanced debilitation has been a subject of ethical concerns.[94]

IMPLANTABLE CARDIAC DEFIBRILLATORS

Background

More than 400,000 deaths in the United States each year are classified as sudden and likely to be caused by arrhythmias.[95] Michel Mirowski conceptualized the implantable defibrillator in the late 1960s. Overcoming numerous theoretical, engineering, and financial obstacles, he participated in a successful clinical trial of his device in the early 1980s.[96] Today's implantable cardioverter defibrillator (ICD) reflects dramatic and expensive growth in technology. The efficacy of the ICD in prevention of sudden death is well established. Sophisticated clinical trials, experience, and the passage of time have emphasized the survival advantages of the ICD over other modalities, including antiarrhythmic drugs and subendocardial resection. The ICD is associated with the lowest sudden death mortality (1 to 2% per year) of any known form of therapy.[97–100] The ICD is expensive ($12,000 to $20,000 for the generator and $2000 to $8000 for the lead system), with discomfort and lifestyle issues. Prophylactic ICD insertion is increasing.

Clinical trials including AVID, MUSST, MADIT, SCDHFT, and COMPANION demonstrated benefits of ICD therapy.[101–112] Only the CABG Patch Trial,[113] which compared coronary artery bypass graft (CABG) to CABG+ICD, and DINAMIT,[114] which studied ICD implantation early after myocardial infarction, failed to demonstrate advantages of ICD insertion. Trials now focus on prophylactic ICD therapy, combining ICDs with biventricular pacing, cost effectiveness, and projected costs. Accumulating evidence supports prophylactic use of ICDs and biventricular pacing in patients with ejection fractions <35%, either in association with coronary disease or in association with dilated cardiomyopathy. The appropriate role for prophylactic ICD-biventricular pacing is still evolving. The Heart Rhythm Society will not certify surgeons to implant these devices unless they have passed its certification exam. Patients with prophylactic device insertion are being followed in a national registry. Information about this can be found at http://www.accncdr.com/webncdr/ICD.

ICD battery life has increased beyond 5 years. Today's devices are highly programmable, and their size and weight are similar to those of pacemakers of the 1970s. Lead systems

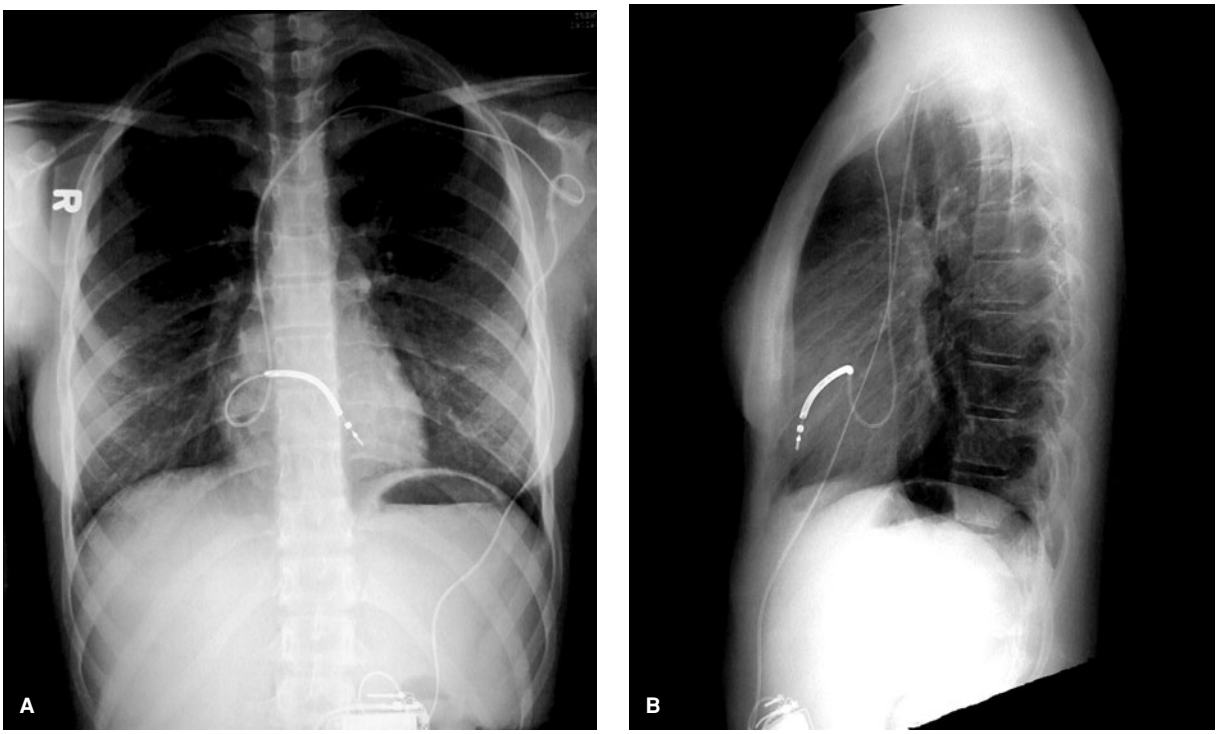


Figure 60-25. (A) ICD implant in 13-year-old female with long QT syndrome. X-rays reveal an intracardiac loop to allow for growth and a strain relief loop in the left shoulder. A single-coil, screw-in lead was used to permit an intracardiac loop, but improved leads now allow twin-coil leads to be used. This implant utilized cosmetic positioning of the generator in the posterior rectus sheath. (B) Lateral x-ray of same patient.

have evolved from epicardial patches requiring thoracotomy to endocardial systems[97–100] with defibrillation thresholds (DFTs) reduced by biphasic shocks[115] and "hot can" technology.[116] Pectoral implantation is the current standard, and many devices are placed beneath the pectoralis major. Abdominal implantation is now reserved for special cases (Figs. 60-25 and 60-26). Electrograms stored by current devices can be downloaded to expedite decisions about antiarrhythmics, to prevent inappropriate shocks, and to detect oversensing.[117] VVI, DDD, and antitachycardia pacing have been integrated into ICDs.[118] Accelerated development has pressured the Food and Drug Administration to rapidly approve new technology. When the U.S. Health Care Finance Administration refused in 1995 to allow Medicare reimbursement to support device development, ICD development shifted overseas.

Physiology

Ventricular tachycardia (VT) associated with ischemic cardiomyopathy is commonly a reentrant arrhythmia[119] that may be prevented by drugs, catheter ablation, or surgical maneuvers that alter the timing and electrical attributes of the reentrant circuit. Myocardial infarction creates areas of scarring and slow conduction needed for reentry. Other forms of VT and ventricular fibrillation (VF) involve aberrancies of automaticity related to acute myocardial ischemia, increased ventricular wall stress, and myopathic cellular injury. Some class I antiarrhythmics have been shown to increase postinfarction mortality,[120] possibly due to proarrhythmic effects.

Indications

A straightforward ICD candidate has suffered a documented VT or VF in the absence of acute myocardial infarction and has been proven unsuitable for antiarrhythmic drug or surgical therapy, based on programmed electrical stimulation studies in the EP laboratory. However, many patients who suffer cardiac arrest do not have inducible VT at EP study, and many patients with a history of syncope and presyncope have inducible VT but no history of a clinical arrhythmia. Many antiarrhythmics have negative inotropic and proarrhythmic effects. Serial EP studies of drug efficacy have been discredited in clinical trials.[115] In mid-1996 the Food and Drug Administration approved an indication for prophylactic ICD insertion based on early termination of the MADIT Trial.[106] If EP studies demonstrate inducible VT in patients with nonsustained VT and a history of myocardial infarction, an ICD is indicated. MADIT II results support ICD insertion in all patients with a history of myocardial infarction and left ventricular ejection fraction $<30\%$.

Device Description

ICDs employ two lead systems (Fig. 60-27)—one for ventricular pacing/rate sensing and the other to deliver the defibrillation current. These systems are usually bipolar, but a unipolar

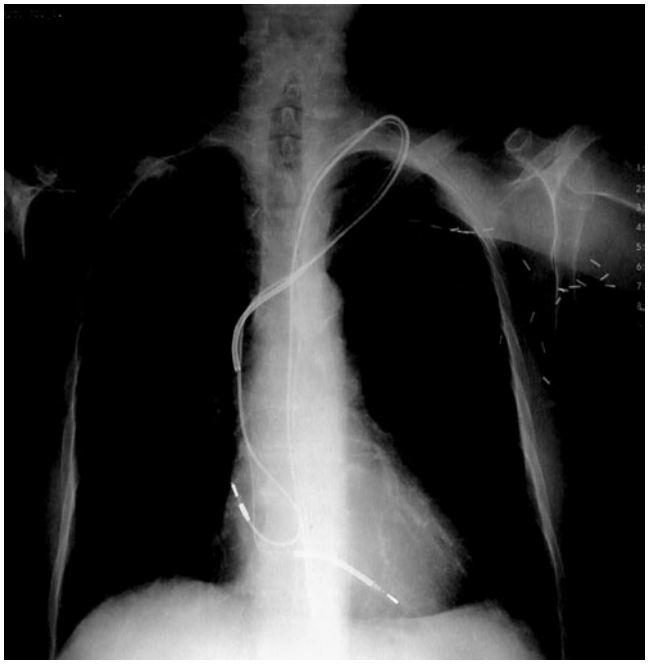

Figure 60-26. ICD/DDD pacemaker implant in a female with ventricular tachycardia and previous bilateral radical mastectomies. Venous access was obtained via the external jugular vein. Positive fixation leads were tunneled vertically in the midline, which was the only location on the chest wall with adequate subcutaneous tissue. The generator was placed subcutaneously in the abdomen. The cosmetic result was quite acceptable to the patient.

ventricular lead paired with an "active can" delivers the defibrillation current in some designs. Algorithms intended to distinguish supraventricular arrhythmias from VT have fallen into disfavor, and rate alone is currently used to determine when a patient requires treatment. As many as 30% of ICD shocks are for sinus tachycardia or other supraventricular tachyarrhythmias.[97,121] A bipolar atrial lead can be added for atrial pacing or differentiation of supraventricular arrhythmias from VT. Subcutaneous patch leads and arrays are available for patients with high defibrillation thresholds (DFTs). Leads come in standard lengths for pectoral implants and long lengths for abdominal implants. Positive fixation leads are available and preferred.

The ICD contains a high-energy battery and a capacitor to step up the output voltage to 600 to 800 V at 35 to 40 J. Biphasic (positive and negative phases) shocks reduce DFTs. The device includes integrated circuits and a telemetry antenna. A broad range of programmable diagnostic and therapeutic functions are supported.

Surgical Procedure

Patient preparation

Most potential ICD recipients would be at high mortality/morbidity risk for any surgery. Therapy of ischemia, heart failure, and systemic illnesses should be optimized before ICD implantation. The overall mortality of ICD implantation in our program has been very low since we began in 1983. We find inadequate control of ischemia in coronary artery disease to be more lethal than advanced cardiomyopathy. When ischemia is severe, a CABG, percutaneous transluminal coronary angioplasty, intra-aortic balloon pump, or deferral of DFT measurement should be considered in place of standard ICD insertion and testing.

Surgical approach

The epicardial approach[122,123] is now rarely used (i.e., for ICD implantation during cardiac surgery). This has been discouraged since the CABG Patch Trial demonstrated that infectious complications were more common in ICD recipients than in control patients.[116] Extrapericardial ICD patches cause less fibrotic reaction, less impairment of diastolic properties,[124,125] and less potential for graft impingement than intrapericardial leads. Biphasic waveforms, improved leads, high-output "hot can" generators, and ancillary subcutaneous patches and arrays contribute to a high rate of success for the endocardial approach.

Manufacturer's representatives

The complexity of current devices has legitimized the presence of manufacturer's representatives with electrophysiologists during ICD implants. This increases influence of the manufacturer on the selection of devices and techniques and warrants oversight.

Technique

We prefer local anesthesia and unipolar cautery for ICD insertion. Positioning and draping is similar to that for pacemaker insertion, with the addition of R2 electrodes over the right breast and beneath the left scapula. R2 electrodes should not be placed directly over the site of a possible subcutaneous ICD patch or array in the lateral axilla; this can result in serious equipment damage from arcing if external defibrillation is necessary.

The most distressing part of ICD insertion for the patient is the induction and reversal of VF for DFT measurement. This can be managed with deep sedation for a small number of DFTs. When multiple shocks are required, endotracheal intubation gives better control. Intravenous vancomycin and gentamicin are used for perioperative antibiotic prophylaxis in our center.

We prefer a cephalic vein cutdown via a 6-cm incision over the deltopectoral groove. If the vein is small, a guidewire is used to position a 7 or 9F introducer. Enlargement of the cephalic venotomy may be helpful if the vein is too small for the introducer (see Fig. 60-9). The guidewire can be left in place if a multiple-lead system is to be employed. Introducer kinking can lead to difficulty passing rough-surfaced ICD leads centrally. This is awkward, and high central pressures can lead to bleeding until the introducer is removed. Introducer kinking is avoided by aligning the introducer with the course of the cephalic vein before removing the obturator.

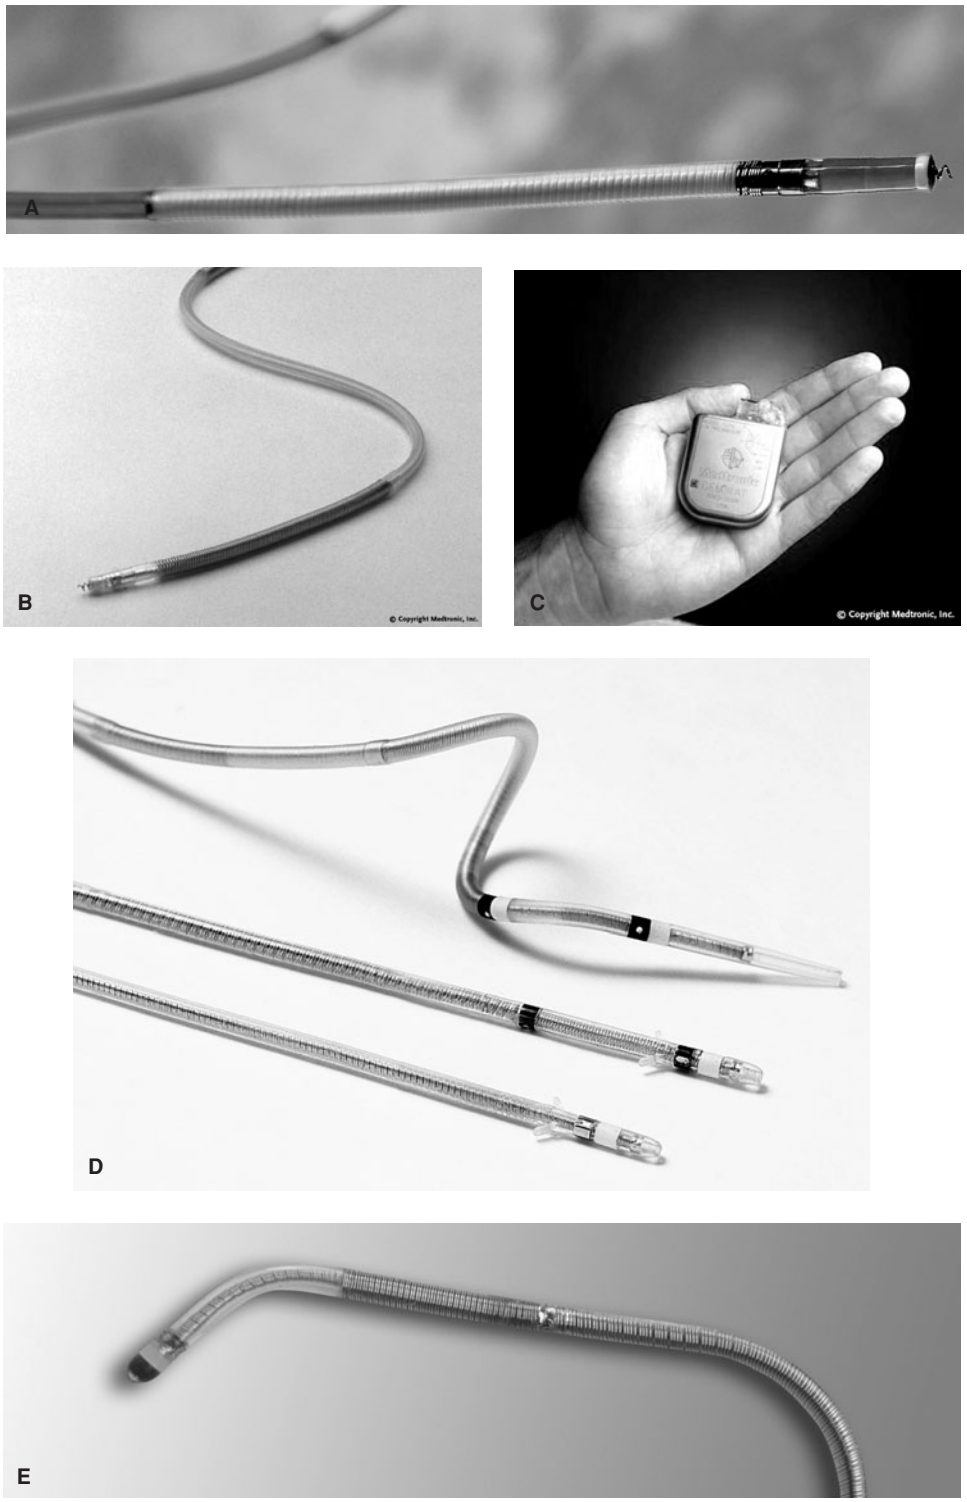

Figure 60-27. (A) Recent 9F ICD lead with Gore-Tex–coated shocking coils. (B) Recent 7F ICD lead with retractable screw. (C) Recent ICD/pacemaker . (D) Recent over-the-wire leads for coronary sinus pacing. (E) Recent over-the-wire lead for coronary sinus pacing. (*A and D: Courtesy Guidant Corp., Indianapolis, Ind; B, C, and E: Courtesy of Medtronic, Inc., Minneapolis, Minn.*)

As the lead is advanced to the ventricle, VT or VF may be triggered. This is not disruptive if an external defibrillator is available, connected to disposable R2 electrodes and precharged by a capable OR nurse. It is important to advance the ventricular lead as far as possible to the apex and to find a secure location. We prefer positive fixation ICD leads for both the right atrium and right ventricle. During measurement of DFTs, fluoroscopy should be used to check for lead displacement, particularly if external defibrillation is necessary. An intravenous infusion of norepinephrine is used when necessary to maintain systolic blood pressure. Transesophageal echocardiography is useful for monitoring patients at high risk of electromechanical dissociation during DFTs. We do not use Swan-Ganz catheters for monitoring, because their removal can lead to ICD lead dislodgment.

Locating ICDs in the left upper quadrant of the abdomen is now uncommon and is reserved primarily for cosmetic insertions, which can also include placing the generator in the posterior rectus sheath (see Fig. 60-25). With general anesthesia or sedation and local anesthesia, a tunneler is passed from the abdomen to the subclavian incision. Caution should be exercised with the tunneler; it must pass anterior to the costal margin. The lead is looped in the shoulder and firmly secured to minimize the possibility that a tug on the abdominal portion of the lead would displace the lead (see Fig. 60-25).

Defibrillation threshold

The DFT is critical to ICD insertion and the point of maximum risk. VF is generally induced twice and reversed by the ICD. The DFT should be at least 10 J less than the maximum output of the ICD. If DFTs are too high with optimized endocardial leads, an axillary subcutaneous patch or array helps distribute the defibrillation current over the lateral left ventricle. High-output generators and reversal of shock polarity may also be helpful. DFT measurement can, rarely, depress left ventricular function[106–108,126,127] and result in a low-output state. The mortality of ICD insertion with present techniques is on the order of 1%.[128] Complications include myocardial infarction, heart failure, lead displacement, infection, and venous occlusion.

Refractory ventricular fibrillation

A left-sided pneumothorax from a ruptured bleb, or technical error during subclavian puncture or subcutaneous array insertion raises the DFT, resulting in refractory VF. The differential diagnosis of refractory VF also includes myocardial ischemia, electromechanical dissociation, and poor anatomic localization of ICD shocks. Refractory VF rarely may require open cardiac massage or cardiopulmonary bypass until a solution can be found.

Postoperative care

Telemetry is indicated during an overnight stay after ICD insertion. Pacing and sensing properties of the lead should be checked to confirm lead stability before discharge. In some cases, DFTs may also be checked before discharge. Wherever patients with a fresh ICD are located, ready availability of an ICD magnet is essential. Personnel should be trained to use a magnet to inhibit inappropriate ICD shocks caused by right ventricular lead displacement or supraventricular arrhythmias. We administer ciprofloxacin for 5 days after discharge to complete prophylaxis. A postoperative office visit is scheduled 7 to 14 days after implant.

Surgical follow-up

At the postoperative office visit, lead position, patient symptoms, and the surgical wound are assessed. If drainage is present, the wound is cultured and treated appropriately. For persistent sterile drainage, ciprofloxacin or trimethoprim-sulfamethoxazole is administered for 10 days, and the patient is asked to keep the wound dry until healing is complete. Patients are referred for EP follow-up. Established infection requires hospitalization and usually ICD explantation.

Device follow-up

ICDs require outpatient EP evaluation at 1- to 3-month intervals to cycle the capacitors, confirm battery life, test pacing thresholds, and download electrograms. The electrograms define aborted charging cycles and arrhythmias. Programming is adjusted accordingly. For patients reporting ICD shocks, telemetry can confirm proper function, detect inappropriate shocks, and demonstrate electrical noise and oversensing that require lead revision.

Late Follow-Up and Generator Replacement

Battery depletion

ICD battery life is now typically more than 60 months. Complications of generator replacement include infection, myocardial infarction, and death. Progression of heart failure and/or coronary artery disease increases the risk of replacement. Replacement is now commonly done under local anesthesia, with sedation during DFT measurement. DFT measurement may be deferred if the risk of the test appears greater than the risk of sudden death. Patients are usually discharged on the same day, unless the high-voltage lead is replaced.

Lead dysfunction

The incidence of failure of any given lead progresses with implant duration. Approximately 50% of ICD recipients require lead revision at 10 years of follow-up.[129–132] Problems include lead fracture, high DFTs, oversensing, undersensing, and exit block. The incidence of transvenous lead displacement is 7% and of fracture is 6% at 2-year follow-up.[132] Oversensing can be caused by insulation damage in the ICD pocket. Oversensing can be corrected with a new transvenous rate-sensing lead, preferably of the positive-fixation type. Visible

insulation damage inside the defibrillator pocket may be repairable with silicone sleeves, silicone glue, and ligatures.[133]

Patch leads can fail due to conductor fracture or distortion by fibrosis. With endocardial leads, DFTs may increase as a result of cardiac enlargement, which shifts the left ventricle laterally, away from the original right ventricular lead system. Insertion of a subcutaneous patch and/or a high-output generator can correct high DFTs.

Additional Issues

Bridge to transplant

The benefits and liabilities of ICD therapy for VT/VF in patients who are awaiting cardiac allografting are under investigation,[134,135] with cost an important concern.

Quality of life

Issues include the discomfort and distress of repeated shocks and inconvenience of mandatory outpatient visits. These are particularly trying for elderly patients. ICD generators, though steadily shrinking in size and weight, remain bulky compared to pacemakers. While many patients are elated to be rescued by their ICD from a malignant arrhythmia, others find their plight distressing.[136–138] Many ICD patients do not comply with recommended limitations on driving automobiles. Fortunately, the rate of accidents in ICD recipients is reportedly low.[139]

Cost effectiveness

ICD therapy is expensive, but the cost of VT/VF management in the absence of an ICD is also substantial. The incremental cost per year of life added has been estimated at $10,000 to $200,000.[140–142] Reduction in the cost of ICD generators and leads would increase the economic appeal of ICD prophylaxis.

CHAPTER 61

Adult Congenital Heart Disease

Hillel Laks • Daniel Marelli • Mark Plunkett • Jeff Myers

The steady rise in individuals who have survived congenital heart disease (with or without treatment) into adulthood is expected to create specialized requirements that mandate strategic collaborative care protocols for this swelling subpopulation. If one excludes all patients born before 1990 and those not diagnosed in the first year, assuming stable mortality in early adulthood, nearly 760,000 adults will have congenital heart disease by 2020.[1–6]

Adults with congenital heart disease who are referred for surgery fall into three general categories: those without previous surgery, those with previous palliation, and those with complete physiologic or anatomic repair returning for revision of their repair because of residual defects or sequelae from their repairs.[1,2,4–6]

In the current era, there is a trend toward surgical correction of congenital heart defects in the neonatal period or during infancy. This approach aims at minimizing the long-term consequences of congenital heart defects, such as myocardial dysfunction, endocarditis, and the hematologic and cerebral complications of cyanosis.[7–20]

There are, however, some patients who present as adults (particularly from underdeveloped countries) without previous surgery. More common lesions in this category include aortic valve disease, coarctation, pulmonary stenosis, atrial septal defect, and patent ductus arteriosus. Less commonly seen are tetralogy of Fallot, ventricular septal defect, Ebstein anomaly, and coronary arteriovenous fistulas. Palliated adults are also unusual and include patients with systemic-to-pulmonary artery shunts, Glenn cavopulmonary shunts, and pulmonary artery bands. The largest group includes adults who present with residual lesions or sequelae from previous surgeries. These conditions may include patch leaks, recurrent valvular or outflow tract stenoses, recurrent coarctation, pulmonary valve regurgitation, valve stenosis after tissue valve replacement or homograft insertion, or aneurysm formation in the pulmonary artery or aorta. Both primary repair and redo procedures are frequently complex and at increased risk from long-standing abnormal physiology and hemodynamics. Surgical care of the adult with congenital heart disease requires a multidisciplinary team experienced in pediatric and adult cardiology and cardiac surgery.

GENERAL MANAGEMENT

Preoperative Evaluation

The natural history of the congenital defect, the sequelae of previous surgical interventions, and the development of newly acquired cardiovascular disease mandate thorough evaluation during preoperative surgical planning. Long-standing cyanosis and pressure or volume overload may all result in right or left ventricular dysfunction and secondary valvular regurgitation that may require repair. Additionally, cyanosis and underperfusion of the lungs may cause the development of aortopulmonary collaterals that may require coil embolization prior to reoperation. Pulmonary vascular resistance is usually affected by long-standing excessive flow or by severe underperfusion and, in older patients, by ongoing pulmonary thromboembolism. Older patients may also develop coronary artery disease that requires concomitant revascularization.

Transthoracic or transesophageal echocardiography provides excellent information regarding the segmental and morphologic cardiac anatomy. Additionally, hemodynamic data can assist in evaluating valvular function, stenosis, and direction of shunting. In most complex cases, cardiac catheterization is required and pulmonary vascular resistance is calculated directly. Quantitative perfusion lung scans are useful to assess right- and left-sided blood flow. Magnetic resonance angiograms with three-dimensional reconstruction can provide excellent views of anatomy and are particularly

helpful in preparation for redo coarctation procedures to delineate the aortic arch and descending aorta.

Procedures Requiring Reoperation

Redo median sternotomy can be hazardous and result in massive hemorrhage if thin-walled vascular structures are adherent to the posterior sternum. We obtain computed tomography scans in select patients to view the retrosternal structures. In some patients, the femoral artery and vein are exposed prior to sternotomy. If the aorta, right atrium, or a conduit is adherent to the back of the sternum, cardiopulmonary bypass may be initiated with femoral artery and vein cannulation using thin-walled cannulas. If the right atrium or right ventricle is entered inadvertently, an intracardiac defect such as an atrial or ventricular septal defect could result in catastrophic systemic air embolism. This complication can be avoided by instituting deep hypothermia with cardiopulmonary bypass, keeping the heart full, and discontinuing the cardiac dissection until the heart fibrillates. In the presence of aortic regurgitation, decompression of the left ventricle is accomplished by cannulating the left ventricular apex via a small submammary incision. Bleeding may be a problem during chest opening due to the presence of numerous large thin-walled vessels throughout the mediastinum that are commonly found in chronically cyanotic patients. Chronic cyanosis and polycythemia are associated with a coagulopathy due to platelet dysfunction. Chronic hepatic congestion affects the coagulation factors and exacerbates coagulopathy. The use of antifibrinolytic agents such as aprotinin, aminocaproic acid, or tranexamic acid is considered in high-risk patients except when circulatory arrest is used. Topical hemostatic agents have proven very useful for oozing surfaces. Autologous blood donation (when not contraindicated) and the use of cell-saving devices are routine.

A polytetrafluoroethylene (GORE-TEX or PTFE) pericardial substitute is used at closure for patients requiring later surgery, such as palliative procedures or after use of homografts or tissue valves. This membrane facilitates the dissection of reentry and the risk of injuring a retrosternal structure is markedly reduced.

Myocardial Protection

Right and left ventricular hypertrophy, dilatation, or dysfunction may be present. Noncoronary collateral flow is usually increased and bronchial flow can be torrential. Myocardial protection is therefore critical to the outcome of complex procedures. A left ventricular vent and deeper hypothermia to 24°C are required, and both antegrade and/or retrograde cardioplegia are given every 10 minutes. A purse-string suture is placed around the coronary sinus to improve retrograde distribution.

Postoperative Care

The adult with congenital heart disease may present a far more complex postoperative course than the usual adult with acquired heart disease. Both right and left ventricular function may be compromised and require support. Both pulmonary and systemic vascular resistance may require manipulation. For this reason, right atrial (RA), pulmonary artery (PA), and left atrial (LA) pressure-monitoring lines are used when indicated. LA lines are used rather than attempting to obtain PA wedge pressures because of the danger of PA rupture and possible discrepancy between PA diastolic pressures and LA pressure. Transesophageal echocardiography is required postoperatively to assess left and right ventricular function, to evaluate left- and right-sided valve function, and to look for shunts. Ventilator control to reduce partial carbon dioxide pressure, as well as inhaled nitric oxide and milrinone, all are useful ways to reduce pulmonary vascular resistance.

Associated Procedures

Many adults with congenital heart disease require corrective surgery after associated procedures. In particular, all patients above the age of 40 years require preoperative coronary angiography. Due to a history of shunts or increased chest wall collaterals from cyanosis, many patients have aortic insufficiency secondary to increased venous return to the systemic ventricle. Such patients should be considered for aortic valve repair.[21]

Other associated procedures often performed in adults with congenital heart disease include bicuspid aortic valve repair or replacement, mitral or tricuspid valve repair or replacement, and implantation of epicardial pacemaker leads and generator.[22–33]

Our preferred approach for epicardial pacemaker implantation is a subxiphoid approach. Atrial tissue is easily identified near the inferior vena cava in most patients. A ventricular site is usually identified on the diaphragmatic surface of the heart. We prefer nonpenetrating steroid-eluding leads that are sutured onto the epicardium. The pacemaker battery is placed in the preperitoneal position beneath the fascia or in the subcutaneous tissues of the left upper quadrant. Transvenous leads are generally contraindicated in the systemic circulation because of the risk of thromboembolism. This is of particular importance in patients with single-ventricle physiology.

SPECIFIC CONGENITAL MALFORMATIONS

Atrial Septal Defects

Anatomy

Atrial septal defects (ASDs) of the secundum type are the most common lesions, but sinus venosus defects of both the superior and inferior vena caval types, as well as ostium primum ASDs, are seen in adults (Fig. 61-1).

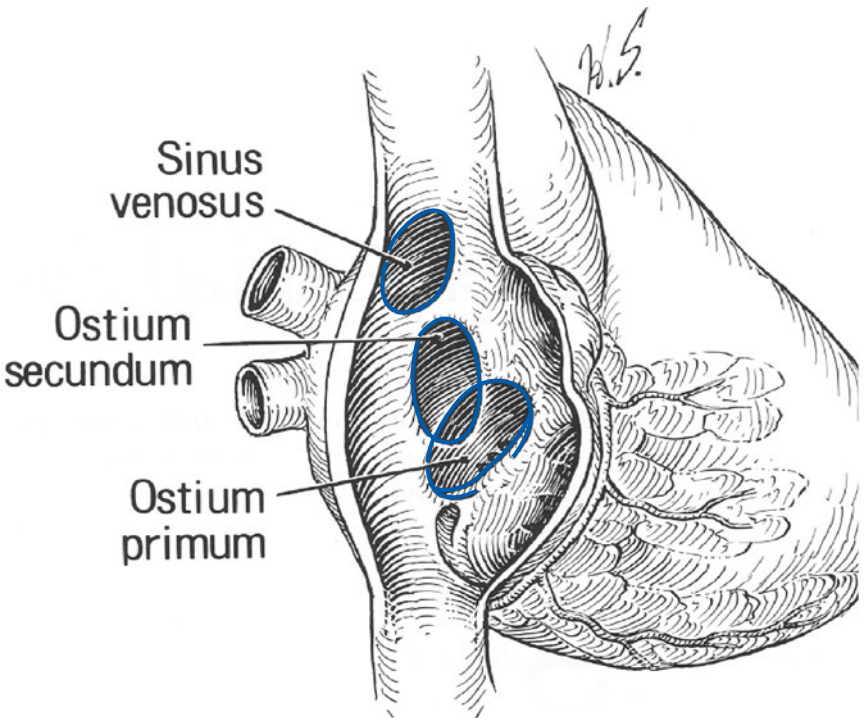

Figure 61-1. Diagram showing the locations of the most common types of atrial septal defects. Sinus venosus defects are close to the superior vena cava-to-right atrial junction and are frequently associated with partial anomalous pulmonary venous drainage (not shown). The right superior pulmonary vein may drain directly into the superior vena cava or at the junction of the superior vena cava and right atrium.

Physiology and indications for surgery

The amount of left-to-right atrial shunting is variable. In older patients, as right ventricular dysfunction and tricuspid regurgitation develop, the degree of left-to-right shunting may decrease. The left-to-right shunt may increase in other patients due to hypertension and reduced left ventricular compliance. Although most patients with an ASD are asymptomatic through the second decade, by the third or fourth decade adults commonly develop atrial fibrillation or a reduction in exercise tolerance, and eventually heart failure.[34–40] It is preferable to close the defect when the diagnosis is made, before the development of these sequelae. As long as the Qp:Qs (pulmonary flow:systemic flow ratio) is greater than 1.5:1 and the calculated pulmonary vascular resistance is less than 6 to 8 U/m^2 (or Wood units/m^2), depending on systemic vascular resistance at the time of measurement, closure is usually indicated. There is often associated tricuspid valve regurgitation, which is the result of annular dilatation due to volume overload of the right ventricle. Indeed, such regurgitation may account for shortness of breath on exertion. This can be particularly true for patients who have patch leaks after repair and who are referred for reoperation to address symptoms out of proportion to shunt size. Patients with a patent foramen ovale and systemic embolization are also candidates for closure of the defect.

About 15 to 20% of children with an ASD eventually develop pulmonary vascular disease.[41–43] If it does not occur by the end of the second decade, it is very unlikely to occur. Pulmonary vascular disease eventually causes reversal of the shunt and development of hypoxia that may be intermittent and severe, depending on right ventricular function and tricuspid regurgitation. Patients with a patent foramen ovale and systemic embolization are candidates for closure of the defect. In the past, patients with pulmonary vascular disease were considered inoperable and were candidates for eventual lung transplants and ASD closure. The use of long-term prostacyclin has allowed some patients to lower their pulmonary vascular resistance and develop a left-to-right shunt. We have successfully proceeded to ASD closure and continued prostacyclin therapy in some of these patients. Another option is an adjustable (see below) or flapped patch closure, to allow a small amount of residual right-to-left shunting postoperatively.[44]

Operative procedure

The operation is performed using cardiopulmonary bypass and moderate hypothermia. For cosmetic purposes in young women, a submammary skin incision with median sternotomy is used. For the last 10 years we have used a small right anterolateral thoracotomy (Fig. 61-2). Another option is a midline incision in the lower half of the sternum. Superior and inferior vena cava cannulation is achieved directly through the thoracotomy incision using right-angled metal-tipped cannulas. If aortic cannulation is difficult, femoral artery cannulation is used. The aorta is clamped and cold blood cardioplegia alternating with cold blood is run continuously to keep the left atrium and ventricle full to prevent air entry. The chest cavity is filled with carbon dioxide throughout the procedure. The ASD is closed either primarily or with a pericardial patch. The right-sided pulmonary veins must all be identified, and if they are draining anomalously, they are baffled to the left

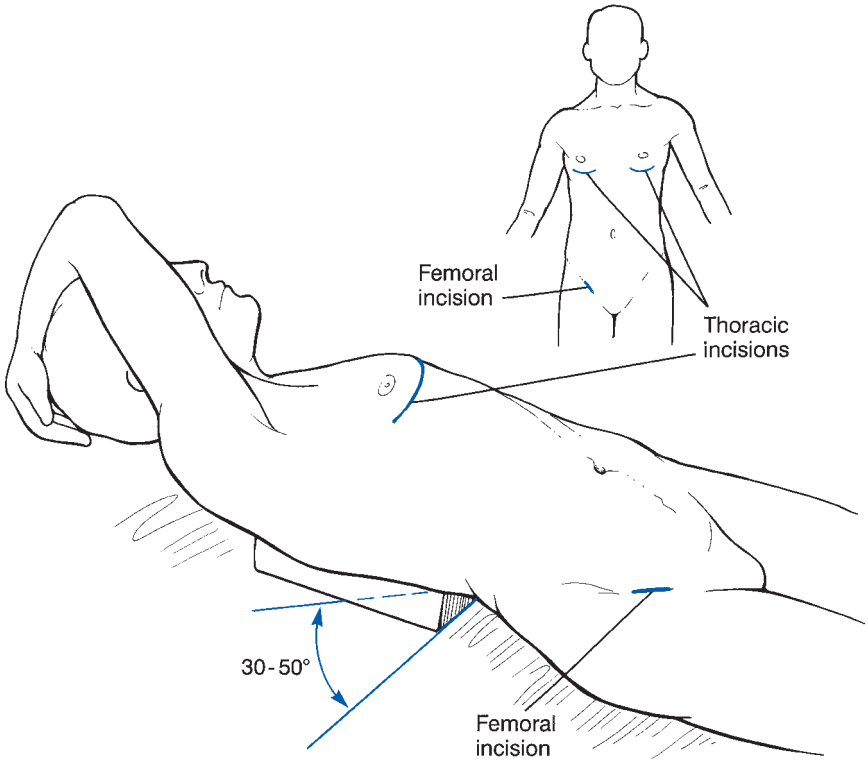

Figure 61-2. Patient position for minimally invasive right thoracotomy approach for repair of an atrial septal defect. A 5- to 7-cm incision is made in the submammary crease. An additional incision may be made in the groin crease for femoral artery cannulation.

side with a pericardial patch. It is also important to identify the inferior vena caval orifice so that it is not inadvertently baffled into the left atrium by sewing the patch to a well-developed eustachian valve.

Redundant right atrial wall may be excised and a regurgitant tricuspid valve (if present) is repaired with an annuloplasty, particularly if the tricuspid annulus is dilated to >34 to 38 mm. In patients with chronic atrial fibrillation, a Maze procedure is performed.[45,46] After closure of the defect and right atrium, extensive de-airing is performed prior to releasing the cross-clamp. This includes syringe and large-bore needles, de-airing of the left atrium, and venting of the aorta. Rarely, if air has entered the left ventricle during the procedure, a small submammary left-sided thoracotomy is made, and a small left ventricular apical vent is also inserted to assist in de-airing. The left ventricle is inspected with transesophageal echocardiography for residual air prior to release of the cross-clamp.

Outcomes

Long-term follow-up after repair of isolated ASDs is well documented.[47–51] When patients are operated on at or before 25 years of age, normal life expectancy is anticipated, but this may not be the outcome when patients are corrected after 25 years, when both right and left ventricular reserve are diminished following a long-standing ASD. However, patients with ASD closure after 40 years of age may still realize improvement of symptoms. At the University of Alabama, it was found that age and New York Heart Association (NYHA) class were fairly well correlated, thus suggesting that ASD closure is indicated when the defect is hemodynamically significant (Qp:Qs >1.5:1). Older age per se is not a risk factor for operative mortality.

Recently, keen interest in the use of intravascular devices to close ASDs has developed.[52–56] The Amplatzer device was recently approved by the Food and Drug Administration for clinical use. Follow-up of 5 to 7 years is now available showing good long-term results. This trend will grow, as the Amplatzer and CardioSEAL devices are currently approved by the Food and Drug Administration for atrial septal defect closure. Long-term follow-up is pending. There is growing interest in the use of endoscopically assisted placement of these devices, with or without robotic aid, to close these defects.[57]

Ostium Primum Defects and Late Reoperations After Repair of an Atrioventricular Canal

Ostium primum (partial canal) defects

Ostium primum defects are unusual in adults; however, survival similar to that for a large ASD is expected for partial atrioventricular canal defects with minimal valvular incompetence. The suture line is placed on the tricuspid aspect of the defect and outside the conduction tissue, which is left beneath the patch. Atrioventricular valve (right or left) regurgitation is often present and should be

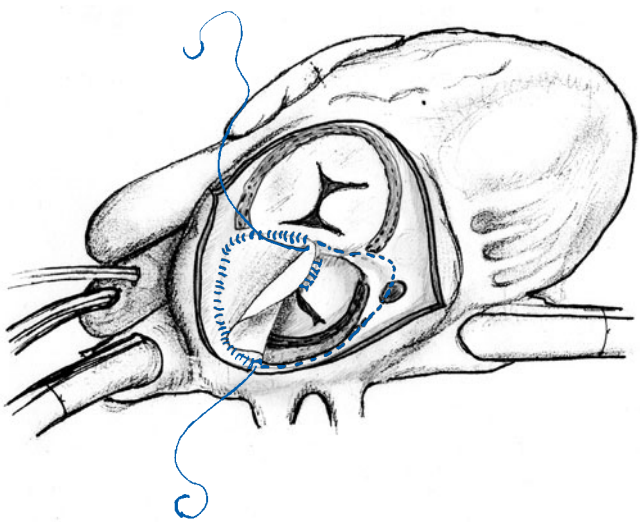

Figure 61-3. Diagram showing closure of ostium primum atrial septal defect combined with mitral valve repair and tricuspid annuloplasty. The cleft in the anterior leaflet is closed with interrupted sutures. A mitral annuloplasty is used when indicated or the commissures are plicated. Autologous pericardium is used to close the atrial septal defect. The suture line is placed on the tricuspid valve side, and then continued inferiorly on the atrial wall, outside the conduction tissue (shown by the dotted line in the diagram), then under the lip of the coronary sinus and back to the edge of the ASD. The conduction tissue is thus left under the patch, and the coronary sinus drains into the right atrium. When indicated a tricuspid annuloplasty is performed using glutaraldehyde-fixed autologous pericardium and 2-0 polytetrafluoroethylene sutures for the annuloplasty.

repaired at surgery[58–62] (Fig. 61-3). Long-term results are excellent.

Late left atrioventricular valve regurgitation after repair of atrioventricular canal

About 10 to 30% of operated atrioventricular canal patients may present because of left atrioventricular valve malfunction.[63,64] They are often successfully treated with a re-repair of the mitral valve; the most common cause is a residual or recurrent cleft in the anterior leaflet. Annuloplasty or commissuroplasty may also be needed.[65–67] This can be in the form of several isolated stitches along the annulus or a band along the posterior aspect of the annulus. There is limited experience with creating a double-orifice valve.[68,69] A unique approach has been reported by the group from Toronto. The dysplastic superior and inferior bridging leaflets are detached radially along the anterior annulus. They are then augmented using glutaraldehyde-fixed autologous pericardium, allowing for better leaflet coaptation. An annuloplasty is also performed.[70]

Some will require valve replacement which can be difficult due to the annulus projecting towards the left ventricle outflow tract. This is because the inlet septum is shortened and the outlet septum is lengthened. A crescent-shaped patch may be used to lengthen the mitral-to-aortic continuity along the circumference of the annulus in the section of A1 and P1. In this way, a low-profile mechanical valve can be positioned away from the left ventricle outflow, with a projection into the left atrium.[71] Leaflet remnants are used to anchor the valve along the other segments of the annulus.

Left ventricular outflow tract obstruction after atrioventricular canal repair

While left ventricular outflow tract obstruction (LVOTO) due to tunnel-like narrowing is unusual in the setting of either partial or complete canal, there have been reports of other types of obstruction occurring late after repair. del Nido and associates have summarized this possibility well. They observed that it is more common in partial canal, and that it may be acquired rather than congenital. This underlines the need for lifelong surveillance.[72,73] Repairs must be individualized and can be complex. Later reoperations are not uncommon.

The anatomy that results in left ventricular outflow tract obstruction may be related to left superior leaflet chordae that are attached to the outlet septum, or to outgrowths of accessory valve tissue in the left ventricular outflow tract. If they are primary chordae, the former requires division and re-attachment, repair, or valve replacement, while the latter may simply be excised. Other causes of left ventricular outflow tract obstruction include a subaortic membrane or abnormal papillary muscle position.[72] Many of these can be approached through the aortic valve.[73]

The group from Toronto has suggested that the outflow tract can be effectively shortened and widened, by augmenting or lifting the left side of the superior bridging leaflet. This is likened to conversion of a Rastelli A anatomy to a Rastelli C. This restores (increases) the angle between the plane of the outlet septum and that of the septal crest toward normal.[74] A patch of glutaraldehyde-fixed pericardium may then be used to close the resulting defect and lifts the leaflet away from the left ventricle outflow. A modified or full Konno procedure may be needed for cases in which there is tunnel-like narrowing with ventricular hypertrophy.

Ventricular Septal Defects

Unrestrictive ventricular septal defects (VSDs) are mostly associated with congestive heart failure in infancy and are usually repaired in early childhood. Adult survival with an unrestrictive VSD can occur if there is concurrent pulmonary outflow obstruction that restricts pulmonary blood flow, or if the development of severe pulmonary vascular disease reduces or reverses the left-to-right shunt (Eisenmenger syndrome). Restrictive VSDs are more commonly found in the adult and may be the result of a persistent small defect, partial spontaneous closure of a larger defect, or a residual patch leak following surgical repair.

Controversy continues as to whether restrictive VSDs should be closed. A large study by Kidd and associates showed a 25-year survival of 87%, but noted a significant increase in the risk of serious arrhythmias and sudden death.[75] The evolving concept of monitoring unoperated

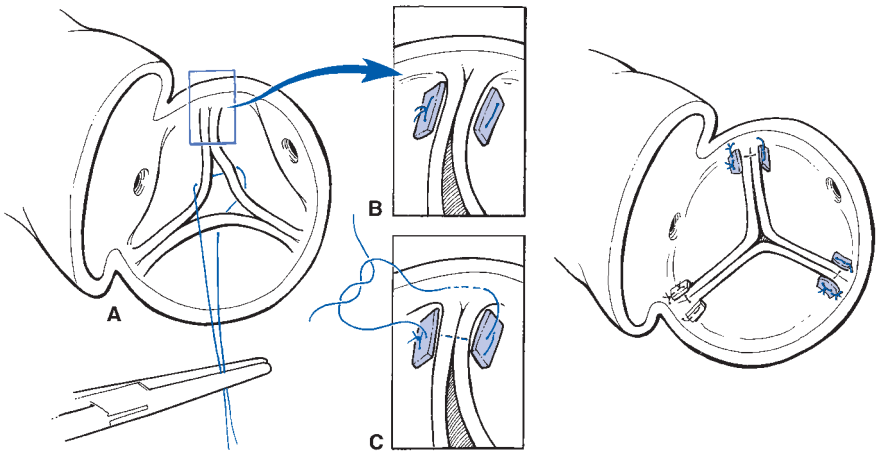

Figure 61-4. Technique of aortic valve repair using pericardial pledgeted sutures to resuspend redundant leaflets. Additional apposition can be achieved by adding sutures below the commissures or at the level of the annulus.

patients in adults with congenital heart disease was reinforced by Glen and coworkers in a study of 1448 patients with VSDs.[76] He noted that 22% of these patients had associated defects. Most were detected initially but aortic insufficiency and infundibular stenosis often developed subsequently. If follow-up of these patients was continued until age 30, 89% of patients with secondary aortic regurgitation would be detected. Nonoperative intervention is most appropriate in patients with small defects, a Qp:Qs ratio of <1.5:1.0, no left ventricular overload, and normal pulmonary artery pressures.

Anatomy

Most VSDs are categorized into four anatomic types. The *perimembranous* type is the most common. It is located under the septal leaflet of the tricuspid valve. The *subarterial* VSD is located in the supracristal area and may lie directly beneath the annulus of the pulmonary valve. Because of the proximity of the aortic annulus to such defects, the right cusp of the aortic valve may prolapse into the defect, reducing the effective orifice and limiting the shunt. Aortic regurgitation is frequently associated with this defect.[77] With surgical closure of a subarterial VSD, the aortic valve may require repair with suspension of the prolapsing valve leaflet (Fig. 61-4).

The *endocardial cushion* type of VSD is located in the inlet of the right ventricle and beneath the septal leaflet and posterior leaflet of the tricuspid valve. This VSD may have associated mitral valve defects such as cleft anterior leaflet and therefore require mitral valve repair at the time of surgery. The repair usually involves suture closure of the anterior leaflet cleft and may require reduction of the dilated annulus with annuloplasty. The *muscular* type of VSD may occur anywhere within the muscular ventricular septum. This type is unusual in adults, as it has a tendency to close spontaneously in the first years of life.[78]

Physiology

Use of the term *restrictive* implies a pressure gradient between the ventricles and a restriction to flow across the defect. The amount of left-to-right shunting across the defect can be quantified by calculation of the Qp:Qs ratio. VSDs with left-to-right shunting that results in a Qp:Qs ratio of <1.5:1 are usually not considered for repair, if there is no other associated pathology (e.g., aortic leaflet prolapse and insufficiency).

Double-chambered right ventricle is an obstruction in the mid-portion of the right ventricle that divides the chamber into two segments: a high-pressure lower chamber and a low-pressure upper chamber. The development of obstructive tissue in the right ventricle is a direct result of a restrictive VSD producing a "jet effect" that strikes adjacent myocardium and produces an area of fibromuscular proliferation. Right ventricular hypertrophy develops secondary to the obstruction and contributes to the progression of right ventricular hypertension. In many patients the VSD will eventually close, as the fibromuscular rim of tissue proliferates around and over the defect. In these patients, the VSD is often identified at the time of surgery with resection of the obstructing tissue in the right ventricle.

In patients with large unrestrictive VSDs, the probability of developing severe pulmonary vascular disease is about 50% by the third decade of life.[79,80] Consequently, patients eventually die of complications of Eisenmenger syndrome if their VSDs remain unrepaired. These patients ultimately will become cyanotic as a result of right-to-left shunting, and the only surgical options available at that point are either heart-lung transplantation or lung transplantation with repair of the VSD. A pulmonary vascular resistance greater than 6 U/m^2 is considered a high risk for isolated VSD closure. A number of promising new medical therapies are being applied to patients with pulmonary hypertension. Use of nitric oxide donors such as sildenafil, endothelin antagonists, and prostaglandin analogs may alter the outcome in these patients and potentially reverse the pulmonary hypertension to levels that will allow for surgical correction.

Preoperative evaluation

An adult patient with a VSD should be evaluated by chest radiograph and echocardiography. A chest radiograph may

show an enlarged right heart shadow and right ventricular hypertrophy. It may also reveal chronic changes in the pulmonary vasculature, prompting further evaluation by catheterization. Transthoracic and transesophageal echocardiography are both useful in defining VSDs anatomically and identifying associated lesions.[81] An estimate of the pulmonary artery pressures may also be obtained. Indications for surgery are helpful in determining the need for catheterization. Patients with embolic complications and very small defects with high gradients and no evidence of pulmonary hypertension can usually be closed without catheterization. However, patients with significant symptoms attributed to their VSD should undergo catheterization to rule out pulmonary hypertension. Right and left heart catheterization is useful to confirm the anatomic findings and to accurately measure the pulmonary vascular resistance and estimate the Qp:Qs ratio. In patients more than 40 years old or in those with increased risk factors, coronary artery disease must also be excluded by angiography.

Indications for surgery

Adults with small restrictive VSDs who are asymptomatic often require no surgical intervention and should receive endocarditis prophylaxis as necessary. In general, if the Qp:Qs ratio is >1.5:1 and the calculated pulmonary vascular resistance is under 6 U/m^2, surgical closure of a VSD can be performed safely and is recommended. The development of a double-chambered right ventricle with outflow obstruction is also an indication for operative intervention. The occurrence of infective endocarditis in an adult with a restrictive VSD is a rare but compelling indication for repair of the defect. In adults with VSD and Eisenmenger syndrome, heart-lung transplantation or lung transplantation with closure of the defect may be considered.

Operative procedure

Operative repair of VSDs is performed on cardiopulmonary bypass with moderate systemic hypothermia and blood cardioplegia for myocardial protection. Generally, greater operative exposure is required than for the repair of ASDs. However, many of the cosmetic modifications discussed in the section on atrial septal defects are appropriate here. Bicaval cannulation with caval snares helps to produce a bloodless field. A left-sided vent is also helpful in evacuating blood from the left heart. This can either be placed through the left superior pulmonary vein or through an incision in the atrial septum. An appropriately sized patch is then created and sewn in place using either interrupted, pledgeted horizontal mattress sutures or a continuous running suture. The patch is cut slightly larger than the defect so that the sutures can be placed away from the edge and the conduction system. Most adults with a perimembranous, inlet, and/or muscular VSD can have the defect repaired through the tricuspid valve annulus. If the edges of the defect are difficult to visualize due to multiple attachments of the septal leaflet to the edges of the defect, the septal leaflet may be incised at its base adjacent to the annulus or radially through the septal leaflet, exposing the VSD under the leaflet. Subarterial VSDs may be approached through the pulmonary valve or the right ventricular outflow tract. Exposure through the pulmonary valve is particularly helpful in placing sutures through the pulmonary valve annulus without damaging the valve. The patch material for closure of VSDs may be synthetic (e.g., PTFE or Dacron), or glutaraldehyde-fixed autologous pericardium, which we have preferred for over 15 years. PTFE may produce less hemolysis than pericardial patches. However, it may also be less well-incorporated and therefore small residual VSDs may not close as readily. Postoperatively, elevated pulmonary artery pressures may be treated with inhaled nitric oxide. A fenestrated VSD patch can be created to transiently allow right-to-left shunting and maintain cardiac output in the immediate postoperative period. It can subsequently be closed in the cardiac catheterization lab. Currently, transcatheter closure of VSDs remains experimental.[82,83]

Outcomes

Long-term follow-up is recommended to monitor pulmonary artery pressures in those adult patients with large VSDs that are repaired late in life.[84] This is achieved echocardiographically if there is a mild tricuspid regurgitation from which to calculate the right ventricular pressure, or by measuring the pulmonary valve opening time. The pulmonary vascular resistance may continue to rise after VSD closure, resulting in systemic or suprasystemic right ventricular pressures. This may eventually cause the onset of angina, right heart failure, or even sudden death.

In an analysis of 52 patients between the ages of 16 and 67 years repaired at the University of California, Los Angeles, there was no mortality. In most patients, the VSD repair was combined with additional procedures such as aortic valve repair, pulmonary valve replacement, and tricuspid valve repair. Except in patients with congenitally corrected transposition, the incidence of complete heart block following VSD closure is approximately 1%. Overall, the long-term outcome for these patients has been excellent.

Patent Ductus Arteriosus

Natural history and indications for surgery

Isolated patent ductus arteriosus (PDA) may present with congestive heart failure by the third or fourth decade of life.[85] Occasionally, the ductus may become aneurysmal secondary to flow characteristics. The aortic end of the PDA is usually calcified in the older adult patient. A long-standing left-to-right shunt may lead to pulmonary vascular disease. The cumulative death rate in childhood is about 0.5% per year. This doubles to 1% by adulthood and increases to 2 to 4% by midlife. There is always a risk of endocarditis (regardless of the PDA size) that is dependent on the presence of abnormal flow. Adults with

large PDAs may develop Eisenmenger syndrome and the classic finding of differential cyanosis in the lower body. It is imperative to determine pulmonary vascular resistance and reactivity preoperatively. If the resistance is >6 to 8 U/m^2, the ductus should not be closed, and the patient may be considered for lung or heart-lung transplantation.

Operative procedure

Surgical closure of a PDA is usually carried out via a small posterior thoracotomy. Thoracoscopic procedures are probably not appropriate for the adult because of the frequency of calcification and the greater risk of rupture while ligating the ductus.[86,87] In patients over 40 years of age, or in the presence of severe ductal calcification or aneurysm, consideration should be given to performing PDA ligation via a median sternotomy using cardiopulmonary bypass.[88,89] During cooling, the branch pulmonary arteries are snared. This prevents steal from the descending aorta. The ductus is exposed via an incision in the PA. Using low flow, the ductus is closed on the PA side with horizontal pledgeted mattress sutures, or the PA defect is patched with glutaraldehyde-fixed pericardium or a PTFE patch.

Patients with Eisenmenger syndrome may be candidates for either single- or double-lung transplantation combined with PDA closure, or heart-lung transplantation if there is significant ventricular dysfunction and tricuspid valve regurgitation.

Catheter closure by interventional cardiology specialists using coils or other devices may be possible depending on the size and length of the ductus.[90–93] In the last 5 years, catheter-based closure of this lesion in the adult has been reported as the most common after ASD, VSD, and coarctation.[94] Similarly, surgeons have also reported a catheter-based approach in which the patent ductus is excluded with a stent graft placed in the proximal descending aorta.[95–97]

Coarctation of the Aorta

Anatomy

Coarctation in adults may occur in previously unrepaired patients or patients who have had prior surgical correction. In unrepaired patients an abnormality of the media creates a posterior shelf, opposite the ligamentum arteriosum. This shelf may extend circumferentially. The abnormality, similar to cystic medial necrosis histologically, predisposes patients to late complications such as dissection and aneurysm formation. There is often extensive collateral circulation in adults with coarctation. The source is mainly from branches of the subclavian artery and internal mammary arteries, and intercostal chest wall circulation. Collateral flow into the descending aorta is dependent on enlarged intercostals at the level of the third and fourth ribs beyond the coarctation. Additional cardiovascular anomalies occur in 59 to 92% of patients and include a bicuspid aortic valve in 40 to 80% and aortic arch hypoplasia in 33%.[98]

Natural history and indications for surgery

Aortic coarctation in adults usually presents with upper-body hypertension, typically in the second or third decade of life.[99] Lower extremity pulses are usually weak and delayed. Although these patients comprise a selected group who have survived free of complications beyond childhood, long-term complications include aneurysm formation of the aorta and aneurysmal dilatation of intercostal arteries, which may eventually rupture. This latter anomaly is important because the initial portion of these arteries should be occluded at the time of surgery if they appear disproportionately enlarged. Other complications include premature coronary artery disease, left ventricular hypertrophy, aortic dissection and rupture, endocarditis, and intracranial hemorrhage. In adults with coarctation, congestive heart failure may develop from long-standing hypertension. Patients with an associated bicuspid aortic valve may develop stenosis and/or incompetence. [23] If aortic coarctation is left untreated, 90% of patients eventually die by the age of 50 due to cardiac causes or stoke. The oldest patient in our series was 81 years old.

Repair also may be required for patients who have had previous coarctation repairs with recurrence or for patients who have developed recurrence after previous balloon aortoplasty. As many as 70% of infants who have unrepaired arch hypoplasia at their initial operation may require reoperation as adults. Residual coarctation following repair in childhood is also due to failure of growth of the anastomosis or technical factors such as a short subclavian flap aortoplasty. In patients who were initially treated with a patch, aneurysm formation may occur and require reoperation. Surgical repair is indicated when the gradient across the coarctation is ≥30 mm Hg at rest.[100] If the gradient is less and the anatomic obstruction severe, an exercise test will reveal a more severe gradient, and repair is indicated.

Preoperative evaluation

The anatomy of the entire left ventricular outflow tract and thoracic aorta must be defined prior to surgical intervention. Previously repaired patients may have additional levels of obstruction from a hypoplastic aortic arch that has failed to grow or a stenotic/regurgitant aortic valve. Surgical intervention should be tailored to address all levels of obstruction. Echocardiography is performed to evaluate the aortic valve, ventricular function and hypertrophy, and the aorta. In adults, magnetic resonance angiography with three-dimensional computerized reconstruction to assess the transverse arch, isthmus, and descending aorta is often useful (Fig. 61-5).

Operative procedure

The preferred method is resection with extended end-to-end anastomosis (Fig. 61-6), although patch repair is used for

Figure 61-5. Angiogram of a 27-year-old patient who presented with residual coarctation after initial repair in which a 16-mm interposition graft was inserted. She presented with stenosis at the distal transverse arch and at the interposition graft with proximal hypertension. Repair using a left atrial-to-aortic bypass circuit involved repairing the distal arch and replacing the graft with a 20-mm PTFE conduit and extended anastomosis.

reoperations or where the collaterals are particularly enlarged and difficult to mobilize.[99,101–103] Tube-graft interposition is used when indicated to relieve long segments of obstruction. Special precautions are taken to reduce the major risk of spinal cord ischemia. Arterial lines are placed in the upper and lower extremities for monitoring blood pressure during aortic clamping. The distal pressure should be maintained above 50 mm Hg throughout the procedure. Somatosensory evoked potentials are monitored intraoperatively to aid in the decision to use extracorporeal circulation to help prevent spinal cord ischemia during aortic cross-clamping. In extensive reoperations or operations for aneurysms, the cerebrospinal fluid pressure is monitored by catheter, and the fluid is allowed to drain if pressure exceeds 10 cm H_2O (essentially central venous pressure). The cerebrospinal fluid pressure is monitored for 24 hours postoperatively. The goal is to optimize perioperative perfusion of the spinal cord by increasing the pressure gradient during and after aortic clamping.

The patient is placed on a temperature-regulated blanket and cooled to 33 to 34°C. Cold saline is used to bathe the left chest cavity to aid in cooling, and the room is cooled. Positioning for the left thoracotomy is important in that one must prep and drape the groins to have access to the femoral arteries if left atrial-to-femoral artery (or descending aorta) bypass becomes necessary during the operation. One must carefully identify chest wall collaterals, which can bleed massively and which must be ligated individually during the thoracotomy.

The aorta is mobilized extensively, and the ligamentum arteriosum is divided and oversewn. Large intercostal branches are identified and encircled in preparation for snaring. On induction of anesthesia, the patient is given 30 mg/kg of methylprednisolone sodium succinate and lidocaine 2 mg/1 kg intravenously, as well as 8 g of mannitol. The patient is anticoagulated with 1 mg/kg of heparin. The aorta is clamped when the rectal temperature is 34°C or below. Once the aorta is clamped proximally and distally, if the distal pressure is below 50 mm Hg, distal aortic bypass is instituted. The distal pressure is maintained above 60 mm Hg. This consists of left atrial-to-descending aortic bypass using a centrifugal pump. In more complex redo or aneurysm procedures, pulmonary artery-to-descending aortic bypass can be used with an oxygenator. Upper extremity pressure is maintained at about 120 mm Hg systolic. Once the aortic coarctation is resected, reconstruction with a tube graft or end-to-end anastomosis is carried out with 4-0 polypropylene suture mounted on a small needle.

For patients undergoing reoperation for recurrent coarctation, mobilization of the aorta for end-to-end anastomosis may be difficult and cause excessive blood loss. In these patients, the aorta is clamped proximal to the left subclavian artery, and a glutaraldehyde-fixed autologous pericardial patch may be used to enlarge the aorta from the base of the subclavian artery to the distal aorta. An excessively large patch should be avoided to prevent late aneurysm development.

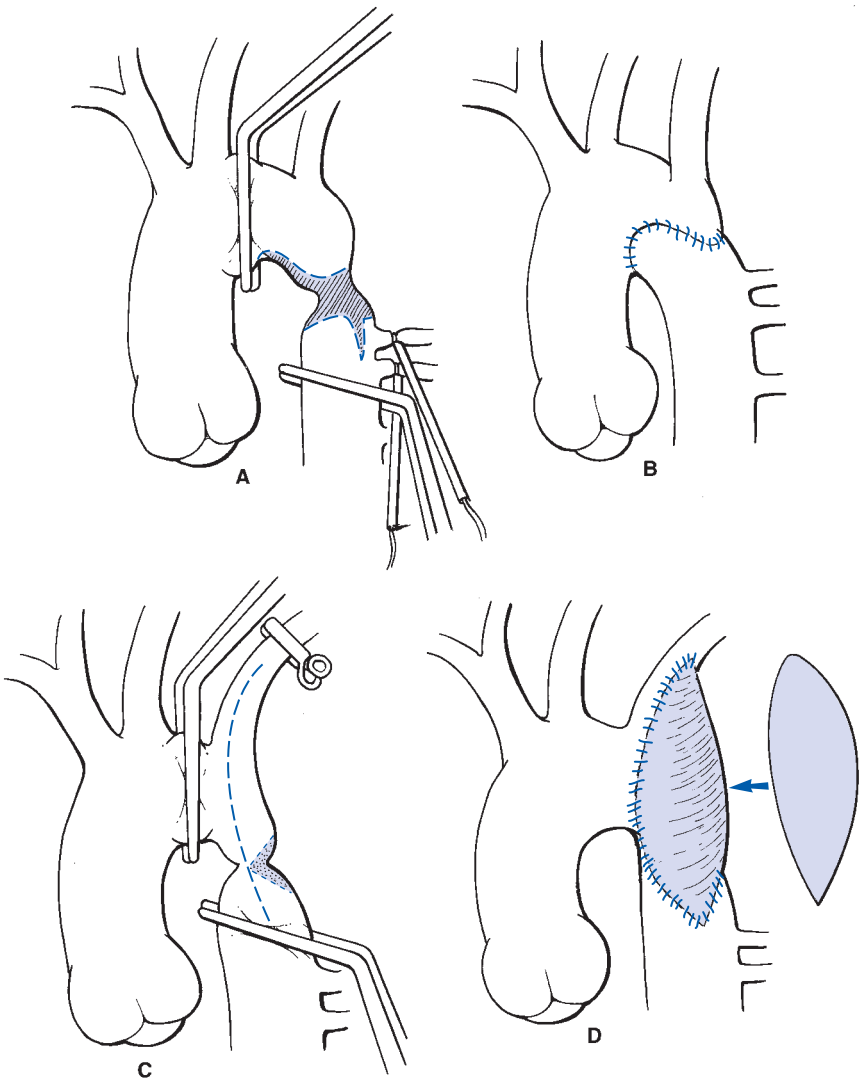

Figure 61-6. Resection of coarctation of the aorta. (A, B) With extended end-to-end anastomosis. (C, D) After excision of the coarctation site and reconstruction of the posterior wall by end-to-end anastomosis, a glutaraldehyde-fixed autologous pericardial patch is used to enlarge the isthmus and the site of coarctation repair. The patch is measured to avoid excessive dilatation, which can result in late aneurysm formation.

Some institutions prefer construction of an ascending-to-descending aortic bypass graft in patients with recurrent coarctation. The operation has been performed through either a right thoracotomy or via a posterior pericardial approach through a median sternotomy.[104,105] Both have reported a low mortality and morbidity with excellent relief of hypertension and resolution of the blood pressure gradient between the upper and lower extremities. A 16- to 20-mm graft is used and the repair through the right chest can be performed off bypass. Both approaches avoid the complications associated with a redo left thoracotomy, including injury to the recurrent laryngeal nerve, intercostal arteries, and lung. Aortic bypass graft also addresses significant arch hypoplasia and avoids the need for clamping of the "hostile aorta" that may be thin or calcified.

There should be no gradient between the upper and lower extremities upon release of the clamps. During closure, special care is taken to control intrathoracic bleeding and to check chest tube and pericostal suture sites.

Hypertension is controlled and is treated aggressively in the intensive care unit. Abdominal pain and distension may be present in 5% of patients postoperatively. Management is usually conservative. The patient is given nothing by mouth for at least 24 hours postoperatively until bowel sounds return.

In older patients who have a coarctation and also require coronary revascularization or aortic valve repair or replacement, we prefer a median sternotomy approach with cannulation of both the ascending aorta and the femoral artery. After completing the coronary revascularization, an adequately sized Dacron graft can be placed between the ascending aorta and the proximal abdominal aorta through the diaphragm. Another option to consider is a clamshell-type incision to access the descending thoracic aorta and the mediastinum simultaneously.

Outcomes

Outcome following repair is generally good, and follow-up may be assisted with transesophageal echocardiogram, computed tomographic scan, or magnetic resonance imaging. The latter is useful to detect aneurysm formation or recoarctation.[106,107] *Recoarctation* is defined as a gradient >20 to 30

mm Hg at rest. The possibility of coronary disease and systemic hypertension requires lifelong monitoring.

Catheter-based techniques are being used for both primary coarctations and recurrences.[108–110] Residual mild gradients are common after angioplasty and/or stenting of primary coarctations and we therefore prefer surgical therapy.[99] Since the presence of a residual gradient of >10 mm Hg is associated with an increased risk of adverse cardiovascular events, intervention must result in long-term, near-total resolution of the gradient.[111] Remembering that the primary goal is resolution of hypertension, surgery has consistently resulted in long-term relief in over 60% of patients. Recent analyses have shown that angioplasty alone results in a high rate of reintervention and is markedly worse at curing hypertension than surgery.[112] Angioplasty was found to be comparable to surgery with regard to morbidity, but appears to be much less effective in the cure of hypertension. For selected recurrent coarctations, stenting may be the preferred method, provided that an excellent anatomic relief of the obstruction can be achieved.[113] However, in younger patients in whom a long-term result is required, surgery may still be preferable, even in complex lesions.

Tetralogy of Fallot

Tetralogy of Fallot (TOF) is the most common cyanotic heart defect in children, constituting approximately 10% of all congenital heart disease. It is therefore one of the most common cyanotic congenital heart defects found in adults. Successful repair of TOF in childhood has spanned almost four decades, with many of those patients now returning as adults for reoperation.[114–123] These patients constitute the majority of adults presenting for surgical intervention for TOF. There are also adults with TOF who underwent palliative procedures in childhood but never underwent complete repair of the defect.[124] Occasionally, a patient with a well-balanced TOF defect and adequate pulmonary stenosis to protect their pulmonary vasculature will reach adulthood without any operative intervention.

Anatomy

TOF is classically defined by Fallot's four original pathologic findings: obstruction of right ventricular outflow, ventricular septal defect, overriding aorta, and right ventricular hypertrophy. The defect is the result of an anterior displacement of the infundibular septum during development, resulting in obstruction to right ventricular outflow and a malalignment ventricular septal defect. The aorta is displaced toward the ventricular septum, resulting in an overriding position, and hypertrophy of the right ventricle is a direct consequence of the outflow obstruction. The obstruction to pulmonary blood flow is often at multiple levels, which may include subvalvular, valvular, and supravalvular stenosis. The pulmonary valve is frequently malformed or bicuspid and the annulus is often small. Hypoplasia of the pulmonary arteries may be present if the obstruction to pulmonary blood flow is severe, and there is often stenosis of the branch pulmonary arteries, either primarily or secondary to shunts. Aortopulmonary collaterals arising from the aorta may coexist, as is commonly found in patients having pulmonary atresia with ventricular septal defect. Occasionally, cyanotic adults will present with unrepaired TOF and severe pulmonary obstruction, but adequate collateral pulmonary blood flow to allow survival beyond childhood.

Physiology

The pathophysiology of TOF results in restriction of pulmonary blood flow secondary to obstruction of right ventricular outflow and right-to-left shunting across the ventricular septal defect. The age at presentation and the degree of cyanosis vary directly with the degree of obstruction to pulmonary blood flow. Patients undergoing palliative shunt procedures in childhood to increase pulmonary blood flow may do quite well if the resulting oxygenation remains adequate with subsequent growth. These systemic-to-pulmonary shunts are often outgrown at an early age, requiring reintervention for additional palliation or more definitive repair. While currently the modified Blalock-Taussig shunt or central shunt is used for palliation in most patients, the Potts (ascending aorta-to-right pulmonary artery) and Waterston (descending aorta-to-left pulmonary artery) shunts were used in the past and may be found in some adult patients.

Indications for surgery

Residual VSDs, residual or recurrent obstruction to pulmonary blood flow, and severe pulmonary insufficiency with progressive right ventricular dilatation and dysfunction are all indications to consider reoperation in adults who have undergone previous complete repair of TOF. Patients who have previously undergone right ventricle-to-pulmonary artery conduit placement often present later in life with conduit stenosis requiring replacement. Patients who have had TOF repair in late childhood may have other sequelae that may have an impact on late reoperative surgery. The long-term volume load from a large shunt may produce permanent left ventricular dysfunction. The pulmonary vascular resistance may be elevated. Mild or even moderate aortic valve regurgitation is not uncommon due to dilatation of the aorta and may require aortic valve repair or replacement.

Pulmonary valve regurgitation is very common after repair of TOF, since approximately 70 to 80% are repaired with a transannular patch. Even though exercise capacity may be decreased, the vast majority of patients tolerate this well unless they have an additional residual VSD or pulmonary artery stenosis. In addition, some patients, without these associated residual defects, will slowly develop right ventricular dilatation and severe tricuspid regurgitation. This may progress for over 20 years, and patients are currently presenting late as they become symptomatic from combined pulmonary and tricuspid valve regurgitation. In view of the risks of sudden death and the progressive nature of right ventricular dysfunction, surgical intervention is recommended.

Figure 61-7. A three-dimensional magnetic resonance image documenting aneurysmal dilatation of the right ventricular outflow tract in a patient with previous repair of tetralogy of Fallot.

Aneurysms of the right ventricular outflow tract may occur following the use of an excessively large transannular pericardial patch with the initial repair (Fig. 61-7).

Such aneurysmal dilatation may progress, especially if there is associated right ventricular outflow tract obstruction.

Sudden death after TOF repair accounts for a significant number of late deaths. It usually occurs in patients who have had a right ventricular incision and have right ventricular dilatation combined with an elevated right ventricular pressure above 60 mm Hg.[125] All else being equal, a QRS duration of greater than 180 milliseconds is associated with an increased risk of sudden death, and a progressive increase in QRS duration is considered a factor in deciding on reoperation.[126] Any ventricular arrhythmias should be evaluated by electrophysiologic studies and focal pathways should be treated with catheter ablation. Pacemakers are required in fewer than 4% of patients late after TOF repair.[127] They may be indicated for sick sinus syndrome, the combination of right bundle-branch block with left anterior hemiblock, or the late onset of complete heart block.

Preoperative evaluation

The preoperative evaluation in adults with TOF must take into consideration the patient's previous operative interventions. In addition to chest radiography and electrocardiography, transthoracic or transesophageal echocardiography has become the fundamental diagnostic tool in most of these patients. Angiography is indicated to define specific hemodynamics such as the pulmonary vascular resistance and to define the pulmonary artery anatomy. Aortic and selective injections are performed to look for aorta-pulmonary collaterals. The coronary anatomy must be known, as 4 to 5% of TOF patients have an left anterior descending artery arising from the right coronary artery, which can be injured by a transannular incision. Adults over age 40 and those with risk factors for early coronary artery disease should undergo coronary angiography to evaluate the need for concomitant coronary bypass. Magnetic resonance imaging with angiography or computed tomography scans with three-dimensional reconstruction have proven valuable for defining the anatomy. In all patients with TOF, there should be an evaluation of the size and patency of the pulmonary trunk and its branches, the size of the pulmonary annulus, the stenosis and/or competency of the pulmonary valve, the proximal coronary artery location, and the presence of systemic-to-pulmonary artery collaterals. If there is a right ventricle-to-pulmonary artery conduit or an aneurysmal transannular patch present, magnetic resonance angiography or computed tomographic imaging studies should be used to evaluate the proximity of these structures to the sternum and to the midline site of the redo sternotomy. Preoperative electrophysiologic studies may be indicated if significant arrhythmias are identified.

Operative procedure

In most adults with TOF, bicaval cannulation is used, and myocardial protection involves both antegrade and retrograde cold blood cardioplegia followed by warm blood cardioplegia and warm blood reperfusion. Ventricular distension is avoided with venting of the left ventricle. Atrial septal defects should be sutured primarily or closed with a patch of native pericardium. Ventricular septal defects may be approached through the right atrium or through the right ventricular scar or outflow tract patch. A PTFE or glutaraldehyde-fixed pericardial patch may be used. The right ventricle is remodeled by resection of scar from the previous ventriculotomy and any aneurysmal tissue in the right ventricular outflow tract. The pulmonary valve is replaced, usually with an oversized porcine bioprosthetic valve seated below the native annulus in the right ventricular outflow tract (Fig. 61-8). A 27- or 29-mm porcine valve can usually be accommodated in all adults. A transannular hood of pericardium or PTFE is used to cover the porcine valve and establish continuity to the pulmonary artery. Homografts are used to replace previously inserted conduits (Fig. 61-9). The pulmonary homograft lasts longer than the aortic homograft but develops regurgitation earlier. The tricuspid valve can usually be repaired with an annuloplasty and rarely requires replacement. In some cases adherence of the septal leaflet to the VSD patch can be repaired by suturing it to the adjacent anterior and posterior leaflets.

Definitive procedures in adults may require takedown of previously placed shunts. Systemic-to-pulmonary artery type shunts should be controlled as soon as cardiopulmonary bypass is instituted. Takedown of a Waterston shunt is done from within the pericardium. The right pulmonary artery is mobilized. The aortic cannulation site for cardiopulmonary bypass is placed distally. When cardiopulmonary bypass is initiated, shunt flow is controlled with a clamp flush with the aorta, and the patient is cooled to 20°C. Cardioplegia is administered after aortic clamping. With the heart arrested and at low flow, the shunt clamp is released, and the anastomosis is excised from the aorta. This mobilizes the right pulmonary artery. The aorta is closed primarily. The incision in the right pulmonary artery is extended proximally and distally to relieve any stenoses. The right pulmonary artery is reconstructed with a pericardial or PTFE patch. Takedown of a Potts anastomosis usually requires a period of low flow or circulatory arrest.[128] The shunt is occluded by pressure on the left pulmonary artery while blood is cooled to below 20°C. With the head down, the left pulmonary artery is incised and opened under low flow so that the opening to the aorta can be occluded with a Hegar dilator. Under low flow or circulatory arrest, the aortic side is closed primarily, and the pulmonary artery is repaired with a pericardial patch (Fig. 61-10).

Takedown of a Blalock-Taussig shunt is usually achieved by dissection, ligation, and division of the shunt at the initiation of cardiopulmonary bypass.

Outcomes

Long-term results are well documented in patients who had complete repair of TOF in the late 1950s and early 1960s.[129–134] Actuarial survival ranges from 77 to 90% at between 20 and 30 years of follow-up. Late mortality from cardiac causes accounts for about two-thirds of all late deaths. Between 40 and 60% of these are sudden and presumed to be due to arrhythmias or to heart block. Other causes include right ventricular outflow abnormalities

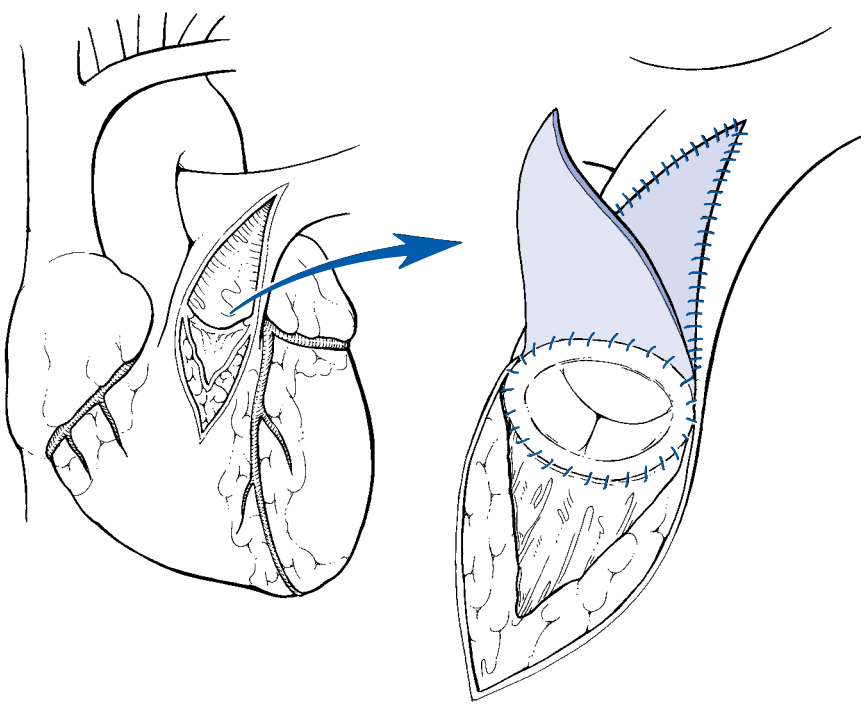

Figure 61-8. Pulmonary valve replacement with patch enlargement of the right ventricular outflow tract. The incision extends across the annulus and beyond the bifurcation to the left pulmonary artery. The outsized porcine valve (27 or 29 mm) is placed within the right ventricular outflow tract to accommodate the larger size valve.

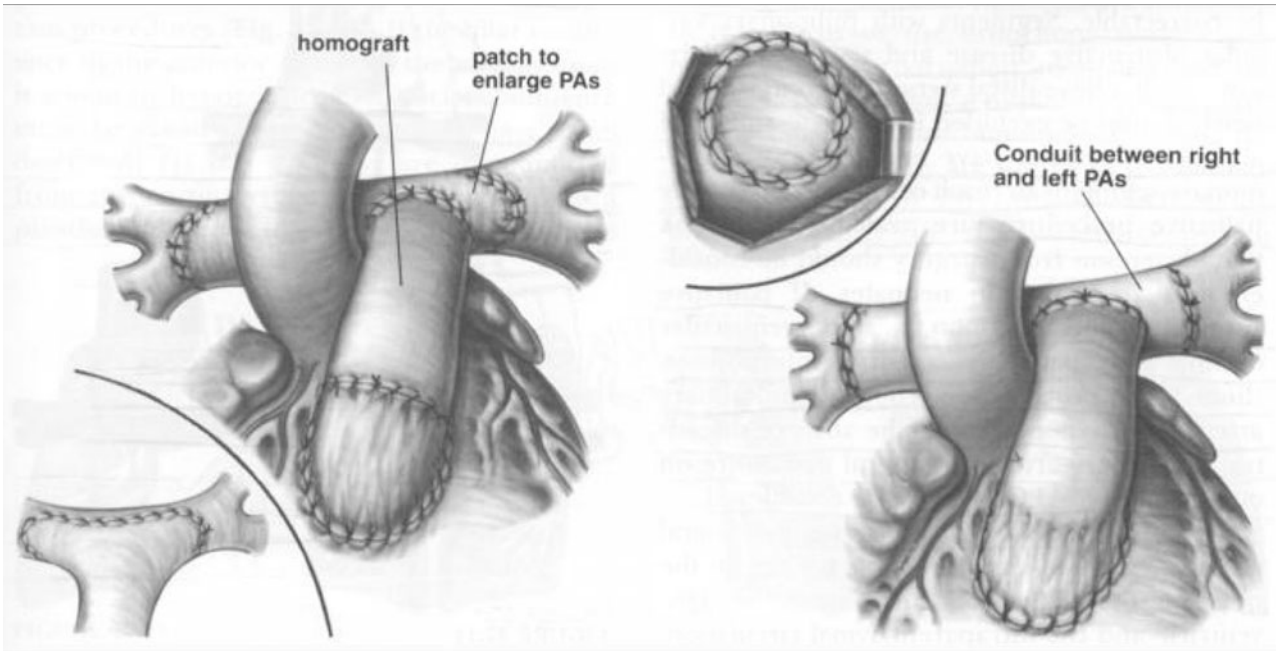

Figure 61-9. Homograft replacement of the right ventricular outflow tract with hood augmentation of the proximal anastomosis and patch enlargement of the branch pulmonary arteries. A reinforced PTFE conduit may be placed behind the aorta to re-establish continuity between the right and left pulmonary arteries.

(obstruction, pulmonary incompetence, and aneurysm) and congestive heart failure partly related to residual VSDs, which were reported in 1 to 8% of all operated patients in these early series. Currently, residual VSDs are expected in less than 5% of repairs for TOF.

The results of primary repair of TOF in adults are very good. Presbitero and colleagues reported an operative mortality of 2.8% in a series of 40 adults with TOF repairs.[129] There were two residual VSDs and two patients with residual right ventricular outflow tract obstruction. The results of

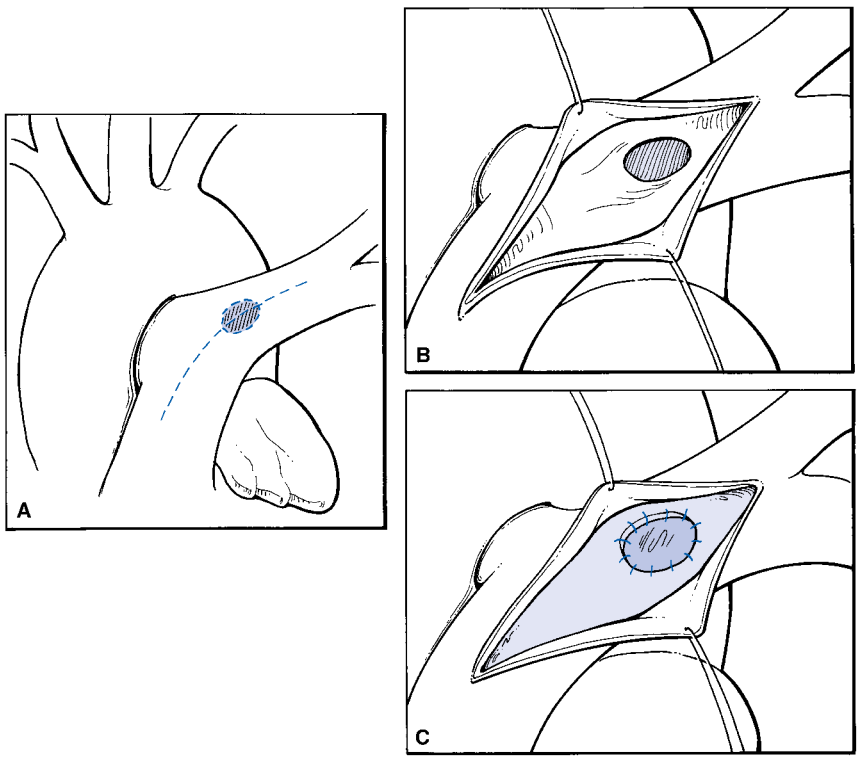

Figure 61-10. Patch repair of a Potts shunt anastomosis. The main and left pulmonary arteries are incised (A) to expose the opening (B) in the posterior proximal left pulmonary artery. The defect is closed with a pericardial or prosthetic patch (C).

reoperative surgery in adults with TOF are also generally good. Mortality ranges from 7 to 20%. Pome and associates reported an actuarial survival of 87% for 22 patients at 20-year follow-up for this particular cohort.[122] Eighty-nine percent of patients were NYHA class I, and only 1 patient (5.5%) was in class III. Two women in this series experienced uncomplicated pregnancy. In the series from the Mayo Clinic reported by Uretzky and coworkers, 5 patients (12%) had a second reoperation.[133]

At the University of California, Los Angeles, we have operated on adults with TOF ranging in age from 16 to 65 years. Most had patch repairs of the ventricular septum, insertion of a right ventricular outflow patch, and pulmonary valve replacement. The oldest TOF patient underwent primary repair and coronary artery bypass grafting. There was no mortality or significant morbidity in this series.

Pulmonary Atresia with Ventricular Septal Defect and Major Aorta-to-Pulmonary Artery Collaterals

Patients with this complex lesion sometimes survive to adulthood without surgery because of adequate pulmonary blood flow from collaterals. Others have shunts or unifocalization procedures or complete repairs.[135–140]

Anatomy

The true pulmonary arteries may be absent, hypoplastic, and continuous or discontinuous. The collaterals may be the dominant or only blood supply to the lung or supply only lesser areas of the lung. The VSD is subaortic and usually single. Depending on previous shunts, there may be stenoses in the proximal or distal pulmonary arteries. If repaired there may be a residual VSD, obstruction between the right ventricle and PA, and tricuspid valve regurgitation.

Physiology

Patients who have not had repair and who are considered "well-balanced" have a saturation of 80 to 84%. These patients with complete mixing have a left-to-right shunt of between 1.5:1 and 2:1. Therefore, they all have a volume-overloaded heart. The volume overload results in reduced exercise tolerance. Because of high flow and elevated pressure, they may have developed increased pulmonary vascular resistance in the area of some of the collaterals. The aorta and aortic valve tend to dilate, and 50% develop aortic valve regurgitation. Ventricular dilatation and dysfunction can also occur.

Preoperative evaluation

Echocardiography is used to exclude additional VSDs and to evaluate the aortic valve. Angiography is performed to delineate the collaterals and true pulmonary arteries, as well as to evaluate transpulmonary gradient, which may be high if there was uncontrolled large collateral flow hypertension. Such elevated gradients may preclude complete repair. Magnetic resonance angiograms with three-dimensional reconstruction give detailed pictures of the anatomy.

Indications for surgery

Patients with inadequate pulmonary blood flow are limited due to cyanosis and may require unifocalization if they have an adequate bed for future repair. If they do not, they may be candidates for a palliative shunt. Patients with excessive pulmonary blood flow and failure can also be treated by unifocalization with reduction of the total flow. The size of the shunt to the unifocalization is crucial to adjust flow to the pulmonary vasculature. After unifocalization on one side (Fig. 61-11), the opposite side is unifocalized 6 months to 1 year later (Fig. 61-12), followed 6 months to 1 year later by a complete repair (Fig. 61-13).

Shunted patients should be repaired if they have an adequate size pulmonary bed, unless they are inoperable because of high pulmonary vascular resistance or poor ventricular function. A residual VSD should be closed in previously repaired patients if the left-to-right shunt is 1.5:1 or above. Conduit or valve obstruction is reoperated when there are symptoms, or if the right ventricular pressure at rest is two-thirds to three-fourths of systemic pressure. If there is severe pulmonary valve regurgitation with right ventricular dilatation or tricuspid regurgitation, reoperation should be undertaken.

Staged surgical repair

The goal of surgical management of pulmonary atresia, ventricular septal defect, and multiple aorta-to-pulmonary collateral arteries is closing the ventricular septal defect and establishing continuity between the right ventricle and pulmonary artery. Ultimately, successful definitive repair requires an adequate pulmonary vascular bed, without which VSD closure and right ventricular-to-PA continuity will lead to right ventricular failure due to a prohibitively high pulmonary vascular resistance. Thus, all efforts during the operative staging are designed to maximize the size, distribution, and normal flow of the pulmonary arteries while preserving myocardial function.

Early palliative procedures in patients with excessive or inadequate pulmonary blood flow were designed to create a balanced pulmonary blood flow and encourage growth of the true pulmonary arteries.

Unifocalization procedures join the multifocal sources of pulmonary flow (true pulmonary arteries and aorta-to-pulmonary artery collaterals) into a single source that can ultimately be accessed in the anterior mediastinum via median sternotomy. The unifocalization procedure is performed through a posterolateral thoracotomy incision. A double-lumen endotracheal tube is employed, when possible, for large children and adults. Single-lung ventilation of the contralateral lung, when tolerated, greatly facilitates exposure. We prefer autologous pericardial tube unifocalization of aortopulmonary collaterals and true pulmonary arteries.

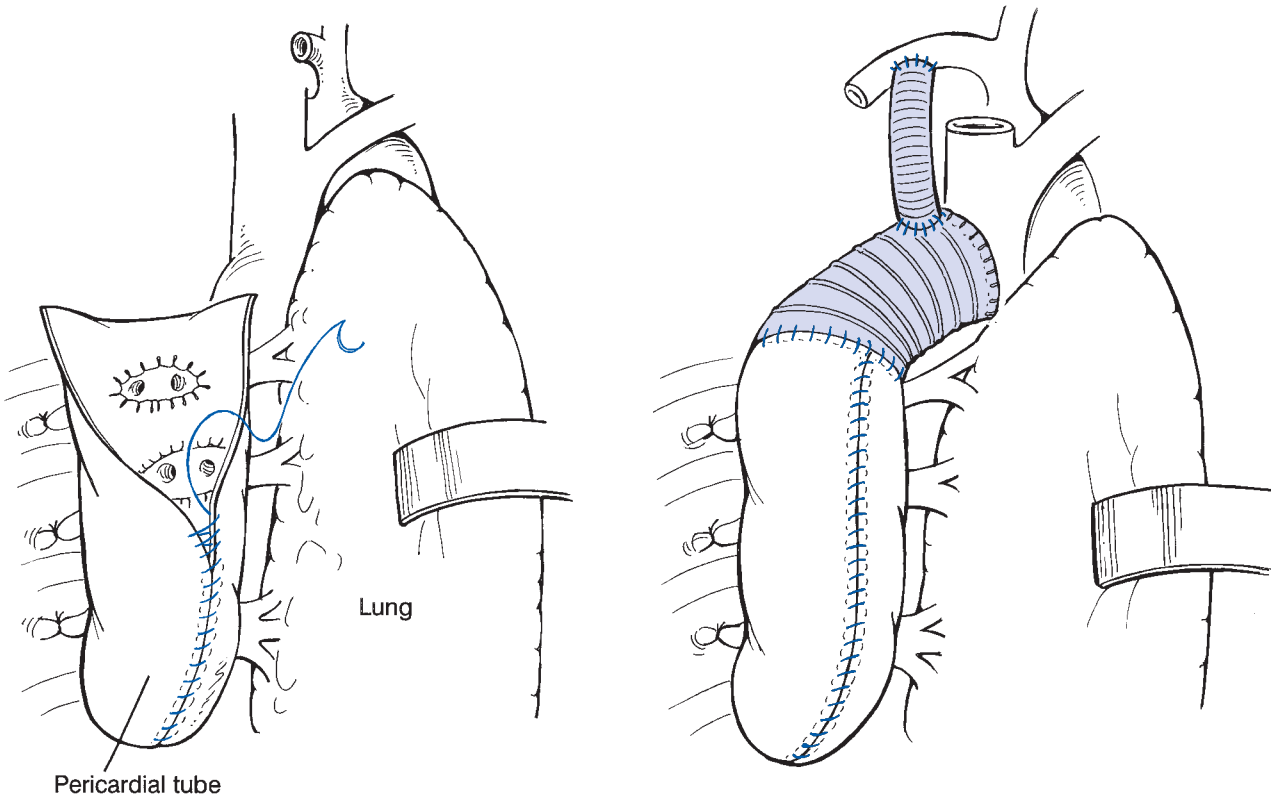

Figure 61-11. Unifocalization of the pulmonary artery blood supply to the right lung using a pericardial tube. Through a lateral thoracotomy a side-to-side anastomosis is created to each major collateral and an adjacent incision made in the autologous pericardium placed behind the lung. The pericardium is turned into a tube by suturing the edges and the collaterals are ligated proximal to the tube. The posteriorly lying tube is extended by a 16-mm PTFE graft to the anterior mediastinum. A 6-mm PTFE shunt is made between the subclavian artery and the 16-mm PTFE extension.

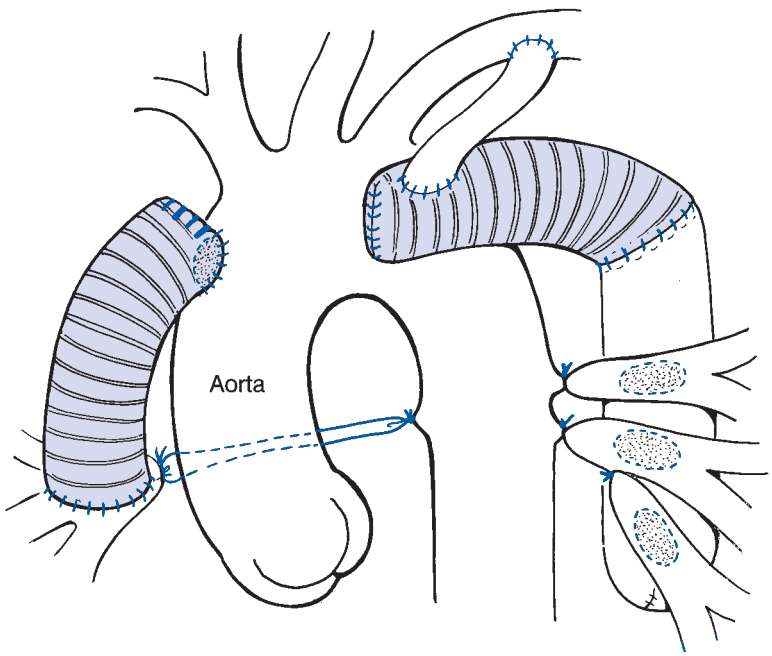

Figure 61-12. A 19-year-old patient previously underwent left pericardial tube unifocalization to three collaterals at age 18 years. On the right side there was a single collateral to a large pulmonary artery supplying the entire right lung. Right-sided unifocalization was achieved by ligating the collateral and placing a 20-mm PTFE graft from the right pulmonary artery to the ascending aorta, creating a central restrictive anastomosis.

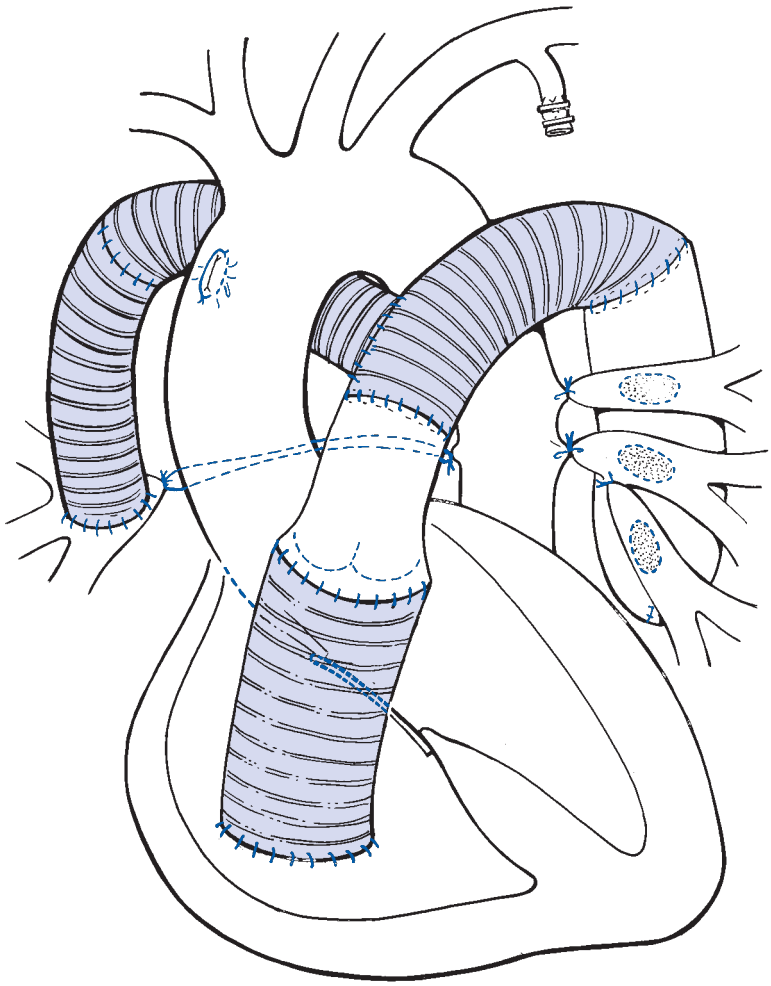

Figure 61-13. The complete repair performed 6 months after the right unifocalization shown in Fig. 61-12. The ventricular septal defect was closed. An aortic homograft conduit was placed between the right ventricle and the left unifocalization. The right unifocalization was then connected to the homograft by a 16-mm reinforced PTFE tube placed behind the aorta.

Finally, definitive repair in this disorder entails patch closure of the anterior malaligned ventricular septal defect and establishment of continuity between the right ventricle and the pulmonary arteries. All systemic-to-pulmonary artery shunts, including redundant collaterals and surgically created shunts, have been previously occluded or are readily accessible from the anterior mediastinum for occlusion at the time of definitive biventricular repair. Measurement of the ratio of right ventricle-to-left ventricle systolic pressure allows intraoperative assessment of the repair. A ratio of 0.75 or less immediately after termination of cardiopulmonary bypass is acceptable, and the ratio can be expected to decrease in the first few days after operation. Higher ratios suggest inadequate pulmonary runoff and will likely result in right ventricular failure. If the pressure on the right side is near systemic or suprasystemic, perforation of the ventricular septal defect patch may provide survival and reasonable palliation.

Outcomes

From 1983 through 2000, 105 children and adults have presented to our institution with pulmonary atresia, ventricular septal defect, and multiple aorta-to-pulmonary artery collaterals. All patients were subject to a strategy of staged repair. Sixty-four patients in this cohort underwent palliation in the newborn period at a median age of 1 week. Surgical palliation included systemic-to-pulmonary artery shunts, right ventricular outflow patches, and banding of aorta-to-pulmonary artery collaterals to reduce high pressure and flow. Interventional cardiac catheterization procedures were performed to promote growth of the pulmonary arteries as necessary.

Ninety-four patients underwent unifocalization at a median of 3.5 years (range, 6 months to 37 years). Fifty-eight (range, 1 to 34 years) of these 94 patients have proceeded to complete repair at a median of 7.2 years. Unifocalization was performed in 19 adults, and of this group, 8 patients have undergone uneventful complete repair. There was neither mortality nor significant morbidity in this group. At a median follow-up of 60 months there were a total of 18 deaths for a 17% early and late mortality rate. Survival after initial palliation was 92%, after unifocalization 91%, and after complete repair 91%. There were 36 reoperations (12%) and 16 patients required catheter-based interventions after surgery. The mean right ventricle-to-left ventricle pressure ratio was 0.46. Nearly all the survivors are asymptomatic and do not exhibit any signs of exercise intolerance.

Although there is some debate about whether a one-stage repair is preferable in neonates and children, patients

presenting as adults, with or without prior palliation, may be excellent candidates for the staged approach described above. We prefer a staged approach to one-stage correction in adults whose predominant blood supply to the lungs is from collaterals. In adults with a predominant blood supply from the true pulmonary arteries a one-stage repair may be utilized. The strategy of staged repair for patients with tetralogy of Fallot with major aorto pulmonary collaterals provides good functional results.

The mortality rate and requirements for postoperative interventional cardiac catheterization with this approach are lower than published reports of single-stage repair.

As patients age and mature they will require reoperations to replace right ventricle-to-pulmonary artery homografts and degenerative bioprostheses in the pulmonary position. Long-standing pressure and volume load on the right ventricle will lead to tricuspid regurgitation and right atrial enlargement that may predispose some patients to atrial arrhythmias.

Late Reoperations for Transposition of the Great Arteries

Anatomy and natural history

Dextraposed transposition of the great arteries is characterized by atrioventricular concordance and associated ventriculoarterial discordance. Prior to the introduction of the arterial switch procedure in 1982, the Mustard and Senning procedures were the standard operations for dextraposed transposition. In the Mustard procedure, a pericardial baffle was used to redirect the systemic and pulmonary venous return. In the Senning procedure, the atrial septum and wall were used for the baffle. This allowed deoxygenated blood to be pumped to the pulmonary circulation and the oxygenated blood to be pumped to the systemic circulation. As a consequence of these operations, such patients have the morphologic right ventricle acting as the systemic ventricle, and the natural history of such anatomy is well documented. There is about 70 to 80% survival at 20 years; 10% of patients have symptomatic right ventricular dysfunction, and about 60% have dysfunction that becomes evident at exercise testing. Additionally, atrial arrhythmias are common, and many patients are in junctional rhythm at 10 years of follow-up. With either procedure, baffle obstruction can lead to a high incidence of vena caval obstruction or pulmonary venous obstruction requiring reoperation.[141,142] Eventual morphologic right ventricular failure in these patients will require either transplantation or a staged procedure with left ventricular reconditioning and arterial switch.

Sudden death has been identified as the most common cause of mortality in patients having undergone an atrial switch procedure.[143] Most sudden death events occurred during exercise. Predictors of sudden death were found to be documented atrial fibrillation/flutter and the presence of symptomatic arrhythmias or heart failure. Electrocardiogram, chest x-ray, and Holter monitoring were not predictive.

Preoperative evaluation

Transthoracic or transesophageal echocardiography usually delineates the site of systemic or pulmonary venous obstruction, ventricular function, and valvular regurgitation. In some cases angiography is also required. Magnetic resonance imaging has become a sensitive tool for assessing ventricular function and can be used to follow patients undergoing ventricular retraining. This allows for a rapid, noninvasive assessment of ventricular function during sequential banding so that the band can be loosened in the face of left ventricular failure.[144]

Operative procedure

Reoperation for obstruction of either systemic veins or pulmonary veins can almost always be accomplished by incision of the site of obstruction and patching using a pericardial patch when it is available. Usually, with repair of the caval part of the baffle, the functional left atrium is also enlarged.

For patients who present with right ventricular dysfunction and tricuspid valve regurgitation, the choice of therapy is more complex. If the major problem is tricuspid valve regurgitation in the presence of relatively well-preserved right ventricular function, we prefer to repair or replace the tricuspid valve. The results of tricuspid valve repair or replacement in suitable patients are generally good. Care must be taken to avoid conduction tissue that is very vulnerable at the junction of the septal and anterior leaflets. If right ventricular function is significantly depressed, the left ventricular function and the left ventricular outflow tract (LVOT) and pulmonic valve are evaluated. If left ventricular function is good and there is no fixed LVOT obstruction or pulmonic stenosis, the patient may be considered for left ventricle preparation and the arterial switch procedure. Preparation of the left ventricle requires PA banding to a pressure of 60 to 70% of systemic pressures initially and then delayed rebanding to systemic pressures. It should be noted that retraining the left ventricle in the mature heart is a longer process than in the neonate, and that there is less margin for error when placing a band in a fully septated heart. Six months to a year may be required to achieve this and to obtain a normal left ventricular wall thickness.

Once this is achieved, the arterial switch operation may be performed. The atrial baffle is removed, and a new atrial septum is constructed in the anatomic position (Fig. 61-14). In adults, left ventricle preparation by successive tightening of a pulmonary artery band can be hazardous and ultimately unsuccessful with the onset of left ventricular failure. The outcomes from this approach have been quite variable and the overall experience is limited. If significant left ventricular dysfunction or fixed LVOT obstruction is identified, the patient may be considered for heart transplantation.

Results

The outcomes from reoperations to repair baffle obstructions in patients with previous Mustard and Senning procedures are quite good if the systemic right ventricular function is

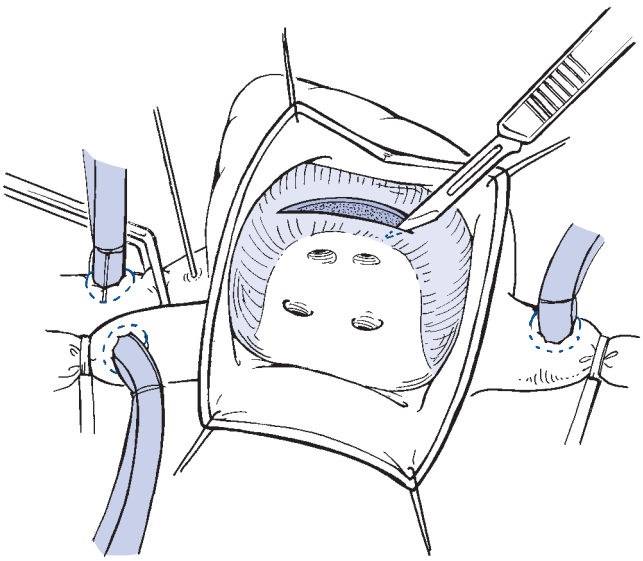

Figure 61-14. Takedown of a Mustard baffle. After opening the anatomic right (functional left) atrium, the four pulmonary veins surrounded on three sides by the Mustard baffle are visible. The illustrated incision enters the atrial chamber that receives systemic venous blood, and when completed will expose both caval-atrial junctions and the four pulmonary veins entering a common atrial chamber. For venous return to the perfusion circuit, the superior and inferior venae cavae can be cannulated directly or via peripheral venous cannulas.

preserved.[141,142,145–157] Generally adolescents and adults are highly variable in their response to a staged conversion to an arterial switch procedure.[148,153] This is a critical point since few patients have undergone atrial switch procedures for transposition in the last 20 years, and most new patients will be in the third decade of life and later. While no age cutoff has been identified, attempts to identify risk factors indicate that complex coronary anatomy, severe morphologic right ventricular failure, and supraventricular arrhythmias result in worse outcomes. In these patients cardiac transplantation as an initial therapy may be the preferred course.

Single Ventricle

Anatomy

Single ventricle is a term that describes various forms of congenital heart disease characterized by malformation and hypoplasia of one ventricular chamber, resulting in a single functioning ventricle. The specific defects include tricuspid atresia, mitral atresia, unbalanced atrioventricular canal defects, severe forms of pulmonary atresia with intact ventricular septum, hypoplastic left heart syndrome, double inlet left and right ventricles, and absent ventricular septum (Holmes heart). Malposition or transposition of the great arteries is present in many of these patients.

Physiology

All of these patients have single-ventricle physiology with initial mixing of the systemic oxygenated blood and the venous deoxygenated blood within the ventricle. Pulmonary blood flow is supplied by either a true pulmonary artery (PA), a patent ductus arteriosus, systemic-to-pulmonary collaterals, or a surgical shunt. The PA may have pulmonary or subpulmonary stenosis or may have been surgically banded. With complete intracardiac mixing, pulmonary blood flow must be approximately 1.5 times the systemic blood flow (Qp:Qs = 1.5), to achieve a systemic arterial oxygen saturation of 80 to 85%. This increased pulmonary blood flow results in a volume overload on the ventricle and the aorta. The clinical manifestations in patients with any form of single ventricle are directly related to the pulmonary blood flow and pulmonary artery pressure. These will be determined by the presence or absence of pulmonary stenosis and the pulmonary vascular resistance. Of note, over half of these patients will have some form of pulmonary stenosis or atresia.

Indications for surgery

There are a few patients reported in the literature with single ventricle who have survived to adulthood without surgical intervention.[23] Most patients will require intervention because of too much pulmonary blood flow, causing heart failure, or too little pulmonary blood flow, causing cyanosis. Patients are stratified according to their pulmonary artery pressure, pulmonary vascular resistance (PVR), ventricular function, and anatomic complexity into low-, medium-, and high-risk candidates for a Fontan procedure. In medium- and high-risk patients with elevated PA pressure, PVR, and impaired ventricular function, a bidirectional Glenn shunt is performed as a first stage to a Fontan procedure or as long-term palliation until a heart transplant may be considered.

Glenn shunt

PHYSIOLOGY: By connecting the end of the superior vena cava (SVC) to the superior aspect of the right PA, about one-third of the systemic venous return is diverted to the lungs for oxygenation. This is a more efficient shunt than a systemic-to-PA shunt and does not cause a volume overload on the ventricle. It is therefore better tolerated in the presence of impaired ventricular function. Provided the SVC pressure is 18 mm Hg or less, the elevation in SVC pressure is well tolerated.

OPERATIVE PROCEDURE: As shown in Fig. 61-15, the Glenn shunt is performed without cardiopulmonary bypass in most patients by using an SVC-to-PA shunt. If additional procedures are required, such as the relief of subaortic obstruction, atrial septectomy, or atrioventricular valve repair, an open procedure on cardiopulmonary bypass is required. An additional source of pulmonary blood flow aims for a pulmonary-to-systemic blood flow ratio of 1 to 1.3, depending on the PVR. Either a banded pulmonary artery or a small systemic-to-PA shunt is used. The additional source of blood flow improves oxygenation at rest and with exercise, and may prevent late arteriovenous fistula development in the lungs.

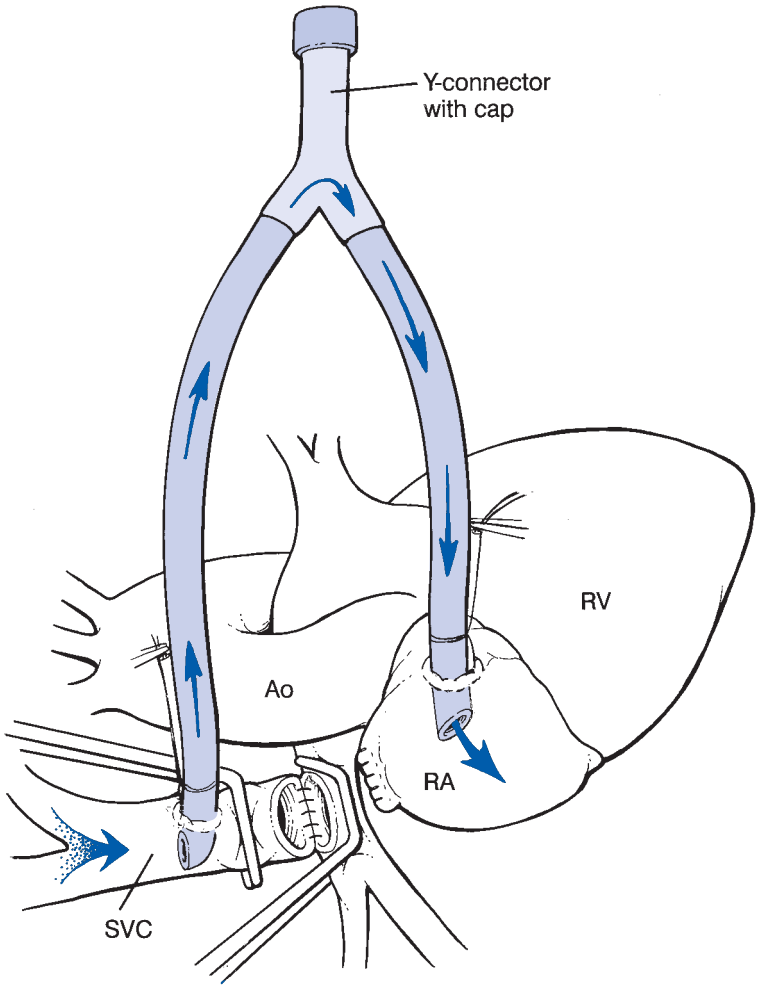

Figure 61-15. Creation of a bidirectional Glenn shunt (superior vena cava to right pulmonary artery) using an extracorporeal shunt (with systemic heparin) to maintain superior vena caval flow into the right atrium. A de-airing chamber and port are needed to prevent air entry into the heart.

OUTCOMES: The early mortality for an isolated Glenn shunt is low (1 to 4%), depending on factors such as the PVR and ventricular function.[158–161] Additional intracardiac procedures increase the risk. In the long term the Glenn shunt slowly loses its effectiveness due to the development of venous collaterals from the superior vena cava to the inferior vena cava.[158,160,161] These can be coil embolized by catheter technique. If there is no additional source of pulmonary blood flow, there is usually severe desaturation on exercise and systemic-to-PA collaterals develop over time. Intrapulmonary arteriovenous fistula can also develop in this situation, resulting in desaturation. In patients with no additional source of pulmonary blood flow and with severely impaired ventricular function, oxygenation can be improved with a controlled shunt by performing an axillary artery-to-vein fistula.[162]

Modified Fontan procedure

INDICATIONS: Because of the limited palliation provided by the Glenn shunt, patients who meet hemodynamic criteria should be considered for a Fontan procedure. The criteria include good ventricular function, ejection fraction 50% or higher, normal or close-to-normal PVR, PA pressure <20 mm Hg, and no additional severe hemodynamic lesions that require prior attention, such as residual coarctation of the aorta, severe subaortic obstruction, or severe atrioventricular valve regurgitation. Generally, correctable lesions should be addressed at the time of the Glenn shunt or before completion of the Fontan procedure.

OPERATIVE PROCEDURE: Many different modifications of the Fontan procedure have evolved to connect both the superior and inferior vena caval blood to the pulmonary arteries. Currently, the two most commonly performed operations are the lateral tunnel Fontan (Fig. 61-16) and the extracardiac Fontan (Fig. 61-17). The lateral tunnel has the advantage of not requiring warfarin anticoagulation in the majority of cases, and a fenestration can be easily included in the procedure. The extracardiac Fontan can be done without arresting the heart and is therefore associated with improved postoperative ventricular function. It can be fenestrated with a separate small shunt from the conduit to the atrium. Treatment with warfarin anticoagulation is indicated for at least 1 year and possibly for life to reduce the incidence of conduit thrombus. Because of the extensive atrial suture lines, arrhythmias and sick sinus syndrome may be more common with the lateral tunnel Fontan. A newer modification of the

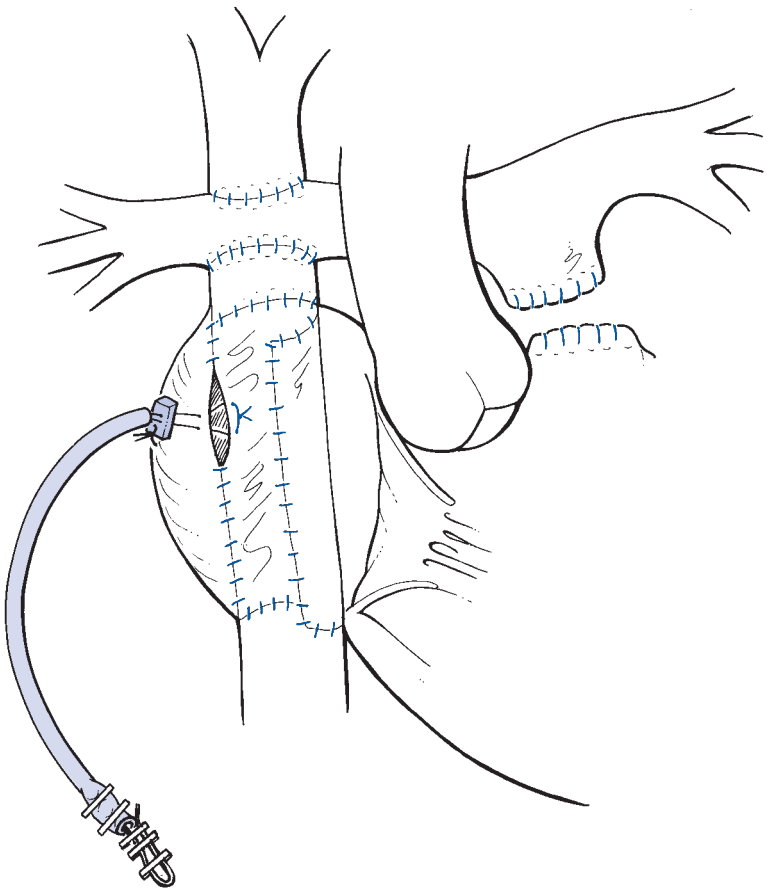

Figure 61-16. A lateral tunnel Fontan operation enlarges the right atrium and directs inferior caval flow into the right pulmonary artery using an end-to-side anastomosis to provide bidirectional flow into both pulmonary arteries. A snared purse-string suture adjusts the size of an atrial septal opening that is used to decompress caval pressures and to control the amount of right-to-left shunting.

extracardiac Fontan using bovine pericardium and the native atrial wall has recently been reported.[1]

OUTCOMES: The early mortality of the Fontan procedure in adults depends on selection of patients and the presence of risk factors. Reported series have an early mortality of 5%.[163,9,21] Fontan patients may be candidates for pacemakers (10%) and reoperations for valvular (5%) and obstructive problems, and may require transplantation for deteriorating ventricular function.[164] Protein-losing enteropathy can occur in 5 to 10% of patients.[163,165,166]

Late Reoperations after Modified and Classic Fontan Procedures

Surgical reintervention following a Fontan procedure may be indicated for arrhythmias, cyanosis, exercise intolerance, protein-losing enteropathy, atrioventricular valve regurgitation, or failing Fontan circulation. Surgical procedures include pacemaker insertion, revision of Fontan, fenestration of Fontan, Maze procedure, repair or replacement of the atrioventricular valve, and heart transplantation.[8] Patients who have had a right atrial-to-PA connection may develop massive right atrial enlargement.[164,165,166] This can eventually result in atrial arrhythmias, thrombus formation, and thromboembolism. Supraventricular arrhythmias as well as atrioventricular node dysfunction are common, and preoperative evaluation by an electrophysiologist is usually indicated. When the right atrium is enlarged, warfarin anticoagulation is indicated. Such patients should be considered for reoperation with conversion to either a lateral tunnel or to an extracardiac conduit with reduction of the enlarged right atrium, and a right-sided Maze procedure has resulted in improved NYHA functional class and reduced incidence of arrhythmias.[7,22,24,25,167] Many will require a permanent pacemaker. If they do not meet the criteria for Fontan conversion, they could be considered candidates for a heart transplant.

The long-term results after modified Fontan procedures have shown that a significant number of patients require late reoperation. The highest incidence was for patients in whom a valved conduit was used.[168,169] Older age at operation remains a risk factor for late death after the Fontan procedure. Revision of the atrioventricular valve closure in double-inlet ventricles or repair of the atrioventricular valve in tricuspid atresia is needed in more than 5% of patients. Adult patients with systemic single right ventricles have significant risk for ventricular dysfunction with congestive heart failure and increased mortality.[26] In addition to arrhythmias and reoperations, adult Fontan patients may also suffer from clinically silent pulmonary emboli and thromboembolic events that may reduce the quality of life and have severe long-term consequences.[10,27]

Protein-losing enteropathy occurs in about 10% of Fontan patients. It is characterized by a low serum albumin level, persistent ascites, and peripheral edema with or without

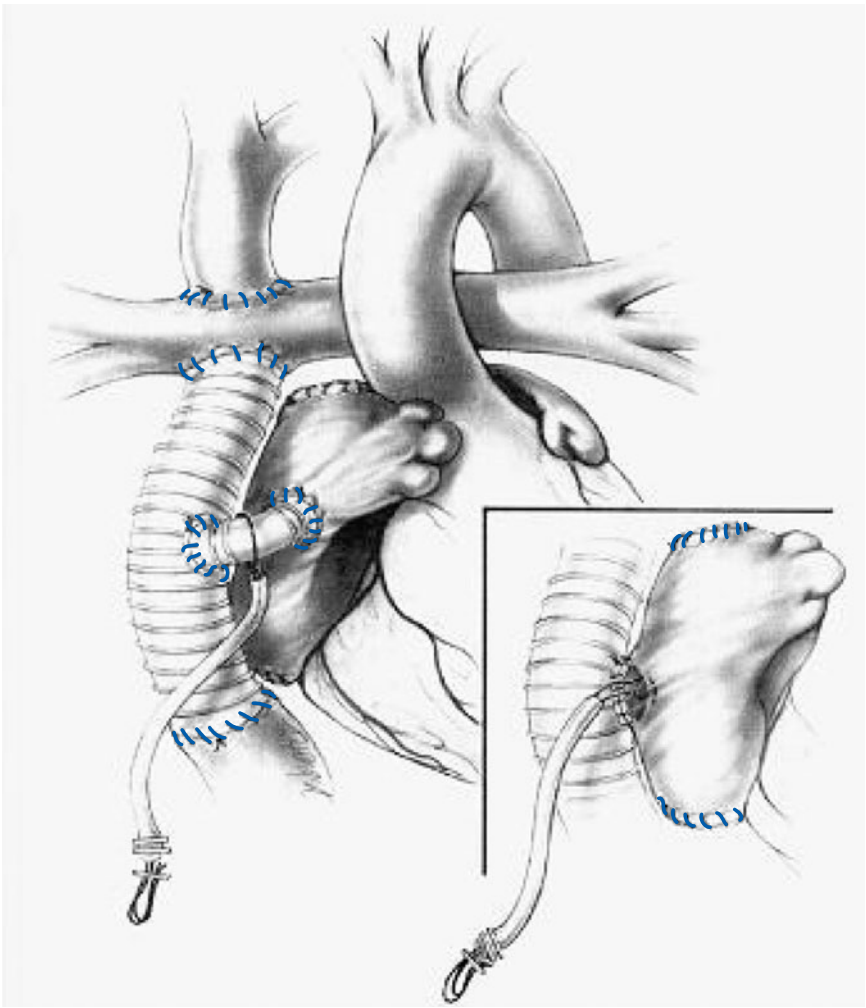

Figure 61-17. Extracardiac Fontan with adjustable conduit-to-atrial connection.

diarrhea. It may be associated with a mortality up to 20%.[163,164,166] It occurs more frequently in patients with heterotaxia or polysplenic syndromes, as well as in those with elevated pulmonary vascular resistance or abnormal systemic venous drainage. Some of these patients can be helped by transcatheter fenestration of the atrial septum or Fontan conduit with stenting.[2] If they do not meet criteria for a Fontan revision, they should be evaluated for transplantation.[170–177] In many patients, protein-losing enteropathy will resolve following successful heart transplantation.

Ebstein Anomaly

Ebstein malformation is a rare congenital cardiac defect accounting for less than 1% of all congenital heart disease. The primary pathologic finding is an abnormal development of the tricuspid valve marked by a downward displacement of the septal and posterior leaflets into the cavity of the right ventricle. This defect is characterized by a remarkable morphologic variability and a broad spectrum of clinical presentations. Consequently, the diagnosis may be made in symptomatic newborn infants, in children, or in adults.[178,179] The degree of tricuspid regurgitation varies depending on the anatomic abnormality. If there is an atrial septal defect, patients may present with cyanosis. If the atrial septum is intact, they may present with cardiomegaly, right-sided heart failure, or arrhythmias. Those patients with atrial or ventricular arrhythmias may present with episodes of syncope, near syncope, or recurrent palpitations.

Paroxysmal supraventricular arrhythmias occur in 25 to 40% of patients and are most often found in teenagers or young adults.[180] Aberrant right atrial to right ventricular tracts resulting in tachycardia (Wolff-Parkinson-White syndrome) occur in 10 to 18% of patients.[181] Sudden death due to ventricular arrhythmias may occur in as many as 5 to 7% of patients. Likewise, patients with mild manifestations of the Ebstein malformation may present as late as the third or fourth decade of life with complaints of palpitations or mild exercise intolerance.[182,183] While some patients may reach advanced age without serious clinical manifestations, most will eventually develop significant symptoms.[184] The most common causes of death are congestive heart failure, severe hypoxia, and cardiac arrhythmias.[185]

Anatomy

Ebstein malformation is defined by a downward displacement of the annular attachments of the septal and posterior

leaflets of the tricuspid valve into the inlet portion of the right ventricle.[186] This downward displacement of the leaflets reduces the distal chamber of the right ventricle, leaving part of the ventricle above the valve as an extension of the right atrium. The atrialized right ventricle is variable in size and thickness, depending on the extent of downward displacement of the leaflets. The entire wall of the right ventricle, both above and below the tricuspid valve, is often thin, dilated, and dysfunctional. In most patients, annular dilatation and malformation of the leaflets result in moderate to severe insufficiency of the tricuspid valve. It usually occurs in the pulmonary right ventricle, but can occur in the systemic right ventricle in patients with corrected transposition of the great arteries. An atrial septal defect or patent foramen ovale is present in more than 50% of patients, allowing predominantly right-to-left shunting at the atrial level.

Physiology

In patients with Ebstein malformation, the tricuspid valve is incompetent, but the degree varies depending on the anatomic features. In addition, there is some degree of functional impairment of the right ventricle. The atrialized right ventricle moves paradoxically with right atrial and right ventricular contractions. The net effect is reduced forward blood flow through the right ventricle and pulmonary arteries. The impaired filling of the functional right ventricle and the incompetence of the tricuspid valve both result in systemic venous hypertension. The right atrium and the atrialized right ventricle become dilated, often to extreme degrees. In patients with atrial septal defects, right-to-left shunting occurs, resulting in cyanosis. Both atrial and ventricular arrhythmias may contribute to impaired right ventricular function.

Although the primary pathology involves the right ventricle, patients with Ebstein malformation may also demonstrate abnormal left ventricular geometry and function. The severity of left ventricular dysfunction is associated with the degree of displacement of the tricuspid valve, the size and dysfunction of the right ventricle, and the severity of paradoxical motion of the interventricular septum.

Preoperative evaluation

On a chest radiograph, the right border of the heart in the area of the right atrium is enlarged and there may be massive cardiomegaly. Typically, the shadow of the great vessels is narrow due to a small aorta and main pulmonary artery. Right atrial and right ventricular enlargement produce a globular shape to the heart shadow. The apical region of the left ventricle may be elevated from the diaphragm, as seen in right ventricular enlargement. Pulmonary vascularity may range from normal to significantly decreased in the presence of an ASD. A cardiothoracic ratio greater than 0.65 has been shown to be a predictor of sudden death and is considered by some to be an indication for surgery.

Echocardiography has evolved as the primary diagnostic tool for patients with Ebstein malformation. The preoperative echocardiogram is helpful in predicting the ability to repair the valve. Echocardiography can define the morphology of the tricuspid valve and the specific abnormalities of the leaflets. Of the greatest importance are the length and mobility of the anterior leaflet. In addition, the function, thickness, and size of the right and left ventricles can be assessed. Coexisting cardiac lesions can also be identified. Color flow Doppler allows a better assessment of tricuspid valve incompetence and the degree of shunting at the atrial level.[187] If echocardiography is inadequate, magnetic resonance angiography imaging with three-dimensional reconstruction is useful for diagnostic purposes. Diagnostic cardiac catheterization should be avoided, as it is usually unnecessary and can result in arrhythmias. Currently, cardiac catheterization is reserved for patients with associated cardiac defects, previous shunt placements, possible pulmonary artery stenosis, or possible coronary artery disease. Therapeutic catheterization may be performed in older patients for identification and ablation of accessory conduction pathways prior to surgical intervention.

Indications for surgery

The indications for surgical intervention in patients with Ebstein malformation include the following: functional NYHA class III or IV symptoms; significant or progressive cyanosis; decline in exercise tolerance; severe cardiomegaly (cardiothoracic ratio >0.65); associated cardiac anomalies (including right ventricular outflow tract obstruction); refractory atrial or ventricular arrhythmias; and a history of paradoxical embolus. With the improved outcomes and a greater ability to repair the valve, there is a trend to perform early repair in the presence of severe tricuspid regurgitation and atrial enlargement.

Operative procedure

The goals of surgical intervention in patients with Ebstein malformation are to increase pulmonary blood flow, minimize tricuspid insufficiency, reduce or eliminate right-to-left shunting, optimize right ventricular function, and reduce or eliminate arrhythmias. Ideally, the tricuspid valve can be repaired, which may avoid valve replacement with a bioprosthetic valve and the need for future valve replacements. Patients with preoperative Wolff-Parkinson-White syndrome are treated by catheter ablation prior to the surgery.

If the anterior leaflet is adequate in size and is not extensively bound down by muscular attachments, repair is almost always possible. Two main techniques of repair have been described. Danielson and colleagues were the first to demonstrate the ability to repair these valves and avoid replacement.[188] Repair includes plication of the atrialized right ventricle back to the true annulus and an annuloplasty (Fig. 61-18).

Carpentier and associates described a technique in which the atrialized right ventricle is plicated perpendicular to the valve annulus toward the apex of the heart.[189] The displaced leaflets are detached from the right ventricle at their

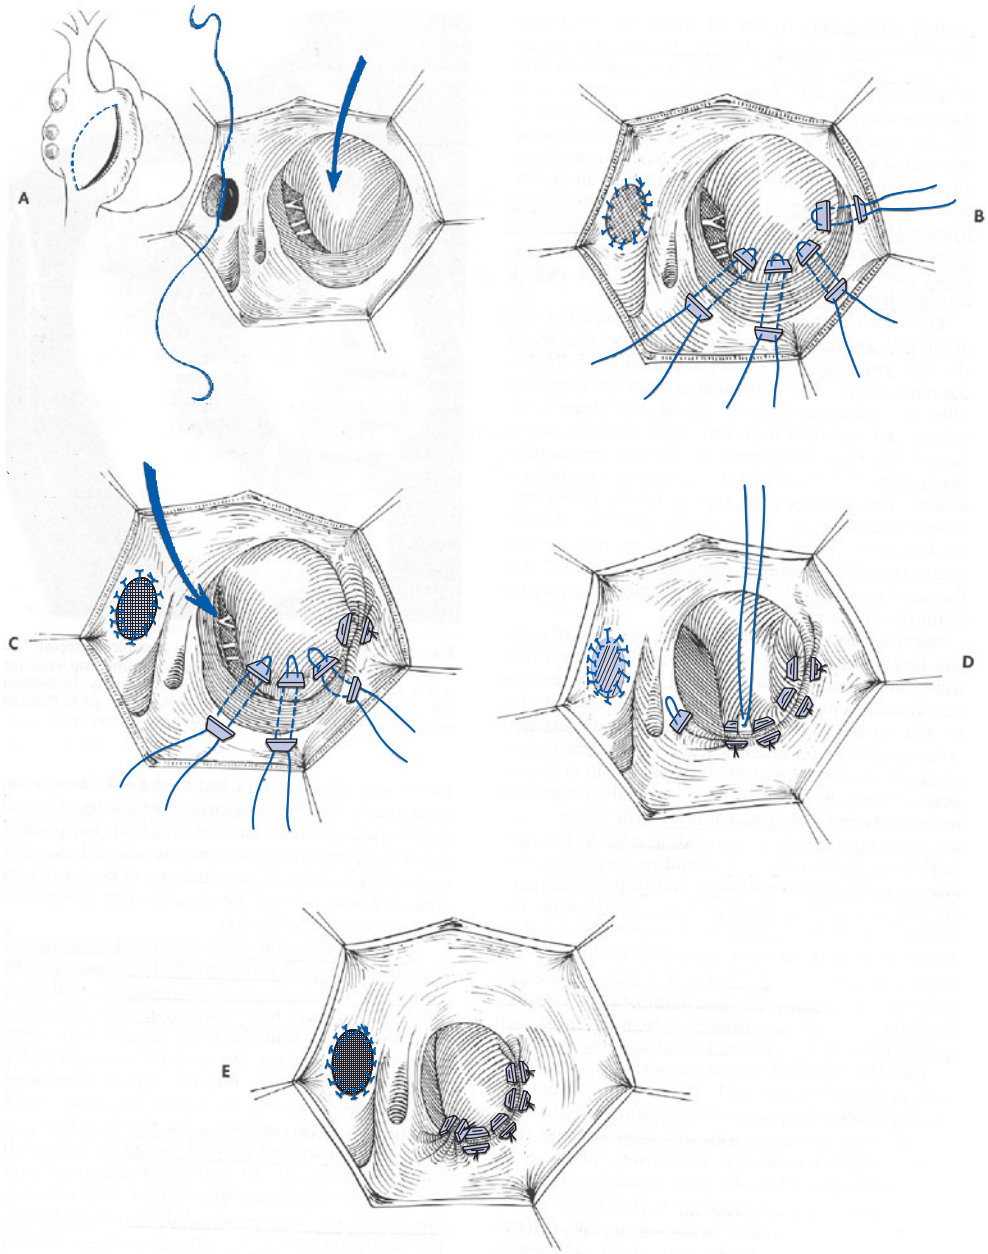

Figure 61-18. Danielson's repair of the tricuspid valve in Ebstein anomaly.

base and attached to the true annulus (Fig. 61-19). We perform an annuloplasty using a glutaraldehyde-fixed strip of pericardium. The redundant right atrium wall and appendage are excised, and the ASD is closed. In patients with a large preoperative right-to-left shunt and a thinned-out underdeveloped right ventricle, a snare-controlled adjustable atrial septal defect may be used to allow continued controlled right-to-left shunting until the right ventricle recovers. The ASD can then be closed using the snare, which is exposed under local anesthesia. In addition, electrophysiologic mapping for localization of accessory pathways may be performed in patients with arrhythmias.

A recently described technique of posterior annular plication without plication of the atrialized right ventricle or repositioning the tricuspid valve has been successful in non-neonatal patients.[2] Further experience and follow-up will be needed to determine the usefulness and efficacy of this type of tricuspid repair in adults with Ebstein anomaly.

For tricuspid valve replacement, we prefer to use a porcine bioprosthetic valve. In the absence of atrial arrhythmias or severe atrial wall thickening, this allows anticoagulation with aspirin only. Generally, tissue valves are preferred in the tricuspid position because of the risk of thrombosis of a right-sided mechanical valve in a low-pressure setting.

The right atrial Maze procedure is a modification of the Maze procedure and has been used to treat atrial arrhythmias in patients with Ebstein malformation. This procedure may reduce or eliminate atrial arrhythmias by preventing reentry conduction at the atrial level (Fig. 61-20).

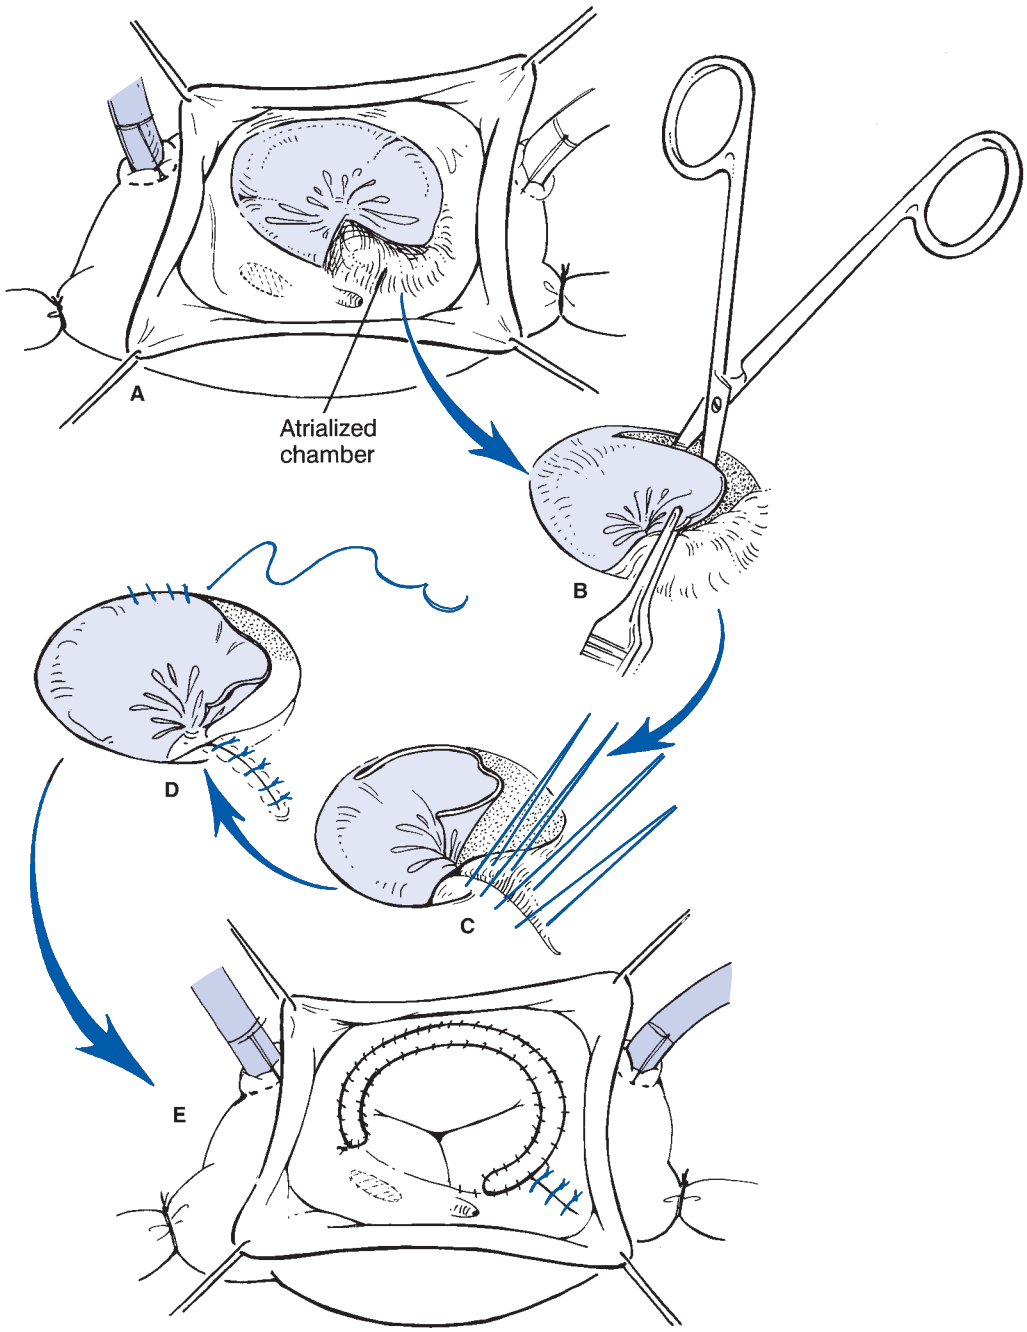

Figure 61-19. Carpentier's repair of the tricuspid valve in Ebstein anomaly.

Outcomes

Results of surgical repair for Ebstein anomaly in children and adults continue to improve. Patients who present at a younger age with associated defects or severe symptoms have a worse prognosis. Those patients presenting in early adulthood for surgical repair have a much better prognosis.

Danielson and colleagues at the Mayo Clinic currently have a surgical experience of more than 500 patients with Ebstein malformation.[190] The data have been analyzed for the first 312 patients who had surgical intervention dating back to 1972. The ages in this series range from 9 months to 71 years, with a mean age of 20.7 years. There were no neonates in this group. In 43% a tricuspid valve repair was successful, and in 53% a bioprosthesis was used to replace the tricuspid valve. Approximately 4% of patients underwent a Fontan reconstruction or other procedures. There were 20 hospital deaths (6.4% early mortality) in this series. Forty-four patients had accessory conduction pathways (Wolff-Parkinson-White syndrome) and underwent successful pathway ablation as part of their repair. Fifteen patients underwent right-sided Maze procedures for control of atrial dysrhythmias and four underwent ablation of the atrioventricular

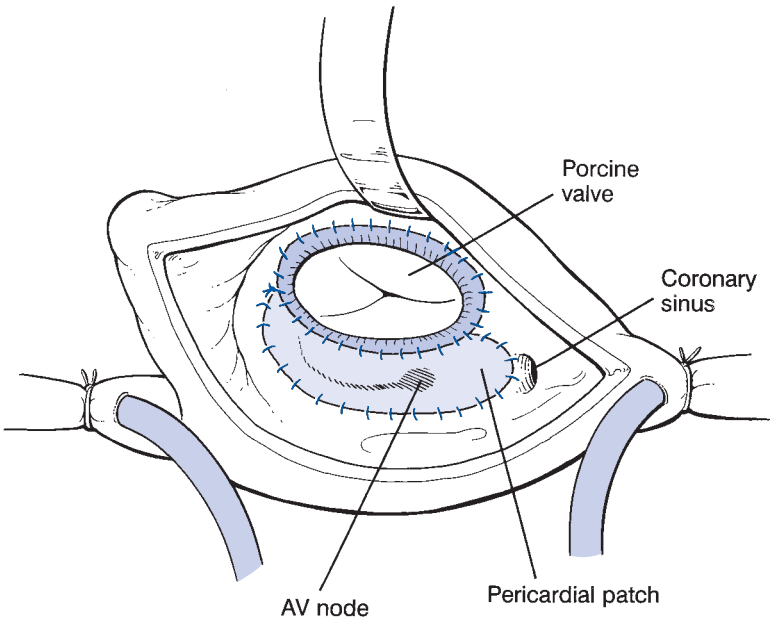

Figure 61-20. Injury to the conduction system may be avoided during tricuspid valve replacement by suturing a triangular patch of pericardium over the atrioventricular (AV) node and triangle of Koch.

node for re-entry tachycardia. There were 24 late deaths (7.3%). Seventeen of the 135 patients (12.6%) who underwent valve repair required reoperation for valve regurgitation 1.5 to 18 years later (mean, 8.7 years). Eight bioprosthetic valves required replacement 1 to 16 years after implantation. Follow-up of those patients evaluated more than a year after operation determined that 93% were in NYHA functional class I or II.

Other authors have recently reported similar results using different repair techniques in a smaller series of patients.[191,192] The addition of a right atrial Maze procedure to the repair is often successful in reducing or eliminating atrial arrhythmias. Furthermore, the addition of epicardial mapping and intraoperative ablation of accessory pathways at the time of repair has also been successful.[1,7,193,194] The durability of a porcine bioprosthesis for tricuspid valve replacement in these patients has been quite favorable, with freedom from reoperation of 97% at 5 years and 81% at 15 years.[195]

Heart Transplantation

Adults with congenital heart disease may not be amenable to palliation or repair due to severe ventricular dysfunction or pulmonary vascular disease. They may be candidates for heart, lung, or heart-lung transplantation. In addition, patients previously repaired may deteriorate and may have no other options.[196–211]

Other reparative options are always considered prior to choosing heart transplantation as a surgical treatment. In this regard, there have been several reports of "one and one-half" ventricle repairs in cases of right ventricular pathology.[212–215]

In symptomatic patients who are NYHA class III or IV and who have an acceptable pulmonary vascular resistance, heart transplantation is usually feasible. Anomalies of systemic and pulmonary venous return can be corrected. Deformities of the pulmonary artery can be repaired. This may require quite extensive repair, particularly in some patients after the Fontan procedure. Dextrocardia and transposition may be challenging, but with current reconstructive techniques, transplantation is almost always possible.[204–208,216,217]

Preoperative evaluation

General evaluation is as for all heart transplant recipients. Cardiopulmonary exercise testing, and pulmonary, dental, and psychosocial evaluations are routine. Pulmonary vascular resistance must be carefully assessed; the cutoff is at 4 to 6 Wood units or a transpulmonary gradient of 12 to 14 mm Hg. Panel-reactive antibody screening is essential, as most patients have had previous surgery and blood transfusions. If these values are higher than 10%, then prospective cross-matching is preferable. Chest wall collaterals may increase left-sided return, particularly after previous surgery or cyanosis, and therefore it is usual to oversize donors by 20%. Some larger aortopulmonary or veno-venous collaterals may be coil embolized preoperatively.[218]

Renal and liver function and reserve require careful evaluation. Renal function may be compromised due to a low-output state, as well as renal vein congestion from elevated central venous pressure. Ideally, pretransplant creatinine clearance should be at least 40 mL/min.[219] Cardiac hepatopathy is poorly understood. Our experience is that these patients are at high risk for liver dysfunction due to frequent right ventricular failure or Fontan physiology. Many of these potential recipients will have normal liver function tests but abnormal liver histology. Preoperative histology may be useful to rule out cirrhosis. Centrilobular fibrosis may be seen on occasion.[220,221] Our experience has revealed that noninvasive imaging may underestimate the possibility

of cardiac cirrhosis. Even though this is rare, it is an important contraindication to heart transplantation.

Two to three hours of cardiopulmonary bypass time will unmask poor liver reserve. This is especially true in the third decade of life. Postoperatively, one may observe increasing total bilirubin with minimal rise in other tests of liver function. Total bilirubin may rise as high 35 to 40 mg/dL before returning to normal levels over a period of as many as 3 to 4 weeks.[222] Such a clinical course may be explained by a compromised liver preoperatively, to which is added an ischemic insult. Such livers require high flows during cardiopulmonary bypass and are thought to poorly tolerate hypothermia.[223] As described below, this may not always be possible.

Operative procedure

It is important to anticipate the recipient anatomy. For example, in tricuspid atresia dextraposed transposition is common, and the aorta may be immediately behind the sternum. A computed tomography scan is obtained preoperatively to assess the retrosternal structures. It is rarely necessary to institute bypass before opening the sternum. Aprotinin is used in all cases and it is important to plan correct timing for the arrival of the donor heart, since redo sternotomy in these patients is more complex than usual. Meticulous hemostasis is essential prior to starting cardiopulmonary bypass, as postoperative coagulopathy is common. If needed, patients are cooled to 22 to 24°C in order to minimize the pulmonary venous return, which can be torrential. This can warm the donor heart, and after the aortic anastomosis is completed, may wash out the preservation solution if the aortic root is not vented. A vent in the left atrium is therefore used to collect this return. Anomalies in systemic or pulmonary venous return and the pulmonary arteries are reconstructed prior to bringing the donor heart onto the field. We apply intracardiac cooling to the left ventricle using a catheter passed through the left atrial anastomosis into the left ventricle apex. Generally, we prefer a bicaval anastomosis (Figs. 61-21 and 61-22).

Outcomes

Due to previous surgeries, anatomic complexity, borderline pulmonary vascular resistance, hepatic congestion, and other factors, these patients (particularly the Fontan patients) are at higher risk for transplantation. Between 1984 and 2002, 30 adults and adolescents with congenital heart disease have undergone transplantation at our institution. Close to 50% of the patients had single-ventricle physiology, and on average all had had at least two previous sternotomies. Age range was 13 to 49 years old. The early mortality for this high-risk group was 18%. The single-ventricle-physiology patients are probably the highest-risk recipients. Quaegebeur, Addonizio, and Hsu and colleagues have reported a cohort of 35 recipients with 28% early mortality.

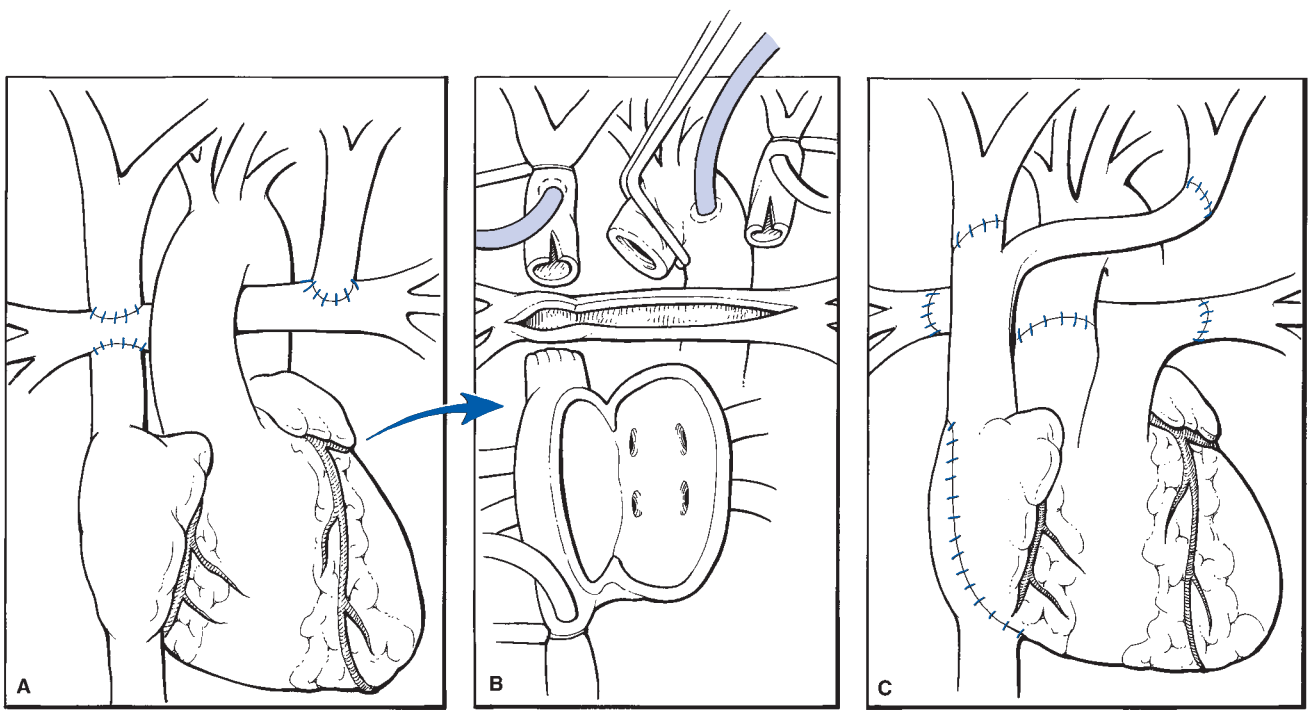

Figure 61-21. Heart transplantation after total cavopulmonary connection in a patient with bilateral superior venae cavae. The innominate vein from the donor is used to reconstruct the left superior vena cava. Alternatively (not shown), if the left superior vena cava is too short, a synthetic graft can be used to route the left superior vena caval blood along the coronary sinus of the donor heart into the recipient native inferior vena cava.

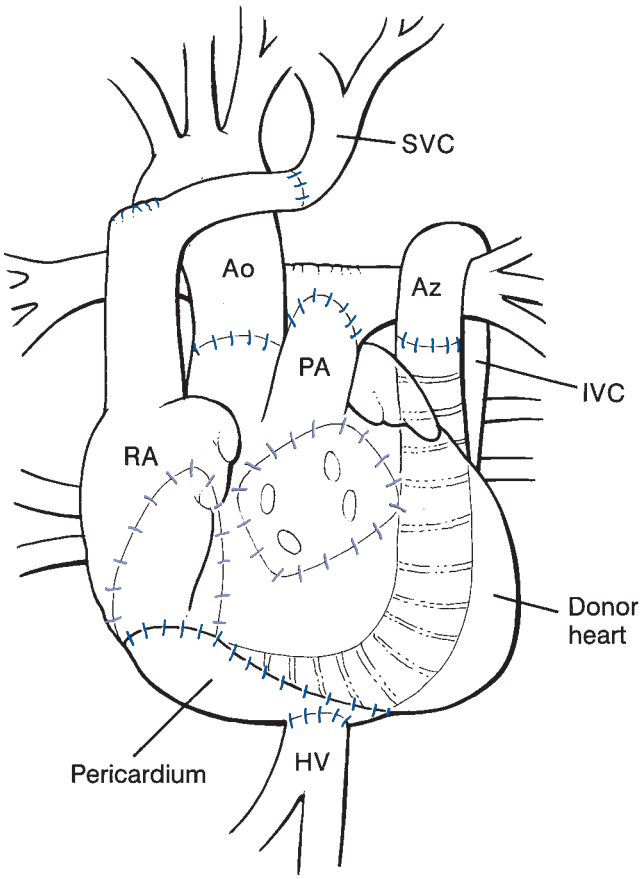

Figure 61-22. Heart transplant in a patient with dextrocardia, right-sided arch, and interrupted inferior vena cava with azygos continuity who previously had undergone a Fontan procedure. Ao = aorta; Az = azygos vein; HV = hepatic vein; IVC = inferior vena cava; PA = pulmonary artery; RA = right atrium; SVC = superior vena cava.

Similar results have been reported by Dark and associates. The group in Bergamo has reported a survival of 86% for heart transplantation in patients with previous Fontan operations.[224–226]

CHAPTER 62

Pericardial Disease

Abeel A. Mangi • David F. Torchiana

The pericardium envelops the heart like a cocoon; when incised and suspended from a chest retractor it nicely presents the heart for surgical correction. The surgical significance of the pericardium arises from its involvement in derangements of cardiac filling. When the limited space between the noncompliant pericardium and heart is acutely filled with blood or fluid, cardiac compression and tamponade may result. When inflammation and scarring cause the pericardium to shrink and densely adhere to the surface of the heart, constrictive pericarditis is the consequence. In this chapter, we will discuss pericardial anatomy and function and describe the conditions that commonly give rise to the surgical problems of pericardial constriction and tamponade. The chapter also includes steps for the diagnosis and therapy of these entities, the management of tamponade early and late after cardiac surgery, and the rationale for and against pericardial closure at the time of cardiac surgery.

ANATOMY AND FUNCTION

The pericardium serves two major functions: (1) to maintain the position of the heart within the mediastinum, and (2) to prevent cardiac distention by sudden volume overload. The position of the pericardium is maintained by loose attachments to the undersurface of the sternum and to the vertebral bodies, and by firm attachment to the central tendon of the diaphragm. The pericardium attaches to the ascending aorta, just inferior to the innominate vein, and attaches to the superior vena cava several centimeters above the sinoatrial node. The pericardial reflection encompasses the superior and inferior pulmonary veins, and encircles the inferior vena cava, thereby making it possible for the surgeon to control the inferior vena cava from within the pericardium. The pericardial reflection attaches to the left atrium near the entrances of the pulmonary veins just below the atrioventricular groove (Fig. 62-1). The pericardium is perfused by the pericardiophrenic arteries that travel with the phrenic nerves, as well as by branches of the internal mammary arteries and feeder branches directly from the aorta. It is innervated by vagal fibers from the esophageal plexus, and the phrenic nerves course within it.

The pericardium is made up of two layers. The inner layer (visceral layer) of the pericardium is transparent, and is made up of a monolayer of mesothelial cells, making it essentially indistinguishable from the epicardium. Parietal pericardial lymphatic drainage is largely to the anterior and posterior mediastinal nodes, whereas visceral pericardial lymphatic drainage is via the tracheal and bronchial mediastinal lymph nodes.[1] The pericardial mesothelial cells contain dense microvilli that are 1 μm wide and 3 μm high,[2] ideal for facilitating fluid and ion exchange.[3]

The parietal layer is made up of elastin fibers interspersed among dense parallel bundles of collagen, which render this layer relatively noncompliant. Because the pericardium is stiffer than cardiac muscle, it tends to equalize the compliance of both ventricles. By doing so, the pericardium contributes to the resting cavitary diastolic pressure of both ventricles, maximizing diastolic ventricular interaction.[4] An example of this phenomenon is the diminution of systemic arterial pressure during inspiration. Intrapericardial pressure tends to approximate pleural pressure, and varies with respiration. The negative intrathoracic pressure generated during inspiration augments right ventricular filling. The interventricular septum shifts toward the left to accommodate the increase in right ventricular volume. Because pericardial constraint does not allow equal filling of the left ventricle, the decrease in volume ejected by the systemic chamber results in a slight diminution of systemic arterial pressure during inspiration. This phenomenon is greatly magnified with an increase in intrapericardial pressure (for example, during acute filling of the pericardial space or circulatory volume overload), resulting in production of the pulsus paradoxus.[5–7]

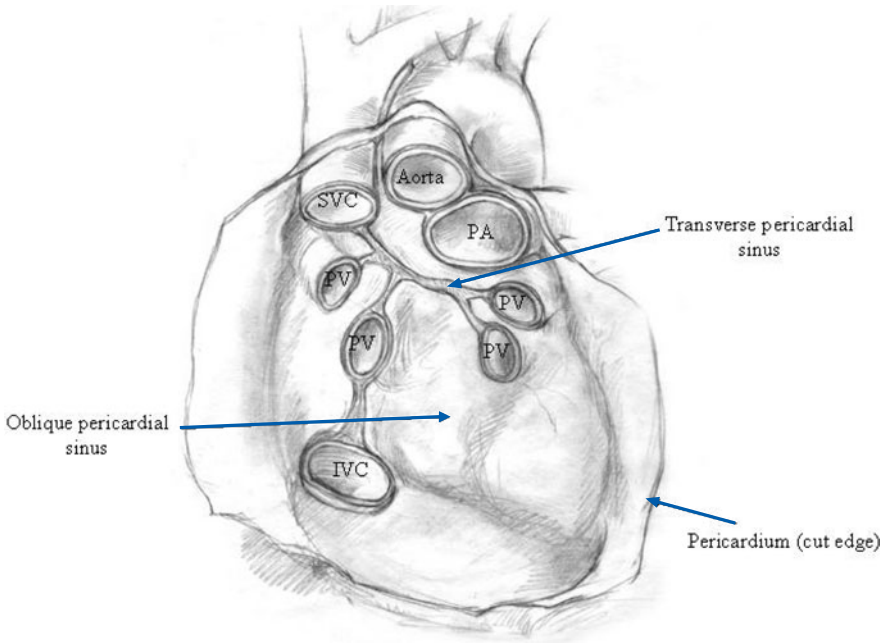

Figure 62-1. Pericardial attachments and reflections. IVC = inferior vena cava; PA = pulmonary artery; PV = pulmonary vein; SVC = superior vena cava.

Normally, the volume of the pericardium exceeds that of the heart by about 10 to 20%.[8] The pericardium contains several sinuses and recesses that are not readily evident at the time of surgery or at postmortem examination (Fig. 62-1). The largest (the transverse pericardial sinus) is the space between the ascending aorta and pulmonary artery bifurcation anteriorly, and the dome of the left atrium and superior vena cava posteriorly. Such potential spaces allow the pericardium to expand and accommodate a limited volume load. Under normal conditions, the pericardium contains approximately 20 mL of fluid, which is an ultrafiltrate of plasma. This pericardial fluid serves to lubricate the moving surfaces where the beating heart makes contact with fixed structures.[9]

CONGENITAL ABNORMALITIES

Most congenital abnormalities of the pericardium are discovered accidentally at cardiac surgery, on routine chest imaging, or while investigating unrelated problems.[10] They are rare, and less than 200 cases have been reported in the world literature.[11] The rarest of congenital pericardial abnormalities are pericardial bands that obstruct the superior vena cava. The most common are pericardial celomic cysts.

Partial absence of the pericardium is the most common form of pericardial agenesis. It occurs in approximately 1 out of 14,000 births, and has a male preponderance.[11] It is usually associated with cardiac, pulmonary, or skeletal anomalies.[11] Most defects tend to occur on the left side, and are due to premature atrophy of the left common cardinal vein, or duct of Cuvier, which normally goes on to form a portion of the left superior intercostal vein. The right duct of Cuvier goes on to form the superior vena cava and ensures closure of the right pleuropericardial membrane.[12] Accordingly, right-sided defects tend to be lethal. While complete pericardial agenesis is of little clinical significance, unilateral absence is potentially problematic, as it may accentuate cardiac mobility and allow the heart to be displaced into the pleural space with resulting incarceration[13] and tricuspid insufficiency.[12] The treatment for this lesion is pericardial resection, which may be accomplished thoracoscopically.[11] Alternatively, the pericardium can be replaced using patch material via thoracotomy. Both therapies appear to yield good outcomes.

Cysts can occur anywhere on the pericardium, but are found most often in the right costophrenic angle.[10] They do not communicate with the pericardial space, and contain a clear yellow fluid. They are typically unilocular, smooth, and less than 3 cm in diameter. Most remain clinically silent, and are discovered on routine chest imaging. Cysts have been associated with chest pain, dyspnea, cough, and arrhythmias, probably owing to compression and inflammatory involvement of adjacent structures. They can also become secondarily infected.[14,15] Cysts are relatively easy to diagnose by echocardiography or computed tomographic imaging, and can be followed in asymptomatic patients. In symptomatic patients, cysts can be aspirated under radiologic guidance, or resected either via the thoracoscope or at thoracotomy.[16]

PATHOPHYSIOLOGY OF PERICARDIAL COMPRESSION

The relative noncompliance of the pericardium results in a nonlinear relationship between intrapericardial volume and intrapericardial pressure. Although the pericardium may gradually expand to accommodate large volumes over time without appreciable increases in intrapericardial pressure, acute volume overload may result in a large increase in intrapericardial pressure (Fig. 62-2).

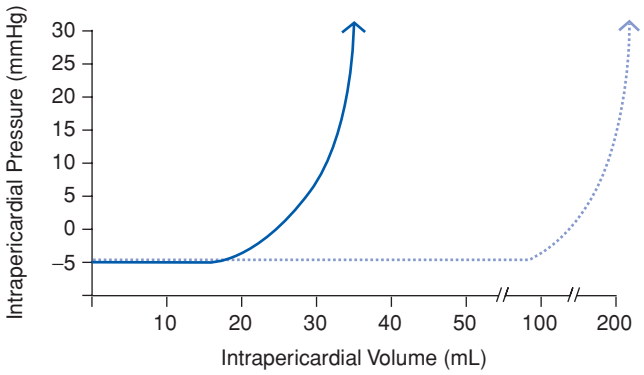

Figure 62-2. Relationship of intrapericardial volume and pressure. The pericardium of a healthy individual can accommodate 15 to 20 mL of fluid with minimal increases in intrapericardial pressure. However, when the elastic limit of the pericardial space is acutely exceeded, small increases in intrapericardial volume will result in large increases in intrapericardial pressure (solid line). Intrapericardial volume and pressure are not linearly related. With gradual development of an effusion, the pericardial space can dilate considerably (dotted line). It may therefore accommodate a relatively large effusion without an appreciable increase in intrapericardial pressure. (*Modified with permission from Harken et al.*[8])

Tamponade

Tamponade results from cardiac compression due to increased intrapericardial pressure with low cardiac output and elevated systemic venous pressure due to compromised cardiac filling. The clinical spectrum of tamponade varies widely, and is a reflection of the severity of hemodynamic impairment, as well as the physiologic resilience of the host. Although blood in the pericardial space is the most common etiology, exudative effusions, clot, pus, or gas, or any combination of these may also produce tamponade. When the pericardium is filled with fluid acutely, pericardial reserve volume (10 to 20 mL) is rapidly depleted. As fluid enters the pericardial space faster than the rate at which the parietal pericardium stretches, the noncompliant parietal pericardium prevents further expansion and intrapericardial pressure rises abruptly. At this point, pericardial volume can only increase by reducing cardiac chamber volumes. As a result, diastolic compliance is reduced equally in all chambers of the heart. This loss in compliance, coupled with the increase in intrapericardial pressures, means that higher pressures are required to fill the cardiac chambers, which may be partially achieved by parallel increases in systemic and pulmonary venous pressure by vasoconstriction.[17,18] Other compensatory mechanisms include tachycardia, time-dependent pericardial stretch, and blood volume expansion.[19] The latter two mechanisms have little impact in acute tamponade. The rapid accumulation of as little as 150 mL of fluid in the pericardial space (for example, after a penetrating cardiac wound) does not allow the parietal pericardium to develop any degree of compliance. In such a setting, the rapid accumulation of a relatively small volume of blood in the pericardial space can result in critical tamponade. On the other hand, the gradual accumulations of large pericardial effusions (over 1 L) can be compensated for in a chronic inflammatory condition such as rheumatoid arthritis. Chronic distention of the pericardial space is usually obvious on chest x-ray (Fig. 62-3) or echocardiogram (Fig. 62-4). In acute tamponade, the cardiac silhouette may appear normal.

Pericardial Constriction

A wide range of disease processes can result in formation of a pericardial scar, the pathologic process behind constrictive pericarditis (CP). As with tamponade, the physiologic basis of the disease is compromised cardiac filling leading to

Figure 62-3. Enlarging pericardial effusion detected on chest x-ray. (A) At discharge; (B) 3 weeks after discharge.

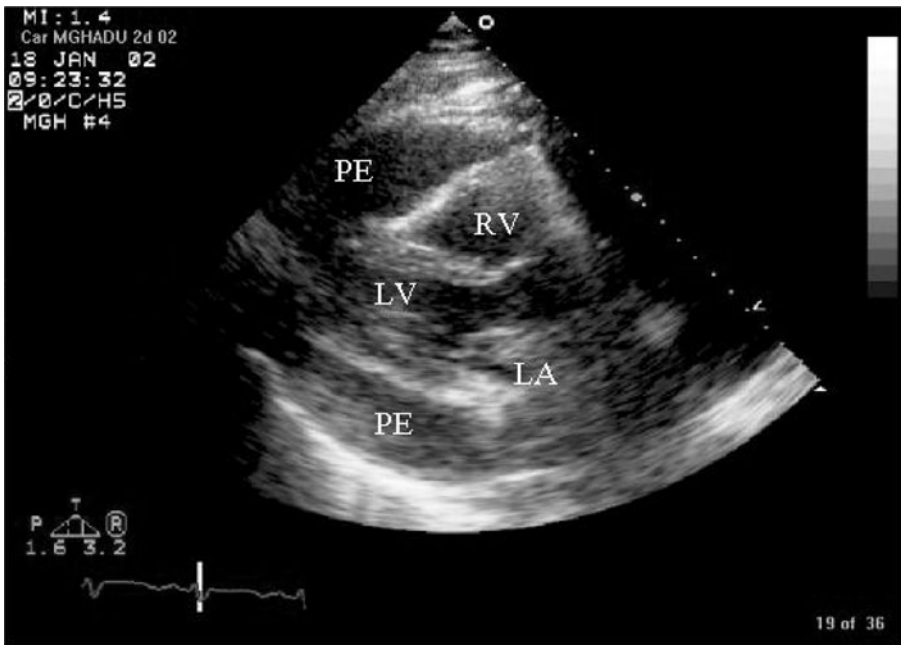

Figure 62-4. Large pericardial effusion detected on echocardiogram. LA = left atrium; LV = left ventricle; PE = pericardial effusion; RV = right ventricle.

systemic venous congestion and low cardiac output. In contrast to tamponade, patients with CP present with a subacute onset, often after a year or more of symptoms consisting of fatigue, decreased exercise tolerance with dyspnea/orthopnea, as well as peripheral edema and ascites from hepatic congestion in advanced disease. The principal etiologies behind pericardial scar formation have changed over the last 25 years. The incidence of infectious etiologies (particularly tuberculosis) has declined, whereas the incidence of cases resulting from therapeutic irradiation of the mediastinum and cardiac surgery (Fig. 62-5) has been increasing.[20]

Constrictive pericarditis is important to recognize, because it is curable with surgery. Evaluation begins with echocardiographic evaluation which typically shows small, normally contracting ventricles, and relatively dilated atria. The abrupt end to ventricular filling that occurs when the ventricles encounter the noncompliant scarred pericardium creates a phenomenon described as "septal bounce," the echocardiographic correlate to the "square root" sign described below. The hallmark of echocardiographic examination in CP is the reciprocal variation of right- and left-sided Doppler flows with inspiration, caused by interventicular

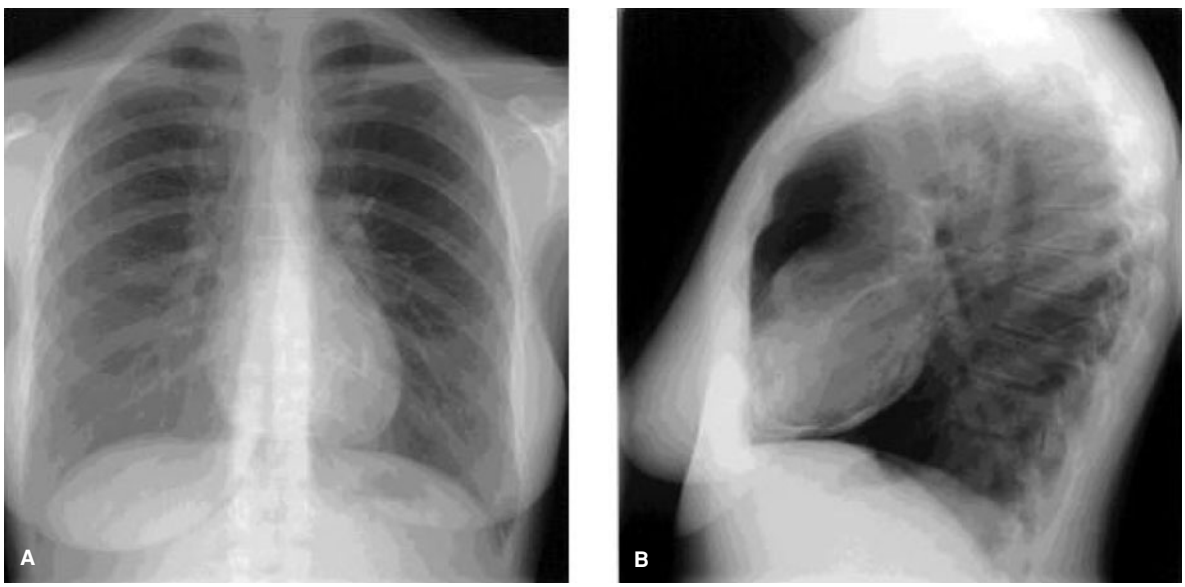

FigurE 62-5. Pericardial calcification on posteroanterior (A) and lateral (B) chest x-ray in a young patient with a history of thoracic trauma.

dependence ; again this has a hemodynamic correlate that will be discussed below. Modern axial imaging with spiral computed tomographic scanning or magnetic resonance imaging has helped greatly in being able to visualize thickened and/or calcified pericardium, with or without coexisting effusion. Importantly, while pericardial thickening is usually present in constrictive pericarditis, it remains possible to have CP with normal pericardial thickness and also to have thickening of the pericardium without CP.[21]

Pericardial constriction exerts its pathophysiologic effects by limiting cardiac filling. Unlike tamponade, in which cardiac filling is limited right from the beginning of diastole, constriction does not restrict filling in the very earliest stages of diastole. As the ventricles fill, they are prevented from their normal distention as they encounter the stiff, contracted, and noncompliant pericardium. As a result, in patients with CP, 70 to 80% of diastolic filling is forced to occur in the first 25 to 30% of diastole.[22] Although early diastolic filling pressures are normal (while the ventricle is free from the overlying stiff pericardium), later diastolic filling pressures are much higher. This sudden increase in diastolic pressure is reflected in the dip and plateau or "square-root" sign (Fig 62-6), which occurs when ventricular pressures are measured during cardiac catheterization. Similarly, right atrial pressure tracings reveal a deep *y* descent, which correlates to the nadir of the square-root sign. The clinical manifestation of this phenomenon is seen in the Kussmaul sign, which is frequently present in CP, although it is not specific for CP. Under normal circumstances, inspiration results in a 3- to 7-mm Hg drop in right atrial pressure. The high pressure of pericardial constriction prevents the right atrium from accepting inspiratory acceleration of blood from the neck veins. Instead, neck veins become prominently distended during inspiration in patients with CP, a phenomenon referred to as Kussmaul sign.[23]

Prior to the modern era of echocardiography and axial imaging, the diagnosis of CP was dependent on hemodynamic tracings obtained at cardiac catheterization. Catheterization tracing remains a valuable illustration of the underlying

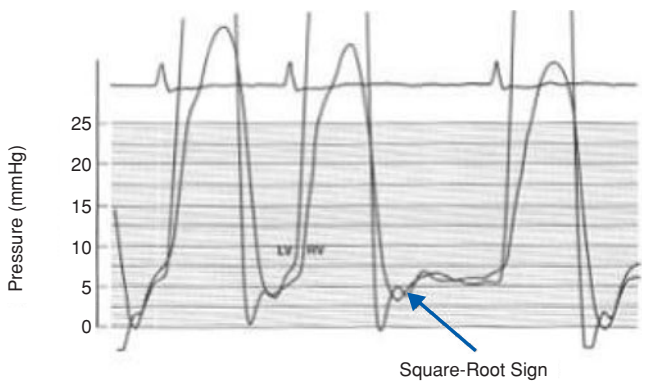

Figure 62-6. Square-root sign in right ventricular pressure tracing in constrictive pericarditis. (*Modified with permission from Spodick DH [ed]: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997; p 4.*)

physiology of CP, and in some cases may help in making the critical differentiation between CP and restrictive cardiomyopathy (RCM):[24,25]

1. *Equalization of pressures.* When pericardial compression is a dominant determinant of hemodynamic status, left and right ventricular end-diastolic pressures are within 5 mm Hg of each other. This classic criterion, however, has limited sensitivity and specificity.
2. *Elevation of mean atrial pressures.* Mean atrial pressure of over 10 mm Hg is suggestive of either cardiac tamponade or of pericardial constriction.
3. *Square-root sign.*
4. *Prominent* y *descent* in right atrial pressure tracing.
5. *Elevated right ventricular end-diastolic pressure.* This should be more than one-third of right ventricular systolic pressure. This criterion has a sensitivity of 93% and a specificity of 57% for constrictive pericarditis.

RCM is characterized by noncompliant ventricular muscle and diastolic dysfunction which hamper cardiac filling. RCM is caused by a variety of infiltrative or fibrosing conditions (e.g., amyloidosis, sarcoidosis, radiation, carcinoid, and anthracycline toxicity). While RCM may mimic some of the presenting features of CP, it is not a surgical disease and must be distinguished from CP for this reason. Systolic ventricular function may be normal or near normal function. RCM patients tend to have a poor prognosis. Criteria for the diagnosis of restrictive cardiomyopathy include:

1. Increased jugular venous pressure
2. Prominent *x* and *y* descents
3. A small or normal-sized heart
4. Pulmonary congestion
5. Hepatic congestion
6. Absence of ventricular hypertrophy or dilatation
7. Normal to mildly depressed ventricular systolic function

Additional criteria to help in distinguishing CP from RCM include evidence of thickened pericardium, which favors but does not clinch the diagnosis of CP, as there are instances, particularly in radiation-induced CP, in which the conditions coexist. Distinctive myocardial speckling may be found on echo with amyloidosis or other infiltrative conditions. Endomyocardial biopsy is useful to establish the presence of one of the conditions known to be associated with RCM; unfortunately a negative biopsy does not rule it out.[24]

In an attempt to provide additional criteria to differentiate patients with CP and RCM, Hurrell and colleagues[26] measured the respiratory variation of the gradient of left ventricular pressure to pulmonary capillary wedge pressure during the rapid filling phase of diastole. This was done to assess the dissociation of intrathoracic and intracardiac pressures that is seen in constrictive pericarditis. A difference of 5 mm Hg in the gradient between inspiratory and expiratory cycles had 93% sensitivity and 81% specificity for constrictive

pericarditis. Furthermore, increased ventricular interdependence was assessed by comparing left ventricular systolic pressure and right ventricular systolic pressure during respiration. Although concordant increases in left ventricular systolic pressure and right ventricular systolic pressure are expected during inspiration, discordant pressures are encountered during inspiration in patients with constrictive pericarditis. This finding has 100% sensitivity and 95% specificity for constrictive pericarditis.[26]

ACQUIRED ABNORMALITIES

A large number of factors can cause irritation of the pericardium, inducing the condition known as pericarditis (Table 62-1). The etiologies include myocardial infarction (Dressler syndrome); drugs such as procainamide and hydralazine; viral, bacterial, and fungal infections; metabolic (e.g., uremia) and autoimmune diseases (e.g., rheumatoid arthritis); neoplasms; trauma; and mechanical irritation at the time of surgery. The clinical syndrome is similar regardless of cause, and includes pain, constitutional symptoms (such as weakness and malaise), fever (occasionally with rigors), and other symptoms such as cough or odynophagia. The pain is variably described as sharp, dull, aching, or pressure-like. It is generally acute in onset and precordial but can follow referred patterns similar to those of angina, such as to the arm, epigastrium, jaw, shoulder, or ridge of the trapezius. The pain is generally pleuritic, and exacerbated by inspiration, cough, or recumbency. These patients therefore like to sit up and lean forward for relief.

The cardinal sign of pericarditis is the pericardial rub. Echocardiogram may reveal fibrinous thickening of the pericardium with or without a small effusion. The electrocardiogram may range from normal, to nonspecific ST-segment deviations, to diffuse concave elevation of the ST segments without reciprocal depressions. This may be associated with PR-segment depression, and T-wave inversions in V_3 to V_6. It should be noted that ventricular arrhythmias and conduction abnormalities are not commonly seen in pericarditis, and are suggestive of an underlying cardiac abnormality if present.

After excluding other entities in the differential diagnosis, such as myocardial ischemia, pneumonia, chest wall pain, and pulmonary embolism, treatment of pericarditis should aim to relieve symptoms and eliminate etiologic agents. Nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstay of treatment,[27] and may be supplemented with colchicine.[28] Further treatment must be tailored to address the specific etiologic agent, some of which are discussed in greater depth below.

Infectious Pericarditis

Viral pericarditis

The cardiotropic viruses that cause myocarditis are the ones most likely to cause pericarditis as well. Pericardial inflammation is a result of immune complex deposition, direct viral attack, or both.[27] The clinical illness involves pain, friction rub, and typical changes on the electrocardiogram. Treatment is expectant, and symptoms generally resolve within 2 weeks. Surgical intervention is rarely required.

Bacterial pericarditis

Microorganisms may invade the pericardial space from contiguous infections in the heart, lung, subdiaphragmatic space, or from the wound in postoperative patients. Patients with septicemia can also seed the pericardial space. This problem is more common in immunosuppressed patients.[29]

Acute suppurative pericarditis is a life-threatening disease that has the potential to induce tamponade and septicemia. The most common organisms remain streptococcal, pneumococcal, and staphylococcal,[30,31] but the incidence of gram-negative organisms such as *Escherichia coli*, *Salmonella*, and opportunistic infections is increasing. In adults, pneumopyopericardium is often due to fistula formation between a hollow viscus and the pericardium. However, invasion from contiguous foci, implantation at the time of surgery or trauma, mediastinitis, endocarditis, and subdiaphragmatic abscess can all induce this condition. The clinical course is acute and fulminant. The patient appears toxic and can have a high fever. Acute surgical intervention is required in the setting of purulent pericarditis, which may result in tamponade in a third of cases,[29] or in cases in which scarring results in pericardial constriction.

Tuberculous pericarditis

After decades of decrease, the incidence of tuberculous pericarditis has been increasing recently because of the rising numbers of immunocompromised patients, particularly those with human immunodeficiency virus.[32] The pericardium is infected by hematogenous, lymphatic (from lung, bronchial, and mediastinal lymph nodes), peribronchial, or contiguous spread of tuberculosis. The classic pathologic stages of this entity include:[31]

1. Fibrinous exudation, with robust polymorphonuclear infiltration
2. Serous or serosanguineous effusions with a mainly lymphocytic exudation
3. Absorption of effusion, with organization of caseating granulomas, and pericardial thickening due to fibrin and collagen deposition and fibrosis
4. Constrictive scarring, often with extensive calcification occurring over a period of years

Most often, the clinical course of this entity is insidious. Children and immunocompromised patients may, however, present with a more fulminant course, often demonstrating both constrictive and tamponade physiology.[32] The diagnosis is established by examining pericardial fluid for the presence of the mycobacteria. These patients require urgent institution of triple drug therapy. In addition certain groups advocate addition of aggressive surgical management in order to avoid development of chronic constrictive pericarditis.[33,34]

Acquired Etiologies of Acute Pericarditis (*continued*)

UNCERTAIN ETIOLOGIES AND PATHOGENESIS	
Sarcoidosis	Takayasu syndrome
Fat embolism	Castleman disease
Bile fistula to pericardium	Fabry disease
Wissler syndrome	Kawasaki disease
PIE syndrome	Degos disease
Stevens-Johnson syndrome	Histiocytosis X
Gaucher disease	Campylodactyly-pleuritis-pericarditis syndrome
Diaphragmatic hernia	Farmer lung
Atrial septal defect	Idiopathic
Giant cell aortitis	

Fungal pericarditis

Fungal pericarditis is an unusual entity and occurs predominantly in immunocompromised or debilitated individuals, patients with severe burns, infants, and patients taking steroids. *Candida* and *Aspergillus* generate an insidious clinical picture, and may come to attention after the patient develops tamponade or constriction. Fungi such as *Histoplasma* that tend to be endemic to certain geographic areas may cause pericarditis in young, healthy, immunocompetent patients, and will often resolve within 2 weeks. There may be late sequelae such as constriction, but this is rare. Similarly, *Coccidioides* can also infect young healthy individuals, but will generally produce a more severe illness. Acute pericardial coccidioidomycosis usually will accompany pneumonia from the same organism, with systemic adenopathy, osteomyelitis, or meningitis. The potential for chronic constriction is higher in this disease. These conditions all tend to resolve either spontaneously or after treatment with appropriate antifungal medical regimens. Surgical intervention is not usually required in the acute setting.

Metabolic Causes of Pericarditis

Pericarditis has been recognized to occur in the presence of renal failure, hypothyroidism, and autoimmune diseases (such as rheumatoid arthritis), in response to certain drugs (e.g., procainamide and hydralazine), and after mediastinal radiation.

Uremic pericarditis

Uremic pericarditis was first recognized by Bright in 1836.[35] Although it is recognized that nitrogen retention (blood urea nitrogen levels are generally >60 mg/dL) is required for uremic pericarditis, the inciting agent is still unknown. The clinical profile is of a patient with chronic renal insufficiency who has symptoms of pain, fever, and a friction rub. There is usually a pericardial fluid collection, which can be exudative or transudative, and is usually hemorrhagic. Tamponade may occur; although the incidence of tamponade is decreasing due to the more widespread use of renal dialysis,[36,37] it remains the primary danger of this condition. Management of uremic pericarditis is controversial. Initial therapy includes NSAIDs and aggressive dialysis, and there is also a role for pericardiocentesis or drainage. The timing, however, remains uncertain.[38,39] Drainage has been advocated if a pericardial effusion persists despite 2 weeks of aggressive dialysis.[40] Any patient with hemodynamic compromise deserves immediate drainage.

Drug-induced pericarditis

Procainamide (with or without associated lupus syndrome), hydralazine, methysergide, and emetine have all been associated with pericardial inflammation. Minoxidil has been associated with pericardial effusion.[41] The clinical presentation and guidelines for management in these settings are similar to those for other types of pericarditis. The inciting agent should be discontinued.

Pericarditis associated with rheumatoid arthritis

Pericarditis is common in patients with rheumatoid arthritis (RA). Approximately half of patients with RA have pericardial effusions, and almost half of all patients with RA have significant pericardial adhesions at autopsy.[42] The condition is encountered more often in patients with advanced RA, and is thought to be due to the higher rheumatoid factor titers. The deposition of immune complexes in the pericardium appears to be the inciting event behind the inflammatory response.[43] The clinical syndrome varies widely. The most common mode of presentation is a friction rub that lasts days to years with an asymptomatic effusion. The diagnosis is often complicated by the many clinical variants, and by intercurrent diseases such as viral pericarditis and drug-induced pericarditis. Treatment is required only in patients with symptomatic effusions. Constriction may occur late in RA patients. These patients should then be considered for pericardiectomy.

Hypothyroidism

Severe hypothyroidism produces large, clear, high-protein, high-cholesterol, and high-specific-gravity effusions in 5 to 30% of patients. The effusion may precede other signs of

hypothyroidism.[44,45] These effusions are often asymptomatic and are recognized on chest x-ray. Clinical tamponade is rare because of the slow accumulation of fluid. However, acute exacerbations due to intercurrent acute pericarditis, hemorrhage, or cholesterol pericarditis can induce cardiac tamponade.

Radiation Pericarditis

Radiation is now the most common etiology of constrictive pericarditis in the United States.[46] This was first recognized in patients who received high-dose mantle radiation for Hodgkin lymphoma in the 1960s and 1970s and developed cardiac and pericardial pathology, on average 10 to 15 years after therapy. Radiation induces acute pericarditis, pancarditis, and accelerated coronary artery disease in a dose-dependent fashion.[47,48] Patients may present with a combination of pericardial constriction, restrictive cardiomyopathy, valvular heart disease, and coronary artery disease with a predilection for ostial lesions.[49,50]

Neoplastic Pericarditis

Secondary neoplasms of the pericardium (i.e., tumors that involve the pericardium by metastasis or by infiltration from adjoining structures) account for over 95% of pericardial neoplastic diseases. Primary pericardial tumors are rare, and paraneoplastic effusions can also occur that are in response to remote tumors.[51]

The most common secondary tumors involving the pericardium in males (including both metastasis and local extension) are carcinoma of the lung (31.7%) and esophagus (28.7%) and lymphoma (11.9%). In females, carcinoma of the lung (35.9%), lymphoma (17.0%), and carcinoma of the breast (7.5%) are most common.[52] Tumors of the lung, thymus, chest wall, or esophagus are more likely to involve the pericardium by direct spread. Lymphomas, Hodgkin disease, leukemias, melanomas, and multiple myeloma can infiltrate the pericardium as well as the myocardium. Primary pericardial tumors are uncommon. Benign tumors are generally encountered in infancy or childhood. Malignant tumors such as mesotheliomas, sarcomas, and angiosarcomas most often present in the third or fourth decade of life.[53]

In both primary and secondary tumor involvement, the clinical presentation is usually silent, and may be associated with large pericardial effusions. Tamponade can result if hemorrhage occurs into a malignant effusion. Occasional tumors can induce constriction, due to neoplastic tissue, adhesions, or both. The role of the surgeon is limited to diagnosis and palliation in most of these cases.[54] Large refractory and tamponading effusions may need to be surgically drained. Pericardiocentesis has a high failure rate. Subxiphoid drainage or percutaneous balloon pericardiotomy are transiently effective. A pericardioperitoneal shunt may be considered in children. While extensive resection and debulking may be necessary in persistent or recurrent malignant pericardial constriction, it has only transient benefit without effective adjunctive chemotherapy and/or radiation therapy. Life expectancy in cancer patients with malignant pericardial involvement averages less than 4 months.[55,56]

Traumatic Pericardial Disease

Penetrating trauma

Knives, bullets, needles, and intracardiac instrumentation are the most common causes of penetrating trauma to the pericardium.[57] Tamponade is more common in stab wounds than in gunshot wounds. The right ventricle is most often involved in anterior chest wounds. Because tamponade provides hemostasis and prevents exsanguination, patients in tamponade have a better survival rate than patients with cardiac stab wounds not in tamponade.[58] Pericardiocentesis has no role in the management of penetrating wounds to the heart. Stable patients can be explored in the operating theater, but unstable patients should undergo thoracotomy in the emergency department.

Blunt trauma

Blunt injuries to the pericardium rarely occur in isolation. Trauma due to compression, blast, and deceleration will produce a spectrum of injuries, ranging from cardiac contusion to cardiac rupture, and pericardial laceration with herniation or luxation of the heart. Patients with pericardial laceration and cardiac herniation typically have suffered deceleration injuries and are invariably hypotensive. They may initially respond to volume resuscitation. A pericardial rub may be the only physical finding, but is not specific for this entity. On chest imaging, free air may be seen in the pericardium, and the heart may be displaced. Intra-abdominal organs may have migrated into the pericardial sac. If the heart has herniated into the left pleural space, positioning the patient right side down may reduce the herniation. Thoracotomy is required for definitive treatment and repair of associated injuries.[59–61]

Pericarditis Associated with Myocardial Infarction/Dressler Syndrome

This entity is thought to occur in almost half of patients suffering a transmural myocardial infarction, although it is symptomatic in far fewer.[62] Chest pain is almost universally present, and it is important to distinguish the pain of pericarditis from ischemic pain by its positional and pleuritic nature. The pain of pericarditis tends to start 1 week after myocardial infarction. A rub is present on auscultation. The electrocardiographic signs of pericarditis may be obscured by those of infarction. Patients may develop a small pericardial effusion. Patients suffering from pericarditis appear to have a worse long-term prognosis than those without post-infarct pericarditis,[63] possibly because they tend to have larger infarctions as judged by enzyme release and degree of ST-segment elevation. The diagnosis is clinical, and is treated with aspirin and/or NSAIDs.

Cardiac Surgery and the Pericardium

Postinfarction pericarditis

Postinfarction pericarditis is an important entity for the surgeon to be mindful of in the evaluation of patients with acute coronary syndromes. To the unwary it may masquerade as postinfarction angina and lead to a needless early operation after a myocardial infarction. Extensive fibrinous adhesions and murky gelatinous fluid may be present in the pericardial space and obscure epicardial vessels. When the pericardium is opened late in such a patient, the surgeon should expect dense pericardial adhesions.

Postpericardiotomy syndrome

Pericardial friction rubs are almost universal after cardiac surgery, and some patients will develop Dressier syndrome[64] with pleural and pericardial effusions, pleuritic pain, and generalized malaise. Such patients will almost always respond to NSAIDs or a short course of corticosteroids when the symptoms remain refractory.

Cardiac tamponade

Early postoperative tamponade rarely goes undetected for long because of the high level of vigilance and close hemodynamic monitoring that attend the patient during this time. It is equally important for surgeons to be aware of the potential for late cardiac tamponade that presents after hospital discharge and often initially to a clinician other than the cardiac surgeon. This entity is a potentially lethal complication and occurs in between 0.5 and 6% of patients after heart surgery, almost exclusively in those taking warfarin. Late cardiac tamponade (i.e., tamponade occurring more than 7 days after cardiac surgery) is more common in younger patients who have undergone isolated valve (as opposed to coronary artery bypass graft) surgery. Patients present on average 3 weeks after surgery, frequently in the setting of an elevated prothrombin time. They are often severely symptomatic, with declining exercise tolerance, dyspnea, an inability to urinate, and sometimes hypotension. Classic physical signs of tamponade like distant heart sounds, pulsus paradoxus, or distended neck veins may or may not be present. A high index of suspicion is required; any patient on warfarin whose recovery begins an otherwise unexplained decline in this interval should be suspected of having late tamponade and undergo echocardiographic examination. Echocardiography will demonstrate a pericardial effusion, although the typical echocardiographic signs of tamponade are detected in less than half of all patients. The diagnosis is therefore a clinical one. Nearly all patients with late tamponade will respond favorably to pericardiocentesis, and are able to safely resume anticoagulation.[65]

Pericardial closure

Redo sternotomy may be more hazardous when the heart is adherent to the inner table of the sternum. Closing the pericardium at the time of surgery interposes a protective layer of tissue between the sternum and the heart and may reduce the risks of redo sternotomy. Surgeons vary in their approach toward closing the pericardium after routine cardiac surgery. The value of any added protection against cardiac injury on sternal reentry is limited by the relative infrequency of reoperation and the already low incidence of cardiac injury at resternotomy when the pericardium is left open. On the negative side, closing the pericardium can cause kinking of bypass grafts after coronary bypass surgery and may result in hemodynamic compromise due to cardiac compression.

Rao and associates demonstrated that pericardial closure at the time of cardiac surgery adversely affects postoperative hemodynamics.[66] In this ingenious study, the pericardial edges were marked with radiopaque markers and the pericardium was closed with a running suture, the ends of which were exteriorized. After obtaining a postoperative chest film that demonstrated pericardial approximation, a set of baseline hemodynamics were measured. The suture was then removed, another x-ray taken to demonstrate that the pericardial edges had become distracted, and then the hemodynamic measurements were repeated. Pericardial closure reproducibly resulted in transient, moderate hemodynamic compromise in the first 8 hours after operation (Table 62-2). The risks of pericardial closure must therefore be weighed against its potential benefits if it is to be used in everyday clinical practice, and the practice should be individualized to the patient. Pericardial closure is probably not advisable after coronary artery bypass graft or in a patient with marginal hemodynamics.

OPERATIONS

Mediastinal Reexploration

Standard management for the postoperative cardiac surgical patient involves leaving the pericardium open, and placing anterior and posterior mediastinal thoracostomy drains. Despite this, postoperative tamponade may occur. The typical clinical scenario is one in which chest tube output falls after a period of early postoperative bleeding, the patient develops tachycardia, narrowing of the pulse pressure, increase in right-sided filling pressures, decrease in urine output, and a drop in the cardiac index. This setting is diagnostic of tamponade, and arrangements should be made for expedient mediastinal exploration. Echocardiography is not routinely helpful because the pericardial space is difficult to visualize in the immediate postoperative patient and thrombus may be difficult to resolve. Subtle echocardiographic findings that have been reported include an inspiratory increase in right ventricular end-diastolic diameter and a reciprocal decrease in left ventricular end-diastolic diameter,[67] as well as an increase in early peak tricuspid flow velocity and reduction in flow across the mitral valve.[68]

Table 62–2.

Structural and Hemodynamic Changes After Pericardial Closure in Patients Undergoing Elective Isolated Coronary Artery Bypass Grafting

Parameters measured	Open pericardium	Closed pericardium	*p* value
Retrosternal space at 1 wk (cm)	13 ± 5	20 ± 7	.0003
Retrosternal space at 3 mo (cm)	7 ± 3	14 ± 7	.0001
CI L/min/m^2 1 h postoperation	3.1 ± 0.8	2.3 ± 0.6	.003
CI L/min/m^2 4 h postoperation	3.1 ± 0.9	2.7 ± 0.7	.156
CI L/min/m^2 8 h postoperation	3.0 ± 0.8	2.8 ± 0.5	.402
LVSWI g/m/m^2 1 h postoperation	72 ± 18	52 ± 13	.002
LVSWI g/m/m^2 4 h postoperation	68 ± 17	54 ± 8	.016
LVSWI g/m/m^2 8 h postoperation	62 ± 22	52 ± 10	.087

CI = cardiac index; LVSWI = left ventricular stroke work index.

Pericardiocentesis

Pericardiocentesis can be performed at the bedside under local anesthesia in a calm patient, but it is usually performed in the catheterization laboratory and at some institutions, by interventional radiology under computed tomographic guidance. Arterial and right heart catheterization monitoring are frequently used. After administration of 1% lidocaine to the skin and the deeper tissues of the left xiphocostal area, a 25-mL syringe is affixed to a three-way stopcock and then to an 18-gauge spinal needle. This pericardial needle is connected to an electrocardiograph "V" lead. Under electrocardiographic and imaging guidance, the needle is advanced from the left of the subxiphoid area aiming toward the left shoulder. A discrete pop may be felt as the needle enters the pericardial space. ST-segment elevation may be seen on the V lead tracing when the needle touches the epicardium. Under these circumstances, the needle is retracted slightly until ST-segment elevation disappears. Once the pericardial space is entered, a guidewire is introduced into the pericardial space through the needle. The needle is removed and a catheter is inserted into the pericardial sac over the guidewire. At our institution, a pigtail-shaped drainage catheter with an end hole and multiple side holes is used. Intrapericardial pressure is measured by attaching a pressure transducer system to the intrapericardial catheter. Pericardial fluid may then be removed. Symptom relief may be immediate and dramatic. When appropriate, samples of pericardial fluid are sent for cell count, chemistry, cytology, cultures, and special stain studies to assist with the diagnosis of the etiology of the effusion. In the presence of pericardial tamponade, aspiration of fluid is continued until there is clear clinical and hemodynamic improvement. If blood is withdrawn, 5 mL should be placed on a sponge to see if it clots. Clotting blood suggests that the needle has either inadvertently entered a cardiac chamber or caused epicardial injury. Defibrinated blood that has been present in the pericardial space for even a short time usually does not clot.[69] The catheter is frequently left in place to monitor pericardial fluid drainage. It is secured to the skin with 4-0 silk sutures and covered with a sterile dressing, and the patient is started on prophylactic antibiotics. The pericardial space is drained every 8 hours and the catheter is flushed with heparinized solution and in general is removed within the next 24 to 72 hours. Pneumothorax is a potential complication, and chest x-ray is mandatory after the procedure.

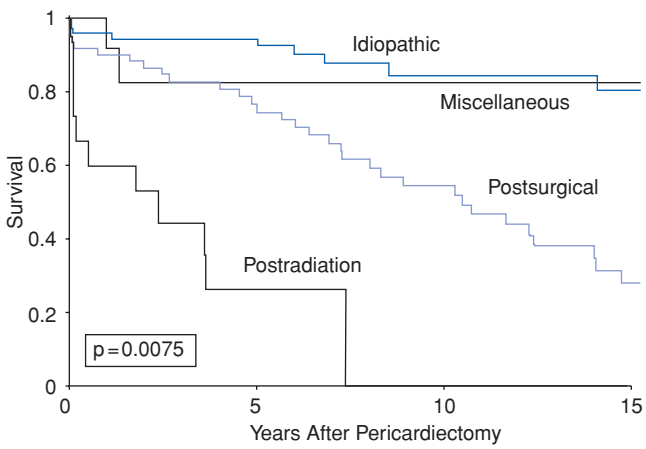
Pericardial Window

The purpose of partial pericardial resection (window) is to drain fluid into the pleural or peritoneal compartment in order to avoid the reaccumulation of pericardial fluid if the patient has had prior pericardiocentesis and reaccumulation. The procedure can be performed via thoracoscopy, anterior thoracotomy, or subxiphoid incision. General anesthesia is desirable, with the caveat that it may be poorly tolerated in patients with cardiac compression. When the pericardium is incised, fluid will invariably drain under pressure. The excised portion of pericardium should be as large as is feasible. Through an anterior thoracotomy, all accessible pericardium ventral to the phrenic nerve should be excised. The surgeon should remain mindful of the rare possibility of cardiac prolapse. Similarly, via the subxiphoid approach, as much diaphragmatic pericardium should be excised as is possible. Thoracostomy drainage catheters should be left within the pericardium.

Pericardial Stripping

Chronic pericardial constriction is treated by pericardial excision. Because of dense adhesions and calcification that can penetrate into the myocardium, pericardial resection can be a technical challenge. At most centers, the procedure is done via median sternotomy with the capability to use cardiopulmonary bypass as needed.[18,33] Practice is variable, as some use cardiopulmonary bypass routinely, while others prefer to avoid the additional burden of coagulopathy unless absolutely necessary. Left anterior thoracotomy is preferred by some surgeons, and was the approach taken by Dr. Edward Churchill, who reported the first pericardiectomy for CP done in the United States.[70] The objective of the procedure is to release the ventricles from the densely adherent pericardial shell. The lack of a surgical plane can make this a bloody operation, and attention must be paid to salvage and reinfusion of blood. Epicardial coronary vessels are at risk in this dissection and particular care must be taken when dissecting in the regions of these vessels. The goal is to excise the pericardium from phrenic nerve to phrenic nerve, and also posteriorly, around the entrance of the venae cavae and pulmonary veins to the pericardium. Complete resection should restore pressure-volume loops to their normal position.[71] Complete pericardial resection is not feasible in all cases, notably with radiation-induced disease, and leaving densely adherent scar, particularly over the venae cavae and atria, may be safer for the patient.

The results vary with the etiology and severity of the disease. Operative mortality has been reported as high as 10 to 20%,[72,73] and varies based on severity of heart failure, elevation of right atrial pressure, and comorbidities. Although surgery alleviates or improves symptoms in the vast majority of patients, long-term survival is diminished in patients who have had prior heart surgery, and particularly in patients with radiation-induced constrictive pericarditis (Fig. 62-7).[20,74,75]



Number at risk				
Idiopathic	75	48	30	21
Miscellaneous	12	10	10	5
Post-surgical	60	38	24	9
Post-radiation	15	6	0	0

Figure 62-7. Kaplan-Meier curve showing a significant difference (log-rank test, $p = 0.0075$) in overall survival of patients after pericardiectomy, based on the presumed cause of constrictive pericarditis. (*Reprinted with permission from Bertog et al.*[75])

Acknowledgments

The authors would like to thank Marcia Williams for the preparation of Fig. 62-1.

CHAPTER 63

Cardiac Neoplasms

Jon-Cecil M. Walkes • W. Roy Smythe • Michael J. Reardon

Neoplasms of the heart can be divided into primary cardiac tumors arising in the heart and secondary cardiac tumors that have metastasized to the heart. Primary cardiac tumors can be further stratified into benign and malignant tumors. Secondary involvement of the heart is relatively uncommon; between 10% and 20% of patients dying of disseminated cancer have metastatic involvement of the heart or pericardium.[1,2] Surgical resection is seldom possible or advisable for these tumors, and surgical intervention usually is limited to drainage of malignant pericardial effusions and/or diagnostic biopsies.

Primary tumors of the heart are uncommon but not rare. The incidence of primary cardiac neoplasm ranges between 0.17% and 0.19% in unselected autopsy series.[3–8] Approximately 75% of primary cardiac tumors are benign, and 25% are malignant.[2,9] Approximately 50% of the benign tumors are myxomas, and about 75% of the malignant tumors are sarcomas.[2,9] The clinical incidence of these tumors is approximately 1 in 500 cardiac surgical patients, and with the exception of myxomas, most surgeons will encounter primary cardiac tumors rarely. The purpose of this chapter is to summarize useful information for the evaluation and management of patients with primary and secondary cardiac tumors and to provide a reference for additional study on these subjects.

HISTORICAL BACKGROUND

A primary cardiac neoplasm was first described by Realdo Colombo in 1559.[10,11] Alden Allen Burns of Edinburgh described a cardiac neoplasm and suggested valvular obstruction by an atrial tumor in 1809.[12] A series of six atrial tumors, with characteristics we now recognize as myxoma, was published in 1845 by King.[13] In 1931, Yates reported nine cases of primary cardiac tumor and established a classification system similar to what we use today.[14] The first antemortem diagnosis of a cardiac tumor was made in 1934 when Barnes diagnosed a cardiac sarcoma using electrocardiography and biopsy of a metastatic lymph node.[15] In 1936, Beck successfully resected a teratoma external to the right ventricle,[16] and Mauer removed a left ventricular lipoma in 1951.[17] Treatment of cardiac tumors was profoundly influenced by two events: the introduction of cardiopulmonary bypass in 1953 by John Gibbon, which allowed a safe and reproducible approach to the cardiac chambers, and the introduction of cardiac echocardiography, which allowed safe and noninvasive diagnosis of an intracardiac mass. The first echocardiographic diagnosis of an intracardiac tumor was made in 1959.[18] An intracardiac myxoma was diagnosed by angiography in 1952 by Goldberg, but attempts at surgical removal were unsuccessful.[13] A large right atrial myxoma was removed by Bhanson in 1952 using caval inflow occlusion, but the patient died 24 days later.[19] Crafoord in Sweden first successfully removed a left atrial myxoma in 1954 using cardiopulmonary bypass,[20] and Kay in Los Angeles first removed a left ventricular myxoma in 1959.[21] By 1964, 60 atrial myxomas had been removed successfully, with a steady increase owing to the increasing safety of cardiopulmonary bypass and increased use of echocardiography for detection.[22] Operations are currently performed routinely on the vast majority of patients with atrial myxoma with minimal mortality.[9,23–33] Primary malignant tumors, however, continue to represent a challenge.

CLASSIFICATION

Surgeons generally classify cardiac tumors as primary or secondary, as noted previously, and divide primary tumors into benign and malignant categories. However, the tissue of origin may influence clinical behavior, and an understanding of the pathologic classification of cardiac tumors is important. Pathologic classification is listed in Table 63-1. Mural thrombus is listed as a pseudotumor. Although not really a cardiac tumor, its presentation may mimic myxoma clinically and

Table 63–1.

Types of Cardiac Tumors by Pathology

Pseudotumors
Mural thrombi
Heterotopias and tumors of ectopic tissue
Tumors of the atrioventricular nodal region
Teratoma
Ectopic thyroid
Tumors of mesenchymal tissue
Hamartoma of endocardial tissue
Papillary fibroelastoma
Hamartomas of cardiac muscle
Rhabdomyoma
Histiocytoid cardiomyopathy (Purkinje cell hamartoma)
Tumors and neoplasms of fat
Lipomatous hypertrophy, interarterial septum
Lipoma
Liposarcoma
Tumors and neoplasms of fibrous and myofibroblastic tissue
Fibroma
Inflammatory pseudotumor (inflammatory myofibroblastic tumor)
Sarcomas (malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma)
Vascular tumors and neoplasms
Hemangioma
Epithelioid hemangioendothelioma
Angiosarcoma
Neoplasm of uncertain histogenesis
Myxoma
Neoplasms of neural tissue
Granular cell tumor
Schwannoma/neurofibroma
Paraganglioma
Malignant schwannoma/neurofibrosarcoma (rare)
Malignant lymphoma
Malignant mesothelioma
Metastatic tumors to the heart

pathologically. Most mural thrombi are associated with underlying valvular disease, myocardial infarction or dysfunction, or atrial fibrillation.[32] Mural thrombi also have been noted in hypercoagulable syndromes, particularly antiphospolipid syndrome.[33] With increasing use of long-term central catheters, we have seen several right atrial masses that were difficult to tell from myxoma; these masses turned out to be mural thrombi on removal. Simple removal must be combined with addressing the underlying cause, and long-term anticoagulation is needed frequently.

Heterotopias and tumors of ectopic tissue include cystic tumors of the atrioventricular node consisting of multiple benign cysts in the region of the atrioventricular node that can cause heart block or sudden death. Most are diagnosed at autopsy, but biopsy diagnosis of atrioventricular nodal tumor has been reported.[34] Germ cell tumors of the heart usually are teratomas, occurring within the pericardial sac, but yolk sac tumors have been described in infants and children.[35,36] Ectopic thyroid tissue may occur within the myocardium and is referred to as *struma cordis*. Right ventricular outflow track obstruction may be present, but most patients are asymptomatic.[37,38]

Most of the remaining tumors arise in the mesenchymal, fat, fibrous, neural, or vascular cells of the heart, with myxoma representing a tumor of undetermined histogenesis. Primary cardiac lymphoma and mesothelioma and metastatic tumors to the heart represent the remaining pathologic categories that comprise the greater part of this chapter.

PRIMARY BENIGN TUMORS

Myxoma

Myxoma comprises 50% of all benign cardiac tumors in adults but only 15% of such tumors in children. Occurrence during infancy is rare (Tables 63-2 and 63-3). A vast majority of myxomas occur sporadically and tend to be more common in women than men.[4,31] The peak incidence is between the third and sixth decades of life, and 94% of tumors are solitary.[39] Approximately 75% occur in the left atrium.[31] The deoxyribonucleic acid (DNA) genotype of sporadic myxomas is normal in 80% of patients.[40] Tumors are unlikely to be associated with other abnormal conditions and have a low recurrence rate.[4,39]

About 5% of myxoma patients show a familial pattern of tumor development based on autosomal dominant inheritance.[41,42] These patients and 20% of those with sporadic myxoma have an abnormal DNA genotype chromosomal pattern.[40] In contrast to the "typical" sporadic myxoma profile of a middle-aged, frequently female patient with a single left atrial myxoma, familial myxoma patients are more likely to be younger, equally likely to be male or female, and more often (22%) have multicentric tumors originating from either the atrium or ventricle.[43–48] Although familial myxomas have the same histology as sporadic tumors, familial myxoma has a higher recurrence rate after surgical resection (21 to 67%).[44,49,50] Approximately 20% of familial patients have associated conditions such as adrenocortical nodule hyperplasia, Sertoli cell tumors of the testes, pituitary tumors, multiple myxoid breast fibroadenomas, cutaneous myomas, and facial or labial pigmented spots.[39,49] These conditions often are described as *complex myxomas* within the

Table 63–2.

group of familial myxoma.[40] A familial syndrome with autosomal X-linked inheritance characterized by primary pigmented nodular adrenocortical disease with hypercortisolism, cutaneous pigmentous lentigines, and cardiac myxoma is referred to as *Carney's complex.*[39,49]

Pathology

Myxomas occur in any chamber of the heart but have a special predilection for the left atrium, from which approximately 75% originate.[32] The next most frequent site is the right atrium, where 10 to 20% are found. The remaining 6 to 8% are equally distributed between the left and right ventricles.[2] Both biatrial and multicentric tumors are more common in familial disease. Biatrial tumors probably arise from bidirectional growth of a tumor originating within the atrial septum.[51] Atrial myxomas generally arise from the interatrial septum at the border of the fossa ovalis but can originate anywhere within the atrium, including the appendage[4] (Figs. 63-1 and 63-2). In addition, isolated reports confirm that myxomas arise from the cardiac valves, pulmonary artery and vein, and vena cava.[52,53] Right atrial myxomas are more likely to have broad-based attachments than left atrial tumors; they also are more likely to be calcified[45,46] and thus visible on chest radiographs (Fig. 63-3). Ventricular myxomas occur more often in women and children and may be multicentric.[2,54] Right ventricular tumors typically arise from the free wall, and left ventricular tumors tend to originate in the proximity of the posterior papillary muscle.

Grossly, about two-thirds of myxomas are round or oval tumors with a smooth or slightly lobulated surface.[31] Most are polypoid, relatively compact, pedunculated, mobile, and not likely to fragment spontaneously.[2,4] Mobility depends on the

length of the stalk, the extent of attachment to the heart, and the amount of collagen in the tumor.[4] Most tumors are pedunculated with a short, broad base, and although sessile forms occur, they are unusual.[2,55] Less common villous or papillary myxomas are gelatinous and fragile and prone to fragmentation and embolization, occurring about one-third of the time.[31,56] Myxomas are white, yellowish, or brownish in color, frequently covered with thrombus.[2] Focal areas of hemorrhage, cyst formation, or necrosis may be seen in cut section. The average size is about 5 cm in diameter, but growth to 15 cm in diameter and larger has been reported.[4] Most myxoma tumors appear to grow rapidly, but growth rates vary, and occasionally, tumor growth arrests spontaneously.[4] Weights range from 8 to 175 g, with a mean between 50 and 60 g.[8]

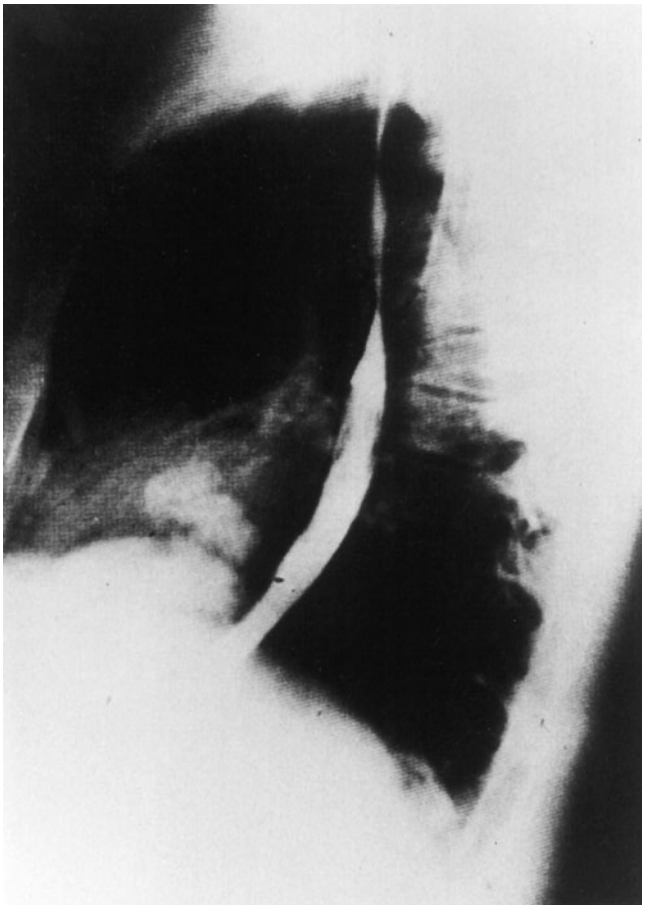

Figure 63-3. Calcified right atrial myxoma. *(Reproduced with permission from Hurst JW et al: Atlas of the Heart. New York, McGraw-Hill, 1988.)*

Histologically, myxomas are composed of polygonal-shaped cells and capillary channels within an acid mucopolysaccharide matrix[4] (Fig. 63-4). The cells appear singularly or in small clusters throughout the matrix, and mitoses are rare.[57] The matrix also contains a smattering of smooth muscle cells, reticulocytes, collagen, elastin fibers, and a few blood cells. Cyst, areas of hemorrhage, and foci of extramedullary hematopoiesis are present throughout the matrix.[49,56,58] Ten percent of the tumors have microscopic deposits of calcium and metastatic bone deposits, as well as sometimes glandular-like structures.[49,56] The base of the tumor contains a large artery and veins that connect with the subendocardium but do not extend deeply beyond the subendocardium in most cases.[49] We have seen a myxoma recently that on coronary angiography had a large feeding vessel and was suspected originally of being an

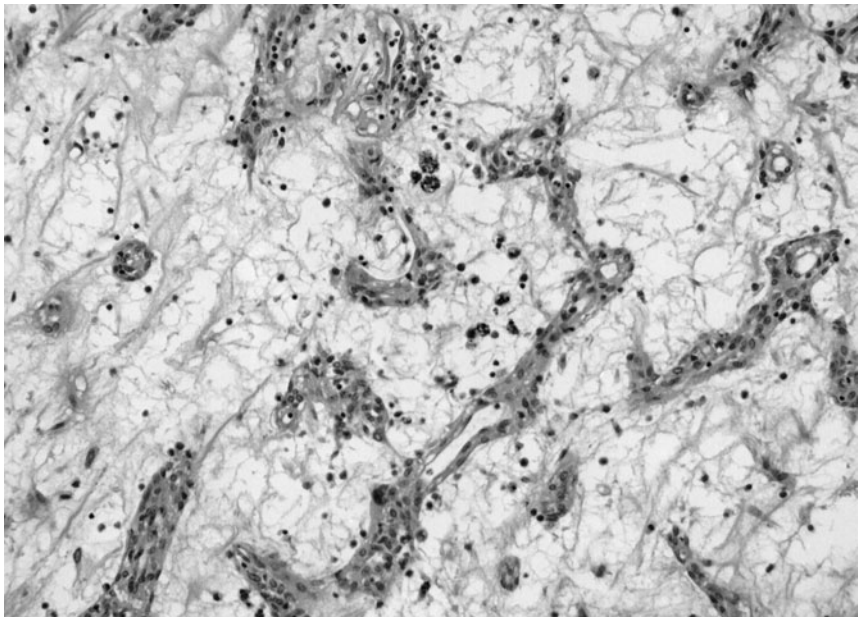

Figure 63-4. Typical microscopic appearance of atrial myxoma with nests of small stellate cells and blood vessels immersed in abundant acellular matrix rich in proteoglycans. These tumors often contain smooth muscle, areas of hemorrhage and calcification, hemosiderin-laden macrophages, and chronic inflammatory cells. Hematoxylin & eosin, ×200. (*Courtesy of Dr. G. G. Pietra.*)

angiosarcoma but on histology proved to be a typical benign myxoma. Myxomas tend to grow into the overlying cardiac cavity rather than into the surrounding myocardium. The tumor surface is covered by a monolayer of polygonal cells with interspersed primitive blood vessels.

Myxomas arise from the endocardium and are considered derivative of the subendocardial multipotential mesenchymal cell,[59,60] although origin from endocardial nervous tissue also has been suggested.[61] The multipotential mesenchymal cells are thought to be embryonic cells left behind during septation of the heart and are capable of differentiating into endothelial cells, smooth muscle cells, angioblasts, fibroblasts, myoblasts, and cartilage. This accounts for the occasional presence of hematopoietic tissue and bone in these tumors. There is no evidence that these tumors are of thrombotic origin, as was speculated formerly.[62]

Interestingly, myxomas have developed after cardiac trauma, including repair of atrial septal defects and transseptal puncture for paracutaneous dilatation of the mitral valve.

Clinical presentation

The classic triad of myxoma clinical presentation is intracardiac obstruction with congestive heart failure (67%), signs of embolization (29%), systemic or constitutional symptoms of fever (19%) and weight loss or fatigue (17%), and immunologic manifestations of myalgia, weakness, and arthralgia (5%), with almost all patients presenting with one or more of these symptoms.[31] Cardiac rhythm disturbances and infection occur less frequently.

CONSTITUTIONAL SYMPTOMS: Nearly all myxoma patients on careful questioning admit to a variety of constitutional symptoms that may include weight loss, fever, and lethargy. These complaints may be accompanied by laboratory abnormalities, including leukocytosis, elevated erythrocyte levels and sedimentation rate, hemolytic anemia, thrombocytopenia, and elevated C-reactive protein. Immunoelectrophoresis may reveal abnormal immunoglobulin levels with increased circulating IgG.[63] These symptoms often suggest an inflammatory autoimmune disease and are unrelated to the location and size of the tumor.[4]

The recent discovery of elevated levels of interleukin-6 in patients with myxoma has been linked to a variety of associated conditions, including lymphadenopathy, tumor metastasis, ventricular hypertrophy, and development of constitutional symptoms.[54,64–66] Other less frequent complaints include Raynaud phenomenon, arthralgias, myalgias, erythematous rash, and clubbing of the digits.[4,67,68]

Possible etiologies of such varied complaints and symptoms include tumor embolization with secondary myalgias and arthralgias and elevated immunoglobulin response.[69] Circulating antibody–tumor antigen complexes with complement activation also may play a role in the constitutional symptom complex.[70] More important, such symptom complexes tend to resolve following surgical resection of the tumor.[58,71,72]

OBSTRUCTION: Obstruction of blood flow in the heart is the most common cause of acute presenting symptoms. The nature of these symptoms is determined by which of the chambers is involved and the size of the tumor.

Myxomas in the left atrium tend to mimic mitral valvular heart disease. They produce dyspnea, which may be positional,[73] and other signs and symptoms of heart failure associated with elevated left atrial and pulmonary venous pressures. Clinically, mitral stenosis often is suspected and leads to echocardiography and diagnosis of myxoma. On occasion, large myxomas may interfere with mitral leaflet closure and produce mitral regurgitation, but this is uncommon.[4] Syncopal episodes occur in some patients and are thought to result from temporary occlusion of the mitral orifice.[46,73–75] Right atrial myxomas can produce a clinical picture of right-sided heart failure with signs and symptoms of venous hypertension, including hepatomegaly, ascites,

and dependent edema. The tumor simulates tricuspid valve stenosis by partially obstructing the valve orifice.[46,73–75] If a patent foramen ovale is present, right-to-left atrial shunting may occur with central cyanosis, and paradoxical embolization has been reported.[74,76,77]

Large ventricular myxomas may mimic ventricular outflow obstruction. The left ventricular myxoma may produce the equivalent of subaortic or aortic valvular stenosis,[77–79] whereas right ventricular myxomas can simulate right ventricular outflow track or pulmonic valve obstruction.

EMBOLIZATION: Systemic embolization is the second most common mode of presentation for patients with myxoma. It occurs in 30 to 40% of patients.[2,4,46,73,74] Because the majority of myxomas are left-sided, approximately 50% of embolic episodes affect the central nervous system owing to both intracranial and extracranial vascular obstruction. The neurologic deficits following embolization range from transient to permanent, but a high number do not resolve.[80] Specific central nervous system consequences include intracranial aneurysms, seizures, hemiparesis, and brain necrosis.[81–84] Retinal artery embolization with visual loss has occurred in some patients.[85,86]

Embolic material for cardiac myxoma has been found in iliac and femoral arteries, causing acute lower extremity ischemia.[87–89] Other sites of tumor embolization include abdominal viscera and the renal and coronary arteries.[90] Histologic examination of surgically removed peripheral myxoma that has embolized provides the diagnosis of an otherwise unsuspected tumor.[46,91,92]

Right-sided myxomatous emboli usually do not cause clinical manifestations but do obstruct pulmonary arteries and cause pulmonary hypertension and even death from acute obstruction.[4,77]

INFECTION: Infection arising in a myxoma is a rare complication and produces a clinical picture of infectious endocarditis,[91–95] and a number of bacterial pathogens and fungus forms[93] have been isolated.[96] Infection increases the likelihood of systemic embolization,[4] and infected myxoma warrants urgent surgical resection.

Diagnosis

CLINICAL EXAMINATION: Findings at the time of clinical assessment of a patient with cardiac myxoma vary according to the size, location, and mobility of the tumor. Left atrial myxomas may produce auscultatory findings similar to mitral stenosis, just as these tumors may mimic the symptoms of mitral disease. The well-described "tumor plop" is an early diagnostic sound heard and sometimes confused with a third heart sound. The diagnostic tumor plop occurs just after the opening snap of the mitral valve and is believed to be secondary to contact between the tumor and endocardial wall.[97,98] Of note, the murmur of cardiac myxoma may depend on its position, and this may aid in the auscultatory diagnosis. Left atrial myxomas that cause partial obstruction of left ventricular filling may result in elevated pulmonary vascular pressures with augmentation of the pulmonary component of the second heart sound.[99]

Right atrial myxomas may produce the same auscultatory findings as left atrial myxomas with the exception that they are best heard along the lower right sternal border rather than the cardiac apex. These include both systolic and diastolic murmurs and a tumor plop. In addition, right atrial hypertension may produce a large *a* wave in the jugular venous pulse and, when severe, may mimic superior vena caval syndrome. Similarly, elevated right atrial pressure can lead to right-to-left shunting across the patent foramen ovale. This may produce polycythemia, cyanosis, and clubbing of the digits. Lower body manifestations of venous hypertension are hepatomegaly, ascites, and peripheral edema.

CHEST RADIOGRAPH AND ELECTROCARDIOGRAM: The findings on chest roentgenogram, although not specific, may include generalized cardiomegaly, individual cardiac chamber enlargement, and pulmonary venous congestion. More specific occasional findings are density within the cardiac silhouette caused by calcification within the tumor (see Fig. 63-3). This finding occurs more often with right-sided myxomas[4]; however, the majority of our myxoma patients have normal chest roentgenograms.

ELECTROCARDIOGRAPHIC FINDINGS: Similar to plain-film imaging, nonspecific abnormalities are noted, including chamber enlargements, cardiomegaly, bundle-branch blocks, and axis deviation.[100] Fewer than 20% of patients have atrial fibrillation.[48] Evaluation of nonspecific electrocardiographic abnormalities occasionally leads to an incidental diagnosis of myxoma, but as with chest x-rays, most electrocardiograms are not helpful in establishing a diagnosis.

ECHOCARDIOGRAPHY: Cross-sectional echocardiography is the most useful test employed for the diagnosis and evaluation of myxoma. The sensitivity of two-dimensional (2-D) echocardiography for myxoma is 100%, and this imaging technique largely has supplanted angiocardiography.[101] However, coronary angiography usually is performed in patients over 40 years of age to rule out significant coronary arterial disease in a patient who has another indication for cardiac surgery. A transthoracic echocardiogram usually provides all the information for surgical resection, but transesophageal echocardiography (TEE) provides the best information concerning tumor size, location, mobility, and attachment.[102,103]

Transesophageal echocardiograms detect tumors as small as 1 to 3 mm in diameter.[104] Our practice is to obtain a transesophageal echocardiogram in the operating room before beginning the operation (Fig. 63-5). We particularly evaluate the posterior left atrial wall, atrial septum, and right atrium, which often are not well displayed on transthoracic examination, to exclude the possibility of biatrial multiple tumors. Additionally, operative TEE ensures a normal echocardiogram prior to leaving the operating room.

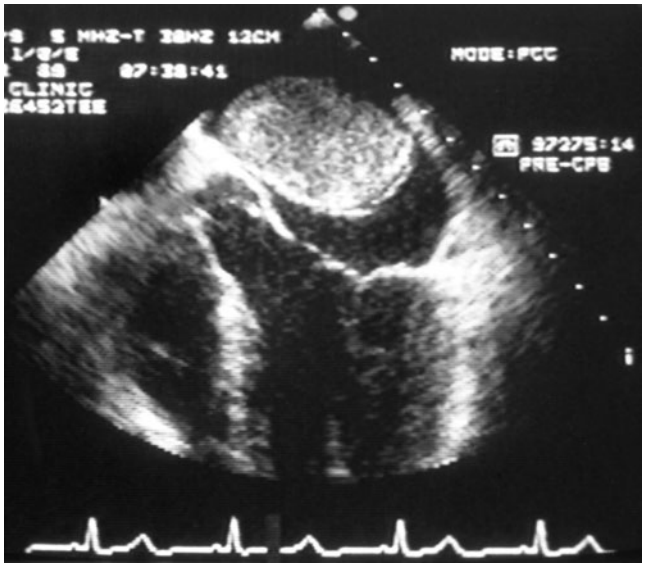

Figure 63-5. Transesophageal echocardiogram of large left atrial myxoma in patient presenting with symptoms of mitral valve disease. The tumor is attached to the interatrial septum above the normal mitral valve. (*Reproduced with permission from Hall RA, Anderson RP: Cardiac neoplasms, in Edmunds LH Jr (ed): Cardiac Surgery in the Adult. New York, McGraw-Hill, 1997; p. 1350.*)

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING: Although myxomas have been identified using computed tomography (CT),[100,105] this modality is most useful in malignant tumors of the heart because of its ability to demonstrate myocardial invasion and tumor involvement of adjacent structures.[100] Similarly, magnetic resonance imaging (MRI) has been employed in the diagnosis of myxomas and may yield a clear picture of tumor size, shape, and surface characteristics.[100,103,105,106] MRI is particularly useful in detecting intracardiac and pericardial extension and invasion of malignant secondary tumors and also is useful in the evaluation of ventricular masses that occasionally turn out to be myxoma. Both CT and MRI detect tumors as small as 0.5 to 1.0 cm and provide information regarding the composition of the tumor.[4] Neither CT nor MRI is needed for atrial myxomas if an adequate echocardiogram is available because the information from these studies is not likely to alter the surgical approach. The exception is the occasional right atrial myxoma that extends into one or both caval or tricuspid orifices. CT or MRI should be reserved for the situation in which the diagnosis or characterization of the tumor is unclear after complete echocardiographic evaluation.

Surgical management

Surgical resection is the only effective therapeutic option for patients with cardiac myxoma and should not be delayed because death from obstruction to flow within the heart or embolization may occur in as many as 8% of patients awaiting operation.[107,108] A median sternotomy approach with ascending aortic and bicaval cannulation usually is employed. Manipulation of the heart before initiation of cardiopulmonary bypass is minimized in deference to the known friability and embolic tendency of myxomas. For left atrial myxomas, the venae cavae are cannulated through the right atrial wall, with the inferior cannula placed close and laterally to the inferior vena cava–right atrial junction (Fig. 63-6). Caval snares are always used to allow opening of the right atrium, if necessary. If extensive exposure of the left atrium is needed or a malignant left atrial tumor is suspected, we mobilize and directly cannulate the superior vena cava, which allows it to be transected if necessary for additional

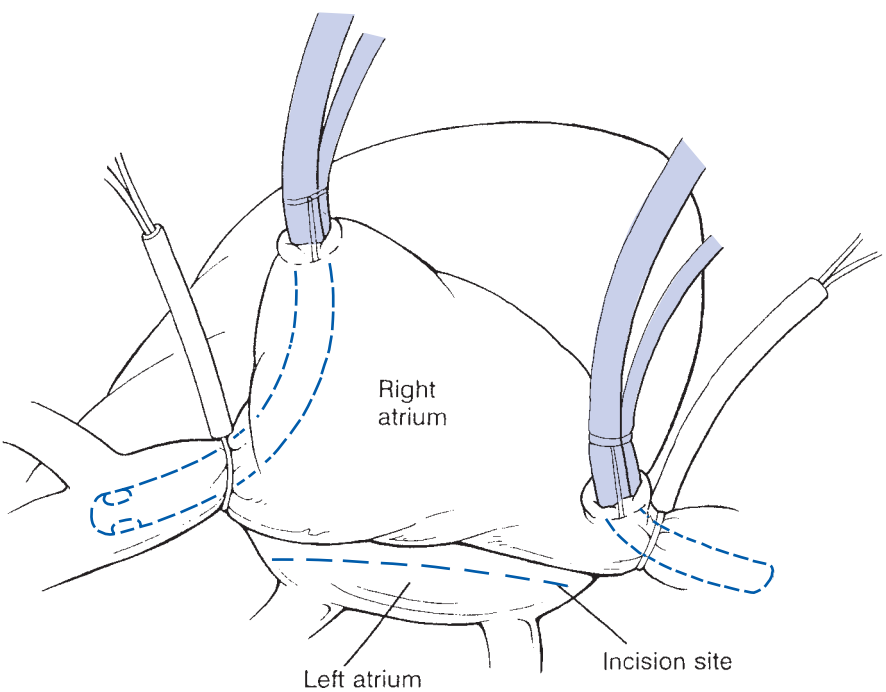

Figure 63-6. Standard venous cannulation for atrial myxomas and left arteriotomy site for left atrial myxoma.

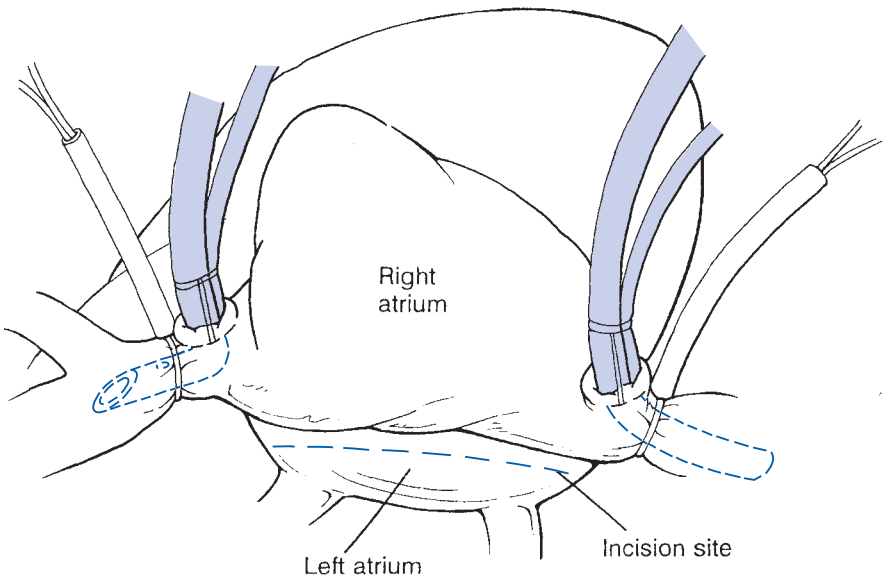

Figure 63-7. Superior vena cava cannula to allow increased right atrial exposure or division of superior vena cava for additional left atrial exposure.

exposure (Fig. 63-7). Body temperature is allowed to drift down, but there is no attempt to induce systemic hypothermia unless the need for reduced perfusion flow is anticipated. Modern cardioplegic techniques yield a quiet operative field and protect the myocardium from ischemic injury during aortic cross-clamping. Cardiopulmonary bypass is started, and the aorta is clamped prior to manipulation of the heart.

Exposure of left atrial myxomas is maximized by using several principles from mitral valve repair surgery. The surgeon desires the right side of the heart to rotate up and the left side of the heart to rotate down. Therefore, stay sutures are placed low on the pericardium on the right side, and no pericardial stay sutures are placed on the left prior to placing the chest retractor. This rotates the heart for optimal exposure of both the right and, particularly, the left atrium (Fig. 63-8). For left atrial tumors, the superior vena cava is mobilized extensively, as is the inferior vena cava–right atrial junction, allowing increased mobility and exposing the left atrial cavity. Left atrial myxomas can be

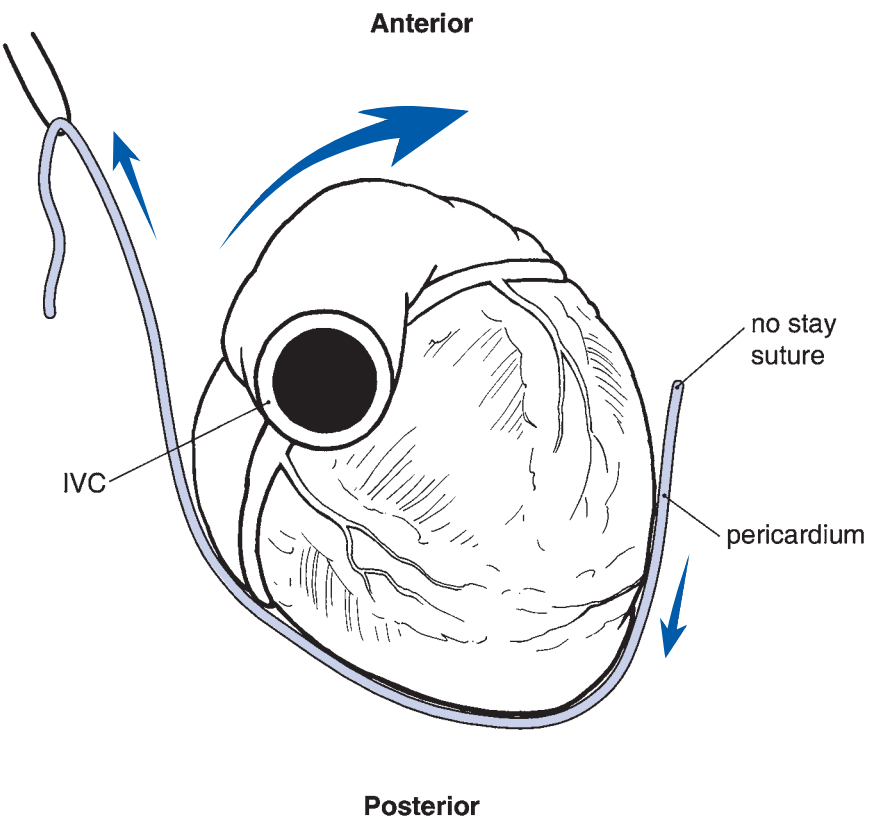

Figure 63-8. Rotation of the heart with pericardial stay sutures for left atrial exposure. IVC = inferior vena cava.

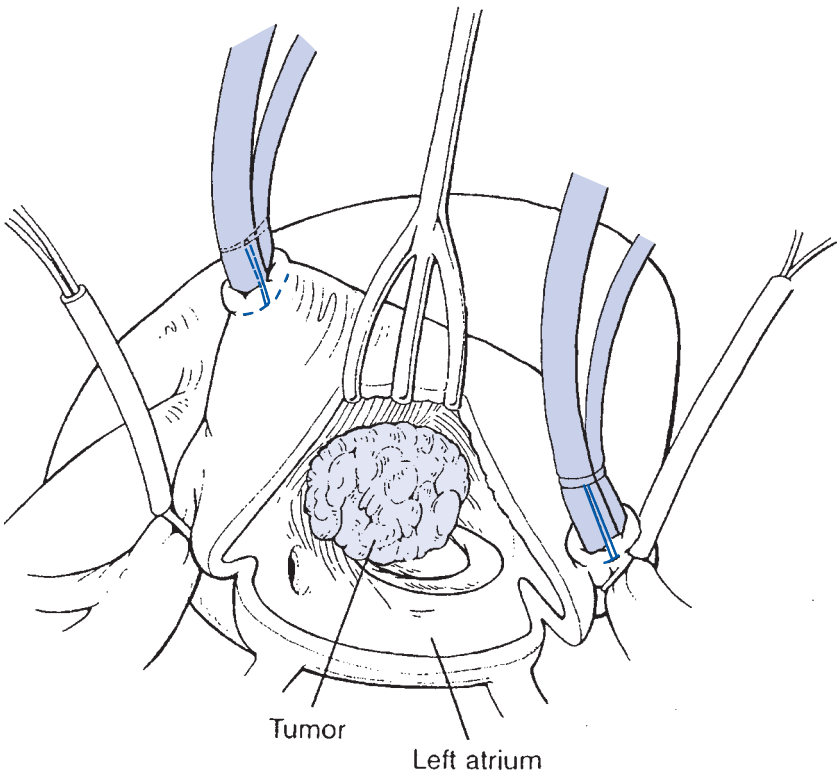

Figure 63-9. Left atriotomy and exposure of myxoma.

approached by an incision through the anterior wall of the left atrium anterior to the right pulmonary veins (Fig. 63-9). This incision can be extended behind both cavae for greater exposure (Figs. 63-10 and 63-11). Exposure and removal of large tumors attached to the interatrial septum may be aided by a second incision parallel to the first in the right atrium going posterior to the superior vena caval cannula and anterior to the inferior vena caval cannula. This biatrial incision allows easy removal of tumor attached to the fossa ovalis with full-thickness excision at the site of

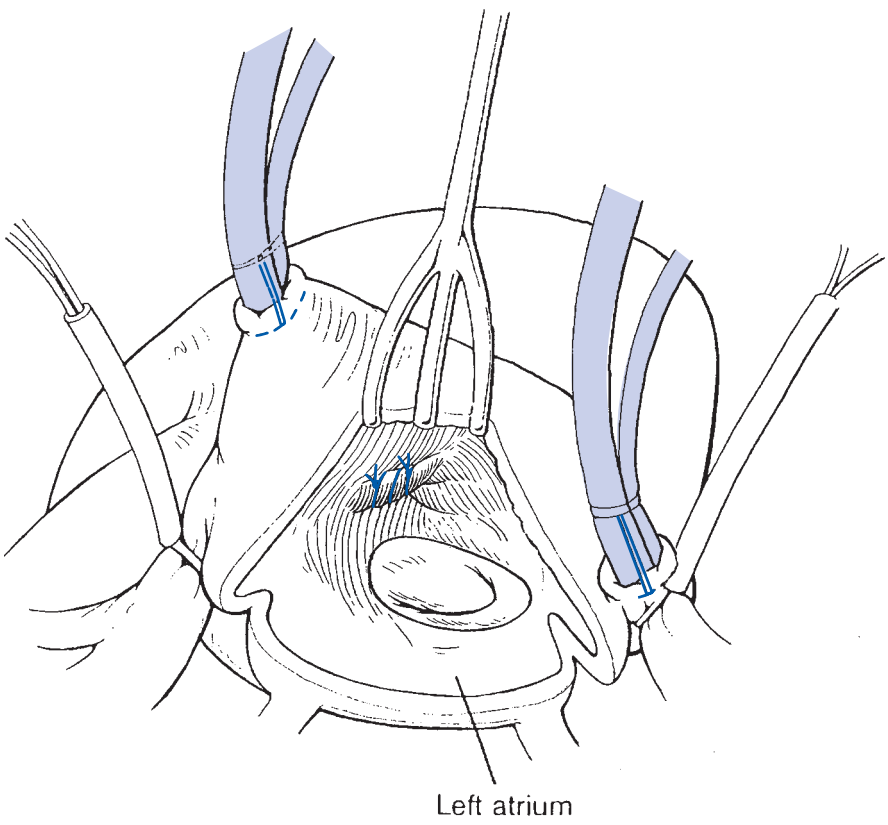

Figure 63-10. Repair of left atrial wall after removal of myxomas.

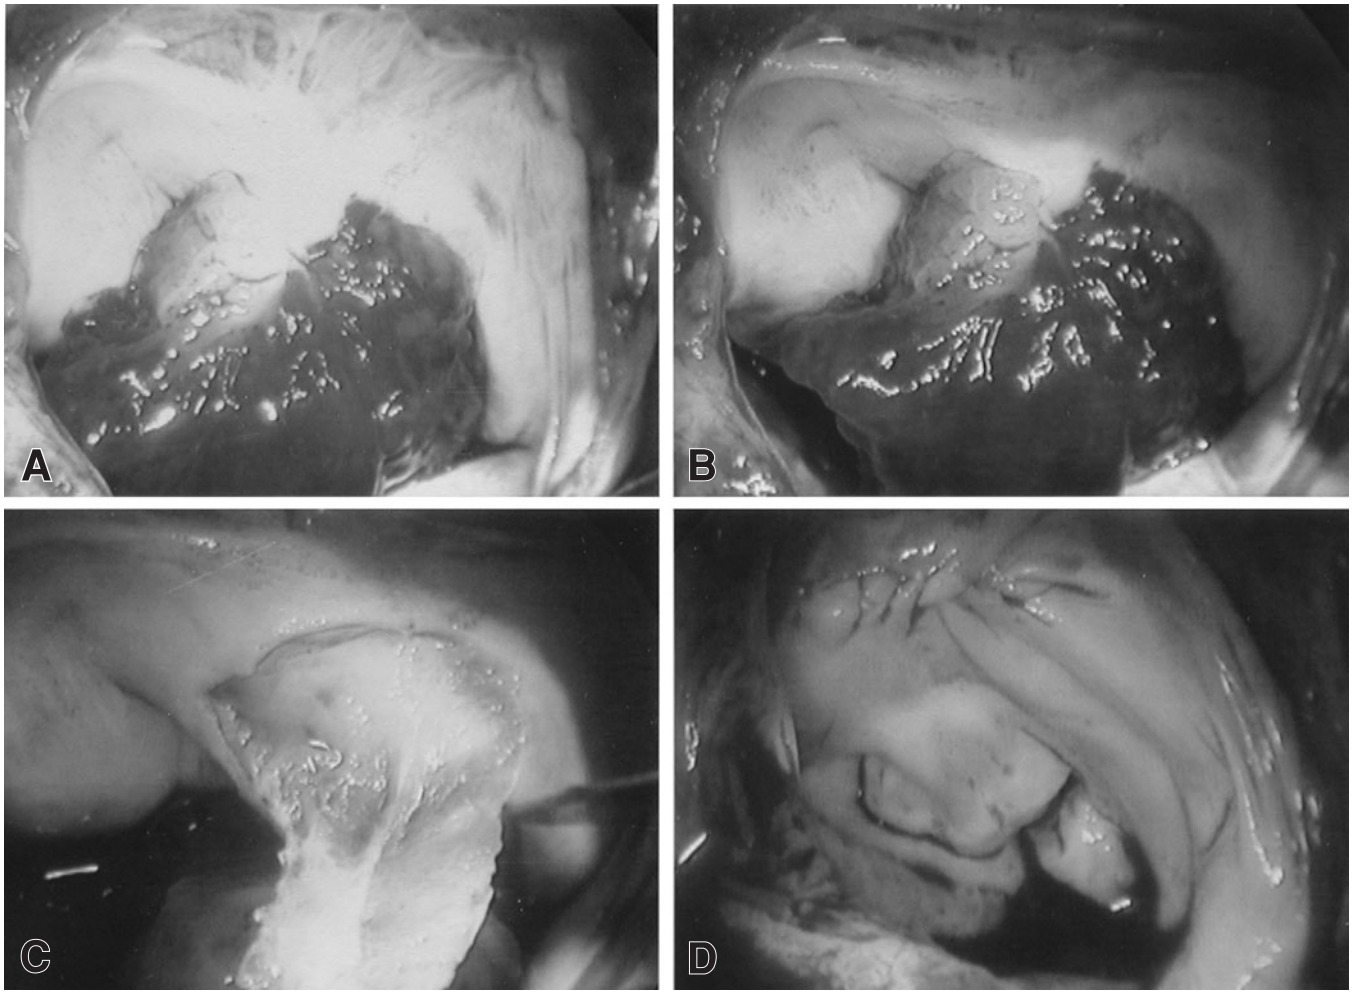

Figure 63-11. Photographs of left atrial myxoma removal and repair.

attachment and easy patch closure of the atrial septum if necessary.

Right atrial myxomas pose special venous cannulation problems, and intraoperative echocardiography may be of benefit in allowing safe cannulation. Both venae cavae may be cannulated directly. When low- or high-lying tumor pedicles preclude safe transatrial cannulation, cannulation of the jugular or femoral vein can provide venous drainage of the upper or lower body. In general, we always can cannulate the superior vena cava distal enough from the right atrium to allow adequate tumor resection, but occasionally femoral venous cannula drainage has been necessary for low-lying right atrial tumors encroaching on the inferior vena caval orifice. If the tumor is large or attached near both caval orifices, peripheral cannulation of both jugular and femoral veins may be used to initiate cardiopulmonary bypass and deep hypothermia. After the aorta is cross-clamped and the heart is arrested with antegrade cardioplegia, the right atrium may be opened widely for resection of the tumor and reconstruction of the atrium using pericardium or polytetrafluoroethylene during a period of circulatory arrest if this is needed for a dry field. Resection of large or critically placed right atrial myxomas often requires careful preoperative planning, intraoperative TEE, and special extracorporeal perfusion techniques to ensure complete removal of the tumor, protection of right atrial structures, and reconstruction of the atrium. Because myxomas rarely extend deep in the endocardium, it is not necessary to resect deeply around the conduction tissue. The tricuspid valve and the right atrium, as well as the left atrium and ventricle, should be inspected carefully for multicentric tumors in patients with right atrial myxoma, with or without familial myxoma. However, in the age of pre- and intraoperative TEE, it is unusual to find additional tumors not seen on echocardiography.

Regardless of the surgical approach, the ideal resection encompasses the tumor and a portion of the cardiac wall or interatrial septum to which it is attached. Whether excision of full-thickness wall is necessary or excision of only an endocardial attachment is sufficient to prevent recurrence is controversial. Our policy is to resect full thickness whenever possible. However, only partial-thickness resection of the area of tumor attachment has been performed when anatomically necessary without a noted increase in recurrence rate.[109,110]

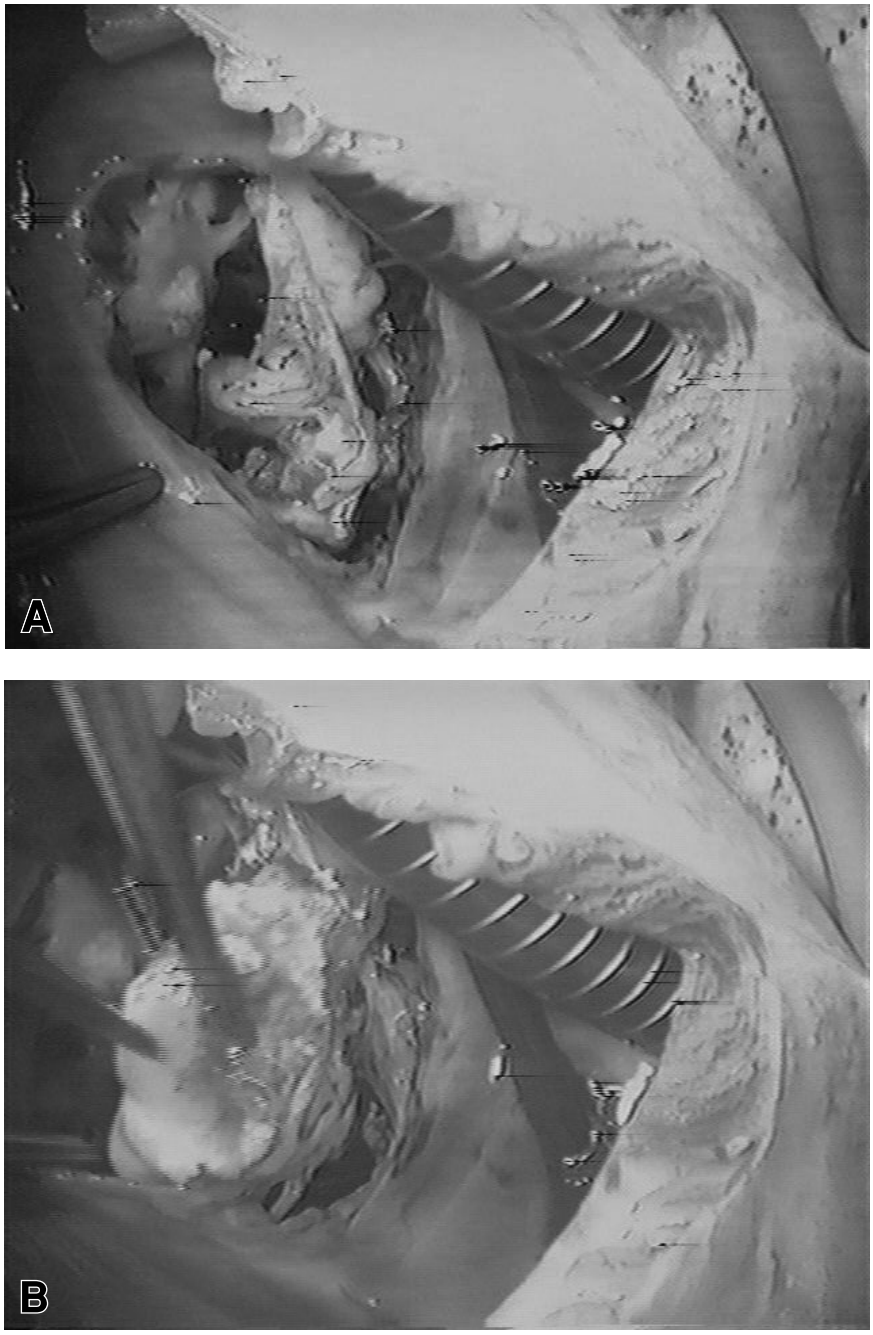

Figure 63-12. *A.* Takedown of atrial ventricular valve for ventricular exposure. *B.* Tumor exposure after valve takedown.

Ventricular myxomas usually are approached through the atrioventricular (AV) valve[111] or by detaching the anterior portion of the AV valve for exposure and resection and reattachment after resection (Fig. 63-12). Occasional small tumors in either outflow tract can be removed through the outflow valve.[111,112] If necessary, the tumor is excised through a direct incision into the ventricle, but this is unusual. It is not necessary to remove the full thickness of the ventricular wall because no recurrences have been reported with partial-thickness excisions. As with right atrial myxoma, the presence of ventricular myxoma prompts inspection for other tumors because of the high incidence of multiple tumors.

Every care should be taken to remove the tumor without fragmentation. Following tumor removal from the field, the area should be liberally irrigated, suctioned, and inspected for loose fragments. Whether blood removed from the field during tumor manipulation should be discarded or returned to the pump circuit is also controversial. There are rare instances of distant metastases from myxoma many years after tumor resection, and these reports raise the issue of potential intraoperative dissemination of tumor.[113,114] We use the cardiotomy suction during operation but use the wall suction during the brief time that the tumor is actually excised. We reason that tumor macroemboli entering the

profusion circuit will be filtered out in the cardiotomy reservoir. Considering the growth of the tumor within the bloodstream, its friable character would seem to pose no greater threat for distant metastases during tumor removal than it did during tumor development. The low malignant potential of the vast majority of myxomas and the rarity of metastasis further support this policy of retaining rather than discarding blood, and we believe that most cases of metastatic implantation of myxoma represent a preoperative embolic event.

MINIMALLY INVASIVE APPROACHES TO SURGICAL REMOVAL: Minimally invasive approaches are being applied with increasing frequency in all areas of cardiac surgery, and cardiac tumors are no exception. Experience is confined to benign tumors and is quite limited. Approaches have included right parasternal or partial sternotomy exposure with standard cardioplegic techniques,[115] right submammary incision with femoral-femoral bypass and nonclamped ventricular fibrillation,[116] and the right submammary port access method with antegrade cardioplegia and ascending aortic balloon occlusion.[117] Minimally invasive cardiac surgery may be used in a select group of patients with cardiac tumors. Thoracoscopic techniques have been used to aid in visualization and removal of ventricular fibroelastomas[118–120] (Fig. 63-13). There have been case reports of myxoma removal via thoracoscopy.[121] It is important to remember that use of a minimally invasive technique must not compromise complete surgical excision. Results in this limited number of selected patients have been good, but more experience and longer follow-up are needed before this can be recommended as a standard approach.

Results

Removal of atrial myxomas carries an operative mortality rate of 5% or less.[31] A review of 202 resections indicates that operative mortality is related to advanced age or disability and comorbid conditions.[113] Excision of ventricular myxomas carries a higher risk (approximately 10%), but the experience is small. Our experience over the last 15 years with 85 myxomas shows no operative or hospital mortality.

Recurrence of nonfamilial sporadic myxoma is approximately 1 to 4%.[4,109,110] It probably is even lower in patients with a normal DNA genotype. Many large series report no recurrent tumors.[109,122–125] The 20% of patients with sporadic myxoma and abnormal DNA have a recurrence rate estimated at between 12% and 40%.[4,62] The recurrence rate is highest in patients with familial complex myxomas, all of whom exhibit DNA mutation, and this is estimated to be about 22%.[4] Overall, recurrences are more common in younger patients. The disease-free interval averages about 4 years and can be as brief as 6 months.[109] Most recurrent myxomas occur within the heart, in the same or different cardiac chambers, and may be multiple.[29,46,126,127] The relationship of local recurrence to the adequacy of the original resection remains unsettled because sporadic tumors rarely recur even if full-thickness excision of the base is not done and because recurrent tumors often do not recur at the site of the original tumor.[109,128] Extracardiac recurrence after resection of tumor, presumably from embolization and subsequent tumor growth and local invasion, has been observed.[29,126–128] The biology of the tumor, dictated by gene expression rather than histology, may be the only reliable factor predicting recurrence. DNA testing of all patients with cardiac myxoma may prove to be the best predictor of the likelihood of recurrence.[129]

Uncertainty concerning the true malignant potential of myxomas has increased as reports that myxomas generally classified as "malignant" are found on subsequent review to be sarcomas with myxoid degeneration.[130] However, this issue also remains unsettled because of reports of metastatic growth of embolic myxoma fragments in the brain, arteries, soft tissue, and bones.[80,128,131–137] Symptomatic lesions of possible metastatic myxoma should be excised if possible.[80,131]

The extent to which patients should be subjected to long-term echocardiographic surveillance after myxoma resection is not standardized. It would seem prudent to closely follow patients who are treated initially for multicentric tumors, those whose tumors are removed from unusual locations in the heart, all tumors believed to have been incompletely resected, and all tumors found to have an abnormal DNA genotype. Patients undergoing resection of tumors thought to be myxomas but with malignant characteristics at pathologic examination should have long-term, careful follow-up.

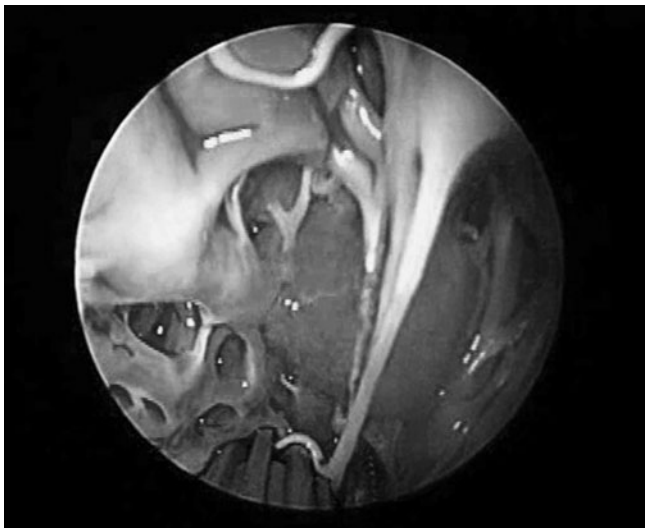

Figure 63-13. Thoracoscopic view of left atrial fibroelastoma.

Other Benign Cardiac Tumors

As shown in Table 63-2, myxomas comprise approximately 41% of benign cardiac tumors, with three other tumors (i.e., lipoma, papillary fibroelastoma, and rhabdomyoma) together contributing a similar proportion. A number of rarely encountered tumors account for the remainder.

Lipoma

Lipomas are well-encapsulated tumors consisting of mature fat cells that may occur anywhere in the heart but also are found in the pericardium, subendocardium, subepicardium, and intra-atrial septum.[2] They may occur at any age and have no sex predilection. Lipomas are slow growing and may attain considerable size before producing obstructive or arrhythmic symptoms. Many are asymptomatic and are discovered incidentally on routine chest roentgenogram, echocardiogram, or at surgery or autopsy.[138,139] Subepicardial and parietal lipomas tend to compress the heart and may be associated with pericardial effusion. Subendocardial tumors may produce chamber obstruction. The right atrium and left ventricle are the sites affected most often. Lipomas lying within the myocardium or septum can produce arrhythmias or conduction abnormalities.[140,141] Large tumors that produce severe symptoms should be resected. Smaller, asymptomatic tumors encountered unexpectedly during cardiac operation should be removed if excision can be performed without adding risk to the primary procedure. These tumors are not known to recur.

Lipomatous hypertrophy of the interatrial septum

Nonencapsulated hypertrophy of the fat within the atrial septum is known as *lipomatous hypertrophy.*[2] This abnormality is more common than cardiac lipoma and usually is encountered in elderly, obese, or female patients as an incidental finding during a variety of cardiac imaging procedures.[123] Various arrhythmias and conduction disturbances have been attributed to its presence.[124,141,142] The main problem is differentiation from a cardiac neoplasm when the lesion is discovered on echocardiography.[143] After the demonstration of a mass by echocardiography, the typical T1 and T2 signal intensity of fat on MRI usually can establish a diagnosis.[144,145] Arrhythmias and heart block are considered by some as indications for resection, but data are lacking as to the long-term benefits from resection.[146]

Papillary fibroelastoma of the heart valves

Papillary fibroelastomas are tumors that arise characteristically from the cardiac valves or adjacent endocardium.[147] Grossly, these tumors are described as resembling sea anemones with frondlike projections (Fig. 63-14). The AV and semilunar valves are affected with equal frequency. Papillary fibroelastomas formerly were thought to be innocuous because they were incidental findings at autopsy. It is now known that they are capable of producing obstruction of flow, particularly coronary ostial flow, and may embolize to the brain and produce stroke.[148–161] They are usually asymptomatic until a critical event occurs but now are found more often because of the more frequent use of echocardiography. Papillary fibroelastomas of the cardiac valve should be resected whenever diagnosed because of their known tendency to produce life-threatening complications. Valve repair rather than replacement should follow the resection of these benign tumors whenever technically feasible, using conservative margins of resection. Cytomegalovirus has been recovered in these tumors, suggesting the possibility of viral induction of the tumor and chronic viral endocarditis.[156]

Figure 63-14. Papillary fibroelastoma of the tricuspid valve demonstrating delicate fronds.

Rhabdomyoma

Rhabdomyoma is the most frequently occurring cardiac tumor in children. It usually presents during the first few days after birth. It is thought to be a myocardial hamartoma rather than a true neoplasm.[162] Although rhabdomyoma appears sporadically, it is associated strongly with tuberous sclerosis, a hereditary disorder characterized by hamartomas in various organs, epilepsy, mental deficiency, and sebaceous adenomas. Fifty percent of patients with tuberous sclerosis have rhabdomyoma, but more than 50% of patients with rhabdomyoma have or will develop tuberous sclerosis.[163,164] The exceptional patient is one with a solitary, single rhabdomyoma who does not have or develop tuberous sclerosis.

Over 90% of rhabdomyomas are multiple and occur with approximately equal frequency in both ventricles.[165] The atrium is involved in fewer than 30% of patients. Pathologically, these tumors are firm, gray, and nodular and tend to project into the ventricular cavity. Micrographs show myocytes of twice normal size filled with glycogen and containing hyperchromatic nuclei and eosinophilic-staining

cytoplasmic granules.[2,166] Scattered bundles of myofibrils can be seen within cells by electron microscopy.[165]

The most common presentation is heart failure caused by tumor obstruction of cardiac chambers or valvular orifice flow. Clinical findings may mimic valvular or subvalvular stenosis. Arrhythmias, particularly ventricular tachycardia and sudden death, may be a presenting symptom.[166] Atrial tumors may produce atrial arrhythmias.[166] The diagnosis is suggested by clinical features of tuberous sclerosis and is made by echocardiography. Rarely, no intramyocardial tumor is found in a patient with ventricular arrhythmias, and the site of rhabdomyoma is located by electrophysiologic study.[166]

Early operation is recommended in patients who do not have tuberous sclerosis before 1 year of age.[125] The tumor usually is removed easily in early infancy, and some can be enucleated.[125] Unfortunately, symptomatic tumors often are both multiple and extensive, particularly in patients with tuberous sclerosis, who, unfortunately, have a dismal long-term outlook. In such circumstances, surgery offers little benefit.

Fibroma

Fibromas are the second most common benign cardiac tumor, with over 83% occurring in children. These tumors are solitary, occur exclusively within the ventricle and the ventricular septum, and affect the sexes equally. Fewer than 100 tumors have been reported, and most are diagnosed by age 2 years. These tumors are not associated with other disease, nor are they inherited. Fibromas are nonencapsulated, firm, nodular, gray-white tumors that can become bulky. They are composed of elongated fibroblasts in broad spiral bands and whirls mixed with collagen and elastin fibers. Calcium deposits or bone may occur within the tumor and occasionally are seen on roentgenography (Figs. 63-15 and 63-16).

Most fibromas produce symptoms through chamber obstruction, interference with contraction, or arrhythmias. Depending on size and location, such a tumor may interfere with valve function, obstruct flow paths, or cause

Figure 63-15. Left atrial fibroma.

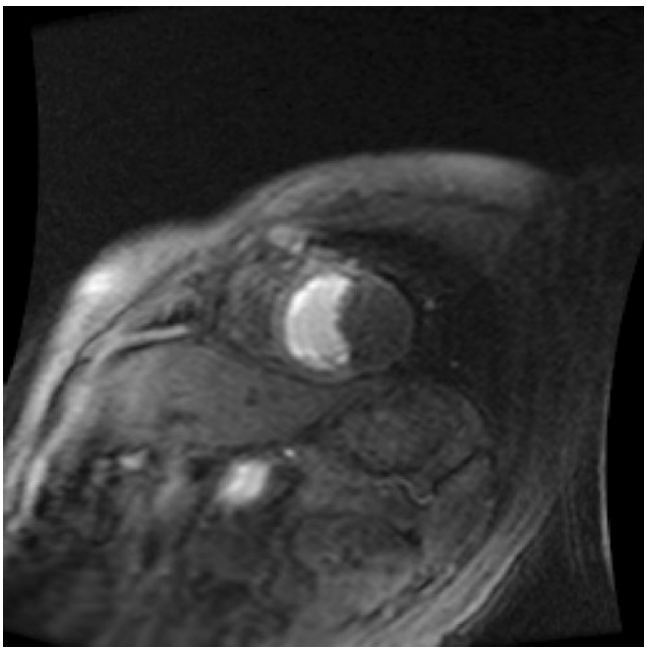

Figure 63-16. MRI of left ventricular fibroma.

sudden death from conduction disturbances in up to 25% of patients.[125] Intracardiac calcification on chest roentgenograms suggests the diagnosis, which is confirmed by echocardiogram.

Surgical excision is successful in some patients, particularly if the tumor is localized, does not involve vital structures, and can be enucleated.[125,167–169] However, it is not always possible to remove the tumor completely, and partial removal is only palliative, although some patients have survived many years.[125,168] Operative mortality may be high in infants. Most cases are in adolescents and adults.[125,167,168] Successful, complete excision is curative.[167,168] Children with extensive fibromas have been treated with cardiac transplantation.[169,170]

Mesothelioma of the AV node

Mesothelioma of the AV node, also termed *polycystic tumor, Purkinje tumor,* or *conduction tumor,* was mentioned in the pathologic classification of tumors. It is a relatively small, multicystic tumor that arises in proximity to the AV node and may extend upward into the interventricular septum and downward along the bundle of His.[2] Mesothelioma is associated with heart block, ventricular fibrillation,[171] and sudden death. Cardiac pacing alone does not prevent subsequent ventricular fibrillation. Surgical excision has been reported.[34]

Pheochromocytoma

Cardiac pheochromocytomas arise from chromaffin cells of the sympathetic nervous system and produce excess amounts of catecholamines, particularly norepinephrine. Approximately 90% of pheochromocytomas are in the adrenal glands. Fewer than 2% arise in the chest. Only 32 cardiac

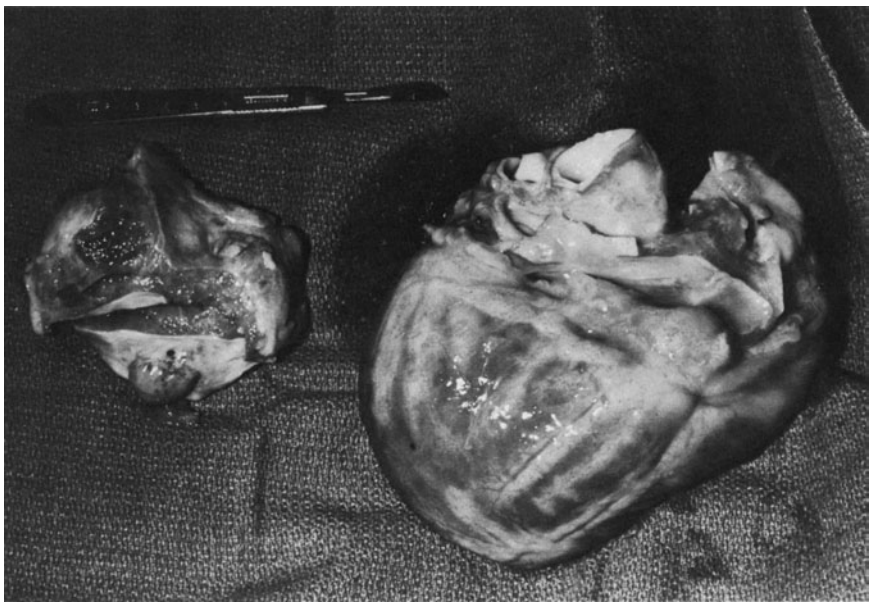

Figure 63-17. Excised left atrial pheochromocytoma and explanted heart prior to reimplantation.

pheochromocytomas had been reported by 1991.[172] The tumor predominantly affects young and middle-aged adults with an equal distribution between the sexes. Approximately 60% occur in the roof of the left atrium. The remainder involve the interatrial septum or anterior surface of the heart. The tumor is reddish brown, soft, lobular, and consists of nests of chromatin cells.

The patients usually present with symptoms of uncontrolled hypertension or are found to have elevated urinary catecholamines. The tumor usually is located by scintigraphy using [^{131}I]metaiodobenzylguanidine[173,174] and CT or MRI.[173,174] Cardiac catheterization with differential blood chamber sampling sometimes is necessary.[172] Because these tumors are vascular and may be near major coronary arteries, coronary arteriograms are advisable.

After the tumor is located, it should be removed using cardiopulmonary bypass with cardioplegic arrest. Patients require preanesthetic alpha and beta blockade and careful intraoperative and immediate postoperative monitoring. Most tumors are extremely vascular, and uncontrollable operative hemorrhage has occurred.[174] Resection may require removal of the atrial and/or ventricular wall or a segment of a major coronary artery.[172] Explantation of the heart to allow resection of a large left atrial pheochromocytoma has been attempted[175] (Fig. 63-17). Transplantation has been performed for nonresectable tumor. Complete excision produces cure.[168–170]

Paraganglioma

Paragangliomas are endocrine tumors that can secrete catecholamines. As a result, their presentation is often similar to that of pheochromocytomas. When found within the thoracic cavity, they are located most often in the posterior mediastinum. Paragangliomas typically present with atypical chest pain.[176,177] On echocardiography, they are often large and highly vascular tumors.[178] On cardiac catheterization, they may be intimately associated with the coronary arteries (Fig. 63-18). If they involve the left atrium, the technique of cardiac autotransplantation may be used to completely resect them[179] (Figs. 63-19 and 63-20).

Hemangioma

Hemangiomas of the heart are rare tumors (24 clinical cases reported), affect all ages, and may occur anywhere within the heart.[180,181] These are vascular tumors composed of capillaries or cavernous vascular channels. Patients usually develop dyspnea, occasional arrhythmias, or signs of right-sided heart failure.[182] Diagnosis is difficult, and chest roentgenography may be abnormal but is not specific. Echocardiography or cardiac catheterization usually but not always establishes a diagnosis of cardiac tumor by showing an intracavity filling defect.[183] CT and MRI should be done. Axial T2-weighted MRI should show a high signal mass owing to

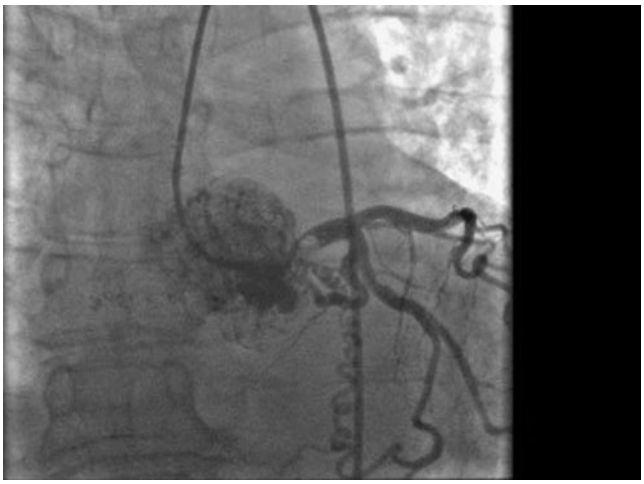

Figure 63-18. Paraganglioma blush of tumor.

Figure 63-19. MRI of left atrial paraganglioma.

vascularity[184] (Fig. 63-21). Coronary angiography typically shows a tumor blush and maps the blood supply to the tumor.

The tumors can be resected in asymptomatic patients, and cardiopulmonary bypass is recommended. Meticulous ligation of feeding vessels is required to prevent postoperative residual arteriovenous fistulas or intracavity communications. Partial resections have produced long-term benefits.[180] Tumors rarely resolve spontaneously.[185]

Teratoma

Cardiac teratoma is a rare tumor that usually presents in infants and young children but has occurred in adults.[186]

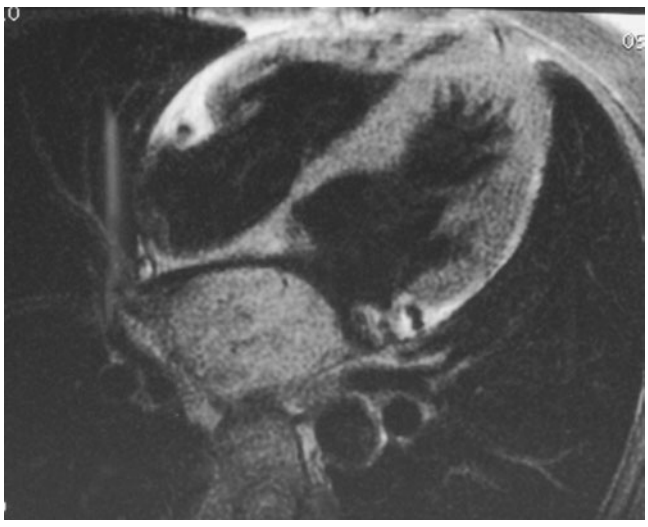

Figure 63-20. MRI of left atrial paraganglioma.

About 80% of the tumors are benign, and the remainder have microscopic or clinically malignant cells.[187] These tumors are discovered by echocardiography after a variety of symptoms lead to cardiac or mediastinal evaluation. There is little experience with surgical removal, which should be possible with modern imaging and surgical technology.

Castleman tumor

Castleman disease is a poorly understood lymphoproliferative disorder. The disease was first described by Castleman and colleagues in 1956.[188] It typically presents as a solitary lesion in the mediastinum. The most common histologic type is hyaline vascular, which accounts for approximately 90% of cases and often behaves in a benign fashion. The more aggressive subgroups are the plasma and mixed-cell types, which have a more malignant behavior.[189,190] Patients may have a localized or multicentric disease with lymph node involvement, typically in the mediastinum. These tumors typically present as well-circumscribed masses.[191] There have been reports of Castleman disease with myocardial and coronary artery invasion. In these more aggressive cases, cardiac assist devices have been used as a bridge to recovery[192] (Figs. 63-22 and 63-23). CT imaging of the lesions reveals atypical or target-like enhancement that corresponds to various degrees of degeneration, necrosis, and fibrosis. Technetium-99m tetrofosmin and [^{123}I]beta-methyl-iodophenyl pentadecanoic acid (BMIPP) imaging may aid in the diagnosis. On BMIPP, these tumors show reduced uptake compared with the surrounding normal myocardium.[193,194] Complete surgical resection is considered curative.[195]

PRIMARY MALIGNANT TUMORS

Primary cardiac malignancy is very uncommon, with only 21 surgically treated cases noted in a 25-year surgical experience

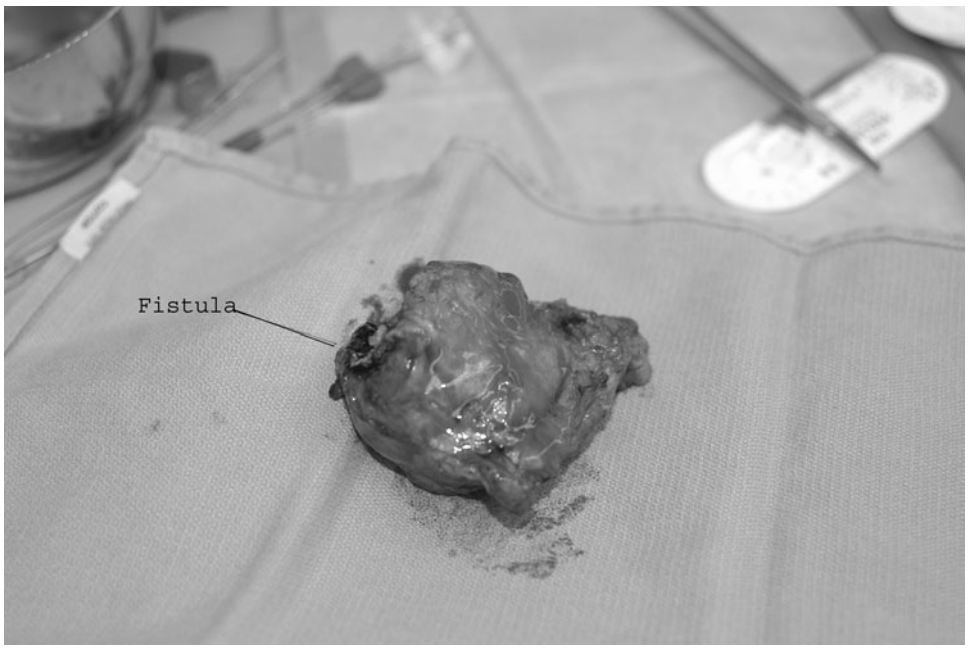

Figure 63-22. Castleman tumor showing fistula site.

from 1964 to 1969, combining the experience of two large institutions, the Texas Heart Institute and the M.D. Anderson Cancer Center in Houston.[196] Even in busy centers, primary cardiac malignancy continues to challenge the diagnostic ability and surgical skills of thoracic surgeons. Approximately 25% of primary cardiac tumors are malignant, and of these, about 75% are sarcomas. McAllister's survey of cardiac tumors found the most common to be angiosarcomas (31%), rhabdomyosarcomas (21%), malignant mesotheliomas (15%), and fibrosarcomas (11%)[2] (Table 63-4).

Primary malignant cardiac tumors arise sporadically, showing no inherited linkage. Although they may span the entire age spectrum, they usually occur in adults over 40 years of age. The patients usually present with symptoms of congestive heart failure, pleuritic chest pain, malaise, anorexia, and weight loss.[186,197] The most common symptom has been dyspnea[196] (Table 63-5). Some develop refractory arrhythmias, syncope, pericardial effusion, and tamponade.[196] The chest x-ray may be abnormal and even show a mass lesion, but the definite diagnosis usually is made with cardiac echocardiography.[197,198] We have seen an angiosarcoma of the right side of the heart that presented as multiple nodules on chest x-ray, and at thoracoscopy it was found to present multiple reddish lesions of the lung consistent with angiosarcoma. Subsequent cardiac echocardiography was used to confirm the diagnosis of a cardiac primary tumor. Right atrial lesions are more frequently malignant (usually angiosarcoma) than left-sided lesions (usually myxoma but, when malignant, often malignant fibrous histiocytoma). If malignancy is suspected, chest CT or MRI may suggest histology and provide detailed anatomy and help in staging and assessing resectability. The current status of positron-emission tomographic (PET) scans in evaluating these patients remains controversial. We perform cardiac catheterization on all patients over 40 years of age presenting with intracardiac masses and on all patients with large right atrial masses. Malignancy may be suggested and coronary involvement suspected by tumor blush (Fig. 63-24). This is not pathognomic because we have seen a large feeding vessel and tumor blush in a histologically confirmed myxoma.

Unfortunately, primary cardiac malignancy may grow to a large size prior to detection and involve portions of the heart not amenable to resection. Some of these patients have been considered for transplantation and will be discussed later. Otherwise, palliative medical therapy can be attempted with radiation therapy, although success in both symptom relief and longevity has been somewhat limited. Whether the tumor is primary or secondary, the decision to resect is based on tumor size and location and an absence of metastatic spread seen on complete evaluation. Unfortunately, most primary cardiac malignancies that have been referred to our center were considered to be benign initially and were resected incompletely at presentation. If malignancy is suspected or confirmed, and if the lesion appears anatomically resectable and there is no metastatic disease, then resection should be considered. If complete resection is possible, surgery provides better palliation and potentially can double

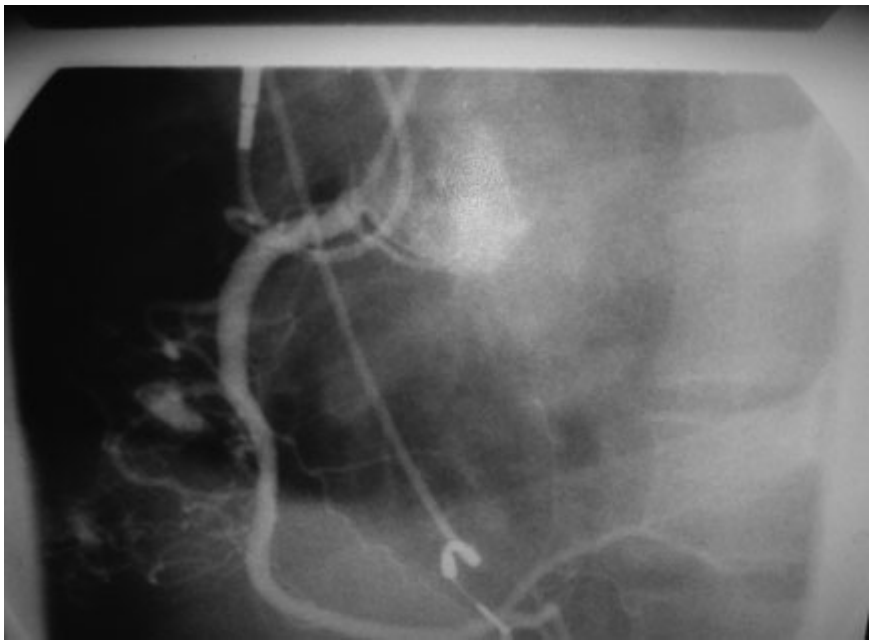

Figure 63-24. Tumor blush in right atrial sarcoma.

Figure 63-25. Angiosarcoma with extensive involvement of mediastinum.

survival.[199] After resection, we recommend adjuvant chemotherapy and believe that this will improve survival slightly[187,199,200] and add to our ability to treat this desperate disease. Complete resection will depend on the location of the tumor, the extent of involvement of the myocardium and/or fibrous skeleton of the heart, and histology.

Angiosarcoma

Angiosarcomas are two to three times more common in men than in women and have a predilection for the right side of the heart. Eighty percent arise in the right atrium.[197,201,202] These tumors tend to be bulky and aggressively invade adjacent structures, including the great veins, tricuspid valve, right ventricular free wall, interventricular septum, and right coronary artery[201] (Fig. 63-25). Obstruction and right-sided heart failure are not uncommon. Pathologic examination of resected specimens demonstrates anastomosing vascular channels lined with typical anaplastic epithelial cells. Unfortunately, most of these tumors have spread by the time of presentation, usually to the lung, liver, and brain.[197] Without resection, 90% of the patients are dead within 9 to 12 months of diagnosis despite radiation or chemotherapy.[32,197] We have seen carefully selected patients without evidence of spread on metastatic evaluation who have undergone complete surgical resection with subsequent chemotherapy (Fig. 63-26). Surgical resection may include the right atrium. In addition, right coronary bypass and even tricuspid valve repair or replacement may be undertaken (Figs. 63-27 and 63-28). We have had no hospital mortality in this small group, and the main problem remains metastasis rather than recurrence at the local site.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) is the most common soft tissue sarcoma in adults. Its occurrence as a cardiac primary malignancy has been relatively recently accepted as a specific entity. It is characterized histologically by a mixture of spindle cells in a storiform pattern, polygonal cells resembling histiocytes, and malignant giant cells. The cell of origin is the fibroblast or histioblast.[198,204] It usually occurs in the left atrium and often mimics myxoma. In fact, every left atrial MFH referred to our institution has been previously incompletely resected when thought to represent a myxoma. The tendency to metastasize early is not as prominent as with angiosarcoma. Several reports exist documenting rapid symptomatic recurrence after incomplete resection despite chemotherapy. These patients often die of local cardiac disease prior to the development of metastases. We believe that if complete resection can be obtained (particularly if the malignant nature is recognized and complete resection can be done at the original operation) and adequate chemotherapy can be provided, we may improve survival in this otherwise dismal disease. Our group believes that incomplete resection is usually due to inadequate exposure of these broad-based tumors, which often extend to the anterior wall of the left atrium. Difficulty in exposing this posterior portion of the heart leads to inhibition of aggressive resection for clear margins and makes reconstruction difficult. We believe that these difficulties can be overcome by excising the heart and inverting it so that the posterior left atrium is now an anterior structure. This allows excellent visualization for aggressive resection and reconstruction done ex vivo, after which the heart is reimplanted (Fig. 63-29).

This was first attempted by Cooley in 1984 for a pheochromocytoma, and although it was accomplished technically, it was unsuccessful because of severe hemorrhage owing to the vascular nature of the tumor.[186] Our program first attempted this approach for MFH in 1998[204] (Fig. 63-30).

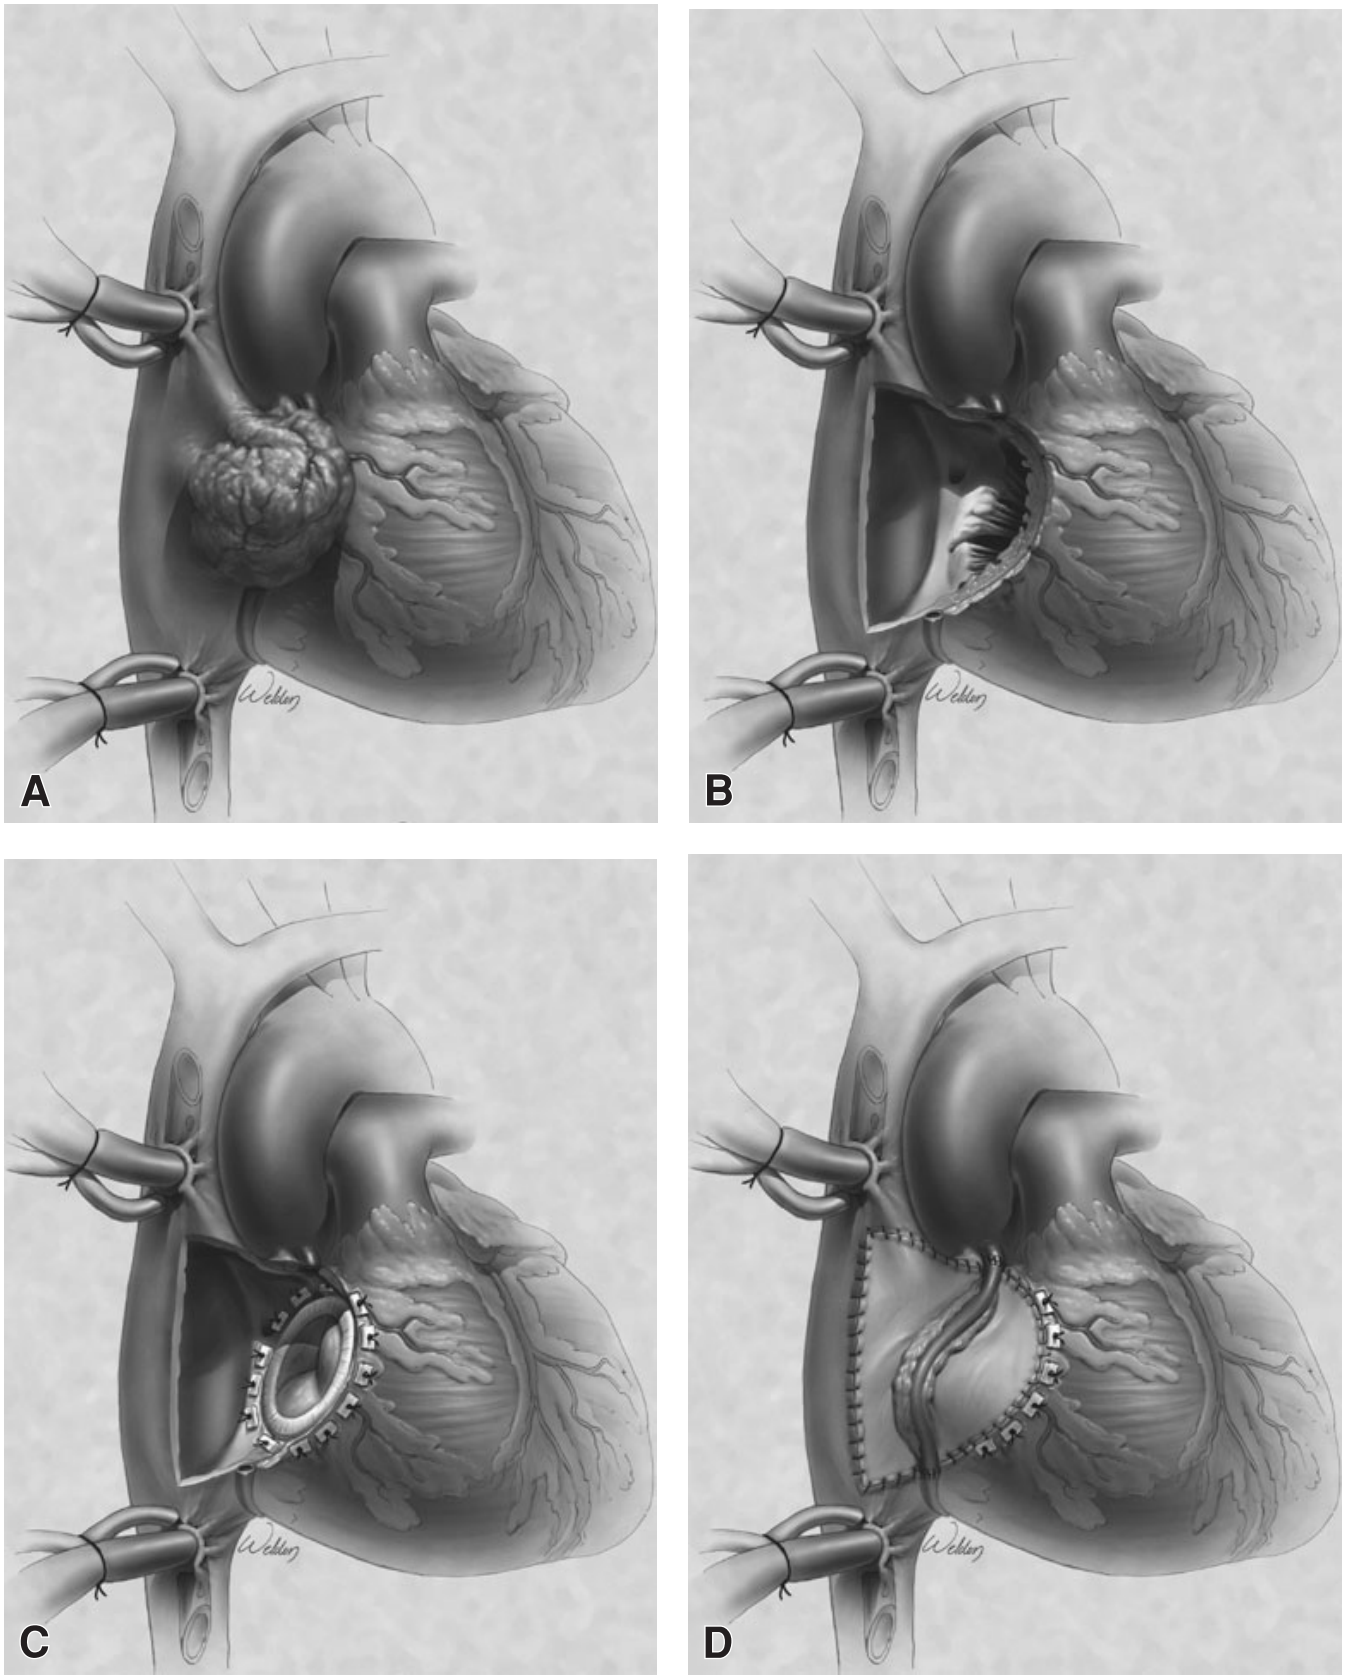

Figure 63-26. (A) Right atrial angiosarcoma involving right coronary artery and tricuspid valve. (B) Excision of tumor with right coronary artery and tricuspid valve. (C) Tricuspid valve replaced. (D) Completed repair using bovine pericardium. (*Copyright 2002, Baylor College of Medicine.*)

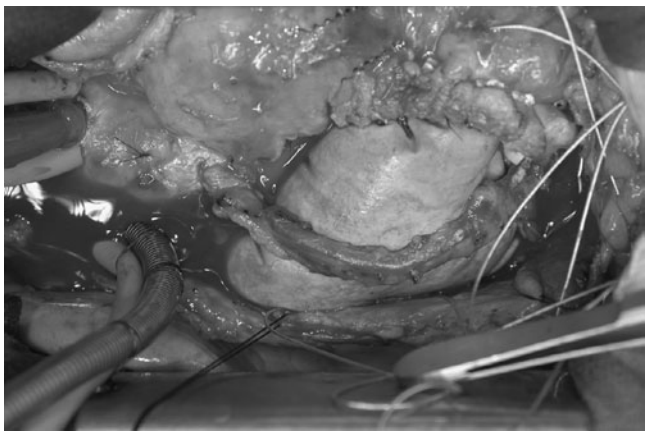

Figure 63-27. Right atrial angiosarcoma (final repair).

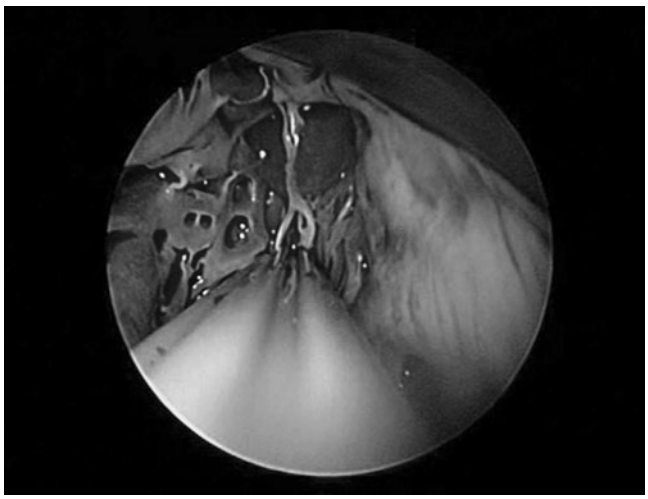

Figure 63-28. Thoracoscopic view of left atrial fibroelastoma.

We have performed 14 of these autotransplant procedures with no operative or hospital mortality. Seven patients have died of metastatic disease without local recurrence, and six are alive. Our longest survivor lived for 6 years and died of local recurrence and metastatic disease. All patients were given adjuvant chemotherapy. This has proven to be an efficacious technique at local control with a low mortality in our hands, but metastasis is still common and strongly suggests that further improvements in survival will require more effective, biologically based systemic therapy.

Rhabdomyosarcoma

Rhabdomyosarcomas do not evolve from rhabdomyomas and occur equally in the sexes. The tumors are multicentric in 60% of patients and arise from either ventricle. These tumors frequently invade cardiac valves or interfere with valve function because of their intracavitary bulk. Microscopically, tumor cells demonstrate pleomorphic nuclei and spidery, wispy, streaming eosinophilic cytoplasm, usually in a muscle-like pattern (Fig. 63-31).

The tumors are aggressive and may invade pericardium. Surgical excision of small tumors may be rational, but local and distant metastases and poor response to radiation or chemotherapy limit survival to less than 12 months in most of these patients.[167,186,187,199,205,206]

Other Sarcomas and Mesenchymal-Origin Tumors

McAllister and Fenoglio found that malignant mesotheliomas arising from the heart or pericardium and not from the surrounding pleura were the third most common malignant cardiac tumors and that fibrosarcomas were fourth.[2] However, in the two decades since their work, clinicians have

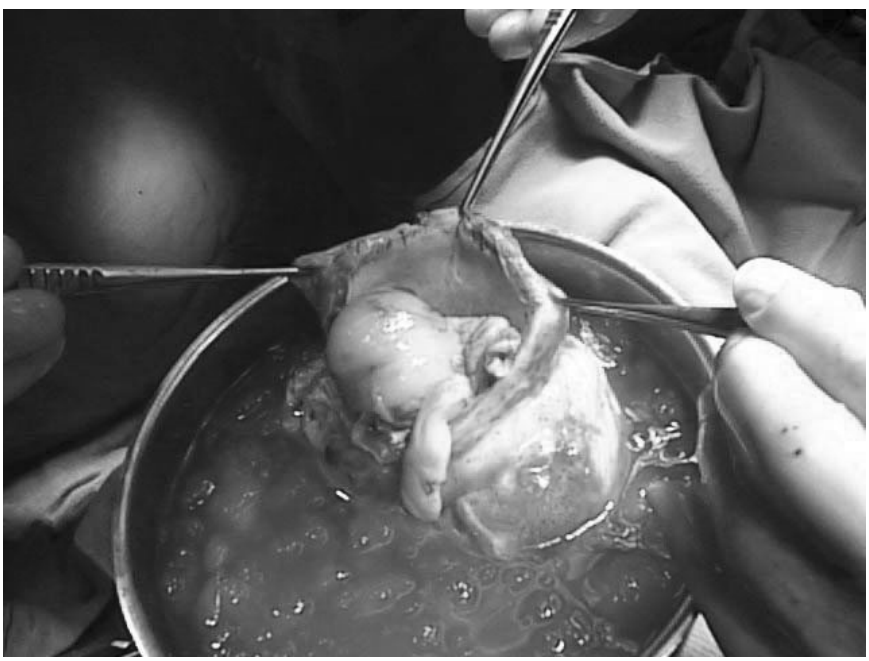

Figure 63-29. Ex vivo heart showing large sarcoma arising from the anterior left atrial wall.

rarely encountered these tumors. This apparent decrease in incidence may be related to changes in histologic criteria for classifying primary malignant neoplasms since their study.[5,180,187,196–200,206–208]

The histology of these tumors can be ambiguous and difficult. These neoplasms can resemble other sarcomas, and some might be deemed fibrous histiocytomas today. The behavior of these tumors is more important, and as with other cardiac sarcomas, resection of small tumors in the absence of known metastasis perhaps is justified, but data are scarce.[32,196,199,206] This being said, it is important to rule out more diffuse thoracic involvement with mesothelioma before considering resection of an isolated cardiac or pericardial mesothelioma. A PET scan may be considered, and any suspicious pleural thickening or effusion should be evaluated carefully both radiographically and histologically.

Myosarcoma, liposarcoma, osteosarcoma, chondromyxosarcoma, plasmacytoma, and carcinosarcoma arising from the heart all have been reported,[125,208–211] but by the time diagnosis is made, only palliative therapy usually can be

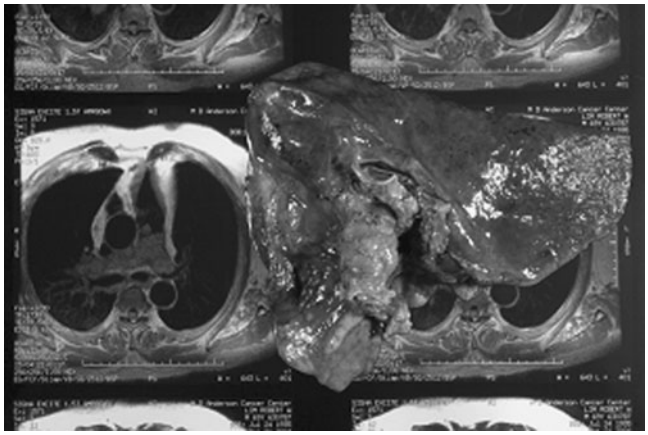

Figure 63-32. Pulmonary artery sarcoma.

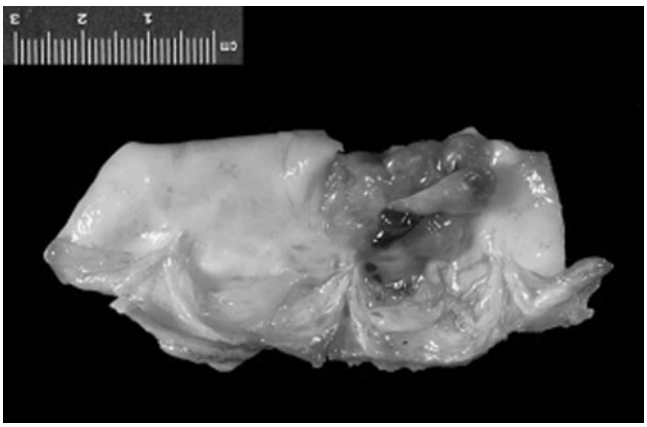

Figure 63-33. Pulmonary artery angiosarcoma showing valve involved.

offered, and surgery is indicated only occasionally. Regardless of therapy, it is unusual for patients with these diagnoses to survive more than a year.

Lymphomas

Lymphomas may arise from the heart, although this is rare.[212] Most of these tumors respond to radiation and chemotherapy. Even when complete resection is not possible, and incomplete resection is performed to relieve acute obstructive systems, radiation and chemotherapy have allowed for up to 3-year survival in selected patients.

Pulmonary Artery Sarcomas

Most pulmonary artery sarcomas are classified as angiosarcomas when a specific diagnosis has been possible. The most frequent presenting symptom is shortness of breath and peripheral edema from concomitant right-sided heart failure. The diagnostic modalities of choice for pulmonary artery sarcomas are chest CT or MRI (Fig. 63-32).

Surgical resection has been used both to improve functional status and for debulking prior to initiation of chemotherapy. Chemotherapy and radiotherapy are ineffective in the rapid relief of functional pulmonary artery obstruction caused by these tumors. These tumors usually are discovered after they have grown to considerable size (Fig. 63-33). Smaller tumors usually are clinically silent but may be discovered at the time of pulmonary artery endarterectomy for what is thought to be a case of chronic pulmonary emboli. Resection often requires replacement of a portion of the pulmonary root and branch pulmonary arteries using pulmonary homografts. Pneumonectomy may be required to resect the tumor completely. We have data on 5 patients with pulmonary artery sarcoma, 3 of whom required concomitant pneumonectomy. There were no in-hospital or 30-day deaths, and all patients were discharged home. Our longest survivor currently has lived 42 months and has no known disease. In all cases, adjuvant chemotherapy is used, even in the face of clear surgical margins.

Heart Transplantation

Malignant primary cardiac tumors may grow to a large size prior to detection. Additionally, extensive myocardial involvement or location affecting the fibrous trigone of the heart may make complete resection impossible. Because complete resection yields better results than incomplete resection,[199] orthotopic cardiac transplantation has been considered as a treatment option in some patients. Reports of transplantation for a number of cardiac tumors, including sarcoma,[213–215] pheochromocytoma,[216] lymphoma,[217] fibroma,[170] and myxoma,[218] have appeared. However, the long-term results are uncertain because some patients die from recurrent metastatic disease despite transplantation.[216,217,219] As of 2000, 28 patients had been reported who had undergone orthotopic transplantation for primary cardiac tumors, and of these, 21 had malignant tumors.[219] The mean survival for patients with primary cardiac malignancy was 12 months. Although technically feasible in some cases, orthotopic transplantation is hindered by a scarcity of donor organs, coupled with an extensive recipient list of patients without cancer. In addition, the large size of the tumor when diagnosed often necessitates rapid intervention for progressive congestive heart failure. Finally, the morbidity and mortality involved with immunosuppression, as well as the unknown effect of immunosuppression on any remaining malignancy, should be considered. For these reasons, orthotopic cardiac transplantation for primary cardiac tumor remains controversial and should be considered carefully on a case-by-case basis by experienced transplant and tumor boards. In most cases, orthotopic transplantation should be reserved for unresectable benign tumors, such as cardiac fibroma.

SECONDARY METASTATIC TUMORS

Approximately 10% of metastatic tumors eventually reach the heart or pericardium, and almost every type of malignant tumor has been known to do so.[2,5,9,220] Secondary

Table 63–6.

Figure 63-34. Hematogenous metastases within the myocardium of a patient with renal cell cancer. (*Reproduced with permission from Hurst JW et al: Atlas of the Heart. New York, McGraw-Hill, 1988.*)

neoplasms are 20 to 40 times more common than primary cardiac malignancies.[4,221] Up to 50% of patients with leukemia develop cardiac lesions.[5] Other cancers that commonly involve the heart include breast and lung cancers, lymphoma, melanoma, and various sarcomas.[2,222,223] Metastases involving the pericardium, epicardium, myocardium, and endocardium roughly follow that order of frequency[2,9] as well (Table 63-6).

The most common means of spread, particularly for melanoma, sarcoma, and bronchogenic carcinoma, is hematogenous and ultimately via coronary arteries. In addition, metastasis can reach the heart through lymphatic channels; through direct extension from adjacent lung, breast, esophageal, and thymic tumors; and from the subdiaphragmatic vena cava. The pericardium is involved most often by direct extension of thoracic cancer; the heart is the target of hematologous and/or retrograde lymphatic metastasis.[5] Cardiac metastases rarely are solitary and nearly always produce multiple microscopic nests and discrete nodules of tumor cells[2,5,9] (Fig. 63-34). Cardiac metastases produce clinical symptoms in only about 10% of afflicted patients.[5,224,225] The most common symptom is pericardial effusion or cardiac tamponade. Occasionally, patients develop refractory arrhythmias or congestive heart failure. Chest radiographs and electrocardiograms tend to show nonspecific changes, but echocardiography is particularly useful for diagnosis of pericardial effusion, irregular pericardial thickening, or intracavity masses interfering with blood flow.

Surgical therapy is limited to relief of recurrent pericardial effusions or, occasionally, cardiac tamponade. In most instances, these patients have widespread disease with limited life expectancies. Surgical therapy is directed at providing symptomatic palliation with minimal patient discomfort and hospital stay. This is most readily accomplished via subxiphoid pericardiotomy, which can be accomplished under local anesthesia if necessary with reliable relief of symptoms, a recurrence rate of about 3%, and little mortality.[223] Alternatively, a large pericardial window in the left pleural space can be created using thoracoscopy, but we would recommend this only under unusual circumstances.[226] This can be accomplished with minimal patient discomfort but does require general anesthesia with single-lung ventilation and may be poorly tolerated by patients with hemodynamic deterioration secondary to large effusions.

RIGHT ATRIAL EXTENSION OF SUBDIAPHRAGMATIC TUMORS

Abdominal and pelvic tumors on occasion may grow in a cephalad direction via the inferior vena cava to reach the right atrium. Subdiaphragmatic tumors are frequently renal carcinomas, although hepatic, adrenal, and uterine tumors occasionally have exhibited this behavior. Up to 10% of renal cell carcinomas invade the inferior vena cava,

and nearly 40% of these reach the right atrium.[227] Radiation and chemotherapy are not effective in relieving the obstruction of blood flow. If the kidney can be fully removed, as well as the tail of tumor thrombus, survival can approach 75% at 5 years.[125,229]

Renal cell tumors with atrial extension typically are resected with abdominal dissection to ensure resectability of the renal tumor. Initially, we performed a concomitant median sternotomy and often used cardiopulmonary bypass with hypothermic circulatory arrest when treating these patients. However, we have changed our approach and now work closely with our liver transplant surgeons who have extensive experience in the area of the retrohepatic vena cava. We have found that we can expose the vena cava up to the right atrium through an abdominal incision. With ligation of the arterial inflow, the tumor tail often shrinks below the diaphragm, and in almost all circumstances, this can be removed without the use of cardiopulmonary bypass. Occasionally venovenous bypass as used in hepatic transplantation is necessary to occlude inflow through the inferior vena cava, but this is unusual. If the tumor is too extensive for this maneuver, then median sternotomy is performed, and cardiopulmonary bypass with hypothermic circulatory arrest can be used to remove the tumor from the cardiac chambers down into the inferior vena cava. Perfusion can be restarted, followed by removal of the rest of the tumor. Although it leads to adequate exposure, significant problems with coagulopathy are often apparent after cardiopulmonary bypass and profound hypothermia.

A 5-year survival rate of 75% has been achieved following nephrectomy with resection of right atrial tumor extension.[228,229] Other subdiaphragmatic tumors with atrial extension that have been resected successfully include hepatic and adrenal carcinoma, as well gynecologic tumors.[230–234]

MOLECULAR- AND BIOLOGIC-BASED DIAGNOSIS AND THERAPY FOR CARDIAC TUMORS

This is an exciting time for investigators involved in the search for novel therapies for tumors such as many of those discussed in this chapter. A "new biology" is being developed in laboratories around the world working in these areas, and this is supplanted by the knowledge that is being obtained from the concerted Human Genome Project and the subsequent development of proteomics.[235] It is incumbent on the thoracic surgeon involved in the care of patients with cardiac tumors to have some degree of familiarity with the terms and promise of these advances because significant additional improvement in survival of many of these patients is unlikely to result from further advances in surgical technique.

Interestingly, many sarcomas demonstrate reproducible translocations that allow for the production of novel chimeric genes that may code for a variety of fusion proteins. Many of these proteins have been found to engender cellular phenotypic malignant changes, resistance to apoptosis, and unfettered growth.[236] Although not associated with cardiac involvement, the fusion proteins EWS-FL11 and EWS-ERG are noted in Ewing's sarcoma. When full-length antisense oligonucleotide constructs are used to target the mRNA of these proteins, protein expression is downregulated, and an eightfold increase in apoptosis sensitivity is noted.[227] These fusion proteins have been noted in some forms of rhabdomyosarcoma, and the most common is PAX3-FKHR. This oncoprotein combines components of two strong transcriptional activators and may increase the production of the downstream antiapoptotic protein BCL-XL. Antisense oligonucleotides directed at this oncoprotein mRNA have led to apoptosis in rhabdomyosarcoma cells.[237,238] Similarly, in our laboratory we have demonstrated that antisense oligonucleotides directed at the mRNA of the downstream antiapoptotic protein BCL-XL in mesothelioma can induce apoptotic cellular death and engender chemosensitivity.[239] A similar translocation and fusion protein have been noted in fibrosarcoma. This translocation [t(12;15)(p13q25)] brings together genes from chromosomes 12 and 15, which combines a transcription factor with a tyrosine kinase receptor. The resulting fusion protein is a tyrosine kinase that has oncogenic potential.[240] Reproducible translocations and fusion proteins with downstream effectors of malignant behavior have not been described for angiosarcoma, but they are actively being sought. Antisense treatment has been maligned in the past owing to problems with both delivery and stability of therapeutic constructs. However, sophisticated biochemical alteration of these molecules has improved stability, and two recent solid tumor trials using antisense therapy for salvage have demonstrated positive results.[241,242] Additional methods of delivering antisense to tumor cells, including viral vector delivery, have been developed. Finally, in addition to antisense methods, small molecule inhibition of many of these fusion proteins should be possible.

Angiosarcoma is an obvious target for therapies based on antiangiogenesis. The weak antiangiogenic properties of interferon-alfa are presumed to be the mechanism that accounts for responses to this agent in this tumor.[243] Multiple new antiangiogenic agents are being evaluated currently in phase I and II trials, and a number of noncardiac angiosarcoma patients have been treated at our institution on this basis. We have noted several to develop stabilized disease, but no definitive data are yet published. Certainly, the use of these agents in these vascular-origin tumors is theoretically attractive.

Viral vector–mediated gene therapy has been evaluated for various sarcomas in the preclinical setting. A number of potential targets exist for these sorts of therapies. Although *p53* is not commonly mutated or absent, *mdm-2* is often overexpressed in many sarcomas, including angiosarcoma. This gene is a known oncogene that is able to directly

induce cellular transformation. Importantly, when overexpressed, it binds to and inhibits *p53* activity, even though expression of *p53* may appear normal. Overexpression of *mdm-2* also has been associated with VEGF overproduction and angiogenesis.[243,244] Preclinical studies of adenoviral vector *p53* transduction of sarcoma in SCID mice have demonstrated growth delay, tumor regression, and decreases in VEGF expression.[245] Many other targets for this approach, including inhibition of NF-κB expression using an adenoviral-dominant negative Iκ-Bα construct and prodrug-mediated gene therapy using a doxorubicin prodrug and adenoviral transfer of a metabolizing enzyme in sarcoma cells, have been shown to be effective.[230,231] Unfortunately, the application of viral-mediated gene therapy paradigms to this tumor suffers the same problems of targeting, transgene expression durability, and immune response that are problematic for the field in general.

In regard to molecular diagnosis, there are no reproducible familial patterns for development of most malignant tumors. However, familial cardiac myxoma, rhabdomyoma, and fibroma may exhibit reproducible genetic abnormalities that lend themselves to the development of genetic testing to identify individuals at risk. Familial myxoma syndrome, or Carney complex, has been associated with mutations in the 17q24 gene *PRKAR1α* that codes for the R1α regulatory subunit of cAMP-dependent protein kinase A (PKA).[248] Although not widely available, genetic diagnosis of this syndrome is now technically achievable.[249] Reproducible mutations in the *TSC-1* and *TSC-2* genes in patients with tuberous sclerosis and cardiac rhabdomyoma, as well as mutations in the *PTC* gene of patients with the Gorlin syndrome and cardiac fibroma, have been noted.[250–252] It is hoped that in the near future we will be able to predict who is at particular risk for these and other cardiac tumors. This could allow for more intense surveillance, earlier detection, and a higher rate of surgical or multimodality cure for these patients.

CHAPTER 64

Immunobiology of Heart and Heart-Lung Transplantation

Bartley P. Griffith • Michel Haddad • Robert S. Poston

The purpose of this chapter is to introduce the immune biology of heart and lung transplantation to the surgeon with the hope that it will provide a better understanding of the complex events that occur outside the operating room and give the subsequent strategies of immunosuppression a clear rationale. This work differs from the more usual approach in the thoracic surgical textbook, which typically lists established classification systems used for diagnosing various grades of rejection and reiterates the results of various conventional immunosuppression therapies generally already well known to the reader. It has been a challenge to distill the more germane aspects of the molecular events surrounding the allogeneic response in a way that those events can be better understood by those heart and lung transplant surgeons not intimately involved in the field of immunology. It is hoped that transplant recipients will benefit if the fundamentals presented here can be understood and made useful by clinicians.

THE MAJOR HISTOCOMPATIBILITY COMPLEX

An allogeneic organ is one that is transferred from one individual to another of the same species but with a different genetic repertoire. A donor heart or lung is immunologically incompatible with the host tissues, and an immunologic reaction or alloresponse is directed against donor proteins (antigens) located on the surface of endothelial, mesenchymal, and epithelial cells of the allograft. Both major and minor surface proteins contribute to eliciting such an allogeneic response.

The major histocompatibility complex (MHC) proteins are produced by multiple polymorphic genes whose glycoprotein products, the MHC proteins, are expressed on the surfaces of cells. These protein products, along with the ABO blood antigens, are the principal determinants of whether an organ is deemed as self or nonself and hence are the primary targets of the immune response to allografts. The MHC proteins, which are called *human leukocyte antigens* (HLAs) in humans, guide the development of T lymphocytes to have a low affinity to self and to use the reaction to self as a way in which foreign peptides are recognized (MHC restriction). The genes that express HLAs are among the most variable (or have the largest number of polymorphisms) in the human genome.

The HLA gene complex encodes two main classes of HLAs. Class I HLA molecules include types A, B, and C, which are cellular antigens that exist in most cells and stimulate cytotoxic T lymphocytes that express the cell surface receptor CD8 (Fig. 64-1). In addition, the HLA gene complex encodes HLA class II molecules, which also include three types, DP, DQ, and DR. These are expressed on antigen-presenting cells such as B cells and helper T lymphocytes that express the CD4 surface receptor.

At least 20 definable loci, or *alleles*, at HLA-A, 40 at HLA-B, and 10 at HLA-DR[1] have been identified that are inherited as a unit called the *haplotype*. With two possible alleles at each HLA-A, HLA-B, and HLA-DR loci, one being maternal and one paternal, an antigen *mismatch* is possible for 0 through 6 antigens. Because of their proximity on chromosome 6, the alleles for HLA-C, HLA-DQ, and HLA-DP are predictably inherited as extended haplotypes with HLA-A, HLA-B, and HLA-DR in a defined donor population (i.e., linkage disequilibrium). Tissue compatibility for transplantation traditionally has required only HLA-A, HLA-B, and HLA-DR typing and preferably compatibility as well. Only in unusual cases, such as bone marrow transplant procedures that draw donors from a worldwide registry, have there been clinically important mismatches of the other HLA alleles.[2] Although either serology or DNA sequencing is used for typing, recent data suggest that a serologic (i.e., antigen) mismatch has a greater effect on outcome than a DNA (i.e., allele) mismatch.[3]

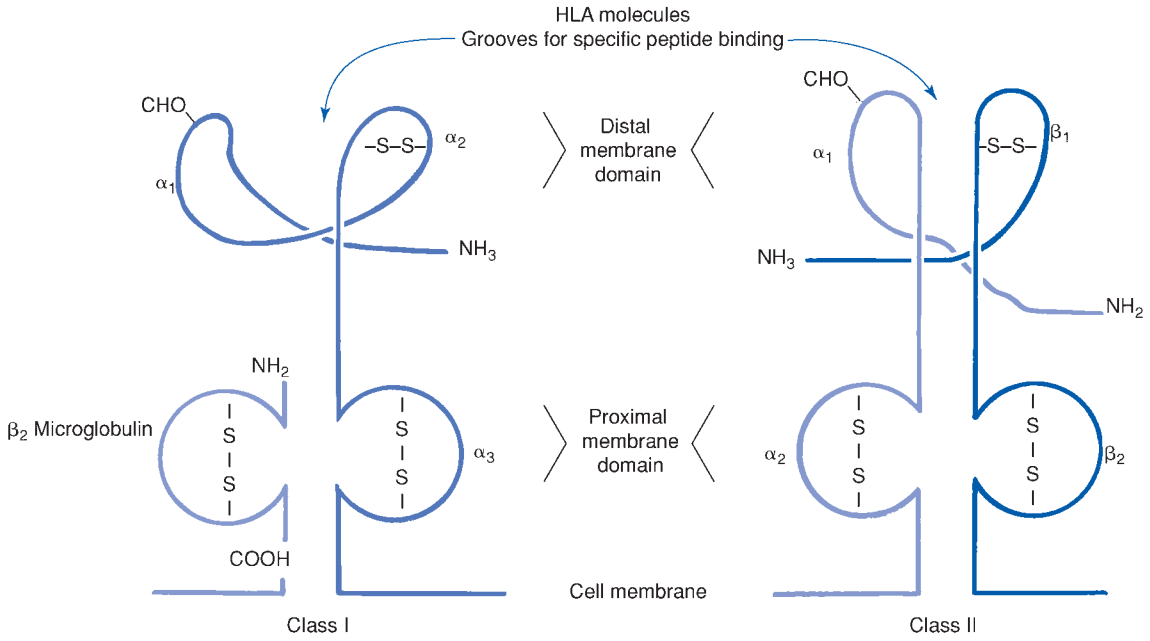

Figure 64-1. Class I and II HLA molecules are made up of polypeptide chains with intrachain disulfide bonds. The α_1 and α_2 distal domains of class I and the α_1 and β_1 domains of class II make up the peptide binding site for alloantigen. *(Adapted with permission from Parham M, in Haber E (ed): Immunobiology of Transplantation Molecular Cardiovascular Medicines. New York, Scientific American Press, 1995.)*

In heart and lung transplantation, several single-institution studies examining the effect of HLA matching on outcome have found an association between the degree of serologic HLA-DR matching and actuarial graft survival at 1, 5, and 10 years. In general, an association was not present for HLA-A and HLA-B matching. In fact, in a report from the Texas Heart Institute, Kerman and colleagues reviewed 448 heart transplants[4] and found an inverse relationship between HLA-A and HLA-B mismatches and death from cardiac allograft vasculopathy!

Most studies draw from a system of random allocation of donor organs, resulting in fewer than 8% of closely matched donor-recipient pairs (defined as 0, 1, or 2 mismatches). Given this low frequency, an adequate pool of closely matched pairs for comparison to recipients that are mismatched at multiple loci with the donor is made possible only by a multi-institutional study of significant size. Two cardiac transplantation registries have fulfilled this size requirement and verified the relationship between HLA matching and acute graft survival: the Collaborative Transplant Study,[5] with 8331 recipients, and the United Network for Organ Sharing/International Society for Heart-Lung Transplantation (UNOS/ISHLT) Registry,[6] with 10,752 recipients. In the Collaborative Transplant Study, 128 patients (1.5%) with either 0 or 1 combined HLA-A, HLA-B, or HLA-DR mismatches were compared with those with 2 mismatches and 3 to 6 mismatches. Mean rates of survival at 3 years were a striking 83%, 76%, and 71%, respectively. Multifactorial regression analysis further established that HLA matching had a strong independent effect on graft survival, with the most pronounced effect at 6 months. While the timing might suggest a predominant role for acute rejection, only graft survival and not rejection rates were reported.

The UNOS/ISHLT Registry investigators also found a progressive reduction in risk for greater donor-recipient HLA matching. Unlike the Collaborative Transplant Study, however, data obtained from this registry are derived from a database whose use is compulsory for all transplant centers in the United States and subject to auditing and verification. Follow-up in this patient population was found to be virtually complete. The primary benefit of matching appeared to be at the HLA-A and HLA-DR loci with no independent effect of matching at the HLA-B locus. However, these retrospective data, similar to the previous study, were based on serologic methods of tissue typing that are less accurate than current DNA techniques. Again, the effect of HLA matching was greatest at 6 months, with the survival curves between matched and mismatched patients becoming parallel at later time points. Considering the results of these two registry studies in light of prior work,[7] HLA matching is unlikely to influence chronic graft rejection. Larger numbers of well-matched transplants studied at a prolonged follow-up are needed to investigate the influence of HLA matching on chronic rejection.

Data demonstrating the effect of HLA matching on outcomes in heart-lung and lung transplantation are sparse.

In one study from the University of Pittsburgh, 74 single- and double-lung transplant recipients were analyzed, and a strong effect of HLA-DR matching on 6-month graft survival was evident (100% versus 75% versus 56% for 0, 1, and 2 HLA-DR mismatches, respectively).[8] Combining HLA-A, HLA-B, and HLA-DR mismatches showed 100% survival for 0 to 2 mismatches, 78% for 3 to 4, and 58% for 5 to 6. The Collaborative Transplant Study showed a trend toward improved survival for well-matched grafts in both heart-lung and lung recipients, but this did not reach statistical significance (1176 patients enrolled in the lung transplant group and 640 in the heart-lung group).[5] The UNOS/ISHLT Registry data also showed a less impressive effect of matching on lung allograft outcome. A significant reduction in risk with any degree of HLA matching was seen, but there was no progressive improvement with increasing levels of matching.

These data support the conclusion that HLA matching confers an important benefit after heart transplantation and probably after heart-lung and lung transplantation. The conventional wisdom that deems prospective HLA matching to be logistically unfeasible in thoracic organ transplantation may be changing. The former requirement of HLA typing using serologic methods for donor splenic tissue retrieved during procurement did not provide sufficient time for prospective typing given that heart and lung allografts tolerate only 4 to 6 hours of ischemia time. This formidable restriction has been overcome by the use of polymerase chain reaction (PCR)–based HLA typing on peripheral blood lymphocytes prior to the procurement procedure. Future advances in our current preservation methods such as the use of continuous, warm, sanguineous perfusion of the ex vivo cardiac allograft[9] will permit procurements from longer distances, a certain requirement of an organ allocation system that takes into consideration HLA matching.

Some groups have, in fact, reported impressive advances in achieving prospective HLA matching. One is the Harefield group, which recently reported that within their donor allocation zone, HLA typing was available before organ retrieval in 69% of cases performed in 1994. Based on outcome data from their institution, this group has focused on HLA-DR matching only and has seen an increase in prospective matching from 5 to 25% of transplants in a recent 1-year time period and a reduction in acute rejection in those matched. However, widespread adoption of cardiac HLA matching has been hindered by continued limitations. A benefit on early cardiac allograft survival was seen mainly for those with more than three antigen matches, an infrequent event (fewer than 8% of cases) in the current system of random allocation of donor organs. Increasing this frequency of close matches via prospective matching would require significantly prolonged ischemia and waiting-list times for the donor organ and transplant candidate, respectively. Given current methods of organ preservation, limited organ supplies, and the high recipient waiting-list mortality, such a requirement would seem unacceptable in light of the modest impact on acute organ survival and lack of evidence supporting an effect on long-term graft outcome and chronic rejection.

ANTIGEN PROCESSING/AFFERENT RESPONSE

HLA class I and class II molecules are not uniformly expressed on the same cells. HLA expression is low at baseline in human donor hearts and lungs but can be found to stain prominently for both classes in response to inflammatory stimuli (Fig. 64-2). After transplantation, class I molecules present protein products produced from the endogenous breakdown of their own MHC protein to previously activated CD8± cytotoxic lymphocytes (CTLs) (Fig. 64-3). Class I molecules are found on the surfaces of all cells except the erythrocyte, which incidentally protects a malaria-infected red blood cell from cytotoxic (CD8±) T-lymphocyte surveillance. Class II expression is found constitutively on the professional *antigen-presenting cells* (APCs) such as dendritic cells, B lymphocytes, macrophages, and thymic epithelium. It is also induced on other cell types by cytokines such as interferon (INF), which is produced as part of the alloimmune response. Originating either from the donor organ (i.e., passenger cells) or from the host, these APCs internalize, process, and present shed fragments of donor proteins on class II molecules (see Fig. 64-3). The allogenic class II molecule and bound peptide exclusively react with a large number of CD4± T cells (perhaps 1%) in a process called the *direct* or *allorestricted pathway.*[10,11]

The direct recognition of a few allogenic donor class II and I MHC epitopes by host CD4 and CD8 cells soon draws other epitopes into the response as a result of a general upregulation of antigen processing and presentation.[12] This process, called *epitope spreading,* is a potent initiator of cell-mediated rejection when accompanied by costimulatory signals

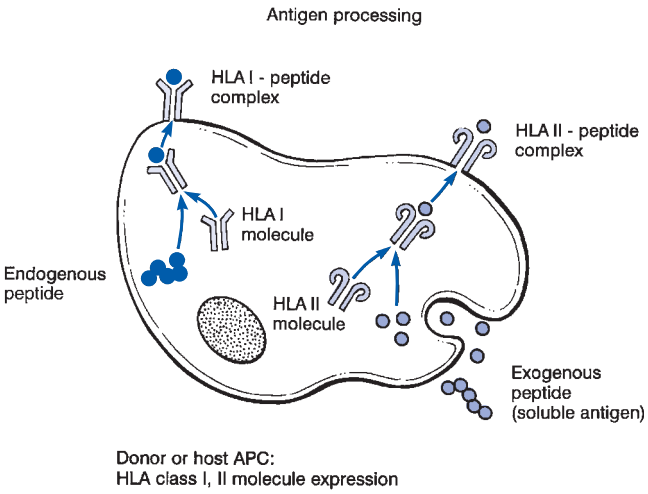

Figure 64-2. Donor antigen derives from either the endogenous pathway or the exogenous pathway.

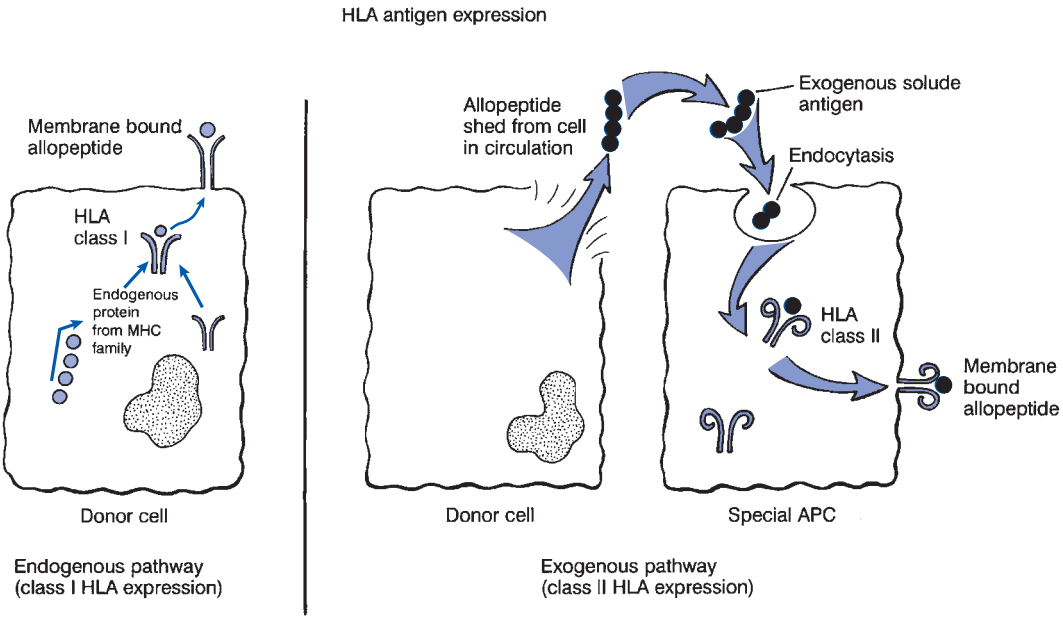

Figure 64-3. Generally, HLA class I molecules bind protein fragments of donor MHC protein produced from endogenous cellular processes. Allopeptides from MHC donor cell membrane fragments are brought into special APCs that process and bind them to HLA class II molecules for presentation to host T cells.

generated by the interaction of certain cell surface proteins on APCs and T cells (Fig. 64-4). The indirect or self-restricted pathway is the physiologic mechanism of T-cell immune recognition. In this pathway, host-derived APCs process exogenous allo-MHC fragments and bind them to host class II and I MHC molecules for presentation to host T cells. The exact role for the indirect alloresponse in transplantation is not well characterized, but it is believed to be a significant contributor to late and chronic rejection when donor APCs eventually are replaced by those of the host.[13] Its role in chronic rejection is supported by the observation that T cells from patients with chronically rejected renal, cardiac, and lung transplants show evidence of indirect, but not direct, reactivity to presented donor HLA allopeptides.[14] Indirect alloresponses may be especially important in xenograft responses, in which recipient T cells and donor APCs cannot make efficient contact with each other. On the other hand, indirect antigen presentation in the absence of costimulation has been proposed as one of the mechanisms of tolerance, which is thought to explain the immunosuppressive effects of blood transfusions.

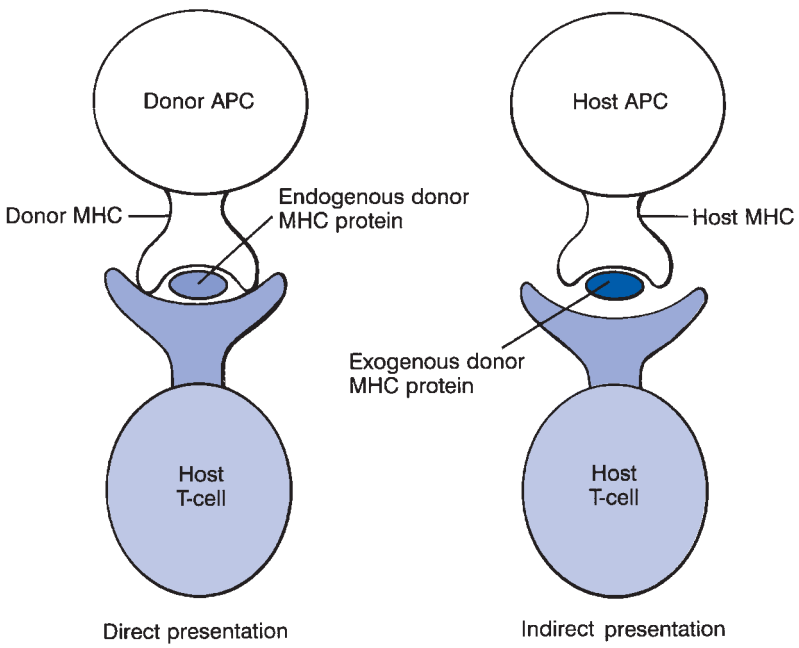

Figure 64-4. Host T lymphocytes can respond to alloantigens by the direct or indirect pathway. On direct presentation, donor cells bind endogenous MHC protein to donor MHC molecules (allorestricted). In the direct path, host cells respond to processed donor MHC peptide bound to host MHC (self-restricted). The direct pathway can stimulate many T cells and is responsible for most acute rejections, whereas fewer T cells respond to the small foreign peptide presented in host MHC molecule. The indirect pathway has been implicated as an important part of the late chronic rejection process when host APCs replace those of the donor within the allograft.

The direct and indirect pathways likely have differential sensitivities to immunosuppressive drugs.

CD4 cells elaborate various cytokines that amplify the generalized inflammatory response. Two different mature CD4 cells have been characterized: TH1 cells, which secrete interferon (INF) and interleukin 2 (IL-2) and stimulate cellular immunity, and TH2 cells, which secrete IL-4 and IL-10 and stimulate B lymphocytes to produce antibodies. Because TH1 and TH2 cells are known to mutually suppress each other's subsets, the TH2 cells have been implicated in tolerance against cell-mediated rejection.[15] While mechanisms are evolving, it appears that the TH1 cells arise in regional lymph nodes following class II presentation on macrophages and mature dendritic cells (DCs). Mature DCs are the most effective APCs at activating naive T cells because they express high levels of HLA, intercellular adhesion, and costimulatory molecules. TH2 cells arise from class II presentation by B lymphocytes or immature DCs, cells that are capable of presenting antigen but that provide low levels of costimulation.[16]

Only mature DCs provide the appropriate costimulatory signal for the conversion of naive CD8 T cells to activated cytotoxic lymphocytes (CTLs). In addition, this process typically requires exogenous IL-2 from CD4 "helper" T cells. A more stringent requirement for stimulation of CD8± versus CD4± T cells ensures that CTLs are formed only when evidence of their need is unambiguous.[1]

EFFERENT ALLORESPONSE

After recognizing a heart or lung allograft as foreign, the immune system unleashes cellular and humoral (antibody) attacks (Fig. 64-5). The efferent response usually begins when activated CD4 cells secrete various cytokines that drive the inflammatory response.[17] IL-2 increases the expression of its own receptors (IL-2Rs) on CD4 cells, driving the proliferation and further differentiation of CD4 cells. The activated CD4 cells secrete additional lymphokines, including INF, which along with IL-2 stimulates the activated CTLs to bind to the allograft cells presenting donor MHC protein molecules. The CTLs proliferate and specifically kill the allotarget by at least two mechanisms.[18] In the presence of Ca^{2+}, the protein perforin polymerizes onto the target cell and causes 16- to 20-nm pores to open in the cell membrane, resulting in osmotic collapse. The other likely method is by stimulation of apoptosis (programmed cell death) by interaction of the lymphocyte Fasligand with the APO-1/Fas receptor of the target cell. Second messengers are elicited that activate endonucleases and proteases to cause fragmentation of DNA and T-cell dissolution. Tissues that appear to have an immune privilege, such as the testis, eye, brain, and some tumors, use this Fas/Fas-L apoptotic pathway to destroy autoreactive lymphocytes. This pathway is being exploited for the development of tolerance to allogenic tissues in experimental models.[19]

Graft ischemia and reperfusion provoke a nonspecific immune response involving neutrophils and macrophages. Through the production of cytokines such as INF and tumor necrosis factor (TNF), these cells upregulate costimulatory and MHC class I and II molecules, thereby enhancing immunogenicity and T-cell recruitment to the graft. Macrophages also release IL-1, which promotes a positive-feedback cycle by driving IL-2 production by T cells. Through this mechanism, a significant bout of reperfusion injury (RI) has been shown clinically to increase the incidence of acute rejection.[20] In addition, by activating the coronary endothelium and initiating smooth muscle cell proliferation, RI has been hypothesized to be an important contributor to chronic allograft vasculopathy.[21] Inhibition of RI has been shown to reduce this vasculopathy both experimentally[22] and clinically.[23]

On the other hand, recent data suggest that host reparative responses may mitigate the immunogenic effects of RI. By analyzing female cardiac allografts transplanted into male recipients, Quaini and colleagues documented the migration of host stem cells that matured into myocytes, endothelium, and capillaries in the donor hearts as soon as 4 days posttransplantation.[24] With the discovery of this capacity for rapid formation of an organ chimera with up to 20% mature host-derived tissue, it is hypothesized that RI actually may result in a reduction rather than enhancement of allograft immunogenicity. The overall effect of RI on the allograft likely depends on which pathway plays a greater role in any given donor-recipient pair, illustrating an important future area for investigation.

The humoral response begins as host and B cells are drawn into the alloresponse by the lymphokines and by their own class I and II cell receptor engagement with the donor cells. The activated B cells evolve into plasma cells that produce allospecific antibodies against the donor class I and II HLA molecules and engage the complement cascade.

T-CELL LYMPHOCYTE MATURATION AND ALLOACTIVATION

Recognition of antigens belonging to the body versus antigens that are foreign begins in the thymus. A very large number of T cells with variable TCR protein sequences are formed in the thymus. These receptors, similar to antibodies produced by B cells, recognize specific peptide sequences. However, unlike antibodies, the TCRs cannot be released from the cell membrane and require an association with five invariant polyproteins collectively called the *CD3 complex*. The TCRs cannot recognize free antigen but are restricted by the HLA molecule with which they interact. Genes responsible for the TCRs randomly rearrange within the thymus to provide an astonishing array ($\sim 10^{16}$) of potential binding sites necessary for diversity. Immature T cells are selected to survive in the thymus based on whether and how strongly their TCRs bind the body's own HLA class I and II molecules expressed on the thymic

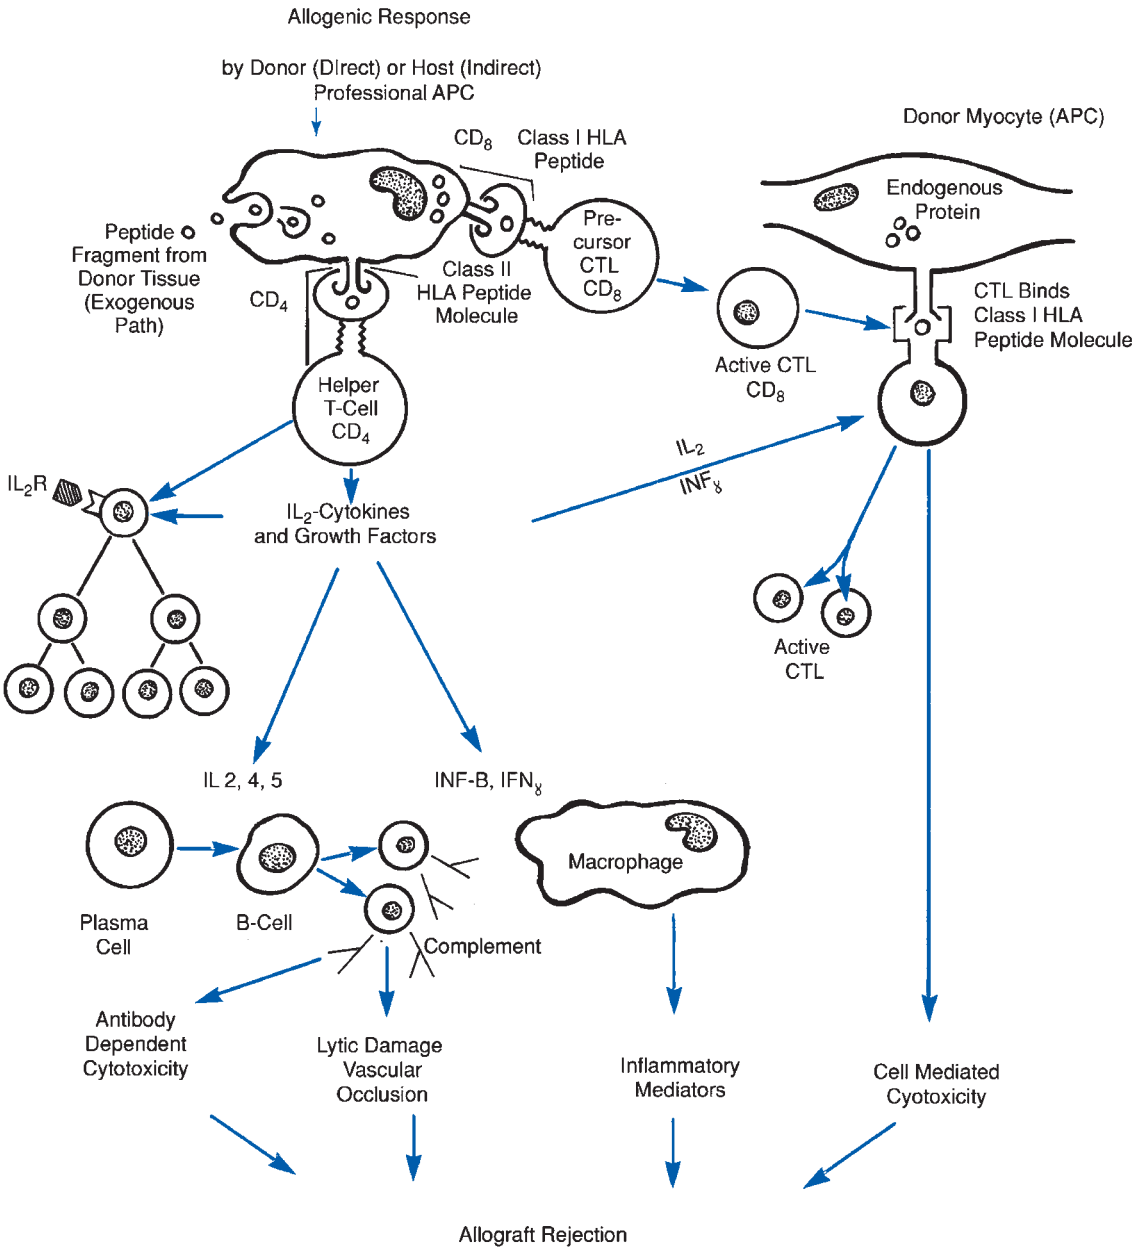

Figure 64-5. The alloresponse is a complicated cellular and humoral process that generally begins when a CD4 cell recognizes a class II donor HLA molecule–peptide complex presented on a donor heart or lung APC (direct path) and a precursor CTL cell of CD8 lineage binds to a class I donor molecule. The CD4 proliferates and produces IL-2 that drives the process further. The activated CTL cells seek class I donor-specific targets and are stimulated by IL-2 and INF to kill targets. These CTL CD8 cells are responsible primarily for destruction of the allograft. Antibodies are produced selectively by B cells and draw inflammatory cells to the targets by antibody-dependent cytotoxicity. Complement is also activated by the humoral arm and initiates lytic changes and thrombosis in the allograft. Other inflammatory cytokines attract polymorphonuclear cells into the response, and TNF and INF mix to activate macrophages.

epithelium (Fig. 64-6). This leads to the differentiation and selection of T cells that recognize self molecules from nonself sequences. T cells that have receptors that interact with the body's own HLA antigens are selected out, leaving the cells that recognize all other nonself HLA sequences. It is believed that when T cells react too strongly or too weakly to HLA molecules in the thymus, they are negatively selected and die by apotosis or DNA fragmentation to prevent the establishment of autoreactive T-cell clones that would be detrimental to the body. In fact, 95% of the thymocytes do not survive this selection. The importance of the thymus is illustrated when it fails to develop in DiGeorge syndrome. This disease results in an increased risk for a wide range of opportunistic infections that is reversed by thymic transplantation.[25]

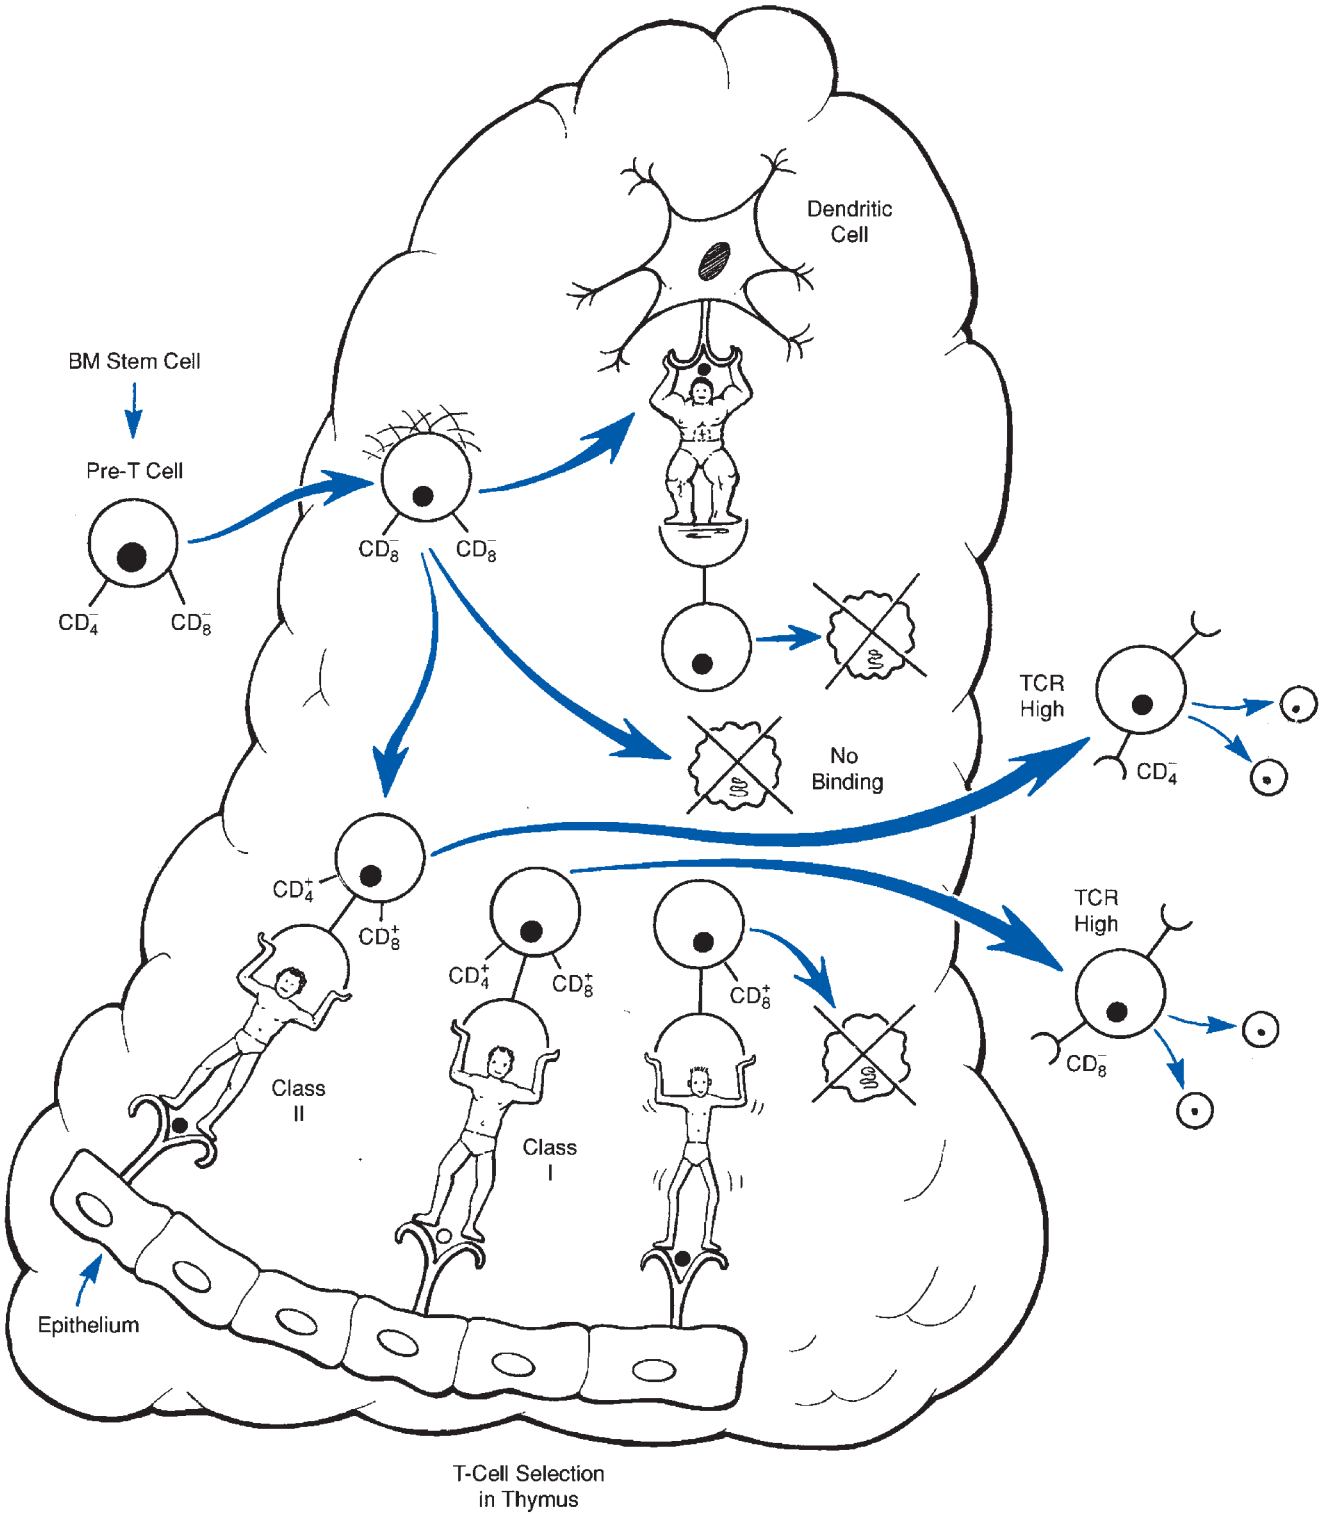

Figure 64-6. T cells enter the thymus from the bone marrow, where they differentiate and assemble diverse TCRs that cause the cells to be pl or mi selected, based on their usefulness. Diversity is based on rearrangement of genes responsible for variable portions of the chains that form the TCR heterodimer. When the TCR is pl selected on a class I HLA molecule, CD8 will form part of the receptor complex, and when a class II molecule is involved, then CD4 will form.

T cells are said to be naive until they are exposed to specific antigens in the periphery. When the TCR expressed on a T-helper lymphocyte engages its specific membrane-bound MHC (HLA) molecule on an APC, a series of reactions occurs in the cell, leading to a rise in intracellular calcium (Fig. 64-7). The Ca^{2+} influx results in the accumulation of calcineurin, which, in turn, removes a phosphate from the nuclear factor for activation of T cells (NFAT-P).[26] NFAT then can enter the nucleus, where it promotes transcription of the cytokine IL-2. IL-2 prompts the appearance of IL-2 receptors (IL-2Rs) on the surfaces of T cells with which it reacts (autostimulation), prompting proliferation and differentiation of the lymphocytes and enabling them to interact with B cells and cytotoxic T cells. While the TCR/CD3-dependent signal is necessary, it alone is not sufficient to activate quiescent T cells. Full activation requires a second or costimulatory signal provided by physical contact between various T-cell surface proteins known as *integrins* and their ligands on the APC surface.[27] The molecules on the surfaces of T cells that form an "immunologic synapse" with costimulatory molecules on APCs include CD28, whose ligand is B7; CD154, which binds to CD40; CD2, the ligand for CD58 (LFA-3); and LFA-1, the ligand for ICAM-1. CD8 and CD4 receptors also assist in the binding of the T cell to its MHC peptide of class I or class II specificity and modify the TCR signal (see Fig. 64-7). T cells that have been activated express CTLA-4, which may act as a competitive inhibitor of CD28, thereby blocking the generation of costimulatory signals.[28] Inhibition of costimulation using monoclonal antibodies against ICAM,[29] CD40L,[30] and CD28[31] has generated donor-specific tolerance in preclinical transplantation models. Stimulation of alloresponsive T cells in the absence of costimulation seems to be a central feature in this form of tolerance because the addition of less specific immunosuppressive medications such as FK506 or corticosteroids inhibits its development. Other T-cell integrins combine with matrix molecules of the allograft that are exposed during inflammation, including fibronectin, lamenin, fibrinogen, and vitronectin. These sites link the immune response to the organizing framework of all tissues and provide further evidence of the connection between early graft injury and chronic rejection. Another family of cell adhesion molecules called *selectins* has been identified on the endothelium and assists in the first contact of leukocytes, macrophages, and platelets with the donor organ by inducing rolling, sticking, and finally, transepithelial migration. The selectins are upregulated by the inflammatory cytokines IL-1, INF, and TNF that are elaborated from immune cells during the alloresponse.

REJECTION OF HEART AND LUNGS

Hyperacute Rejection

Hyperacute rejection (HAR) is said to occur when edema, hemorrhage, and thrombosis are noted shortly following reperfusion of the graft. This process involves preformed antibodies that immediately bind to the endothelium of blood vessels in the graft, leading to activation of the complement and coagulation cascades. These antibodies bind to oligosaccharide antigens of the ABO blood group and xenoreactive antigens that are similar to those found on numerous endemic bacteria, protozoa, and viruses. The cross-reactivity of antibodies directed against these endemic microbes is likely to be responsible for the preexisting natural antibodies that cause HAR after transplantation with either ABO-incompatible or xenogenic organs. Because the titer and avidity of preformed antibodies against the blood group antigens in newborn infants is low, ABO-incompatible cardiac allografts have shown greater success in these patients.[32] HAR also occurs from antibodies directed against nonself HLA antigens, especially in patients with a prior history of exposure to allogenic HLA through blood transfusions or pregnancies. Mechanical support with a ventricular assist device is also a strong risk factor for development of anti-HLA antibodies, which can be alleviated in part by the use of leukocyte-depleted cytomegalovirus (CMV)–negative blood transfusions.[33]

Although anti–class I antibodies (Abs) are more destructive of the graft endothelial cells, class II HLAs are expressed on graft vasculature during periods of inflammation and also can provoke HAR when bound by anti–HLA class II Abs following allotransplantation. Although HAR can be treated by cobra venom factor to deplete complement,[34] it is best prevented during allotransplantation by avoiding blood group disparities and identifying preexisting antibodies to HLA antigens, as will be discussed in the next section.

Despite their high endothelial avidity, neither the pre- nor the posttransplant presence of anti-HLA antibodies guarantees HAR. By using an aggressive perioperative regimen of plasmapheresis, intravenous immunoglobulin (IVIG), and Cytoxan, patients have successfully avoided HAR after transplantation despite a positive prospective crossmatch, as will be discussed below.[35] Antidonor HLA antibodies have developed in some patients after transplant despite a negative prospective crossmatch. Titers may rise as early as 3 to 4 days after transplantation, which implies a secondary antibody response with undetectable levels of preformed anti-HLA antibodies from prior exposures. Although a process known as *accelerated acellular rejection* occurs in a few, the induction of a protective phenotype (e.g., bcl-x_L, bcl-2, and A20) inhibits endothelial activation and prevents vascular injury in the vast majority of cases.[36]

Acute Rejection

Acute rejection involves both cellular and humoral immunity and is most common within weeks to months after transplantation. Although late acute episodes can occur, they often do so in the setting of a change in the balance of the immunosuppression regimen versus host immunity. A decrease in the blood level of immunosuppressant either by prescription drug interaction, poor compliance, or an upregulation in alloreactivity owing to viral infection can cause a late allorejection. Myocardial and pulmonary parenchymal infiltration by lymphocytes on endomyocardial or pulmonary biopsy is the

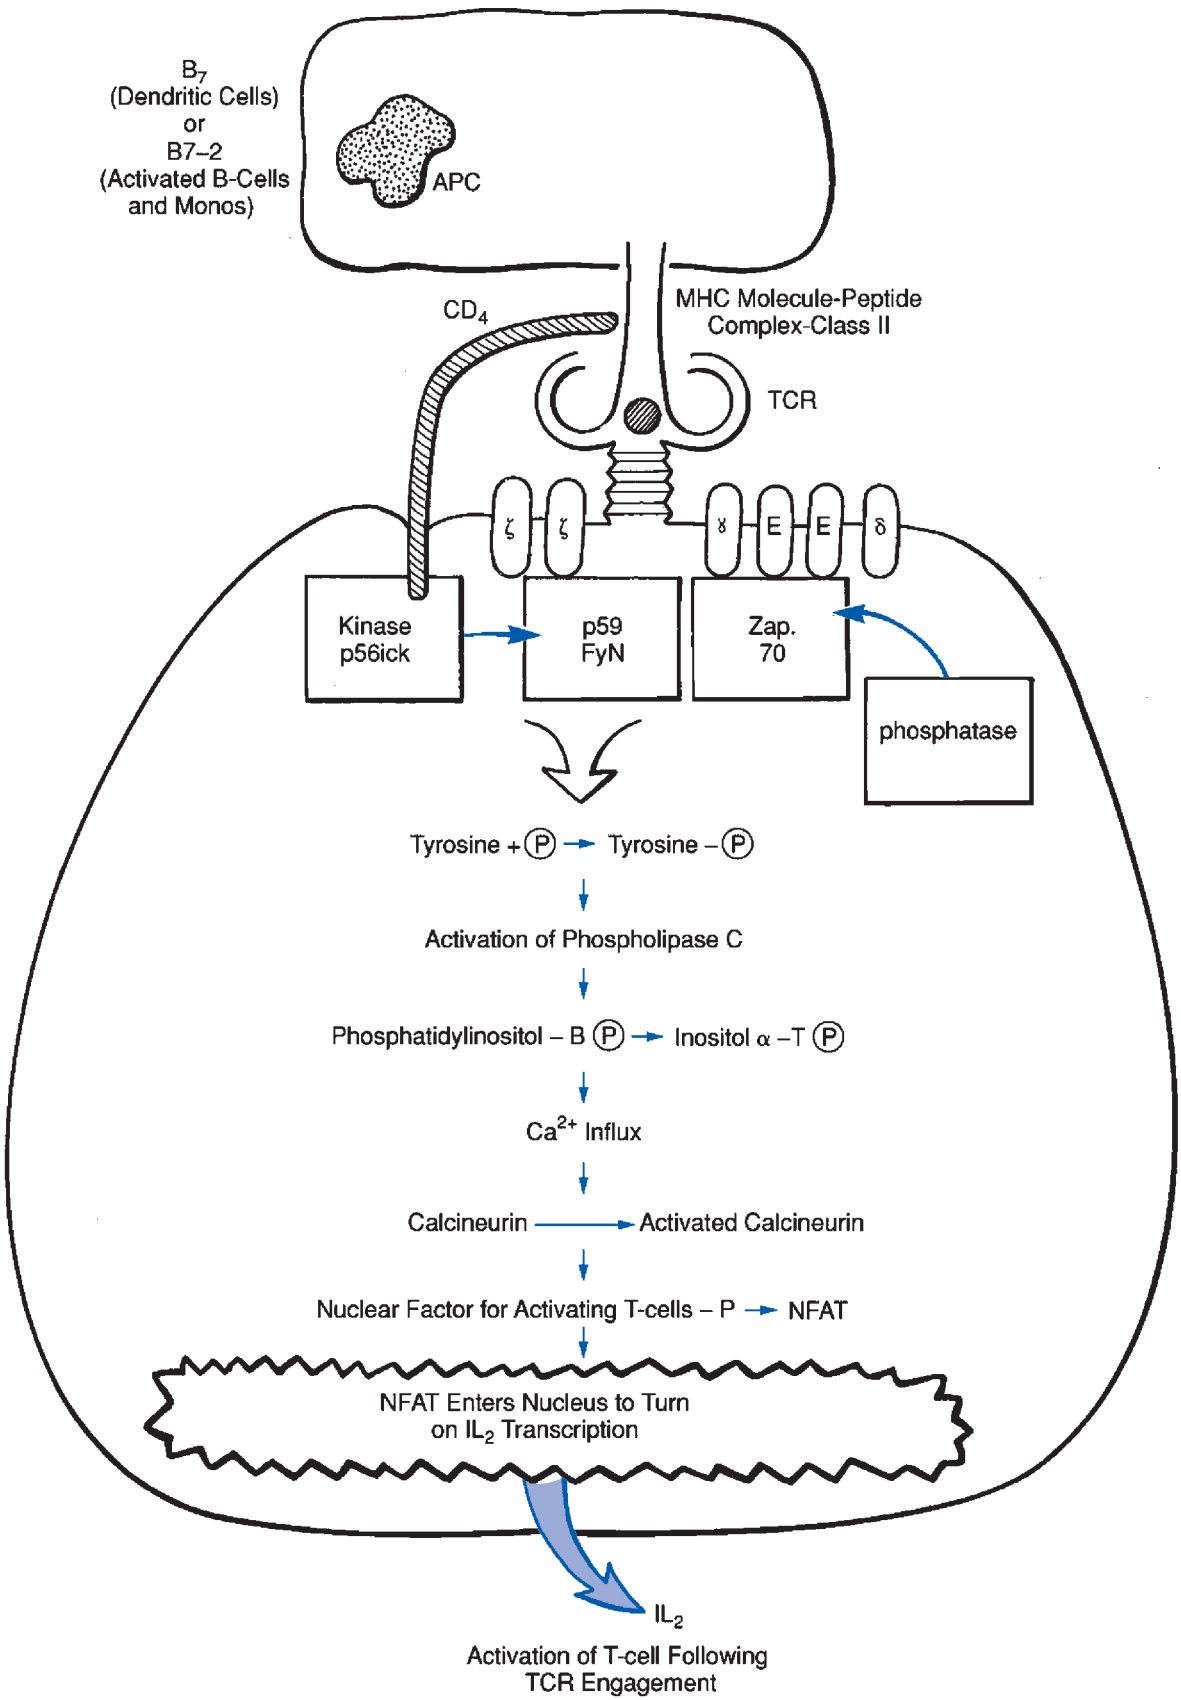

Figure 64-7. CD4 cell's TCR has engaged its specific MHC class II molecule and bound allopeptide. The TCR complex initiates cytotoxic signal transduction that enables a Ca^{2+} influx activation of calcineurin nuclear factor for activating T cells, loses phosphate, and enters the nucleus to begin the promotor sequence to activate the IL-2 gene. *(Adapted with permission from Parham M, in Haber E (ed): Immunobiology of Transplantation Molecular Cardiovascular Medicines. New York, Scientific American Press, 1995.)*

Table 64–1.

New ISHLT Morphologic Grading of Acute Rejection

Heart		Lung	
Grade 1a	Focal aggregates of perivascular activated lymphocytes; rarely interstitial foci	Grade 1	Minimal perivascular and interstitial mononuclear infiltrates*
Grade 1b	Diffuse but sparse interstitial foci; activated lymphocytes	Grade 2	Mild perivascular and interstitial mononuclear infiltrates*
Grade 2	One focus of perimyocytic-activated lymphocytes with myocyte damage	Grade 3	Moderate perivascular and interstitial mononuclear infiltrates*
Grade 3a	Multifocal areas of myocyte damage caused by activated lymphocytes and eosinophils	Grade 4	Severe perivascular and interstitial mononuclear infiltrates*
Grade 3b	Borderline severe rejection		
Grade 4	Diffuse mixed (eosinophils, often neutrophils) infiltrate with vasculitis, hemorrhage, and myocyte necrosis		

**Without lymphocytic bronchitis or bronchiolitis.*

finding that supports the presence of acute rejection. The presence of cellular necrosis implies a higher rejection grade (Table 64-1). Nonhistologic modalities for diagnosing this condition, including measurement of hemodynamic parameters, echocardiograms, radionuclide scanning, and magnetic resonance imaging, have shown good correlation with established high-grade rejections but have not demonstrated sufficient predictive values. Severe acute rejection episodes have been noted in patients with normal echocardiograms. However, the existence of ventricular dysfunction or hemodynamic compromise should raise the suspicion of rejection.

Acute vascular rejection has been used primarily after cardiac transplantation to refer to depositions of immunoglobulin and complement within the walls of the coronary artery.[37] Although it has been proposed that this is a common form of acute rejection that can lead to allograft ischemia and dysfunction, many physicians believe that the deposits are nonspecific and more related to endothelial injury from ischemia. Enhanced perioperative immunosuppression, such as the use of polyclonal antithymoglobulins or the monoclonal anti-CD3 antibody (OKT3) for induction immunosuppression, can protract the healing phase of ischemic myocardial injury and confuse the histologic diagnosis of ischemic injury versus acute rejection.[38] This condition has been found, however, to account for many cases of allograft dysfunction in the presence of "normal" myocardial biopsies without cytolysis long after allograft implantation. The diagnosis was made on further evaluation of blood vessels on biopsy samples including the presence of C4d antibody deposits on endothelial cells with or without thrombosis or cell necrosis. Although some physicians advocate aggressive therapy when there is a suspicion, some will not treat with increased immunotherapy unless there is significant allograft dysfunction.

Chronic Rejection of the Heart

This process account for most cases of graft loss after the first year following transplantation. Although chronic, persistent cell-mediated rejection causes progressive myocardial fibrosis and dysfunction, the term *chronic allograft vasculopathy* (AV) takes into consideration the role of multiple nonimmune factors in the etiology of this process. AV to various degrees has a prevalence of at least 40 to 60% within 5 years of transplantation.[39] This obstructive process can progress to near-complete occlusion of the coronary arteries causing micro- and macroinfarction (Figs. 64-8 and 64-9) and is the leading cause

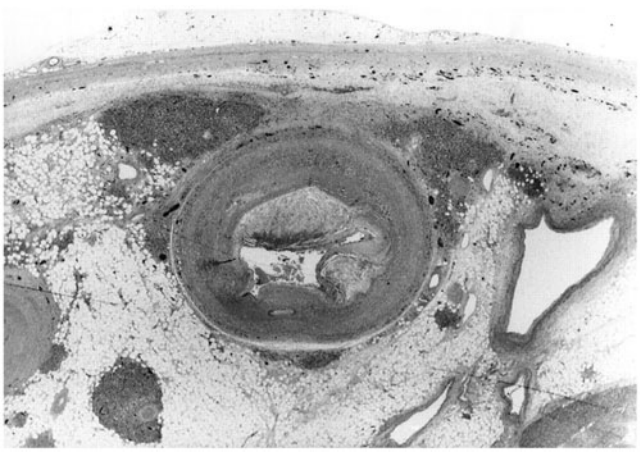

Figure 64-8. Obliterative arteriopathy, or chronic allograft vasculopathy (CAV), results in concentric narrowing of the epicardial coronary arteries and their large intramyocardial branches. This section was taken from an explanted cardiac allograft resected at the time of retransplantation for chronic rejection. Note the fibrointimal hyperplasia and adventitial and mural inflammation.

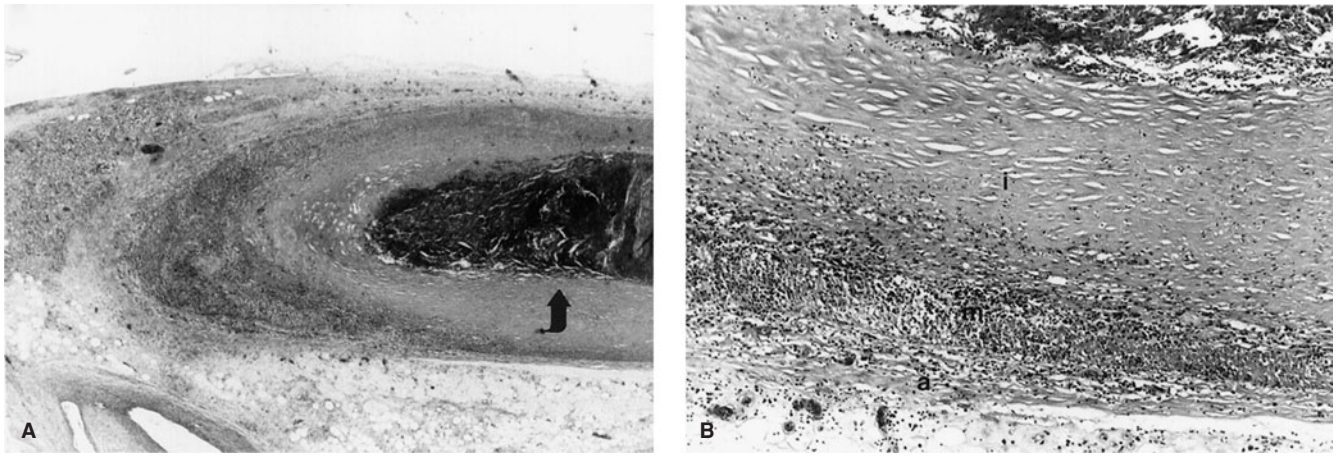

Figure 64-9. *A.* Predisposition to thrombosis is a complication of chronic allograft vasculopathy (CAV). In this photomicrograph, an artery already narrowed by CAV shows a complicating thrombus (*arrow*). *B.* A higher magnification of the artery shown in part *A* illustrates the adventitial (a), medial (m), and intimal (i) mononuclear inflammation, which is more prevalent and severe in CAV than in atherosclerosis seen in the general population.

of death after the first year following cardiac transplantation. Contrary to classic atherosclerotic lesions, the histologic findings of AV are characterized by diffuse, concentric involvement of both epicardial and small-caliber coronary vessels. There is a uniform pattern of near-luminal occlusion by neointimal proliferation and fewer early accumulations of extracellular lipid than with classic atherosclerosis. Infiltrates of T cells that encircle the entire vessel are characteristic.[40] The concentric nature of the lesion has led to emergence of intravascular ultrasound (IVUS) as the optimal method for clinical detection of AV given the failure of routine angiography to detect such concentric lesions reliably.[41] Endothelial cells generally remain intact but are known to be dysfunctional based on a paradoxical constrictive response to acetylcholine.[42]

AV has been linked to multiple potential etiologies with no clear single cause. Earlier belief that AV might be solely due to an arterial injury secondary to the ischemia-reperfusion associated with graft harvest and implantation is not tenable because animal models of syngeneic transplants do not develop the lesion. However, events around the procurement process that result in early endothelial activation and dysfunction have demonstrated a convincing correlation with the development of experimental[43] and clinical AV.[44] It has been difficult to correlate any of the usual risk factors for natural atherosclerosis, including hypertension, pretransplant hyperlipidemia, history of smoking, or prior atherosclerosis, with an increased risk of AV. However, aggressive treatment of posttransplantation hyperlipidemia with pravastatin was shown to reduce the incidence of AV in a randomized, placebo-controlled clinical trial using both IVUS and angiography.[45] Some studies have revealed the association of this condition with older donor age, whereas others have suggested that CMV infection might prompt the atherosclerotic process. Although there appears to be some association, it has been clearly demonstrated that CMV infection is not required for the process to occur, and the association may be more an association than cause and effect.[46,47] Antidonor cellular[48,49] and humoral[50–52] immune responses are associated with clinical AV lesions, but these processes might equally well be a marker for high risk as opposed to a direct cause of chronic rejection. Despite a significant improvement in the 1-year half-life of allografts in the modern cyclosporine era of improved immunosuppression, AV has remained refractory.[53] Increased expression of ICAM-1 and other adhesion molecules in AV lesions[54–56] points to the role of a smoldering, nonspecific immune response in the chronic rejection process, as documented in development and activation of nontransplant atherosclerosis.[57] Furthermore, there also might be an association between humoral rejection causing endothelial dysfunction and the development of future chronic vascular disease. Strategies aimed at treating humoral rejection therefore may lead to a reduction in the prevalence of AV.

Our current limited pathophysiologic understanding of this relentless process is based largely on small-animal models and retrospective patient series. By systematically isolating possible etiologic factors, animal models have provided significant insight into the basic science of the vasculopathic process in cardiac allografts. However, out of logistical necessity, the surrogate pathologic lesion occurs much earlier than the typical changes of chronic rejection in clinical patients. Thus the pathogenesis of the process being studied experimentally is almost certainly not the same as that occurring clinically. Indeed, many of the commonly used rodent models demonstrate suppression of AV lesion formation with standard immunosuppression such as cyclosporine,[58] a finding that significantly limits clinical relevance (Fig. 64-10).

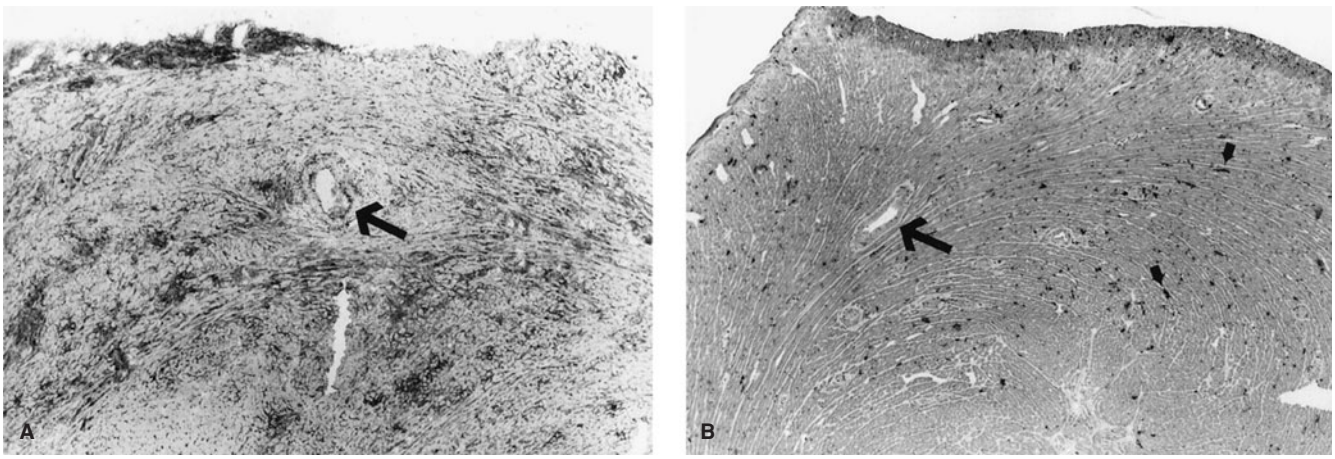

Figure 64-10. *A.* Experimental animal models of chronic allograft vasculopathy suggest that tolerance induction via the introduction of hematolymphoid chimerism can prevent chronic class II antigens on the microvasculature and large intramyocardial coronary arteries, which show early changes of chronic allograft vasculopathy (*arrow*). *B.* In contrast, donor MHC class II antigens in a cardiac allograft that is resistant to chronic rejection show staining only in the interstitial hematolymphoid cells (*small arrows*), whereas the arteries are normal appearing (*large arrows*).

Murase and colleagues have investigated pathogenic mechanisms of AV using MHC class I–mismatched miniature swine.[59] This more clinically relevant large-animal model supports the findings of most rodent models and suggests that there is an immune-mediated injury that initiates changes in the arterial wall. The artery then follows a "response to injury" pathway common to other forms of arteriosclerosis, prompting physical changes and relocation of smooth muscle cells from the media to a neointima. In addition, there is evidence that host stem cells deposit in the vessel wall and contribute to this neointimal hperplasia.[60] Irrespective of the cells of origin, neointimal formation is accelerated with growth factors, TNF, and IFN elaborated from the endothelium, as well as CD4 T cells. Macrophages are recruited and contribute cytokines and growth factors that promote the proliferation and synthesis of matrix by vascular smooth muscle cells.

Treatment strategies will remain elusive unless more complete control of the alloresponse can be maintained by the newer xenobiotics and monoclonal antibodies or induction of tolerance. Clinicians are anxious to explore the potential for new xenobiotics that have demonstrated a striking reduction in experimental AV based on their suppression of the smooth muscle response to the growth factors.[58]

Chronic Rejection of Lung Allografts

The lung allograft, too, appears to be affected by a chronic process that limits the long-term usefulness of the organ. This chronic attrition can affect 30 to 50% of recipients within 3 years of pulmonary transplantation and 60 to 70% of patients who survive for 5 years.[61] In the majority of patients, the problem is difficult to resolve once it develops, and the mortality rate at 3 years after diagnosis is 40% or higher. The term used to describe this chronic loss of function, *obliterative bronchiolitis* (OB), comes from the histologic findings of obliteration and fibrotic scarring of the terminal bronchioles[62] (Fig. 64-11). However, the clinical diagnosis is rarely based on histology given the low sensitivity of transbronchial biopsy.[63] The lesions of OB involve the lung in a nonuniform manner, and biopsy is performed mostly to rule out other causes of graft dysfunction, such as acute rejection, infection, and airway complications. Because symptoms are nonspecific, the most sensitive test for early detection of OB is a fall in forced expiratory flow between 25% and 75% of the FVC ($FEF_{25–75}$).[64] The term *bronchiolitis obliterans syndrome* (BOS) was formulated to describe chronic allograft dysfunction in the absence of confirming histology by a progressive decline

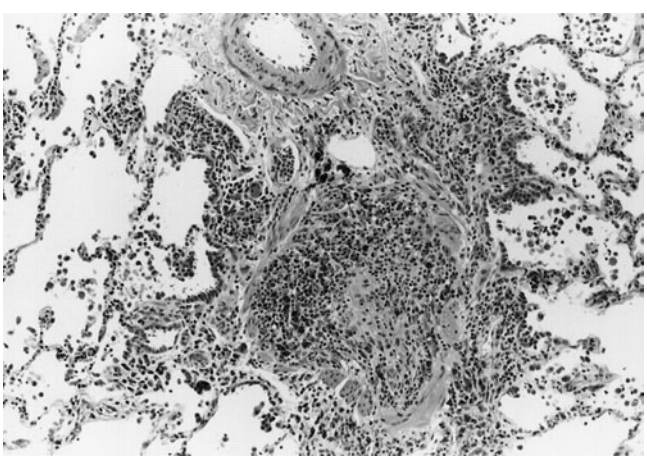

Figure 64-11. Bronchiolitis obliterans. A small bronchiole has its lumen completely obliterated by dense scar tissue and mononuclear inflammatory cells.

in FEV_1, deemed a more reliable and reproducible pulmonary function test.[65] BOS grades 0 to 3 are assigned according to the percentage of FEV_1 to best postoperative baseline value obtained. Bronchial wall thickening, distension of distal airways with air trapping, and frequent association of secondary acute infection have been detected on high-resolution chest computed tomographic (CT) scanning and are proposed as helpful in making the diagnosis.[66]

The histologic changes provide insight into the etiology of the process, including potential therapy. As in cardiac AV, OB appears to be the end result of an exaggerated injury response to the interplay among allogenic, ischemic, and viral etiologies. The lungs and airways appear to be quite susceptible to ischemia-reperfusion injury. Possible reasons include a propensity for ischemic damage of the delicate alveolar-capillary unit, difficulty in lung preservation given a static column of air in the graft, postoperative pulmonary hypertension owing to a hypertrophic right ventricle, and the lack of a direct arterial supply to the bronchus after transplant. It has been proposed that ischemia to the bronchial epithelium causes an exaggerated and chronic inflammatory response resulting in airway scarring. Although animal models have demonstrated a connection, ischemic time has not been shown convincingly to be an independent clinical risk factor for long-term graft failure.[67] However, clinical success has been achieved against chronic rejection in renal transplantation with the perioperative use of the free-radical scavenger superoxide dismutase[23]; the availability of a proven strategy for inhibiting RI in lung transplants with inhaled nitric oxide and pentoxifylline[68] warrants further follow-up to investigate a long-term effect on OB.

The transplanted lung is unique among solid-organ transplants in that it is exposed to the outside world. As a result, these lungs are particularly susceptible to the immunomodulary effects of respiratory viruses. By serving as an adjuvant for the cellular immune response or by a direct cytopathic effect on the airway, respiratory viruses such as CMV, respiratory syncytial virus, adenovirus, influenza, and parainfluenza infection all have been implicated as risk factors for BOS.[69] CMV infection, in particular, has a potent effect on donor-specific and nonspecific immune responses. An increase in INF and MHC class II antigen expression has been noted in bronchoalveolar lavage (BAL) cells during infections with CMV.[70] Most transplant centers believe in an association between CMV infection and BOS, although a precise relationship is far from uniformly accepted.

Although other facilitating factors certainly exist, several lines of clinical evidence support the alloresponse as a more important force behind the development of OB than cardiac AV (Figs. 64-12 and 64-13). First, acute rejection has been found consistently to be the leading risk factor for the eventual development of OB.[71] In particular, OB develops in the setting of indirect alloimmune[72] and alloantibody[73] responses to HLA-A mismatches and is stabilized occasionally by augmented immunosuppression[74,75] (see Fig. 64-13). Second, an identical form of OB can occur in bone marrow transplant recipients with graft-versus-host disease following recognition of the host lungs by the grafted alloreactive T cells.[76] Third, cells from bronchial lavages of OB patients have demonstrated TH1 cytokine mRNA profiles (i.e., IL-1, IL-2, IL-6, and IFN).[77] Finally, in the Pittsburgh study of microchimerism, it appeared that patients with OB had less evidence of microchimerism in blood, lymph nodes, and skin, which follows the general concept of less immune reactivity for those patients with a generalized chimeric state.[78]

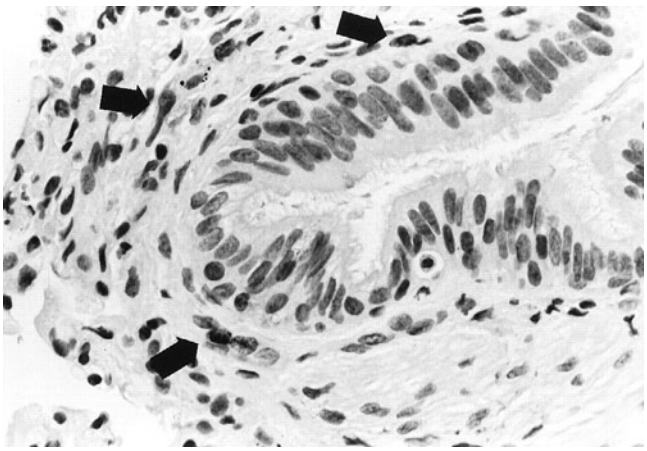

Figure 64-12. Bronchiolitis obliterans. Stains for S-100 protein decorate antigen-processing dendritic cells (*arrows*) present in increased numbers in the airways of lung allografts experiencing rejection.

The currently available experimental models of OB have provided insight into the human condition and new avenues for investigation. However, the lack of a large-animal model significantly limits their relevance. Attempts to model OB in nonhuman primate lung allografts have resulted in either acute rejection or normal lung tissue

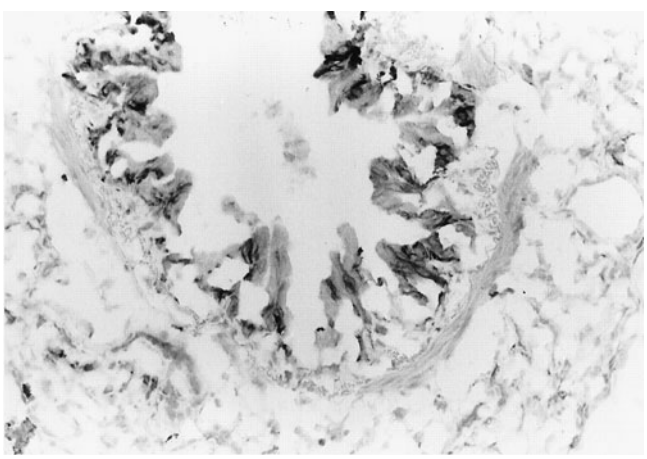

Figure 64-13. Bronchiolitis obliterans. Chronic airway rejection is characterized by increased expression of HLA class II antigens, especially HLA-DR (shown here) on respiratory epithelial cells.

depending on the level of immunosuppression used. Subcutaneous and intra-abdominal tracheal implants in rodents, but not nonhuman primates, develop close approximations of the pathologic lesions of OB at 1 and 2 months.[79,80] As in cardiac AV, the dissimilarity of the pathophysiology of these lesions prevents conclusions that have direct clinical relevance, especially regarding treatment. At present, the focus is on the newer immune drugs that might reduce not only the initial allogeneic response but also the secondary effects that result in mesenchymal cell recruitment for luminal scarring.

PRETRANSPLANT IMMUNOLOGIC EVALUATION AND MANAGEMENT OF SENSITIZED TRANSPLANT CANDIDATES

The prevention of donor organ rejection by the host continues to be of paramount importance in the field of thoracic transplantation given the detrimental sequelae of such episodes on short- and long-term graft function and survival. This remains to be the case despite the presence of multiple treatment modalities for such rejection episodes.

Various limbs of the immune system, both the specific and nonspecific arms, are responsible for hyperacute, acute, and chronic rejection episodes.

Preoperative Immune Screening and Prevention of Hyperacute Rejection

As mentioned in the preceding section, this type of rejection is believed to be the consequence of preformed host antibodies that cross-react with and attack the endothelium of blood vessels in donor organs. Hence the prevention of such a devastating event is based on the preoperative screening of transplant candidates for the existence of preformed antibodies that potentially could attack the donor graft. These include serologic studies to determine the ABO and HLA types (class I and II) of both hosts and donors in addition to the detection of preformed antibodies (PRAs) in transplant candidates against the major histocompatibility complexes.

Abo and RH compatibility

Transplantation should be performed between identical blood groups (such as A to A and B to B) or compatible blood groups (such as O to A, O to B, or A to AB) in order to avoid severe hyperacute rejection. Certain cases of successful organ transplantation, especially in the pediatric population, have been reported.[81] This, however, continues to be the exception rather than the rule, especially in the adult patient population.

HLA tissue typing of host and donor

The major histocompatibility complexes also play a central role in the immune response of hosts against donor grafts. Hence determination of the exact types of HLA antigens of both hosts and donors plays a very important role in solid-organ transplantation. HLA tissue typing generally is performed using the cytotoxicity method. More complex DNA typing methods are used when tissue typing cannot be identified using the cytotoxicity methods. Owing to donor shortages and logistics, transplantation between HLA-identical people is very difficult and not practical, especially in light of the fact that long-term outcomes are not strongly affected by HLA mismatches particularly if such mismatch is less than three of the important six HLA alleles of HLA-A, HLA-B, and HLA-DR, as discussed earlier in this chapter. This is in contrast to the case in other transplants, such as bone marrow transplantation, for instance. Recipients who possess antibodies against HLA types that are present in the donor, however, are at a higher risk of developing hyperacute rejection, and such organs generally are avoided.

Panel reactive antibodies

This is also considered to be an essential part of the pretransplant immune evaluation process. The host's serum is screened for the presence of anti-HLA antibodies (both HLA class I and class II). A high antibody titer (>10%) increases the risk of rejection (hyperacute if anti–class I antibodies are present and vascular or future chronic allograft rejection if anti–class II antibodies are present). Various reports have demonstrated inferior graft survival results with higher PRA titers in both heart and lung transplantation.[82,83] PRA levels generally are measured using the cytotoxicity method or the more sensitive flow beads method. Various interventions are used to decrease the PRA load if elevated, including plasmapheresis, Cytoxan, intravenous immunoglobulins, rituximab, and a combination of all, as will discussed below.[82,83]

Crossmatching

Prospective crossmatching usually is used at the time of transplantation prior to donor-organ procurement when PRA levels in the recipient are elevated (>10%). This is the last and most definitive test of donor versus recipient immunologic compatibility. The crossmatch tests the sera of recipients, which might contain anti-HLA antibodies, against donor lymphocytes (B and T cells) obtained from peripheral donor blood samples. Hyperacute rejection episodes posttransplantation have been reduced dramatically in sensitized patients owing to the use of prospective crossmatching techniques. The requirement of prospective crossmatching is time-consuming, however, and limits the eligibility of potential organs to closer geographic areas. Consequently, this is only used in patients with high PRA levels and therefore at a higher risk of developing hyperacute or accelerated acute rejection episodes (5 to 7 days). Retrospective crossmatching is also carried out routinely in many institutions in order to determine the presence of antidonor antibodies in transplant recipients that might account for any unexpected graft dysfunction posttransplantation.

Management of Pretransplant High PRA Levels and Treatment of Hyperacute Rejection

Various modalities have been used with different degrees of success to reduce the PRA load in sensitized transplant candidates or in the treatment of hyperacute rejection episodes[84,85]:

1. *Plasmapheresis.* This treatment modality has been used to treat a variety of autoimmune conditions such as multiple sclerosis and idiopathic thrombocytopenia. It works by replacing patients' own antibodies rich plasma with clean, fresh plasma or albumin solution. Multiple pheresis runs usually are required to achieve a meaningful reduction in PRA levels. This treatment has been shown to be effective in desensitizing transplant candidates, especially when combined with other agents such as Cytoxan or immunoglobulins.[86–93]
2. *Cytoxan (cyclophosphamide).* Cytoxan is an alkylating agent with cytotoxic and immunosuppressive activities. Its exact mechanism of action is not very well understood, but it works via an active intermediate metabolite that is purported to reduce B-cell production of antibodies. Cytoxan is used to treat certain cancers and some nonmalignant autoimmune diseases such as Wegener granulomatosis. This agent also has been used to reduce PRA levels in highly sensitized transplant candidates with variable degrees of success.[86,94–96] The combination of Cytoxan and immunoglobulins has been shown in certain studies to reduce PRA levels to levels safe enough to allow for successful heart transplantation.[95] Various side effects, however, are associated with this agent, such as bone marrow suppression and hemorrhagic cystitis.
3. *Intravenous immunoglobulins (IVIGs).* Many studies have demonstrated the efficacy of IVIGs in the treatment of sensitized transplant candidates. This treatment also has been combined with plasmapheresis or Cytoxan to treat high PRA levels.[88,94] Pretreatment with antihistamines and steroids is recommended to reduce the possible side effects of serum sickness–like symptoms such as fever and nausea.
4. *Rituximab.* This murine/human chimeric monoclonal antibody is specific for CD20 receptors that are expressed primarily by B cells. This agent dramatically reduces the number of circulating B cells in the blood. B-cell counts remain low for 6 to 9 months after treatment. This agent has been shown to be effective in the treatment of posttransplant lymphoproliferative disorders (PTLDs) in kidney, liver, heart, and lung transplant recipients.[97] Recent reports also have demonstrated the effectiveness of this compound in the treatment of hyperacute rejection in addition to the reduction in PRA levels pretransplantation. Some studies have reported a small risk of hypogammaglobulinemia and multiple fungal or viral infections in organ transplant recipients treated with rituximab.[98–101]
5. *Photopheresis.* Extracorporeal photopheresis (ECP) has been under investigation for a few years. It is based on the separation of a leukocyte/lymphocyte-enriched cell fraction from the peripheral blood, extracorporeal treatment of these cells with 8-methoxypsoralen (8-MOP), followed by exposure to ultraviolet A (UVA) light with subsequent reinfusion of the cells into the patient. This seems to lead to changes in the immunologic behavior of the photoinactivated/modulated cells. The treatment is well tolerated and causes few side effects. Some studies have demonstrated the efficacy of this modality in the treatment of heart and lung rejection, in addition to other conditions such as graft-versus-host rejection in bone marrow transplant patients.[102–105]
6. *Total bone marrow irradiation.* This therapy also has been used with variable degrees of success to treat high PRA levels or rejection episodes that are resistant to conventional treatment modalities.[106]

NEW IMMUNOSUPPRESSIVE DRUGS

The improved outlook for transplant recipients has followed the introduction of xenobiotic immunosuppressants, i.e., drugs produced by organic synthesis or microorganisms that suppress the immune system. Between 1960 and 1985, only steroids, azathioprine (AZA), and cyclosporine (CsA) had been adopted for use in clinical transplantation. These agents have been joined more recently by polyclonal and monoclonal anti-T-cell antibodies. In the last few years, progress in the molecular understanding of the alloresponse has made new discoveries possible and has allowed agents to be classified by mechanism of molecular action (Fig. 64-14 and Table 64-2).

Corticosteroids

Transplant physicians have recognized the benefits of corticosteroids from the very early days of clinical transplantation. These molecules have protean effects that, like any steroid, are mediated through intracellular receptors that alter gene transcription. The predominant anti-inflammatory effects of glucocorticoids, such as blockade of NF-κB-induced transcription of inflammatory cytokines and adhesion molecules, derive from the inhibition of gene transcription. On the other hand, the metabolic side effects, such as muscle wasting and diabetes, derive from positive transcriptional effects.[107] This concept of differing mechanisms of action has prompted investigations to develop corticosteriod analogues that bind to intracellular receptors to promote the inflammatory effects without the metabolic effects.

Glucocorticoids have been found to induce apoptosis in malignant T cells[108] and are therefore an especially appropriate choice of sole immunosuppression in the setting of

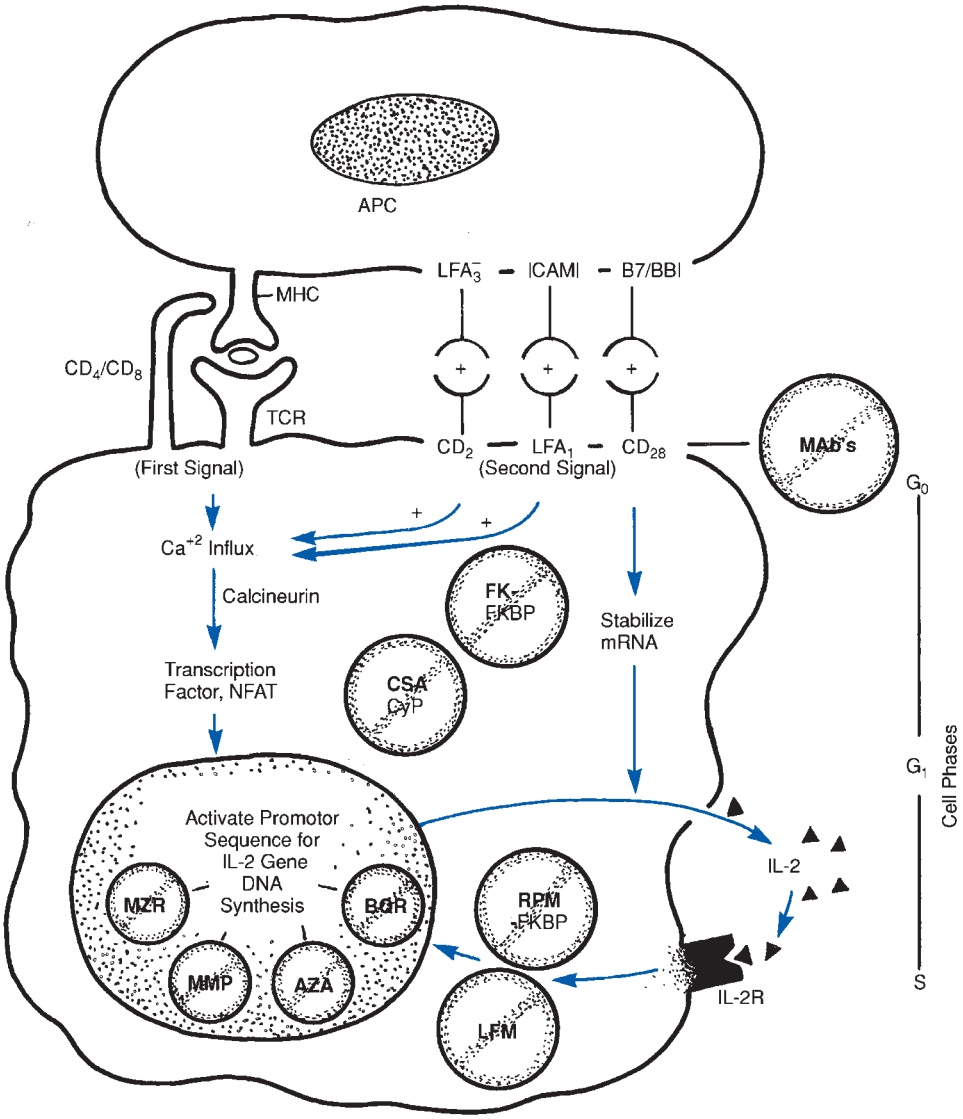

Figure 64-14. Immunosuppressants available to clinicians are directed toward inhibiting T-cell activation at various steps and by varied mechanisms, including interference with TCR complex (OKT3 Mab) and other surface ligands (anti-ICAM-1, anti-CD2, and others); Ca^{2+}-dependent (CsA and FK) signal transduction; inhibition of cytokine IL-2 action in promoting cellular proliferation (RPM and LFM); and inhibition of purine (AZA, MZR, and MMP) or pyrimidine synthesis BQR.

posttransplant lymphoproliferative disorder. Outside this subgroup, however, recent advances in the development of tolerance protocols have suggested that steroid use blocks certain immune signaling pathways necessary to induce donor-specific anergy or suppressor cells.[30] In addition, steroid weaning reduces the tendency toward diabetes and dyslipidemia, which may decrease the incidence of AV.[109]

Cytokine Synthesis Inhibitors

Cyclosporine (CsA) inhibits the gene activation necessary for IL-2 production. To accomplish this, CsA inhibits the function of a Ca^{2+}-activated calcineurin phosphatase when bound to its cytoplasmic receptor.[110] This prevents activation and nuclear translocation of the nuclear factor for activation of T cells (NFAT), precluding its engagement with the promoter sequence of the IL-2 gene. Blockade of the Ca^{2+} calcineurin phosphatase complex also inhibits the production of nitric oxide synthetase, a potential mechanism by which CsA seems to promote AV in animal models.[111]

Originally oil-based, CsA has been replaced by a novel microemulsion formula, Neoral, which has improved its bioavailability significantly and reduced pharmacokinetic variability among patients. Approximately 30% of heart transplant recipients develop nephrotoxicity, the primary toxicity of CsA, which appears to be mediated by the inhibition of prostaglandin metabolites. However, the prostaglandin analogue misoprostol has afforded little clinical benefit.[112] In

Table 64–2.

Compendium of Immunosuppressants

Drug	Proposed mechanism	Status
Cytokine synthesis		
Cyclosporine A	Inhibits SER/THR phosphatase	FDA approved
Tacrolimus (FK506)	Inhibits SER/THR phosphatase	FDA approved
Growth factor inhibitor		
Rapamycin	Unclear	FDA approved
Leflunomide (LFM)	Inhibits tyrosine kinase	In clinical trials
DNA synthesis inhibitor		
Azathioprine (AZA)	Inhibits PRPP amidotransferase (purine)	FDA approved
Methotrexate	Inhibits dihydrofolate reductase	FDA approved
Mycophenolate (MFF)	Inhibits IMP dehydrogenase (purine)	FDA approved
Mizoribine (MZR)	Inhibits IMP dehydrogenase (purine)	In clinical trials
Brequinar (BQR)	Inhibits DHO dehydrogenase (pyrimidine)	On hold
Receptor antagonists		
Antithymocyte globulin (equine or rabbit)	Kills T cells or alters traffic	FDA approved
Anti-CD3 (OKT3)	Kills CD3+ cells or alters traffic	FDA approved
Anti-IL-2 receptor	Kills IL-2R+ or alters traffic	In phase III clinical trials
DAB486-IL-2	Kills CD25+ cells or alters traffic	In clinical trials
Anti-LFA-1	Inhibits intercellular adhesion	In clinical trials
Anti-ICAM-1	Inhibits intercellular adhesion	In clinical trials
OKT4A	Induces CD4+ cell anergy	In clinical trials
IL-1 receptor antagonist	Inhibits IL-1 receptor	In clinical trials
Soluble HLA	Inhibits antigen presentation	Preclinical
Deoxyspergualin	Inhibits antigen presentation	In clinical trials
Cytokine inhibitors		
Anti-IL-6	Neutralizes IL-6	In clinical trials
Anti-TNF	Neutralizes TNF	In clinical trials
Soluble IL-1 receptor	Neutralizes IL-1	In clinical trials
IL-10	Inhibits cytokine synthesis	Preclinical

two recent series of heart transplant patients, calcineurin inhibition was the sole indication for metachronous kidney transplantation.[113,114] CsA-induced alterations in cell phenotype explain other side effects, such as hypertension and dyslipidemia.[115,116]

CsA was widely embraced as the central component for effective multidrug immunosuppression until FK506 (tacrolimus) was introduced to patients in Pittsburgh in 1988. Tacrolimus combines with a different cytosolic protein than CsA (FK-binding protein) but complexes with the same Ca^{2+}-activated calcineurin to prevent the activation of NFAT.[76] Tacrolimus has proven to be at least as effective in heart transplant patients[117] and possibly better in lung transplant patients.[118] It has found particular success following a switch from CsA-based immunosuppression when faced with a refractory acute rejection of the heart or lung[119] or bronchiolitis obliterans.[74] Given a mechanism of action similar to that of CsA, the reason for the improved effectiveness of tacrolimus in refractory rejection likely relates to more predictable pharmacokinetics.[120] Therefore, ongoing clinical trials comparing tacrolimus with Neoral are of great interest with regard to efficacy but are not likely to change the improved side-effect profile already demonstrated with tacrolimus in multicenter trials.[117] Compared with recipients receiving CsA, tacrolimus was found to be associated with less facial disfigurement, hirsutism, hypertension, and hyperlipidemia but equal nephrotoxicity and was perhaps associated with greater neurotoxic and diabetogenic effects.

Inhibitors of DNA Synthesis

Antimetabolites are immunosuppressive because they inhibit the synthesis of nucleotides necessary for DNA's rapidly dividing cells. The classic antimetabolite has been azathioprine (AZA), which inhibits purine synthesis and therefore DNA and RNA synthesis throughout all dividing cells. Mycophenolate mofetil (MMF) appears to be more selective for T and B cells than AZA[121] based on its ability to block the activity of the enzyme inosine monophosphate dehydrogenase and therefore the synthesis of purines in the de novo pathway. Unlike other parenchymal and peripheral blood cells, T and B cells cannot use the salvage pathway and depend solely on the de novo pathway for purine synthesis. Compared with AZA, randomized clinical trials have shown a reduction in acute rejection events and antibody production with MMF in both heart[122] and lung[123] transplant patients. The reduction in chronic graft loss that has been demonstrated with the use of MMF versus AZA in renal transplantation has not yet been confirmed in cardiothoracic transplants. Neutropenia has not been a limiting factor, as it has been with AZA.

Brequinar sodium (BQR) is a new addition to the antimetabolite group.[124] Unlike MMF, its action appears to be directed against dihydro-orotate dehydrogenase (DHODH), an enzyme in the pathway leading to synthesis of pyrimidines. The rationale for use of BQR is similar to that for MMF, given that activated immune cells are relatively more dependent on de novo synthesis of pyrimidine's effects than nonimmune cells, although unlike for purines, a salvage pathway does exist. As a result, BQR appears to be less selective for immune cells. Another DHODH inhibitor, leflunomide, has demonstrated a much more favorable therapeutic window, although profound weight loss has been seen in animal and human trials.[125] Leflunomide depletes ATP-dependent enzymes, which inhibits the glycosylation of adhesion molecules, providing another possible mechanism of immunosuppression.[126] Clinical utility of both BQR and leflunomide has been limited by myelotoxicity and gastrointestinal effects; planned clinical trials have been stopped.

IL-2 Signal Transduction Inhibitor

Rapamycin (RPM, sirolimus) is structurally similar to tacrolimus and binds with FK-binding protein (FKBP) but surprisingly does not inhibit the calcium-activated calcineurin.[120] Instead, RPM acts at a point downstream from the cytokine inhibitors and upstream from the antiproliferative agents. In alloreactive T cells, stimulation of the IL-2 receptor leads to clonal proliferation following initiation of the cell cycle and conversion from the resting (G_0) to proliferative (G_1/S) state. The RPM-FKBP complex binds the so-called target of rapamycin, a lipid kinase,[127] and prevents the signaling between IL-2 receptor activation and cell cycle initiation. Because of theoretical concerns of competition for FK-binding protein, sirolimus was combined initially with CsA,[128] but recent clinical trials in renal transplantation actually have demonstrated greater success when it is combined with FK506.[129] In vitro studies have demonstrated that RPM also induces cell cycle arrest in B cells and smooth muscle cells.[130] This smooth muscle cell antiproliferative effect is thought to be responsible for the arrest of AV in both small-animal[60] and large-animal[131] experimental models and for the clinical prevention of restenosis after using RPM-coated intracoronary stents.[132] In preliminary randomized studies, the use of RPM instead of AZA following heart transplantation has resulted in reduced AV by IVUS evaluation at 6 months[133] and 1 year.[134] Sirolimus is not nephroxic, but it may enhance the renal toxic effects of calcineurin inhibitors[103]; its main toxicity is hyperlipidemia.

Combinations of these drugs that act at the level of cytokine production, the proliferative response to cytokines, and/or the signaling between the two have demonstrated additive immunosuppressive effects.[135] This not only will effectively reduce the alloresponse but also potentially will do so with lower doses of each.

Inhibition of T- and B-Cell Maturation

Deoxyspergualin (DSG) does not inhibit the synthesis or actions of cytokine but has been shown to inhibit the maturation of T and B cells and APCs.[136] Clinical trials that were conducted in high-risk renal allograft recipients were stopped owing to a high incidence of leukopenia.

Receptor Antagonists and Monoclonal Antibodies

Polyclonal anti-T-cell preparations (ATGs) have been developed that recognize T-cell surface structures and kill these targets by inducing Fc-receptor-mediated cell lysis or by complement-dependent cell lysis. In the mid-1980s, the murine anti–human CD3 monoclonal antibody (OKT3) was developed that recognizes the epsilon protein of the CD3 complex on all T cells. When used as induction agents in thoracic transplantation, ATG and OKT3 have been found only to delay the onset of acute rejection at the expense of a profound, uncontrolled immunosuppression that increases the risk for opportunistic infections and malignancy.[137] Furthermore, their main toxicity, the cytokine release syndrome, is tolerated particularly poorly in heart and lung transplant recipients. As a result, their current use is limited in most centers for the treatment of refractory acute rejection and as a calcineurin inhibitor–sparing agent in those with prolonged postoperative renal dysfunction.

The development of a humanized monoclonal antibody (mAb) against the IL-2 receptor provided the opportunity for a more selective targeting of activated T cells, the only cells that express this receptor. In a small (55 heart transplant recipients) randomized clinical trial, induction therapy using this mAb, dacluzimab, reduced the frequency and severity of acute rejection events over the study period. In addition, there were essentially no side effects and no increased risk of infection or malignancy.[138] Pilot studies using mAb against the cell adhesion molecules LFA-1[139] and

ICAM-1[140] showed promise in preventing reperfusion injury but variable success against acute rejection. The combination of the two, which was synergistic against acute rejection in rodent models, has not been tried clinically. Also awaiting clinical trial is a strategy that inhibits T-cell costimulation such as the anti-CD154 mAb or CTLA-4 Ig that have produced tolerance in the nonhuman primate model.[30] Other monoclonal antibodies that are in various stages of clinical development may have a specific role in therapy, but hopes for a magic bullet likely will not be realized because the immune response is far from simple and is based on redundancy by way of alternative pathways. A combination of various mAbs likely would be the best protocol to address this redundancy. Unfortunately, no preclinical or clinical trials using a combination strategy have been performed in large part owing to financial conflicts between the different pharmaceutical companies that own the rights to these agents.

TOLERANCE

While immunosuppressive agents have permitted the replacement of heart and lungs to become realities, their toxic side effects and inability to prevent more chronic forms of rejection have driven the search for alternative strategies. Experimental models have suggested that the induction of tolerance is the most effective way to prevent chronic rejection.[141] Indeed, the absence of AV or OB has been considered to be the best clinical endpoint for the evaluation of successful tolerance induction in future trials by the National Heart, Lung and Blood Institute Heart and Lung Tolerance Working Group.[142] While a myriad of protocols have induced tolerance in small animals, only a few have been reproduced in swine or nonhuman primate transplant models. The list of studies relevant to thoracic surgery shrinks further when considering the elusiveness of translating tolerance protocols from one organ to the other. In addition, there is a general belief that induction of tolerance in thoracic organs is more difficult than for other organs, such as the liver or kidney.[143] To date, only three protocols have induced prolonged survival of cardiac allografts in large animals without immunosuppression (none in lung allografts): (1) the induction of mixed chimerism, which is thought to work through central tolerance, (2) the use of costimulatory blockade to induce peripheral tolerance, and (3) the cotransplantation of heart and kidney allografts, which works by unknown mechanisms.[143]

By introducing allogenic bone marrow cells into newborn mice, Billingham and colleagues induced a mixed chimeric state that was the first demonstration of allograft tolerance in 1953.[144] A recent analysis of renal transplant recipients from sibling donors has shown this type of tolerance to occur toward noninherited maternal HLA owing to prior in utero exposure to this foreign antigen.[145] In these mixed chimeras, bone marrow–derived elements of both host and donor appear in the thymus and present ligands for negative selection of newly developing T cells that are either donor or host reactive.[146] This induces clonal deletion, one of the most reliable approaches to achieving long-term donor-specific tolerance. In an adult organism, creation of a mixed chimera requires the infusion of donor hematopoietic cells along with a conditioning regimen to enhance engraftment. Conditioning using antilymphocyte serum has been attempted but has produced little[147] to no[148] evidence of durable hematopoietic cell engraftment and minimal impact on allograft survival. The most common method employed in preclinical and clinical trials has been the use of a toxic dose of total lymphoid irradiation (TLI), similar to that used to treat Hodgkin disease.[149] The use of a nonmyeloablative conditioning regimen of CD3 monoclonal Abs bound to the diphtheria immunotoxic instead of TLI has enabled the induction of stable mixed chimerism using donor stem cells with significantly less toxicity. Subsequent transplantation resulted in long-term tolerance in the swine model despite a minor-antigen mismatched histocompatibility barrier. Recently, the use of pleuripotent embryonic stem cells has allowed the development of mixed chimerism and tolerance without conditioning in rodents.[150] These preliminary results have not yet been reproduced in large animal models.

It has been observed that in heart[151] and lung[152] transplant recipients enjoying long-term survival, donor-type lymphoid and dendritic cells migrate from the graft and establish themselves in the unconditioned recipient's periphery.[153] In this case, donor cells exist at levels below cytometric detection in the periphery of solid-organ transplant recipients (1 in 10^5 cells, as detected by PCR techniques) with a kinetics and patchy distribution that resemble a spreading infection. In lung transplant recipients, this microchimerism has been associated with donor-specific hyporeactivity and a lower incidence of OB.[154]

The observations that microchimerism is a common event after heart and lung transplantation and that it is associated with long-term graft acceptance have stimulated attempts to augment microchimerism with perioperative bone marrow transfusion. Pham and colleagues have provided proof of the principle that induced microchimerism influences acute and chronic rejection in clinical heart[155] and lung[156] transplantation without producing graft-versus-host disease. However, a causal relationship between microchimerism and a decrease in target events such as rejection or graft survival was not established. The association between microchimerism and graft survival is inconsistent with the identification of both long-term survivors who do not have it and patients with multiple episodes of rejection who do.[157] Furthermore, only mixed chimerism, and not microchimerism, has been shown in animal models to induce systemic, stable allograft-specific tolerance.[158]

The second mechanism for the induction and maintenance of tolerance that occurs following costimulatory blockade is anergy, also known as *peripheral tolerance.*[159] The two-signal model of T-cell activation holds that an alloresponse to the interaction of the T-cell receptor with its antigen requires a second signal prompted by the other molecular participants of the immunologic synapse. Engagement of the T-cell receptor without these signals induces

anergy or a lack of T-cell proliferation on antigen stimulation. The advantage of this mechanism is achieved by exposing T cells to alloantigen under the umbrella of mAbs blocking costimulatory molecules such as CD28,[31] LFA-1, and CD2 ligand.The period of immunosuppression lasts only as long as the mAbs are at therapeutic levels in the host. As the mAbs clear, the immune competence returns to all antigens other than those to which tolerance had been induced.

It has long been recognized that passenger leukocytes, i.e., cells derived from the organ transplant, most commonly dendritic in nature, can escape the organ and accumulate in peripheral host lymphoid tissues. It is possible that donor-derived immature passenger dendritic cells mediate a form of anergy by indirect and direct presentation of alloantigen, with limited secondary signals necessary for T-cell proliferation. Kidney transplants are thought to have enhanced numbers of these cells as the proposed mechanism of their immunosuppressive effect on cardiac allograft rejection.

XENOTRANSPLANTATION

Animal-to-human transplantation, known as *xenotransplantation,* has been proposed to alleviate the critical shortage of human donor organs. Approximately 30% of the patients waiting for hearts and lungs will die without receiving a transplant. In 1964, four years before the first human allotransplant, Hardy attempted to replace a 68-year-old man's failing heart with one obtained from a chimpanzee.[160] Since then, there have been only six additional attempts at xenotransplantation reported using pig, sheep, baboon, or chimpanzee donors.[161,162] These cases, although unsuccessful, have provided insight and promise to the field. In 1984, Bailey and colleagues placed an ABO-incompatible baboon heart into a child with a hypoplastic left heart syndrome. Baby Faye, as the child was known, made remarkable progress for 20 days, when rather suddenly the xenograft stopped functioning. Examination of the heart gave evidence consistent with a humoral rejection, perhaps related to the blood group incompatibility.

Although nonhuman primates provide concordant organs for cross-species transplantation, phylogenetically disparate or discordant donor organs from pigs are favored for several reasons. First, broad use of the relatively rare and sentient primates is unlikely to gain societal acceptance. Second, retroviruses from pigs are much less likely than those from nonhuman primates to transmit disease to humans.[163] Finally, the short gestation, time to maturation, and large litters of pigs relative to primates simplify their breeding and improve their candidacy for germ-line gene therapy. Accordingly, the porcine heart has been the focus of most of the experimental work in heart and lung xenotransplantation and was the most recent clinical xenograft reported for use in cardiac transplantation in 1992.[164]

Xenograft Hyperacute Rejection

The first major obstacle to discordant cross-species transplantation generally is believed to be the process described as hyperacute rejection (HAR). Hyperacute rejection is mediated largely by preformed xenoreactive antibodies and the relative incompatibility of discordant xenograft complement regulatory proteins (e.g., decay-accelerating factor) with the human complement system. The primary human xenoreactive antibodies that initiate HAR against discordant pig hearts are specific for the blood group carbohydrate Gal (1–3 Gal), an antigen not present in concordant nonhuman primates.[165,166] Using the classical pathway, the binding of xenoreactive antibodies to the pig endothelium leads to the unregulated activation of complement owing to inadequate function of swine counterregulatory proteins for human complement. The resulting uncontrolled deposition of the terminal complement complexes (C5b67) on the swine endothelial cells disrupts the endothelial cell barrier function because they retract and generate intracellular gaps (type 1 activation). Platelets then are attracted to exposed extracellular matrix and release vasoactive substances, including thromboxane A2, that stimulate vasoconstriction. The procoagulant state is intensified because of the loss of heparin sulfate proteoglycans from their surfaces.

These findings have led White, Pedor, and Platt to develop swine that are transgenic for human DAF and CD-59. By overexpressing human DAF and CD-59, these transgenic organs successfully avert hyperacute rejection following pig-to-primate renal, heart, and lung transplantation.[167–169] The temporary, pretransplant depletion of complement using cobra venom[34] and anti-Gal antibodies using any of several different methods has provided further success against HAR.[170] Evidence exists that if HAR and acute vascular rejection (AVR) can be prevented initially, then the xenograft may "accommodate" in a manner in which it becomes resistant to future exposure to human antibody and complement.[36,171] This is thought to be mediated by increased expression of antiapoptotic genes and inhibition of NF-κB transcriptional activation in the xenograft endothelium. The enhancement of this pathway would serve obvious benefits in xenotransplantation. However, the greatest potential for a significant advance has been achieved by the recent creation of Gal-1,3 galactosyl transferase knockout pigs.

Acute Vascular Xenograft Reaction

Despite prevention of HAR by either disrupting antibody binding or by depleting or inhibiting complement, xenografts are subjected to a process named *acute vascular rejection* (AVR).[171] Although the histologic picture of AVR with its hemorrhage and thrombosis is very characteristic of HAR, it appears to be a distinct process not dependent on complement or appearing in concordant transplant combinations. The pathophysiology begins with naturally occurring antipig antibodies binding to the endothelial surface. This leads to levels of complement activation through the

membrane attack complex (MAC) that are below lytic levels but that lead to the induction of IL-1, which mediates other changes on the surface of the endothelial cell that, by and large, create a strongly procoagulant state (type 2 activation). These changes include the induction of procoagulant tissue factor, release of plasminogen activator inhibitor, a decrease in tissue plasminogen activator, and a loss in thrombomodulin activity. Thrombomodulin is expressed on the surface of vascular endothelial cells and reduces thrombotic process by thrombin-dependent activation of protein C, which, in turn, degrades the procoagulant cofactors factors Va and VIIIa. It has been noted also that E-selectin, responsible for leukocyte rolling on the endothelium, is also upregulated during AVR.

Cell-Mediated Xenograft Rejection

Although cell-mediated rejection has not been studied extensively in the xenograft model because of difficulties in overcoming HAR and AVR, recent investigations have suggested that xenografts have increased susceptibility to cell-mediated injury and as well as to attack by natural killer (NK) cells.[172] NK cells normally are inhibited by class I MHC receptors, yet when added to xenograft tissue culture, NK cells have been demonstrated to cause cytotoxicity and phenotypic changes in a disruptive endothelial cell monolayer consistent with retraction and gap formation typical of the activated endothelium described in HAR.[173,174] It was hoped that thymic selection, which permits T lymphocytes to recognize allogeneic cells directly, might be less effective in producing T lymphocytes that might recognize the porcine xenogenic cells. However, it has been determined that human T cells can recognize porcine cells directly through MHC class II antigen.[175]

Significant progress has been made with the discordant porcine-to-primate model. However, an impact on human transplantation awaits additional studies that promote a further understanding of the effects of the inhibition of early HAR, methods to persistently reduce AVR, and finally, a way of dealing with an enhanced cell-mediated rejection. It is likely that a combination of immunosuppressants, transgenic animals, and even tolerance-induction protocols may provide a suitable therapeutic cocktail. Chief clinical investigators in the field of xenotransplantation have stressed the need to look for intermediate endpoints as means of understanding processes because the long-term goal of routinely successful discordant xenografting will require solving multiple complex processes. It is likely, then, that well-prepared surgical groups will soon initiate bridge trials in which short-term survival of the xenograft might be predicted, and information gained will be invaluable to the science.

CHAPTER 65

Heart Transplantation

Lois U. Nwakanma • Ashish S. Shah • John V. Conte • William A. Baumgartner

The number of patients with heart failure is growing. End-stage heart failure is associated with significant morbidity, need for recurrent hospitalizations, decrease in quality of life, and increased mortality. Cardiac transplantation has evolved as an effective therapy for many of these patients. Tremendous advancements in the fields of immunosuppression, rejection, and infection have transformed what was once considered an experimental intervention into a routine treatment available worldwide.

HISTORY OF HEART TRANSPLANTATION

The innovative French surgeon Alexis Carrel performed the first heterotopic canine heart transplant with Charles Guthrie in 1905.[1,2] Frank Mann at the Mayo Clinic further explored the idea of heterotopic heart transplantation in the 1930s. The neck became the preferred site of implantation in early experimental animal models because of the ease of monitoring the organ and the simplicity of gaining access to major vessels and because the recipient's heart acted as a built-in cardiac assist device for the transplanted organ.[3] Mann also proposed the concept of cardiac allograft rejection, which involved biologic incompatibility between donor and recipient manifested by an impressive leukocytic infiltration of the rejecting myocardium. In 1946, after unsuccessful attempts in the inguinal region, Vladimir Demikhov of the Soviet Union successfully implanted the first intrathoracic heterotopic heart allograft.[4] He later demonstrated that heart-lung and isolated lung transplantation also were technically feasible.

The use of moderate hypothermia, cardiopulmonary bypass, and an atrial cuff anastomotic technique permitted Norman Shumway (Fig. 65-1) and Richard Lower at Stanford University to further explore orthotopic heart transplantation using a canine model in 1960.[5] The first human cardiac transplant was a chimpanzee xenograft performed at the University of Mississippi by James Hardy in 1964.[6] Although the procedure using Shumway's technique was technically satisfactory, the primate heart was unable to maintain the recipient's circulatory load, and the patient succumbed several hours postoperatively. Despite great skepticism that cardiac transplantation ever would be performed successfully in humans, South African Christiaan Barnard surprised the world when he performed the first human-to-human heart transplant on December 3, 1967.[7] Over the next several years, poor early clinical results led to a moratorium on heart transplantation, with only the most dedicated centers continuing experimental and clinical work in the field. The pioneering efforts of Shumway and colleagues at Stanford eventually paved the way for the reemergence of cardiac transplantation in the late 1970s. The introduction of transvenous endomyocardial biopsy by Philip Caves in 1973 finally provided a reliable means for monitoring allograft rejection.[8] Ultimately, however, it was the advent of the immunosuppressive agent cyclosporine that dramatically increased patient survival and marked the beginning of the modern era of successful cardiac transplantation in 1981.[9,10] Heart transplantation is now a widely accepted therapeutic option for end-stage cardiac failure; however, the annual number of transplants in the United States (approximately 2200 per year) has remained relatively constant because of limited donor-organ availability.[11]

THE CARDIAC TRANSPLANT RECIPIENT

Recipient Selection

The evaluation of patients with end-stage heart disease and the selection of potential candidates for cardiac transplantation are undertaken by a multidisciplinary committee to ensure an equitable, objective, and medically justified allocation of the limited donor organs to patients with the greatest

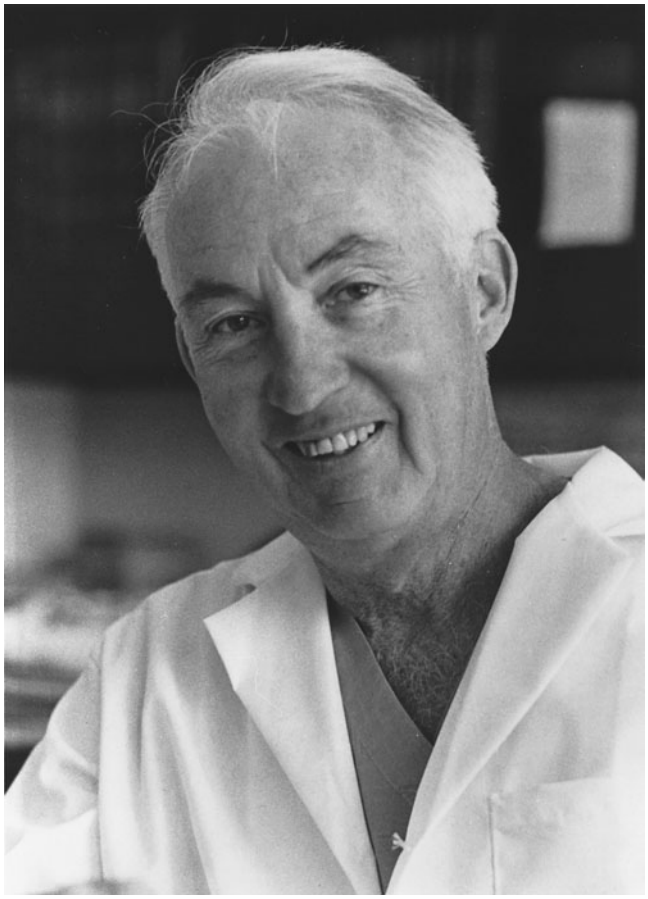

Figure 65-1. Norman Shumway.

chance of postoperative survival and rehabilitation. It is very important to establish a mutual long-term working relationship between patient, social support system, and the entire team at the beginning.

Indications and potential contraindications for cardiac transplantation are outlined in Table 65-1.[12] These inclusion and exclusion criteria vary somewhat among transplantation centers.[12–16] The basic objective is to identify those relatively healthy patients with end-stage cardiac disease refractory to other appropriate medical and surgical therapies who possess the potential to resume a normal active life and maintain compliance with a rigorous medical regimen after cardiac transplantation.

Etiology of end-stage cardiac failure

Determination of the etiology and potential reversibility of end-stage heart failure is critical for the selection of transplant candidates. Overall, from 1982 to 2004, the diagnosis for adult heart transplant recipients has been equally balanced between ischemic heart failure and nonischemic cardiomyopathy (45% each). Valvular (3 to 4%), adult congenital (2%), retransplantation (2%), and miscellaneous causes make up the remainder.[17]

The perception of the irreversibility of advanced cardiac failure is changing with the growing efficacy of tailored medical therapy, high-risk revascularization procedures, and newer antiarrhythmic pharmacologic agents, as well as implantable defibrillators and biventricular pacing. Additionally, other surgical modalities, such as ventricular assist devices (VADs) and surgical ventricular restoration (SVR), are gaining increasing application.[18,19] Furthermore, it is important to consider that prognosis may differ in patients with cardiomyopathy who have neither ischemic nor valvular heart disease. Caution should be exercised when judging prognosis in these patient subgroups, and a period of observation, intense pharmacologic therapy, and/or mechanical support should be undertaken before heart transplantation is considered.[16]

Evaluation of the potential cardiac transplant recipient

The complexity of the recipient evaluation mandates a team approach. The initial evaluation involves a comprehensive history and physical examination because this will help to determine etiology and contraindications. Table 65-2[15] summarizes the cardiac transplant evaluation tests. Routine hematologic and biochemical analyses and pertinent tests as illustrated by organ system are performed.

For the assessment of the heart itself, in addition to routine 12-lead electrocardiogram, Holter monitor, and echocardiography, all patients should undergo cardiopulmonary exercise testing to evaluate functional capacity if disease severity allows. Peak exercise oxygen consumption measured during maximal exercise testing ($\dot{V}O_{2,max}$) provides a measure of functional capacity and cardiovascular reserve, and an inverse relationship between $\dot{V}O_{2,max}$ and mortality in heart failure patients has been demonstrated.[20,21] Documentation of adequate effort during exercise, as evidenced by attaining a respiratory exchange ratio greater than 1.0 or achievement of an anaerobic threshold at 50 to 60% of $\dot{V}O_{2,max}$, is necessary to avoid underestimation of functional capacity.[13] Right-sided heart catheterization should be performed at the transplanting center to evaluate the severity of heart failure and thus the status level for transplant and to evaluate for the presence of pulmonary hypertension. It also helps to guide therapy while awaiting transplantation. Coronary cineangiography should be reviewed to confirm the inoperability of coronary artery lesions in ischemic cardiomyopathy. Either a positron-emission tomographic (PET) scan, a thallium-201 redistribution study, or a cardiac magnetic resonance imaging (MRI) study for viability is appropriate in selected patients who would be candidates for revascularization if sufficient viability is found.[13,15] Endomyocardial biopsy should be performed on all patients in whom the etiology of heart failure is in question, especially those with nonischemic cardiomyopathies symptomatic for fewer than 6 months.[15] This will assist in therapeutic decision making and exclude diseases such as amyloidosis, which is considered a relative contraindication to transplantation.

The neuropsychiatric evaluation should be performed by persons experienced in evaluating cardiac patients to determine if organic brain dysfunction or psychiatric illness is present. An experienced social worker should assess for the

Table 65–1.

Recipient Selection for Heart Transplantation

Indications

I. Systolic heart failure (as defined by ejection fraction <35%)
  A. Inclusive etiology
    1. Ischemic
    2. Dilated
    3. Valvular
    4. Hypertensive
    5. Other
  B. Excluded etiology
    1. Amyloid (controversial)
    2. HIV infection
    3. Cardiac sarcoma

II. Ischemic heart disease with intractable angina
  A. Ineffective maximal tolerated medical therapy
  B. Not a candidate for direct myocardial revascularization, percutaneous revascularization, or transmyocardial revascularization procedure
  C. Unsuccessful myocardial revascularization

III. Intractable arrhythmia
  A. Uncontrolled with pacing cardioverter defibrillator
    1. Not amenable to electrophysiology-guided single or combination medical therapy
    2. Not a candidate for ablative therapy

IV. Hypertrophic cardiomyopathy
  A. Class IV symptoms persist despite interventional therapies
    1. Alcohol injection of septal artery
    2. Myotomy and myomectomy
    3. Mitral valve replacement
    4. Maximal medical therapy
    5. Pacemaker therapy

V. Congenital heart disease in which severe fixed pulmonary hypertension is not a complication

VI. Cardiac tumor
  A. Confined to the myocardium
  B. No evidence of distant disease revealed by extensive metastatic work-up

Absolute Contraindications

I. Age > 70 years (may vary at different centers)

II. Fixed pulmonary hypertension (unresponsive to pharmacologic intervention)
  A. Pulmonary vascular resistance >5 Wood units
  B. Transpulmonary gradient >15 mm Hg

III. Systemic illness that will limit survival despite transplant
  A. Neoplasm other than skin cancer (less than 5 years disease free survival)
  B. HIV/AIDS (CDC definition of CD4 count of <200 cells/mm^3)
  C. Systemic lupus erythematosus (SLE) or sarcoid that has multisystem involvement and is currently active
  D. Any systemic process with a high probability of recurrence in the transplanted heart
  E. Irreversible renal or hepatic dysfunction

(continued)

Table 65–1.

Recipient Selection for Heart Transplantation (*continued*)

Potential Relative Contraindications
I. Recent malignancy
II. Chronic obstructive pulmonary disease
III. Recent and unresolved pulmonary infarction and pulmonary embolism
IV. Diabetes mellitus with end-organ damage (neuropathy, nephropathy, and retinopathy)
V. Peripheral vascular or cerebrovascular disease
VI. Active peptic ulcer disease
VI. Current or recent diverticulitis
VIII. Other systemic illness likely to limit survival or rehabilitation
IX. Severe obesity or cachexia
X. Severe osteoporosis
XI. Active alcohol or drug abuse
XII. History of noncompliance or psychiatric illness likely to interfere with long-term compliance
XIII. Absence of psychosocial support

presence of adequate social and financial support. At the time of listing, the transplant coordinator should ensure that the patient and family are informed of and understand the peculiarities of the waiting time, the preoperative period, the long-term maintenance medication, and the rules of living with the new heart. It is also important to discuss such issues as the patient's preferences for duration and type of life support if irreversible organ dysfunction ensues owing to deterioration of heart failure while awaiting transplant.

Indications for cardiac transplantation

Cardiac transplantation is reserved for a select group of patients with end-stage heart disease not amenable to optimal medical or surgical therapies. Prognosis for 1-year survival without transplantation should be less than 50%. Prediction of patient survival involves considerable subjective clinical judgment by the transplant committee because no reliable objective prognostic criteria are available currently. Low ejection fraction (<20%), reduced $\dot{V}O_{2,max}$ (<14 mL/kg per minute), arrhythmias, high pulmonary capillary wedge pressure (>25 mm Hg), elevated plasma norepinephrine concentration (>600 pg/mL), reduced serum sodium concentration (<130 mEq/dL), and more recently, N-terminal probrain natriuretic peptide (>5000 pg/mL) all have been proposed as predictors of poor prognosis and potential indications for transplantation in patients receiving optimal medical therapy.[20–26] Reduced left ventricular ejection fraction and low $\dot{V}O_{2,max}$ are widely identified as the strongest independent predictors of survival.

The indications for cardiac transplantation listing are continuously reviewed as new breakthroughs in the medical and surgical treatment of heart disease emerge.

Contraindications for cardiac transplantation

Table 65-1 lists the traditional absolute and relative contraindications. It should be acknowledged that strict guidelines can be problematic; therefore, each transplant program will vary regarding absolute criteria based on clinical circumstances. Furthermore, traditional contraindications for transplant listing are being questioned. Age is one of the most controversial exclusionary criteria for transplantation. The upper age limit for recipients is center-specific, but emphasis should be placed on the patient's physiologic rather than chronologic age. The Official Adult Heart Transplant Report 2005 from the registry of the International Society for Heart and Lung Transplantation (ISHLT) noted that over the last 20 years, the percentage of recipients older than 60 years of age has increased steadily, approaching 25% of all heart transplants between 1999 and 2003 compared with just above 5% between 1982 and 1988.[17,27] Although the elderly have a greater potential for occult systemic disease that may compli-

Table 65–2.

Cardiac Transplant Evaluation Tests

Laboratory	Complete blood count with differential and platelet count, creatinine, blood urea nitrogen, electrolytes, liver panel, lipid panel, calcium, phosphorus, total protein, albumin, uric acid, thyroid panel, antinuclear antibodies, erythrocyte sedimentation rate (ESR), rapid plasma reagin (RPR), iron binding tests, partial thromboplastin time, prothrombin time Blood type, IgG and IgM antibodies against cytomegalovirus, herpes simplex virus, HIV, varicella-zoster virus, hepatitis B surface antigen, hepatitis C antigen, toxoplasmosis, other titers when indicated Tuberculin skin test Prostate-specific antigen (male >50 years) Mammogram and Pap smear (female >40 years) Screening against a panel of donor antigens (panel reactive antibodies) and human leucocyte antigen phenotype 24-hour urine for creatinine clearance and total protein, urinalysis, urine culture Baseline bacterial and fungal cultures, stool for ova and parasites if indicated
Cardiac	12-lead ECG, 24-hour Holter monitor Echocardiogram Thallium-201 imaging, positron-emission tomographic (PET) scan, or cardiac magnetic resonance imaging (MRI) to assess viability if indicated Exercise stress test and respiratory gas analysis with oxygen uptake measurements: peak exercise oxygen consumption ($\dot{V}O_{2,max}$). Right- and left-sided heart catheterization at the transplant center Myocardial biopsy on selected patients in whom etiology of heart failure is in question
Vascular	Peripheral vascular studies Carotid Doppler and duplex ultrasound >55 years
Renal	Renal ultrasound and or intravenous pyelogram if indicated
Pulmonary	Chest x-ray Pulmonary function tests Chest CT scan to evaluate abnormal chest x-ray or thoracic aorta in older patients (usually >65 years)
Gastrointestinal	Upper endoscopy/colonoscopy if indicated Upper gastrointestinal series and/or barium enema if indicated Percutaneous liver biopsy if indicated
Metabolic	Bone densitometry
Neurologic	Screening evaluation
Psychiatric	Screening evaluation
Dental	Complete dental evaluation
Physical therapy	Evaluation
Social work	Patient attitude and family support, medical insurance, and general financial resources
Transplant coordinator	Education

cate their postoperative course, some recent reports have suggested that morbidity and mortality in carefully selected older patients are comparable with those of younger recipients, and they have fewer rejection episodes than younger patients.[28–31]

Fixed pulmonary hypertension (PH), usually manifested as elevated pulmonary vascular resistance (PVR), is one of the few absolute contraindications to orthotopic cardiac transplantation. Fixed PH increases the risk of acute right ventricular failure when the right ventricle of the allograft is unable to adapt to significant PH in the immediate postoperative period.[32] Use of the transpulmonary gradient (TPG), which represents the pressure gradient across the pulmonary vascular bed independent of blood flow, may avoid erroneous estimations of PVR, such as those that may occur in patients with low cardiac output.[16] Some have advocated the use of PVR index unit (PVRI), which corrects for body size.[33]

PVR, PVRI, and TPG are calculated by means of following formulas:

$$\text{PVR (Wood units)} = \frac{\text{MPAP (mm Hg)} - \text{PCWP (mm Hg)}}{\text{CO (L/min)}}$$

$$\text{PVRI (units)} = \frac{\text{MPAP (mm Hg)} - \text{PCWP (mm Hg)}}{\text{CO (L/min)} \times \text{BSA}} = \frac{\text{PVR}}{\text{BSA}}$$

$$\text{TPG (mm Hg)} = \text{MPAP (mm Hg)} - \text{PCWP (mm Hg)}$$

where MPAP is mean pulmonary arterial pressure, PCWP is pulmonary capillary wedge pressure, CO is cardiac output, CI is cardiac index, and BSA is body surface area.

A fixed PVR greater than 5 to 6 Wood units and a TPG greater than 15 mm Hg generally are agreed as absolute criteria for rejection of a candidate.[12,13,15,16,26] Over the years, several studies have found PH to have a significant effect on posttransplant mortality using variable parameters, threshold values, and follow-up periods.[33–38] There are also a few studies that found no significant difference in mortality at different time periods after transplantation between patients with and without preoperative PH.[39,40] Perhaps more significantly, measurable parameters of pulmonary hypertension improved significantly after heart transplantation. A study of 172 patients followed for up to 15.1 years, published in 2005 from the Johns Hopkins Hospital, showed that mild to moderate pretransplantation PH (PVR = 2.5 to 5.0 Wood units) was not associated with higher mortality rate, although there was increased risk of posttransplantation PH within the first 6 months.[41] However, when the continuous variable PVR was examined, each 1 Wood unit increase in preoperative PVR demonstrated a 15% or more increase in mortality, especially within the first year, but these associations did not reach statistical significance. Severe preoperative PH (PVR $\geq$ 5 Wood units) was associated with death within the first year after adjusting for potential cofounders but not with overall mortality or mortality at other time points.

In the preoperative evaluation of the transplant recipient, if PH is discovered, an assessment of its reversibility should be performed in the cardiac catheterization laboratory.[36] Sodium nitroprusside traditionally has been used at a starting dose of 0.5 μg/kg per minute and titrated by 0.5 μg/kg per minute until there is an acceptable decline in PVR, ideally 2.5 Wood units or at least by 50%, with maintenance of adequate systemic systolic blood pressure. If sodium nitroprusside fails to produce an adequate response, other vasodilators such as adenosine, prostanglandin E_1, milrinone, or inhaled nitric oxide or prostacyclin (e.g., aerosolized Illoprost) may be used.[13,42–44] Some patients who do not respond acutely may respond to continuous intravenous inotropic therapy, and repeat catheterization can be performed after 48 to 72 hours. Intravenous B-type natriuretic peptide, e.g., nesiritide (Natrecor), has shown some efficacy in refractory pulmonary hypertension.[45] Recently, ventricular assist devices (VADs) are playing an important role in heart transplantation candidates with PH.[46] A period of left ventricular assist device (LVAD) support may allow for a decrease of pulmonary artery pressure secondary to unloading of the left ventricle. Patients with irreversible PH may be candidates for heterotopic heart or heart-lung transplantation.[47] Use of modestly larger donor hearts for recipients with severe pretransplantation PH can provide additional right ventricular reserve.

Systemic diseases with poor prognosis and potential to recur in the transplanted heart or the potential to undergo exacerbation with immunosuppressive therapy are considered absolute contraindications for heart transplantation. Heart transplantation for amyloid remains controversial because amyloid deposits recur in the transplanted heart. Although case reports of long-term survival can be found in the literature,[48] survival beyond 1 year tends to be reduced.[49] In some cases, patients now have combined heart and kidney or heart and liver transplant for amyloidosis.[50] Human immunodeficiency virus (HIV)–infected patients generally are excluded. Previously, any occurrence of neoplasm was a reason to exclude patients from transplantation. Currently available data do not appear to justify excluding these patients.[14,51] Most surgeons consider only patients who are free of disease for at least 5 years.

Irreversible renal dysfunction is a contraindication to heart transplantation. A creatinine clearance of less than 50 mL/min and a serum creatinine concentration of greater than 2 mg/dL are associated with increased risk of postoperative dialysis and decreased survival following heart transplantion.[16,52,53] However, patients may be considered for combined heart and kidney transplantation. Irreversible hepatic dysfunction has implications similar to renal dysfunction.[16] If transaminase levels are more than twice their normal value and associated with coagulation abnormalities, percutaneous liver biopsy should be performed to exclude primary liver disease. This should not be confused with chronic cardiac hepatopathy, which is characterized by elevated cholestatic parameters along with little or no changes in transaminases and is potentially reversible after heart transplantation.[54]

Severe chronic bronchitis or obstructive pulmonary disease may predispose patients to pulmonary infections and may result in prolonged ventilatory support after heart

transplantation. Patients who have a ratio of forced expiratory volume in 1 second to forced vital capacity (FEV_1/FVC) of less than 40 to 50% of predicted or an FEV_1 of less than 50% of predicted despite optimal medical therapy are considered poor candidates for transplantation.[13,16] Transplantation in patients with diabetes mellitus is only contraindicated in the presence of significant end-organ damage (e.g., diabetic nephropathy, retinopathy, or neuropathy).[13,14,16] Some centers have expanded their criteria successfully to include patients with mild to moderate end-organ damage.[55] Active infection was a sound reason to delay transplantation before assist devices became more commonplace. Up to 48% of patients with implanted LVADs reportedly have evidence of infection. Interestingly, treatment for LVAD infection in these patients is to proceed with urgent transplantation.[56]

Other relative contraindications include severe noncardiac atherosclerotic disease, severe osteoporosis, and active peptic ulcer disease or diverticulitis, all of which may lead to increased morbidity.[13,14,16] Cachexia, defined as a body mass index (BMI) of less than 20 or less than 80% ideal body weight (IBW), and obesity, defined as BMI greater than 35 or greater than 140% of IBW, are associated with an increased mortality after transplantation.[57] Poor nutritional status also may limit early postoperative rehabilitation.

The ultimate success of transplantation depends on the psychosocial stability and compliance of the recipient.[58] The rigorous postoperative regimen of multidrug therapy, frequent clinic visits, and routine endomyocardial biopsies demands commitment on the part of the patient. A history of psychiatric illness, substance abuse, or previous noncompliance (particularly with medical therapy for end-stage heart failure) may be sufficient cause to reject the candidacy of a patient. Lack of a supportive social system is an additional relative contraindication.

Management of the Potential Cardiac Recipient

Medical therapy for end-stage cardiac failure

In addition to conventional management of congestive heart failure, specific comorbidities should be managed aggressively. Patients with elevated levels of preformed panel reactive antibodies (PRAs) to human leukocyte antigens (HLAs) have higher rates of organ rejection and decreased survival than do patients without such antibodies.[59] Consequently, before proceeding with transplantation, many medical centers do prospective cross-matching, i.e., mix lymphocytes from the organ donor with sera from the prospective organ recipient, to determine whether a higher rejection rate or an immediate episode of rejection will occur. The problem has been compounded by the increased frequency of preformed reactive antibodies in patients with VADs who are awaiting cardiac transplantation.[60] Performing a prospective crossmatch can be time-consuming and often is impossible because of the unstable condition of the organ donor or travel logistics, leading to increased costs for transplantation and longer waiting times for recipients. Plasmapheresis, intravenous immunoglobulins, cyclophosphamide, and mycophenolate mofetil all have been used to lower the PRA levels with variable results.[13,61]

Pharmacologic bridge to transplantation

Critically compromised patients require admission to the intensive-care unit for intravenous inotropic therapy. Dobutamine, a synthetic catecholamine, remains the prototype of this drug group. However, the phosphodiesterase III inhibitor milrinone is similarly effective.[62,63] The catecholamine dopamine is used often as a parenteral positive inotrope, but at moderate to high dose it evokes considerable systemic vasoconstriction. In candidates in whom an inotropic infusion has progressed to higher doses, combinations of dobutamine with milrinone are used. For transplant candidates dependent on inotropic infusions, eosinophilic myocarditis may develop as an allergic response to the dobutamine and may result in accelerated decline.[64] VADs are being considered earlier, particularly as indices of nutrition decline.

Mechanical bridge to transplantation

Placement of an intra-aortic balloon pump (IABP) may be necessary in patients with heart failure who are refractory to initial pharmacologic measures. Ambulatory IABP through the axillary artery has been reported in few patients as a bridge to cardiac transplantation.[65]

The landmark Randomized Evaluation of Mechanical Assistance in Treatment of Chronic Heart Failure (REMATCH) trial provided evidence that LVAD support provided a statistically significant reduction in the risk of death from any cause when compared with optimal medical management. The survival rates for patients receiving LVADs ($n = 68$) versus patients receiving optimal medical management ($n = 61$) were 52% versus 28% at 1 year and 29% versus 13% at 2 years ($P = .008$, log-rank test).[18,66] The extended follow-up confirmed the initial observation that LVAD therapy renders significant survival and quality-of-life benefits compared with optimal medical management for patients with end-stage heart failure. A recent systematic review of the published literature supported these findings. In the studies reviewed, implantation of an LVAD provided support for up to 390 days, with as many as 70% of patients surviving to transplantation.[67]

The total artificial heart (TAH) positioned orthotopically replaces both native cardiac ventricles and all cardiac valves. Potential advantages of this device include eliminating problems commonly seen in the bridge to transplantation with left ventricular and biventricular assist devices, such as right-sided heart failure, valvular regurgitation, cardiac arrhythmias, ventricular clots, intraventricular communications, and low blood flows. Copeland and colleagues reported that the TAH allowed for bridge to transplantation in 79% of their patients with 1 year and 5-year survival rates after transplantation of 86% and 64%, respectively.[68]

Since these devices cannot be weaned, it is imperative that the patient's candidacy for transplantation be scruti-

Table 65–3.

Current Recipient Status Criteria of the United Network for Organ Sharing (UNOS)*

Status IA
A. Patients who require mechanical circulatory assistance with one or more of the following devices: 1. Total artificial heart 2. Left and/or right ventricular assist device implanted for 30 days or less 3. Intra-aortic balloon pump 4. Extracorporeal membrane oxygenator (ECMO)
B. Mechanical circulatory support for more than 30 days with significant device-related complications
C. Mechanical ventilation
D. Continuous infusion of high-dose inotrope(s) in addition to continuous hemodynamic monitoring of left ventricular filling pressures
E. Life expectancy without transplant less than 7 days
Status IB
A. A patient who has at least one of the following devices or therapies in place: 1. Left and/or right ventricular assist device implanted for more than 30 days 2. Continuous infusion of intravenous inotropes
Status II
All other waiting patients who do not meet status Ia or Ib criteria

**UNOS Executive Order, August 1999.*

nized prior to placement of the device. Trends toward better device durability and reduced complication rates likely will continue to improve through the development of newer, more innovative VADs, allowing destination therapy to be considered more frequently.[69]

Life-threatening ventricular arrhythmias

Symptomatic ventricular tachycardia or fibrillation and a history of sudden cardiac death are indications for placement of an automatic implantable cardioverter-defibrillator (AICD), long-term antiarrhythmic therapy with amiodarone, or occasionally, radiofrequency catheter ablation, which have shown improved survival.[70,71]

Recipient Prioritization for Transplantation

The prioritization of appropriate recipients for transplantation is based on survival and quality of life expected to be gained in comparison with maximal medical and surgical alternatives.[15] The United Network for Organ Sharing is a national organization that maintains organ transplantation waiting lists and allocates identified donor organs on the basis of recipients' priority status.[72] This priority status is based on a recipient's status level (e.g., IA, IB, or II), blood type, body size, and duration of time at a particular status level.[13] Geographic distance between donor and potential recipient is also taken into consideration. Highest priority is given to local status IA patients possessing the earliest listing dates. The recipient status criteria established by UNOS in 1999 are outlined in Table 65-3. In 1994, the percentage of patients awaiting transplantation for more than 2 years was 23%; this increased to 49% by 2003. From 1999 (with the institution of a new status system) through 2003, the distribution of patient status at transplant was 40% of transplanted recipients classified as status 1A, 35% as status 1B, and 25% as status 2.[73] Patients considered for transplantation should be examined at least every 3 months for reevaluation of recipient status. Yearly right-sided heart catheterization is indicated for all candidates on the waiting list and in selected cases for patients rejected because of pulmonary hypertension. Presently, there is no established method to delist patients who have stabilized on medical therapy without loss of their previously accrued waiting time.

THE CARDIAC DONOR

Donor Availability

The availability of donor organs remains the major limiting factor to heart transplantation. In the early years of heart

transplantation, the number of heart transplants performed in the United States increased steadily to a peak in 1995 of 2363 and then reached a plateau in 1998. Since 1998, there has been a gradual decline in heart transplants per year to a level of 2055 in 2003.[73] Interestingly, likely owing to improved preoperative care, the death rate for patients on the waiting list for a cardiac allograft has decreased steadily.[73]

The Uniform Anatomic Gift Act of 1968 states that all competent individuals over the age of 18 may donate all or part of their bodies and established the current voluntary basis of organ donation practiced in the United States.[74] To accommodate the increasing demand for organs, the original stringent criteria for donor eligibility have been relaxed, and educational campaigns have increased awareness of the need for a larger donor pool. In 1986, the Required Request Law, which required hospitals to request permission from next of kin to recover organs, was passed to encourage physician compliance in the donor request process.[75] Future reforms will be molded by the evolving public attitude to transplantation and likely will focus on continued public and physician education.

Allocation of Donor Organs

In an effort to increase organ donation and to coordinate an equitable allocation of allografts, Congress passed the National Organ Transplant Act in 1984.[76] This act resulted in the drafting of the aforementioned Required Request Law, as well as the awarding of a federal contract to the United Network of Organ Sharing (UNOS) for the development of a national organ procurement and allocation network.[77] To facilitate transplantation, the United States is divided into 11 geographic regions.

Organs are offered to sick patients within the region in which they were donated before being offered to other parts of the country. This helps to reduce organ preservation time, improve organ quality and survival outcomes, reduce the costs incurred by the transplant patient, and increase access to transplantation.

Donor Selection

Once a brain dead individual has been identified as a potential cardiac donor, the patient undergoes a rigorous three-phase screening regimen. The primary screening is undertaken by the organ procurement agency. Information regarding the patient's age, height and weight, gender, ABO blood type, hospital course, cause of death, and routine laboratory data including cytomegalovirus (CMV), HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) serologies are collected. Cardiac surgeons or cardiologists perform the secondary screening, which involves further investigation in search of potential contraindications (Table 65-4), determination of the hemodynamic support necessary to sustain the donor, and review of the electrocardiogram, chest roentgenogram, arterial blood gas determination, and echocardiogram. Even when adverse donor criteria are reported, a team often is dispatched to the hospital to evaluate the donor on-site.

Table 65–4.

Donor Selection for Heart Transplantation

I. Suggested criteria for cardiac donor
   A. Age < 55
   B. Absence of the following:
      1. Prolonged cardiac arrest
      2. Prolonged severe hypotension
      3. Preexisting cardiac disease
      4. Intracardiac drug injection
      5. Severe chest trauma with evidence of cardiac injury
      6. Septicemia
      7. Extracerebral malignancy
      8. Positive serologies for human immunodeficiency virus, hepatitis B (active), or hepatitis C
      9. Hemodynamic stability without high-dose inotropic support (<20 μg/kg per minute of dopamine)

II. Suggested cardiac donor evaluation
   A. Past medical history and physical examination
   B. Electrocardiogram
   C. Chest roentgenogram
   D. Arterial blood gases
   E. Laboratory tests (ABO, HIV, HBV, HCV)
   F. Echocardiogram, pulmonary artery catheter evaluation, and in selected cases, coronary angiogram

Although echocardiography is effective in screening for anatomic abnormalities of the heart, the use of a single echocardiogram to determine the physiologic suitability of a donor is not supported by evidence.[78] The Papworth Hospital transplant program in Great Britain increased its donor yield substantially by using a pulmonary artery catheter to guide the physiologic assessment and management of ventricular dysfunction.[79] Coronary angiography is indicated in the presence of advanced donor age (traditionally for male donors > 45 years of age and female donors > 50 years of age).[80] Angiography also should be performed if there is a history of cocaine use or if the donor has three risk factors for coronary artery disease (CAD), such as hypertension, diabetes, smoking history, dyslipidemia, or family history of premature CAD.[78]

The final and often most important screening of the donor occurs intraoperatively at the time of organ procurement by the cardiac surgical team. Direct visualization of the heart is performed for evidence of ventricular or valvular dysfunction, previous infarction, or myocardial contusion secondary to closed-chest compressions or blunt chest trauma. The coronary arterial tree is palpated for gross calcifications indicative of atheromatous disease. If direct examination of the heart is unremarkable, the recipient hospital is notified, and the procurement surgeons proceed with donor cardiectomy, usually in conjunction with multiorgan procurement.

Expanded Donor Criteria and Alternate Listing

As the donor shortage has worsened and the number of patients waiting for transplants has increased, one of the areas of increasing interest is the use of marginal donors for marginal recipients. For this purpose, an alternate recipient list is being used by some centers to match certain recipients who might be excluded from a standard list with marginal donor hearts that otherwise would go unused. Expanded donor criteria include the use of donors substantially smaller than the recipients, donors with coronary artery disease that may require coronary artery bypass grafting (CABG), left ventricular dysfunction, or donors from older age groups.[78] Acceptable operative mortality has been reported,[81] and the University of California, Los Angeles (UCLA) heart transplant group has shown that alternate listing did not independently predict early or late mortality.[82]

It also appears more beneficial in terms of patient survival to receive an allograft from a donor older than 40 years of age than to remain on the waiting list.[83] Other high-risk donors, such as HCV-positive or HBV (core IgM-negative)–positive donors, may be appropriate in selected higher-risk recipients.[78]

Also of special interest is the effect of donor alcohol and cocaine abuse on heart transplantation. A small single-center study showed unfavorable early outcome of patients receiving hearts from alcoholic donors (>2 oz of pure alcohol daily for 3 or more months), suggesting the presence of a subclinical preoperative alcoholic cardiomyopathy and poor tolerance of rejection episodes after transplantation.[84] Because of widespread cocaine abuse, donor guidelines have declared intravenous drug abuse a "relative" contraindication for donor selection.[80] However, the dilemma of selecting donor hearts from nonintravenous drug abusers remains an open issue. A favorable outcome for patients who received transplanted hearts obtained from nonintravenous cocaine users has been reported.[85] However, judicious use of donors with a history of cocaine use is strongly advised.[86] Specific recommendations were made in a recent consensus report to improve the yield of donor hearts.[78]

Management of the Cardiac Donor

Medical management of cardiac donors, an integral part of organ preservation, is complicated by the complex physiologic phenomenon of brain death and the need to coordinate procurement with other organ donor teams. Brain death is associated with an "autonomic and cytokine storm." The release of noradrenaline (norepinephrine) leads to subendocardial ischemia. Subsequent cytokine release results in further myocardial depression. This is accompanied by pronounced vasodilatation and loss of temperature control.[15] Rapid afterload reduction may be achieved with sodium nitroprusside, whereas volatile anesthetics assist in reducing the intensity of sympathetic bursts. The initial period of intense autonomic activity is followed by loss of sympathetic tone and a massive reduction in systemic vascular resistance. Overall, brain stem death results in severe hemodynamic instability, the degree of which appears to be directly related to the severity of the brain injury and may result from vasomotor autonomic dysfunction, hypovolemia, hypothermia, and dysrhythmias.[87]

Aggressive volume resuscitation sometimes is necessary, and the use of a Swan-Ganz catheter may be crucial to guide therapy.[88] Fluid overload should be avoided to prevent postoperative allograft dysfunction caused by chamber distension and myocardial edema. Inotropic support (e.g., dopamine or dobutamine, epinephrine, or norepinephrine) to maintain a mean arterial blood pressure (MAP) of 60 mm Hg or more in the presence of a central venous pressure (CVP) of 6 to 10 mm Hg is recommended.[78] ATP is depleted rapidly by exogenous catecholamine administration, and this has an adverse effect on posttransplantation cardiac function.[87] Low-dose vasopressin is being used increasingly as first-line support because, in addition to treating diabetes insipidus, it independently improves arterial blood pressure and reduces exogenous inotrope requirements in brain stem dead donors.[89,90] Maintenance of normal temperature, electrolyte levels, osmolarity, acid-base balance, and oxygenation is critical for optimal donor management. Central diabetes insipidus develops in more than 50% of donors because of pituitary dysfunction, and massive diuresis complicates fluid and electrolyte management.[91] The initial treatment of diabetes insipidus is aimed at correcting hypovolemia and returning the plasma sodium concentration to normal levels by fluid replacement with 5% dextrose or nasogastric water. In severe cases, intermittent treatment with the synthetic

analogue 1-D-amino-8-D-arginine vasopressin (DDAVP) also may be required in addition to vasopressin infusion.[87]

Several studies have demonstrated beneficial effects of thyroid hormones and steroids on cardiac performance in brain stem dead organ donors.[79,89,92] Recent guidelines advocate the addition of a standardized hormonal resuscitation package consisting of methylprednisolone (15 mg/kg bolus), triiodothyronine (4-μg bolus followed by infusion of 3 μg/h), and arginine vasopressin (1-unit bolus followed by 0.5 to 4 units/h) to the standard donor management protocol.[78] Donors also receive insulin, titrated to keep blood glucose at 120 to 180 mg/dL. Other pertinent strategies include standard ventilator management with diligent endotracheal suctioning and a thermoregulation goal of 34 to 36°C using warming blankets and lights, warm intravenous fluids, and warm inspired air. Broad-spectrum antibiotic therapy with a cephalosporin is initiated following collection of blood, urine, and tracheal aspirate for culture. The approach for management of the cardiac donor recommended at the conference entitled, "Maximizing Use of Organs Recovered from the Cadaver Donor: Cardiac Recommendations," is shown on Table 65-5 and summarized in Fig. 65-2.[78]

Table 65–5.

Management of the Cardiac Donor

I. Conventional management, before the initial echocardiogram
   - A. Adjust volume status (target central venous pressure 6 to 10 mm Hg).
   - B. Correct metabolic perturbations, including
     1. Acidosis (target pH 7.40 to 7.45).
     2. Hypoxemia (target P_{O_2} > 80 mm Hg, O_2 saturation >95%).
     3. Hypercarbia (target P_{CO_2} 30 to 35 mm Hg).
   - C. Correct anemia (target hematocrit 30%, hemoglobin 10 g/dL).
   - D. Adjust inotropes to maintain mean arterial pressure at 60 mm Hg. Norepinephrine and epinephrine should be tapered off rapidly in favor of dopamine or dobutamine.
   - E. Target = dopamine <10 μg/kg per minute or dobutamine <10 μg/kg per minute.

II. Obtain an initial echocardiogram
   - A. Rule out structural abnormalities (substantial left ventricular hypertrophy, valvular dysfunction, congenital lesions).
   - B. If left ventricular ejection fraction is 45%, proceed with recovery (consider aggressive management as shown below to optimize cardiac function before recovery) with final evaluation in the operating room.
   - C. If left ventricular ejection fraction is <45%, aggressive management with placement of a pulmonary arterial catheter and hormonal resuscitation is strongly recommended.

III. Hormonal resuscitation
   - A. Triiodothyronine (T_3): 4-μg bolus, then continuous infusion at 3 μg/h.
   - B. Arginine vasopressin: 1-unit bolus, then continuous infusion at 0.5 to 4 units/h, titrated to a systemic vascular resistance of 800 to 1200 dyne/s/cm^5.
   - C. Methylprednisolone: 15 mg/kg bolus
   - D. Insulin: 1 unit/h minimum; titrate to maintain blood sugar at 120 to 180 mg/dL.

IV. Aggressive hemodynamic management
   - A. Initiated simultaneously with hormonal resuscitation.
   - B. Placement of pulmonary artery catheter.
   - C. Duration of therapy 2 hours.
   - D. Adjustment of fluids, inotropes, and pressors every 15 minutes based on serial hemodynamic measurements to minimize use of beta-agonists and meet the following target (Papworth) criteria:
     1. Mean arterial pressure >60 mm Hg.
     2. Central venous pressure 4 to 12 mm Hg
     3. Pulmonary capillary wedge pressure 8 to 12 mm Hg
     4. Systemic vascular resistance 800 to 1200 dyne/s/cm^5.
     5. Cardiac index >2.4 L/min/m^2.
     6. Dopamine <10 μg/kg per minute or dobutamine <10 μg/kg per minute.

Donor Heart Procurement

A median sternotomy is performed, and the pericardium is incised longitudinally. The heart is inspected and palpated for evidence of cardiac disease or injury. The superior and inferior venae cavae and the azygous vein are mobilized circumferentially and encircled with ties. The aorta is dissected from the pulmonary artery and isolated with umbilical tape. To facilitate access to the epigastrium by the liver procurement team, the cardiac team often then temporarily retires from the operating room table or assists with retraction. Once preparation for liver, pancreas, lung, and kidney explantation is completed, the patient is administered 30,000 units of heparin intravenously. The azygous vein and superior vena cava are doubly ligated (or stapled) and divided distal to the azygous vein, leaving a long segment of superior vena cava (Fig. 65-3). The inferior vena cava is clamped at the level of the diaphragm (if the abdominal inferior vena cava is vented) and then divided proximal to the clamp to permit efflux of the cardioplegia. Additional venting is achieved with transection of the right superior pulmonary vein. If the lungs are to be recovered, the left atrial appendage is incised. The aortic cross-clamp is applied at the takeoff of the innominate artery, and the heart is arrested with a single flush (1000 mL or 10 to 20 mL/kg) of cardioplegia solution infused through a 14-gauge needle inserted proximal to the cross-clamp. Rapid cooling of the heart is achieved with copious amounts of cold saline and cold saline slush poured into the pericardial well. Following the delivery of cardioplegia, cardiectomy proceeds as the apex of the heart is elevated cephalad and any remaining intact pulmonary veins are

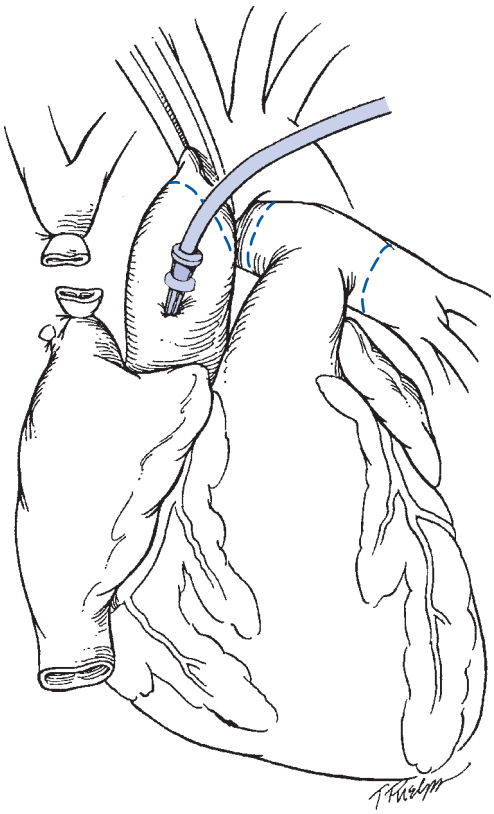

Figure 65-3. Donor cardiectomy.

divided. This maneuver is modified appropriately to retain adequate left atrial cuffs for both lungs and the heart if the lungs also are being procured. While applying caudal traction to the heart with the nondominant hand, the ascending aorta is transected proximal to the innominate artery, and the pulmonary arteries are divided distal to the bifurcation (again, modification is necessary if the lungs are being procured). More generous segments of the great vessels and superior vena cava may be required for recipients with congenital heart disease.

Once the explantation is complete, the allograft is examined for evidence of a patent foramen ovale, which should be closed at that time. Any valvular anomalies are identified. The allograft then is placed in a sterile container for transport to the recipient hospital.

Organ Preservation

Current clinical graft preservation techniques generally permit a safe ischemic period of 4 to 6 hours.[93] Factors contributing to the severity of postoperative myocardial dysfunction include insults associated with suboptimal donor management, hypothermia, ischemia-reperfusion injury, and depletion of energy stores. A single flush of a cardioplegic or preservative solution followed by static hypothermic storage at 4 to 10°C is the preferred preservation method by most transplant centers.[94] Crystalloid solutions of widely different compositions are available, and the debate over them speaks for the fact that no ideal solution currently exists. Depending on their ionic composition, solutions are classified as intracellular or extracellular.[93] Intracellular solutions, characterized by moderate to high concentrations of potassium and low concentrations of sodium, purportedly reduce hypothermia-induced cellular edema by mimicking the intracellular milieu. Commonly used examples of these solutions include University of Wisconsin, Euro-Collins, and in Europe, Bretschneider (HTK) and intracellular Stanford solutions. Extracellular solutions, characterized by low to moderate potassium and high sodium concentrations, avoid the theoretical potential for cellular damage and increased vascular resistance associated with hyperkalemic solutions. Hopkins, Celsior, Krebs, and St. Thomas Hospital solutions are representative extracellular cardioplegic solutions. Several comparisons of the different types of intracellular and extracellular solutions have shown variable results.[95–99] Although a plethora of pharmacologic additives have been included in cardioplegic-storage solutions, the greatest potential for future routine use may lie with impermeants, substrates, and antioxidants.[100] A number of pharmacologic and mechanical strategies for leukocyte inhibition and depletion also have been explored.[101] Potential benefits of continuous hypothermic perfusion (CHP) preservation such as uniform myocardial cooling, continuous substrate supplementation, and metabolic by-product washout are currently overshadowed by exacerbation of extracellular cardiac edema and logistical problems inherent to a complex perfusion apparatus. Newer portable apparatus are being developed, and recent studies showed reduction in oxidative stress and attenuation of DNA damage in canine heart transplant models preserved by 24-hour CHP compared with 4 hours of static preservation.[102–104]

Donor-Recipient Matching

Criteria for matching potential recipients with the appropriate donor are based primarily on ABO blood group compatibility and patient size. ABO barriers should not be crossed in heart transplantation because incompatibility may result in fatal hyperacute rejection. Donor weight should be within 30% of recipient weight except in pediatric patients, where closer size matching is required. In cases of elevated pulmonary vascular resistance in the recipient (5 to 6 Wood units), a larger donor is preferred to reduce the risk of right ventricular failure in the early postoperative period. Although practices vary by transplant program, generally, if the percent of panel reactive antibody (PRA) is greater than 10%, indicating recipient presensitization to alloantigen, a prospective negative T-cell cross-match between the recipient and donor sera is mandatory prior to transplantation.[59,105] A cross-match is always performed retrospectively, even if the PRA is absent or low. Retrospective studies also have demonstrated that better matching at the HLA-DR locus results in fewer episodes of rejection and infection with

an overall improved survival.[106] Because of current allocation criteria and limits on ischemic time of the cardiac allograft, routine prospective HLA matching is not possible logistically.

Hyperacute Rejection

Hyperacute rejection results from preformed donor-specific antibodies in the recipient.[107] ABO blood group and panel reactive antibody screening have made this condition a rare complication. The onset of hyperacute rejection occurs within minutes to several hours after transplantation, and the results are catastrophic. Gross inspection reveals a mottled or dark red, flaccid allograft, and histologic examination confirms the characteristic global interstitial hemorrhage and edema without lymphocytic infiltrate. Immunofluorescence techniques reveal deposits of immunoglobulins and complement on the vascular endothelium.[108] Immediate plasmapheresis, intravenous immunoglobulin (IVIG), and mechanical support are instituted, and retransplantation may be the only successful strategy.

OPERATIVE TECHNIQUES IN HEART TRANSPLANTATION

Orthotopic Heart Transplantation

Operative preparation of the recipient

The original technique of orthotopic cardiac transplantation described by Shumway and Lower is still used commonly today.[5] Following median sternotomy and vertical pericardiotomy, the patient is heparinized and prepared for cardiopulmonary bypass. Bicaval venous cannulation and distal ascending aortic cannulation just proximal to the origin of the innominate artery are optimal. Umbilical tape snares are passed around the superior and inferior venae cavae. Bypass is initiated, the patient is cooled to 28°C, caval snares are tightened, and the ascending aorta is cross-clamped. The great vessels are transected above the semilunar commissures, whereas the atria are incised along the atrioventricular grooves, leaving cuffs for allograft implantation. Removal of the atrial appendages reduces the risk of postoperative thrombus formation. Following cardiectomy, the proximal 1 to 2 cm of aorta and pulmonary artery are separated from one another with electrocautery, taking care to avoid injuring the right pulmonary artery. Continuous aspiration of pulmonary venous return from bronchial collaterals is achieved by insertion of a vent into the left atrial remnant either directly or via the right superior pulmonary vein.

Timing of donor and recipient cardiectomies is critical to minimize allograft ischemic time and recipient bypass time. Frequent communication between the procurement and transplant teams permits optimal coordination of the procedures. Ideally, the recipient cardiectomy is completed just prior to arrival of the cardiac allograft.

Implantation

The donor heart is removed from the transport cooler and placed in a basin of cold saline. If not previously performed, preparation of the donor heart is accomplished. Electrocautery and sharp dissection are used to separate the aorta and pulmonary artery. The left atrium is incised by connecting the pulmonary vein orifices, and excess atrial tissue is trimmed, forming a circular cuff tailored to the size of the recipient left atrial remnant (Fig. 65-4). Implantation begins with placement of a double-armed 3-0 Prolene suture through the recipient left atrial cuff at the level of the left superior pulmonary vein and then through the donor left atrial cuff near the base of the atrial appendage (Fig. 65-5). The allograft is lowered into the recipient mediastinum atop a cold sponge to insulate it from direct thermal transfer from adjacent thoracic structures. The suture is continued in a running fashion caudally and then medially to the inferior aspect of the interatrial septum (Fig. 65-6). On completion of the posterior left atrial suture line, continuous topical cold saline irrigation of the pericardial well is initiated, and the patient is oriented in a left-side down and head-up position to allow drainage of the saline away from the operative field and maximal cold saline exposure of the left and right ventricles. Alternatively, saline slush is applied generously to the surface of the heart. The second arm of the suture is run

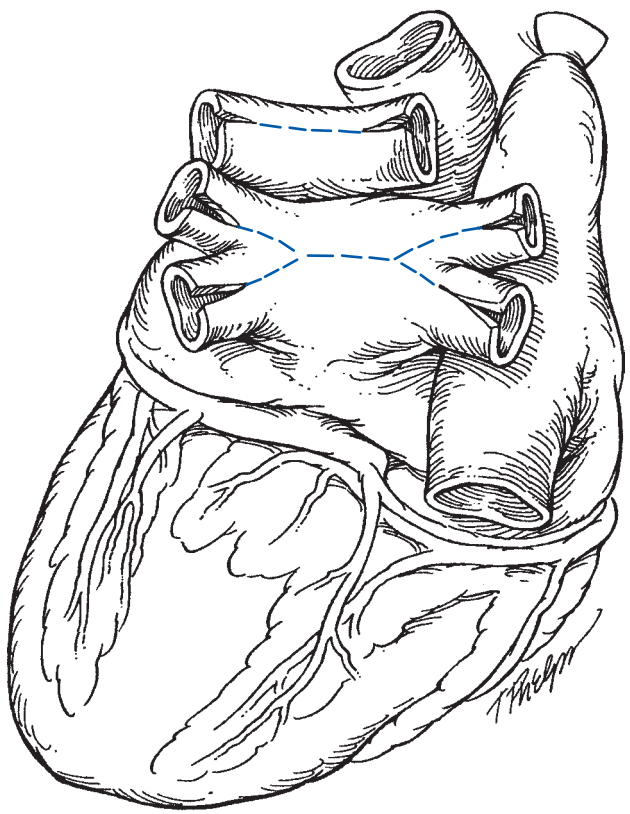

Figure 65-4. Donor allograft preparation for orthotopic heart transplantation. Pulmonary vein orifices joined to form left atrial cuff.

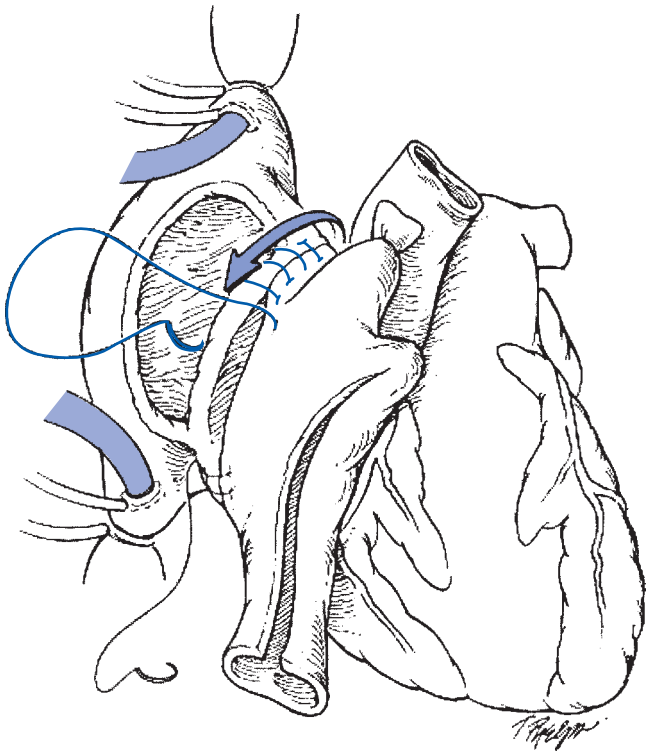

Figure 65-5. Implantation of allograft. First suture is placed at the level of the left superior pulmonary vein.

along the roof of the left atrium and down the interatrial septum. It is important to continually assess size discrepancy between donor and recipient atria so that appropriate plication of excess tissue may be performed. The left atrium is filled with saline, and the two arms of suture are tied together on the outside of the heart. Some centers introduce a line into the left atrial appendage for continuous endocardial cooling of the allograft (50 to 75 mL/min) and evacuation of intracardiac air. Other centers use constant insufflation of carbon diaoxide into the mediastinum.

Once the left atrial anastomosis is complete, a curvilinear incision is made from the inferior vena caval orifice toward the right atrial appendage of the allograft. This modification in the right atriotomy initially introduced by Barnard reduces the risk of injury to the sinoatrial node and accounts for the preservation of sinus rhythm observed in most recipients.[109] The tricuspid apparatus and interatrial septum are inspected. Recipients are predisposed to increased right-sided heart pressures in the early postoperative period owing to preexisting pulmonary hypertension and volume overload. Both conditions are poorly tolerated by the recovering right ventricle. To avoid refractory arterial desaturation associated with right-to-left shunting, patent foramen ovale are oversewn.[110] The right atrial anastomosis is performed in a running fashion similar to the left, with the initial anchor suture placed either at the most superior or inferior aspect of the interatrial septum so that the ends of the suture meet in the middle of the anterolateral wall (Fig. 65-7).

The end-to-end pulmonary artery anastomosis is next performed using a 4-0 Prolene suture beginning with the

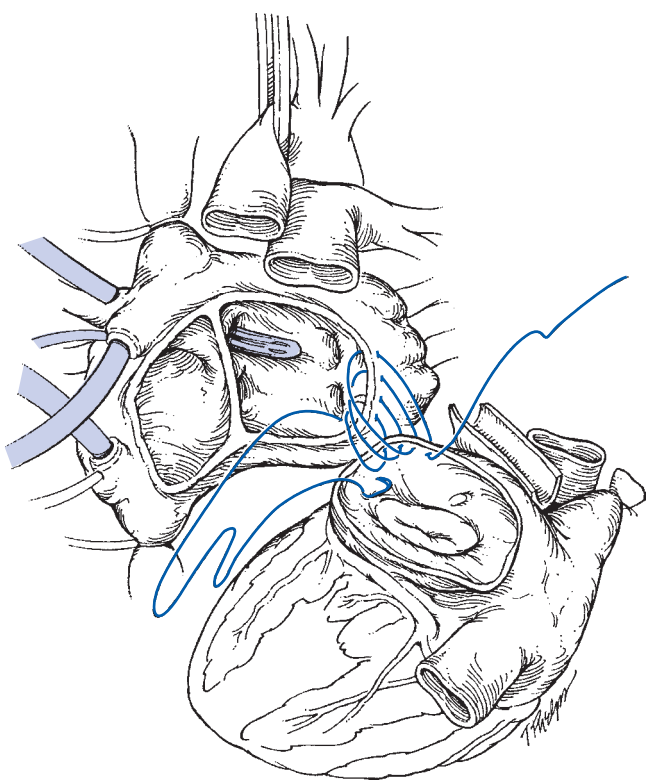

Figure 65-6. Implantation of allograft (continued). Left atrial anastomosis.

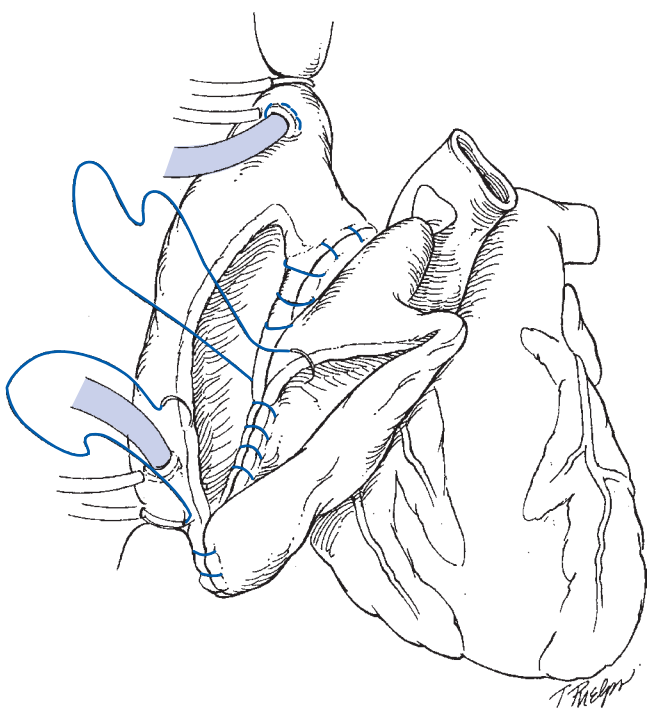

Figure 65-7. Implantation of allograft (continued). Right atrial anastomosis.

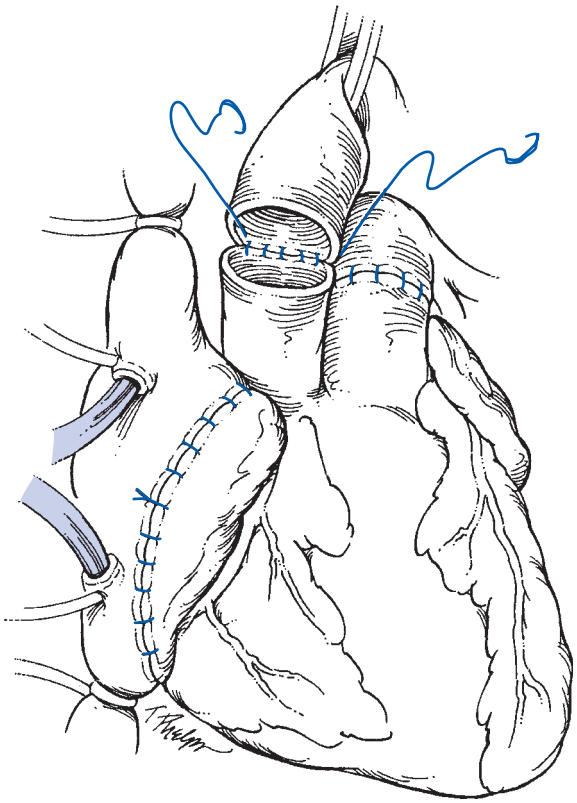

Figure 65-8. Implantation of allograft (continued). Aortic anastomosis.

posterior wall from inside of the vessel and then completing the anterior wall from the outside. It is crucial that the pulmonary artery ends be trimmed to eliminate any redundancy in the vessel that might cause kinking.[111] Finally, the aortic anastomosis is performed using a technique similar to that for the pulmonary artery, except that some redundancy is desirable in the aorta because it facilitates visualization of the posterior suture line (Fig. 65-8). Rewarming usually is begun prior to the aortic anastomosis, which is performed in a standard end-to-end fashion. Routine deairing techniques then are employed. Cold saline lavage is discontinued, lidocaine (100 to 200 mg intravenously) is administered, and the aortic cross-clamp is removed. Half of patients require electrical defibrillation. A needle vent is inserted in the ascending aorta for final deairing, with the patient in steep Trendelenburg position. Suture lines are inspected carefully for hemostasis. Inotrope infusion is initiated, and temporary pacing may be required. The patient is weaned from cardiopulmonary bypass, and the cannulae are removed. Temporary epicardial pacing wires are placed in the donor right atrium and ventricle. Following insertion of mediastinal and pleural tubes, the median sternotomy is closed in the standard fashion.

Cold blood cardioplegia is used in many centers. An initial dose often is given following removal from the cold storage solution prior to implantation. A second dose, or the single dose as given by some centers, is administered after the right atrial anastomosis or inferior vena cava (IVC) anastomosis when a bicaval technique is used.

Alternative techniques for orthotopic heart transplantation

The most commonly employed technique today is a bicaval anastomotic technique. With this technique, the recipient right atrium is excised completely, leaving a left atrial cuff and a generous cuff of the IVC and superior vena cava (SVC), respectively. The left atrial cuff of the donor is anastomosed to the left atrial cuff of the recipient as with the standard Shumway technique. Individual end-to-end anastomoses of the IVC and SVC are performed. The IVC anastomosis usually is performed following the left atrial anastomosis and the SVC anastomosis depending on the surgeon's preference. Total heart transplantation involves complete excision of the recipient heart with bicaval end-to-end anastomoses and bilateral pulmonary venous cuff anastomoses.[112] The Wythenshawe bicaval technique is performed in a similar fashion except that the recipient left atrium is prepared as a single cuff with all four pulmonary vein orifices[113] (Fig. 65-9). Although these procedures are more technically difficult than standard orthotopic transplantation, series using these techniques have reported shorter hospital stays, reduced postoperative dependence on diuretics, and lower incidences of atrial dysrhythmias, conduction disturbances, mitral and tricuspid valve incompetence, and right ventricular failure.[114–116] Furthermore, a study comparing biatrial versus bicaval transplant showed an improved 12-month survival in the bicaval group.[117] Long-term outcomes and prospective, randomized studies evaluating these alternative techniques are still needed.

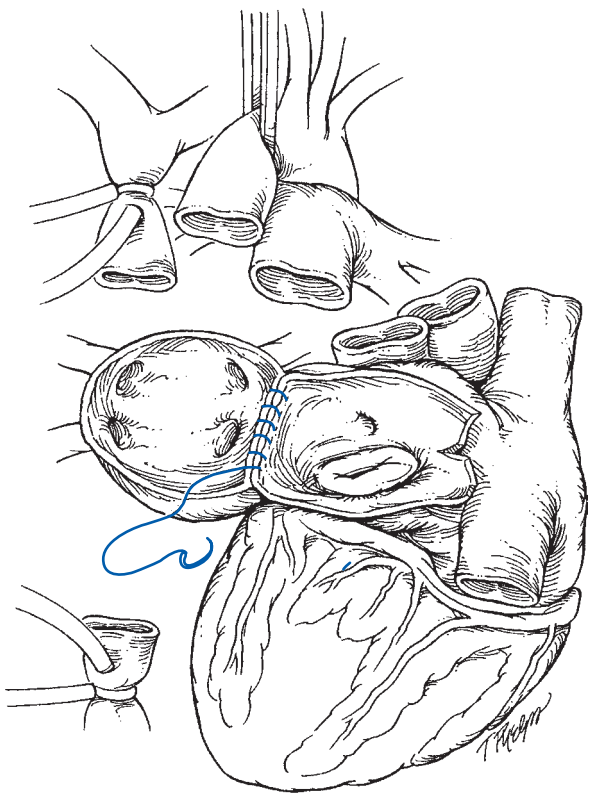

Figure 65-9. Bicaval heart transplantation.

Heterotopic Heart Transplantation

Pulmonary hypertension and right-sided heart failure have remained the leading causes of death in cardiac transplantation. This has led to an interest in heterotopic heart transplantation. Currently, heterotopic heart transplants are performed rarely but may be indicated in patients with irreversible pulmonary hypertension or significant donor-recipient size mismatch.[47,118]

POSTOPERATIVE MANAGEMENT

Hemodynamic Management

Heart allograft physiology

The intact heart is innervated by antagonistic sympathetic and parasympathetic fibers of the autonomic nervous system. Transplantation necessitates transection of these fibers, yielding a denervated heart with altered physiology. Devoid of autonomic input, the sinoatrial (SA) node of the transplanted heart fires at its increased intrinsic resting rate of 90 to 110 beats per minute. The allograft relies on distant noncardiac sites as its source for catecholamines; thus its response to stress (e.g., hypovolemia, hypoxia, and anemia) is somewhat delayed until circulating catecholamines can exert their positive chronotropic effect on the heart.[119] The absence of a normal reflex tachycardia in response to venous pooling accounts for the frequency of orthostatic hypotension in transplant patients.

Denervation alters the heart's response to therapeutic interventions that act directly through the cardiac autonomic nervous system.[120] Carotid sinus massage, Valsalva maneuver, and atropine have no effect on SA node firing or atrioventricular conduction. Because of depletion of myocardial catecholamine stores associated with prolonged inotropic support of the donor, the allograft often requires high doses of catecholamines.

Routine hemodynamic management

Donor myocardial performance is transiently depressed in the immediate postoperative period. Allograft injury associated with donor hemodynamic instability and the hypothermic, ischemic insult of preservation contribute to the reduced ventricular compliance and contractility characteristics of the newly transplanted heart.[121] Abnormal atrial dynamics owing to the midatrial anastomosis exacerbate the reduction in ventricular diastolic loading. An infusion of epinephrine or dobutamine is initiated routinely in the operating room to provide temporary inotropic support. Cardiac denervation brings in several consequences, which may include a chronotropic and an inotropic supersensitivity to exogenous catecholamines.[122] Restoration of normal myocardial function usually permits the cautious weaning of inotropic support within 2 to 4 days.

Early allograft failure

Early cardiac failure still accounts for up to 20% of perioperative deaths of heart transplant recipients.[123] The cause may be multifactorial, but the most important etiologies are myocardial dysfunction owing to donor instability, pulmonary hypertension, ischemic injury during preservation, and acute rejection. Mechanical support with an intra-aortic balloon pump or ventricular assist device can be attempted in patients refractory to pharmacologic interventions, although this measure, as well as retransplantation, is associated with very high mortality.[124,125]

Chronic left ventricular failure frequently is associated with elevated pulmonary vascular resistance, and the unprepared donor right ventricle may be unable to overcome this increased afterload. Although recipients are screened to ensure that those with irreversible pulmonary hypertension are not considered for transplantation, right-sided heart failure remains a leading cause of early mortality.[126] Initial management involves employing pulmonary vasodilators such as inhaled nitric oxide, nitroglycerin, or sodium nitroprusside. Pulmonary hypertension that is refractory to these vasodilators sometimes responds to prostaglandin E_1 (PGE_1) or prostacyclin.[32,127,128] Intra-aortic or pulmonary artery balloon counterpulsation and right ventricular assist devices also can be used in patients unresponsive to medical therapy.[129]

Arrhythmias

Denervation of the transplanted heart leads to loss of autonomic nervous system modulation of the heart's electrophysiologic properties. Parasympathetic denervation causes loss of basal suppression of SA node automaticity, leading to a persistent increase in resting heart rate and a loss of normal, rapid heart rate modulation. This parasympathetic loss also causes elimination of the chronotropic effects of digoxin and atropine after heart transplantation. At the same time, sympathetic denervation causes a decrease and delay in exercise- or stress-induced augmentation of SA node automaticity, resulting in a decreased maximum heart rate with exercise.[130]

Sinus or junctional bradycardia occurs in up to half of transplant recipients. Risk factors for sinus node dysfunction include prolonged organ ischemia, angiographic nodal artery abnormalities, biatrial as opposed to bicaval anastomosis, preoperative amiodarone use, and rejection.[131–133] Adequate heart rate is achieved with inotropic drug infusions and/or temporary epicardial pacing. Most bradyarrhythmias resolve over 1 to 2 weeks. Theophylline has been effective in patients with bradyarrhythmias and has decreased the need for permanent pacemakers in this patient population.[134]

Atrial fibrillation, atrial flutter, and other supraventricular arrhythmias have been reported in 5 to 30% of patients after heart transplantation.[130] Individual assessment of the risk:benefit ratio for anticoagulation therapy is necessary. Supraventricular tachycardia (SVT) in transplant patients should be treated in the same manner as in nontransplant

patients but with lower doses. Recurrent arrhythmias from reentry circuits or defined ectopic foci often can be cured by radiofrequency ablation.

Premature ventricular complexes (PVCs) generally are considered not ominous. Because of their rapidly terminal nature, sustained ventricular tachycardia (VT) and ventricular fibrillation presumably are responsible for a significant portion of the 10% of sudden and unexplained deaths in heart transplant patients.[135]

Unique aspects of common antiarrhythmic drugs reflecting the differences in their therapeutic effects in heart transplant recipients compared with nontransplant patients are shown in Table 65-6.[130] Persistence of any form of arrhythmia should warrant further investigative efforts and an aggressive search for the presence of indicators of cardiac ischemia, rejection, pulmonary pathology, or infection. If arrhythmic episodes are frequent or underlying cardiac pathology is severe, retransplantation may be considered.

Systemic hypertension

Systemic hypertension should be treated to prevent unnecessary afterload stress on the allograft. In the early postoperative period, intravenous sodium nitroprusside or nitroglycerin usually is administered. Nitroglycerin is associated with less pulmonary shunting because of a relative preservation of the pulmonary hypoxic vasoconstrictor reflex.[136] Nicardipine infusion has been reported to control postoperative hypertension more rapidly and was superior to sodium nitroprusside in maintaining left ventricular performance immediately after drug infusion.[137] If hypertension persists, an oral antihypertensive can be added, if possible, to permit weaning of the parenteral agents.

Respiratory Management

The respiratory management of the cardiac transplant recipient uses the same protocols employed following routine cardiac surgery.

Renal Function

Preoperative renal insufficiency owing to chronic heart failure and the nephrotoxic effects of calcineurine inhibitors cyclosporine place the recipient at increased risk of renal insufficiency. Acute calcineurine inhibitor cyclosporine-induced renal insufficiency usually will resolve with a reduction in dose. Continuous intravenous infusion to eliminate the wide fluctuations in levels associated with oral dosing can be attempted. Furthermore, concurrent administration of mannitol with calcineurine inhibitor cyclosporine may reduce its nephrotoxicity. Most centers administer a cytolytic agent in the immediate postoperative period and delay the initiation of calcineurine inhibitor cyclosporine therapy.

Outpatient Follow-up

Prior to discharge, patients should receive comprehensive education about their medications, diet, exercise, and infection recognition. Close follow-up by an experienced transplant team is the cornerstone for successful long-term survival after cardiac transplantation. This comprehensive team facilitates the early detection of rejection, opportunistic infections, patient noncompliance, and adverse sequelae of immunosuppression. Clinic visits routinely are scheduled concurrently with endomyocardial biopsies and include physical examination, a variety of laboratory studies, chest roentgenogram, and electrocardiogram.

IMMUNOSUPPRESSIVE THERAPY

An organism's ability to distinguish self from nonself is critical for its survival in a hostile environment. In transplantation, the recipient's host defense mechanisms recognize the human leukocyte antigens (HLAs) on allograft cells as being nonself and, if permitted, will respond to eradicate the foreign cells.[138] The ultimate goal of immunosuppressive therapy is selective modulation of the recipient's immune response to prevent rejection while concurrently sparing immune defenses against infections or neoplasia and minimizing the toxicity associated with immunosuppressive agents. The mechanisms of action and toxicity of currently used immunosuppressive agents are summarized in Table 65-7.

Pharmacologic Immunosuppressive Strategies

With the current 30-day mortality of less than 10%, the overwhelming majority of posttransplant deaths occur after 30 days.[139] Thus the "perfect" immunosuppressive regimen would save many more lives than the "perfect" surgical technique or donor organ. Changes in immunosuppressive therapy have had a major impact on improving survival after heart transplantation, as evidenced by the decreasing number of deaths owing to rejection in recent years.[140]

Immunosuppression following transplantation consists of an early induction phase followed by a long-term maintenance phase. This basic strategy essentially is universal, although the choice of immunosuppressive agents, dosages, and combination protocols vary between transplantation centers.

Currently, the "standard" maintenance immunosuppression protocols for heart transplantation (so-called triple therapy) include (1) a calcineurin inhibitor (CNI) such as cyclosporine or tacrolimus, (2) an antiproliferative agent such as azathioprine (AZA), mycophenolate mofetil (MMF), or rarely, cyclophosphamide, and (3) corticosteroids such as prednisone or prednisolone. Many centers also add an antilymphocyte antibody perioperatively such as antithymocyte globulin (ATG), OKT3, or an interleukin-2 (IL-2) receptor blocker (basiliximab or daclizumab) to create a quadruple-drug regimen. In recent years, sirolimus (Rapamycin) and everolimus (a derivative of Rapamycin), which act by blocking several events downstream of the IL-2 receptor, have been introduced into clinical heart transplantation. In the

Table 65–6.

Differences in Therapeutic Agent Effects in Heart Transplant Recipients Compared with Nontransplant Patients

Arrhythmia therapy	Differences in after transplantation
Drugs	
AV nodal agents	
Digoxin	No effect on heart rate
β-Adrenergic antagonists	Exacerbation of exercise intolerance
Calcium channel antagonists	Accentuated slowing of SA and AV nodes; may alter cyclosporine levels
Adenosine	Accentuated slowing of SA and AV nodes
Adrenergic agonists	
Norepinephrine	Unchanged peripheral effect, slightly more inotropic and chronotropic effect
Epinephrine	Unchanged peripheral effect, slightly more inotropic and chronotropic effect
Dopamine	Unchanged peripheral effect, less inotropic effect
Dobutamine	Unchanged
Ephedrine	Unchanged peripheral effect, less inotropic effect
Neosynephrine	Unchanged peripheral effect, no reflex bradycardia
Isoproteronol	Unchanged
Antiarrhythmic agents	
Class Ia (quinidine, disopyramide, procainamide)	No cardiac vagolytic effect
Class Ib (lidocaine, mexilitine)	None reported
Class Ic (flecainide, encainide, moricizine, propafenone)	None reported
Class III (amiodarone, sotalol, ibutilide, dofetilide)	Possible exaggerated or atypical response
Anticoagulants	
Heparin	None reported
Warfarin	None reported
Miscellaneous	
Atropine	No effect on heart rate
Methylxanthines (theophylline, aminophylline)	Possibly more chronotropic effect
Cardioversion	None reported
Radiofrequency catheter ablation	Possible differences in pathway or chamber anatomy
Electrical devices	
Pacemaker	None reported
Intracardiac defibrillator	None reported

Table 65–7.

Actions and Toxicities of Immunosuppressive Agents

Drug	Classification and action	Adverse effects
Corticosteroids	Lymphocyte depletion Affect elements involved in all stages of the T-cell activation process. Inhibits cytokine production of macrophages	Cushingoid appearance Weight gain with central obesity Hypertension Hyperglycemia/diabetes Hyperlipidemia Peptic and esophageal ulceration and gastrointestinal (GI) bleeding Cataract formation Aseptic bone necrosis Osteoporosis Myopathy Personality changes and psychosis Poor wound healing Easy bruising
Cyclosporine	Calcineurine Inhibitor; blocks T-cell IL-2 production. Inhibits T-cell proliferation and differentiation	Nephrotoxicity Hypertension Neurotoxicity (parasthesia, seizure, tremor, headache) Gingival hyperplasia Hypertrichosis (hirsutuism) Hyperuricemia, gout Hepatotoxicity Hyperlipidemia Hyperglycemia
Tacrolimus (FK506)	Calcineurine inhibitor; blocks T-cell IL-2 production. Inhibits T-cell proliferation and differentiation	Equivalent to cyclosporine: Nephrotoxicity Higher incidence than cyclosporine: Diabetes mellitus Neurotoxic reaction Lower incidence than cyclosporine: Hypertension Hyperlipidemia Hirsutism Gingival hyperplasia
Azathioprine	Antiproliferative. Inhibits early stages of purine metabolism. Blocks most T-cell functions; inhibits primary antibody synthesis; decreases number of circulating monocytes and granulocytes	Bone marrow suppression: Leukopenia Anemia Thrombocytopenia Pancytopenia Pancreatitis Hepatitis GI distress (nausea, vomiting, abdominal pain, diarrhea) Cholestatic jaundice
Mycophenolate	Antiproliferative	GI upsets
Mofetil (MMF)	Selective inhibitor of de novo pathway of purine biosynthesis, thereby providing more specific and potent inhibition of T-cell and B-cell proliferation	Diarrhea Increased risk of tissue-invasive cytomegalovirus infection Leukopenia Thrombocytopenia Pancytopenia

Actions and Toxicities of Immunosuppressive Agents (*continued*)

Sirolimus (Rapamycin) Everolimus (Certican)	Antiproliferative Proliferation signal inhibtor; prevents T-cell progression from the G_1 to the S phase by blocking signaling downstream IL-2	Hyperlipidemia Thrombocytopenia Leukopenia Hypertension Peripheral edema Impaired wound healing
Polyclonal antibodies, thymoglobulin, Antithymocyte, sera/globulin (ATS, ATG-Frenius,) antilymphocyte globulin (ALG)	Deplete circulating T cells using several antibody-mediated mechanisms of destruction of immune cells	Fever and chills Serum sickness Polyarthralgias Anemia Leukopenia Thrombocytopenia GI distress Rash Alopecia
OKT3 (Muronomab-CD3)	Monoclonal antibody Blocks the function of both naive T cells and established cytotoxic T cells	Cytokine release syndrome: Fever, chills, weakness, bronchospasm, hypotension (peripheral vasodilatatio GI distress Pulmonary edema Increased opportunistic infections Increased lymphoproliferative disorders Antimurine antibody development Rebound rejection after drug discontinuation.
Daclizumab (Zenepax) Basiliximab (Simulect)	IL-2 receptor blockers Inhibit IL-2-dependent T-cell activation Monoclonal antibodies with greater human component	Generally well tolerated. Studies ongoing

setting of pretransplant renal insufficiency, a popular protocol involves delaying the initiation of the calcineurin inhibitors for 1 to 2 weeks postoperatively to allow for recovery of renal function and using antilymphocyte antibody therapy in the interim, so-called sequential therapy.[141] The use of a multidrug regimen permits adequate immunosuppression with reduced doses of individual agents to minimize their toxicity. The immunosuppressive regimen currently used at the Johns Hopkins Hospital is outlined in Table 65-8.

Individual Immunosuppressive Agents

Corticosteroids

Corticosteroids have played an integral role in immunosuppression since the beginning of cardiac transplantation. These nonselective agents influence essentially all limbs of the immune response.[142] Currently, methylprednisolone is used during induction, and prednisone usually is part of maintenance immunosuppressive regimens. Corticosteroids are also the first-line therapy for acute rejection in most centers. The numerous untoward sequelae associated with long-term corticosteroid therapy have driven clinicians to reduce doses significantly or even eliminate these drugs from maintenance regimens.[143]

The timing of steroid withdrawal varies; some clinicians discontinue prednisone within several weeks of transplantation,[144,145] whereas others delay the taper until several months after transplantation.[146,147] Successful early withdrawal of corticosteroid therapy has been associated with improved long-term survival.[148] The 2005 ISHLT report indicates that prednisone is still used by almost 75% of patients at 1-year after transplant.[17]

Cyclosporine

Cyclosporine (Sandimmune) is an 11-amino-acid cyclic peptide produced by the fungus *Tolypocladium inflatum*.[149] It inhibits the calcium-calcineurin pathway, one of the three sig-

Table 65–8.

Immunosuppressive Regimen for Heart Transplantation at the Johns Hopkins Hospital

I.	Preoperative preparation: None
II.	Intraoperative management: Methylprednisolone: 500 mg IV (after administration of protamine) Daclizumab (Zenapax) 1 mg/kg IV
III.	Immediate postoperative therapy: Methylprednisolone: 125 mg/kg IV for 3 doses followed by Prednisone: 1 mg/kg PO qd tapered to 20 mg over 2 to 3 weeks Mycophenolate mofetil 1 g PO/IV bid Cyclosporine (prefer Neoral): Initiate at 50 mg PO bid, and titrate dose to maintain serum level between 250 and 300 ng/mL during first 3 months *or* Tacrolimus: Initiate at 2 mg PO bid, and titrate to maintain serum level between 10 and 15 ng/mL during the first 3 months. Daclizumab (Zenapax) 1 mg/kg IV on postoperative day 7, then given every 2 weeks for a total of 5 doses
IV.	Postoperative maintenance therapy: Prednisone: 20 mg PO qd until 3 months, decrease to 10 mg qd to 6 months, 5 mg qd, and taper to off by the end of 1 year. Mycophenolate mofetil: 1 g PO/IV bid Cyclosporine (prefer Neoral): Initiate at 50 mg PO bid, and titrate dose to maintain serum level between 250 and 300 ng/mL during first 3 months *or* Tacrolimus: Initiate at 2 mg PO bid, and titrate to maintain serum level between 10 and 15 ng/mL during the first 3 months

[*] *CycloTrac SP ^{125}I RIA Kit, INCSTAR, Stillwater, MN.*

nal transduction pathways that activate transcription factors triggering the expression of molecules with key roles in the immune response, including IL-2, CD154, and CD25.[150] Consequently, cytotoxic T-lymphocyte proliferation is attenuated. By sparing macrophages, neutrophils, suppressor T lymphocytes, and some B lymphocytes, cyclosporine provides more selective immunosuppression than azathioprine and corticosteroids.[151] It also has permitted the reduction in corticosteroid doses in maintenance immunosuppression.[143] After cyclosporine was introduced in clinical heart transplant in the early 1980s, prognosis after heart transplant improved markedly, and in 2001, the ISHLT Registry showed that approximately 50% of patients who underwent heart transplantation after 1982 survived more than 10 years.[152] Indeed, the improved survival of cardiac recipients in the cyclosporine era is primarily a result of a reduction in infection-related mortality likely associated with a relative preservation of host defense against microbials.[153] Doses of cyclosporine are adjusted to achieve trough serum levels of between 150 and 300 ng/mL.[154] The low therapeutic index of cyclosporine and wide variation in individual pharmacokinetics mandates close monitoring of levels. For patients who develop renal insufficiency, cyclosporine temporarily may be administered as a continuous infusion to reduce wide fluctuations in serum levels. In 1995, the original oil-based formulation largely was replaced by a new microemulsion formulation (Neoral) with greater bioavailability and more predictable intestinal absorption and pharmacokinetics.[155,156]

Tacrolimus

Tacrolimus (FK506) is a macrolide antibiotic from *Streptomyces tsukubaensis* that binds to another immunophilin, FK506-binding protein 12 (FKBP12), thereby forming a complex that inhibits calcineurin with greater molar potency than does cyclosporine and decreases the formation of IL-2.[157] Two prospective, multicenter, randomized trials, one in Europe and the other in the United States, have compared the standard oil-based cyclosporine formulation with tacrolimus in association with azathioprine and steroids. The two calcineurin inhibitors showed similar efficacies in preventing rejection and death within the first year after transplant, but tacrolimus caused fewer cases of hypertension and hyperlipidemia than cyclosporine.[158,159] Similarly, the 18-month results of a large multicenter tacrolimus versus cyclosporine microemulsion study have shown the two drugs to be associated with similar incidences of rejection and death but that recurrent rejection was less severe and the incidences of hypertension and hyperlipidemia were lower if

tacrolimus was used.[160] Furthermore, FK506 has been found to be most effective in reversing recalcitrant rejection.[161] This has prompted some institutions that use cyclosporine to employ FK506 as a "rescue" agent. It also has been suggested that ethnic disparity in clinical outcome after heart transplantation is abrogated using tacrolimus-based immunosuppression.[162]

So far, neither cyclosporine nor tacrolimus has been shown to prevent cardiac allograft vasculopathy (CAV) or to reduce the progression of this complication during long-term follow-up, although with tacrolimus the risk of CAV associated with hypertension and hyperlipidemia may be lower, but the risk associated with impaired glucose metabolism may be higher. With both drugs, the risk of CAV is exacerbated by the concomitant use of corticosteroids.[163] Overall, the choice of calcineurin inhibitor currently seems to be dictated by their adverse-effect profiles, by the results obtained for individual patients, and possibly by institutional preference. The 2005 ISHLT report indicates that tacrolimus has just surpassed cyclosporine as the most commonly used calcineurin inhibitor.[17]

Azathioprine

An imidazole derivative from 6-mercaptopurine, azathioprine is an antimetabolite that inhibits DNA synthesis during the crucial synthetic (S) phase of cell replication. This leads to the inhibition of the antigen-stimulated proliferation of lymphocytes.[164] Dosage adjustments are made to maintain the leukocyte count at between 4000 and 5000/mm^3. Azathioprine causes a dose-related bone marrow suppression that can be profound if it is administered concurrently with allopurinol.[165]

Mycophenolate mofetil (MMF)

MMF (Cellcept), an ester prodrug of mycophenolic acid, inhibits a key step in the de novo biosynthesis of purines, selectively affecting cells (such as lymphocytes) that are unable to use salvage pathways.[166] In the latest reported randomized, double-blind, controlled trial comparing MMF with azathioprine, the MMF groups had reduced mortality and graft loss up to 3 years after transplantation (11.8% versus 18.3%, $p < .01$).[167] Time to retransplantation or patient death was significantly shorter for azathioprine- than for MMF-treated patients ($p = .029$). Congestive heart failure, atrial arrhythmia, and leukopenia were more common in the azathioprine group, whereas diarrhea, esophagitis, herpes simplex, herpes zoster, and CMV tissue invasion were more common in MMF-treated patients. Several other studies in the past also demonstrated the superiority of MMF.[168] Furthermore, MMF has novel properties that may contribute to the prevention of cardiac allograft rejection and also provide benefits in reducing the progression of CAV. In a study by Pethig and colleagues, cardiac transplant patients receiving MMF had lower levels of high-sensitive C-reactive protein, a marker of inflammation having a strong association with cardiovascular disease, than did patients receiving azathioprine.[169] However, there was no significant difference in intimal hyperplasia, although there was a weak trend toward vascular enlargement by intravascular ultrasound in the MMF group. MMF largely has replaced azathioprine and currently is the predominant antiproliferative agent, used in more than 75% of heart transplant recipients.[17]

Sirolimus and everolimus

Sirolimus (Rapamycin), which is another antibiotic from *Streptomyces,* and its derivative everolimus (Certican; formerly SDZ-RAD) are potent proliferation signal inhibitors that have made major breakthroughs in the field of coronary stenting. They act by blocking several events downstream of the IL-2 receptor. Interestingly, these drugs bind to the same binding proteins as tacrolimus (primarily FKBP-12), but rather than inhibiting calcineurin, they inhibit cytoplasmic proteins collectively termed *target-of-Rapamycin* (TOR) proteins. These proteins are required for cell cycle progression from G_1 to S phase in response to IL-2 stimulation, and hence sirolimus and everolimus are able to block the proliferative response of T cells after immune activation.[170,171]

In a randomized, open-label multicenter study conducted in Australia and New Zealand, sirolimus was compared with azathioprine in combination with cyclosporine (Neoral) and steroids administered from the time of cardiac transplantation.[172] One-hundred and thirty-six first cardiac allograft recipients were randomly assigned (2:1) to sirolimus ($n = 92$; 5 or 3 mg/d maintenance dose) or azathioprine ($n = 44$). At 6 months, the proportion of patients with grade 3a or greater acute rejection was 32.4% for sirolimus 3 mg/d ($P = .027$), 32.8% for sirolimus 5 mg/d ($P = .013$), and 56.8% for azathioprine. The trial was not powered to detect differences in mortality; however, survival rates at 12 months did not differ significantly. Intravascular ultrasound at 6 weeks, 6 months, and 2 years demonstrated highly significant progression of transplant vasculopathy in azathioprine-treated patients. A small single-center randomized trial of patients who already had CAV showed that treatment with sirolimus slowed its progression.[173] The use of sirolimus in heart transplant has doubled from 7% in 2002 to 14% in 2004.[17]

The efficacy and safety of everolimus (1.5 or 3.0 mg/d) was compared with azathioprine (1.0 to 3.0 mg/kg per day) in a large 2-year phase III, multicenter, randomized study in 634 recipients of primary heart transplants receiving concomitant full-dose cyclosporine microemulsion (Neoral), corticosteroids, and statins.[174–176] Rates of acute rejection (grade $\geq$ 3a) were significantly lower for patients receiving everolimus than for those receiving azathioprine and maintained at 24 months (22.7% versus 48.1%; $p \leq .001$), indicating a 52.8% reduction. Furthermore, everolimus-treated patients had a significantly lower incidence of CMV infection at 12 months than azathioprine-treated patients (7.7% and 7.6% versus 21.5%; $P < .001$). Both average coronary artery intimal thickness assessed by intravascular ultrasonography and the incidence of CAV were significantly lower in patients receiving everolimus than in those receiving azathioprine at both 12[174] and 24 months.[175] Patient survival was excellent in this study,

with no significant differences noted between the everolimus 1.5 and 3 mg/d groups (88.6% and 91.4%) and the azathioprine group (92.1%) at 12 and 24 months (90.0%, 86.3%, and 88.8%, respectively). At 24 months, overall safety and survival rates were better with everolimus dosed at 1.5 mg/d than at 3 mg/d.[176] There was a high discontinuation rate, especially in the group receiving 3.0 mg of everolimus (nearly 40%). Thrombocytopenia and elevated lipid levels (despite the administration of statins) were seen more frequently in the everolimus groups.

Since CAV is the main risk factor for mortality after the first year posttransplantation and acute rejection and CMV infection play a key role in its development, this pivotal study suggests that primary immunosuppression including everolimus could provide important benefits for heart transplant patients.[177] Coadministration with calcineurin inhibitors (CNIs) can exacerbate CNI-related nephrotoxicity, but evidence suggests that everolimus administered with reduced-exposure cyclosporine in the maintenance phase preserves renal function without loss of immunosuppressive efficacy.[178] Notably, the preceding trials compared sirolimus or everolimus with azathioprine and not with MMF. However, MMF has not been associated with a significant reduction in intravascular ultrasound–defined vasculopathy.[141]

Polyclonal antibodies

Polyclonal antibodies (e.g., antithymocytes and antilymphocytes) are produced by animals following immunization with human lymphocytes. Their mechanisms of action include complement-dependent cytolysis of the recipient lymphocytes, opsonization with destruction of immune cells by the reticuloendothelial system, and induction of apoptosis following binding to surface antigens.[179] These antibodies thereby can decrease the level of circulating T cells to less than 10% of normal. Thymoglobulin, an injectable solution of purified IgG immunoglobulins with pronounced lymphocytotoxic antibody activity, is obtained by hyperimmunization of rabbits with human thymocytes. ATG-Fresenius, which is produced in rabbits after hyperimmunization with an immortalized cellular line (Jurkat), contains various immunoglobulin fractions with high antilymphocyte activity. Antithymocyte sera (ATS) and equine antibodies also are used. These antibody preparations have been introduced for perioperative prophylaxis as part of induction therapy protocols to delay administration of cyclosporine, thus avoiding acute nephrotoxicity during the immediate postoperative period and to permit reduction in early corticosteroid doses.[141,180] Several retrospective series have shown the efficacy of this strategy to achieve low rates of early acute rejection episodes without significantly increasing the incidence of infection or malignancy.[181,182] The antibodies also are used for rescue therapy for acute rejection refractory to corticosteroids.

OKT3

The first monoclonal antibody (mAb) available for therapeutic use in the treatment and prevention of allograft rejection was OKT3. It is a murine mAb directed against the ϵ chain of CD3 molecule, which is part of the T-cell recognition (TCR) complex and functions to modulate the receptor and inactivate T-cell function. By engaging the TCR complex, OKT3 blocks not only the function of naive T cells but also the function of established cytotoxic T cells.[183] As with polyclonal preparations, administration of OKT3 also can eliminate almost all circulating T lymphocytes, although its monoclonal specificity prevents it from having a cytolytic effect on other circulating cells.[184] Monitoring of T3 subpopulation cell counts can be used to determine adequacy of therapy. While it has been used for induction therapy, OKT3 has demonstrated its greatest benefit on rescue therapy.[185,186] Studies comparing the results obtained with OKT3 versus horse or rabbit polyclonal antibodies have yielded conflicting results.[187–189] OKT3 appears to be more aggressive therapy and has been associated with serious adverse effects, which include the following: (1) the development of a cytokine release syndrome owing to the ability of OKT3 to activate T cells, ranging in severity from a mild febrile illness to a syndrome of severe volume overload and hemodynamic compromise,[190] (2) the appearance of human antimouse antibodies that decrease the efficacy or preclude the use of subsequent OKT3 courses and can mediate humoral rejection,[191] (3) the increased incidence of opportunistic infections such as those caused by CMV,[189,192] and (4) the increased incidence of posttransplant lymphoproliferative disorders.[193] Interestingly, the 2005 ISHLT report showed that patients receiving OKT3 as part of an induction protocol have higher rejection rates during the first year after transplant than those receiving polyclonal or IL-2 antibody induction and those receiving no antibody induction. Overall, the perioperative use of OKT3 as an induction agent continues to decrease (only 4% of heart transplant procedures in 2001–2004).[17]

Daclizumab and basiliximab

The preceding limitations of OKT3 have spurred the development of mAbs that have a greater human component and achieve a more selective suppression of the immune system.[194] Because only activated T cells express the Tac antigen (IL-2Rα chain or CD25 antigen), anti-Tac IL-2R mAbs are expected to target graft-reactive lymphocytes immediately after transplantation in an induction or sequential immunosuppression therapy protocol. There are two new anti-Tac mAbs, which generally are known as IL-2 receptor (IL-2R) blockers, and they became available in 1998. Basiliximab (Simulect) is a chimeric antibody retaining the murine elements of the variable portion of the immunoglobulin chain. Daclizumab (Zenapax) is more completely humanized, retaining a smaller region of the murine antibody.[183] The immunogenicity of these molecules, as measured by in vivo circulating half-life and by the appearance of antibodies against the agents, is reduced significantly compared with strictly murine anti-CD25 mAbs. Although these agents are given only for a limited period after transplantation, effective IL-2R blockade is achieved for several weeks after the last

dose, thereby covering the critical period when acute rejection is most common.

In a randomized, single-center evaluation of 55 heart transplant recipients, there was a striking decrease in the rate of rejection, by a factor of 2.8, among patients receiving daclizumab, with no increase in the rate of infection.[195] Hershberger and colleagues recently reported on 434 first heart transplant recipients recruited from 31 transplantation centers in the United States, Canada, Germany, and Sweden.[196] Patients were assigned randomly in a double-blind manner to receive either daclizumab or placebo in combination with cyclosporine, MMF, and corticosteroids. The risk of their primary composite endpoint of histologic rejection, graft dysfunction, a second transplantation, or death within 6 months was reduced by treatment with the mAb daclizumab (47.7% versus 35.6%; $P = .007$). The rate of rejection was lower in the daclizumab group than in the placebo group (41.3% versus 25.5%). Among patients reaching the primary endpoint, the median time to the endpoint was almost three times as long in the daclizumab group at 6 months (61 versus 21 days) and at 1 year (96 versus 26 days). However, the efficacy benefit of the active drug was solely accounted for by the histologic rejection component of the composite endpoint. A worrisome finding was that overall mortality was greater in the daclizumab group than in the placebo group (6.5% versus 3.2%) at 6 months, and this trend continued at 1 year ($P = .11$). Most of the deaths were due to infections and occurred in patients who received both daclizumab and a second monoclonal or polyclonal preparation of antilymphocyte antibody. Also worrisome was the higher incidence of graft dysfunction in the daclizumab group.[197]

A small 1-year double-blind, randomized, placebo-controlled study evaluated the safety, tolerability, and pharmacokinetics of basiliximab with cyclosporine, MMF, and steroids in 56 adult first heart transplant recipients.[198] Basiliximab generally was well tolerated. There were no significant differences between treatment groups with respect to adverse-event profiles, serious adverse events, or infections. The mean number of days to first biopsy-proven acute rejection was longer with basiliximab (73.7 $\pm$ 59.68 days) than placebo (40.6 $\pm$ 53.30 days) at 6 months but not statistically significant. Further studies will be needed to clearly define the role that daclizumab and basiliximab will play in heart transplant immunosuppressive therapy.

ACUTE REJECTION

Cardiac allograft rejection is the normal host response to cells recognized as nonself. The vast majority of cases are mediated by the cellular limb of the immune response through an elegant cascade of events involving macrophages, cytokines, and T lymphocytes. Humoral-mediated rejection (also called *vascular rejection*) is less common. The highest risk factors are allografts from younger and female donors (irrespective of recipient sex).[199] Although about 85% of episodes can be reversed with corticosteroid therapy alone,[200] rejection is still a major cause of morbidity in cardiac transplant recipients.[17,201]

Diagnosis of Acute Rejection

In the precyclosporine era, the classic clinical manifestations of acute rejection included low-grade fever, malaise, leukocytosis, pericardial friction rub, supraventricular arrhythmias, low cardiac output, reduced exercise tolerance, and signs of congestive heart failure. In the cyclosporine era, however, most episodes of rejection characteristically are insidious, and patients can remain asymptomatic even with late stages of rejection. Thus routine surveillance studies for early detection are crucial to minimize cumulative injury to the allograft. Right ventricular endomyocardial biopsy remains the "gold standard" for the diagnosis of acute rejection. The most frequently used technique for orthotopic allografts is a percutaneous approach through the right internal jugular vein.[202] Interventricular septal specimens are fixed in formalin for permanent section, although frozen sections are performed occasionally if urgent diagnosis is necessary. Hemodynamic parameters also may be obtained with a pulmonary artery catheter. Complications are infrequent (1 to 2%) but include venous hematoma, carotid puncture, pneumothorax, arrhythmias, heart block, and right ventricular perforation and injury to the tricuspid valve. The exact schedule for endomyocardial biopsies varies among institutions but reflects the greater risk of rejection during the first 6 months following transplantation. Biopsies are performed initially every 7 to 10 days in the early postoperative period and eventually tapered to 3- to 6-month intervals after the first year. Suspicion of rejection warrants additional biopsies.

Evaluation of sample adequacy for the ISHLT grading scheme requires a minimum of four good endomyocardial tissue fragments, with less than 50% of each fragment being fibrous tissue, thrombus, or other noninterpretable tissues (e.g., crush artifact or poorly processed fragments).[203] The pattern and density of lymphocyte infiltration, in addition to the presence or absence of myocyte necrosis in the endomyocardial biopsy, determine the severity grade of cellular rejection.[204] Further elaboration of the pathologic features and identification of antibody-mediated rejection were addressed more recently.[205] In 2004, the ISHLT Pathology Council proposed simplification of the 1990 diagnostic categories for cellular rejection to mild, moderate, and severe and identification of the histologic characteristics of antibody-mediated rejection.[206] The new grading scale is supposed to better address the challenges and inconsistencies in use of the old grading system.[207] Tables 65-9 and 65-10 show the new 2004 ISHLT grading scale.[206]

Noninvasive studies for the diagnosis of acute rejection have been unreliable. Electrocardiographic voltage summation and E-rosette assay techniques were useful adjuncts in the early cardiac transplant experience[208]; however, they currently are of no value in patients receiving cyclosporine.[209] More recent attempts with signal-averaged electrocardiography,[210]

Table 65–9.

ISHLT Standardized Cardiac Biopsy Grading: Acute Cellular Rejection, 2004*

Grade 0 R†	No rejection
Grade 1 R (Mild)	Interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage
Grade 2 R (Moderate)	Two or more foci of infiltrate with associated myocyte damage
Grade 3 R (Severe)	Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage ± vasculitis

**The presence or absence of acute antibody-mediated rejection (AMR) may be recorded as AMR 0 or AMR 1, as required (see Table 65-10).*
†Where R denotes revised grade to avoid confusion with 1990 scheme.

echocardiography,[211] or the combination[212] and magnetic resonance imaging,[213] technetium ventriculography,[214] and a variety of immunologic markers[215] have not provided sufficient sensitivity and specificity to warrant widespread use.[216] Peripheral blood gene expression profiling is an exciting new field that may provide the answer to noninvasive discrimination of rejection in cardiac allograft recipients.[217,218]

Treatment of Acute Rejection

Corticosteroids are the cornerstone for antirejection therapy. The treatment of choice for any rejection episode occurring during the first 1 to 3 postoperative months or for an episode considered to be severe is a short course (3 days) of intravenous methylprednisolone (1000 mg/d). Virtually all other episodes are treated initially with increased doses of oral prednisone (100 mg/d) followed by a taper to baseline over several weeks.[219] Although not yet universally accepted, many centers have reduced the doses of these corticosteroids successfully with reversal rates of rejection similar to traditional dosing.

Repeat endomyocardial biopsy should be performed 7 to 10 days after the cessation of antirejection therapy to assess adequacy of treatment. If the biopsy does not show significant improvement, a second trial of pulse-steroid therapy is recommended; if rejection has progressed (or if the patient becomes hemodynamically unstable), rescue therapy is indicated.

Substitution of tacrolimus for cyclosporine may obviate the need for admission in patients with steroid-refractory persistent rejection.[220] Alternatively, sirolimus may be substituted for mycophenolate or azathioprine.[221] The use of OKT3, antithymocyte globulin, and thymoglobulin generally is reserved for severe rejection with hemodynamic compromise.[222] Methotrexate has been particularly successful in eradicating chronic low-grade rejection.[223,224] Total lymphoid irradiation and photopheresis also have demonstrated success in some cases of refractory rejection.[224] Cardiac retransplantation is the ultimate therapeutic option for patients who do not respond to the aforementioned interventions. However, the results of retransplantation for rejection are dismal, and in most centers, it is no longer performed for this indication.

Asymptomatic mild rejection (grade 1) usually is not treated but is monitored with repeat endomyocardial biopsies because only 20 to 40% of mild cases progress to moderate rejection.[225] On the other hand, the presence of myocyte necrosis (grades 3b and 4) represents a definite threat to allograft viability and is a universally accepted indication for therapy. Management of moderate rejection (grade 3a) is controversial and requires consideration of multiple variables.[226,227] Notably, Stoica and colleagues recently demonstrated that acute moderate to severe cellular rejection has a

cumulative impact on CAV onset.[228] Regardless of the biopsy results, allograft dysfunction is an indication for hospitalization, antirejection therapy, and if severe, invasive hemodynamic monitoring and inotropic support.

Acute Vascular Rejection

Vascular rejection is mediated by the humoral limb of the immune response.[229] Unlike cellular rejection, hemodynamic instability often necessitating inotropic support is common in cases of vascular rejection.[230] Diagnosis requires evidence of endothelial cell swelling on light microscopy and immunoglobulin-complement deposition by immunofluorescence techniques.[231] Aggressive treatment of patients with allograft dysfunction consists of plasmapheresis, high-dose corticosteroids, heparin, IgG, and cyclophosphamide.[232] Despite these interventions, symptomatic acute vascular rejection is associated with a high mortality.[230,232] Repeated episodes of acute vascular rejection or chronic low-grade vascular rejection are believed to play a dominant role in the development of allograft coronary artery disease.[233]

INFECTIOUS COMPLICATIONS IN HEART TRANSPLANTATION

Organisms and Timing of Infections

Infection is a leading cause of morbidity and mortality in the cardiac transplant population.[17,234] The introduction of new chemoprophylactic regimens and the prevention of serious disease caused by CMV have resulted in significant reductions in the number of infectious episodes and a delay in presentation after heart transplantation.[234,235] Patients are at greatest risk of life-threatening infections in the first 3 months after transplantation and following increases in immunosuppression for acute rejection episodes or retransplantation.[234] Table 65-11 illustrates the most common organisms causing infections in the cardiac recipient.

Preventive Measures and Prophylaxis against Infection

Transmission of infections such as CMV, *Toxoplasma gondii,* HBV, HCV, and HIV after organ transplantation is well documented.[236,237] Prevention of postoperative infection begins with pretransplant screening of the donor and recipient.[238] Current suggested guidelines are outlined in Table 65-12. Perioperative and postoperative antimicrobial prophylaxis, as well as immunizations, are also outlined.

Specific Organisms Causing Infection Following Heart Transplantation

Bacteria

Gram-negative bacilli are the most common cause of bacterial infectious complications following heart transplantation. Furthermore, *Escherichia coli* and *Pseudomonas aeruginosa* are the most prevalent organisms and usually cause urinary tract infections and pneumonias, respectively.[235] *Staphylococcus* species have been shown to cause the majority of gram-positive related infections.

Viruses

CMV remains the single most important cause of infectious disease morbidity and mortality in the heart transplant patient.[239] CMV not only results in infectious disease syndromes but also is indirectly associated with acute rejection episodes, acceleration of CAV, and posttransplant lymphoproliferative disease.[239] Furthermore, the reduction in leukocytes associated with CMV infection predisposes the patient to superinfection with other pathogens (e.g., *Pneumocystis carinii* pneumonia).[240] Infections develop secondary to donor transmission, reactivation of latent recipient infection, or reinfection of a CMV-seropositive patient with a different viral strain.[239] Variable regimens for CMV prophylaxis with ganciclovir are being used by different centers.[241] The standard of care for symptomatic CMV disease is 2 to 3 weeks of intravenous ganciclovir (at a dose of 5 mg/kg twice daily, with dosage adjustment for renal dysfunction). For tissue-invasive disease, particularly pneumonia, many centers add anti-CMV hyperimmune globulin to this regimen.[242] Preemptive treatment strategies employ periodic surveillance using techniques such as plasma polymerase chain reaction (PCR) and CMV antigenemia, a rapid diagnostic test that detects viral protein in peripheral blood leukocytes at a significant interval before clinical disease.[243] Valganciclovir (Valcyte) is an oral prodrug of ganciclovir with a 10-fold greater bioavailability than oral ganciclovir. It has been shown to be effective for prophylaxis and preemptive treatment of CMV and allows for more convenient use.[244,245]

Although not a cure for herpes simplex or zoster viruses, acyclovir can reduce recurrences and the discomfort associated with the vesicular lesions. Epstein-Barr virus infection may be associated with posttransplant lymphoproliferative disorders in immunocompromised hosts.[246]

Fungi

Mucocutaneous candidiasis is common and usually can be treated with topical antifungal agents (nystatin or clotrimazole). Fluconazole is indicated for candidiasis refractory to this therapy or involving the esophagus.[247] It is also useful for therapy of candidemia. One important caveat in the treatment of *Candida* infection with fluconazole is that certain species such as *C. krusei* and *C. glabrata* have a low susceptibility in vitro.[240]

Among patients undergoing heart transplantation, *Aspergillus* is the opportunistic pathogen with the highest attributable mortality.[248] It causes a serious pneumonia in 5 to 10% of recipients during the first 3 months after transplantation. Dissemination of *Aspergillus* to the central nervous system is almost uniformly fatal.[249] Because aspergillosis is highly lethal in the immunocompromised host, even in the

Table 65–11.

Infections in Cardiac Transplant Recipients

Early infections (first month)

I. Pneumonia: Gram negative bacilli (GNB)

II. Mediastinitis and sternal wound infections:
Staphylococcus epidermidis
Staphylococcus aureus
GNB

III. Catheter-associated bacteremia:
S. epidermidis
S. aureus
GNB
Candida albicans

IV. Urinary tract infections:
GNB
Enterococcus
C. albicans

V. Mucocutaneous infections:
Herpes simplex virus (HSV)
Candida spp.

Late infections (after first month)

I. Pneumonia:
A. Diffuse interstitial pneumonia:
Pneumocystis carinii
Cytomegalovirus (CMV)*
HSV
B. Lobar or nodular (cavitary) pneumonia:
Cryptococcus
Aspergillus
Bacteria (community-acquired, nosocomial)
Nocardia asteroides
Mycobacterium spp.

II. Central nervous system infections:
A. Abscess or meningoencephalitis
Aspergillus
*Toxoplasma gondii**
Meningitis
Cryptococcus
Listeria

III. Gastrointestinal (GI) infections:
A. Esophagitis
C. albicans
HSV
B. Diarrhea or lower GI hemorrhage
Aspergillus
Candida spp.

IV. Cutaneous infections:
A. Vesicular lesions
HSV
Varicella-zoster
B. Nodular or ulcerating lesions
Nocardia
Candida (disseminated)
Atypical *Mycobacterium* spp.
Cryptococcus

**Known donor-transmitted pathogens.*

face of therapy, work-up must be prompt and aggressive, and therapy may need to be initiated on suspicion of the diagnosis without definitive proof. Amphotericin B, itraconazole, and recently, voriconazole are acceptable therapy.[250,251]

Protozoa

In heart transplant recipients, the reported incidence of *P. carinii* pneumonia ranges from less than 1% to 10%.[235,252] Since the organism resides in the alveoli, bronchoalveolar lavage usually is necessary for diagnosis.[253] In the case of lung biopsy specimens, histopathologic examination is also helpful. *P. carinii* pneumonia is treated with high-dose trimethoprim-sulfamethoxazole or intravenous pentamidine.[240]

Toxoplasmosis following heart transplantation usually is the result of reactivation of latent disease in the seropositive donor heart because of the predilection of the parasite to invade muscle tissue.[254] *T. gondii* infection may be acquired from undercooked meat and cat feces.[255] The diagnosis is made with certainty only by histologic demonstration of trophozoites with surrounding inflammation in biopsy tissue; PCR also has been used.[256] *T. gondii* usually causes central nervous system infections and is treated with pyrimethamine with sulfadiazine or clindamycin.[240]

CHRONIC COMPLICATIONS FOLLOWING HEART TRANSPLANTATION

Cardiac Allograft Vasculopathy

CAV is a unique, rapidly progressive form of atherosclerosis in transplant recipients that is characterized in its early stages by intimal proliferation and in its later stages by luminal stenosis of epicardial branches, occlusion of smaller arteries,

Table 65–12.

Guidelines for Routine Screening and Prophylaxis of Infections in Heart Transplantation

I. Preoperative Screening
- A. Donor
  1. Clinical assessment
  2. Serologic studies (HIV, HBV, HCV, CMV, *Toxoplasma gondii*)
- B. Recipient
  1. History and physical examination
  2. Serologic studies (HIV, HBV, HCV, CMV, *Toxoplasma gondii*, herpes simplex virus, varicella-zoster virus, Epstein-Barr virus, endemic fungi)
  3. PPD (tuberculin) skin test
  4. Urine culture
  5. Stool for ova and parasites (*Strongyloides sterocoralis*; center-specific)

II. Antimicrobial prophylaxis
- A. Perioperative
  1. First-generation cephalosporin (or vancomycin)
- B. Postoperative
  1. Trimethoprim-sulfamethoxazole or pentamidine (for *Pneumocystis carinii*)
  2. Nystatin or clotrimazole (for *Candida* spp)
  3. Ganciclovir followed by acyclovir once dischared (for all patients except CMV-negative recipient and donor)
  4. Acyclovir (for herpes simplex and zoster; routine use is controversial)
  5. Standard endocarditis prophylaxis
- C. Postoperative immunizations
  1. Pneumococcal (booster every 5 to 7 years)
  2. Influenza A (yearly; center-specific)
  3. Exposure to measles, varicella, tetanus, or hepatitis B by a nonimmunized recipient often warrants specific immunoglobulin therapy (e.g., varicella-zoster immune globulin, VZIG)

and myocardial infarction.[257] Long-term survival of cardiac transplant recipients is limited primarily by the development of CAV, the leading cause of death after the first year post-transplantation.[17,37] Angiographically detectable CAV is reported in approximately 40 to 50% of patients by 5 years after transplantation.[258] Although CAV resembles atherosclerosis, there are some important differences that are illustrated in Fig. 65-10.[259] In particular, intimal proliferation is concentric rather than eccentric, and the lesions are diffuse, involving both distal and proximal portions of the coronary tree. Calcification is uncommon, and the elastic lamina remains intact.

The detailed pathogenesis of CAV is unknown, but there are strong indications that immunologic mechanisms that are regulated by nonimmunologic risk factors are the major causes of this phenomenon.[260] The immunologic mechanisms include acute rejection and anti-HLA antibodies, and some of the implicated risk factors relating to the transplant itself or the recipient are donor age, hypertension, hyperlipidemia, and preexisting diabetes. The side effects often associated with immunosuppression with calcineurin inhibitors or corticosteroids, e.g., CMV infection, nephrotoxicity, and new-onset diabetes, after transplantation also play significant roles.[261–265]

It is generally believed that the initiating event of CAV is subclinical endothelial cell injury in the coronary artery of the allograft, which leads to a cascade of immunologic processes involving cytokines, inflammatory mediators, complement activation, and leukocyte adhesion molecules. These changes produce inflammation and, ultimately, thrombosis, smooth muscle cell proliferation, and vessel constriction. The initial endothelial injury may be the result of ischemia-reperfusion damage or the host-versus-graft immune response.[264,265]

CAV may begin within several weeks posttransplantation and progress insidiously at an accelerated rate to complete obliteration of the coronary lumen with allograft failure secondary to ischemia. The clinical diagnosis of CAV is difficult and complicated by allograft denervation resulting in silent myocardial ischemia. Ventricular arrhythmias, congestive heart failure, and sudden death are commonly the initial presentation of significant CAV.[266] An annual coronary angiogram usually is performed for CAV surveillance.[267] Intravascular ultrasound (IVUS) is better equipped to provide important quantitative information regarding vessel wall morphology and the degree of intimal thickening.[268,269]

Since angiography and IVUS are invasive tests, they pose increased risks for patients. Noninvasive tests (e.g.,

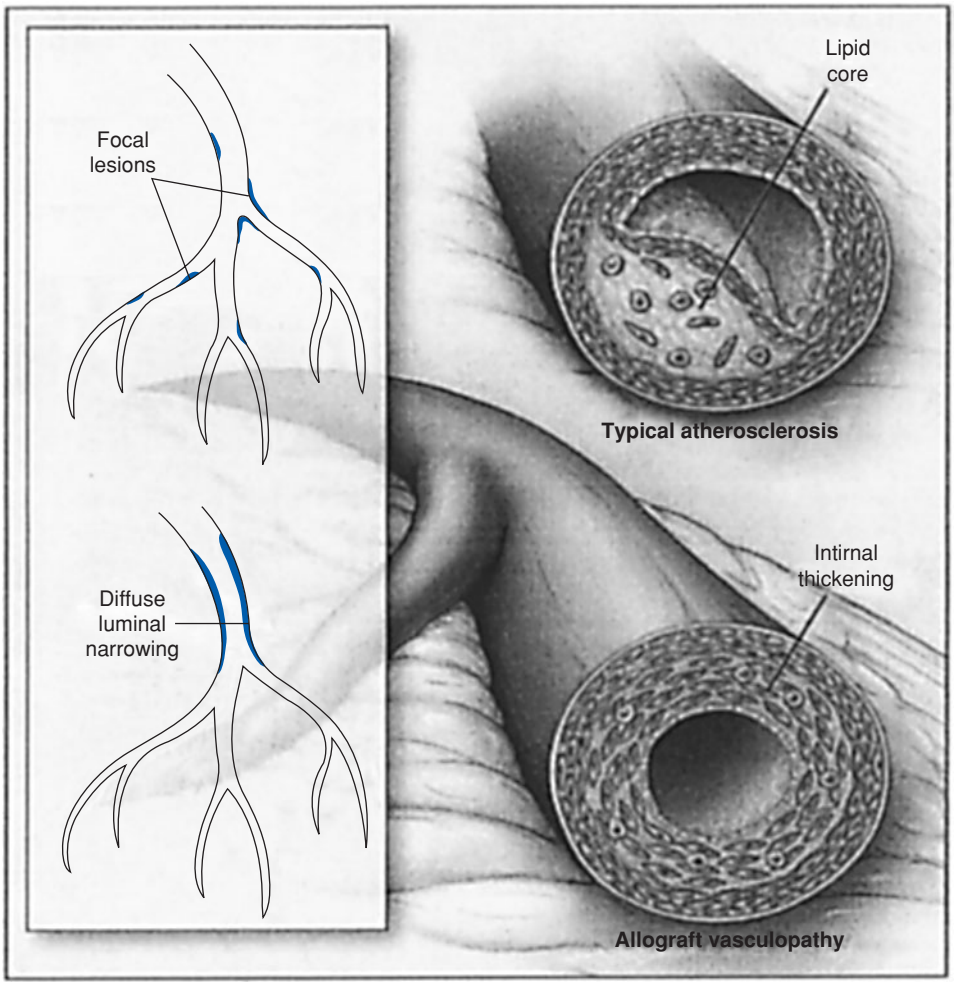

Figure 65-10. Schematic illustration of typical atherosclerosis and cardiac allograft vasculopathy. *(Source: Reprinted with permission from Avery RK.[259])*

thallium scintigraphy and dobutamine stress echocardiography), however, have not been sensitive or specific enough to be a reliable screen for CAV.[270] Other possible modalities include pulse-wave tissue Doppler imaging, electron beam computed tomography (CT), fast CT scanning, and MRI. These modalities may replace invasive procedures in the future.[271]

Currently, the only definitive treatment for advanced CAV is retransplantation, which has risks for the patient and poses problems associated with scarcity of donor organs.[266] Owing to the diffuse and distal nature of the disease, procedures such as stenting and angioplasty are inherently less effective than in nontransplant patients and result in a higher need for repeated procedures.[272] Prophylactic management therefore is of paramount importance. Prior to transplantation, the focus should be on preventing endothelial injury at brain death, reducing cold ischemia time, and improving myocardial preservation during storage and transportation.[266] Postransplantation care focuses on empirical risk factor modification (e.g., dietary and pharmacologic reduction of serum cholesterol, cessation of smoking, hypertension control, etc.). Several studies have demonstrated a decrease in CAV in patients treated with a calcium channel blocker and angiotensin-converting enzyme (ACE) and HMG-CoA reductase inhibitors.[273,274]

Newer immunosuppressive drugs, specifically the proliferation signal inhibitors (e.g., everolimus and sirolimus), may be useful in reducing the incidence and severity of CAV and slowing disease progression.[173–178]

Renal Dysfunction

The 2005 ISHLT registry reported that only 60% of heart transplant recipients are free of severe renal dysfunction (defined as a creatinine concentration of more than 2.5 mg/dL and the need for dialysis or renal transplantation) by Kaplan-Meier estimates at 9.5 years.[17] Furthermore, the risk of death after heart transplantation is markedly increased by the development of end-stage renal failure.[275,276]

Cyclosporine nephrotoxicity after heart transplantation is well recognized and well documented.[277] The improved bioavailability of cyclosporine microemulsion (Neoral) compared with the conventional formulation has led to investigations into monitoring of cyclosporine levels 2 hours after

dosing (C2).[278] Neoral C2 monitoring may be a better indictor of immunosuppression efficacy than trough levels and a better measure to avoid nephrotoxicity and other cyclosporine-associated side effects.[279] Lowering cyclosporine dose may be helpful in slowing the progression of renal disease, especially with concomitant use of newer immunosuppressive regimens such as mycophenolate mofetil and sirolimus (Rapamycin).[280,281] Calcineurin-free immunosuppression is also being implemented by some centers.[282]

Hypertension

Moderate to severe systemic hypertension afflicts 50 to 90% of cardiac transplant recipients.[17,283] Peripheral vasoconstriction in combination with fluid retention seems to play the greatest role. Although the exact mechanisms are unclear, it likely involves a combination of cyclosporine-induced tubular nephrotoxicity and vasoconstriction of renal and systemic arterioles mediated by sympathetic neural activation.[284] Tacrolimus is associated with a lower incidence of hypertension than is cyclosporine.[159] No single class of antihypertensive agents has proven uniformly effective, and treatment of this refractory hypertension remains empirical and difficult. In a prospective, randomized trial, titrated monotherapy with either diltiazem or lisinopril controlled the condition in fewer than 50% of patients.[285] Diuretics should be used cautiously because the balance between edema/hypertension and volume depletion/hypotension can be tenuous in a subset of these patients. Overzealous diuresis can potentiate the apparent nephrotoxicity of cyclosporine by further reducing renal blood flow and altering cyclosporine pharmacokinetics.[286] Beta blockers also should be used with caution because they may further blunt the heart-rate response to exercise.[287]

Malignancy

Chronic immunosuppression is associated with an increased incidence of malignancy ranging from about 4 to 18%, which is 100-fold greater than in the general population.[288] Improved graft and patient survival owing to pharmacologic advances in the area of immunosuppressive therapy has determined an increase in the incidence of neoplasms.[289] Malignant neoplasias have become, along with graft vasculopathy, a significant limiting factor for the long-term survival of heart transplant recipients.[17,139] Lymphoproliferative disorders and carcinoma of the skin are the most common malignancies found in heart transplant recipients.[289–291] Attenuation of T-lymphocyte control over Epstein-Barr virus (EBV)–stimulated B-lymphocyte proliferation appears to be the primary mechanism for the development of lymphoproliferative disorders.[292] The risk of these malignancies is increased further following monoclonal and polyclonal antibody therapy.[193,293] Treatment options in transplantation include a reduction in immunosuppression and high-dose acyclovir (to attenuate EBV replication), in addition to conventional therapies for carcinoma (e.g., chemotherapy, radiation therapy, and surgical resection), which are associated with very high risk and limited success.

Other Chronic Complications

Hyperlipidemia eventually develops in the majority of recipients and is managed with dietary restrictions, exercise, and lipid-lowering agents.[294] Other complications that commonly contribute to posttransplant morbidity include osteoporosis, obesity, cachexia, and gastrointestinal complications, notably cholelithiasis.[295,296]

CARDIAC RETRANSPLANTATION

Retransplantation accounts for fewer than 3% of the cardiac transplants currently performed.[12] Primary indications for retransplantation are early graft failure, allograft coronary artery disease, and refractory acute rejection.[297,298] The operative technique and immunosuppressive regimen are similar to those employed for the initial transplantation. Despite reduced mortality in the cyclosporine era, actuarial survival remains markedly reduced. Analysis of the ISHLT registry for retransplantations performed between 1987 and 1998 reveals survival to be 65%, 59%, and 55% for 1, 2, and 3 years, respectively. Intertransplant interval of 6 months or less was associated with a dismal 1-year survival of 50% in this analysis. Conversely, when the interval between primary and retransplantation was more than 2 years, 1-year survival after retransplantation approached that of primary transplantation.[298] Likewise, in the 2005 registry report, when the subset of recipients in the more recent era between 1996 and 2003 was analyzed, patients undergoing retransplantation at 12 months or more after initial transplantation have 1-year survival rates of approximately 82% (similar to the contemporary cohort of primary transplants at 83%).[17] Advanced donor age also was a predictor of increased mortality among these recipients.[298] These data suggest that although cardiac retransplantation is associated with significant morbidity and mortality, careful selection of patients, especially those who are younger and with longer intertransplant intervals, may be associated with more favorable outcome. Nonetheless, the disparity between the demand and supply for donor hearts makes cardiac retransplantation an ethical issue.[299]

RESULTS OF HEART TRANSPLANTATION

Although no direct comparative trials have been or are likely to be performed, survival following heart transplantation remains favorable if compared with both the medical and device arms of the REMATCH trial.[13,18] The superiority of heart transplantation is more clearly evident in the medium- and high-risk patients with end-stage heart failure.[300] The overall results actually are improving despite increasing risk profiles.[123] Remarkably, transplants performed in 2002 experienced an 18% lower risk of 1-year mortality than those performed in 2000.[17] The reported operative (i.e., 30-day) mortality for cardiac transplantation ranges from 5 to 10%.[301] Overall 1-year survival is up to 85%.[17,123] After the steep fall in survival during the first 6

months, survival decreases at a very linear rate (approximately 3.4% per year), even well beyond 15 years posttransplantation.[17] Graft failure (primary and nonspecific), multiorgan-system failure, and infection account for most deaths within the first 30 days. Infection, graft failure, and acute rejection are the leading causes of death during the first year; thereafter, cardiac allograft vasculopathy and malignancy are the major causes of death.[17,123,302] Studies examining the health-related quality of life (HRQOL) in patients following cardiac transplantation demonstrate marked improvement, particularly in the absence of complications, and approaches the general population by 10 years after transplantation.[303,304]

THE FUTURE

As a result of a series of unprecedented advances over the past decade, the clinical outcome of heart transplantation has improved dramatically. Although cardiac replacement remains the best therapeutic option for patients with end-stage heart failure, a number of challenges await future investigators to further improve survival and reduce transplant-related morbidity. A major factor limiting long-term survival of recipients is allograft rejection and the untoward effects of immunosuppression. Development of reliable, noninvasive diagnostic studies will permit more frequent evaluations for the early detection of rejection and for monitoring the effectiveness of therapy. Ultimately, this will allow more precise control of immunosuppression and, in turn, a reduction in cumulative allograft injury and infectious complications. Molecular tests and gene expression profiling could be available soon and may provide the best noninvasive option.[207,216,217]

Immunosuppressive strategists will continue their efforts to establish specific unresponsiveness to antigens of transplanted organs in hopes of preserving much of the recipient's immune responses. Proliferative signal inhibitors such as sirolimus and everolimus are showing promising results. Alternatively, donor organs may be made less susceptible to immunologic attack through genetic engineering techniques by altering the expression of cell membrane–bound molecules. This approach is being used currently in the pursuit of clinically applicable xenotransplant sources. Xenografts eventually may be an additional source of donor organs, although extended xenograft survival remains an elusive goal.[305] Complicating this alternative are unresolved ethical issues concerning transgenic experimentation and the potential for transmission of veterinary pathogens to an immunosuppressed recipient.

Future improvements in organ preservation permitting extension of the storage interval will have several benefits. In addition to a modest increase in the donor pool, extension of storage times would permit better allocation of organs with respect to donor-recipient immunologic matching. Assist devices are being used currently both as a bridge to transplantation and as a destination therapy. It appears that as the technology of assist devices continues to improve, it is only a matter of time before they become a long-term solution for patients with severe congestive heart failure. Finally, surgical ventricular restoration is gaining increasing application in patients with end-stage heart failure with acceptable results.[306,307]

The concept of regenerating the failing heart using cardiomyocytes of different sources, autologous smooth muscle cells, and dermal fibroblasts is in the experimental stage. Lineage-negative bone marrow cells or bone marrow–derived endothelial precursor cells are also being studied to induce new blood vessel formation after experimental myocardial infarction.[308,309] Cardiac transplantation remains a remarkable achievement of the twentieth century and has revolutionized therapy for end-stage heart failure. Further investigations are needed to overcome the current obstacles to long-term graft function and patient survival.

CHAPTER 66

Heart-Lung and Lung Transplantation

Ahmad Y. Sheikh • Marc P. Pelletier • Robert C. Robbins

The birth and evolution of thoracic organ transplantation have occurred over the past 60 years. With improvement of operative techniques, organ preservation, and immunosuppressive regimens, combined heart-lung and isolated lung transplantation have emerged as life-saving procedures for patients with end-stage cardiopulmonary or pulmonary disease. To date, 3154 combined heart-lung transplants, 10,223 single lung transplants, and 8268 bilateral lung transplants have been reported worldwide.[1] While the number of heart-lung transplants performed annually has declined in recent years, the number of single lung transplantation procedures remains stable, accompanied by a steady increase in bilateral lung transplant procedures. Clinical progress in thoracic organ transplantation has been considerable, yet significant barriers that limit the scope of these procedures still remain. These include donor organ shortage, limited preservation techniques, graft rejection, and infectious complications. This chapter summarizes the state of the art in combined heart-lung and isolated lung transplantation.

HISTORICAL BACKGROUND

History of Heart-Lung Transplantation

Long before the first successful human heart-lung transplants were reported, thoracic organ transplantation flourished in the laboratory. In the 1940s, Demikhov developed the first successful method of en bloc heart-lung transplantation in dogs. In his series of 67 dogs, the longest survivor lived for 6 days postoperatively.[2] These remarkable studies demonstrated the technical feasibility of heart and lung replacement, yet remained largely unknown in the West until the 1960s. In 1953, Marcus and colleagues at the Chicago Medical School described a technique for heterotopic heart-lung grafting to the abdominal aorta and inferior vena cava in dogs (Fig. 66-1).[3] Later studies in the 1960s and early 1970s examined the physiologic effect of total denervation on heart and lung function. Studies by Webb and Howard in 1957 proved discouraging, as they showed failure to resume normal spontaneous respiration following heart-lung replacement in dogs.[4] This physiologic phenomenon was confirmed by several other groups utilizing canine models, including Lower and colleagues in 1961.[5] Fortunately, later studies in primates by Haglin,[6] Nakae,[7] and Castaneda[8,9] and their colleagues showed that unlike dogs, primates resume a normal respiratory pattern following complete denervation with cardiopulmonary replacement. The 1970s saw the development of improved immunosuppressive medications, particularly cyclosporine, which prevented rejection of primate heart-lung allografts after transplantation. Studies from Stanford University showed survival for well over 5 years after heart-lung allografting in primates.[10] In the 1980s, Reitz and colleagues reported a modification to the standard technique of heart-lung replacement, using a retained portion of the right atrium for a single inflow anastomosis instead of separate caval anastomoses (Fig. 66-2).[11] This technique preserved the donor sinoatrial node and eliminated the potential for caval anastomotic stenosis. These studies laid the groundwork for a clinical trial of heart-lung transplantation at Stanford University. On March 9, 1981, Reitz and colleagues performed the first successful human heart-lung transplant in a 45-year-old woman with end-stage primary pulmonary hypertension.[12]

History of Lung Transplantation

Experimental lung transplantation developed in parallel with heart-lung transplantation. In 1949, Henry Metras described important technical concepts, including preservation of the left atrial cuff for the pulmonary venous anastomoses and reimplantation of an aortic patch containing the origin of the bronchial arteries to prevent bronchial dehiscence.[13] Airway dehiscence was a major obstacle in

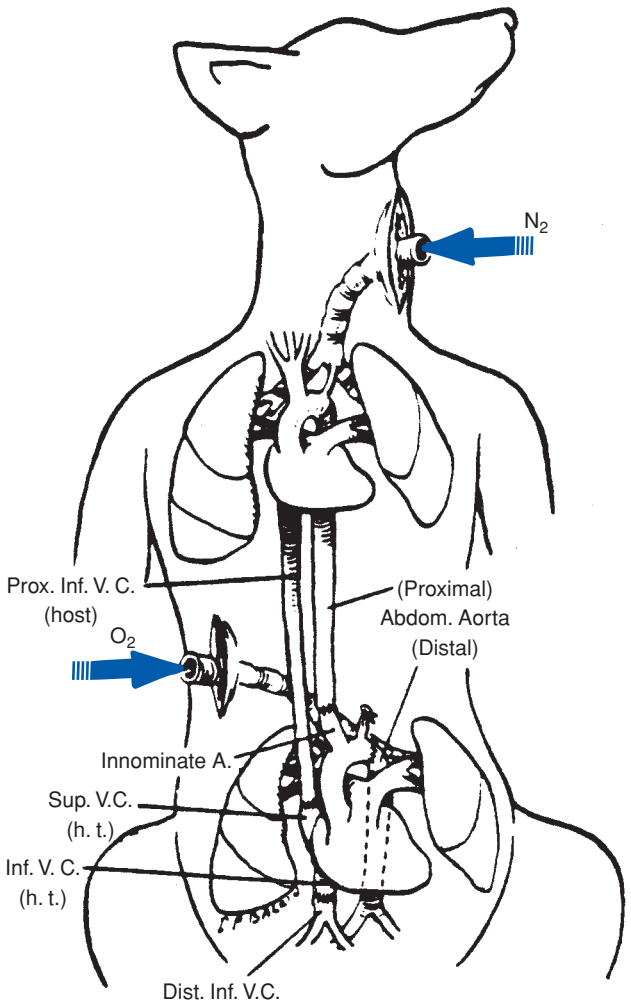

Figure 66-1. Heterotopic heart-lung transplantation in canines as reported by Marcus and associates in 1953. (*From Marcus E, Wong SNT, Luisada AA: Homologous heart grafts. Arch Surg 1953; 66:179. Copyright © 1953, American Medical Association, used with permission.*)

experimental lung transplantation, and he proposed that preservation of the bronchial arterial supply was critical to airway healing. Unfortunately, this technique was technically cumbersome and never gained widespread popularity. In the 1960s, Blumenstock and colleagues advocated transection of the transplant bronchus close to the lung parenchyma to prevent ischemic bronchial necrosis.[14] Additional surgical modifications were developed to prevent bronchial anastomotic complications, including telescoping of the bronchial anastomosis, described by Veith and Richards in 1970,[15] and coverage of the anastomosis with an omental pedicle flap, described by the Toronto group in 1982.[16] Corticosteroids were found to be another contributor to poor bronchial healing,[17] a problem ameliorated by the introduction of cyclosporine immunosuppression. Thus by the 1970s, the stage was set for successful clinical lung transplantation.

The first human lung transplant was described in 1963 by Hardy and colleagues at the University of Mississippi.[18] The patient, a 58-year-old man with lung cancer, survived 18 days postoperatively. Over the next two decades, nearly forty lung transplants were performed without long-term success. In 1986, the Toronto Lung Transplant Group reported the first successful series of single lung transplants with long-term survival.[19] Improved immunosuppression, along with careful recipient and donor selection, were pivotal to their success. For patients with bilateral lung disease, en bloc double lung replacement was introduced by Patterson and associates in 1988.[20] This technique was later replaced by sequential bilateral lung transplantation, described by Pasque and colleagues in 1990.[21] More recent operative innovations include living lobar transplantation, an alternative to cadaveric bilateral lung transplantation.

INDICATIONS AND EVALUATION FOR HEART-LUNG AND LUNG TRANSPLANTATION

Indications for Heart-Lung Transplantation

Upon its introduction in 1982, heart-lung transplantation provided a life-saving therapeutic option for patients with end-stage cardiopulmonary and septic lung disease. Since that time, the techniques of single and double lung transplantation have improved considerably, with fewer indications for combined heart-lung replacement. Moreover, donor organ distribution algorithms, which appropriately distribute donor hearts to critical heart recipients, have also limited the availability of heart-lung blocs.

Heart-lung transplant volumes peaked in the late 1990s, and in 2003 only 74 operations were reported worldwide.[1] The most common indications include congenital heart disease with Eisenmenger syndrome, primary pulmonary hypertension, and cystic fibrosis. The diagnostic profile of heart-lung transplant recipients reported to the Registry of the International Society for Heart & Lung Transplantation (ISHLT) is shown in Fig. 66-3.

Congenital heart disease (atrial and ventricular septal defects and patent ductus arteriosus) with secondary pulmonary hypertension (Eisenmenger syndrome) is the most frequent indication, found in over one-third of patients. Congenital cardiac lesions that may lead to Eisenmenger syndrome include atrial and ventricular septal defects, patent ductus arteriosus, and truncus arteriosus. Other complex congenital heart defects have also been treated successfully with heart-lung transplantation, including univentricular heart with pulmonary atresia, truncus arteriosus, and hypoplastic left heart syndrome.

Data regarding the long-term survival benefit of heart-lung transplantation in patients with Eisenmenger syndrome remain unclear.[22] Some data suggest that pulmonary hypertension in these patients has a more favorable prognostic course than other types of pulmonary hypertension. There is clear evidence, however, that quality of life is improved by transplantation.[23] In patients with simpler cardiac defects,

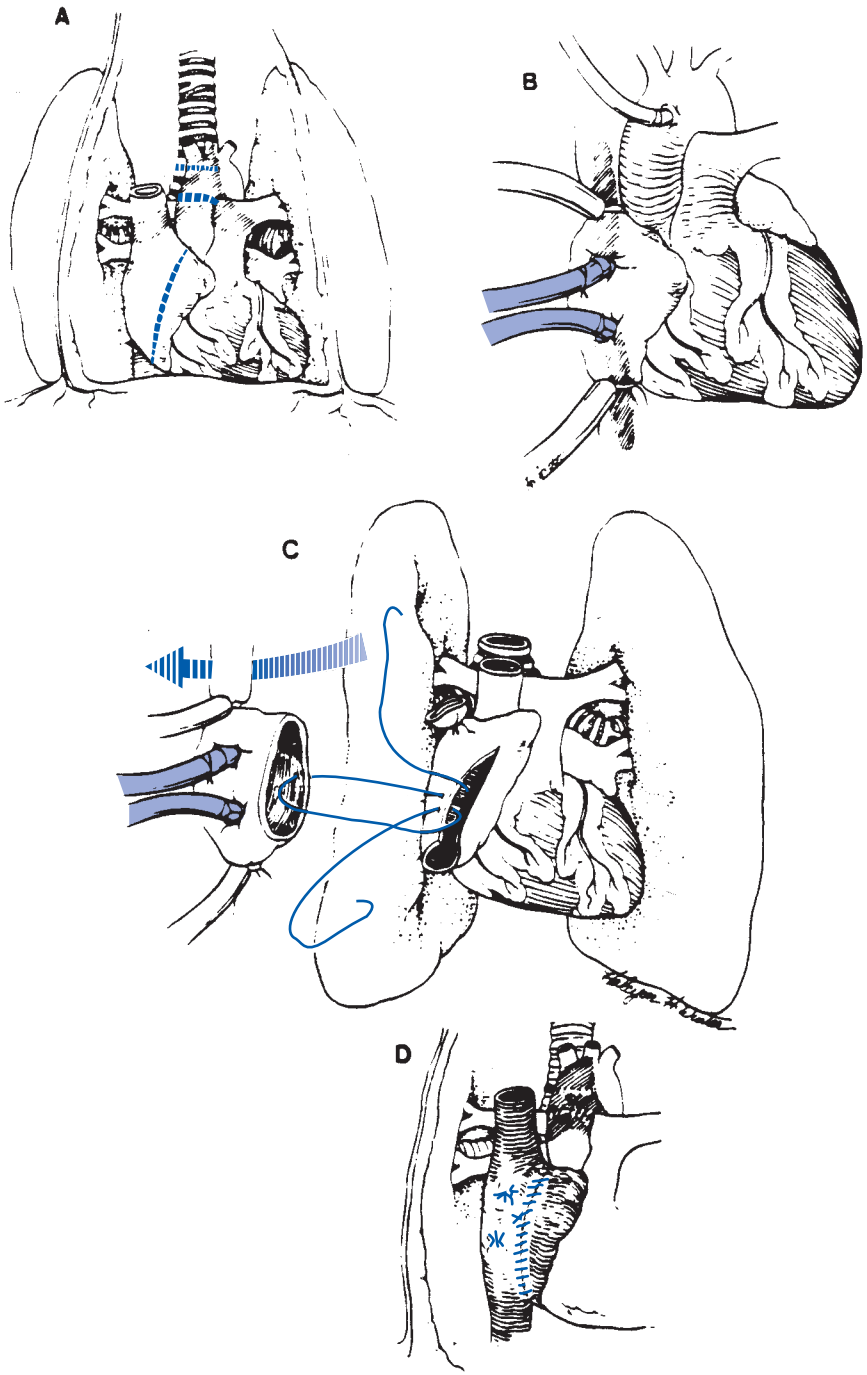

Figure 66-2. Simplified technique for heart-lung transplantation as described by Reitz and colleagues in 1981. (A) Native heart-lung en bloc dissection with preservation of phrenic nerves on pedicles and lines of transection along the right atrium, aorta, and trachea. (B) Cannula configuration for recipient cardiopulmonary bypass with venous cannulas placed in the lower right atrium and arterial cannula in the ascending aorta. (C) Inflow (right atrial) anastomosis. The graft right atrial cuff is constructed by ligating the superior vena cava and opening the right atrium from the inferior vena caval orifice toward the appendage. Note that the right lung is passed behind the vena cava and right phrenic nerve pedicle. (D) Completed transplantation with right atrial, aortic, and tracheal anastomoses shown. (*From Reitz BA, Pennock JL, Shumway NE: Simplified operative method for heart and lung transplantation. J Surg Res 1981; 31:1. Used by permission from Academic Press, Inc.*)

repair of the cardiac defect combined with single or bilateral lung transplantation is an alternative option.

Primary pulmonary hypertension with right-sided heart failure is the second most common diagnosis in heart-lung transplant recipients. Nearly one-quarter of patients in the ISHLT registry carry this diagnosis. Recently there has been a shift toward single and bilateral lung transplantation in this population.[24] This new paradigm is based on the finding that normalization of pulmonary pressures following lung transplantation often allows for recovery of right heart function. However, in patients with severe right-sided heart failure and primary pulmonary hypertension, heart-lung transplantation is clearly the operation of choice.

The balance of heart-lung transplants are performed for a variety of cardiac and pulmonary diseases. These include cystic fibrosis and other septic lung diseases, severe coronary artery disease with intercurrent end-stage lung disease, and primary parenchymal lung disease with severe right-sided heart failure (e.g., idiopathic pulmonary fibrosis, lymphangioleiomyomatosis, sarcoidosis, and desquamative interstitial pneumonitis).

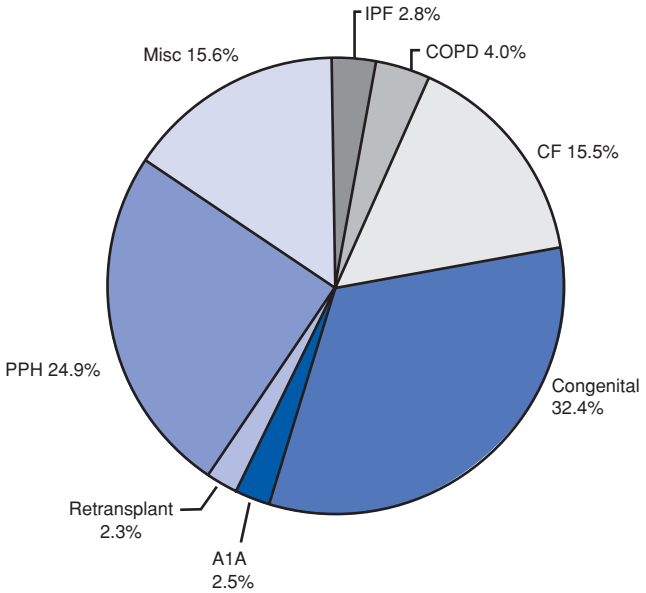

Figure 66-3. Distribution of indications for patients requiring heart-lung transplantation. A1A = alpha$_1$-antitrypsin deficiency; CF = cystic fibrosis; COPD = chronic obstructive pulmonary disease; IPF = idiopathic pulmonary fibrosis; Misc = miscellaneous; PPH = primary pulmonary hypertension. (*Adapted from Trulock EP, Edwards LB, Taylor DO, et al: Registry of the International Society for Heart & Lung Transplantation: Twenty-second official adult lung and heart-lung transplant report—2005. J Heart Lung Transplant 2005; 24:956. Used with permission from Elsevier Science.*)

Septic lung disease was a historically significant indication for heart-lung transplantation. The domino procedure, which emerged in the late 1980s, took explanted hearts from these patients and offered them to a second recipient in need of heart transplantation.[25–27] While studies show equivalent survival in recipients of domino heart grafts, the domino procedure is now rarely performed. Instead, bilateral lung transplantation has become the procedure of choice for end-stage septic lung disease.[28,29] Bilateral transplants avoid the pitfalls of cardiac denervation and graft coronary artery disease associated with heart-lung transplantation.

Indications for Lung Transplantation

In recent years, the number of lung transplant procedures performed annually has plateaued. Worldwide, 1703 lung transplants were reported in 2003. In recent years, the number of bilateral lung transplants has surpassed that of single lung transplants, accounting for nearly 55% of all lung transplant procedures. A small number of living lobar transplants are also being performed annually.[1]

The primary indications for single lung transplantation are emphysema and pulmonary fibrosis (Fig. 66-4A). Patients with emphysema comprise over half of single lung transplant recipients. In some cases, hyperinflation of the native emphysematous lung may lead to compressive atelectasis and restriction of the donor lung. This may result in a significant ventilation-perfusion mismatch. In such cases, native lung volume reduction can be used to preserve allograft function.[30] Some evidence demonstrates that late allograft function may be superior in emphysematous patients treated with bilateral rather than single lung transplantation.[31] However, given the donor organ shortage, single lung transplantation remains the preferred therapeutic option.

The principal indications for bilateral lung transplantation are septic lung disease, emphysema, primary pulmonary hypertension, and pulmonary fibrosis (see Fig. 66-4B).[30] While

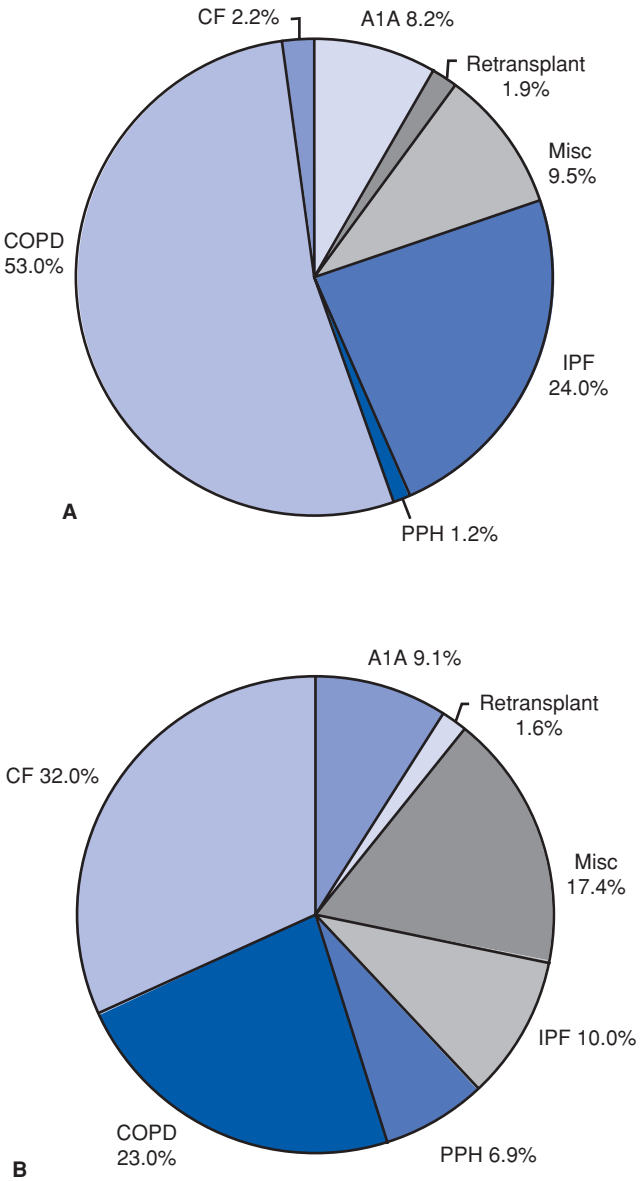

Figure 66-4. Distribution of indications for patients requiring single (A) and bilateral (B) lung transplantation. A1A = alpha$_1$-antitrypsin deficiency; CF = cystic fibrosis; COPD = chronic obstructive pulmonary disease; IPF = idiopathic pulmonary fibrosis; Misc = miscellaneous; PPH = primary pulmonary hypertension. (*Adapted from Trulock EP, Edwards LB, Taylor DO, et al: Registry of the International Society for Heart & Lung Transplantation: Twenty-second official adult lung and heart-lung transplant report—2005. J Heart Lung Transplant 2005; 24:956. Used with permission from Elsevier Science.*)

single lung transplantation may be performed for emphysema, primary pulmonary hypertension, and pulmonary fibrosis, it is not an option for septic lung disease. In these patients, bilateral sepsis mandates removal of both native lungs. Primary pulmonary hypertension can be treated with both bilateral and single lung transplants, though most centers advocate bilateral lung transplantation. There is evidence from long-term survivors demonstrating that the effects of bronchiolitis obliterans are better tolerated in bilateral lung transplant recipients. However, in a single-center, retrospective study of 58 patients undergoing either single lung or bilateral lung transplantation for pulmonary hypertension, Gammie and colleagues found equivalent survival at 1 and 4 years.[24] While Gammie's group advocates the preferential application of single lung transplantation in this patient population, this indication will remain controversial until larger clinical trials are conducted.

Less than 2% of all single and bilateral lung transplants are retransplantations.[1] Overall, survival is poor compared to first-time transplantation, though certain subsets of patients perform better than others. In fact, the Pulmonary Retransplant Registry has collected data from 230 patients at over 40 centers and found that 1-year survival of ambulatory, nonventilated patients undergoing retransplantation after 1991 is comparable to that of first-time transplants.[32]

Finally, lobar transplantation is another option for end-stage lung disease. Living lobar transplantation was developed by Starnes and colleagues and has its greatest application in children with cystic fibrosis. The left and right lower lobes from two separate donors are transplanted into the recipient. The procedure is most applicable to children and adults of small stature. In children, lobar transplantation affords improved long-term survival and freedom from bronchiolitis obliterans syndrome compared to cadaveric transplants. In the adult population, however, results have been comparable to those of cadaveric transplants.[33–35]

Recipient Selection Criteria

The primary objective in recipient evaluation is to select individuals with progressively disabling cardiopulmonary or pulmonary disease who still possess the capacity for full rehabilitation after transplantation. Notably, early attempts at thoracic transplantation were thwarted by selection of critically ill recipients, and it was not until the development of strict recipient selection criteria that heart-lung and lung transplantation achieved success.

Candidates should have a projected life expectancy of less than 18 to 24 months despite appropriate medical or alternative surgical strategies. On average, waiting times can range from 6 to 36 months. Unfortunately, mortality while on the waiting list remains nearly 20% for both lung and heart-lung transplant candidates. Therefore it is imperative that recipients be identified as early as possible within the "transplant window."[36]

Disabling symptoms prompting consideration for transplantation typically include dyspnea, cyanosis, syncope, and hemoptysis. Most recipients for heart-lung transplantation also fall within New York Heart Association functional classes III or IV.[37] Potential recipients are identified by their local primary physicians and referred to transplantation centers for further evaluation. This includes a complete history, physical exam, laboratory tests, specialized studies, and a psychosocial evaluation.

Among most heart-lung transplant programs, the upper recipient age limit is 50 years. For bilateral lung transplantation the limit is 55 years, and for single lung transplantation 60 years. These values represent a relaxation of previous age limits, reflecting the ongoing evolution of recipient selection criteria. Unfortunately, the expansion of recipient eligibility further exacerbates the problem of donor organ shortage.

There are well-established contraindications to lung and heart-lung transplantation (Table 66-1). Significant

Table 66–1.

Recipient Contraindications to Heart-Lung and Lung Transplantation

Age >50 years (heart-lung), >55 years (bilateral lung), and >60 years (single lung)
Significant systemic or multisystem disease (e.g., peripheral or cerebrovascular disease, portal hypertension, or poorly controlled diabetes mellitus)
Significant irreversible hepatic or renal dysfunction (e.g., bilirubin >3.0 mg/dL or creatinine clearance <50 mg/mL/min)
Active malignancy
Corticosteroid therapy (>10 mg/d)
Panresistant respiratory flora
Cachexia or obesity (<70% or >130% of ideal body weight)
Current cigarette smoking
Psychiatric illness or history of medical noncompliance
Drug or alcohol abuse
Previous cardiothoracic surgery (considered on a case-by-case basis)
Severe osteoporosis
Prolonged mechanical ventilation
Human immunodeficiency virus infection
Hepatitis B surface antigen positivity
Hepatitis C infection with biopsy-proven liver disease

multisystem disease is a contraindication, though multiorgan transplants have occasionally been performed. Renal dysfunction, active malignancy, infection with human immunodeficiency virus (HIV), hepatitis B antigen positivity, hepatitis C infection with biopsy-proven liver disease, and infection with panresistant respiratory flora are absolute contraindications. Relative contraindications include active extrapulmonary infection, symptomatic osteoporosis, recent history of active peptic ulcer disease, cachexia or obesity, drug or alcohol abuse, and psychiatric illness or history of medical noncompliance. Cigarette smokers must quit smoking and remain abstinent for several months before transplantation. Patients with histories of previous thoracic surgery are evaluated on a case-by-case basis. For patients who require systemic corticosteroids, tapering to the lowest tolerable level, preferably below 10 mg/d, is critical to prevent airway healing complications. Finally, mechanical ventilation is generally considered a contraindication to transplantation; repeated studies have shown that these patients have significantly worse immediate and long-term survival after transplantation.[38] In addition to meeting these criteria, a stable and supportive socioeconomic environment is an important criterion. Recipients should be carefully evaluated by social workers and psychologists. It is important that recipient candidates be educated about lifestyle modifications necessary for the success of a transplant, and willingness to comply with immunosuppression regimens and extensive posttransplant medical and surgical follow-up is a must.

Clinical and Laboratory Criteria for Listing

Tests required for transplant listing are reviewed in Table 66-2. Diagnostic studies that are particularly useful in evaluating potential recipients include full pulmonary function tests, an exercise performance test, electrocardiogram, echocardiogram, 24-hour creatinine clearance, and liver function tests.

Certain patient populations may require additional evaluation. For example, cystic fibrosis recipients should have an otolaryngologic evaluation before being placed on an active waiting list. Most of these patients will require endoscopic maxillary antrostomies for sinus access and monthly antibiotic irrigation to decrease the bacterial load of the upper respiratory tract. This measure has decreased the incidence of serious posttransplant bacterial infections.[39] Former smokers must undergo screening to exclude smoking-related illnesses, such as peripheral vascular disease and malignancy. A negative sputum cytology, thoracic computed tomography scan, bronchoscopy, otolaryngologic evaluation, and carotid duplex scan are required. In addition, left heart catheterization and coronary angiography should be performed in recipient candidates who have a history of smoking.

Patients deemed suitable for transplantation during the initial evaluation are subjected to a final phase of testing (see Table 66-2). If accepted by the transplant review committee, they are listed on the national transplant registry on the basis of clinical urgency, time on the waiting list, ABO

Table 66–2.

Typical Laboratory Tests and Studies Obtained During Recipient Evaluation for Heart-Lung and Lung Transplantation

Suitability for transplantation (phase I)

Required laboratory tests and studies

- Complete blood cell count with differential, platelet, and reticulocyte count
- Blood type and antibody screen (ABO and Rh)
- Prothrombin and activated partial thromboplastin time
- Bleeding time
- Immunology panel (fluorescent antinuclear antibody and RF)
- Electrolytes, including Mg^{2+}
- Creatine kinase with isoenzymes
- Serum protein electrophoresis
- Urinalysis
- Viral serologies
  - Compromised host panel (cytomegalovirus, adenovirus, varicella-zoster, herpes simplex, and Epstein-Barr virus)
  - Hepatitis A, B, and C antibodies and hepatitis B surface antigen
  - Cytomegalovirus (quantitative antibodies and IgM)
  - Human immunodeficiency virus
- Electrocardiogram
- Chest x-ray

Studies obtained as indicated

- Echocardiogram with bubble study
- Multiple-gated acquisition (MUGA) scan for right and left ventricular ejection fraction
- Cardiac catheterization with coronary angiogram
- Thoracic computed tomography scan
- Quantitative ventilation-perfusion scans
- Carotid duplex scan
- Mammogram
- Colonoscopy
- Sputum for Gram stain, acid-fast bacillus smear, potassium hydroxide test, and routine bacterial, mycobacterial, and fungal cultures

Required for listing (phase II)

- Human leukocyte antigen (HLA) and HLA-DR typing
- Transplant antibody
- Quantitative immunoglobulins
- *Histoplasma, Coccidioides,* and *Toxoplasma* titers
- Purified protein derivative tuberculin test
- Pulmonary function tests with arterial blood gases
- 12-Hour urine collection for creatinine clearance and total protein
- Urine viral culture

blood group, and thoracic cage dimensions. Listed candidates should be seen every 3 to 6 months at the transplant center and regularly by their primary physicians in order to maintain optimal medical condition. If appropriate, a period of exercise rehabilitation and nutritional modification may be initiated. Most transplant centers will require patients to reside within several hours of the center by automobile or air charter.

ABO compatibilities are strictly adhered to, because isolated cases of hyperacute rejection have been reported in transplants performed across ABO barriers. Donor-to-recipient lung volume matching is based on the vertical (apex to diaphragm along the midclavicular line) and transverse (level of diaphragmatic dome) radiologic dimensions on chest x-ray, as well as body weight, height, and chest circumference. Matching donor and recipient height seems the most reproducible method for selection of appropriate donor lung size, and donor lung dimensions should not be greater than 4 cm more than those of the recipient. If need be, donor lungs may be downsized by lobectomy.

In a series of 82 heart-lung transplants at Papworth Hospital, Tamm and associates recorded recipient lung volumes posttransplantation followed by a comparison to preoperative and predicted volumes to evaluate the influence of donor lung size and recipient underlying disease.[40] The investigators demonstrated that by 1 year after surgery, total lung capacity and dynamic lung volume returned to values predicted by the patient's sex, age, and height. They proposed that the simplest method of matching donor lung size to that of the recipient is to use their respective predicted total lung capacity values. Moreover, they concluded that recipients should attain their predicted lung volumes by 1 year posttransplantation, and failure to do so suggests possible complications within the transplanted lungs.

In contrast to renal transplantation, human leukocyte antigen (HLA) matching is not a criterion for thoracic organ allocation. Because only short ischemic times are tolerated by lung and heart-lung blocs, it is not possible to perform this tissue typing preoperatively.[41] However, several retrospective studies have been performed evaluating the influence of HLA matching on long-term graft survival and development of obliterative bronchiolitis. Wisser and colleagues examined the relationship between HLA matching and long-term survival in 78 lung transplant recipients, finding improved graft survival with matching at the HLA-B locus.[42] In a retrospective study of 74 lung transplant patients, Iwaki and associates also correlated matching at the HLA-B and HLA-DR loci with improved graft survival.[43] Harjula and coworkers at Stanford evaluated the relationship between HLA matching and outcomes in heart-lung transplantation.[44] Among 40 heart-lung transplant recipients evaluated, they found a significant increase in graded obliterative bronchiolitis with total mismatch at the HLA-A locus. These studies all suggest a relationship between HLA matching and long-term graft function.

Once an appropriate donor-recipient pairing is made, the recipient is screened for preformed antibodies against a panel of random donors. A percent reactive antibody level greater than 25% prompts a prospective specific cross-match between the donor and recipient. A positive cross-match indicates the presence of anti-donor circulating antibodies in the recipient that would likely lead to hyperacute rejection. In the event of a positive cross-match, the donor organ cannot be accepted for that recipient.

RECIPIENT MANAGEMENT AFTER LISTING

It is essential that a candidate's medical condition be optimized prior to heart-lung and lung transplantation. Standard medical measures should be aggressively employed by the patient's local physician, and the patient should have routine follow-up at the transplant center.

Supplemental oxygen is recommended for any patient exhibiting arterial hypoxemia, defined as either an arterial oxygen saturation $<90\%$ or an arterial partial oxygen pressure <60 mm Hg at rest, during exertion, or while asleep.

For patients with heart failure, standard therapeutic measures are applied, including dietary restrictions, diuretics, and vasodilators. Restriction of dietary water and salt combined with diuretic therapy facilitates intravascular fluid management. Particular care must be exercised when using loop diuretics in patients with underlying pulmonary disease. These potent diuretics can result in metabolic alkalosis, thereby depressing the effectiveness of plasma carbon dioxide as a stimulus for breathing. Vasodilators reduce afterload, improve functional capacity, and prolong survival in patients suffering from severe cardiac failure.[45] Commonly used vasodilators include nitrates, hydralazine, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers.

Although primary pulmonary hypertension may stem from a broad range of etiologies, conventional medical therapy targets the sequelae of pulmonary vascular derangements associated with this disease. In cases of arterial hypoxemia, supplemental oxygen therapy is recommended to prevent hypoxia-induced pulmonary vasoconstriction and secondary erythropoiesis. This eases the burden placed on the right side of the heart and diminishes the likelihood of cardiac arrhythmias. Pulmonary vasodilator therapy is important in the treatment of primary pulmonary hypertension, and includes the use of calcium channel blockers and continuous prostacyclin infusions.[46] As most standard vasodilators have potent systemic effects, careful dosing and follow-up is essential. Approximately 20% of patients with primary pulmonary hypertension will respond to calcium channel blockers. Often a favorable response to short-acting vasodilators during cardiac catheterization is predictive of a successful response to calcium channel blocker therapy. In contrast, response to an acute vasodilator challenge does not always predict the response to long-term prostacyclin infusion.

Interstitial lung disease in patients awaiting transplantation results from a wide variety of diffuse inflammatory processes such as sarcoidosis, asbestosis, and collagen vascular

diseases. Increases in pulmonary vascular resistance leading to right-sided heart failure are thought to arise from interstitial inflammatory infiltrates that entrap and eventually destroy septal arterioles, thus reducing the distensibility of the remaining pulmonary vessels.[47] This process, coupled with closure of peripheral bronchioles, results in arterial hypoxemia, further aggravating pulmonary hypertension. Corticosteroids are the mainstay of treatment in this class of diseases. The adverse effects of steroids on airway healing are well-established[17,48] and mandate significant dose reductions in anticipation of heart-lung and isolated lung transplantation.

The multisystem manifestations of cystic fibrosis, particularly chronic bronchopulmonary infection, malabsorption, malnutrition, and diabetes mellitus, pose difficult management problems in potential transplant recipients. These patients require aggressive chest physiotherapy, antibiotics, enteral or parenteral nutritional supplementation, and tight serum glucose control.[49]

Certain underlying diagnoses are associated with increased rates of pulmonary and systemic thrombosis and embolization. These include patients with dilated cardiomyopathy, congestive heart failure, and primary pulmonary hypertension,[47] and most centers recommend routine prophylactic anticoagulation with heparin, warfarin, or antiplatelet agents.

ORGAN PROCUREMENT AND PRESERVATION

Donor Selection

Standard criteria have been established for donor selection (Table 66-3).[50,51] Donors must have sustained irreversible brain death, but due to the susceptibility of the lungs to edema and infection, particularly in the setting of brain death and trauma, suitable heart-lung and lung blocs are more difficult to obtain than other organs. Less than 20% of organ donors possess lungs suitable for transplantation.

Table 66–3.

Heart-Lung and Lung Donor Selection Criteria

Age <40 years (heart-lung), <50 years (lung)
Smoking history less than 20 pack-years
Arterial partial oxygen pressure of 140 mm Hg on a fraction of inspired oxygen (F_{IO_2}) of 40% or 300 mm Hg on an F_{IO_2} of 100%
Normal chest x-ray
Sputum free of bacteria, fungi, or significant numbers of white blood cells on Gram and fungal staining
Bronchoscopy showing absence of purulent secretions or signs of aspiration
Absence of thoracic trauma
Human immunodeficiency virus negative

Initial donor evaluation consists of a directed history and physical examination, chest x-ray, 12-lead electrocardiogram, arterial blood gases, and serologic screening (including HIV, hepatitis B surface antigen, hepatitis C antibodies, herpes simplex virus, cytomegalovirus [CMV], *Toxoplasma*, and rapid plasma reagin). A donor age of less than 50 is preferred. The chest x-ray should be clear and the arterial partial oxygen pressure (P_{O_2}) should exceed 140 mm Hg on a fraction of inspired oxygen (F_{IO_2}) of 40% or 300 mm Hg on an F_{IO_2} of 100%. Lung compliance can be estimated by measuring peak inspiratory pressures, which should be less than 30 cm H_2O. Bronchoscopy should ensure the absence of purulent secretions or signs of aspiration. Combined heart-lung donors must have no significant cardiac history, be free of coronary atherosclerosis, and possess normal heart function by echocardiography. Coronary angiography may also be indicated in donors with cardiac risk factors. Finally, direct inspection and palpation of the heart and lungs at explantation is an essential part of the donor organ evaluation.

Absolute contraindications to lung and heart-lung donation include prolonged cardiac arrest, arterial hypoxemia, active malignancy (excluding basal cell and squamous cell carcinoma of the skin), and positive HIV status. For heart-lung donation, severe coronary or structural heart disease and prior myocardial infarction are additional contraindications. Relative contraindications to both lung and heart-lung donation include thoracic trauma, sepsis, significant smoking history, prolonged severe hypotension (i.e., less than 60 mm Hg for over 6 hours), hepatitis B surface antigen or hepatitis C antibodies, multiple resuscitation attempts, and a prolonged high inotropic requirement (e.g., dopamine in excess of 15 μg/kg per minute for 24 hours). It is important to rule out correctable metabolic or physiologic causes of cardiac rhythm disturbances and electrocardiographic anomalies (e.g., brain herniation, hypothermia, or hypokalemia).

Over the last decade, there has been a trend toward liberalization of standard donor selection criteria. This strategy, initiated in response to the shortage of donor organs, is employed at a large number of transplant centers.[52–56] Donors ranging from age 50 to 64 have been used in thoracic transplantation, with good long-term graft survival.[55] However, reports from the ISHLT document worse outcomes in recipients of lung allografts from donors over 55 that had ischemic times over 6 to 8 hours.[57] In this group of recipients, long-term survival is impaired and the risk of developing bronchiolitis obliterans is increased. A limitation on smoking history is another criterion that has been liberalized. Conventional guidelines limit smoking history to less than 20 pack-years, but modified criteria allow for a more extensive smoking history, assuming there is no evidence of chronic obstructive pulmonary disease or other lung disease

on screening tests. Other extended criteria include use of lungs from donors whose sputum Gram stains show presence of bacteria. In such cases, treatment with antimicrobials is initiated in the donor and continued post transplantation in the recipient. In general, the presence of fungus in donor sputum samples is a contraindication to donation. Some groups have accepted donors with small pulmonary infiltrates on chest x-ray, though clinical correlation is necessary. Others have selectively used donor lungs in patients with partial arterial oxygen pressure (Pa_{O_2}) less than 300 mm Hg on F_{IO_2} of 100%.

Gabbay and associates in Australia have adopted an aggressive approach to donor management and "organ resuscitation."[53] By manipulating donors with antibiotic therapy, chest physiotherapy, careful fluid management, ventilator adjustments, and pulmonary toilet, 34% of donors with an initial Pa_{O_2} less than 300 mm Hg on F_{IO_2} of 100% had increases in their Pa_{O_2}, becoming acceptable donors.

Areas of investigation in the field of donor organ procurement include the use of non-heart-beating donors. In 2001, Steen and colleagues reported transplantation of lungs from a non-heart-beating donor into a 54-year-old woman with chronic obstructive pulmonary disease,[58] with good functional results during the first 5 months of follow-up. However, ethical, logistic, and scientific questions remain on the use of non-heart-beating donors, and this strategy is far from being widely applicable.

It is essential that each donor be evaluated on a case-by-case basis. While certain selection criteria remain absolute, others must be considered in the context of the individual donor and recipient. Moreover, as knowledge in the field of thoracic transplantation grows, selection criteria will likely require further modification.

Donor Management

The overriding goal in managing the thoracic organ donor is to maintain hemodynamic stability and pulmonary function. Patients suffering from acute brain injury are often hemodynamically unstable due to neurogenic shock, excessive fluid losses, and bradycardia. Donor lungs are prone to neurogenic pulmonary edema, aspiration, nosocomial infection, and contusion. Continuous arterial and central venous pressure monitoring, judicious fluid resuscitation, vasopressors, and inotropes are usually required.

Meticulous fluid management prevents intraoperative blood pressure instability and minimizes the need for inotropes and vasopressors that stress the myocardium. Intravascular volume replacement should be given to maintain the central venous pressure between 5 and 8 mm Hg, though fluids should not be administered at rates that far exceed hourly urine output. In general, crystalloid fluid boluses are to be avoided. Diabetes insipidus is common in donors and requires the use of intravenous vasopressin (0.8 to 1.0 U/h) to prevent excessive urine loss.

Dopamine is the standard inotropic agent used to maintain adequate perfusion pressures, although alpha agonists (e.g., phenylephrine) are often appropriate. Blood transfusions should be used sparingly to maintain a hemoglobin concentration of approximately 10 g/dL, ensuring adequate myocardial oxygen delivery. CMV-negative and leukocyte-filtered blood should be used whenever possible. Hypothermia should be avoided, as it predisposes to ventricular arrhythmias and metabolic acidosis.

With regard to mechanical ventilation, F_{IO_2} values in excess of 40%, especially 100% oxygen "challenges," should be avoided, since these oxygen levels may be toxic to the denervated lung. Ventilator settings should include positive end-expiratory pressure (PEEP) between 3 and 5 cm H_2O to prevent atelectasis.

Donor Operation

The donor operation is performed via a median sternotomy (Fig. 66-5A). After the sternum is divided, a standard chest retractor is placed, and both pleural spaces are opened followed by immediate inspection of the lungs and pleural spaces, particularly in cases involving trauma. The lungs are briefly deflated, and the pulmonary ligaments are divided inferiorly using electrocautery. After completely excising the thymic remnant, the pericardium is opened vertically and laterally on the diaphragm and cradled during dissection of the great vessels and trachea. The ascending aorta, pulmonary artery, and venae cavae are dissected. Umbilical tapes are placed around the ascending aorta and venae cavae (Fig. 66-5B). The pericardium overlying the trachea is incised vertically, and the trachea is encircled with an umbilical tape between the aorta and superior vena cava at the highest point possible and at least four rings above the carina (see Fig. 66-5B). The entire anterior pericardium is excised back to each hilum (Fig. 66-5C).

Approximately 15 minutes prior to applying the aortic cross-clamp, prostaglandin E_1 (PGE_1) is infused intravenously, initially at a rate of 20 ng/kg per minute, followed by incremental increases of 10 ng/kg per minute to a target rate of 100 ng/kg per minute (Fig. 66-5D). During PGE_1 infusion, the mean arterial blood pressure should be maintained at or above 55 mm Hg. Ventilation is continued with an F_{IO_2} of 40% and a PEEP of 3 to 5 cm H_2O. The donor is heparinized. The superior vena cava is ligated and a straight Potts clamp is placed across the inferior vena cava. After the heart is allowed to empty, the aortic cross-clamp is applied, and 10 mL/kg of cold crystalloid cardioplegia, commonly the Stanford formulation, is rapidly infused into the aortic root. The inferior vena cava is incised, and the left atrial appendage is amputated to avoid cardiac distension. While the antegrade cardioplegia is being delivered, Perfadex (Vitrolife Inc., Englewood, Colo) is rapidly flushed into the main pulmonary artery at a rate of 15 mL/kg per minute for 4 minutes. Ice-cold saline or Physiosol solution (Abbott Laboratories, North Chicago, Ill) is immediately poured over the heart and lungs. During the cardioplegic and Perfadex infusions, ventilation is maintained with half-normal tidal volumes of room air. Upon completion of the infusions and

topical cold application, all solutions are aspirated from the thoracic cavity and the lungs are fully deflated.

For combined heart-lung blocs, the bloc is dissected free from the esophagus commencing at the level of the diaphragm and continuing cephalad to the level of the carina. Dissection is kept close to the esophagus, and care is taken to avoid injury to the trachea, lung, or great vessels. The posterior hilar attachments are divided. The lungs are inflated to a full normal tidal volume, and the trachea is stapled at the highest point possible with a TA-55 stapler (U.S. Surgical, Norwalk, Conn), at least four rings above the carina (Fig. 66-5E). The trachea is then divided above the staple line, and the entire heart-lung bloc is removed from the chest.

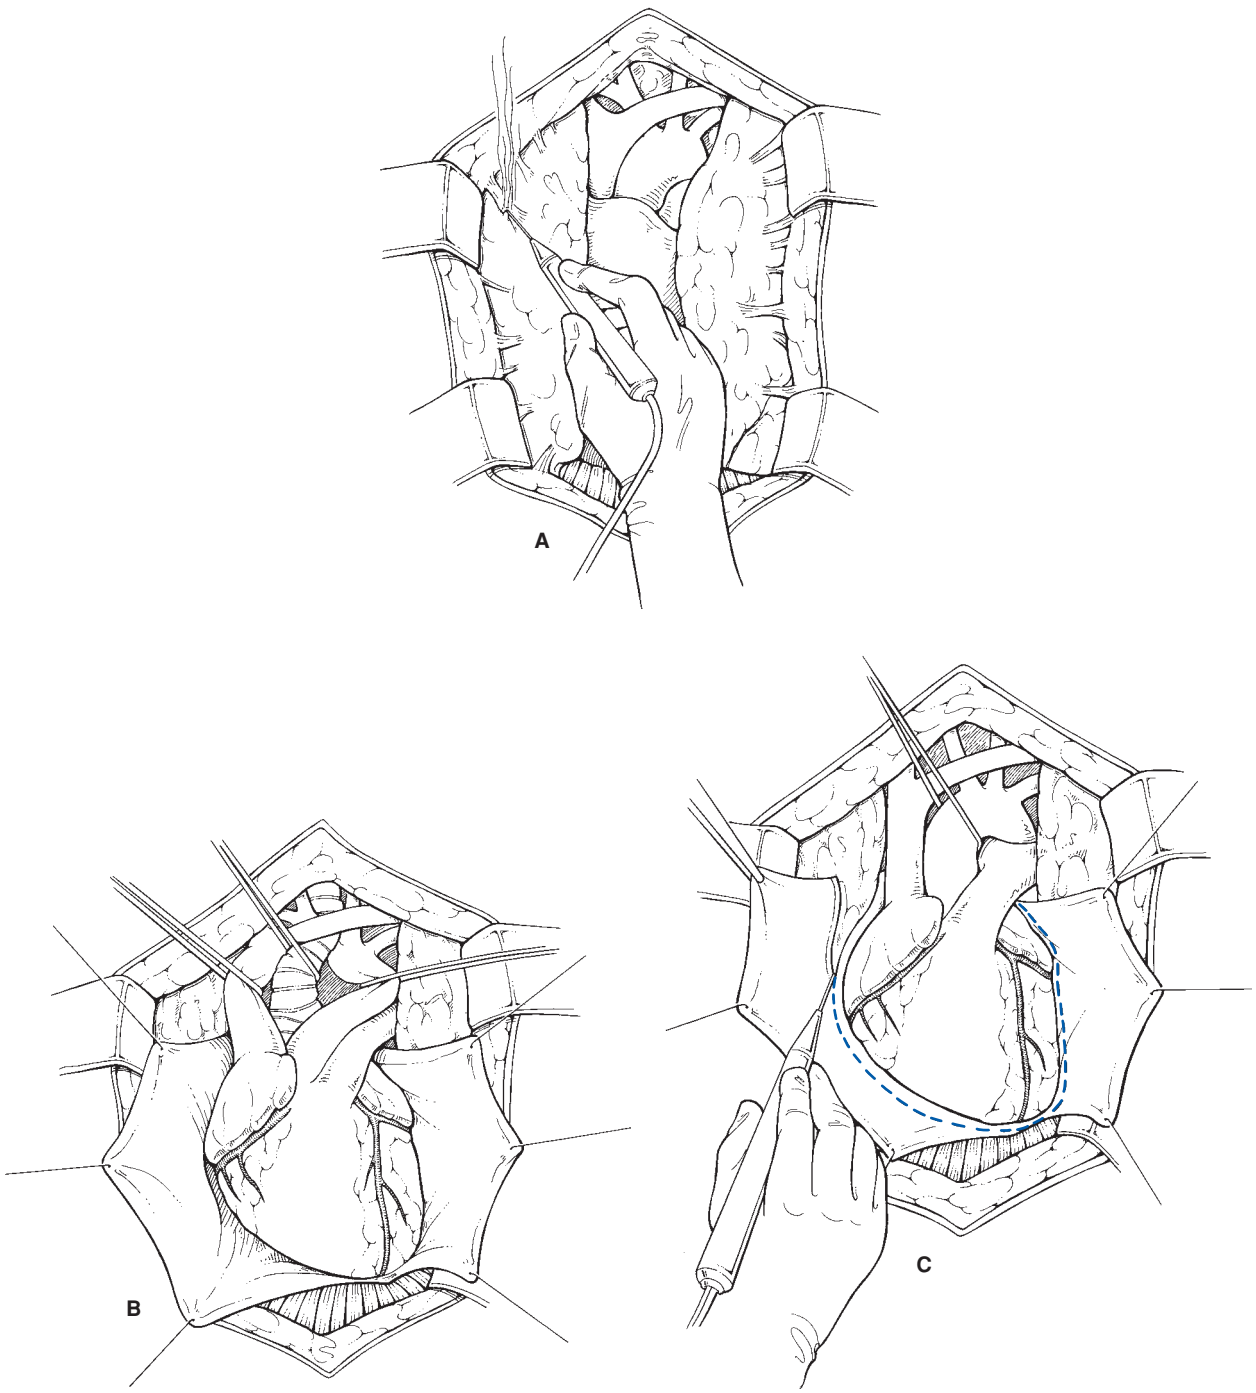

Figure 66-5. Donor operation for heart-lung transplantation. (A) Through a median sternotomy, adhesions are lysed and the pulmonary ligaments are divided inferiorly. (B) The pericardium is opened and cradled followed by dissection of the ascending aorta, venae cavae, pulmonary artery, and trachea. (C) The entire anterior pericardium is excised back to each hilum.

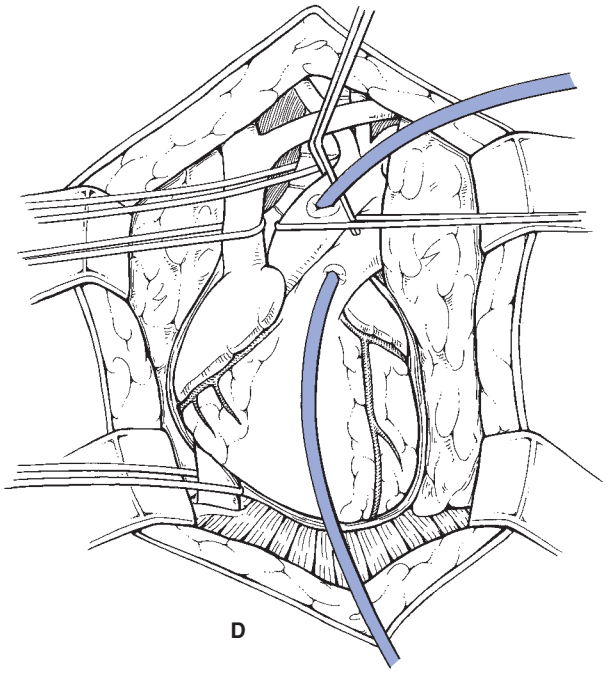

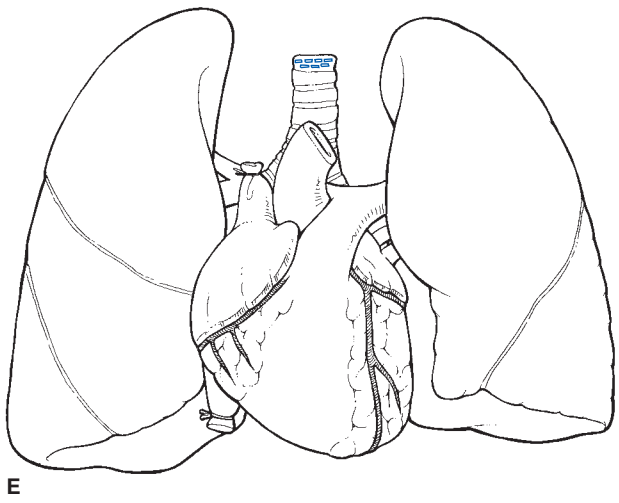

Figure 66-5. (*Continued*) (D) Cardioplegia and pulmonoplegia are infused simultaneously into the aorta and main pulmonary artery after aortic cross-clamping. Application of topical cold Physiosol follows immediately. (E) The venae cavae and aorta are divided, and the heart-lung bloc is dissected free from the esophagus and posterior hilar attachments. After the trachea is stapled and divided at the highest point possible, the entire heart-lung bloc is removed from the chest.

For separate heart and lung blocs, the donor operation is modified slightly, allowing for in situ separation of the heart from the lungs. After delivery of plegic solutions, the great vessels are divided. The heart is reflected anteriorly and a left atriotomy is performed, leaving a 2-cm cuff of atrium around the pulmonary vein orifices. Once this division is complete, the heart is removed from the chest. The lung bloc is then dissected free along the pre-esophageal plane above the level of the carina. The lungs are inflated and the trachea is stapled at the highest possible point. If needed, the bilateral lung bloc can be further separated into left and right lung blocs. The left atrial cuff containing the orifices of the pulmonary veins is divided in half vertically. The left and right pulmonary arteries are divided at their junction. Finally, the left main stem bronchus is stapled near its junction with the trachea.

Once removed from the donor, grafts are wrapped in sterile gauze pads and immersed in ice-cold saline at 2 to 4°C in several sterile plastic bags placed within a sterile plastic container. This, in turn, is placed in an ice-filled chest and transported to the transplant center.

Organ Preservation and Transport

On-site lung procurement was considered essential between 1981 and 1984 due to inadequate lung preservation techniques.[59] Since then, research and clinical experience have resulted in several different preservation protocols permitting distant procurement. Most centers currently tolerate a maximum of 6 to 8 hours of ischemia in lung and heart-lung allografts. This practice is supported by several studies, including independent retrospective studies from the University of Pittsburgh[60] and the University of Virginia,[61] showing comparable long-term survival, rate of acute rejection, and incidence of bronchiolitis obliterans among recipients of grafts with over 6 hours of ischemia compared with those with <4 or 4 to 6 hours of ischemia. In animal studies, successful transplantation of lung allografts with cold ischemia times of up to 18 hours have been reported. Despite such experimental observations, it is believed that beyond a certain threshold, organ ischemia will likely lead to primary graft failure and/or impaired long-term function.

The principal goal of preservation is to minimize injury to the allograft from ischemia and reperfusion.[62] Ischemia-reperfusion injury is mediated by reactive oxygen species, which disrupt the homeostatic mechanisms in myocytes and endothelial cells. As receptors for leukocyte adhesion molecules are upregulated and leukocyte chemotactic factors released, an inflammatory response ensues, leading to cellular injury. Several approaches for minimizing ischemia-reperfusion injury have been developed, including donor pretreatment, use of specialized preservation solutions, and recipient treatments.

Hypothermia is considered by many to be the most important method of organ preservation. It works by reducing tissue metabolic demand by up to 99%. In a small number of centers, hypothermic preservation includes donor core cooling on cardiopulmonary bypass (CPB). Universally, hypothermia is employed during explantation, storage, and

implantation. During explantation, organs are flushed with cold plegic solutions (between 0 and 10°C, depending on the institution and solution employed). Organs are stored at 0 to 10°C, and during implantation they are covered with gauze soaked in saline slush or recipients are cooled through CPB. The optimal temperature for flush and storage of organs remains unknown, but common practice is to rely on the temperature of the ice bath for convenience.

Heart-lung and lung blocs are typically preserved with a cold pulmonary artery flush in conjunction with standard crystalloid cardioplegic arrest. A variety of crystalloid flush solutions are used worldwide, and they can be divided into two categories based on their electrolyte compositions: intracellular and extracellular. Intracellular solutions contain moderate to high concentrations of potassium and little calcium and sodium; Euro-Collins, University of Wisconsin, and Cardiosol are examples. Extracellular solutions contain high concentrations of sodium and low to moderate concentrations of potassium; low-potassium dextran solution is an example (e.g., Perfadex). While Euro-Collins is the most frequently used preservation solution, there is a growing body of evidence in support of low-potassium, dextran-containing extracellular solutions.[63–65] Several centers, including our own, have now moved to using such solutions, but further studies are required to definitively determine the optimal composition of preservation solution.

Prostaglandins are commonly used for donor pretreatment and as an additive in pulmonary flush solutions. The administration of PGE_1 (a potent vasodilator) counteracts reflex pulmonary vasoconstriction induced by the cold flush and permits uniform distribution of perfusate throughout the lung. Studies in large animals also suggest that PGE_1 treatment may minimize reperfusion injury through its anti-inflammatory properties.[66]

Another commonly used pretreatment strategy is steroid treatment. Administration of intravenous methylprednisolone to the donor inactivates lymphocytes, which are thought to mediate ischemic lung graft injury.

Studies suggest that lung graft function is improved when the explanted organ is inflated, 100% oxygen is used for the inflation, and transport is carried out at 10°C.[67] Research in the field of lung preservation has recently focused on the role of various flush and storage solution additives, such as antioxidants, which may act as free radical scavengers. Other additives shown to decrease reperfusion injury in research models include nitric oxide donors and phosphodiesterase inhibitors. Areas of ongoing research include the development of leukocyte depletion strategies, examining the role of gene therapy to modify donor organ susceptibility to ischemia-reperfusion injury, and the development of colloid-based perfusates.

These preservation techniques, coupled with streamlined donor and recipient protocols, have permitted procurements as far as 1000 miles from the transplant center. Extensive communication and coordination must be maintained between the organ procurement agency, donor-recipient operative teams, medical centers, and abdominal procurement teams. Worldwide, the major procurement agencies include the United Network for Organ Sharing in the United States, Multiple Organ Retrieval in Canada, and the EURO Transplant Organization in Europe.

RECIPIENT OPERATION

The recipient operation in heart-lung and lung transplantation proceeds in two phases. The first is excision of the native organ(s) and the second is implantation of the allograft. Cardiopulmonary bypass is mandatory for heart-lung transplantation and occasionally required for single and bilateral lung transplantation. Regardless, CPB should be available as standby at all times. At Stanford, we have favored the use of CPB during bilateral lung transplantation for a variety of reasons. There is improved exposure of the hilar structures, which is particularly helpful in patients with dense adhesions and bronchial collaterals. CPB allows for early pneumonectomies without hemodynamic or respiratory instability, and ischemic time of the second lung is substantially reduced compared to off-CPB bilateral lung transplants. Its use also prevents overperfusion of the first lung graft with the entire cardiac output. In patients with suppurative lung disease, the use of CPB facilitates careful washout of the distal trachea and proximal bronchi to prevent contamination of the first implanted lung. Others prefer to avoid CPB, as it may be associated with increased blood loss, transfusion needs, and reperfusion injury. More detailed experimental and clinical studies are needed to resolve these questions. At present, the need for CBP should be determined on a case-by-case basis.

Anesthetic monitoring includes arterial pressure monitoring, pulse oximetry, continuous electrocardiography, pulmonary artery catheter monitoring, temperature monitoring, and urine output monitoring. The use of double-lumen endotracheal tubes is particularly helpful, allowing for single lung ventilation during certain portions of the dissection. Large-bore intravenous lines are placed for volume infusion. Transesophageal echocardiography is often performed during the procedure.

Heart-Lung Transplantation

The recipient is positioned supine and the chest is entered through a median sternotomy. A sternal retractor is placed, and both pleural spaces are opened anteriorly from the level of the diaphragm to the level of the great vessels (Fig. 66-6A). Electrocautery is used to divide any pleural adhesions. If dense pleural adhesions are anticipated (due to previous thoracotomies or cystic fibrosis, for example), a bilateral "clamshell" thoracotomy is performed. Combined with the use of perioperative antifibrinolytic therapy (e.g., aprotinin) and an argon beam coagulator, this approach improves exposure and facilitates both lysis of adhesions and hemostasis.

The anterior pericardium is excised, and the lateral segments are preserved to support the heart and protect the phrenic nerves. A 3-cm border of the pericardium should be left both anterior and posterior to each phrenic nerve extending from the level of the diaphragm to the level of the

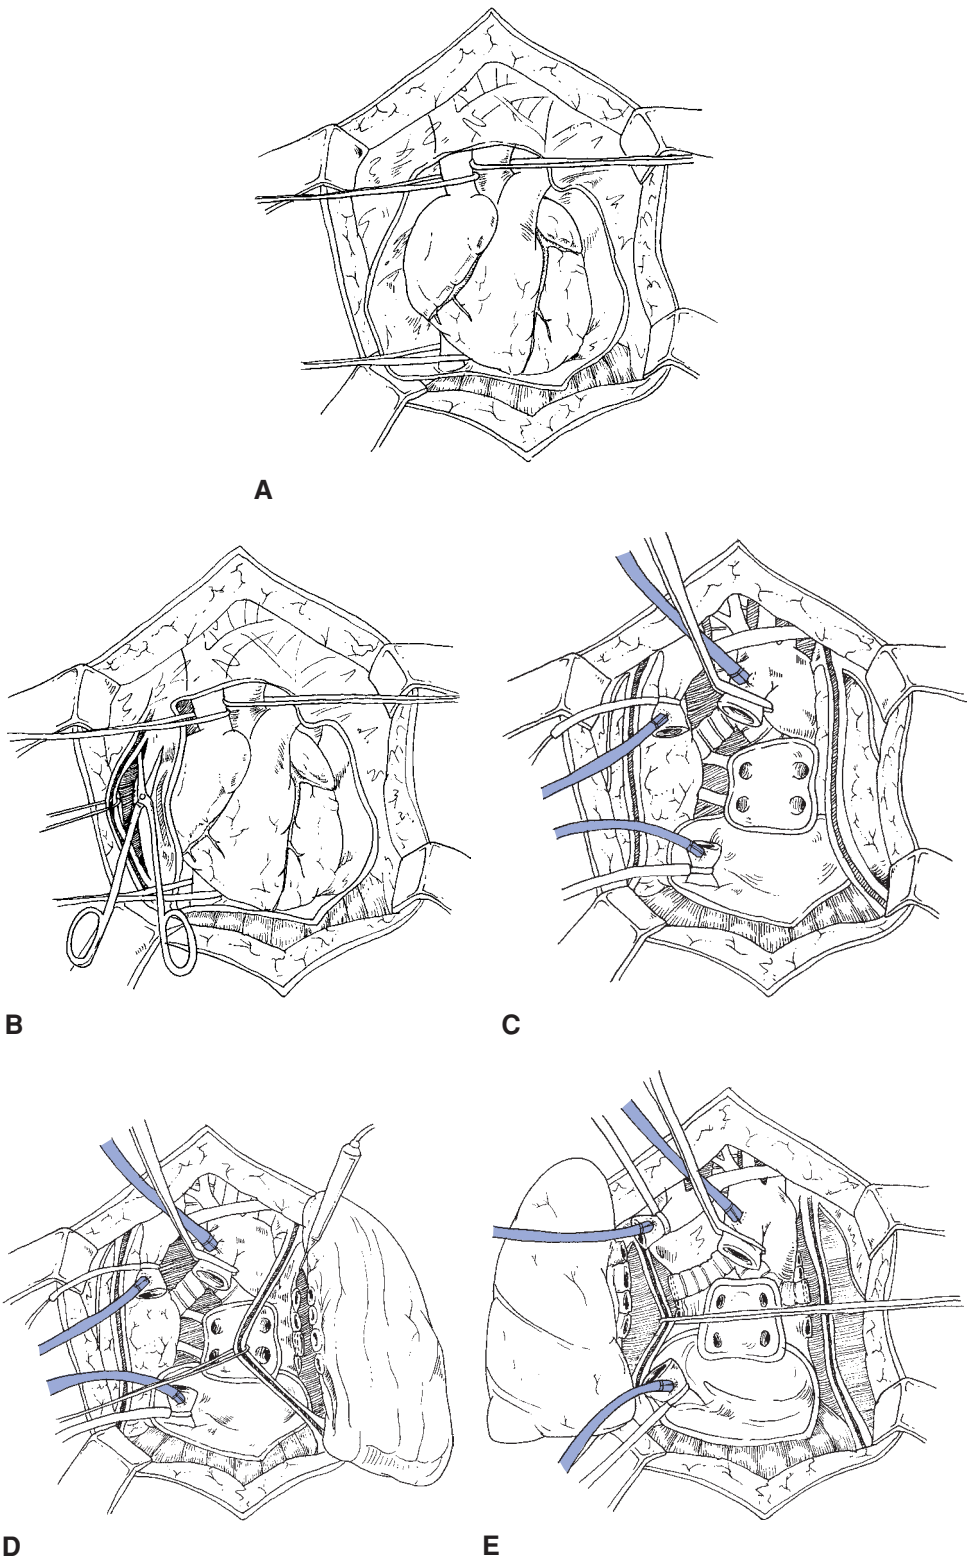

Figure 66-6. Recipient operation for heart-lung transplantation. (A) Through a median sternotomy, the anterior pericardium is partially removed and the ascending aorta and both venae cavae are dissected and encircled with tapes. (B) The right phrenic nerve is carefully separated from the right hilum, providing a space for inserting the right lung of the graft. (C) Cannulation for cardiopulmonary bypass consists of a cannula in the high ascending aorta and separate vena caval cannulas. Once on bypass, the native heart is excised in a manner similar to that for standard cardiac explantation. (D, E) Left and right pneumonectomies are performed by dividing the respective inferior pulmonary ligament, pulmonary artery and veins, and main stem bronchus.

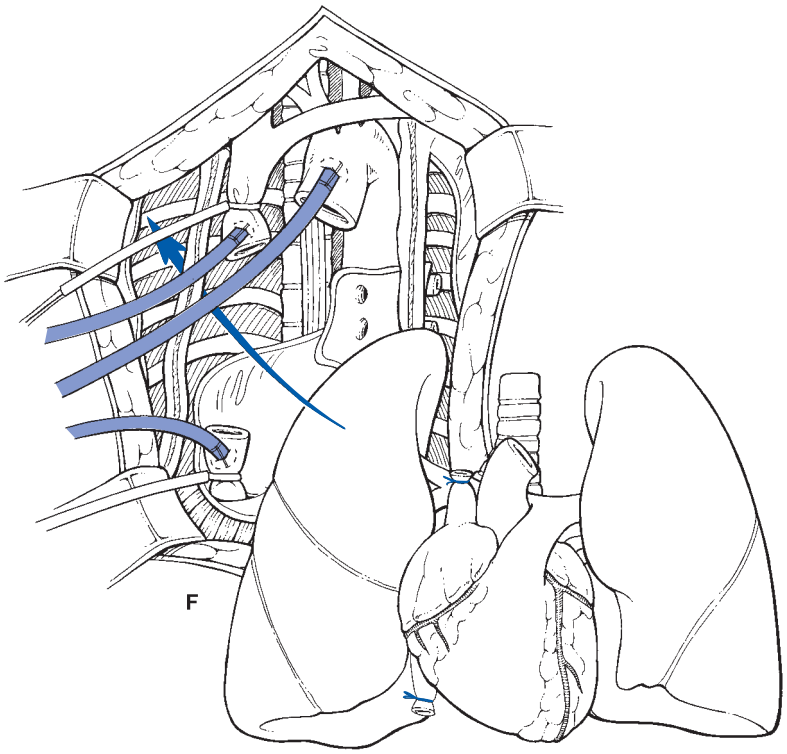
(*Continued*)



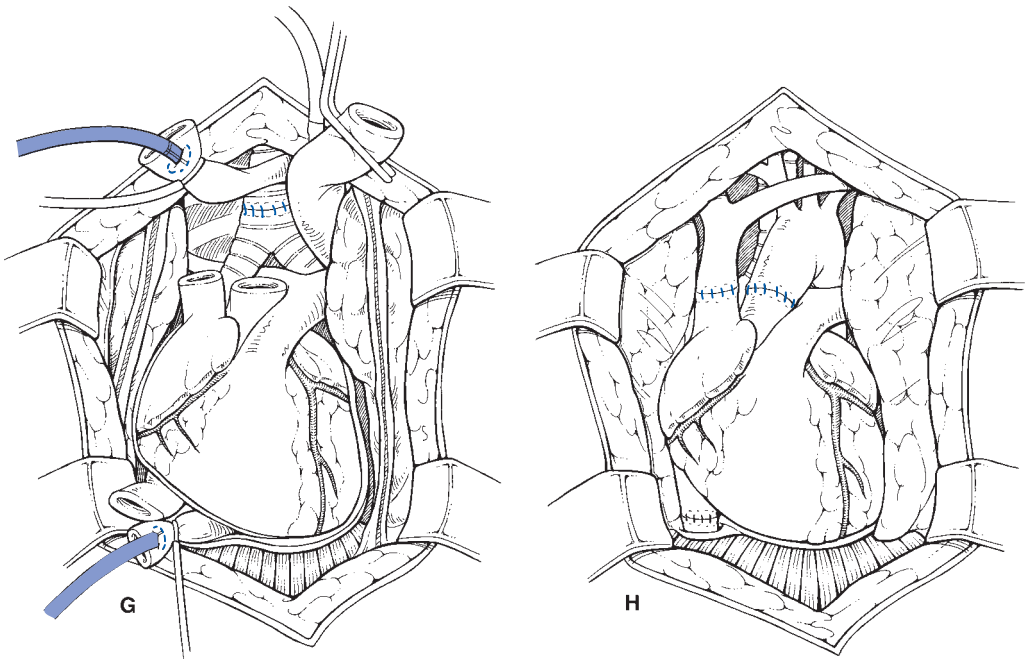


Figure 66-6. (*Continued*) (F) The heart-lung graft is moved into the chest, beginning with passage of the right lung underneath the right phrenic nerve pedicle, followed by manipulation of the left lung beneath the left phrenic nerve pedicle. (G) The tracheal anastomosis is performed with a continuous 3-0 polypropylene suture. (H) The caval and aortic anastomoses are performed with a continuous 4-0 polypropylene suture.

great vessels (Fig. 66-6B). An alternative approach is to create posterior pericardial apertures where the pulmonary veins enter into the pericardium. A border of pericardium is left posterior to the phrenic nerves, while the entire remaining pericardium anterior to the phrenic nerves is left intact.

After fully heparinizing the recipient, the ascending aorta is cannulated near the base of the innominate artery, and the venae cavae are individually cannulated laterally and snared. Cardiopulmonary bypass with systemic cooling to 28 to 30°C is instituted, and the heart is excised at the midatrial

level. The aorta is divided just above the aortic valve, and the pulmonary artery is divided at its bifurcation (Fig. 66-6C). The left atrial remnant is then divided vertically at a point halfway between the right and left pulmonary veins.

The posterior edge of the left atrial and pulmonary venous remnant is developed in a manner allowing the left inferior and superior pulmonary veins to be displaced over into the left chest. Following division of the pulmonary ligament, the left lung is moved into the field, allowing full dissection of the posterior aspect of the left hilum, with care taken to avoid the vagus nerve posteriorly. Once this is completed, the left main pulmonary artery is divided (Fig. 66-6D), and the left main bronchus is stapled with a TA-30 stapler and divided. The same technique of hilar dissection and division is repeated on the right side (Fig. 66-6E), and both lungs are removed from the chest.

The native main pulmonary artery remnant is removed, leaving a portion of the pulmonary artery intact adjacent to the underside of the aorta (near the ligamentum arteriosus) to preserve the left recurrent laryngeal nerve. Attention is then turned to preparing the distal trachea for anastomosis. The stapled ends of the right and left bronchi are grasped and dissection is carried up to the level of the distal trachea. Bronchial vessels are individually identified and carefully ligated. Patients with congenital heart disease and pulmonary atresia or severe cyanosis secondary to Eisenmenger syndrome may have large mediastinal bronchial collaterals that must be meticulously ligated. Perfect hemostasis is necessary in this area of the dissection, because it is obscured once graft implantation is complete. Once absolute hemostasis is achieved, the trachea is divided at the carina with a no. 15 blade. The chest is now prepared to receive the heart-lung graft.

The donor heart-lung bloc is removed from its transport container and prepared by irrigating, aspirating, and culturing the tracheobronchial tree, followed by trimming of the trachea to leave one cartilaginous ring above the carina. The heart-lung graft is then lowered into the chest, passing the right lung beneath the right phrenic nerve pedicle. The left lung is then gently manipulated under the left phrenic nerve pedicle (Fig. 66-6F). The tracheal anastomosis is performed using continuous 3-0 polypropylene suture (Fig. 66-6G). The posterior membranous portion of the anastomosis is performed first, followed by completion of the anterior aspect. Ventilation is then carried out with room air at half-normal tidal volumes to inflate the lungs and reduce atelectasis. Topical cooling with a continuous infusion of cold Physiosol into both thoraces is begun. To augment endomyocardial cooling and to exclude air from the graft, a third cold, "bubble-free" line is placed directly into the left atrial appendage.

Next, the bicaval venous anastomosis is performed. The recipient inferior vena cava is anastomosed to the donor inferior vena cava–right atrial junction with a continuous 4-0 polypropylene suture. At this point the patient is warmed toward 37°C, and the superior vena caval and aortic anastomoses are performed end to end with continuous 4-0 polypropylene sutures (Fig. 66-6H). After the ascending aorta and pulmonary artery are cleared of air, the aortic cross-clamp and caval tapes are removed. The left atrial catheter is removed, and the atrium is allowed to drain. The amputated left atrial stump is oversewn, and the pulmonary artery pulmonoplegia infusion site closed. The heart is defibrillated, and the patient is gradually weaned from cardiopulmonary bypass in the standard fashion. Methylprednisolone (500 mg) is administered to the recipient following heparin reversal with protamine sulfate.

PEEP at 3 to 5 cm H_2O and an F_{IO_2} of 40% is maintained. As in cardiac transplantation, isoproterenol (0.005 to 0.01 μg/kg per minute) is usually initiated on graft reperfusion to increase the heart rate (~100 to 110 bpm) and to lower pulmonary vascular resistance. Temporary right atrial and ventricular pacing wires are placed. Right and left pleural "right angle" chest tubes are placed along each diaphragm, as well as a single mediastinal tube. The chest is closed in the standard fashion. Finally, the double-lumen endotracheal tube is exchanged for a single-lumen tube and the tracheal anastomosis is visualized by bronchoscopy before transporting the patient to the intensive care unit.

Lick and associates describe an interesting alternative to the standard technique in which the pulmonary hila are placed anterior to the phrenic nerves and direct caval anastomoses are used whenever feasible.[68] This modification obviates extensive dissection of the phrenic nerves and posterior mediastinum, decreasing the likelihood of phrenic and vagus nerve injury. Furthermore, the posterior mediastinum can readily be inspected for bleeding after implantation by rotating the heart-lung bloc anteromedially while still on bypass.

Single Lung Transplantation

If possible, the poorer-functioning lung (as determined by preoperative ventilation-perfusion scan) is selected for replacement. The patient is placed in a standard thoracotomy position with access to the groin should CPB be needed. A posterolateral thoracotomy is made at the level of the fourth or fifth intercostal space. Adhesions are lysed and the hilar dissection performed. The pulmonary artery, the superior and inferior pulmonary veins, and the main stem bronchus are isolated. A trial occlusion of the pulmonary artery is used to determine whether the procedure can be conducted without CPB. If the occlusion is tolerated, the pulmonary artery is ligated and divided distal to the upper lobe branch. The pulmonary veins are also ligated and divided. The main stem bronchus is stapled and divided, and the native lung is explanted.

The donor lung is removed from its transport container and prepared for implantation. The donor bronchus is opened and secretions are aspirated and cultured. The bronchus is trimmed, leaving two cartilaginous rings proximal to the orifice of the upper lobe. Any remaining pericardial and lymphatic tissue is removed, and the left atrial cuff is trimmed as needed. The donor lung is then placed in the recipient's chest and covered with saline slush and iced laparotomy pads.

The sequence of anastomoses is a matter of preference, though most perform the deepest anastomosis (the bronchial anastomosis) first and then proceed to the more superficial ones. The bronchial anastomosis is fashioned with 4-0 polypropylene suture. We favor a continuous suture technique for the entire anastomosis, although the membranous portion can be sewn with interrupted suture. Variations on the end-to-end bronchial anastomosis include the use of a telescoping technique, in which the donor bronchus is intussuscepted into the recipient bronchus, and an omental pedicle flap is placed around the anastomosis. These techniques were developed to prevent bronchial anastomotic dehiscence, but are now rarely performed.

Once the bronchial anastomosis is complete, attention is turned to the anastomoses of the pulmonary veins. A side-biting clamp is applied to the left atrium to include the pulmonary veins. The recipient pulmonary vein stumps are opened and the intervening atrial tissue is cut. This creates a cuff which is anastomosed to the donor atrial remnant using continuous 4-0 polypropylene suture (this suture is not tied down until reperfusion). Donor and recipient pulmonary arteries are anastomosed with 5-0 polypropylene suture. Arteries must be trimmed to an appropriate length before fashioning the anastomosis, since kinking can occur upon graft inflation if the vessels are left too long. The pulmonary artery anastomosis is then de-aired. The lung is inflated, and the pulmonary artery clamp is temporarily released to allow flushing of air through the atrial suture line. The left atrial clamp is removed to allow retrograde de-airing of the atrial anastomosis. The pulmonary venous anastomosis is then secured.

After hemostasis is ensured, apical and basal chest tubes are inserted. The ribs are reapproximated and the chest is closed in standard fashion. The double-lumen endotracheal tube is exchanged for a single-lumen tube and bronchoscopy is performed to evaluate the bronchial anastomosis.

Bilateral Lung Transplantation

Bilateral lung transplantation is performed as sequential single lung transplants. The patient is positioned supine and a bilateral anterior thoracosternotomy (clamshell) incision is made at the level of the fourth intercostal space. The lung with the least amount of function (as determined by a preoperative ventilation-perfusion scan) is removed first and replaced with an allograft as described for single lung transplantation above. Once ventilation and perfusion are established in the first allograft, the remaining lung is explanted and the second allograft is implanted. Bilateral chest tubes are placed and the chest is closed. Bronchoscopy is performed to evaluate the bronchial anastomoses.

While single lung transplants are usually performed off CPB, the majority of double lung transplants are still performed on-pump. The use of CPB allows for improved exposure, shorter graft ischemic times, controlled reperfusion, and the use of leukocyte-depleting filters. As the risk of bleeding may be increased with CPB, strategies have been developed to minimize the chance of hemorrhage. These include the routine use of aprotinin and heparin-coated CPB circuits, as well as the availability of an argon beam coagulator. Despite these maneuvers, there remains considerable risk associated with CPB, and many centers prefer to perform all lung transplants off-pump if possible.

POSTOPERATIVE MANAGEMENT

Heart-Lung and Lung Graft Physiology

The structural and functional aspects of transplanted heart-lung or lung blocs are distinct from native cardiopulmonary physiology, as detailed in Table 66-4.

Denervation of the lungs results in a diminished cough reflex and impairment of mucociliary clearance mechanisms. This predisposes recipients to pulmonary infections and necessitates aggressive postoperative pulmonary toilet.[69] Moreover, in the transplanted lung, ischemia-reperfusion injury, along with disrupted pulmonary lymphatics, may result in increased vascular permeability with varying degrees of interstitial edema. For the heart-lung recipient, denervation of the cardiac allograft leads to additional physiologic characteristics. The denervated heart loses its sympathetic and parasympathetic autonomic regulation, and thus recipients of heart-lung grafts do not have normal autonomic regulation of heart rate, contractility, or coronary

Table 66–4.

Structural and Functional Aspects of the Transplanted Heart-Lung and Lung Allograft

Heart-lung only
Denervation from sympathetic and parasympathetic cardiac plexus
Higher resting heart rate
Absence of respiratory sinus arrhythmia and carotid reflex bradycardia
Increased chronotropic and inotropic sensitivity to circulating catecholamines
Slower initial rise in heart rate in response to exercise or stress
Normal coronary flow reserve in the absence of rejection
Heart-lung and isolated lung
Increased pulmonary vascular permeability and interstitial edema (early)
Disrupted pulmonary lymphatics
Diminished cough reflex
Impaired mucociliary airway clearance mechanisms
Hypoxic pulmonary vasoconstriction intact

artery vasomotor tone. The resting heart rate is generally higher due to the absence of vagal input. Respiratory sinus arrhythmia and carotid reflex bradycardia are absent. Interestingly, the denervated heart develops an increased sensitivity to catecholamines due to increased beta-adrenergic receptor density and loss of norepinephrine uptake in postganglionic sympathetic neurons.[70,71] This augmented sensitivity plays an important role in maintaining an adequate cardiac response to exercise and stress. During exercise, the recipient experiences a steady but delayed increase in heart rate, primarily due to a rise in circulating catecholamines. This initial rise in heart rate is subsequently accompanied by an immediate increase in filling pressures resulting from increased venous return. These changes lead to increased stroke volume and cardiac output sufficient to sustain activity. The coronary circulation's ability to dilate, thus increasing blood flow to meet increased myocardial oxygen demand, is normal in cardiac transplant recipients. A similar physiologic response can be expected in recipients of heart-lung grafts. It should be noted, however, that graft coronary vasodilator reserve is abnormal in the presence of rejection, hypertrophy, or regional wall abnormalities.

Clinical Management in the Early Postoperative Period

The acute postoperative management for heart-lung and isolated lung graft recipients centers around careful fluid and ventilatory management. The primary objective in the immediate postoperative period is to maintain adequate perfusion and gas exchange while minimizing intravenous fluid administration, cardiac work, and barotrauma.

Upon completion of the transplant, the patient is transported to the intensive care unit (ICU), where cardiac rhythm, arterial pressures, and central venous pressures are monitored. Strict isolation precautions (previously enforced to reduce the incidence of infection in these immunosuppressed patients) are no longer required. Simple handwashing is now considered sufficient.

Approximately 10 to 20% of heart-lung graft recipients experience some degree of transient sinus node dysfunction in the immediate perioperative period. This often manifests as sinus bradycardia and usually resolves within a week. The use of bicaval venous anastomoses has been reported to lower the incidence of sinus node dysfunction and improve tricuspid valve function.[72] Because cardiac output is primarily rate-dependent after heart-lung transplantation, the heart rate should be maintained between 90 and 110 bpm during the first few postoperative days using temporary pacing or isoproterenol (0.005 to 0.01 μg/kg per minute) as needed. Although rarely seen, persistent sinus node dysfunction and bradycardia may require a permanent transvenous pacemaker. Systolic blood pressure should be maintained between 90 and 110 mm Hg using nitroglycerin or nitroprusside for afterload reduction, if necessary. "Renal-dose" dopamine (3 to 5 μg/kg per minute) is frequently used to augment renal blood flow and urine output. The adequacy of cardiac output is indicated by warm extremities and a urine output greater than 0.5 mL/kg per hour without diuretics. Cardiac function generally returns to normal within 3 to 4 days, at which time inotropes and vasodilators can be weaned.

In the case of heart-lung grafts, several factors may contribute to depressed global myocardial performance during the acute postoperative setting. The myocardium may be subject to prolonged ischemia, inadequate preservation, or catecholamine depletion prior to implantation. Hypovolemia, cardiac tamponade, sepsis, and bradycardia are also potential contributors and should be treated expeditiously if they are present. A Swan-Ganz pulmonary artery catheter should be used in cases of persistently abnormal hemodynamics.

Ventilatory management is a key element in the postoperative management of both heart-lung and isolated lung graft recipients. Barotrauma and high airway pressures can compromise bronchial mucosal flow and should be avoided. Lower tidal volumes and flow rates may be necessary to limit peak airway pressures to less than 40 cm H_2O. Upon arrival in the ICU, an anteroposterior chest x-ray is obtained, and the ventilator is typically set to an Fio_2 of 50%, tidal volume of 10 to 15 mL/kg, an assist-control rate of 10 to 14 breaths per minute, and PEEP of 3 to 5 cm H_2O. These settings are adjusted every 30 minutes to achieve an arterial Po_2 >75 mm Hg on an Fio_2 of 40%, an arterial partial carbon dioxide pressure between 30 and 40 mm Hg, and a pH between 7.35 and 7.45. Pulmonary toilet with endotracheal suctioning is an effective means of reducing mucus plugging and atelectasis. Ventilatory weaning is initiated after the patient is stable, awake, and alert. Usually, weaning is accomplished through successive decrements in the intermittent mandatory ventilation rate, followed by a trial of continuous positive airway pressure. Once ventilatory mechanics and arterial blood gases are deemed acceptable, the patient is extubated. This usually occurs within the first 24 hours after transplantation. Subsequent pulmonary care consists of vigorous diuresis, supplemental oxygen for several days, continued aggressive pulmonary toilet, incentive spirometry, and serial chest x-rays.

A diffuse interstitial infiltrate is often found on early postoperative chest x-rays. Previously referred to as a *reimplantation response*, this finding is better defined as graft edema due to inadequate preservation, reperfusion injury, or early rejection.[73] It appears that the degree of pulmonary edema is inversely related to the quality of preservation. Judicious administration of fluid and loop diuretics is required to maintain fluid balance and minimize this pulmonary edema.

Early lung graft dysfunction occurs in less than 15% of transplants, and is manifest as persistent marginal gas exchange without evidence of infection or rejection.[74] This primary graft failure often results from ischemia-reperfusion injury and is histologically evident as diffuse alveolar damage. Of course, technical causes of graft failure such as pulmonary venous anastomotic stenosis or thrombosis must always be considered. In cases of persistent, severe pulmonary graft

dysfunction refractory to mechanical ventilatory maneuvers, extracorporeal membrane oxygenation[75] and inhaled nitric oxide[76] have been used successfully to stabilize gas exchange. Urgent retransplantation can also be considered if other interventions fail.

The incidence of line sepsis can be reduced by the expedient removal of vascular catheters. Pleural and mediastinal chest tubes are removed when drainage has fallen to <25 mL/h. For heart-lung graft recipients, pacing wires are removed between 7 and 10 days after transplantation, provided no further pacing is required. Barring significant complications, the patient is usually transferred from the ICU to a standard cardiothoracic surgical ward within a few days.

Immunosuppressive Management: Early and Late Postoperative Regimens

For heart-lung and lung graft recipients, immunosuppression begins intraoperatively and is continued for life. The conventional triple-drug combination consists of cyclosporine, azathioprine, and prednisone. Initially, high doses of these drugs are given, and they are later tapered for chronic administration. A typical dosing protocol employed at Stanford University Hospital is outlined in Table 66-5. Cyclosporine is started in the early postoperative period, initially intravenously (0.05 to 0.1 mg/kg per hour) and subsequently orally (5 to 10 mg/kg per day in two divided doses). Dosing is titrated to maintain a trough serum concentration between 150 and 250 ng/mL in the first few weeks after transplantation, and from 100 to 150 ng/mL thereafter. Azathioprine is administered intravenously at 4 mg/kg preoperatively and subsequently maintained at approximately 2 to 3 mg/kg per day. Azathioprine dosages are adjusted to maintain the white blood cell count >4000 cells/mm^3. Methylprednisolone is administered intraoperatively at graft reperfusion (500 mg intravenously) and then continued for the first 24 hours at 125 mg intravenously every 8 hours. Steroids are then suspended for 2 weeks, based on experimental and clinical evidence that they impede bronchial anastomotic healing. After 2 weeks, prednisone is started at a daily oral dose of 0.6 mg/kg and gradually tapered over the next 3 to 4 weeks to 0.1 to 0.2 mg/kg per day.

The conventional triple-drug combination of cyclosporine, azathioprine, and prednisone is modified at some centers. Tacrolimus (FK506) and mycophenolate mofetil are two drugs that have been widely used in kidney and liver transplantation. Experience with use of these drugs in heart-lung and lung transplant recipients is limited. One promising study by Keenan and associates compared triple therapy with tacrolimus, azathioprine, and steroids to triple therapy with cyclosporine, azathioprine, and steroids.[77] Among the 133 lung allograft recipients studied, they found decreased acute rejection episodes and increased freedom from obliterative bronchiolitis at 2 years in the tacrolimus/azathioprine/steroid group. Reichenspurner and colleagues also found lower acute rejection rates and comparable infection rates in lung transplant recipients treated with tacrolimus-based immunotherapy rather than cyclosporine.[78] Larger studies and longer follow-up periods will be needed before conventional immunosuppressive regimens are modified.

Many centers have added prophylactic induction therapy to the standard triple-drug regimen. This includes the use of OKT3, rabbit antithymocyte globulin (RATG) and antithymocyte gamma-globulin (ATGAM), and daclizumab. OKT3 is a murine monoclonal antibody preparation that recognizes the CD3 antigen of human T cells. RATG and ATGAM are polyclonal anti–T-cell anti-

Table 66–5.

Typical Immunosuppression Protocol for Heart-Lung and Lung Transplant Recipients

Immunosuppressant	Early postoperative period	Late postoperative period
Cyclosporine	5–10 mg/kg/d PO*,† or 0.05–1 mg/kg/h IV	3–6 mg/kg/d PO‡
Methylprednisolone	500 mg IV after reperfusion followed by 125 mg IV every 8 hours for three doses	None
Prednisone	0.6 mg/kg/d PO starting on day 15	0.1–0.2 mg/kg/d PO
Azathioprine	2 mg/kg/d PO*	1–2 mg/kg/d PO§
Rabbit antithymocyte globulin	2.5 mg/kg/d IV on days 1, 2, 3, 5, and 7	

* *Intravenous dose only if preoperative serum creatinine >1.5 mg/dL.*

§ *Maintain white blood cell count >4000/mm^3.*

body preparations. Daclizumab is a monoclonal antibody preparation that blocks interleukin-2 (IL-2)-dependent activation of human T cells by binding to their IL-2 receptors. Use of these agents may reduce the rate of acute pulmonary rejection, but may also predispose to infection. Several retrospective and prospective studies have compared the efficacy of all or some of these induction agents. Palmer and coworkers found a decreased incidence of acute rejection in lung transplant recipients receiving RATG induction and conventional triple-drug therapy when compared to patients receiving triple-drug therapy alone.[79] Barlow and associates found that the incidence of acute pulmonary rejection was significantly lower in recipients induced with RATG compared with those induced with OKT3; in addition, there was a trend toward a decreased infection rate in the RATG group when compared to the OKT3 cohort.[80] Brock and colleagues performed a prospective nonrandomized trial comparing OKT3, ATGAM, and daclizumab as induction agents in 87 lung allograft recipients.[81] Across all groups, they found comparable freedom from acute rejection and bronchiolitis obliterans syndrome, with comparable long-term survival. However, daclizumab was associated with a lower rate of infections. Unfortunately, the follow-up for the daclizumab cohort was only 7 months, whereas the other cohorts were followed for 2 years. Long-term follow-up will be important in ascertaining which induction therapy is optimal in heart-lung and lung allograft recipients. Moreover, given that use of certain induction agents increases the risks of infection and/or development of posttransplant lymphoproliferative disorders, these drugs should be used with caution.

Judicious doses of immunosuppressives are usually well tolerated by patients; however, each drug has well characterized side effects. Cyclosporine is commonly associated with nephrotoxicity, hypertension, hepatotoxicity, hirsutism, and an increased incidence of lymphoma. The primary toxicity of azathioprine is generalized bone marrow depression, manifest as leukopenia, anemia, and thrombocytopenia. Steroids are associated with a myriad of side effects, including the development of cushingoid features, hypertension, diabetes, osteoporosis, and peptic ulcer disease. Initial doses of OKT3 and antithymocyte globulin can be associated with a "cytokine release syndrome," characterized by significant hypotension, bronchospasm, and fever. Therefore, patients receiving these induction agents require close monitoring and premedication with acetaminophen, antihistamines, and corticosteroids. Interestingly, daclizumab is not associated with the cytokine release syndrome.

Infection Prophylaxis

Antiviral and antifungal prophylaxis remain important components of the postoperative management strategy in heart-lung and lung transplant recipients. Many centers employ cytomegalovirus prophylaxis with ganciclovir for any CMV-positive recipient and in any CMV-negative recipient receiving an allograft from a CMV-positive donor. Ganciclovir is typically given for a several-week course and can be associated with leukopenia. Some patients may require granulocyte colony-stimulating factor if their white blood cell count falls below 4000/mm^3. Fungal prophylaxis against mucosal *Candida* infection includes use of daily nystatin swish and swallow. *Pneumocystis carinii* prophylaxis consists of trimethoprim-sulfamethoxazole or aerosolized pentamidine. In the immediate postoperative period, *Aspergillus* colonization is inhibited by the use of aerosolized amphotericin B. For *Toxoplasma*-negative recipients of grafts from *Toxoplasma*-positive patients, pyrimethamine prophylaxis is maintained for the first 6 months after transplantation.

Graft Surveillance: Patient Follow-Up Schedule

Routine clinical follow-up for heart-lung and lung allograft recipients is required to monitor graft function and modify immunosuppressive regimens. Regular surveillance protocols developed to monitor graft function typically consist of serial pulmonary function tests, arterial blood gases, and bronchoscopic evaluation. Surveillance is usually conducted at 2, 4 to 6, and 12 weeks, followed by 6 months after transplantation and yearly thereafter. Transbronchial biopsies are obtained from each transplanted lung, and lavage specimens are submitted for staining (i.e., Gram, fungal, acid-fast bacillus, and silver), culture, and cytology. Surveillance endomyocardial biopsies are performed at 3 months and then annually in heart-lung graft recipients.

In addition to routine surveillance, follow-up is often needed to address changes in clinical status. Complications related to transplantation are many, and these must be addressed carefully and expediently to prevent long-term graft failure.

POSTOPERATIVE COMPLICATIONS

Early morbidity and mortality after heart-lung and lung transplantation (within 30 days of operation or before initial discharge from hospital) are most commonly caused by primary graft failure or infection. Late mortality is most commonly caused by obliterative bronchiolitis or infection.[1] Causes of death at various time points after transplantation have been compiled by the ISHLT and are presented in Figs. 66-7 and 66-8.

Hemorrhage

Perioperative hemorrhage is an infrequent but significant cause of early death in heart-lung and lung transplantation. The majority of perioperative hemorrhagic complications stem from operating in the midst of dense adhesions caused by previous operations or inflammation from chronic lung

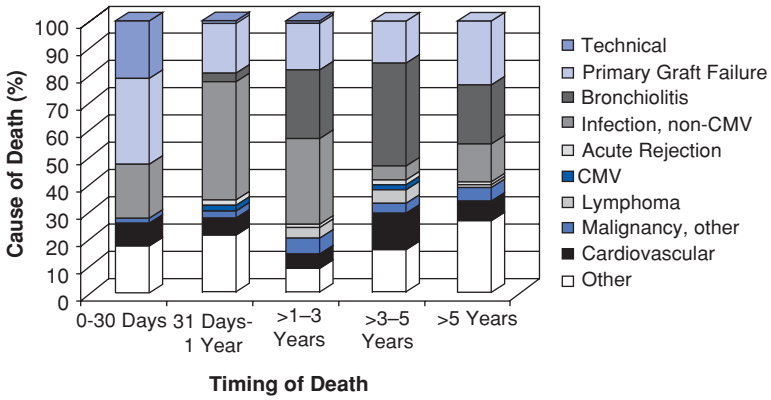

Figure 66-7. Causes of death at various periods after heart-lung transplantation. CMV = cytomegalovirus. (*Adapted from Trulock EP, Edwards LB, Taylor DO, et al. Registry of the International Society for Heart and Lung Transplantation: Twenty-second official adult lung and heart-lung transplant report—2005. J Heart Lung Transplant 2005; 24:956. infection. As mentioned previously, meticulous attention to hemostasis is mandatory, and all available means should be used to achieve a dry field upon completion of the operation.

Hyperacute Rejection

ABO matching of donor and recipient has decreased the rate of hyperacute rejection. This complication, which is almost universally fatal, is mediated by preformed antibodies in the recipient which recognize antigens on the donor vascular endothelium. This humoral immune response results in activation of inflammatory and coagulation cascades, resulting in extensive thrombosis of graft vessels and subsequent graft failure.[68] To reduce the incidence of hyperacute rejection, a prospective cross-match should be performed in recipients with a percent reactive antibody >25%.

Early Graft Dysfunction and Primary Graft Failure

Graft dysfunction in the first few days after transplantation is common. It is often referred to as the "reimplantation response," manifest by abnormal lung function, pulmonary edema, and pulmonary infiltrates on chest x-ray. This phenomenon is thought to be linked to ischemia and reperfusion. Other contributing factors may also include allograft contusion, inadequate preservation, or use of cardiopulmonary bypass during transplantation. While most cases are mild and resolve with supportive care, some progress to primary graft failure. Reported rates of primary graft failure following lung and heart-lung transplantation range between 10 and 15%. Treatment may include the use of extracorporeal membrane oxygenation and inhaled nitric oxide. Unfortunately, primary graft failure is associated with a mortality of over 60%.[74]

Acute Rejection

As in cardiac transplantation, the majority of acute rejection episodes occur within the first year after transplant. From 1981 through 1994 at Stanford University, acute lung rejection (either isolated or simultaneous with heart rejection) occurred in more than 67% of heart-lung patients within the first year.[82] Similar rates of acute rejection have been reported among isolated lung transplant recipients. Despite its prevalence, death is very rarely a direct consequence of acute rejection. It is recognized, however, that the number and severity of acute rejection episodes is a risk factor for ultimately developing obliterative bronchiolitis.

Diagnosis of acute rejection in the early posttransplant period is often based on clinical parameters. Symptoms and signs of rejection include fever, dyspnea,

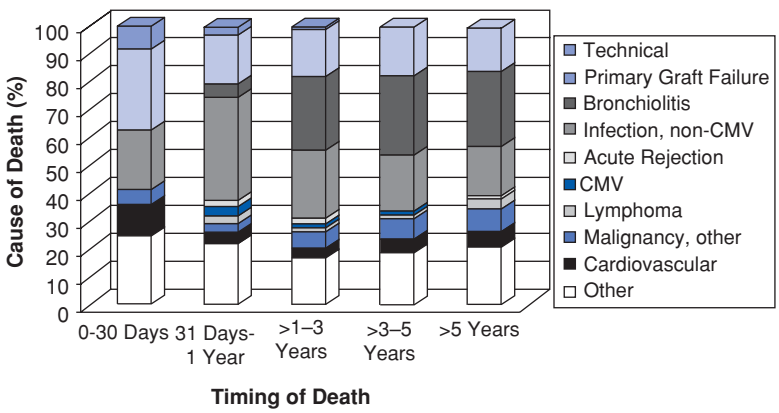

Figure 66-8. Causes of death at various periods after isolated lung transplantation. CMV = cytomegalovirus. (*Adapted from Trulock EP, Edwards LB, Taylor DO, et al. Registry of the International Society for Heart and Lung Transplantation: Twenty-second official adult lung and heart-lung transplant report—2005. J Heart Lung Transplant 2005; 24:956. Used with permission from Elsevier Science.*)

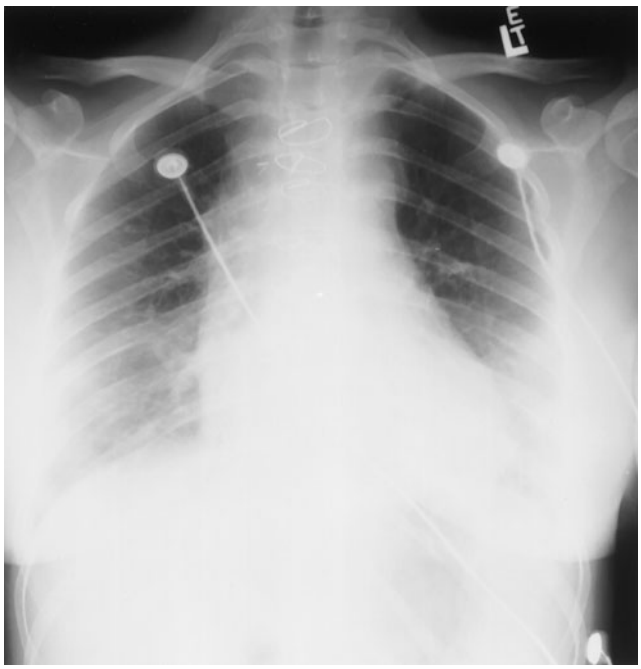
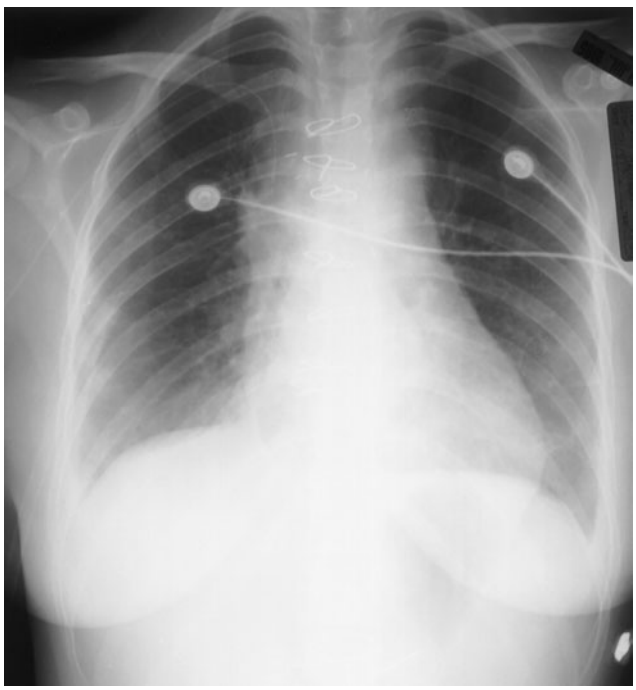
impaired gas exchange (manifest as a decrease in arterial P_{O_2}), a diminished forced expiratory volume in 1 second (FEV_1, a measure of airway flow), a fall in vital capacity, and the development of characteristic bilateral interstitial infiltrates on chest x-ray (Fig. 66-9A). After the first postoperative month, the chest x-ray is frequently normal during episodes of acute rejection, placing greater emphasis on other clinical parameters characteristic of rejection.



A



B

It is often difficult to distinguish between the diagnosis of acute lung rejection and pulmonary infection based on clinical findings alone. It is of paramount importance to distinguish between acute rejection and infection prior to initiating therapy. Fiberoptic bronchoscopy (with transbronchial parenchymal lung biopsy and bronchoalveolar lavage) is the gold standard for the diagnosis of acute lung rejection and pulmonary infection. At least five biopsy specimens are taken from the lung allografts along with bronchoalveolar lavage which is evaluated for cytology, undergoes microbial staining, and cultured.[83] In addition to performing bronchoscopy with transbronchial biopsy in response to changes in clinical status and graft performance, most centers maintain a schedule of surveillance biopsies for lung and heart-lung allograft recipients. Interestingly, surveillance bronchoscopy reveals occult rejection or infection in 17 to 25% of transbronchial biopsy specimens from asymptomatic heart-lung and lung allograft recipients. For patients undergoing bronchoscopy due to a change in clinical condition, 50 to 72% of biopsy specimens have shown evidence of rejection or infection. In most cases, positive biopsies directly guide successful treatment of rejection or infection.[84,85]

Acute lung rejection is histologically characterized by lymphocytic perivascular infiltrates (Fig. 66-10). A grading scheme for acute lung rejection was developed by Clelland[86]

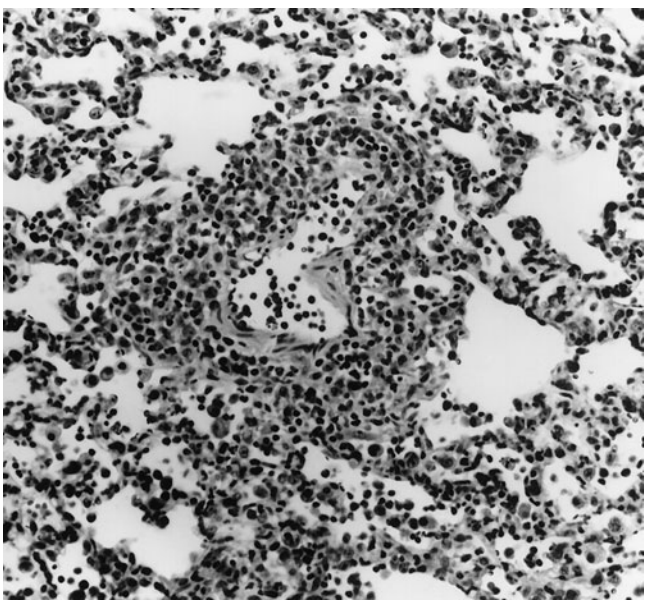

Figure 66-10. Moderate acute lung rejection. Moderate rejection is characterized by perivascular mononuclear cell infiltrates with extension into the adjacent alveolar septa (H&E stain; ×200).

Table 66–6.

Grading System for Acute Lung Rejection

Grade	Histologic appearance (transbronchial biopsy)
0	No significant inflammation; normal specimen
1	Small, infrequent perivascular infiltrates with or without bronchiolar lymphocytic infiltrates
2	Larger, more frequent perivascular lymphocytic infiltrates with or without moderate bronchiolar lymphocytic inflammation; occasional neutrophils and eosinophils
3	Extension of infiltrates into alveolar septa and alveolar spaces with or without bronchiolar mucosal ulceration

and is presented in Table 66-6; a similar scheme was also developed by the Lung Rejection Study Group.[83]

In heart-lung transplantation, experimental and clinical evidence suggests that pulmonary and cardiac rejections occur independently of one other. Higenbottam and associates at Papworth Hospital reported a surprisingly low diagnostic yield from routine endomyocardial biopsies in heart-lung recipients compared with functional or histologic tests of pulmonary rejection. Thus, the authors advanced that transbronchial biopsy eliminates the need for routine endomyocardial biopsies in heart-lung transplant recipients.[87] These findings were confirmed by Sibley and colleagues at Stanford University, who demonstrated discordance between findings on endomyocardial and transbronchial biopsies during episodes of acute rejection. Endomyocardial biopsies are most often normal despite findings of pulmonary rejection on transbronchial biopsy.[85] Combined, these results have led to modifications in surveillance biopsy programs. At Stanford, surveillance endomyocardial biopsies have been abandoned in patients in whom transbronchial biopsies can be reliably performed.

As in cardiac transplantation, efforts are being made to develop noninvasive ways of diagnosing early acute lung rejection. Loubeyre and coworkers at the Hôpital Cardiovasculaire et Pneumologique report an association between "ground-glass" density areas seen on high-resolution computed tomography and histologically confirmed acute lung rejection in heart-lung transplant recipients.[88] They found that ground-glass opacities on high-resolution computed tomography had a sensitivity of 65% for detecting lung rejection and a specificity of 85% for detecting an acute lung complication.

Treatment strategies for rejection involve augmentation of immunosuppression. At most institutions, the timing and severity of rejection episodes dictate therapy. A typical algorithm is shown in Fig. 66-11. Rejection episodes that are

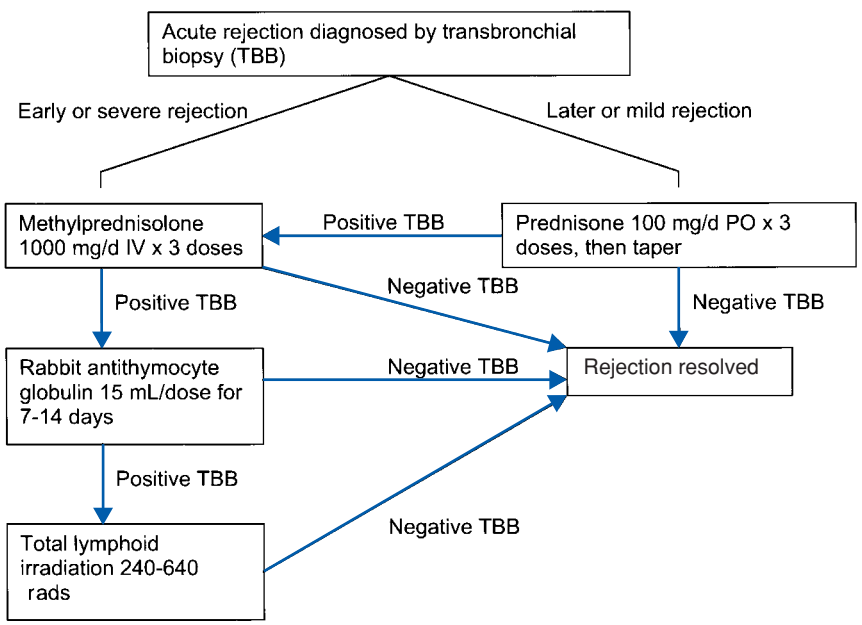

Figure 66-11. Typical algorithm for treating acute rejection in heart-lung and lung transplant recipients.

graded moderate or severe are treated with a "steroid pulse" (intravenous methylprednisolone 500 to 1000 mg/d for 3 consecutive days), followed by augmentation of the oral prednisone maintenance dose to 0.6 mg/kg per day. This maintenance dose is then tapered to 0.2 mg/kg per day over 3 to 4 weeks. Clinical and radiographic improvement (see Fig. 66-9B) following steroid therapy is often dramatic, rapid, and considered confirmatory of rejection. Mild episodes are initially treated by increasing oral prednisone dose, followed by a gradual taper over 3 to 4 weeks. Transbronchial biopsies are repeated 10 to 14 days following antirejection therapy to assess efficacy. Recurrent rejection episodes may be treated by a second steroid pulse and taper. Acute rejection refractory to steroid therapy may be treated with antilymphocyte preparations. Alternatively, primary immunosuppression may be switched from cyclosporine-based therapy to tacrolimus-based therapy. Finally, in especially difficult cases of persistent rejection, total lymphoid irradiation may be useful.[89]

Chronic Rejection

Chronic lung allograft rejection poses the greatest limitation to the long-term benefits of lung and heart-lung transplantation. Chronic lung rejection most commonly presents as obliterative bronchiolitis (OB). It was first noted as a pulmonary corollary to chronic cardiac rejection (cardiac graft atherosclerosis) in recipients of heart-lung transplants.[90] Later, OB was shown to occur in recipients of isolated lung transplants as well. The onset of OB typically occurs after the first 6 months to 1 year after transplantation, with a steadily increasing incidence thereafter. Recent data demonstrate that 70% of heart-lung and lung graft recipients are diagnosed with OB by the fifth postoperative year.[91]

Transbronchial biopsies remain the gold standard for diagnosing OB. The sensitivity of transbronchial biopsy for detecting OB has been reported between 17 and 87%.[85,92] Diagnostic yield of the biopsy procedure is related to the number of specimens taken, and current recommendations advise taking at least five specimens from each transplanted lung. Clearly, OB is a patchy process and therefore a large number of samples will be falsely negative due to sampling error.

OB is a histologic diagnosis and is characterized by dense eosinophilic, submucosal scar tissue that partially or totally obliterates the lumen of small (2 mm) airways, particularly the terminal and respiratory bronchioles (Fig. 66-12). The physiologic consequences are decreased arterial P_{O_2}, FEV_1, $FEF_{25–75}$ (forced expiratory flow at 25 to 75% [midrange] of lung volumes), and FEF_{50}:FVC (ratio of FEF_{50} to forced vital capacity). A characteristic "bowing" of the expiratory limb of the flow-volume loop has also been associated with OB. Clinical symptoms may be nonspecific and include cough and dyspnea with or without exertion. The term *bronchiolitis obliterans syndrome* (BOS) was developed to refer to patients who have clinical manifestations of OB with or without proven histologic characteristics (Table 66-7). A standardized working formulation for the clinical staging of BOS was established by the ISHLT and is based on the ratio of the current FEV_1 to the best posttransplant FEV_1. Patients with a decline of 20% or greater in their FEV_1 (in the absence of infection or other process) are diagnosed with BOS, irrespective of pathologic evidence of OB.[93]

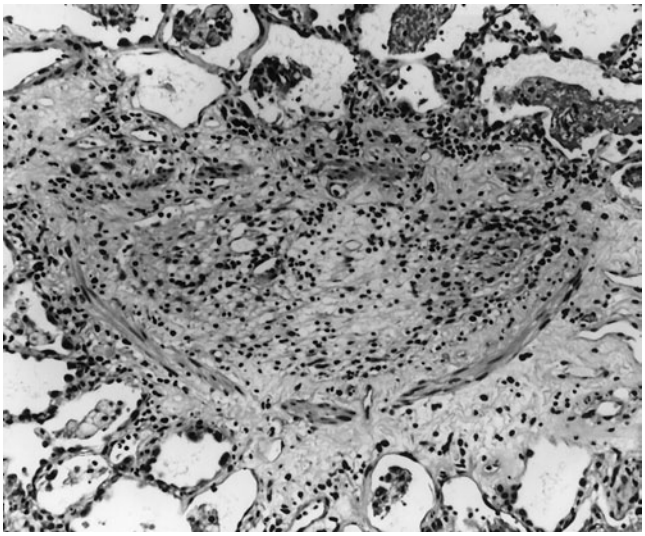

Figure 66-12. Bronchiolitis obliterans. Chronic airway rejection is characterized by luminal narrowing or replacement by dense eosinophilic collagenous scar tissue. Inflammatory cells may be seen in this case (H&E stain; ×150).

Valentine and the Stanford group reported that measurements of small airway function (i.e., $FEF_{25–75}$ and FEF_{50}:FVC) are more sensitive indicators of BOS than the FEV_1 in heart-lung and bilateral lung transplant recipients.[91] An FEF_{50}:FVC persistently below 0.7 for 6 consecutive weeks was the most sensitive predictor of OB. Approximately 50%

Table 66–7.

Working Formulation for Bronchiolitis Obliterans Syndrome

$0_{a \text{ or } b}$	No significant abnormality: FEV_1 80% of baseline
$1_{a \text{ or } b}$	Mild bronchiolitis obliterans syndrome: FEV_1 66–80% of baseline
$2_{a \text{ or } b}$	Moderate bronchiolitis obliterans syndrome: FEV_1 51–65% of baseline
$3_{a \text{ or } b}$	Severe bronchiolitis obliterans syndrome: FEV_1 50% of baseline

FEV_1 = forced expiratory volume in 1 second.
Note: a = without pathologic evidence of bronchiolitis obliterans; b = with pathologic evidence of bronchiolitis obliterans.

of heart-lung and bilateral lung recipients with biopsy-proven OB developed a fall in their FEF_{50}:FVC nearly 4 months prior to fulfilling the ISHLT working group criteria for BOS.

Experimental and clinical evidence suggests that the etiology of OB stems from the injury of the bronchial epithelium by one or more mechanisms. These include infection (particularly CMV), chronic inflammation due to impaired mucociliary clearance, and immunologic mechanisms.[73] These insults result in airway epithelial damage and subsequently an exaggerated healing response. Along with this injury, there is increased expression of major histocompatibility complex class II antigens in the bronchial epithelium. In a recent meta-analysis, Sharples and associates found that acute rejection is a risk factor for later development of OB.[94] In keeping with this finding is the association between BOS and decreased levels of immunosuppression (as may occur with noncompliance). Lymphocytic bronchitis and bronchiolitis were also closely associated with development of OB. CMV pneumonitis, other pulmonary infections, and HLA mismatching are also linked to the development of OB in small retrospective studies. Novick and colleagues recently reported on the relationship between OB, donor age, and graft ischemic times.[57] Using data from the ISHLT registry, they found a higher rate of OB at 3 years in recipients of grafts from donors over 55 that were also subjected to 6 to 8 hours of ischemia.

The current management of OB hinges on prevention, close surveillance, and immediate therapeutic intervention when patients become symptomatic or when asymptomatic physiologic changes occur. Patients are encouraged to perform incentive spirometry to prevent microatelectasis of lungs that are deprived of native innervation, lack bronchial circulation, and have impaired mucociliary clearance mechanisms. Moreover, all recipients are instructed to contact their transplant center or primary care physician upon development of respiratory tract symptoms so that pulmonary function tests can be performed. Any alterations in $FEF_{25–75}$, FEF_{50}:FVC, or specific changes in the flow-volume loop are indications for bronchoscopy with bronchoalveolar lavage and transbronchial biopsy, especially in the absence of infectious bronchitis or pulmonary edema.

Augmentation of immunosuppression is the mainstay of therapy for BOS. The prednisone dose is increased to 0.6 to 1.0 mg/kg per day and slowly tapered to 0.2 mg/kg per day while concomitantly optimizing cyclosporine and azathioprine dosing. Ganciclovir is reinstituted during treatment for those patients at risk of reactivation of CMV infection, and antimicrobial therapy is directed against any organisms isolated from bronchoalveolar lavage. Follow-up pulmonary function tests are performed. Pulmonary function can be stabilized in most patients, but significant improvement is uncommon. Unfortunately, relapse rates are >50% and progressive pulmonary failure or infection due to increased immunosuppression are the most common causes of death in lung transplant patients after the second year. Among 89 heart-lung and 13 bilateral lung recipients who underwent transplantation at Stanford University between 1981 and 1995, a 5-year survival rate of 49% among recipients diagnosed with OB (n = 59) was noted compared to 74% among recipients without OB (n = 43). The 1-, 3-, 5-, 8-, and 10-year actuarial survival rates following the diagnosis of OB were 74, 50, 43, 23, and 11%, respectively, with a median survival of 3 years following diagnosis.

Retransplantation is the only option for terminal respiratory failure secondary to OB. While survival for patients undergoing retransplantation for OB is better than for those undergoing retransplantation for other reasons, it is still worse than survival of first-time transplant recipients. Among heart-lung recipients with OB, Adams and associates at Harefield Hospital noted that retransplant survival rates were worse for those undergoing combined heart-lung replacement compared to patients who underwent isolated lung replacement.[95] The group also noted that the following factors were associated with improved survival after retransplant: absence of preformed antibodies, retransplantation at least 18 months after the original transplantation, and negative preoperative sputum cultures. Novick and colleagues recently reported results from the Pulmonary Retransplant Registry.[32] They reviewed survival rates in 237 patients who underwent pulmonary retransplantation between 1985 and 1996. At 1, 2, and 3 years after retransplantation, survival was 47, 40, and 33%, respectively. Survival was higher in nonventilated ambulatory patients and their freedom from OB was comparable to that of first-time transplant recipients. The authors conclude that pulmonary retransplantation should only be performed in carefully selected recipients who have a reasonable likelihood of long-term survival.

Accelerated graft coronary artery disease (CAD) or graft atherosclerosis is another major obstacle to long-term survival in heart-lung transplant recipients. Significant graft CAD resulting in diminished coronary artery blood flow may lead to arrhythmias, myocardial infarction, sudden death, or impaired left ventricular function with congestive heart failure. Classic angina due to myocardial ischemia is usually not noted in transplant recipients because the cardiac graft is not innervated. Multiple etiologies for graft CAD have been proposed, all focusing on chronic, immune-mediated damage to the coronary vascular endothelium. In fact, elevated levels of anti-endothelial antibodies have been correlated with graft CAD. Unlike coronary artery occlusive disease in the native heart, which tends to be a more focal process, transplant atherosclerosis is a more diffuse vascular narrowing extending symmetrically into distal branches. Histologically, transplant arteriopathy is characterized by concentric intimal proliferation with smooth muscle hyperplasia (Fig. 66-13).

Coronary angiograms are performed on a yearly basis to identify recipients with accelerated CAD. Angiography is limited, however, to assessment of luminal diameter. Intracoronary ultrasound, by contrast, can assess both vascular wall morphology and luminal diameter, making it a more sensitive tool to detect the diffuse coronary intimal thickening typical of graft atherosclerosis. Interestingly, graft CAD occurs at a

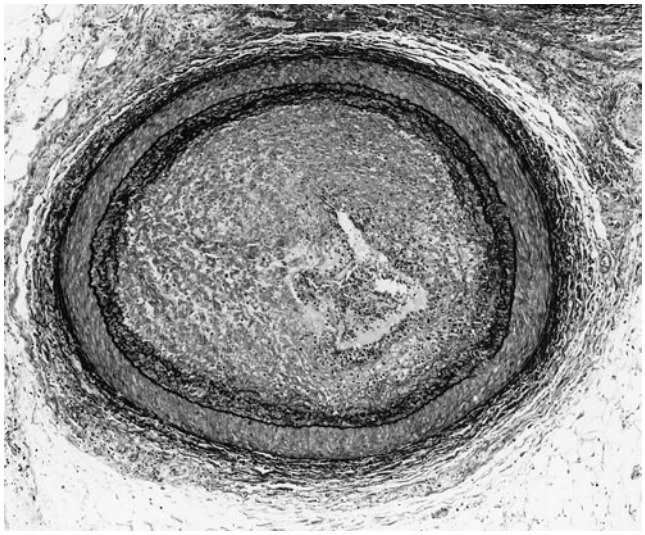

Figure 66-13. Cardiac graft atherosclerosis. Complete luminal obliteration by a concentric fibrointimal proliferation was observed postmortem in this heart-lung transplant patient (Elastin van Gieson stain; ×60).

reduced incidence in heart-lung recipients compared with the cardiac transplantation population.[96] A retrospective survey at Stanford revealed that 89% of heart-lung recipients were free from graft CAD at 5 years compared to 73% of heart transplant recipients. Clinically observed risk factors for developing this condition in heart transplant recipients include donor age >35 years; incompatibility at the HLA-A1, A2, and DR loci; hypertriglyceridemia (serum concentration >280 mg/dL); frequent acute rejection episodes; and documented recipient CMV infection. It is not clear whether these risk factors can be extended to the heart-lung transplant population.

Percutaneous transluminal coronary angioplasty and coronary artery bypass grafting have been used to treat discrete proximal lesions in some cases of graft CAD. However, the only definitive therapy for diffuse graft CAD is retransplantation. Effective prevention of graft CAD will rely on development of improved immunosuppression, recipient tolerance induction, improved CMV prophylaxis, and inhibition of vascular intimal proliferation.

Airway Complications

Improvements in surgical technique and posttransplant management have resulted in a relatively low incidence of airway complications after heart-lung and lung transplantation. Kshettry and colleagues at the University of Minnesota report an airway complication rate of 15% in lung transplant recipients.[97] The avoidance of perioperative steroids has long been considered important in preventing airway complications. However, recent experimental and clinical evidence suggests that the detrimental effect of steroids may be overestimated.[98] The most common airway complications are partial anastomotic dehiscence and stricture. Such complications are usually diagnosed by bronchoscopy. Airway dehiscence is treated by reoperation or close observation and supportive care. Strictures are treated by balloon or bougie dilatation, often with stent placement.

Infection

Bacterial, viral, and fungal infections are leading causes of morbidity and mortality in both heart-lung and lung transplant recipients. The rate of infection is higher in this transplant group compared to other solid organ transplant recipients. This may be related to the lung allograft's direct exposure to airway colonization and aspiration, as well as its impaired cough reflex and mucociliary clearance. The risk of infection and infection-related death peaks in the first few months after transplantation, declining to a low persistent rate thereafter. Between 1981 and 1994 at Stanford, only 20% of heart-lung transplant recipients were free from infection 3 months after transplantation. In a retrospective analysis of 200 episodes of serious infections occurring in 73 heart-lung recipients at Stanford between 1981 and 1990, Kramer and associates[99] found that half of all infections were caused by bacteria, whereas fungal infections accounted for only 14% of total infections. The most common viral agent was CMV, occurring primarily in the second month after transplantation and comprising 15% of all viral infections. Other viral infections (e.g., herpes simplex, adenovirus, and respiratory syncytial virus) were less common. Five percent of infections were attributed to *Pneumocystis jiroveci* (formerly *carinii*), typically occurring 4 to 6 months after transplantation, and 2% were due to *Nocardia*, generally appearing after the first year. There was no significant difference in the incidence of infections between patients receiving triple-drug or double-drug (cyclosporine and prednisone) immunosuppression. Infectious mortality comprised 40% of all deaths.

Posttransplant infections can be classified broadly into those that occur early or late after transplantation. Early infections, occurring within the first month after transplantation, are commonly bacterial (especially gram-negative bacilli) and manifest as pneumonia, mediastinitis, urinary tract infections, catheter-related sepsis, and skin infections. In the late posttransplant period, opportunistic viral, fungal, and protozoan pathogens become more prevalent. The lungs, central nervous system, gastrointestinal tract, and skin are the usual sites of invasion.

Bacterial infections, particularly those caused by gram-negative bacteria, predominate during the early postoperative period. Between 75 and 97% of bronchial washings obtained from donor lungs before organ retrieval culture at least one organism.[100] Posttransplant invasive infections are frequently caused by organisms cultured from the donor. Conversely, bacterial infections developing in patients with septic lung disease, particularly cystic fibrosis, most commonly originate from the recipient's airways and sinuses. Treatment of bacterial infections generally involves characterization of the infective agent (e.g., cultures and antibiotic sensitivities), source control (e.g., catheter removal and débridement), and appropriate antibiotic regimens.

CMV infection occurs most often at 1 to 3 months after transplantation and presents either as a primary infection or as reactivation of a latent infection. By definition, primary infection results when a previously seronegative recipient is infected through contact with tissue or blood from a seropositive individual. The donor organ itself is thought to be the most common vector of primary CMV infections. Reactivation infection occurs when a recipient who is seropositive prior to transplant develops clinical CMV infection during immunosuppressive therapy. Seropositive recipients are also subject to infection by new strains of CMV. Primary infection in previously seronegative recipients is generally more serious than reactivation or reinfection in seropositive patients.

Clinically, CMV infection has protean manifestations, including leukopenia with fever, pneumonia, gastroenteritis, hepatitis, and retinitis. CMV pneumonitis is the most lethal of these, with a 13% mortality, and retinitis remains the most refractory to treatment. Diagnosis of CMV infection is made by direct culture of the virus from blood, urine, or tissue specimens, by a fourfold increase in antibody titers from baseline, or by characteristic histologic changes (i.e., markedly enlarged cells and nuclei containing basophilic inclusion bodies). Most cases respond to ganciclovir and hyperimmune globulin.

The significance of CMV as an infective agent becomes clear when one realizes that it is implicated as a trigger for accelerated graft CAD[101] and OB,[94] as well as an inhibitor of cell-mediated immunity. CMV-negative donors comprise <20% of the donor organ pool, and due to organ scarcity most transplant centers perform transplants across CMV serologic barriers using ganciclovir and/or hyperimmune globulin prophylactic protocols in CMV-positive donors and/or recipients. A recent study by Valantine and associates in 80 heart-lung and lung transplant recipients found that the combined use of ganciclovir and hyperimmune globulin was superior to ganciclovir alone as prophylaxis against CMV. Moreover, the ganciclovir/hyperimmune globulin cohort had longer survival at 3 years and greater freedom from OB.[102]

Invasive fungal infections peak in frequency between 10 days and 2 months after transplantation. Treatment consists of fluconazole, itraconazole, or amphotericin B. Reichenspurner and associates have reported that the actuarial incidence and linearized rate of fungal infections after heart, heart-lung, and lung transplants performed at Stanford University were significantly reduced in recipients who received inhaled amphotericin prophylaxis.[103]

The institution of prophylaxis with oral trimethoprim-sulfamethoxazole (or inhalational pentamidine for sulfa-allergic patients) has effectively prevented *Pneumocystis jiroveci* pneumonia in lung and heart-lung transplant patients. The risk of *Pneumocystis* infection is highest during the first year after transplant. However, as infections can also occur late after transplant, most centers recommend that prophylactic therapy be continued for life.

Infection prophylaxis in heart-lung and lung recipients is comprised of vaccinations, perioperative broad-spectrum antibiotics, and long-term prophylactic antibiotics. Pretransplant inoculations with pneumococcal and hepatitis B vaccines, as well as diphtheria-pertussis-tetanus boosters, are recommended. All transplant recipients should receive annual influenza vaccinations. Although perioperative antibiotic regimens vary widely between transplant centers, first-generation cephalosporins (e.g., cefazolin) or vancomycin are commonly used. Long-term prophylaxis typically includes nystatin mouthwash, trimethoprim-sulfamethoxazole, aerosolized amphotericin B, and antivirals such as acyclovir or ganciclovir.

Neoplasm

Transplant recipients have a higher incidence of neoplasia than that of the general population.[104] This is undoubtedly due to chronic immunosuppression. Recipients are predisposed to a variety of tumors, including skin cancer, B-cell lymphoproliferative disorders, carcinoma in situ of the cervix, carcinoma of the vulva and anus, and Kaposi's sarcoma. On average, tumors appear approximately 5 years after transplantation.[1]

The incidence of B-cell lymphoproliferative disorders in transplant patients is a staggering 350 times greater than that of the normal age-matched population. Posttransplant lymphoproliferative disorder has been reported in 6% of lung transplant recipients.[105] These most commonly occur within the first year after transplantation and are associated with Epstein-Barr virus infection. Treatment consists of reducing immunosuppression and administration of an antiviral agent such as acyclovir or ganciclovir. A response rate of 30 to 40% can be expected, and recurrence is uncommon. Chemotherapy and radiotherapy have been used successfully in some cases. During therapy, close monitoring of the graft, along with clinical assessment of tumor status, is essential.

LONG-TERM RESULTS IN HEART-LUNG AND LUNG TRANSPLANTATION

The Stanford long-term survival for heart-lung and lung transplant recipients is shown in Figs. 66-14 and 66-15, respectively. Similar results are recorded in the ISHLT registry (Figs. 66-16 and 66-17). At Stanford, 1-, 5-, 10-, 15-, and 20-year survival rates after heart-lung transplantation are 72, 50, 32, 25, and 14%, respectively. Lung transplantation survival at 1, 5, 10, and 15 years posttransplantation are 82, 49, 28, and 17%, respectively. Most recipients are able to resume active lifestyles without supplemental oxygen and demonstrate significant increases in exercise capacity posttransplant. Pulmonary function measured by spirometry and arterial blood gases is markedly improved within several months after transplantation, with a normalization of ventilation and gas exchange after 1 to 2 years.[106]

CONCLUSION

The evolution of heart-lung and lung transplantation from rudimentary laboratory experimentation to its current prominence as an accepted therapy for end-stage cardiopulmonary disease is a product of ingenuity, perseverance, skill, and courage. Many debilitated patients, both adult and pediatric, now have an opportunity to resume full and active lifestyles after heart-lung and lung transplantation. Nevertheless, significant hurdles have yet to be overcome, including issues of graft rejection, infection, and a limited donor pool. Important advances on the horizon include cross-species transplantation, improved immunosuppression, the induction of immunologic tolerance to foreign tissue, and improved organ preservation techniques.

CHAPTER 67

Long-Term Mechanical Circulatory Support

Sanjeev Aggarwal • Faisal Cheema • Mehmet C. Oz • Yoshifumi Naka

Heart failure continues to be an ever-growing public health concern facing our country today. The continued aging of the population has contributed to the increasing incidence and prevalence of heart failure. Presently, approximately 5 million people are affected, with over 500,000 new cases diagnosed annually. Economically, this represents over 30 billion dollars in health care spending each year.[1,2]

Despite advances in the understanding of the neurohormonal changes involved in the progression of heart failure and improvements in medical management, the natural history of the disease dictates a dismal prognosis. In the Framingham Study cohort, overt congestive heart failure led to a median survival of 1.7 years in men and 3.2 years in women, with 5-year survival rates in men and women of 25% and 38%, respectively.[3] Overall, it is estimated that congestive heart failure is responsible for approximately 250,000 deaths per year.[4] Cardiac transplantation has been regarded as the gold standard treatment for heart failure. However, limitations on availability of donor organs have made transplantation a viable option for only a very small percentage of this growing population. Over the past decade, the number of transplants being performed annually has remained between 3000 and 4000 worldwide, with a decreasing trend noted in recent years.[5]

Mechanical support of the cardiopulmonary system was first introduced clinically by John Gibbon in 1953, when he successfully employed cardiopulmonary bypass for the repair of an atrial septal defect.[6] In 1963, DeBakey implanted the first ventricular assist device in a patient suffering a cardiac arrest following aortic valve replacement. The patient subsequently died on postoperative day 4. In 1966, DeBakey reported the first successful bridge to recovery with implantation of a pneumatically driven ventricular assist device in a patient suffering from postcardiotomy shock. The patient was supported for 10 days, and ultimately survived to discharge.[7] Soon thereafter, Cooley reported the first successful bridge to transplantation using a pneumatically driven implantable artificial heart.[8] During this time, the National Heart, Lung, and Blood Institute began funding initiatives to further the development of ventricular assist devices and a total artificial heart. DeVries and colleagues reported the successful implantation of the Jarvik-7-100 total artificial heart in 1984.[9] Despite initial success, a high incidence of thromboembolic and infectious complications led to a moratorium on the use of the total artificial heart in 1991. During this period, however, continued advances in the development of left ventricular assist devices culminated in Food and Drug Administration (FDA) approval of a left ventricular assist device as a bridge to transplantation in 1994.

The feasibility of a mechanical-based approach to the treatment of end-stage heart failure was validated by the REMATCH trial in 2004.[10] This prospective randomized trial demonstrated a marked survival benefit in patients receiving mechanical ventricular assistance for the treatment of end-stage heart failure when compared to medical management alone. At the same time, the limitations of current device technology were highlighted by the incidence of adverse events related to mechanical support, such as infection, device failure, and thromboembolic events. Continued technological developments and improvements in device design are necessary for mechanical circulatory support to become an effective means of long-term destination therapy.

INDICATIONS FOR DEVICE SUPPORT

With advances in device technology and improvements in patient selection criteria, the indications for mechanical circulatory support continue to evolve. In general terms, patients considered for mechanical circulatory support can no longer sustain adequate systemic oxygen delivery to maintain normal end-organ function despite maximal medical therapy. Traditional hemodynamic criteria for device implantation include a systolic blood pressure less

than 80 mm Hg, mean arterial pressure less than 65 mm Hg, cardiac index less than 2.0 L/min/m^2, pulmonary capillary wedge pressure greater than 20 mm Hg, and a systemic vascular resistance greater than 2100 dynes-sec/cm.[11,12] The decision to implement mechanical circulatory support must be made with consideration of the ultimate goal of therapy. Devices can be used as a bridge to transplantation, as a bridge to myocardial recovery, or as destination therapy in patients not eligible for cardiac transplantation. The range of disease processes treated with ventricular assist device (VAD) therapy includes both acute and chronic forms of cardiac failure, and will likely continue to expand.[13,14]

Cardiogenic Shock Associated with Acute Myocardial Infarction

It is estimated that cardiogenic shock complicates the clinical presentation of between 6 and 20% of patients suffering from acute myocardial infarction. Cardiogenic shock results from either a loss of more than 40% of the left ventricular myocardium, or is due to isolated right ventricular infarction and subsequent hemodynamic compromise secondary to right ventricular failure.[15] Myocardial infarction complicated by cardiogenic shock has a reported mortality rate of between 70 and 80%.[16,17] In recent years, the trend toward more aggressive and early coronary reperfusion strategies such as intra-aortic balloon counterpulsation, percutaneous coronary interventions, and coronary artery bypass grafting have resulted in a modest decline in the mortality rate of this condition.[17] Early experience with use of left ventricular assist device (LVAD) therapy in the setting of acute myocardial infarction resulted in high mortality rates.[18–20] As experience with the implantation and management of LVADs has grown, there has been a renewed interest in recent years in the use of mechanical circulatory support in the acute setting. Chen and associates have advocated the early implementation of LVAD therapy following acute myocardial infarction as a means of providing a greater chance for ventricular recovery and subsequent device weaning.[21] A more recent series by Leshnower and colleagues retrospectively examined the results of LVAD support in 49 patients suffering from infarction-related cardiogenic shock.[22] Mechanical support in this setting was able to successfully bridge 74% of patients to transplant, with an overall in-hospital mortality of 33%, a marked improvement over historical controls. LVAD therapy will likely play an increasingly important role in the treatment of such patients.

Postcardiotomy Cardiogenic Shock

Approximately 2 to 6% of patients undergoing coronary or valvular cardiac procedures will suffer from postcardiotomy cardiogenic shock.[23] Mehta and colleagues reported the results of 1279 cases of postcardiotomy cardiogenic shock.[24] Forty-five percent of patients were weaned from support, with only 25% surviving to discharge. The mean duration of support was 4 days, with use of both centrifugal and pneumatically driven devices. Similar survival-to-discharge rates in this ill group of patients were found in the New York State cardiac surgery database.[25]

We have advocated the early implementation of mechanical circulatory assistance in the setting of postcardiotomy shock to provide mechanical unloading of the ventricle and rapid restoration of normal end-organ perfusion, with improved survival rates.[26] The creation of regional networks allows for patients to receive bridge-to-bridge therapy with short-term devices implanted early at "spoke" facilities and then subsequent transfer to a specialized "hub" center for either management as bridge to recovery or device exchange to a more permanent implantable VAD. In a series of 44 patients treated in this way, 66% survived to hospital discharge.[27,28]

Special consideration should be given to patients with severely impaired ventricular function undergoing high-risk cardiac procedures. If possible, transplant evaluation is initiated preoperatively and the procedure performed with LVAD back-up. In this way, postcardiotomy failure can be dealt with expeditiously with LVAD implantation either as a bridge to recovery or as a bridge to transplantation.

Chronic Heart Failure

Patients in chronic decompensated heart failure generally fall into one of two categories: those who are eligible for cardiac transplantation and those who are not. Mechanical circulatory support can be instituted in this group of patients as a bridge to transplantation or as destination therapy. Patients who are listed for transplant with a long anticipated waiting time due to limited donor availability, blood type, patient size, or immunologic sensitization with the need for prospective cross-matching may benefit from elective LVAD placement to maintain or restore normal end-organ function. The normalization of hemodynamics and end-organ function with mechanical support in pretransplant patients has been shown to decrease posttransplant mortality rates.[29,30]

Myocarditis

Acute myocarditis typically affects a younger cohort of patients and is characterized by an unpredictable clinical course. Mechanical circulatory support in this setting offers the chance for bridge to recovery. Determining which group of patients will recover and which will require support as a bridge to transplant remains a challenge.[31,32] Due to the frequent involvement of both the right and left ventricles in the disease process, early consideration should be given to instituting biventricular support to achieve optimal clinical outcomes.[33,34]

Ventricular Arrhythmia

There have been several successful reports of device implantation in patients suffering from ventricular arrhythmias refractory to medical therapy.[35–38] While some patients may have ventricular arrhythmias arising in the setting of acute

myocardial infarction with compromised cardiac function, many have de novo arrhythmias with relatively normal cardiac function and hemodynamics. The natural course of the arrhythmia following LVAD implantation is variable, with some patients demonstrating resolution and others having persistent arrhythmias. When persistent, they are usually well tolerated. The impairment in right ventricular function with prolonged ventricular arrhythmias has led some to advocate early biventricular support in these patients.

PATIENT SELECTION AND RISK ASSESSMENT

Appropriate patient selection represents one of the most critical determinants of successful outcomes with VAD therapy. The operative risk of device implantation must be weighed against the potential lifestyle and survival benefit with mechanical support. Patient selection criteria must not be so stringent as to exclude ill patients who may benefit from device therapy, while at the same time avoiding high perioperative mortality rates by the inclusion of patients who have prohibitive risk.

Several reports have sought to identify significant preoperative variables that may predict risk and impact outcomes. The revised Columbia screening scale published in 2003 offers a way of stratifying the risk for LVAD therapy based on several clinical factors: mechanical ventilation; postcardiotomy; prior LVAD insertion; central venous pressure >16 mm Hg; and prothrombin time >16 seconds (Table 67-1).[39] Each factor is given a weight, with a cumulative score of >5 predicting an operative mortality of 46%, versus a mortality rate of 12% for a score ≤5. This scoring system is a revision of a prior scale developed in conjunction with The Cleveland Clinic Foundation.[40] The revised scoring scale was the result of analysis of 130 patients undergoing implantation of the Heartmate vented electrical device. In the new scoring scale, preoperative oliguria (urine output <30 mL/h) and reoperative surgery were not statistically significant factors in predicting postoperative mortality as they were in the old model. McCarthy and colleagues previously reported the results of 100 patients undergoing LVAD implantation.[41] In this group of patients, preoperative factors that increased the risk of death by univariate analysis included the need for mechanical ventilation or extracorporeal membrane oxygenation, low pulmonary arterial pressures, and elevations in bilirubin, blood urea nitrogen, and creatinine. Deng and associates reported the results of 464 patients undergoing implantation of the Novacor left ventricular assist system (LVAS). Sepsis associated with respiratory failure, preoperative right heart failure, age >65 years, acute postcardiotomy state, and acute infarction were independent risk factors for death by multivariate analysis.[42]

Table 67–1.

Revised Risk Factor Summation Score

Variable	Relative risk	Weighting
Ventilated	5.3	4
Postcardiotomy	3.3	2
Prior LVAD insertion	3.3	2
CVP >16 mm Hg	2.1	1
PT >16 seconds	2.1	1

Variables excluded by multivariate analysis: prior right ventricular assist device, coronary artery disease, acute myocardial infarction, urine output <30 mL/h, reoperative surgery.
CVP = central venous pressure; LVAD = left ventricular assist device; PT = prothrombin time.
Source: Reproduced with permission from Rao et al.[39]

The timing of intervention is also an important determinant of clinical outcomes. Optimization of the patient's clinical status with diuresis, correction of coagulation abnormalities, pulmonary rehabilitation, and intra-aortic balloon counterpulsation are important, but should not delay institution of support in critically ill patients with severe ventricular failure and ongoing end-organ malperfusion. In the acute setting of postcardiotomy shock, data from the Abiomed registry demonstrated that delays in instituting mechanical support beyond 6 hours led to a marked increase in mortality.[43,44] Urgency of device implantation also has an impact on overall survival. Deng and coworkers reported the results of patients undergoing device implantation as a bridge to transplantation, showing a decreased rate of survival to transplantation in those receiving LVADs for emergent indications such as acute myocardial infarction, postcardiotomy failure, and acute heart failure when compared to patients receiving devices on an elective basis.[45]

Although inclusion criteria for mechanical support have expanded in recent years, there still exist generally agreed upon contraindications for device implantation. Patients with irreversible end-organ damage, particularly renal, hepatic, or respiratory failure, uniformly demonstrate poor clinical outcomes. Severe and unrecoverable neurologic injury also represents a contraindication to device implantation. Systemic sepsis or bacteremia poses a high risk of device contamination after implantation and should be controlled prior to LVAD insertion.

DEVICE SELECTION

A wide variety of devices exists today, with many more in development. Several factors must be considered when choosing a specific device. These include the anticipated endpoint of treatment (i.e., destination therapy, bridge to transplantation, or bridge to myocardial recovery), the expected duration of support, the type of ventricular support needed (i.e., right, left, or biventricular), and patient

factors such as body size and habitus, blood type, and preexisting contraindications to anticoagulation therapy. Surgeon experience and institutional bias also factor into device selection. The Food and Drug Administration has approved certain devices for particular clinical situations. Some of the most commonly used devices will be reviewed in the next section.

Short-Term Mechanical Support

Several modalities exist for providing short-term mechanical circulatory support. These include counterpulsation and centrifugal, axial, and pneumatic pumps. These devices have the advantage of relative ease of implementation with the hope of providing either a short-term bridge to recovery or a short-term bridge to more permanent ventricular assistance.

The first clinical application of an intra-aortic balloon pump (IABP) was reported by Kantrowitz and colleagues in 1968 for the treatment of postinfarction cardiogenic shock.[46] Since that time, IABP placement has become one of the most common forms of mechanical circulatory assistance. Counterpulsation, which is synchronized to either electrocardiogram or arterial waveforms, provides balloon inflation within the descending thoracic aorta during diastole with deflation at the onset of systole. The result is a reduction in myocardial work through afterload reduction, and improvement in myocardial oxygen supply through augmentation of diastolic blood pressure and coronary perfusion pressure.[47,48] IABP counterpulsation is used today in a variety of clinical settings, including cardiogenic shock associated with myocardial infarction, postcardiotomy shock, mechanical complications of infarction such as acute mitral regurgitation and ventricular septal defect, postinfarction angina, and for the treatment of ventricular arrhythmias in the setting of ongoing ischemia. IABP has also been used preoperatively as an adjunct to high-risk percutaneous interventions or coronary artery bypass grafting.[49,50]

Centrifugal pumps have been used both for intraoperative cardiopulmonary bypass and as a means of providing either right, left, or biventricular mechanical circulatory support. They have the advantage of wide availability, ease of use, and relative low cost compared to other devices.[51–53] Disadvantages include the need for systemic anticoagulation with resultant bleeding complications. Progressive development of interstitial edema secondary to capillary leak and the inability to ambulate and rehabilitate these patients limits this technology to short-term support. Three of the most commonly used pumps in the United States are the Biomedicus Biopump (Medtronic Bio-Medicus, Inc., Eden Prairie, Minn), the Sarns centrifugal pump (3-M Health Care, Ann Arbor, Mich), and the St. Jude Lifestream centrifugal pump (St. Jude Medical, Inc., St. Paul, Minn).

The versatility of centrifugal pumps has allowed them to be clinically implemented in a number of different ways. Extracorporeal membrane oxygenation (ECMO) utilizes a centrifugal pump in combination with a membrane oxygenator to provide complete cardiopulmonary support in the setting of circulatory and respiratory failure. The successful use of ECMO in the pediatric population has been well described.[54,55] The outcomes of ECMO for treatment of cardiac failure in the adult population is more limited. The Extracorporeal Life Support Organization registry reported by Bartlett demonstrates a survival of approximately 40% in over 1600 patients undergoing ECMO for cardiac failure.[56] A large portion of these cases were pediatric patients. Series looking only at adult patients demonstrate lower survival rates.[57] The TandemHeart percutaneous VAD (CardiacAssist, Inc., Pittsburgh, Penn) utilizes a centrifugal pump to pump blood from the left atrium to one or both femoral arteries. The left atrial catheter is placed percutaneously via a transseptal puncture.[58] Thiele and associates reported the results in 18 patients undergoing placement for cardiogenic shock, demonstrating improvements in cardiac index and reductions in pulmonary capillary wedge pressure.[59]

The Impella Recover device (Impella CardioSystems AG, Aachen, Germany) is a miniaturized axial flow pump designed for short-term right, left, or biventricular support. The device is able to generate flows of up to 4 to 5 L/min at rotational speeds of between 28,000 and 32,000 rpm. The device has the advantage of ease of implantation and minimal requirement for anticoagulation. The device can be placed percutaneously and positioned with echocardiographic guidance.[60] Initial clinical experience has been favorable in the setting of postcardiotomy shock and acute heart failure, with some evidence indicating a significant survival benefit in patients receiving the Impella device when compared to IABP placement alone.[61,62]

The Abiomed BVS 5000i (Abiomed Cardiovascular, Inc., Danvers, Mass) is an FDA-approved device for acute postcardiotomy failure. It is a dual-chambered pneumatically driven extracorporeal pump designed for short-term cardiac support. The dual chamber polyurethane blood sacs fill passively, with pneumatically driven ejection. The configuration mimics that of the native atria and ventricles. The device is capable of generating pulsatile flow of up to 6 L/min. The ease of implantation, operation, weaning, cost effectiveness, and widespread availability have made it one of the most commonly used devices in the setting of acute cardiac failure. The indications for use have expanded beyond the postcardiotomy setting to include cardiogenic shock associated with acute infarction, myocarditis, and temporary right ventricular support in association with long-term LVAD implantation.[43,44,63,64] The device has been used extensively in community-based practices, allowing for the transfer of patients to a specialized center for transplantation or more permanent support as previously described.[27,65] Disadvantages include the need for systemic anticoagulation and limited patient mobility. The Abiomed AB5000, also recently approved by the FDA, is the successor to the BVS 5000i system (Fig. 67-1). It consists of a fully automated, vacuum-assisted console with a pneumatically driven blood pump that is placed paracorporeally. It offers the advantage of allowing for patient mobility and rehabilitation and can provide a longer time period of support than its predecessor.

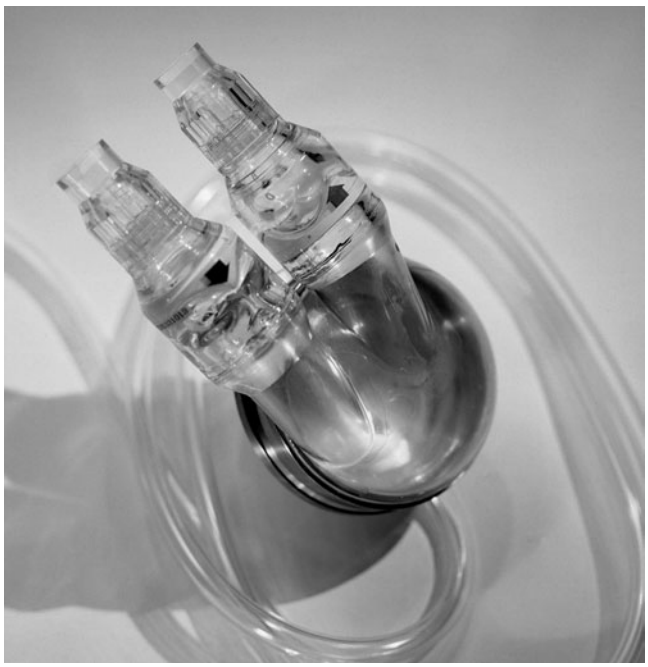

Figure 67-1. The Abiomed AB5000 circulatory support system. *(Courtesy of Abiomed, Inc., used with permission.)*

Early clinical experience with the device is encouraging, although concerns have been raised regarding device-related hemolysis.[66]

Long-Term Mechanical Support

Pulsatile-implantable devices

HEARTMATE XVE: The Heartmate XVE LVAD (Thoratec Corp., Pleasanton, Calif) is FDA approved as a bridge to transplantation and for destination therapy (Fig. 67-2). The original system, developed in 1975, was a pneumatically driven pump. The requirement of a large controller console for the pneumatic unit limited patient mobility and rehabilitative efforts. The newer-generation device is an electrically vented unit with a portable control console and batteries, allowing for greater patient mobility, rehabilitation, and discharge from the hospital.[67]

The pumping chamber is constructed of a titanium alloy and utilizes 25-mm porcine xenograft valves in the inflow and outflow conduits. The device uses pusher plate technology to generate pulsatile flow with a stroke volume of 83 mL and a maximal output of 10 L/min. The LVAD is operated in either fixed mode with a set rate, or in automatic mode, in which the pusher plate is activated when the device senses filling of the blood chamber. In the event of electrical failure of the device, the pusher plate can be driven pneumatically with either a hand pump or the large pneumatic console. The inflow cannula is typically placed in the apex of the left ventricle, with the outflow graft anastomosed to the ascending aorta.[68] The pump is placed either intra-abdominally or in a preperitoneal pocket in the left upper quadrant,

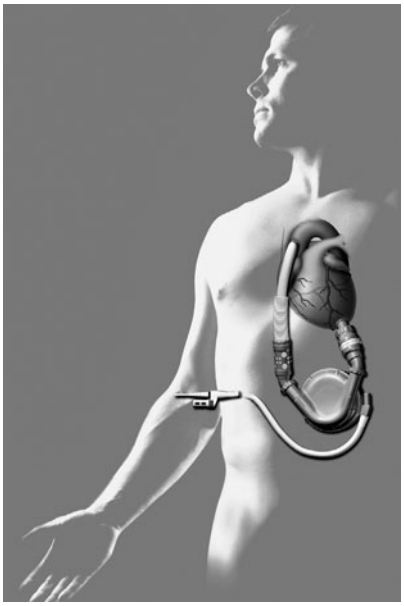

Figure 67-2. The Heartmate left ventricular assist device. *(Courtesy of Thoratec Corp., used with permission.)*

with a driveline tunneled subcutaneously and brought out of the right upper quadrant. Our preference is to create a preperitoneal pocket due to complications associated with intra-abdominal placement.[69] Due to the size and physical characteristics of the Heartmate LVAD, patients undergoing implantation must have a body surface area (BSA) of at least 1.5 m^2.

A unique feature of the device is its sintered titanium and textured polyurethane internal surfaces (Fig. 67-3). This encourages the deposition of circulating cellular elements and the formation of a pseudointima. As a result, the device has a relatively low incidence of thromboembolic events without the need for systemic anticoagulation with warfarin.[70] Patients are maintained on aspirin as an anti-inflammatory agent.

A large amount of clinical experience has been gained with the Heartmate LVAD.[41,68,71] The Thoratec registry is a voluntary database that has collected implantation data from 186 centers worldwide. As of November 2004, 4190 Heartmate LVADs had been implanted (1323 pneumatic and 2867 electric). The average duration of support for patients receiving the Heartmate electrically vented device was 152 days, with support as long as 1854 days being reported.[72]

NOVACOR LEFT VENTRICULAR ASSIST SYSTEM: The Novacor LVAS (World Heart Corp., Oakland, Calif) was first successfully used as a bridge to transplantation in 1984 (Fig. 67-4). It is currently FDA approved for this indication, and has been implanted in over 1700 patients worldwide. Like the Heartmate device, the Novacor LVAS originated as a large console-based system. In 1993, the first portable controller unit with rechargeable batteries was introduced.[73,74]

The device uses dual pusher plates to compress a seamless polyurethane sac, generating pulsatile blood flow of up

Figure 67-3. The textured internal surfaces of the Heartmate left ventricular assist device. *(Courtesy of Thoratec Corp., used with permission.)*

Figure 67-4. The Novacor left ventricular assist system. *(Courtesy of World Heart Corp., used with permission.)*

to 9 L/min. Unidirectional flow is achieved with bioprosthetic valves in both the inflow and outflow conduits. The device can be operated in a fixed mode, an automatic mode, and a synchronized mode. The synchronized mode uses the electrocardiogram signal to coordinate cardiac systole with pump diastole, allowing for maximal device filling. The surgical placement of the device is similar to that of the Heartmate LVAD, with an inflow cannula placed in the left ventricular apex, outflow to the ascending aorta, pump placement in the preperitoneal space of the left upper quadrant, and a percutaneous driveline brought out through the right upper quadrant.

The Novacor system, unlike the Heartmate device, requires systemic anticoagulation with warfarin. Despite systemic anticoagulation, some series have reported thromboembolic rates of over 20%.[75,76] A difficulty, however, in comparing rates of thromboembolism and neurologic events between the Heartmate XVE and Novacor LVAS lies in the variability of definitions used in the literature. Pasque and Rogers used the Heartmate XVE manual definitions of thromboembolic events and applied them to their experience with the Novacor device, finding similar rates of "neurologic dysfunction" (20% for the Novacor versus 27% for the Heartmate) and thromboembolism (10% for the Novacor versus 12% for the Heartmate).[77] The original inflow cannula, constructed of low-porosity polyester (Cooley, Meadox Medical, Oakland, NJ), has been implicated as a source for thromboembolic events. Modifications have included the more recent use of an integral wall reinforced knitted, gelatin-sealed polyester graft (Sulzer Vascutek Ltd., Renfrewshire, Scotland, UK). Portner and colleagues reported on the results of 202 patients receiving the newer inflow conduit (compared to a control group of 280 patients) and found an almost 50% reduction in the incidence of embolic cerebrovascular accidents.[76] Other series have also demonstrated similar results with the use of the Vascutek graft.[78] More recently, expanded polytetrafluoroethylene has been used to construct the inflow conduit (Edwards Lifesciences, Irvine, Calif) with encouraging results.[79]

The Novacor system has demonstrated excellent long-term durability, with over 60% of patients surviving to transplantation.[73,75] Support of more than 4 years without device exchange has been reported.[80] The Investigation of Non Transplant Eligible Patients who are Inotrope Dependent is a nonrandomized trial, currently nearing completion, evaluating the efficacy of the Novacor LVAS for destination therapy.[81]

Figure 67-5. The Thoratec intracorporeal ventricular assist device. *(Courtesy of Thoratec Corp., used with permission.)*

THORATEC INTRACORPOREAL VENTRICULAR ASSIST DEVICE: The Thoratec intracorporeal ventricular assist device (Thoratec Corporation, Pleasanton, Calif) is presently FDA approved for use as a bridge to transplantation and for support in the setting of postcardiotomy shock (Fig. 67-5). The design is based on the success of the Thoratec paracorporeal VAD (described below). Like the paracorporeal system, the intracorporeal VAD offers the advantage of versatility, being able to provide isolated right, left, or biventricular support.

The device housing is constructed of a smooth-surfaced polished titanium alloy. The pumping chamber is a seamless sac made of Thoralon. Unidirectional flow is achieved with the same monostrut occluder disk valves used in the paracorporeal system. Pneumatic compression of an actuation diaphragm achieves pulsatile flow. A small infrared sensor detects whether the sac is full or empty. The device has a stroke volume of 65 mL and is able to generate a maximal flow of about 7.2 L/min. Placement of the housing is either intra-abdominal or preperitoneal, with a percutaneous driveline that exits the skin. As with the paracorporeal system, anticoagulation with heparin and warfarin is required.[82,83]

Clinical data provided by Thoratec on 30 patients undergoing implantation of the device demonstrated a 68% success rate in treatment. Twelve patients were bridged to transplant, 5 patients were bridged to recovery, and 5 patients had ongoing support as of 2003. In this cohort, 63% underwent placement as an LVAD, and 37% for biventricular support. The mean duration of support per patient was 82 days. The size of the device has limited use to a smaller group of patients compared to the larger Heartmate and Novacor LVADs. The mean BSA in these patients was 1.94 m^2, with a range of 1.31 to 2.35 m^2.[84]

Pulsatile-paracorporeal devices

THORATEC PARACORPOREAL VENTRICULAR ASSIST DEVICE: The Thoratec paracorporeal VAD is the result of work done in the 1970s by Pierce and Donachy at Pennsylvania State University (Fig. 67-6). It has been used extensively, with over 2800 implants having been performed worldwide as of November 2004. The device is versatile, offering the option of right, left,

Figure 67-6. The Thoratec paracorporeal ventricular assist device. *(Courtesy of Thoratec Corp., used with permission.)*

or biventricular support. The paracorporeal placement of the pumping chamber allows use in patients with BSAs of $<1.5\ m^2$. The device has been used in a patient weighing only 17 kg with a BSA of $0.73\ m^2$.[84]

The Thoratec paracorporeal VAD consists of a polyurethane blood sac contained within a polycarbonate housing. A large pneumatic console is used to generate pulsatile flow with a maximum stroke volume of 65 mL. Flow rates of up to 7.2 L/min can be achieved. As with the intracorporeal VAD, unidirectional flow is maintained with tilting disk mechanical valves. Since the pumping chamber is placed paracorporeally, less surgical dissection is required at implantation. For left-sided support, inflow cannulas can be placed either in the apex of the left ventricle or in the left atrium, with the outflow graft anastomosed to the ascending aorta. For use as a right VAD, inflow can be achieved either by cannulation of the right atrium or by direct placement into the right ventricle, with outflow into the main pulmonary artery. The device does require systemic anticoagulation with heparin and warfarin. While the dual driver console unit is large and cumbersome, the introduction of the TLC-II portable driver has allowed improved patient mobility and rehabilitation.[85]

As of November of 2004, the voluntary Thoratec registry has reported the use of the paracorporeal VAD system in over 2850 patients, with the longest duration of support being 566 days. In over 1900 patients undergoing implantation for bridge to transplantation, 58% underwent biventricular VAD placement, 35% had left VAD placement, and 7% underwent isolated right VAD placement. Successful bridge to transplantation in various reports has been >60% and is dependent on whether single or biventricular support is required.[85–87]

Axial flow pumps

Axial flow pumps utilize a rotating impeller to provide continuous nonpulsatile blood flow. They typically operate quietly and with less power consumption than the pulsatile LVADs. Due to a decreased number of moving parts and contact bearings, they offer the theoretical advantage of enhanced durability. The smaller size of these devices affords easier implantation and explantation, as well as allowing for support in smaller-sized adults and pediatric patients. Disadvantages of axial flow pumps include the lack of backup mechanisms in the event of device failure, hemolysis secondary to shear forces, and the potential for creating negative intraventricular pressure and subsequent device thrombosis, air embolism, or arrhythmias. Optimization of preload and proper inflow cannula placement are particularly important with axial flow devices to avoid generating negative intraventricular pressure.

At present, the effects of long-term nonpulsatile flow on end-organ function are not entirely known. While differences in the microcirculations of various organs have been demonstrated with nonpulsatile flow, recent evidence seems to suggest that normal end-organ function can be maintained with continuous nonpulsatile axial flow with no adverse effects on morbidity or mortality.[88–91]

MICROMED DEBAKEY VENTRICULAR ASSIST DEVICE: The MicroMed DeBakey VAD (MicroMed Cardiovascular Inc., Houston, Tex) was developed in the late 1980s as a collaborative effort between Drs. Michael E. DeBakey and George P. Noon of the Baylor College of Medicine and National Aeronautics and Space Administration engineers (Fig. 67-7). The pump unit, made of titanium, is only 1.2 inches in diameter and 3 inches long and weighs 95 grams. The impeller /inducer is capable of generating flows of up to 10 L/min. Components of the pump include a titanium inflow cannula, a flowmeter, a Dacron outflow graft (Sulzer CarboMedics Inc., Austin, Tex), and a percutaneous cable that connects to a portable control console and battery packs.[92] The inflow cannula is placed in the left ventricular apex, with the outflow graft anastomosed to either the ascending or descending thoracic aorta. Surgical implantation through both a median sternotomy and left thoracotomy have been described.[93] The pump is usually initiated at 7500 rpm and adjusted to maintain average flow rates of between 3.9 and 5.4 L/min. The ultrasonic flow probe on the outflow graft facilitates pump speed adjustment as well as providing an indication of excessive ventricular suctioning. Patients do require systemic anticoagulation with warfarin to maintain an International Normalized Ratio of 2.0 to 2.5.

The MicroMed DeBakey VAD has been implanted in over 300 patients worldwide. Long-term support of over 200 days in 9 patients has been reported.[94] The results of a preliminary clinical trial in 30 patients demonstrated a bridge-to-transplantation rate of 67%. Bleeding was the most commonly observed adverse event, likely related to the need for systemic anticoagulation.[92,95] The portability of the device has allowed patients to rehabilitate at home while awaiting transplant. The device is presently in ongoing clinical trials.

JARVIK 2000: The Jarvik 2000 (Jarvik Heart Inc., New York, NY) was developed by Dr. Robert Jarvik in the late 1980s (Fig. 67-8). The electromagnetically actuated pump is constructed of titanium, measures 2.5 cm in diameter, and weighs 90 g. It has a displacement of 25 mL. Titanium impeller blades are held in place by ceramic bearings. The impeller rotates at speeds of between 8000 and 12,000 rpm

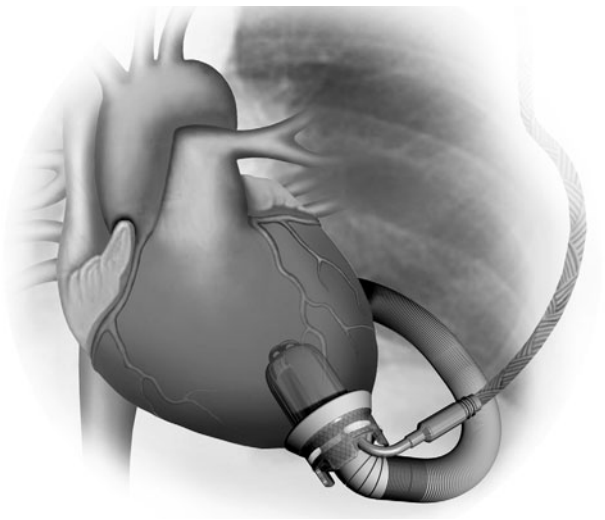

Figure 67-8. The Jarvik 2000 axial flow pump. *(Courtesy of the Texas Heart Institute, used with permission.)*

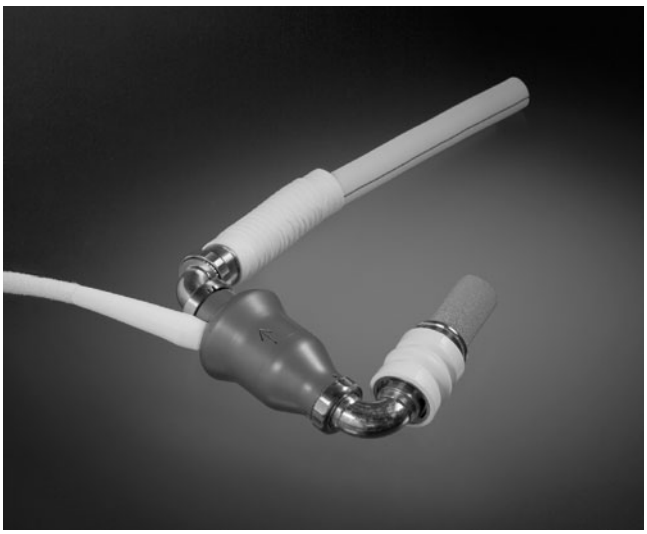

Figure 67-9. The Heartmate II axial flow pump. *(Courtesy of Thoratec Corporation, used with permission.)*

and can generate maximum flows of 7 L/min. A unique feature of this device is that the actual pumping chamber is implanted within the left ventricle. The outflow graft is anastomosed to the descending thoracic aorta. Pump implantation is usually done through a left thoracotomy incision. The pump can be operated via either a fixed-rate analog system or a variable-speed microprocessor-controlled system.[96]

The Jarvik 2000 is available in a few different versions based on the energy systems. There is a percutaneous model, which like other devices has a power line that exits the patient's abdominal wall. There is also a version that is based on skull-mounted pedestals used with cochlear implants, where a titanium pedestal is screwed into the skull with a transcutaneous connector that attaches to the power cord. This vascularity of the skull contributes to a low risk of infection, making this system suitable for long-term support. There is also a completely implantable version that utilizes a transcutaneous energy transfer system.[96]

Siegenthaler and coworkers recently reported on the mechanical reliability of the device. In 102 patients undergoing implantation of the Jarvik 2000 over a 4-year period, there was no implantable component failure. In patients being bridged to transplant, mean support time was 159 days. For destination therapy, mean support time was 551 days, with six patients being supported for >2 years, and the longest being close to 5 years.[97]

HEARTMATE II: The Heartmate II ventricular assist device (Thoratec Corporation, Pleasanton, Calif) is an axial flow device that was developed in the early 1990s through a partnership between the University of Pittsburgh and the Nimbus Company (Fig. 67-9). The device is an axial-flow rotary pump constructed of titanium. The pump can generate flows of up to 10 L/min, and is designed to operate at speeds of between 6000 and 15,000 rpm. Inflow is through the apex of the left ventricle, with an outflow to the ascending aorta. The pump housing is implanted in a small preperitoneal pocket or within the abdominal musculature. A small percutaneous driveline exits the right upper quadrant. The device does require systemic anticoagulation with warfarin. The pump can be operated in both a fixed and an automatic mode.[98]

The device began a multicenter clinic trial in November of 2003. Enrollment in the trial has recently been completed. Pagani and colleagues reported on the initial results of this trial in early 2005. Twenty-three patients underwent implantation, with an increase in mean cardiac index from 2.0 ± 0.5 L/min/m^2 to 3.4 ± 0.5 L/min/m^2 during the first postoperative week. Four patients were successfully bridged to transplant, and 15 patients remained on support, with the longest duration being 318 days.[99]

Totally implantable devices

ARROW LIONHEART LVD-2000: The Arrow LionHeart LVD-2000 (Arrow International, Reading, PA) is a totally implantable pulsatile ventricular assist device designed with the goal of destination therapy for patients in end-stage heart failure. The implantable components of the device include the actual titanium blood pump with inflow and outflow assemblies, motor controller, a compliance chamber, and a transcutaneous energy transmission system. There are no percutaneous lines or connections. The compliance chamber consists of a circular polymer sac and an attached subcutaneous port infusion system. Recharging of the batteries is accomplished through a transcutaneous system with a wand overlying the recharging coil implanted under the skin. Patients may be completely disconnected from the external power supply for only a short period of time. The pump has a stroke volume of 64 mL and generates pulsatile blood flow of up to 8 L/min using pusher-plate technology. Inflow, as with other pulsatile devices, is achieved through the left ventricular apex, with outflow to the ascending aorta. Tilting disk valves in the inflow and outflow assemblies maintain unidirectional flow.[100]

El-Banayosy and associates reported on the results of implantation in six patients. Mean duration of support was 245 days, with the longest being 670 days. Three patients were discharged home. They found no device-related failures or infections.[101] The Arrow LionHeart VAD recently completed European clinical trials. Presently, a new version of the device is undergoing development that has improved battery life and a smaller controller. It will likely undergo clinical trials in the near future.

Total artificial heart

CARDIOWEST TOTAL ARTIFICIAL HEART: The CardioWest Total Artificial Heart (TAH; SynCardia Systems Inc., Tucson, Ariz) is FDA approved for use as a bridge to transplantation in patients with biventricular failure. The device, formerly the Jarvik-7 and Symbion TAH, is a pneumatically driven biventricular assist device that is implanted orthotopically after excision of the native ventricles and cardiac valves. The internal surfaces of the devices are lined with polyurethane, along with a polyurethane diaphragm that is pneumatically displaced. Unidirectional flow is maintained by Medtronic-Hall mechanical valves in the inflow and outflow conduits (Medtronic, Inc., Minneapolis, Minn). The device has a maximum stroke volume of 70 mL and is capable of generating flows of more than 10 L/min. Adequate intrathoracic space is required for device implantation. Patients usually must have a BSA 1.7 m^2 or greater, a cardiothoracic ratio >0.5, an anteroposterior dimension of at least 10 cm, and combined ventricular volumes of >1.5 L. The device does require both antiplatelet therapy and systemic anticoagulation with warfarin. The two pneumatic drivelines, which exit the skin, are connected to a large console controller that limits patient mobility and prevents discharge from the hospital. A more portable controller system is currently under development and has been used in Europe.[9,102–104]

Copeland and coworkers reported the results of a multicenter trial of the TAH as a bridge to transplantation. In 81 patients undergoing implantation of the device, survival to transplant was 79%. One-year survival following device implantation was 70%. The mean time from implantation to either transplantation or death was 79.1 days. Posttransplant survival at 1 and 5 years in patients being bridged with the TAH was comparable to historical United Network for Organ Sharing controls.[102]

ABIOCOR IMPLANTABLE REPLACEMENT HEART: The AbioCor system (Abiomed Cardiovascular Inc., Danvers, Mass) is a totally implantable artificial heart without any percutaneous lines (Fig. 67-10). It is designed for destination therapy. The implantable components of the device are the AbioCor thoracic pumping unit, controller, battery, and transcutaneous energy transfer system. The device is implanted orthotopically once the native heart has been excised, leaving behind atrial cuffs. The two polyurethane pumping chambers have a stroke volume of 60 mL and are capable of providing a cardiac output of up to 8 L/min. A centrifugal pump functions to pressurize a low-viscosity hydraulic fluid, which with a switching valve provides alternating left- and right-sided systole. An atrial flow-balancing chamber is used to adjust for differences in right and left atrial pressures. All blood-contacting surfaces, including the valves of the device, are made of smooth polyurethane. Patients are maintained on systemic anticoagulation with warfarin and antiplatelet therapy with clopidogrel.[105]

Figure 67-10. The AbioCor implantable replacement heart. *(Courtesy of Abiomed, Inc., used with permission.)*

After extensive animal testing at the University of Louisville and the Texas Heart Institute in the late 1990s, the FDA granted approval for a multicenter clinic trial in 2001. Since the device is intended for use as destination therapy, patients in the clinic trial were not transplant eligible. Dowling and associates recently reported the initial clinical experience with the system in seven patients. There were no significant device malfunctions or device-related infections. Thromboembolic complications were seen to result from clot formation on the atrial cage struts, which have been removed for future implants. Three patients were able to make multiple trips outside the hospital, and two patients were discharged. The multicenter clinical trial is presently ongoing.[106]

Newer-generation and future devices

There are presently over 20 new devices either in development or in investigational use. Newer-generation devices try to address the shortcomings of current device technology such as thromboembolic complications, device-related infection, and limited durability. Many third-generation devices make use of magnetic levitation technology, in which a rotating impeller is magnetically suspended within a column of blood, obviating the need for contact-bearing moving parts, providing the theoretical advantage of enhanced durability. Continuous flow pumps are also smaller in size, allowing easier implantation with less surgical trauma, and potentially decreased infectious complications. Advances in

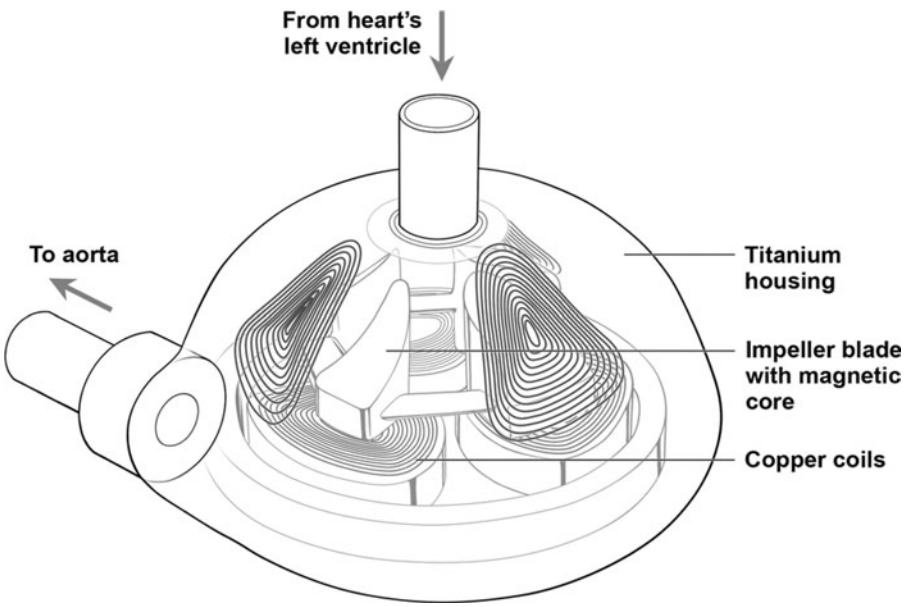

Figure 67-11. The VentrAssist left ventricular assist system. *(Courtesy of Ventracor, used with permission.)*

energy systems have allowed for totally implantable devices without the need for percutaneous lines. Smaller control consoles have afforded greater patient mobility and rehabilitation, as well as allowing patients to be discharged from the hospital. A few of the more recent devices in development and clinical trials will be discussed below.

The Incor left ventricular assist device (Berlin Heart AG, Berlin, Germany) is a magnetically-actuated axial flow pump that weighs 200 g and is 3 cm in diameter. The device's flow is created by an impeller that is held in place by a magnetic bearing. The impeller is not in contact with any other parts and is capable of rotation at 10,000 rpm, producing a flow of up to 7 L/min. Schmid and coworkers reported their initial clinical experience in 15 patients, with 5 patients being successfully bridged to transplant, and one patient being weaned after 171 days of support. Three patients were still supported, and six patients died while on support.[107]

The VentrAssist left ventricular assist system (Ventracor Ltd., Chatswood NSW, Australia) is a centrifugal pump that has a hydrodynamically suspended rotor as its only moving part (Fig. 67-11). The design of the pump maximizes blood flow across all blood-contacting surfaces to avoid stasis and the potential for thrombus formation. The pump weighs about 300 g and measure 2.5 inches in diameter. The device will likely be in clinical trials soon.[108]

WorldHeart (World Heart Corp., Oakland, Calif) has two newer-generation LVADs in development and preclinical testing. The Novacor II is designed to be a totally implantable pump that utilizes pusher plate technology with magnetic actuation to provide pulsatile flow. The WorldHeart rotary ventricular assist device is a magnetically levitated centrifugal pump designed for destination therapy.[109]

Thoratec (Thoratec Corp., Pleasanton, Calif) also is in the process of preclinical evaluation of the Heartmate III. This device is a magnetically suspended centrifugal pump that also uses transcutaneous energy transfer system technology to be totally implantable.[84] Other devices employing magnetic levitation technology include the Terumo DuraHeart (Terumo Heart Inc., Ann Arbor, Mich) and the CorAide blood pump (The Cleveland Clinic Foundation, Cleveland, Ohio).[110]

SURGICAL TECHNIQUE

There are many variations in surgical techniques for left ventricular assist device implantation. In general terms, however, there are a few common steps in the techniques of device implantation. These are (1) mediastinal exposure and creation of the device pocket; (2) outflow graft construction to the ascending aorta; (3) placement of device inflow, usually from the left ventricular apex; (4) de-airing of the device; and (5) device actuation and weaning from cardiopulmonary bypass support. Preoperative preparation includes appropriate correction of coagulopathy with blood product transfusion and vitamin K administration. Preoperative antibiotic prophylaxis covering both gram-positive and gram-negative bacteria is administered and usually continued for 48 to 72 hours postoperatively. Serine protease inhibitors (e.g., aprotinin) are administered prior to skin incision and continued in the perioperative period until mediastinal bleeding has subsided.[111]

A vertical midline incision is made with extension into the abdomen. After standard median sternotomy, a preperitoneal pocket is created in the left upper quadrant.[112] Often the preperitoneal plane is very thin and attenuated, so the posterior rectus sheath is entered and the plane developed. After systemic heparinization, the patient is cannulated for cardiopulmonary bypass. Venous cannulation can be achieved with either a single dual-stage cannula placed in the right atrium, or with standard bicaval cannulation if concomitant procedures are being performed (i.e., tricuspid

valve repair or closure of a patent foramen ovale). Our preference is to cannulate the superior vena cava with a large 31F metal tip right-angle cannula directed into the right atrium. This provides excellent venous drainage while allowing for easy conversion to bicaval cannulation if necessary. The ascending aorta is cannulated distally with consideration for future reoperation for cardiac transplantation.

An effort is made to minimize cardiopulmonary bypass times in this ill group of patients. After cannulation, the device is brought onto the field and positioned in the preperitoneal pocket. The driveline is tunneled percutaneously and brought out of the skin through a counterincision placed in the right upper quadrant. If the hemodynamic status permits, an attempt is made to perform the outflow graft anastomosis off-pump using a partial occluding clamp placed on the ascending aorta. The outflow graft is measured and cut with enough length to allow for a gentle curvature toward the right chest without redundancy that may lead to outflow graft kinking. A longitudinal aortotomy is created and the anastomosis performed using continuous 4-0 polypropylene suture. The anastomosis is reinforced with BioGlue (CryoLife Inc., Kennesaw, Ga).

Cardiopulmonary bypass is initiated and attention is turned to the placement of the left ventricular apical inflow cannula. This is usually done under conditions of normothermia with a beating heart. The presence of left ventricular thrombus may necessitate cardioplegic arrest to prevent systemic embolization. A specialized coring knife is used to create the apical core. Care must be taken to correctly identify the apex of the left ventricle and avoid deviation into the septum. After coring of the apex, care is taken to ensure a clear inflow tract. Any excess trabeculations or myocardium that may impinge on the inflow cannula are excised. Ventricular thrombus is carefully removed. Sutures of 2-0 braided polypropylene reinforced with felt pledgets are then placed around the circumference of the core in a horizontal mattress fashion and passed through the sewing ring of the inflow cuff. The cuff is secured and then attached to the inflow cannula of the device. The heart is allowed to fill with blood and the device is de-aired through a venting hole placed in the outflow graft. Evacuation of air is confirmed with transesophageal echocardiography. The patient is then weaned from cardiopulmonary bypass simultaneously with initiation of the device. After ensuring adequate hemostasis, drains are placed in the mediastinum, pleural spaces, and device pocket. A Gore-tex pericardial membrane (Gore Medical Products, Flagstaff, Ariz) is placed over the anterior mediastinal structures and secured to the pericardial edges to minimize the risk of injury during reoperative median sternotomy. The sternum and soft tissues are then closed in the standard fashion. Particular attention is given to secure abdominal fascial closure to prevent wound dehiscence and subsequent device infection. In certain patients in whom excessive mediastinal bleeding is encountered secondary to coagulopathy, our preference is to pack the mediastinum and perform delayed sternal closure after approximately 24 hours, once bleeding has subsided and the patient has been adequately resuscitated.

POSTOPERATIVE MANAGEMENT

Meticulous postoperative care is critical to successful outcomes in patients undergoing mechanical device implantation. In the immediate perioperative period, proper device function must be ensured to restore and maintain adequate end-organ perfusion. Inadequate device flows may be the result of mechanical problems such as inflow cannula obstruction or malposition, outflow graft kinking, or cardiac tamponade. Phosphodiesterase inhibitors and inhaled nitric oxide are used liberally to support and optimize right ventricular function.[113] Arginine vasopressin has been shown to be effective in treating vasodilatory hypotension in this group of patients.[114] Excessive afterload, particularly with axial flow devices, may impair pump outflow and should be treated accordingly.

Antibiotic prophylaxis is begun preoperatively and is usually continued for 48 to 72 hours postoperatively. The serine protease inhibitor aprotinin is also initiated prior to incision and continued postoperatively until mediastinal bleeding has subsided.[111] Blood product transfusion with platelets, fresh frozen plasma, and cryoprecipitate is given as needed. Once bleeding has subsided, usually by 24 to 36 hours, aspirin and systemic anticoagulation with heparin and warfarin is initiated, depending on the particular device used. Patients are weaned from mechanical ventilatory support as soon as is feasible. Diuretics are administered early in the postoperative course, since many of these patients are in a chronic volume-overloaded state. Perioperative renal insufficiency is usually managed with the early institution of continuous venovenous hemofiltration for optimization of fluid balance. Enteral feedings are resumed early in the postoperative course. Once patients are extubated, attention is focused to physical therapy and rehabilitiation.[115]

COMPLICATIONS

Bleeding

Mediastinal bleeding following left ventricular assist device implantation is relatively common, occurring in some series in as many as 48% of patients.[41,116] This generally requires reoperation early in the postoperative period. Predisposing factors include hepatic congestion and dysfunction related to chronic heart failure, compromised nutritional status, the use of preoperative anticoagulation, extensive surgical dissection, reoperative procedures, prolonged cardiopulmonary bypass, and coagulopathy secondary to interactions between circulating blood elements and the artificial device surfaces.[117]

Due to the requirement of systemic anticoagulation for many devices, as well as the routine use of aspirin as an anti-inflammatory agent, late bleeding and tamponade can occur as well. A high index of suspicion must be maintained in patients with decreased pump flow rates unresponsive to fluid challenge, elevated filling pressures, respiratory distress, or signs of end-organ dysfunction.[118]

The serine protease inhibitor aprotinin has been shown to be of benefit in patients undergoing device implantation. Goldstein and associates reported the retrospective results of 42 patients receiving aprotinin during device implantation compared to a control group of 100 patients. Patients receiving aprotinin had a significant decrease in postoperative blood loss, decreased transfusion requirement, and nearly a 50% reduction in the need for right ventricular assist device placement. Overall perioperative mortality was also reduced in the aprotinin group as well.[111]

Infection

Infection remains a significant source of morbidity and mortality in patients receiving mechanical circulatory support. In the REMATCH trial, the leading cause of death in patients receiving devices was sepsis, accounting for 20 of 52 deaths in this group.[10] A subsequent analysis focusing on infection during the REMATCH trial showed that freedom from sepsis in patients with LVADs was 58% at 1 year and 48% at 2 years. The peak hazard for sepsis occurred early, within 30 days from implantation.[119]

Infections in LVAD patients can affect different components of the device and can vary in severity. These include infections at the driveline exit site, device pocket infections, device endocarditis, and bloodstream infection.[120] Patients can also develop infectious complications at sites remote from the device such as in the respiratory, gastrointestinal, or genitourinary tracts, as well as from indwelling intravenous and central lines. Other patient factors that may increase susceptibility to infection include generalized debilitation and malnutrition, diabetes, renal failure, and immunologic derangements associated with T-cell death seen after device implantation.[121]

A wide range of infection rates has been reported in the literature, partly due to varying definitions of device infections.[41,116] Overall infection rates in patients receiving devices at all sites have been approximately 50%.[120,122] Up to 25% of deaths in LVAD patients are due to systemic sepsis, which occurs in 11 to 26% of patients.[123,124] Bacteria that are able to form a biofilm are common pathogens, including *Staphylococcus*, *Pseudomonas*, *Enterococcus*, and *Candida*.[123,125] While some patients can be treated conservatively with antibiotic-suppressive therapy, others may need surgical drainage of abscesses or fluid collections, débridement, or device exchange. In some cases, the only therapeutic option is device removal and transplantation. Fortunately, device-related infections do not seem to have an adverse impact on transplant outcomes.[126]

Thromboembolism

Thromboembolic events can lead to devastating neurologic and end-organ injury and remain a significant concern in patients undergoing mechanical device placement. Approximately one-third of patients having an LVAD will suffer from such an event.[12] In the REMATCH trial, the rate of neurologic events was 4.35 times higher than in the medically treated group, with 47% of such events being transient.[10] Difficulty in accurately comparing the incidence of thromboembolism among different devices is partly due to inconsistent definitions, as described by Pasque and Rogers.[77] The Heartmate XVE, with its sintered titanium and textured polyurethane internal surfaces, has a relatively low incidence of thromboembolic events without the need for systemic anticoagulation with heparin or warfarin. All device patients are maintained on aspirin, mainly for its anti-inflammatory effect. Most devices presently require anticoagulation with heparin and warfarin to maintain an International Normalized Ratio between 2.5 and 3.5. In addition, depending on the system used, many patients are maintained on antiplatelet therapy with dipyridamole and clopidogrel. Vigilant control of anticoagulation parameters is necessary to balance the risk of thrombus formation with the threat of late mediastinal bleeding.

Right-Sided Heart Failure

Approximately 20% of patients undergoing left ventricular assist device placement will suffer from postoperative right heart failure.[41,127] A recent series from Columbia University examined the incidence of right heart failure in patients with chronic congestive heart failure undergoing LVAD implantation.[128] In 108 patients, right-sided circulatory failure was seen in 42 patients (38.9%), with 14 patients requiring implantation of a right ventricular assist device. Postoperative right ventricular failure has a significant effect on clinical outcomes, leading to increased intensive care unit length of stay, increased 30-day mortality following LVAD implantation, and a lower bridge-to-transplantation rate.[113,128,129]

Right-sided circulatory failure can result from abnormalities both in the right ventricle as well as in the pulmonary vascular bed. Perioperative factors include myocardial stunning, ischemia, infarction, air embolism, and arrhythmias. Changes in ventricular interdependence and septal shifting secondary to mechanical unloading of the left ventricle as described by Santamore and associates can also contribute to impaired right-sided function.[130] In addition, pre-existing right ventricular dysfunction may be unmasked secondary to the augmented preload presented to the right side following LVAD implantation.[113]

Predicting which patients will manifest right-sided failure can be difficult. Several authors have described preoperative risk factors for the development of right ventricular failure. Ochiai and coworkers,[131] in an analysis of 245 patients undergoing LVAD placement, found preoperative circulatory support, female gender, and nonischemic etiology for heart failure as risks for postoperative right ventricular failure requiring right VAD placement. In addition, hemodynamic parameters associated with right VAD use were low mean and diastolic pulmonary arterial pressures, low right ventricular stroke work, and low right ventricular stroke work index, most likely identifying patients with impaired right ventricular contractility. Elevated pulmonary vascular resistance and pulmonary arterial pressures were

not identified as risk factors.[131] Similar findings have been previously reported.[132]

Clinically, the onset of right ventricular failure can be sudden and may occur at the onset of LVAD device initiation. Right-sided failure results in elevations in central venous pressure and impaired filling of the left side, with low device flows and ultimately compromised systemic perfusion. Improvements in medical management of right ventricular failure have resulted in a decreased incidence of right VAD implantation.[133,134] This includes the use of phosphodiesterase inhibitors, inhaled nitric oxide, and aggressive inotropic support of the right ventricle. Blood product transfusion has been shown to have adverse effects on pulmonary vascular resistance.[135] The use of aprotinin has been shown to decrease blood loss, the incidence of right VAD implantation, and perioperative mortality in patients undergoing LVAD placement.[111] When right VAD support is necessary, improved clinical results have been demonstrated by early implantation within 24 hours.[129]

Multisystem Organ Failure

The onset of multisystem organ failure carries a high mortality in patients undergoing device placement, accounting for almost one-third of patient deaths in some series.[124] Patients undergoing VAD implantation have a high incidence of comorbidities, and many manifest significant end-organ dysfunction preoperatively. Some may not recover organ function following device implantation. Other patients may manifest multisystem organ failure as the end result of complications related to device implantation. These include surgical trauma, prolonged cardiopulmonary bypass times, perioperative bleeding, and sepsis.

Device Failure

Device failure is an ever-present concern in patients with mechanical circulatory assistance. Device durability and freedom from device failure are critical factors in establishing mechanical support as a feasible option for providing long-term support and destination therapy. In the REMATCH trial, device failure was the second most common cause of death, after sepsis.[10] While 1-year freedom from device failure and replacement was 87%, this dropped off to 37% by the second year.[10,136] Device failure can occur in any of the components of the system. These include the inflow and outflow conduits, the pumping chamber, or the external components of the system such as the driveline, power source, or controller units. Depending on the mode of failure, urgent reoperation and device replacement may be required. In the event of device failure, some systems have backup support. For instance, in the setting of electrical failure, the Heartmate LVAD can be driven by a pneumatic console. Some newer-generation continuous flow devices, however, lack this provision. In the event of device malfunction, the patients are dependent on their native ventricular function.

Cardiac catheterization as well as transesophageal echocardiography have both been described as useful tools for the diagnosis of device malfunction.[137,138] As clinical experience with individual devices accumulates, modes of failure that are amenable to design change become apparent, allowing for device modification and improvement. Design alterations during and since the conclusion of the REMATCH trial in the Heartmate LVAD include a bend relief to prevent outflow graft kinking, modifications in the inflow assembly to facilitate valve replacement, and smaller size and greater compliance of the percutaneous driveline. Modifications in the controller software allow limitation of pump pressures, thereby reducing stress on bearings, the diaphragm, and the inflow valve.[136] Newer-generation axial and centrifugal flow pumps attempt to address the shortcomings of first-generation devices with smaller pumping chambers and drivelines, transcutaneous energy sources, and the use of magnetic levitation technology to eliminate contact-bearing moving parts, offering the hope of enhanced durability.

Immunologic Effects and Allosensitization

The interaction between prosthetic device surfaces and circulating blood elements has systemic immunologic effects in patients undergoing device implantation. Itescu and John have described the specific cellular changes that occur.[139] First, a number of alterations are seen in T-cell function. These include aberrant T-cell activation and heightened T-cell proliferation, as well as increased apoptotic cell death, and simultaneous defects in T-cell proliferation in response to T-cell–receptor activation. In addition, T cells in LVAD patients demonstrated increased susceptibility to activation-induced cell death. Another aspect of immunologic disturbance that is seen is B-cell hyperreactivity. Alterations in circulating cytokines and cellular milieu are postulated to be responsible for polyclonal B-cell activation. Patients undergoing LVAD placement have a higher frequency of circulating antiphospholipid and anti–human leukocyte antigen antibodies.[121,139]

The overall clinical effect of these changes is twofold. First, patients demonstrate progressive defects in cellular immunity, with a resultant increased risk of infection. Second, B-cell hyperreactivity ultimately leads to allosensitization to human leukocyte antigens. In analysis of a series of 105 patients at Columbia University undergoing cardiac transplantation after being bridged with an LVAD, 66% were sensitized prior to transplant, as opposed to only 6% of non-bridged patients.[140] Untreated allosensitization is associated with prolonged pretransplant waiting times, as well as an increased risk of acute rejection.[140] When sensitization develops, immunomodulation with intravenous immunoglobulin therapy in conjunction with cyclophosphamide has proven to be effective in reducing alloreactivity, and reducing the risk of acute rejection.[139,140]

CLINICAL RESULTS

With limitations in donor availability and prolonged transplant waiting times, mechanical circulatory support has

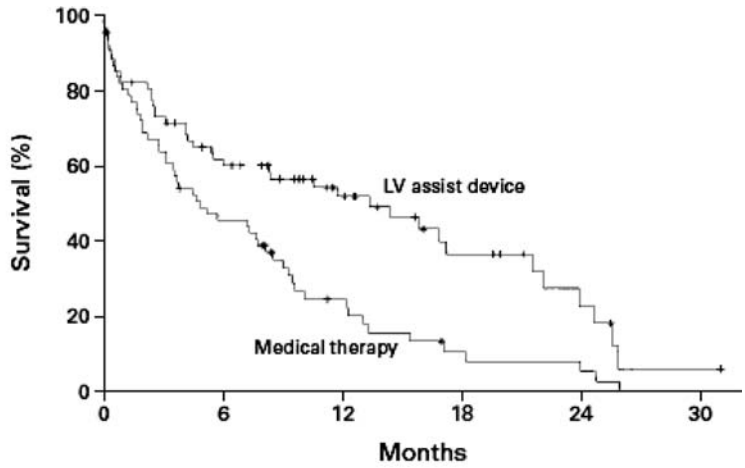

Figure 67-12. Comparison of actuarial survival curves from the REMATCH trial. *(Reproduced with permission from Rose et al.[10])*

emerged as an important tool for both bridging to transplantation and destination therapy, as well as offering a small subset of patients the chance for myocardial recovery.

The multicenter REMATCH trial enrolled 129 patients in end-stage heart failure who were not eligible for transplantation. Patients were randomized to receive either an LVAD (Heartmate VE) or optimal medical therapy. The primary endpoint was death from any cause, with several secondary endpoints such as the incidence of adverse events, days of hospitalization, quality of life, and functional status. When compared to the medically treated group, patients receiving an LVAD had a 48% reduction in the risk of death from any cause (Fig. 67-12). In addition, various quality-of-life and functional status measurements were higher in patients receiving mechanical circulatory support. The limitations of device therapy, however, were highlighted by the increased number of adverse events in the LVAD group. Device patients were more than twice as likely to have an adverse event compared to the medically treated group. The probability of device-related infection was 28% within 3 months after implantation, with the leading cause of death being sepsis. The probability of device failure was 35% at 24 months and represented the second most common cause of death in this group. There was also a significant incidence of bleeding, occurring in 42% of patients by 6 months.[10] Since the conclusion of REMATCH, further analysis of the data by "era" has demonstrated improved survival in device patients enrolled during the second half of the trial.[141] Similar improvements in results for destination therapy have been reported in other series after the REMATCH trial.[142] This is likely a reflection of design enhancements to the device and improvements in patient management. Thus, the REMATCH trial established LVAD therapy as a feasible option for long-term support of patients in end-stage heart failure.

In 2002, the International Society for Heart and Lung Transplantation (ISHLT) began the ISHLT Mechanical Circulatory Support Device database. This voluntary database has collected information on mechanical circulatory support from 60 centers globally. The most recent third annual report in 2005 represents data from 655 patients.[143] The vast majority of patients underwent isolated LVAD placement, approximately 90% of which were pulsatile flow devices. Overall survival was 83% at 1 month and 50% at 1 year. Risk factors for mortality included advanced age and the need for biventricular support. With regard to intent of treatment, 78.3% of patients had device placement as a bridge to transplantation, 12% as destination therapy, and 5.3% as a bridge to recovery. Common adverse events included infection (32.5%), bleeding (27.8%), arrhythmia (24.2%), and renal dysfunction (20.6%). Bridge to transplantation was stratified by age, with 75% of patients <30 years of age transplanted by 1 year. In this group, there was a 13% mortality while on device support. For patients older than 50 years of age, 50% of patients were successfully transplanted, but mortality was considerably higher at 40% while on mechanical support.

Morgan and associates recently reported the bridging-to-transplantation experience at Columbia Presbyterian Hospital.[144] This series of 243 patients spanned a period of 12 years and included three versions of the Thoratec Heartmate device (pneumatic, dual-lead vented electrical, and single-lead vented electrical). Over this time period, improvements were seen in rates of successful bridge to transplantation and in 1-, 3-, and 5-year survival following transplant. The authors attribute this improvement to a combination of factors, including advances in device design, patient selection, surgical technique, and perioperative patient management.

CONCLUSIONS

Mechanical circulatory support has emerged as an important therapeutic option in the treatment of both acute and

chronic heart failure of various etiologies.[145] Active areas of investigation include the effects of mechanical unloading on ventricular remodeling, as well as the potential use of device support in conjunction with other modalities such as gene therapy, pharmacotherapy, and stem cell implantation to promote myocardial recovery. At present, bridge to recovery represents only a small percentage of patients undergoing device placement.[146,147] Limitations of current device technology have fueled intensive research and development efforts to create new devices that offer the hope of improved durability, decreased thromboembolic and infectious complications, and improved quality of life. Decreasing physical size and improved versatility of devices will have important implications for treatment in the pediatric population.[148] Outcomes will likely continue to improve with growing clinical experience and technological advancement.

CHAPTER 68

Total Artificial Heart

O.H. Frazier • Timothy J. Myers • Igor Gregoric

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality in the United States and a significant public health problem in most industrialized nations. Since 1900, it has been the leading cause of death in the United States every year except 1918.[1] In 2002, CVD afflicted 70 million Americans and caused 927,448 deaths. Meanwhile, the number of people with CVD, and especially its advanced forms, has been increasing. There are two main reasons for this. First, while there is still no cure for CVD, palliative therapy has improved to the point that more people are surviving past their initial episodes of CVD to live on with some form of the disease. Second, the average age of the U.S. population is rising as the "baby boom" generation ages.

An increasingly prevalent form of advanced CVD is congestive heart failure (CHF). Almost 4.9 million Americans (approximately 2.4 million men and 2.5 million women) are living with CHF.[1] Its etiology can be ischemic, idiopathic, or viral. More than $36 billion is spent each year on the care of CHF patients, and many therapeutic advances have been made. Nevertheless, between 1979 and 1999 the incidence of CHF increased by 145%. Each year, CHF directly causes 30,000 to 40,000 deaths and indirectly causes another 250,000. As large as the problem is now, its magnitude is expected to worsen as more cardiac patients are able to survive and live longer with their disease and thus increase their chances of developing end-stage CHF.

At present, treatment of advanced CHF takes three forms: medical therapy, surgical therapy, and cardiac replacement.[2] Medical therapy (e.g., intravenous inotropes and vasodilators) relieves symptoms by reducing cardiac work and increasing myocardial contractility. However, while advances in medical therapy have helped improve quality of life for those with heart failure, mortality remains unaffected. Surgical therapy (e.g., revascularization and valve replacement or repair) relieves symptoms of ischemia and valvular dysfunction, but in most cases does not stop the underlying disease process from progressing. When conventional medical and surgical therapies for CHF are exhausted, cardiac replacement (i.e., heart transplantation or implantation of an artificial heart or ventricular assist device) may in some cases become the only therapeutic alternative.

Heart transplantation has evolved into a suitable treatment for advanced CHF. However, it has severe limitations related to patient selection, organ procurement and distribution, and cost-effectiveness. Just over 2000 patients with end-stage heart failure receive heart transplants each year in the United States. However, about 3000 patients are on the active heart transplant waiting list at any given time, and as many as 40,000 more are potential candidates for heart transplantation.[3,4] Heart transplantation for the relatively young (<40 years old) is not very promising because the life expectancy of a donor heart recipient is about 10 years on average and 20 years at most. In 2004, 460 patients on the active waiting list died while awaiting a donor heart. Heart transplantation is also associated with continuous, lifelong, expensive medical therapy.

To help overcome these limitations, engineers and physicians have continued efforts begun over 4 decades ago to develop systems for providing either temporary or permanent mechanical circulatory support (MCS). Originally, such systems were intended to support patients indefinitely because other forms of heart replacement did not appear to be feasible. Temporary MCS has been shown to be a suitable option for some CHF patients who are awaiting heart transplants[5,6] and for others who are not transplant candidates but need support for indefinite periods of time.[7] In recent clinical studies, myocardial function improved sufficiently in some cases to allow removal of the MCS device and avoid heart transplantation.[8,9] Nevertheless, in light of the shortcomings of medical therapy, surgical therapy, and heart transplantation, efforts have continued to develop a total artificial heart (TAH) that would not only save the lives of critically ill CHF patients but also allow them to resume relatively normal lifestyles. Here we review the historical development and current status of TAH technology.

EARLY DEVELOPMENT AND EXPERIENCE

In 1812, LeGallois first proposed the idea of supporting a failing heart with either a permanent or temporary device.[10] In the 1920s, Lindbergh and Carrel discussed and planned an artificial heart.[11] Throughout the 1940s, researchers including Dennis and Gibbon were developing a machine that would bypass the circulation of the heart and lungs to allow open-heart surgery. The modern era of MCS began in 1951 when Dennis first used a heart-lung machine to sustain the circulation while the heart was opened to repair an atrial septal defect.[12] Two years later, Gibbon repeated this procedure.[13] However, high mortality in the first few cases led both Dennis and Gibbon to abandon the use of their heart-lung machines. In 1954, Lillehei began to use cross-circulation (human-to-human perfusion) as a means to support heart and lung function during congenital heart defect repair.[14] However, because of the controversy created by Lillehei's procedure, researchers continued efforts to develop a machine that would allow open-heart surgery.

By 1955, Kirklin at the Mayo Clinic had refined the Mayo-Gibbon machine and the techniques that allowed open-heart surgery.[15] Likewise, DeWall and Lillehei had developed their machine that also allowed for safe open-heart operations.[16] By 1960, Kirklin and Lillehei in Minneapolis and DeBakey and Cooley in Houston had perfected their machines and techniques to the point where heart surgery was becoming routine in Minnesota and Texas. The early developmental work on the use of mechanical circulatory systems by Dennis, Lillehei, DeWall, Gibbon, and Kirklin allowed for many new cardiac operations, including coronary artery bypass, heart transplantation, valve repair, and implantation of a TAH. After refinements of the heart-lung machines, DeBakey and Cooley began to develop many of the surgical techniques that eventually made open-heart surgery routine around the world.

In 1957, Akutsu and Kolff became the first to implant a TAH in vivo.[17] Inserted into the chest of a dog, the pump adequately maintained the circulation for approximately 90 minutes. However, Akutsu and Kolff never applied their TAH technology clinically. In 1964, the National Heart Institute established the Artificial Heart Program to promote the development of the TAH and other cardiac assist devices. In the early 1960s, DeBakey and researchers at Baylor College of Medicine in Houston began developing a TAH. In 1963, DeBakey implanted the first clinical left ventricular assist device (LVAD) into a 42-year-old patient.[18] The pump functioned well, but the patient died of pulmonary complications after 4 days of support. In 1967, DeBakey implanted an LVAD into a 37-year-old patient who presented with symptoms of CHF including easy fatigability and severe dyspnea on slight exertion. This patient also had a history of rheumatic heart disease since age 18 and closed mitral valvulotomy at age 25. The intention was to use the LVAD until sufficient myocardial recovery could be gained. The LVAD supported the patient's circulation for 10 days and was then electively removed. The patient was discharged from the hospital on postoperative day 29 and later resumed normal activity. On follow-up at 18 months after LVAD removal, the patient remained free of CHF symptoms, and a chest x-ray showed a significant reduction in cardiac size.

FIRST TOTAL ARTIFICIAL HEART

The first implantation of a TAH into a human was done by Cooley on April 4, 1969, in a 47-year-old man who could not be weaned from cardiopulmonary bypass (CPB) following left ventricular aneurysmectomy.[19] The intent was to support the patient until a donor heart could be found. The TAH (Fig. 68-1), designed by Liotta, was a pneumatically powered, double-chambered pump with Dacron-lined right and left inflow cuffs and outflow grafts. Wada-Cutter hingeless valves controlled the direction of blood flow through the pump. The TAH itself was connected to a large external power unit, which unfortunately severely restricted patient mobility. The TAH performed adequately for 64 hours until

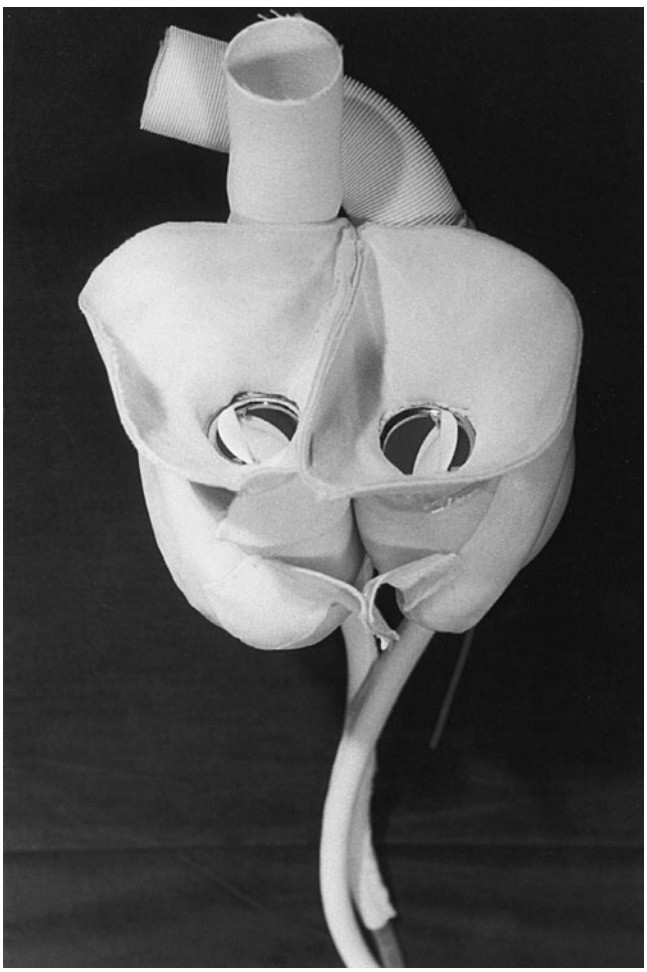

Figure 68-1. The Liotta total artificial heart, the first TAH implanted in a human.

transplantation. The donor heart also functioned well, but the patient died of pseudomonal pneumonia 32 hours after transplantation. Though the Liotta device performed as designed, it was never used clinically again. Nevertheless, this case clearly demonstrated that a TAH could be used safely and effectively in a human as a bridge to transplantation.

AKUTSU-III TOTAL ARTIFICIAL HEART

The second implantation of a TAH in a human was also done by Cooley. On July 23, 1981, Cooley implanted the Akutsu-III TAH into a critically ill 26-year-old man who suffered heart failure after undergoing coronary artery bypass surgery for severe arteriosclerosis. Unable to be weaned from CPB after surgery, the patient was fitted with the TAH in a final effort to sustain his life. The Akutsu-III TAH (Fig. 68-2) consisted of two pneumatically powered, double-chambered pumps featuring reciprocating hemispherical diaphragms.[20] The TAH provided excellent hemodynamics and supported the patient in stable condition for a total of 55 hours until a suitable donor heart was found. The patient finally received a transplant but died of infectious, renal, and pulmonary complications 10 days later. Despite the fatal outcome, this case demonstrated that a TAH could adequately sustain a patient for several days, with no evidence of hemolysis or thromboembolism, until heart transplantation.

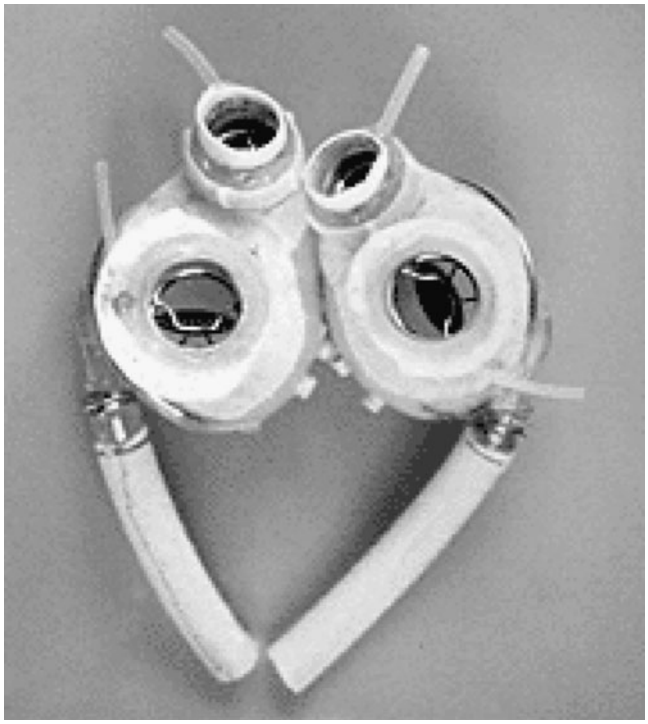

Figure 68-2. The Akutsu-III total artificial heart, the second TAH implanted in a human.

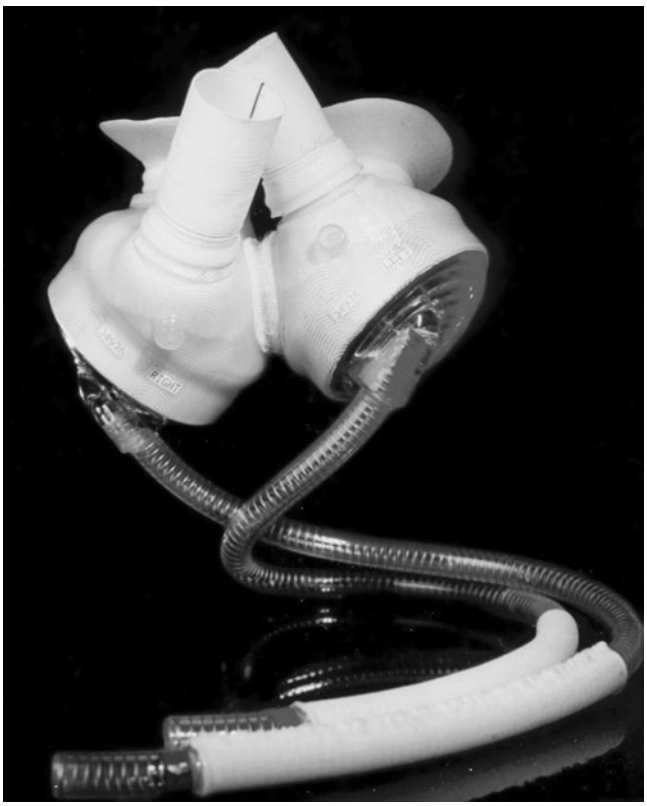

Figure 68-3. The CardioWest total artificial heart (Syncardia Systems, Inc., Tucson, Ariz), formerly the Jarvik-7 and Symbion TAH.

JARVIK-7 TOTAL ARTIFICIAL HEART

In the late 1970s, Kolff and his team at the University of Utah developed the Jarvik-7 TAH. In 1982, DeVries became the first to permanently implant a TAH when he implanted a Jarvik-7 into a dying patient.[21] The Jarvik-7 TAH (Fig. 68-3) was a pneumatically powered, biventricular pulsatile device that replaced the heart.[22,23] The pumps were connected to their respective native atria by synthetic cuffs and connectors. Each pump had chambers for air and blood separated by a smooth, flexible polyurethane diaphragm. The inflow and outflow conduits contained Medtronic-Hall tilting disk valves. The filling of the pumps was aided by vacuum. Pneumatic drivelines, brought out through the chest wall to connect with an external console, shuttled air to the pumps during systole, thereby causing collapse of the pump sac and blood ejection. Pump rate, drive pressure, and systolic duration were monitored and optimized from the external console. The Jarvik-7 had a stroke volume of 70 mL and a normal cardiac output of 6 to 8 L/min (maximum, 15 L/min).

In the initial clinical experience with the Jarvik-7 TAH, a total of five patients were permanently supported for periods ranging from 10 to 620 days. The TAH was able to adequately support circulation, but its large drive console and frequent medical complications limited patient activity. Four

patients were able to make brief trips out of the hospital and to see family and friends. Long-term outcomes, however, were poor. Patients supported by the Jarvik-7 for longer periods suffered several complications including thromboembolism, stroke, infection, and multiorgan failure.

Despite these mixed results, in 1985 the Jarvik-7 (renamed the Symbion) TAH entered clinical trials as a bridge to transplantation. In 1986, Copeland reported the first successful use of this device for this indication.[24] Between 1985 and 1991, approximately 170 patients were supported with the Symbion TAH as a bridge to transplantation.[25] Sixty-six percent underwent successful heart transplantation, a rate similar to those in bridge-to-transplantation studies of left ventricular assist devices. Sepsis and multiple organ failure were the primary causes of death during TAH support.

Although the bridge-to-transplantation study demonstrated that the Jarvik-7 (Symbion) TAH was clinically safe and effective, the U.S. Food and Drug Administration (FDA) withdrew the device's investigational device exemption (IDE) for clinical use in January 1991 because of inadequate compliance with FDA regulations.[26] In January 1993, the investigational device exemption was restored to what was now called the CardioWest TAH, which differed little from the original Jarvik-7. The CardioWest TAH has since been used successfully in the United States, Canada, and France.[27] In a recently completed clinical trial, the survival to transplantation and overall 1-year survival rates were significantly higher for CardioWest recipients (n = 81) than for controls (n = 35) (79% versus 46% and 70% versus 31%, respectively). These results led to market approval of the CardioWest bridge to heart transplantation in 2004.

ABIOCOR TOTAL ARTIFICIAL HEART

On July 2, 2001, as part of an FDA-sponsored phase I clinical trial, surgeons at Jewish Hospital in Louisville, Kentucky, performed the first implantation of the AbioCor TAH in a 59-year-old man suffering from end-stage CHF.[28] The AbioCor totally implantable replacement heart is a self-contained electrohydraulic TAH (Fig. 68-4) that has been developed and tested by ABIOMED, Inc. (Danvers, Mass) and the Texas Heart Institute, with the support of the National Heart,

Figure 68-4. The AbioCor total artificial heart (ABIOMED, Inc., Danvers, Mass).

Table 68–1.

Inclusion and Exclusion Criteria for FDA-Sponsored Phase I Clinical Trial of AbioCor Total Artificial Heart

Inclusion criteria
End-stage heart failure
>70% probability of death within 30 days
Ineligibility for a heart transplant
No other surgical or medical treatment options
Biventricular failure
Exclusion criteria
Significant potential for reversibility of heart failure
Chronic dialysis
Recent cerebrovascular accident
Irreversible liver failure
Blood dyscrasia

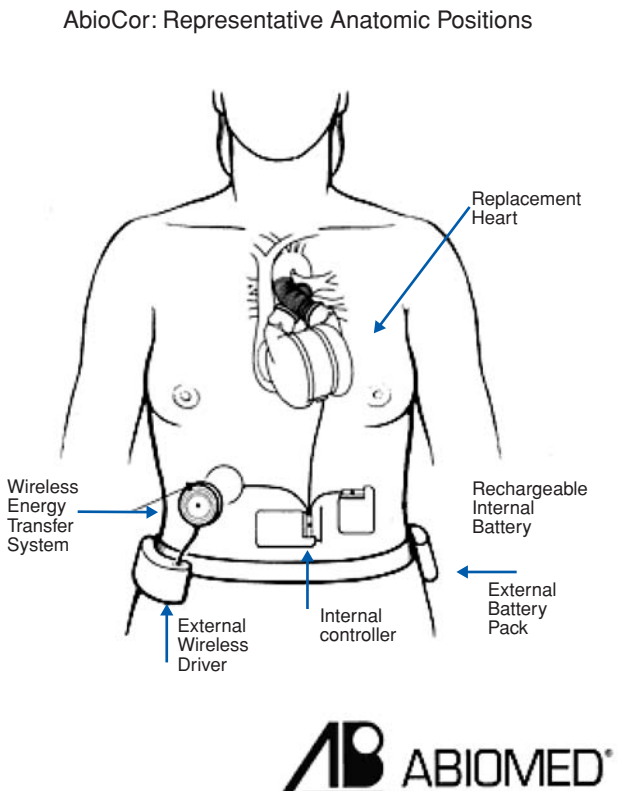

Figure 68-5. The AbioCor system is designed to increase or decrease its pump rate in response to the body's needs. The AbioCor also includes an active monitoring system that provides detailed performance feedback and alarms in the event of irregularities.

Lung, and Blood Institute.[29,30] It is designed to sustain the circulation and extend the lives of patients with end-stage heart failure who have suffered irreversible left and right ventricular failure, for whom surgery or medical therapy is inadequate, and who would otherwise soon die (Table 68-1). The AbioCor is the first TAH to be used clinically that is fully implantable and communicates to external hardware without penetrating the skin. The device utilizes a transcutaneous energy transfer (TET) system and a radiofrequency communication system that allows it to be powered and controlled by signals transmitted across intact skin. A unique feature of the AbioCor is a right-left flow-balancing mechanism that eliminates the need for an external vent or internal compliance chamber.[31]

The internal components of the AbioCor system consist of a thoracic unit, internal TET coil, controller, and battery.[32] The thoracic unit (pump) weighs about 2 pounds and consists of two artificial ventricles, four valves, and an innovative motor-driven hydraulic pumping system (Fig. 68-5). The pump's motor rotates at 6000 to 8000 rpm, which allows sufficient hydraulic fluid pressure to compress the diaphragm around the blood chamber and eject blood. A miniaturized electronics package implanted in the patient's abdomen monitors and controls the pump rate, right-left balance, and motor speed. An internal rechargeable battery, also implanted within the abdomen, provides emergency or back-up power. The internal battery is continually recharged via the TET system and can provide up to 30 minutes of untethered operation.

The AbioCor's external components include a computer console, an external TET coil, and external battery packs. The external computer communicates via the radiofrequency communication system with the abdominally implanted controller, which controls the pump. The external TET coil provides the pump with power from the console or from the external battery packs. The external battery packs can power the AbioCor TAH for 2 to 4 hours.

In the Phase I feasibility trial, 14 patients received the AbioCor as destination therapy (Table 68-2). Thromboembolism was a significant adverse event in this group of patients, and there were two pump failures. However, compared with the known rates of infection for implantable systems with percutaneous drivelines, device-related infections in this trial were relatively rare. The longest surviving patient was supported for 512 days, most of whom lived at home with a good quality of life (Fig. 68-6). A smaller AbioCor TAH is undergoing preclinical testing and is to begin clinical trials in 2006.

COMPLICATIONS

Use of a TAH is associated with serious complications. The most frequent complications are infection, severe postoperative bleeding, and thromboembolism.[33–36] Potentially serious but less frequent complications are renal, hepatic, pulmonary,

Table 68–2.

Summary of Initial Clinical Experience with the AbioCor Total Artificial Heart*

Patient no.	Implantation date	No. of days supported	Age (y)	Institution and city	Outcome
1	July 2, 2001	151	58	Jewish Hospital, Louisville, Ky	Died
2	September 13, 2001	512	70	Jewish Hospital, Louisville, Ky	Died

**As of July 5, 2005.*

and neurologic dysfunction and complications due to technical problems.[33,37] Complicating factors include patient selection, device size, implantation timing and location, the need for extensive surgery at implantation, and the reliability of support equipment.

Life-threatening infections have been the most important complication for patients being supported permanently by a TAH.[38] In the Jarvik-7 experience, all patients supported for many months developed serious infections that eventually contributed to their deaths.[22,39] Patients supported by a TAH for shorter periods while awaiting heart transplantation had infection rates of 30 to 40%.[34–38] During the 1980s, driveline and mediastinal infections in TAH-supported patients were frequent and severe, regardless of the duration of support. However, in the more recent bridge-to-transplantation experience with the CardioWest TAH, the infection rate was no more than 20%.[40,41]

Patients supported with a TAH, regardless of the intended use, are very susceptible to infection. Predisposing factors include the tissue trauma associated with surgical implantation; contamination of the implanted device; depression of the body's immune defenses; the large amount of foreign material present on the surface of the device; and use of the drivelines, tubes, catheters, and other devices that are necessary for the care of these patients. Infections can occur at any point during TAH support. Once an internal component of the TAH system is infectiously colonized, treatment is difficult and often ineffective. Infections are more likely to occur in the early postoperative period, especially in the most critically ill patients, as a result of (1) device

Figure 68-6. The third patient to receive the AbioCor TAH. This patient was supported by the AbioCor for 144 days and underwent physical rehabilitation, but ultimately died of thromboembolic complications.

contamination during the course of care and (2) postoperative bleeding due to intensive care procedures and exposure during reoperation. Meticulous care and numerous infection prevention measures are vital in all TAH patients.

Postoperative bleeding is a frequent and serious complication of TAH implantation. It generally occurs in 40 to 50% of TAH or ventricular assist device recipients.[33] In the more recent CardioWest experience, the rate was approximately 25%. Contributing factors include severe CHF and associated hepatic dysfunction, the extensive surgery and lengthy CPB time required for implantation, and the necessity for postoperative anticoagulation therapy. Severe CHF often leads to hepatic dysfunction and subsequent derangement of the coagulation system. Patients with severe CHF are often receiving continuous preoperative anticoagulant or antiplatelet therapy, the effects of which are often difficult to reverse before TAH implantation. The extensive surgery and lengthy CPB time required for implantation can lead to severe depletion of clotting factors. The necessity for postoperative anticoagulation therapy requires that a proper balance be established between preventing thrombosis and allowing blood to clot, through the careful management of hemostasis and anticoagulant therapy.

Thrombosis within the TAH is of particular concern. Five of the first six Jarvik-7 recipients suffered thromboembolic events. However, the frequency of thromboembolism has decreased significantly since that initial experience and is now an estimated 10 to 15%.[33,34,42] Preventive measures are primarily targeted at precisely monitoring the thrombotic and fibrinolytic systems, maintaining sufficient flow through the device to avoid stasis, and providing adequate anticoagulation and antiplatelet therapy. Generally, heparin and warfarin are used as antithrombotic therapy to achieve a prothrombin time, activated thromboplastin time, or International Normalized Ratio two to three times greater than the baseline or normal value. Aspirin or dipyridamole or both are also used.

There is a complex though poorly understood interrelationship between infection, bleeding, and thromboembolism. Thrombus formation may lead to the development of infection, and bacterial colonization may lead to thrombus formation. Bacteria are often seen in thrombi found in cardiovascular devices.[43] Bacteria embedded in a thrombus are protected from circulating antibiotics and leukocytes. Bacteria, endotoxins, and inflammatory cells may contribute to thrombus formation by their effect on platelet aggregation.[44] Bacterial endotoxins can cause platelet aggregation, endothelial injury, and increased endothelial thromboplastin activity. Excessive bleeding most often results in reoperation, which increases the patient's exposure to contamination. Also, blood transfusions and intravascular monitoring for these critically ill patients are more extensive and result in frequent exposure to the external environment. Infection, bleeding, and thromboembolism can contribute individually and collectively to the development of multiple organ failure, one of the most frequent causes of death in TAH recipients.

Other important problems and issues related to TAH implantation are device malfunction, poor fit or size mismatch between TAH and patient, social and ethical issues, mobility, and nutrition. Device malfunction leading to catastrophic failure of the TAH or ventricular assist device is rare. Most technical issues have involved external components and have been readily resolved. Fit and size mismatch remain a problem. All TAH models used to date have been relatively large and only fit adequately into patients with a body surface area greater than 1.7 m^2. Because the cost of TAH technology is fairly high and most candidates for TAH implantation are in their sixth to seventh decade of life, many groups question whether society should bear the cost of developing this technology. Until recently, the external components of the TAH equipment have been large and cumbersome, thus limiting patient mobility, exercise, and rehabilitation. More recent designs of the TAH allow for much more mobility.

COMMENT

Since the 1950s, when the heart-lung bypass machine was developed, many advances have been made in the surgical treatment of CVD. Many surgical procedures considered impossible just 40 years ago are today considered routine. A

classic example is heart transplantation. However, TAH technology has not evolved at the same pace. Although the first human heart transplantation and first human TAH implantation occurred within 2 years of each other, TAH implantation is still neither routine nor widely available. However, two TAHs are undergoing clinical trials at present in the United States. The CardioWest (formerly the Jarvik-7) TAH, which is the more widely used of the two, is now approved for use as a bridge to transplantation. The AbioCor TAH is still in the early stages of clinical testing and is likely years away from approval as an alternative to heart transplantation. However, should its unique TET system and flow-balancing mechanism prove to be reliable for extended periods of time, the AbioCor may become a widely used alternative to heart transplantation for those patients who have no other treatment options.

There are many obstacles to overcome before any TAH is widely accepted. Infection, bleeding, thromboembolism, and biocompatibility issues are serious problems that affect nearly all implantable cardiovascular devices including TAHs. Improved biomaterials, better prevention, and more effective antibiotic and anticoagulant medications may help overcome these problems. Acceptance by the public, by some critics in the health professions, and by third-party payors may be slow. Quality in manufacturing is needed to ensure reliability of TAH components. Addressing these problems will help bring the TAH more quickly into routine clinical use.

CHAPTER 69

Nontransplant Surgical Options for Heart Failure

Martinus T. Spoor • Steven F. Bolling

Congestive heart failure (CHF) has become a major worldwide public health problem. In our ever-aging population, medical advances that have extended our average life expectancy have also left more people living with chronic cardiac disease than ever before. In the United States alone there are nearly 4.9 million suffering with heart failure, yet of the 500,000 new patients diagnosed each year, less than 3000 are offered transplantation due to limitations of age, comorbid conditions, and donor availability. Despite the significant improvements in medical management, CHF patients are repeatedly readmitted for inpatient care and the vast majority will die within 3 years of diagnosis.[1]

The successful and reproducible long-term results with orthotopic heart transplantation (OHT) have made it the treatment of choice for patients with medically refractory endstage heart failure.[2] Unfortunately, the obvious limitations to OHT include the need for immunosuppression and the severe shortage of donor organs. This past decade has seen the annual number of transplants performed worldwide plateau at less than 4000.[3] This lack of donor availability has thus necessitated that rigorous selection criteria be applied to potential recipients in order to optimize the utility of these precious organs, indicated only for patients with endstage cardiomyopathy in whom all other modes of therapy have been exhausted. Access to OHT has thus been restricted to those without comorbid medical conditions and relatively restricted to those younger than age 65. This leaves the vast majority of CHF patients seeking other options.

Despite the technological strides being made toward total implantability, the role for mechanical support presently remains primarily as a bridge to transplantation or for temporary support. Though there have been a number of clearly successful cases of ventricular assist device (VAD) use as a bridge to recovery, its long-term efficacy for this purpose or its use as a long-term therapy for chronic heart failure remains to be fully evaluated by multicenter clinical trials.[4–9] Though assist device technology may be on the verge of being implemented as a destination therapy for CHF, its current primary indication as a bridge to transplantation results in the restriction of its use to patients fulfilling candidacy for OHT. These confines, and the high cost associated with these devices, have yet to make the VAD an unrestricted surgical solution for the management of most CHF patients.

This clinical dilemma has provided the impetus for surgeons to develop new alternatives for the treatment of heart failure. As OHT and VAD use is more stringently applied, techniques to restore myocardial perfusion, eliminate valvular regurgitation, and restore ventricular geometry have emerged as the first-line surgical approach to heart failure. In response to the growing need for the proficient application and critical appraisal of the expanding menu of surgical options, the new subspecialty of heart failure surgery has emerged. The following will briefly review established nontransplant surgical modalities for heart failure such as coronary revascularization, geometric mitral reconstruction, and geometric ventricular reconstruction. Alternative options such as partial left ventriculectomy and cardiomyoplasty as well as some innovative devices currently being evaluated for clinical application will also be discussed.

CORONARY REVASCULARIZATION

We have known for nearly 20 years that revascularizing patients with left ventricular dysfunction can result in upwards of a 25% improvement in long-term survival.[10,11] Early enthusiasm was tempered by reports of high operative mortality in patients with a low ejection fraction (EF). Since then, as success with the medical and surgical management of heart failure and transplantation grew, so did the interest in applying this experience to patients with ischemic

cardiomyopathy. Successful revascularization can now be performed on patients with an EF less than 30% with hospital mortalities as low as 5%.[12–14]

The premise behind the improvements in EF, long-term survival, and quality of life of these patients following coronary artery bypass grafting (CABG) is believed to be due to postoperative myocyte recruitment. Restoration of perfusion resuscitates dormant viable myocardium and serves to protect the previously functioning portions of the ventricle from further ischemic insults, arrhythmias, and infarction.

In order to minimize morbidity, a multidisciplinary approach to the preoperative management of heart failure is essential. Patients ideally suited for CABG are those who are medically optimized, with or without angina, who have good distal coronary targets, functional hibernating myocardium identified preoperatively, and no evidence of right ventricular dysfunction.[15] As experience in managing these patients increases, many surgeons have operated on patients with ejection fractions less than 10%, those requiring reoperation, and those with moderate elevations in pulmonary artery pressure. Nevertheless, patients with clear documentation of poor right ventricular EF, clinical right-sided congestive symptoms, or fixed pulmonary hypertension above 60 mm Hg systolic should be approached cautiously, because these patients may in fact be better suited for transplantation.

The process of preoperative investigation should coincide with optimizing the patient's medical management. This should entail an aggressive regimen of diuretic and vasodilator therapy to minimize ventricular afterload and normalize the patient's circulating volume. For patients with severe heart failure, a brief period of inotropic therapy for ventricular resuscitation may be necessary to optimize their medical management. Inability to be weaned from this support is often indicative of severe myocardial injury and poor overall prognosis with any surgical therapy other than mechanical ventricular assistance or transplantation.

Preoperative investigations should begin with transthoracic echocardiography to grossly evaluate ventricular function and identify any underlying valvular pathology. Baseline screening physiologic studies of oxygen consumption, pulmonary function, and cardiopulmonary endurance are recommended. Identification of reversible ischemia by means of a nuclear study can be helpful; however, for patients with angina, many centers will proceed directly to coronary angiography. Though angina may be indicative of living ventricular muscle, perhaps the most important correlate of successful surgical recovery is the quantification of myocardial viability. Not only is a determination of myocardial contractile reserve essential to ensure that the patient can be safely separated from cardiopulmonary bypass, this information is predictive of ventricular recovery and long-term survival after operation. Though thallium-201 perfusion scans may distinguish myocytes with membrane integrity from scar, positron emission tomography scanning and dobutamine stress echocardiography permit the preoperative identification of myocardial viability and the prediction of postoperative function.[16–18]

The fundamental premise behind a successful operation is to attain an expeditiously performed and yet complete revascularization. As the failing myocardium is particularly intolerant to further episodes of ischemia, careful consideration should be given to the quality of the distal vessels and the ease with which good anastomoses can be achieved. Operative time expended grafting small or extensively diseased vessels, or performing additional techniques such as endarterectomy, may be counterproductive. Since the price to pay for incomplete revascularization or transient ischemia may be severe, off-pump techniques may not be ideally suited for these patients unless performed flawlessly.

Multiple groups have been uniformly successful in demonstrating improvements in survival, ventricular function, and functional status with coronary revascularization in patients with ischemic cardiomyopathy with ejection fractions less than 25%.[19–21]

The 5-year survival with transplantation ranges from 62 to 82%, whereas with medical therapy alone, it is less than 20%. Most series report survival following CABG for ischemic cardiomyopathy ranging from 85 to 88% at 1 year, 75 to 82% at 2 years, 68 to 80% at 3 years, and 60 to 80% at 5 years. Operative mortality has been reported from 3 to 12%, with the main predictor of increased risk being urgency of operation. When compared to medical therapy, revascularized patients have significant improvements in quality of life. Most series consistently report considerable enhancements in patient mobility, peak oxygen consumption, and functional status. The average preoperative New York Heart Association (NYHA) class of 3.5 reportedly drops to 1.5 after revascularization. Postoperatively, there are substantial reductions in readmissions for CHF and many patients return to work.

It is encouraging to note that the long-term survival of CHF patients following CABG is equivalent to transplantation in many series. The superior survival of CABG over transplant in the first 2 years postoperatively may be due to early attrition from rejection or infection in the latter group. Although there has been little reported on patients with ejection fractions under 10%, from the above data, one could infer that these patients would have a similarly better outcome than their nonrevascularized counterparts. As experience with heart failure surgery expands, refinements in preoperative and operative management of CABG patients will no doubt be reflected in the uniformity of future long-term results.

GEOMETRIC MITRAL RECONSTRUCTION

Functional mitral regurgitation (MR) is a significant complication of endstage cardiomyopathy and it may affect almost all heart failure patients as a preterminal or terminal event. Its presence in these patients is associated with progressive ventricular dilatation, an escalation of CHF symptomatology, and significant reductions in long-term survival, which is estimated to be between only 6 and 24 months.[22]

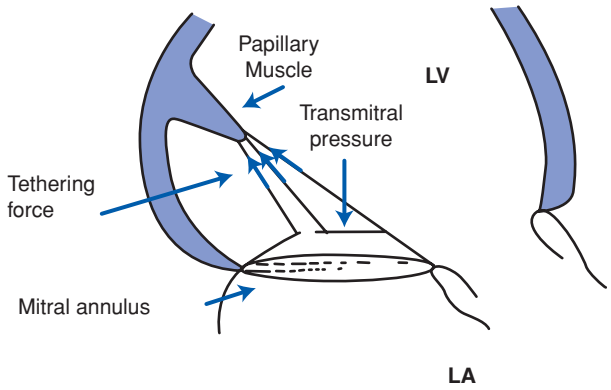

Figure 69-1. Various forces exerted on mitral valve leaflets are provided by the mitral valve apparatus, papillary muscles, and important three-dimensional relationships in the ventricle itself of all of the associated structures. Geometric mitral regurgitation results from a combination of annular dilatation, papillary muscle displacement, increased leaflet tethering forces, and weakened leaflet closing forces.

A firm understanding of the functional anatomy of the mitral valve is fundamental to the management of MR in heart failure. The mitral valve apparatus consists of the annulus, leaflets, chordae tendineae, and papillary muscles, as well as the entire left ventricle. Thus, the maintenance of chordal, annular, and subvalvular continuity is essential for the preservation of mitral geometric relationships and overall ventricular function. As the ventricle fails, the progressive dilatation of the left ventricle gives rise to MR, which begets more MR and further ventricular dilatation (Fig. 69-1). With postinfarction remodeling and lateral wall dysfunction, similar processes combine to result in ischemic mitral regurgitation (Fig. 69-2). Left uncorrected, the end result of progressive MR and global ventricular remodeling is similar regardless of the etiology of cardiomyopathy. Incomplete leaflet coaptation, loss of the zone of coaptation, and regurgitation develop secondary to alterations in the annular-ventricular apparatus and ventricular geometry.[23,24] Thus, reconstruction of this geometric abnormality serves to not only restore valvular competency, but also improve ventricular function.[25–28]

Historically, the surgical approach to MR was mitral valve replacement, yet little was understood of the interdependence of ventricular function and annulus-papillary muscle continuity.[29] Consequently, patients with low EF who underwent mitral valve replacement with removal of the subvalvular apparatus had prohibitively high mortality rates.[30] In an attempt to explain these outcomes, the concept of a beneficial "pop-off" effect of mitral regurgitation was conceived. This idea erroneously proposed that mitral incompetence provided low-pressure relief during systolic ejection from the failing ventricle, and that removal of this effect through mitral replacement was responsible for deterioration of ventricular function. Consequently, mitral valve replacement in patients with heart failure was discouraged. More recent studies documenting the importance of

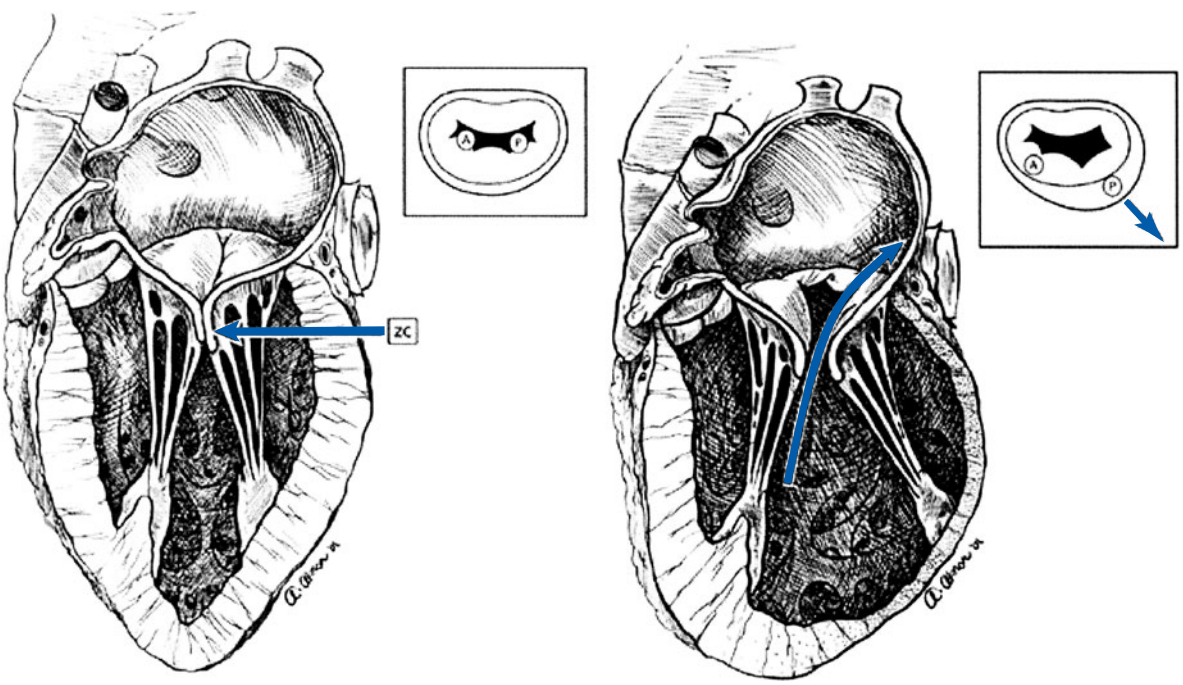

Figure 69-2. In ischemic cardiomyopathy, changes within the left ventricle may be asymmetrical and still lead to functional mitral regurgitation. With ischemic damage and thinning of the ventricular wall, there is lateral tethering, displacement of the papillary muscle, and loss of the zone of coaptation (ZC), resulting in an eccentric jet of mitral regurgitation. This illustrates the concept that ischemic mitral regurgitation results from lateral wall dysfunction that if left untreated, will progress to global left ventricular dysfunction and severe heart failure.

maintaining subvalvular integrity to preserve postoperative left ventricular function have led to surgical techniques that have been applicable to patients with heart failure.[31] Accordingly, preservation of the mitral valve apparatus in mitral surgery has been demonstrated to enhance ventricular geometry, decrease wall stress, and improve systolic and diastolic function.[32] Therefore, maintenance of chordal, annular, and subvalvular continuity is essential for the preservation of optimal mitral geometry and overall ventricular function. Furthermore, preservation of both the leaflet integrity as well as the dynamic function of the mitral apparatus with mitral repair has unmistakable functional benefits.

In treating heart failure patients, the most significant determinant of leaflet coaptation and MR is the diameter of the mitral valve annulus. The left ventricular dimension is of less importance in functional MR, as the lengths of the chordae and papillary muscles are similar in myopathic hearts regardless of the presence of MR. Observations with medically managed patients with severe heart failure and MR reveal that decreasing filling pressure and systemic vascular resistance lead to reductions in the dynamic MR associated with their heart failure.[33] This is attributed to a reduction in mitral orifice area relating to decreased left ventricular volume and decreased annular distention. This complex relationship between mitral annular area and leaflet coaptation may thus explain why an undersized "valvular" repair may help a "ventricular" problem. This restoration of the mitral apparatus and ventricle forms the premise behind geometric mitral reconstruction (GMR) for the treatment of heart failure (Fig. 69-3).

At the University of Michigan from 1992 to 2004, over 289 patients with EF ≤30% received an undersized complete mitral annuloplasty ring as their mitral valve replacement procedure. Of these, 170 patients had a flexible complete ring while the remaining patients received a nonflexible undersized complete ring. In follow-up, 16 flexible ring patients (9.4%) required a repeat procedure for significant recurrent geometric MR and CHF (10 replacements, 3 re-repairs, and 3 transplants). The average time to reoperation was 2.4 years. In contrast, 119 patients with an EF ≤30% received a mitral valve replacement using an undersized nonflexible complete ring. Only 3 nonflexible patients required a repeat operation, 1 a mitral valve replacement and 2 patients required a transplant. The time to reoperation was 4.0 years. There was a significant difference in reoperation rates for recurrent MR between the two groups ($p = 0.012$). There were no differences between groups in terms of age, ring size used, preoperative EF, left ventricular size, MR grade, or NYHA class.[34] All patients were in NYHA class III or IV heart failure despite receiving maximal medical therapy. On immediate postoperative echocardiograms, the mean transmitral gradient was 3 ± 1 mm Hg (range 2 to 6 mm Hg). The overall operative mortality has been under 5%. There have been 27 late deaths: 12 from sudden ventricular arrhythmias, 9 from progression of CHF but without MR, 3 related to complications from other operative procedures, 2 that progressed to transplantation, and 1 suicide. The 1-, 2-, 3-, and 5-year actuarial survivals following GMR are 82%, 71%, 68%, and 57% respectively.

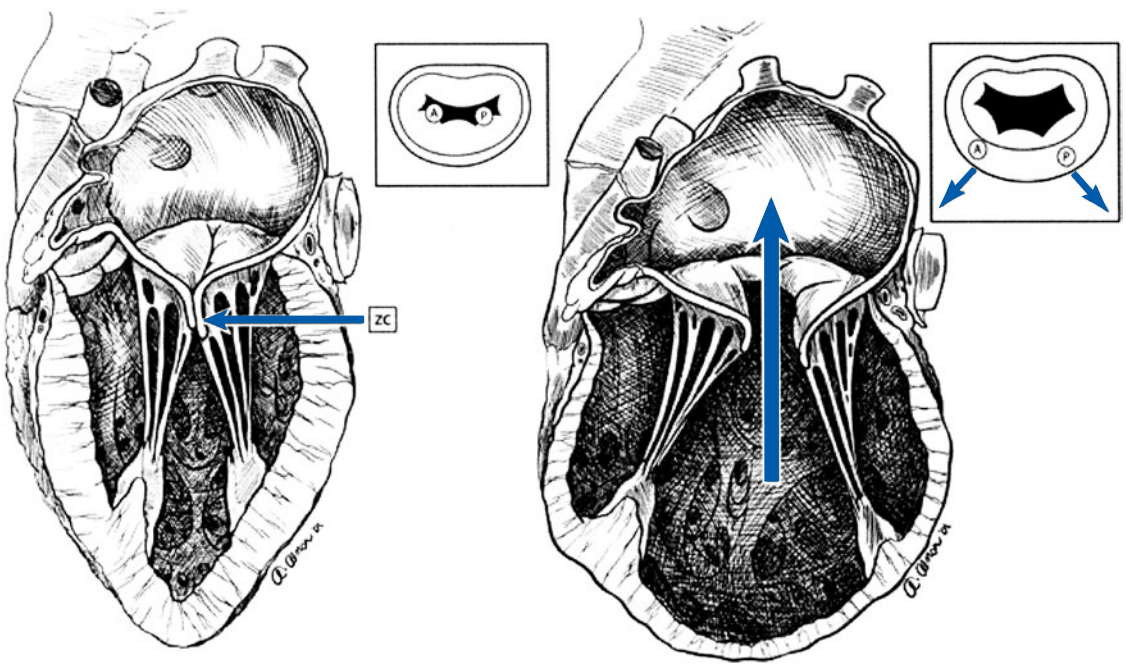

Figure 69-3. In non-ischemic cardiomyopathy note the geometric changes that occur from the normal to the failing left ventricle. With the ventricular and annular dilatation of heart failure, the mitral leaflets cannot adequately cover the enlarged mitral orifice, resulting in the loss of the zone of coaptation (ZC). Geometric mitral regurgitation results from a combination of annular dilatation, papillary muscle displacement, increased leaflet tethering forces, and weakened leaflet closing forces.

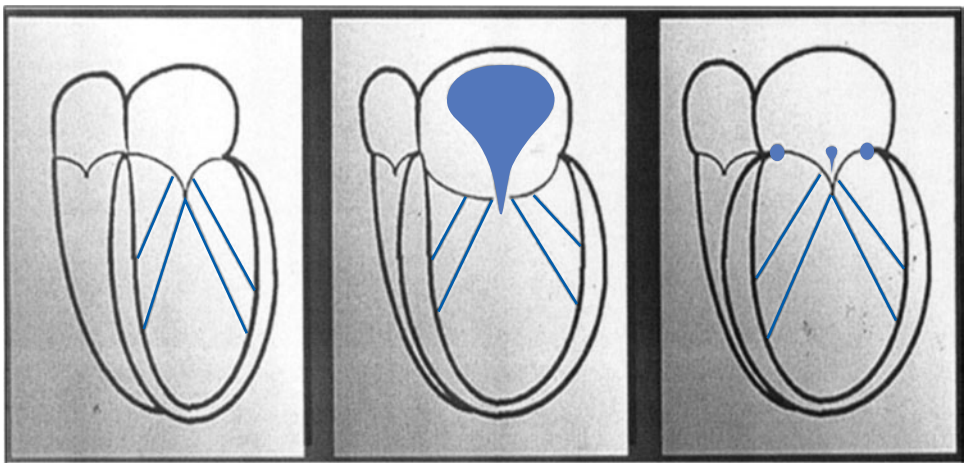

Figure 69-4. Geometric mitral reconstruction for heart failure. Successful augmentation of the zone of coaptation and prevention of recurrent MR can be achieved with placement of an undersized circumferential annuloplasty ring performed with multiple annular sutures. Note the changes in the relationship of the papillary muscles in the left ventricle in the new geometry following mitral repair.

At 24-month assessment, mean EF increased to 26% and all patients were in NYHA class I or II. NYHA symptom scores were reduced from 3.2 ± 0.2 preoperatively to 1.8 1642 ± 0.4 postoperatively. These improvements paralleled subjective functional improvements reported by all patients. Echocardiographically, there were marked improvements in regurgitant fraction, end-diastolic volume, cardiac output, and sphericity index Although significant undersizing of the mitral annulus was employed to overcorrect for the zone of coaptation (Fig. 69-4), no systolic anterior motion of the anterior leaflet or mitral stenosis was noted in these patients.

The technique of undersizing in mitral reconstruction avoids systolic anterior motion in these myopathic patients, likely due to widening of the aorto-mitral angle in these hearts with increased left ventricular size. Furthermore, acute remodeling of the base of the heart with this reparative technique may also reestablish the somewhat normal geometry and ellipsoid shape of the left ventricle. As evidenced by the decreased sphericity index and left ventricular volumes seen in these patients, the geometric restoration from mitral reconstruction not only effectively corrects MR, but also achieves surgical unloading of the ventricle.

Many centers have reported similar consistent findings following GMR.[35–39] With outcomes equating to those of transplant while avoiding immunosuppression, this straightforward reparative operation performed in conjunction with medical management may be offered to all patients with MR and cardiomyopathy as a first-line therapy.

GEOMETRIC VENTRICULAR RECONSTRUCTION

Myocardial revascularization and GMR reliably improve ventricular function. However, further surgical techniques have been developed that attempt to augment left ventricular function through a reduction of end-diastolic wall tension following the principles of the law of Laplace. Since ventricular wall tension is directly proportional to left ventricular radius and pressure and inversely proportional to wall thickness, any intervention to optimize this relationship would be beneficial. As heart failure progresses, so does the progressive thinning and dilatation of the left ventricle, thus leading to increasing wall stress and further dilatation. This remodeling process may result in regional left ventricular dysfunction, as occurs following segmental myocardial infarction, or global left ventricular dysfunction, which may arise from either ischemic or nonischemic etiologies. The concept of reducing wall stress through the surgical restoration of left ventricular cavity size and geometry remains the guiding principle behind many innovative techniques including those developed for the isolation of left ventricular aneurysms and nonfunctioning ventricular segments.

After an acute myocardial infarction, the noncontractile myocardium undergoes thinning and fibrous replacement often following the segmental distribution of the arterial occlusion. This nonfunctional left ventricular segment may remain akinetic or transform into a dyskinetic aneurysm, depending on factors such as age and regional collateral circulation. Though such postinfarct pathologic remodeling may occur in any area of the heart, the most common clinically relevant region that manifests is the anteroapical segment of the left ventricle. The resulting loss of contractile function in the affected segment results in global increases in left ventricular wall tension and myocardial oxygen consumption, in turn leading to compensatory left ventricular dilatation in accordance with the law of Laplace. These geometric ventricular changes may also result in loss of the zone of coaptation and MR following infarction, as discussed earlier. Moreover, when a dyskinetic region expands and becomes aneurysmal, cardiac work is further increased due to the paradoxical systolic motion of the thinned segment. These pathologic alterations often result in CHF. The principle of surgical restoration of left ventricular geometry involves the isolation of these nonfunctional areas and a subsequent reduction in left ventricular volumes. This concept has been clearly

illustrated by Dor and others, who have revealed significant improvement in heart failure after endoventricular patch exclusion of dyskinetic or akinetic ventricular segments.[40–43]

The preoperative selection and preparation for left ventricular reconstruction should follow the identical medical optimization discussed earlier. In addition to viability assessment, echocardiography, and contrast ventriculography, cardiac MRI and left ventricle–gated nuclear imaging have proved valuable tools for pre- and postoperative volume estimation and anatomic assessment of the left ventricular wall and septum. The pre- and intraoperative decision on when to perform left ventricular reconstruction should be based on the function, viability, and thinning of the segment, as well as the location of viability-targeted concomitant coronary grafting. Benefits obtained from repairing dyskinetic thin aneurysmal defects are well established.[40,42] More recently, however, preliminary reports have revealed encouraging results with endoventricular repair of nondilated akinetic segments when combined with CABG. These findings have spawned the multicenter Surgical Treatment of Ischemic Heart Failure (STICH) trial to evaluate its long-term functional benefit.

The operative principles of left ventricular reconstruction involve optimal myocardial preservation, septal exclusion of the nonfunctioning segment with an endoventricular patch, and closure of the excluded ventricular myocardium. To improve the visual and tactile identification of the nonfunctioning segment, the ventricular repair is often performed on the perfused beating unvented heart decompressed with cardiopulmonary bypass. Entry should be at least 1 to 2 cm to the left of the anterior descending coronary artery to avoid the septum. The thinned segment often will pucker when the left ventricle is decompressed, thus marking the initial access point. A point knife is used to gain entry to permit complete decompression and endocardial visualization under direct vision as the incision is further developed. This allows for the safe removal of any left ventricular thrombus if present, as well as for the visual and tactile identification of the septum and demarcation zone between functioning and nonfunctioning myocardium. A circumferential monofilament suture or "Fontan stitch" is then placed within this zone and tied as advocated by Dor. The resulting reduced size of the defect is then patched with bovine pericardium and the residual myocardial defect is buttressed closed with strips of bovine pericardium or felt. Though concomitant GMR and CABG can be performed before or after left ventricular reconstruction, it is often advocated before, so as to allow for improved myocardial recovery and reperfusion following removal of the aortic cross-clamp.

Results from left ventricular reconstruction have been favorable and consistent between groups regardless of whether endoventricular circular patch plasty or a modified linear patch closure technique is utilized. Significant reductions in left ventricular end-systolic volume index and improvements in EF, NYHA class, and long-term survival have resulted. It is being regularly performed with hospital mortalities of under 8% and with a 12-month freedom from readmission for CHF of over 80%.[40,42–46] Therefore, geometric left ventricular reconstruction by endoventricular exclusion of nonfunctional segments should be placed alongside high-risk CABG and GMR as a first-line surgical option for heart failure.

PARTIAL LEFT VENTRICULECTOMY

Batista has furthered the concept of surgical ventricular remodeling to optimize wall tension in dilated ventricles with the contention that all mammalian hearts should share the same mass-diameter ratio regardless of size. He proposes that all hearts not complying with this relationship should have a segment of the left ventricular wall excised in order to diminish mural tension and improve myocardial oxygen consumption in accordance with the law of Laplace.[47,48] This interesting concept was initially presented as a case report of a 34-year-old patient who underwent a partial left ventriculectomy (PLV) that reportedly increased the EF from 17 to 44% at 2 months postoperatively. Batista performed over 150 such procedures predominantly on patients with Chagas disease and dilated cardiomyopathy. Though this experience stimulated much interest, unfortunately no meaningful follow-up data or statistical analyses have ever been made available from this series.

To further evaluate the potential benefits of PLV, the Cleveland Clinic performed 62 such cases on patients with idiopathic dilated cardiomyopathy awaiting transplant. The ventriculectomy involved resection of the lateral wall of the left ventricle in the circumflex coronary artery distribution to the base of the papillary muscles with closure between two strips of felt or bovine pericardium. This was one of the largest North American series, reporting a 3.5% operative mortality with 7 late deaths and a 1-year actuarial survival of 82%. However, of the total 62 patients, 24 (39%) were considered short-term treatment failures: 11 required left VAD support, 6 were listed for transplantation again, and 7 non-left-VAD patients died.[48] Moreover, a further 30% attrition rate at 2 years following PLV has been reported.[49,50] These results may be superior to no surgical treatment, but they fall short of those obtained by other surgical options for heart failure. As a result, PLV has fallen into disfavor in North America. However, in the Asian-Pacific region, where transplantation is not widely available, efforts by Suma and associates to improve selection criteria and introduce echo-guided surgical decision making have resulted in PLV persisting as a viable option for heart failure in this part of the world.[51]

In attempting to elucidate the mechanism behind the relative success of PLV, it is quite interesting to note that over 95% of the cases performed in the Cleveland Clinic experience also involved a mitral reconstruction. Therefore, it becomes difficult to discern the role mitral repair plays in the overall utility of PLV, since patients undergoing mitral reconstruction alone also attain normalization of the left ventricular mass-to-volume ratio, but without the excision of viable myocardium.[26] Furthermore, experimental models of heart failure have revealed that correction of the MR alone permits left ventricular remodeling that may be rapid and complete, with resulting regurgitant fractions of less than 30%.[52]

Though the concept of instantly remodeling the left ventricle through PLV is mechanically appealing, discarding functioning myocardium is not. Patients with ischemic cardiomyopathy with a dyskinetic aneurysmal segment have undergone successful remodeling with an endoventricular patch repair. Patients with dilated cardiomyopathy and MR have undergone mitral reconstruction thereby altering the angulation of the base of the heart and promoting favorable left ventricular geometry and remodeling. Thus, at this time, when similar if not superior results can be obtained by methods that preserve myocardial integrity, the application of PLV to patients with endstage heart failure should be approached with an element of caution.

DYNAMIC CARDIOMYOPLASTY

Another alternative method to surgically optimize Laplace's law is dynamic cardiomyoplasty (DCMP) using the patient's own skeletal muscle wrapped around the heart to help reduce wall stress and provide limited cardiac assistance. The latissimus dorsi muscle is wrapped around the failing heart, and by means of an implantable cardiomyostimulator, the muscle is stimulated to contract in synchrony with cardiac systole.

Starting in 1985, Medtronic Inc. began coordinating a multicenter Food and Drug Administration trial to evaluate the cardiomyostimulator. Pooled observations after DCMP reveal a paucity of positive quantitative hemodynamic or survival data, yet paradoxically, patients report over 30% functional improvement when compared to medical therapy alone.[53,54]

Though DCMP is now only rarely performed in North America, the recently available LD Pace myostimulator out of Russia has allowed this procedure to continue to be available in that country as well as throughout various centers in Europe, Asia, and the Caribbean.

Investigations into the mechanisms of DCMP have generated spinoffs in the fields of myoblast transplantation and remodeling surgery. Studies revealed that the wrap actually contributes to significant reductions in myocardial wall stress.[55] In effect, this conceptually protects myocytes from overt functional stresses and thereby prevents the adaptive progressive dilatation of heart failure. Working in favor of the law of Laplace, this girdling effect of DCMP was seen with unstimulated adynamic cardiomyoplasty. Original experiments comparing adynamic cardiomyoplasty to synthetic material revealed that this beneficial girdling effect even occurs when a passive constraint of prosthetic mesh fabric is applied to the ventricles, and they have spawned the development of novel biomedical devices currently under clinical investigation.[56]

EMERGING BIOMEDICAL DEVICES FOR HEART FAILURE

The Acorn Cardiac Support Device (ACSD; Acorn Medical, Minneapolis, Minn) is a polyester mesh fabric that attempts to reduce ventricular wall stress by providing external support. Much like DCMP, the ACSD is placed around the ventricles from posterior to anterior, using stay sutures as well as an anterior fabric seam for snug tailoring to the patient's heart.

Taking advantage of the girdling effect, the purpose of this device is to passively support the failing ventricles and prevent further dilatation. Preclinical data have shown decreased left ventricular volumes and improvements in regional wall motion, EF, and other functional parameters without any evidence of constrictive physiology.[57] Histologic animal studies have also demonstrated decreased myocyte hypertrophy and interstitial fibrosis, as well as improvements in several biochemical markers of failure.[58,59] A phase I and II clinical trial has been completed to assess the safety and the early remodeling ability of the ACSD when used on heart failure patients with or without concomitant cardiac procedures. While not currently approved by the Food and Drug Administration for general use, the device continues to remain under current investigation. Preliminary experience reveals that the ACSD is easily applied, and may even be performed without the necessity of cardiopulmonary bypass.

The Myocor Myosplint (Myocor Medical, St. Paul, Minn) is a second device developed to reduce ventricular wall stress by directly altering cardiac geometry. Working on the premise of optimizing the law of Laplace, it involves the placement of transventricular tension bands through the right ventricular and left ventricular walls that have the unique ability to be individually tightened in order to achieve a 20% reduction in wall stress. Preclinical animal data have shown improvements in end-diastolic volume, end-systolic volume, and EF. These experiments reveal that the Myocor device becomes readily incorporated within a fibrous capsule that has been free of thrombus formation. A phase I clinical trial is underway to assess device safety in patients prior to cardiectomy at the time of transplant. Preliminary data reveal that the device can be readily deployed without harm to other cardiac structures. Further chronic studies are required to address the efficacy of this unique device.

The Geoform mitral valve annuloplasty ring (Edwards Lifesciences, Irvine, Calif) has a three-dimensional shape that attempts to combine the previously discussed principles of mitral valve repair and geometric remodeling of the left ventricle into the next generation of mitral valve rings (Figs. 69-5 and 69-6). This ring attempts to change and promote remodeling of the left ventricle through alterations in the mitral valve apparatus. The basic anatomic problem in dilated left ventricles, whether from ischemia or not, is the tendency of the posterior mitral valve annulus to fall away from the annular plane, which further promotes increased mitral regurgitation and increased left ventricular wall stress. Restoring the zone of coaptation of the mitral valve using this ring in the normal plane has two combined effects, of correcting the mitral regurgitation and changing the shape of the left ventricle (Fig. 69-7). Based on the elegant and pioneering efforts of Alfieri's group, the new geometry of the

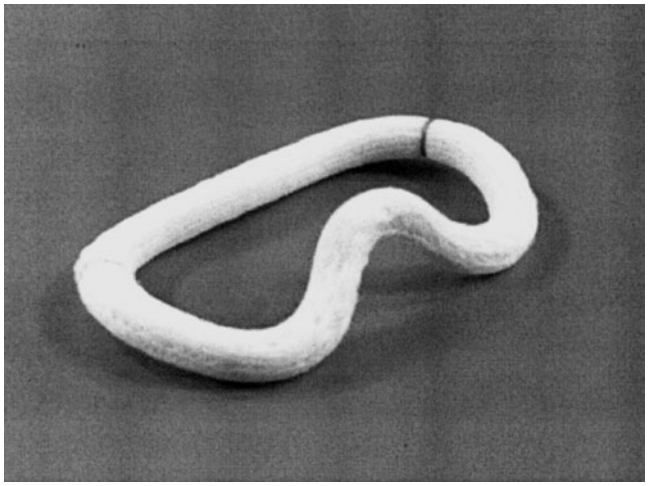

Figure 69-5. Oblique view of the Geoform mitral annuloplasty ring. Note the posterior ring design element which reverses the adverse changes in the posterior mitral annulus associated with geometric mitral regurgitation.

ventricle following this procedure has lower wall stress, which should promote further beneficial changes in the ventricle over time as the volume overload is relieved following correction of the mitral regurgitation[60] (Fig. 69-8). The Geoform ring is currently approved for clinical use with multiple implants performed at several centers worldwide.

PERCUTANEOUS MITRAL VALVE REPAIR

The Edwards Milano II mitral clip (Edwards Lifesciences, Irvine, Calif) and Evalve Mitraclip system (Evalve Inc., Menlo Park, Calif) use a catheter-based approach to deliver a clip to both the anterior and posterior mitral valve leaflets using the principles of mitral repair pioneered by Dr. Otavio Alfieri. Percutaneous catheters are introduced via the femoral vein and cross the atrial septum to enter the left

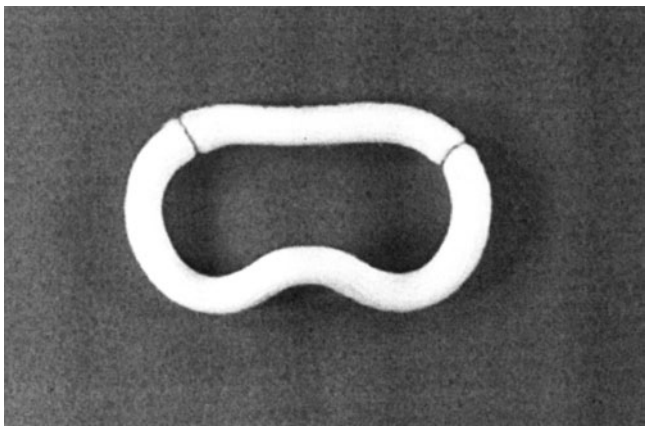

Figure 69-6. Superior view of the Geoform mitral annuloplasty ring. The three-dimensional cross-sectional area is not restrictive to atrial blood flow.

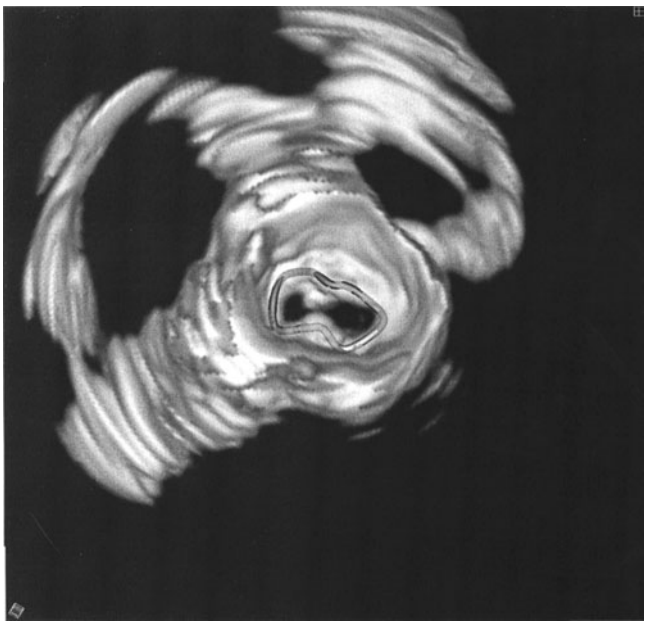

Figure 69-7. Postoperative three-dimensional echocardiography of a mitral repair performed using the Geoform mitral annuloplasty ring. Note the apposition of the central areas of the anterior and posterior mitral valve leaflets which help to establish a zone of coaptation and abolish mitral regurgitation.

atrium similar to a percutaneous mitral balloon annuloplasty approach. A catheter-based clip is then used to create a permanent coaptation point between the leading free edges of the anterior and posterior mitral leaflets. This technology is in the investigational stage with the Evalve clip currently being evaluated in the phase II EVEREST trial.

The Viacor percutaneous mitral annuloplasty system (Viacor Inc., Wilmington, Mass), Edwards Viking percutaneous mitral annuloplasty system (Viking, Edwards Lifesciences Inc.,

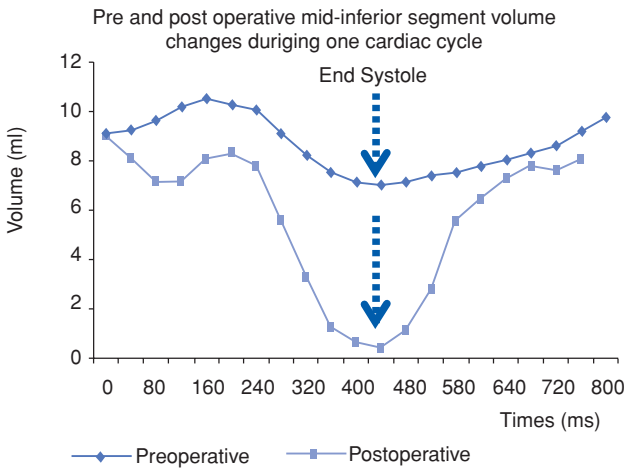

Figure 69-8. Left ventricular volume changes obtained on postoperative day 5 following geometric mitral valve repair. Increases in regional EF in the infero-basal wall are shown which are the opposite of the decreased EF expected following MVR based on historical teaching. (*Courtesy of Nadia Nathan, MD.*)

Irvine, Calif), and Carillon mitral contour system (Cardiac Dimensions, Kirkland, Wash) all use an emerging technology approach to mitral annuloplasty using a catheter-based approach to the mitral valve. Using percutaneous catheters, a permanent nitinol strut is placed into the coronary sinus that wraps around the posterior annulus of the mitral valve and attempts to indirectly influence the action of the posterior mitral valve leaflet similarly to a partial ring annuloplasty by reducing the anterior-posterior dimension of the mitral annulus. The devices are presently under investigational study and are not currently approved for routine use.

CONCLUSIONS

As surgical therapies for heart failure rapidly evolve, the need for their critical appraisal is essential so that they may be offered to the growing population of CHF patients in a prompt yet effective manner. Transplantation continues to offer selected patients reliable long-term survival in a reproducible fashion, and it thus remains the gold standard surgical therapy for heart failure. Though in time we may see mechanical assist devices play a more prevalent role in myocardial recovery or destination therapy, currently their main utility is as a bridge to transplantation. With the growing disparity between donor availability and heart failure patients, experience is mounting with effective nontransplant surgical solutions.

The results of the more conventional techniques of CABG, geometric mitral reconstruction, and ventricular reconstruction, when combined with the optimal medical management of heart failure may now be on a par with transplantation. Therefore, these modalities now form the new first-line surgical therapy for heart failure when applicable. Patients with primary ischemic cardiomyopathy with favorable anatomy may be effectively managed with revascularization alone or in combination with left ventricular reconstruction. Myopathic patients with MR, regardless of etiology, may be effectively managed with mitral reconstruction. With the superior results of these approaches, the use of other techniques such as PLV and DCMP should be reserved as viable alternative surgical options for heart failure. The prudent and effective application of the growing menu of surgical strategies for heart failure enables the scarcely available donor hearts to be efficiently used for patients with truly no other surgical or medical alternatives. Along with the utility of emerging biomedical devices, each of these unique modalities has enhanced the clinically effective armamentarium of the modern surgeon treating patients with heart failure.

CHAPTER 70

Tissue Engineering for Cardiac Valve Surgery

John E. Mayer

Tissue engineering is a developing science, which brings together engineering and biology in an attempt to develop replacement tissues beginning with their individual cellular components. The impetus for our work on tissue engineered cardiovascular structures derives from the need to replace cardiovascular tissues that failed to develop normally during embryogenesis or have become dysfunctional as a consequence of disease, as well as from the fact that currently available replacement structures have significant limitations. In the cardiovascular sphere, the structures most often affected, excluding atherosclerotic coronary disease, are the cardiac valves and the great vessels. Diseases of the heart valves and large "conduit" arteries account for approximately 60,000 cardiac surgical procedures each year in the United States, but all of the currently available replacement devices have significant limitations.[1,2] Ideally, any valve or artery substitute would function in similar fashion to the normal valve or artery to allow blood to pass through it without narrowing or leakage, but would also have the following characteristics: (1) durability, (2) growth potential (for infants and children), (3) compatibility with blood so that thrombus would not form on its surface and activation of inflammatory cascades would not occur, and (4) resistance to infection. None of the currently available devices constructed from either prosthetic or biologic materials meet these criteria. Prosthetic heart valves are very durable, but they require anticoagulation to reduce the risk of thrombosis and thromboembolism.[1,2] Notwithstanding anticoagulation, the incidence of thromboembolic complications is not zero.[1,2] Biologic valves, whether they are of allograft or heterograft origin, remain subject to structural deterioration after implantation.[2–4] Neither prosthetic nor biologic valves have any growth potential, and this limitation represents a major source of morbidity for pediatric patients who must undergo multiple reoperations to replace valves and/or valved conduits as the patients grow. The tissue engineering approach to overcome these shortcomings offers the possibility of creating replacement cardiovascular structures from cells and scaffolds with the result that the tissue-engineered construct is a living structure with the capacity for growth, repair, and remodeling similar to normal tissues. This chapter summarizes some of the progress that has been made in tissue engineering research as it relates to cardiac valves and conduit arteries, and to then outline the areas where additional efforts must be focused in order to make cardiovascular tissue engineering a clinical reality.

Much of the strength and flexibility in normal tissues is due to specialized proteins and polysaccharide-protein complexes (extracellular matrix) that are produced by the cells in the tissue.[5,6] For cardiac valves, the biomechanical demands are particularly high, as there are approximately 40 million openings and closures of the valves per year. The normal valve presents minimal resistance to opening and no pressure gradient during systolic forward flow. In diastole this same structure must close promptly and completely to prevent valvular regurgitation, and must resist pressure differences between the diastolic arterial or pulmonary artery pressure and the ventricular diastolic pressure. The extracellular matrix of the normal semilunar heart valve is not homogeneous,[5] and the arrangement of the extracellular matrix seems uniquely designed to provide a high degree of flexibility during systole but a high degree of strength to resist the diastolic pressure load.[5] In order for a tissue-engineered cardiac valve to function effectively, it seems intuitively obvious that extracellular matrix production, composition, and remodeling processes are critical, and should result in a structure that is similar to the native valve. The determinants of extracellular matrix composition in a given tissue are incompletely understood, but are determined to some extent by the types of cells in the tissue, by the interactions among these cell types, by a variety of cytokine signals that the cells receive, and by the biomechanical signals that the cells receive.[5]

One potential source of insights for the development of a tissue-engineered heart valve (TEHV) is the process by which the normal valve develops from the embryonic to the mature adult form. A recent publication by Aikawa and colleagues[7] demonstrates that the normal semilunar valve undergoes significant in vivo maturational changes during development, which include changes in the extracellular matrix composition, collagen fiber alignment, and cellularity, and the development of a nonhomogeneous layered architecture. The mature semilunar valve structure with a more dense layer of collagen on the valve surface facing the sinus of Valsalva, (fibrosa layer) a middle layer of glycosaminoglycans, (spongiosa) and an elastin-rich layer facing the ventricular cavity and the flow from the ventricle to the great artery (ventricularis) seems uniquely designed to allow optimal semilunar valve function.[6] However, fetal semilunar valves and even those obtained from children are more cellular and do not have a fully mature valve structure.[7] Thus the semilunar valves undergo significant maturation in vivo under continuous biomechanical and other signaling conditions, and studies of tissue-engineered pulmonary valves from our laboratory have shown a similar evolution in histologic appearance, extracellular matrix composition, and organization of the collagen fibers in the extracellular matrix.[8] The signals and genetic changes controlling the early embryonic development of mammalian semilunar valves have recently been reviewed by Armstrong and Bischoff,[9] and it has become evident that the genetic mechanisms and signaling pathways are quite complex and tightly controlled, and are not completely understood at this point. The insights gained from an understanding of normal semilunar valve development is of potential application to the development of TEHVs, although it seems that the complexities of normal valve development will be difficult to replicate completely.

In our laboratory at the Children's Hospital, Boston and in the laboratories of other investigators, attempts to create TEHVs have been made over the last decade with varying degrees of success,[10–18] constructing these valves from a variety of cell types and scaffolding materials. Most of the in vivo studies have been carried out in the lower-pressure pulmonary circulation, which is more forgiving of an imperfectly functioning valve construct. The longest successful in vivo implant from our laboratory is 8 months, but the optimal process for engineering of a tissue-engineered pulmonary valve remains incompletely defined. If a tissue-engineering approach to the creation of a heart valve substitute is to be successful, several basic questions must be addressed: (1) What cell type or combination of cell types is necessary to allow the production and maintenance of an appropriate extracellular matrix? (2) To what extent can cellular phenotype be altered or "engineered" to replicate cells found in the normal valve? (3) How can these cells be spatially organized during the development of the tissue-engineered structures until sufficient extracellular matrix is produced by the cells in the construct? (4) What biochemical signals are necessary during the development of these structures to ensure proper extracellular matrix production? (5) What mechanical signals are necessary for the optimal tissue development? (6) Should a tissue-engineered valve construct be completely developed and "mature" prior to implantation, or can there be further "maturation" of a tissue-engineered construct in vivo after implantation in a fashion similar to the age-related maturational changes in the normal valve?[7] Progress has been made in addressing each of these questions, and this progress will be reviewed.

CELL TYPE OR TYPES FOR TISSUE-ENGINEERED HEART VALVES

A considerable effort has been made to explore the optimal cell source (or sources) for tissue-engineering applications. From a conceptual standpoint, the cells for a TEHV can be derived from fully differentiated cells with the capability to synthesize collagen, elastin, and glycosaminoglycans or from less committed, pluripotent stem cells with the potential to differentiate into multiple cell types. A second-order decision regarding cell source is the choice of autologous versus allograft cells. This choice will have significant implications if the tissue-engineering approach is to become a clinical reality. In order to avoid any confounding effects of immune rejection in our laboratory, we have based all of our research on the use of autologous cell lines, and it is our intuition at this time that if a tissue-engineering approach to development of a cardiac valve is to be successful, then it will likely involve the use of autologous cells, unless a nonantigenic cell source is identified or selective immune tolerance can be established. The ultimate choice of cell type(s) will likely reflect a complex interplay between what is favored in terms of basic cell biology, what tissues are readily available for harvest in the individual patients, and what is clinically acceptable to both patient and physician.

Considerable early success in fabricating a TEHV was achieved in our laboratory using myofibroblasts and endothelial cells derived from the systemic arteries of immature animals.[10–14] These cells were chosen by virtue of their anatomic location within the arterial limb of the cardiovascular system and their known ability to synthesize structural extracellular matrix components such as collagen and elastin. A comparison of myofibroblasts from the wall of the ascending aorta with those from discarded segments of saphenous vein revealed that the latter cells exhibit superior collagen formation and mechanical strength when cultured on biodegradable polyurethane scaffolds.[19] We were able to construct TEHVs based on these cells from the systemic blood vessels that functioned for periods of up to 4 months in vivo.[10,12] However, enhanced collagen formation may be a double-edged sword. The rapid formation of new tissue in the early culture period could give rise to uncontrolled proliferation and synthesis of matrix elements, leading to decreased flexibility and potential tissue shrinkage. Early studies with dermal fibroblasts showed that leaflets constructed from these cells did develop tissue contraction,

which limited the ability of these leaflets to coapt with other leaflets effectively.[21] In addition, mature cells may present a problem of senescence in long-term cell cultures in vitro, which limits the ability to produce sufficient numbers of cells to seed a TEHV construct. Finally, the prospect of harvesting segments of artery from an otherwise normal peripheral circulation in order to obtain cells for a TEHV represents a somewhat unattractive solution clinically, and therefore led to the search for alternative cell sources.

The search for a more clinically palatable source of cells led us to investigate the use of stem cells for tissue-engineering applications. Our initial experience was gained with autologous endothelial progenitor cells (EPCs) that were isolated from the circulating blood of lambs and then seeded onto decellularized arterial segments.[20] These seeded arterial grafts were then implanted as an interposition graft in the carotid artery of the donor lamb.[20] These grafts remained patent and functional for up to 130 days.[20] Cebotari and colleagues have recently reported an initial experience with seeding EPCs onto homograft valves followed by implantation into two children.[39] In our subsequent studies, Sutherland and associates used ovine bone marrow mesenchymal cells to seed a biodegradable scaffold formed into a three-leaflet valve within a conduit[19] (Fig. 70-1). These valved conduits were implanted to replace the pulmonary valve for periods up to 8 months and functioned well hemodynamically. An echocardiographic image of the valve in open position in vivo is shown in Fig. 70-2. Importantly, these valve leaflets underwent a "maturational" process after implantation[18] similar to our earlier findings using myofibroblasts and endothelial cells from systemic arteries,[12] and in both sets of experiments a layered histologic appearance developed during the time after implantation. Other investigators have also used bone marrow as a cell source for tissue-engineered cardiovascular structures. Matsumura and associates have shown that bone marrow cells labeled with green fluorescent protein can be seeded onto a copolymer of lactic acid and ε-caprolactone and found that these seeded cells contribute to the histogenesis of a tissue-engineered vascular graft. Their tissue-engineered vascular grafts remained patent and at explant the constructs contained green fluorescent protein–labeled cells which expressed both endothelial-specific and smooth muscle cell–specific markers.[21] The group at Tokyo Women's Medical College has also carried out implants of tissue-engineered vascular grafts in children undergoing repair of certain types of congenital heart disease using a similar technique with encouraging early results.[23]

Figure 70-1. The tissue-engineered substitute pulmonary valve viewed from below prior to implantation.

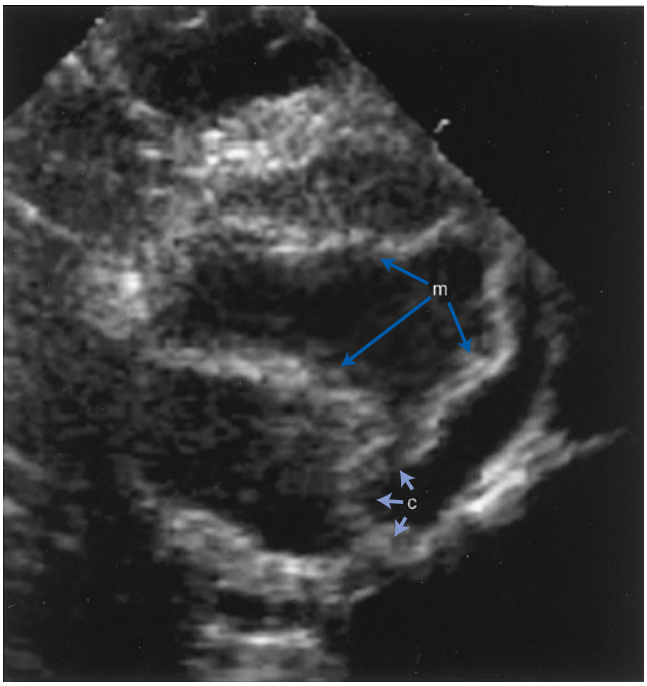

Figure 70-2. Short-axis echocardiogram of a substitute pulmonary valve in late systole showing the leaflet free margins (m) and absence of reverse bending at the commissures (c).

To further complicate the issue of choice of cell type, there is now evidence that stem cells with proliferative and regenerative capacities reside in many tissues. These stem cells are now believed to be capable of not only acting locally in the tissues in which they reside, but they may also be recruited out of the circulation and enlisted in the regeneration of diverse tissues at distal sites.[24] These stem cells are thought to be highly plastic and amenable to change if placed in an appropriate microenvironment.[24] In a recent review Rafii and Lyden have concluded that there is emerging evidence that bone marrow–derived endothelial, hematopoietic stem and progenitor cells can also contribute to tissue vascularization during both embryonic and postnatal physiological processes.[25] Visconti and coworkers have made the intriguing observation that cardiac valve interstitial cells in mice appear to originate in the bone marrow and to be of

hematopoietic origin.[26] Others, however, have cast doubt on whether bone marrow stem cells can migrate to damaged heart muscle and repopulate areas of myocardial infarction,[27] and therefore the ability to repopulate a tissue with circulating stem or progenitor cells remains in some question. The early unfavorable experience with the SynerGraft decellularized heterograft valved conduits, which were implanted in children as right ventricle–to–pulmonary artery conduits with the expectation that they would be repopulated by circulating cells from the bloodstream or by ingrowth from adjacent normal tissue has raised questions about the clinical applicability of these concepts about repopulation of decellularized grafts.[28] However, this progenitor ("adult stem cell") cell population represents an attractive source of cells for application of the tissue-engineering approach to development of cardiac valves because they can be obtained relatively less invasively and because these cells may have the capacity to assume a more appropriate phenotype.

ENGINEERING OF CELLULAR PHENOTYPE

Among the more interesting observations on mesenchymal stem cells is that the phenotype of these cells seems to be dependent on the local environment in which they come to reside.[29] However, the factors in these local environments that control differentiation into various phenotypes remain unknown.[29] For EPCs, there is evidence that these cells have the ability to transdifferentiate in response to various signals in a tissue-engineering environment. Dvorin and colleagues have shown that transforming growth factor (TGF)-β_1 can induce EPCs to express α-smooth muscle actin (α-SMA) after these cells had been seeded onto a tissue engineering scaffold of polyglycolic acid (PGA)/poly-4-hydroxybutyrate copolymer.[30] This α-SMA expression is not characteristic of endothelial cells or EPCs, and its expression suggests that the EPCs have undergone a phenotypic change into a cell type resembling cardiac valve interstitial cells. Human aortic valve endothelial cells, but not vascular endothelial cells, respond to TGF-β_1 in a similar fashion, suggesting that EPCs may be an appropriate cell type to serve as valve endothelium.[30] It is noteworthy that endothelial transdifferentiation to a mesenchymal phenotype is a critical step during the normal embryonic development of cardiac valves, and Dvorin and associates have speculated that the ability to recapitulate some normal steps in embryonic valve development is relevant to the choice of cell types for tissue engineering of cardiac valves.[30] More recent studies by Sales and coworkers in our laboratory have shown that exposure of EPCs to TGF-β_1 while being grown on tissue-engineering scaffolds not only begin to express α-SMA, but also demonstrated increased production of laminin, fibronectin, tropoelastin, and collagen when compared to EPCs seeded on the same scaffold without TGF-β_1.[38]

An additional issue for cell selection for a TEHV is whether better results will be obtained by seeding the scaffold with more than one cell type and whether the different cell types are seeded at the same time or sequentially. In our initial studies, both endothelial cells and vascular smooth muscle cells were seeded sequentially[10] onto a PGA scaffold with favorable results. In subsequent in vitro studies, we observed an interaction between human EPCs and vascular smooth muscle cells when these cells were co-seeded onto PGA/poly-L-lactic acid (PLLA) scaffolds such that microvascular tube formation was observed when these two cell types were co-seeded versus when EPCs alone were seeded onto the same scaffold material.[31] The potential for interactions among cells of differing origin and phenotype adds another dimension of complexity to the tissue-engineering process. It is quite clear that normal embryologic development of semilunar valves involves important interactions between cells of different embryologic origins and between cells and the extracellular matrix surrounding them.[9] It has seemed reasonable to us to conclude that similar interactions could play an important role in the evolution of a TEHV.

STRUCTURAL ORGANIZATION SCAFFOLD

Although it is has been possible to grow individual types of cells in culture for some time, it is more difficult to induce these cells to assemble or organize into the more complex structural arrangements that are found in normal tissues or to produce normal extracellular matrix components in an organized fashion. For this reason, most attempts to create tissue-engineered structures have started with a scaffold onto which cells are "seeded." Any scaffold for tissue engineering applications must be biocompatible and allow cells to adhere and proliferate. Thus the chemistry of the scaffold itself and the scaffold degradation products must be nontoxic at the outset. If the tissue-engineered construct is to have any growth potential, then ultimately the scaffold must either degrade or be able to be remodeled. A fundamental difference in the various tissue-engineering strategies in different laboratories has centered on this choice of scaffold materials. One option is to use decellularized biologic tissues with the extracellular matrix remaining after the decellularization process serving as the scaffold for cellular attachment and structural organization. The alternative approach is to use synthetic biodegradable polymer matrices to provide these scaffold functions with the anticipation that the cells in the tissue-engineered construct will produce their own extracellular matrix and that the synthetic scaffold will be degraded and eliminated. The disadvantages of decellularized grafts include the relative shortage of available homografts and potential immunogenicity problems that may arise from the use of decellularized xenogeneic tissues. Perhaps more importantly, the density of residual extracellular matrix that is attractive from a structural integrity and early post-implant functional perspective may prevent the penetration of seeded cells into the interstices of the matrix. Furthermore, given the complex and poorly understood interactions between the cellular cytoskeleton and the extracellular

matrix in normal tissues, it may be naïve to expect cells seeded onto decellularized tissues to assume those same relationships with matrix that may be altered by the decellularization process or may differ in subtle ways from species to species. There has been some experience gained in cardiac valve tissue engineering using small intestinal submucosa as the scaffold.[16] In our laboratory, we have constructed trileaflet valved conduits and seeded them with EPCs. After these conduits were implanted in an ovine model, there was satisfactory short-term function, but there was no penetration of any cells into the substance of the small intestinal submucosal scaffold.

Our primary laboratory efforts to develop heart valves and large arteries have utilized the alternative approach of seeding cells onto biodegradable polymer scaffolds that temporarily provide the macroscopic structure and the mechanical stability that are necessary for "tissues" to develop from their individual cellular components. Ideally, these polymer scaffolds then degrade during the time that the cells in the developing "tissue" are producing normal structural proteins and are becoming organized and oriented to replicate normal tissue structure. Initially, the biodegradable scaffolds that we used were based on materials already in clinical use, including PGA and PLLA. Each of these materials has differing characteristics, including the length of time to degrade the polymer and the rate at which polymer degradation and loss of strength occur. PGA was introduced into clinical practice as a biodegradable suture material and marketed under the trade name Dexon (U.S. Surgical, Norwalk, Conn). The ability to extrude PGA into fibers permits it to be fabricated into nonwoven sheets with an open porous structure. Pore size has been shown to be important in the choice of scaffold material for tissue engineering liver for a variety of cell types,[32] and it is likely that pore size will also be important for cardiovascular structures. An open pore structure seems to facilitate both cell delivery and subsequent cell proliferation by allowing free access to suspended cells, free diffusion of nutrients and dissolved gases, and removal of waste products of metabolism. These spatial properties combined with a consistent and relatively rapid loss of polymer mass relative to other biodegradable materials have made PGA an attractive choice for tissue engineering. One disadvantage that we have observed is that there is a more rapid loss of strength than polymer mass as the polymer degrades by hydrolysis, and this property limits the amount of time that PGA-based tissue-engineered constructs can be kept in aqueous culture before implantation. This shortcoming of PGA was offset to some degree by impregnating PGA with the thermoplastic polymer poly-4-hydroxybutyrate (P4HB), which allowed flat sheets of scaffolding to be assembled into a trileaflet structure by a series of two or more wraps around a cylindrical mandrel and using heat welding to create a tubular conduit containing a trileaflet valve.[12]

Despite promising early results using the PGA/P4HB composite, in subsequent studies we experienced some problems with the use of this material, particularly continued problems with loss of structural integrity with longer periods of time in an aqueous tissue culture environment. As the rate of loss of strength increases, there is an increased requirement for the cells in the tissue-engineered construct to produce extracellular matrix at an earlier time point prior to implantation. There were problems with suture retention and actual tearing of the wall of the conduit in some of our experiments with valved conduits developed from PGA/P4HB scaffolds. For these reasons, Sutherland and associates in our laboratory adopted a scaffold composed of a mixture of PGA and PLLA.[18] PLLA is the α methyl substituted form of PGA, and it was initially developed for the biodegradable suture market. This polymer hydrolyzes at a much slower rate than PGA, and the initial tensile strength of PLLA is less than that of PGA. This composite material was able to be fabricated into a valved conduit with a three-leaflet valve that functioned quite well at the time of implantation, and then over periods of up to 8 months after implantation, and had significantly improved surgical strength and handling characteristics.[18] The importance of scaffold degradation time was demonstrated in experiments reported by Stock and colleagues from our laboratory,[34] in which the use of polyhydroxy-octanoate as scaffolding material was associated with excessive tissue buildup and leaflet retraction.[34]

These PGA and PLLA scaffolds for cardiac valves have one additional disadvantage, and that is they are significantly stiffer than a normal valve leaflet and only gradually become less stiff with time.[12,18,33] As a consequence of this finding but also because of evidence that mechanical signals influence cellular behavior, a new more elastomeric polymer was designed for tissue-engineered heart valve application by Wang and colleagues at the Massachusetts Institute of Technology. This polymer is a rapidly degrading elastic polymer based on sebacic acid.[35] Preliminary experiments have shown that this polymer will support cell attachment and proliferation, but much additional experimental work will be necessary to determine if this material will be suitable as a scaffold for a tissue-engineered heart valve. However, the availability of this more elastic polymer will allow further studies of the effects of mechanical scaffold properties on the development of a TEHV.

In addition to the influence of the chemical, degradation, and mechanical properties of the scaffold material, there is preliminary evidence that the fabrication techniques can affect the mechanical behavior of the scaffold and may be of importance to the development of tissue-engineered constructs. Engelmayr and associates have shown that dimensions of the pores within a scaffold can guide engineered tissue cellular and collagen orientation in two-dimensional systems,[36] and it seems reasonable to anticipate that similar phenomena will occur in three-dimensional systems. To date, it has been difficult to explore the impact of scaffold fiber orientation on the development of tissue-engineered cardiac valves since the methods needed to fabricate these scaffold materials into more organized structures than films or nonwoven meshes have been limited. A promising fabrication technique that has recently been evaluated for tissue-engineering applications is electrospinning, which

allows the macromechanical characteristics of scaffold materials to be controlled so that they mimic those of a native semilunar valve leaflet.[37] As this and other fabrication methods evolve, it seems likely that further exploration of the effects of scaffold mechanical behavior at the macroscopic level on developing tissue-engineered structures will be necessary.

CYTOKINE SIGNALS

Based on extensive experience with culturing a variety of cell lines, TEHVs have been grown in media containing fetal bovine serum, which is known to contain multiple factors that promote cell proliferation in vitro. To the extent that cytokines can alter cell phenotype, these signals may provide additional opportunities for engineering the environment to guide the development of a tissue-engineered heart valve. The findings that TGF-β_1 could induce endothelial progenitor cells to produce α-SMA[31] and alter the types and amounts of extracellular matrix being produced,[38] are examples of the potential ability to use cytokine signals to affect cell phenotype and protein synthesis. Few studies have been undertaken to explore this approach to engineering the environment in which a tissue-engineered construct takes place. In future engineering of valve tissues, one might envision localizing growth factors within the developing tissue-engineering construct to guide behavior at the microstructural level, particularly in regard to control of the types and amounts of extracellular matrix.

BIOMECHANICAL SIGNALS

Several lines of in vitro and in vivo evidence indicate that both tissue-engineered and normal valve leaflets respond to mechanical signals with changes at the cellular and extracellular matrix levels. In the natural "experiment" provided by the Ross procedure, in which a pulmonary valve from the low-pressure pulmonary circulation is transplanted into the aortic position and subjected to systemic pressure, significant changes in the phenotype of valvular interstitial cells have been observed, including an increase in the activity of matrix remodeling proteins.[9] In experiments from our laboratory reported by Hoerstrup and colleagues,[12] the ability of mechanical flow and pressure signals in vitro were shown to increase the production of collagen in tissue-engineered semilunar valves. Lee and associates have shown that in cultures of vascular smooth muscle cells exposed to tightly controlled mechanical strains, mRNA and protein levels for versican, biglycan, and perlecan increased, while those for decorin decreased. Also hyaluronan-versican aggregation was enhanced following deformation.[40] Engelmayr and coworkers have also shown that vascular smooth muscle cells seeded onto biodegradable scaffolds and then subjected to flexure increased the production of collagen and vimentin, and had increased tissue stiffness.[33] In subsequent studies on bone marrow stem cells, Engelmayr and associates have found that combined flow and flexure signals result in increased collagen concentration and tissue stiffness.[41] These natural and laboratory experiments demonstrate that biomechanical signals clearly alter cellular behavior and therefore engineering of the in vitro mechanical environment, and offer an additional method to guide the development of tissue-engineered cardiac valves.

IN VIVO MATURATION

The experiments from our laboratory reported by Hoerstrup[12] and subsequently by Rabkin[8] indicate that there is an ongoing evolution of tissue-engineered heart valves after implantation into the circulation. This evolution occurs at the macroscopic level with thinning of the tissue-engineered leaflets, as well as at the histologic level with development of distinct layers in the valve leaflet.[12] Picrosirius red staining indicated that there was a progressive evolution of the orientation of the collagen in the tissue-engineered valve with increasing time in the in vivo environment. There was an evolution of cellular phenotype with decreased expression of SMemb, αSMA, and MMP-13, and increased expression of vimentin, a process which is consistent with an evolution from an "activated" state of these valve cells to a more inactive state. Importantly, the microscopic structure of the valve leaflets evolved from a relatively homogeneous appearance to a layered structure with increased collagen on the sinus side of the leaflet and elastin formation on the ventricular side of the leaflet. The mechanisms by which this in vivo evolution of structure and cellular activity occurs remain completely unexplored, but these observations suggest that a tissue-engineered valve may not have to be a "finished product" at the time of implantation into the circulation.

In summary, the tissue-engineering approach to the development of a living heart valve structure represents an exciting new direction for heart valve research. Numerous refinements of the current approaches will likely be necessary, including the optimization of the scaffold materials, cell types, in vitro biochemical and mechanical conditions, and the development of reproducible valve development processes. The observation of in vivo maturation and/or evolution of these tissue-engineered constructs introduces an additional variable that will complicate regulatory efforts to ensure patient safety. It seems likely that initial clinical experience will be gained in the low-pressure pulmonary circulation since valve failure in this position is likely to be well tolerated based on years of clinical experience in patients with tetralogy of Fallot treated with transannular patches. The challenges for application in the systemic circulation will be much greater, as the consequences of valve failure will be much more likely to be catastrophic.

CHAPTER 71

Stem Cell–Induced Regeneration of Myocardium

Robert P. Gallegos • R. Morton Bolman, III

INTRODUCTION TO CELLULAR THERAPY

Cardiovascular disease remains the leading cause of death in industrialized nations despite major advances over the past 60 years in medical and surgical therapy. Largely this relates to the growing worldwide epidemic of congestive heart failure (CHF) currently affecting ~15 million patients and which carries a 5-year mortality of 50%.[1] Heart failure—severe ventricular dysfunction—has numerous etiologies but is most often seen as a result of ischemic cardiomyopathy. The hallmark of end-stage CHF is cardiomyocyte loss unmatched by myocyte regeneration following myocardial infarction (MI). Early rapid revascularization—be it with pharmacotherapy, stenting, or surgery—may potentially improve myocardial blood flow with resultant improvement in the function of remaining viable myocardium. However, current therapeutics cannot regenerate myocytes lost to necrosis. As a result, complete cardiovascular functional restoration remains unattainable with the currently available conventional therapies.

Myocardial regeneration—the replacement of lost myocytes—is seen in organisms such as the newt and zebra fish. In higher mammals, dogma has dictated the impossibility of such myocyte regeneration, as the heart was viewed as a terminally differentiated organ. This lack of regeneration prompted interest in organ transplantation as a means of complete replacement of the failing organ. The successful development and implementation of heart transplantation by Barnard and Shumway has greatly improved the clinical outcome for patients diagnosed with end-stage CHF.[2] Unfortunately, several constraints associated with the origin of the donor heart limit the potential for broad application of transplantation in the affected CHF population. The most significant limitation remains the limited availability of donor organs (Fig. 71-1).[3] Complications of immune rejection and immunosuppression also limit the long-term benefits of heart transplantation. Efforts to eliminate the limitations of organ transplantation with the use of mechanical left ventricular assist devices (bridge to transplantation or destination therapy) have similarly been thwarted by finite device durability or device-related complications.[4]

The need for a broadly applicable causally directed therapeutic option that would complement the function of remaining healthy myocardium has prompted significant interest in cell-based regeneration (Fig. 71-2).[5] Much of the excitement in cell-based therapy lies in the premise that repairing the injured heart will overcome the inherent limitations for the broad application of both organ transplantation and mechanical assist devices. The use of native cardiac myocytes (an obvious choice for cell-based cardiac regeneration) was felt to be impossible, as the mammalian heart was believed to be terminally differentiated. However, recent findings revealing resident stem cells within the heart have challenged this accepted dogma.[6,7] Nevertheless, the use of cardiac stem cells for tissue regeneration currently is not feasible, secondary to technical limitations in isolation and expansion.

Despite significant limitations, the inherent potential in cell-based therapies has incited the search for additional sources of stem cells and methods of restoring cardiac function.[8–10] The potential that noncardiac stem cells, such as those from bone marrow or even other organs, could engraft in injured regions of myocardium was first recognized in the evaluation of myocardial biopsies taken from gender-mismatched heart transplant recipients.[11,12] In these male patients, biopsies taken from hearts derived from female donors were found to contain nucleated cells clearly of male origin, containing both the male chromosome and cell markers consistent with cardiac phenotype. Although the exact origin of these new male cells has been debated, several key points were identified. First, injured myocardium through some unknown mechanism attracts stem cells. Second, these stem cells can engraft into regions of injured myocardium. Finally, these engrafted stem cells, of noncardiac origin, appear to

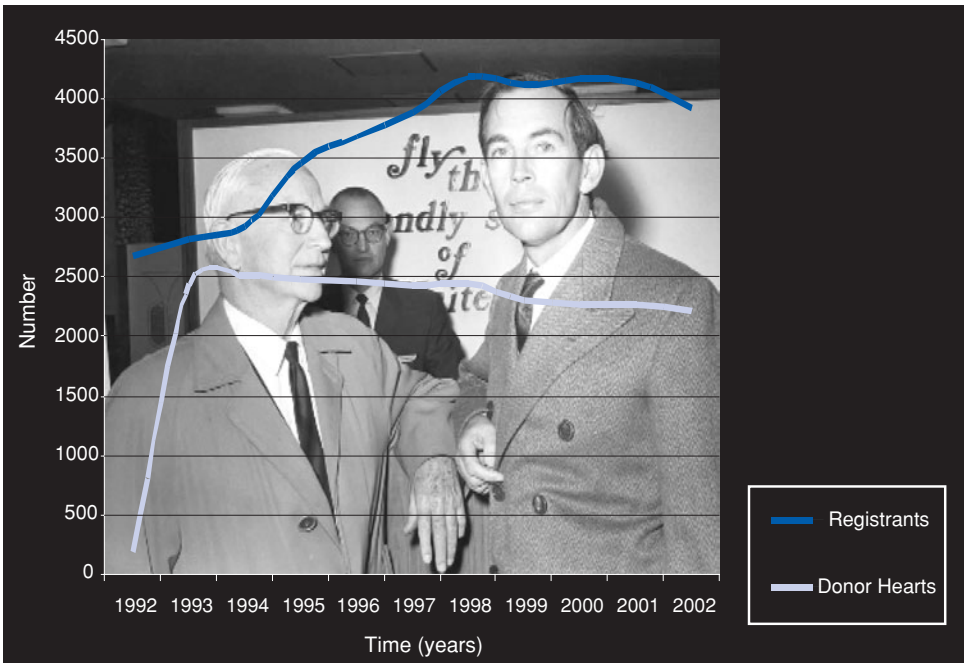

Figure 71-1. Imbalance between donor and recipient ratio. (*R. P. Gallegos; data from United Network for Organ Sharing.* Photo inlay: Dr. Owen Wangenstein (left) with Dr. Christiaan Barnard (right), who performed the first human heart transplant in the world.)

be capable of differentiation into cardiac myocytes that integrate with the surrounding native myocardium.

Cardiovascular disease remains a formidable clinical challenge for which no absolute solution is currently available. Cellular-based tissue regeneration may be of significant importance but remains to be developed further before its true potential may be realized. The following discussion will review the development of cell-based therapy from animal models to current clinical trials.

The Ideal Cell Type

The potential therapeutic benefit offered by cell-based therapies has spurred numerous investigators to search for the ideal stem cell population. This stem cell would effectively engraft and integrate into regions of damaged myocardium and restore cardiac function without improper differentiation into other contaminating cell types. This would require not only neomyogenesis, but also accompanying neoangiogenesis, either as direct or indirect consequence of the implanted cell.

Many cell types with the potential to repair the injured heart have been considered, including differentiated (e.g., fetal myocytes and satellite muscle cells) and undifferentiated primordial cell lines (e.g., embryonic or adult stem cells). Primordial cell lines, or stem cells, that might be utilized for cell-based therapy were first developed from embryonic tissue.[13,14] Embryonic stem (ES) cells are pluripotential (i.e., capable of functional plasticity with the ability to differentiate into all cell types found in the fetus and placenta in vitro). Once established, the cell lines can be propagated in cultures to provide a continuous source of material for transplantation. In fact, ES line–derived cells have shown the ability to form myocytes that generate stable cardiac engraftment.[15] Unfortunately, extensive experimentation in vivo is still necessary to properly direct the formation of integrated, functional cardiac tissue at the site of injury without improper differentiation to form teratomas or other noncardiac cell types. In addition, numerous obstacles that plagued organ transplantation will also likely prevent the widespread use of ES cell therapy. These issues are directly related to the origin of the cell line. First is the issue of allogenicity, which might confer a small potential for rejection, thereby requiring lifelong immunosuppression. But more importantly, the lack of general availability of embryonic stem cells, not dissimilar to the lack of donor hearts, may be most limiting. Current ethical obstacles surrounding the use of embryonic tissue and the current governmental ban on the development of new cell lines will limit the availability of tissue for transplantation.[16–21] New discoveries that have allowed the cloning of ES cells may alleviate this limitation,[22,23] but realization of this potential will await further investigation. Consequently, to utilize stem cell transplantation in a clinical setting, stem cells derived from other sources require investigation.

Stem cells have been demonstrated to be present within various organ tissues in the adult.[24–27] Recent interest has been focused on these cell lines, and the term adult stem cell has been used to differentiate these from ES cell lines. Adult stem cell lines, on exposure to specific signal molecules, have demonstrated the capability of generating myocytes in vitro.[28,29] In addition, the ability to induce in

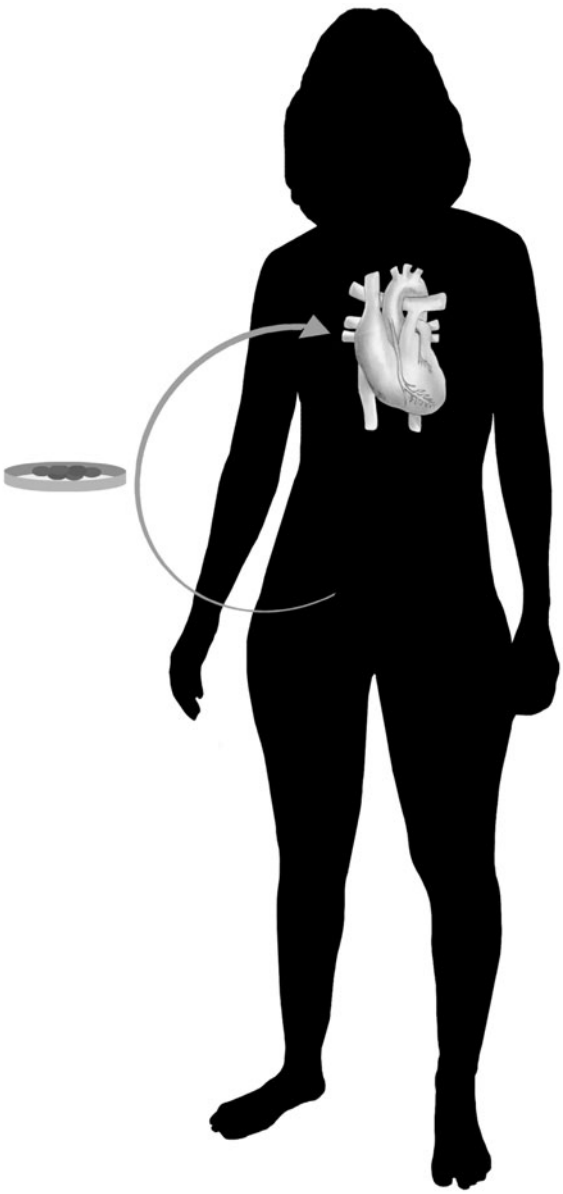

Figure 71-2. Cellular therapy model. Diagram illustrates the use of autologous cells for myocardial repair. Stem cells removed from the body are expanded in culture and then injected into the damaged organ to repair the injured tissue. (*Illustration by Kathy B. Nichols Medical Art, 2006.*)

vivo transformation of bone marrow–derived mesenchymal stem cells into myocytes in the rat has been reported.[30,31] Rather than forcing differentiation to take place in vitro prior to transplantation, it appears that stem cell transplantation, in itself, is a sufficient trigger for differentiation. The implicit assumption made is that the desired native tissue offers to the stem cell an environment rich in the signals of differentiation. Hence adult stem cells may be viewed as the primordial building blocks for selective regeneration of injured myocardium.

Multipotent tissue-specific cells that have already committed to a distinct lineage, such as hematopoietic stem cells, mesenchymal stem cells, and endothelial progenitor cells, have also produced encouraging results when used for cell-based cardiac regeneration therapy.[10] However, to date, the use of these cells often results in incomplete engraftment and a failure to restore cardiac function over time.[32]

Stem Cell Delivery Methods

Multiple methods for stem cell delivery have been investigated, including direct myocardial injection, peripheral transfusion, and/or stem cell mobilization.[33] No current study to date is available to elucidate which approach is superior, though only endocardial and epicardial injections would likely be relevant to cardiac surgeons. Both transfusion and mobilization of resident stem cells offer the least invasive means of stem cell delivery. However, this requires the availability of effective homing signals to direct the correct location for engraftment while preventing the potential for adverse engraftment in other regions (e.g., promoting tumor growth). This impediment is avoided by using direct myocardial injections, either surgically or via interventional catheter techniques (Fig. 71-3). Direct epicardial myocardial injection can be consistently completed intraoperatively during concomitant procedures (e.g., coronary arterial bypass, arrhythmia surgery, mechanical assist device implantation, and valve operations) or via minimally invasive approaches for isolated cell therapy. Direct endocardial injection will likely be accomplished by using commercially available radiographic stem cell injection catheters (Fig. 71-4). Currently, we believe that multiple stem cell injections may be required to achieve full therapeutic myocardial regeneration. As a result, the use of stem cell injection catheters may become the standard of practice following initial open chest cell injection therapy. In addition, the use of advanced imaging techniques (magnetic resonance imaging [MRI] and electromechanical catheters) will likely be used to allow for real-time image-guided smart injection (in a manner akin to guidance of "smart" bombs) at areas of identified myocardial damage. Further investigation is required to identify the best delivery method, number of cells, and treatment regimen. It is likely this information will be gleaned from ongoing clinical trials (Table 71-1) and animal experimentation.

Animal Models for Stem Cell Research

Regardless of the cell type used in cell-based therapy, it is clear that animal models will play a critical role in the translational research that will be necessary to advance this theory out of the lab and into clinical practice. Multiple animal species from rodents to humans have now been used for the study of cell-based therapy. Although many anticipate that cellular therapy will be a panacea for multiple forms of cardiovascular disease, few disease models have actually been rigorously investigated. Much of the early basic and clinical research has been conducted in acute ischemia models. However, while effective treatment options for acute ischemia do exist (thrombolytics, percutaneous transluminal coronary angioplasty, and coronary artery bypass graft

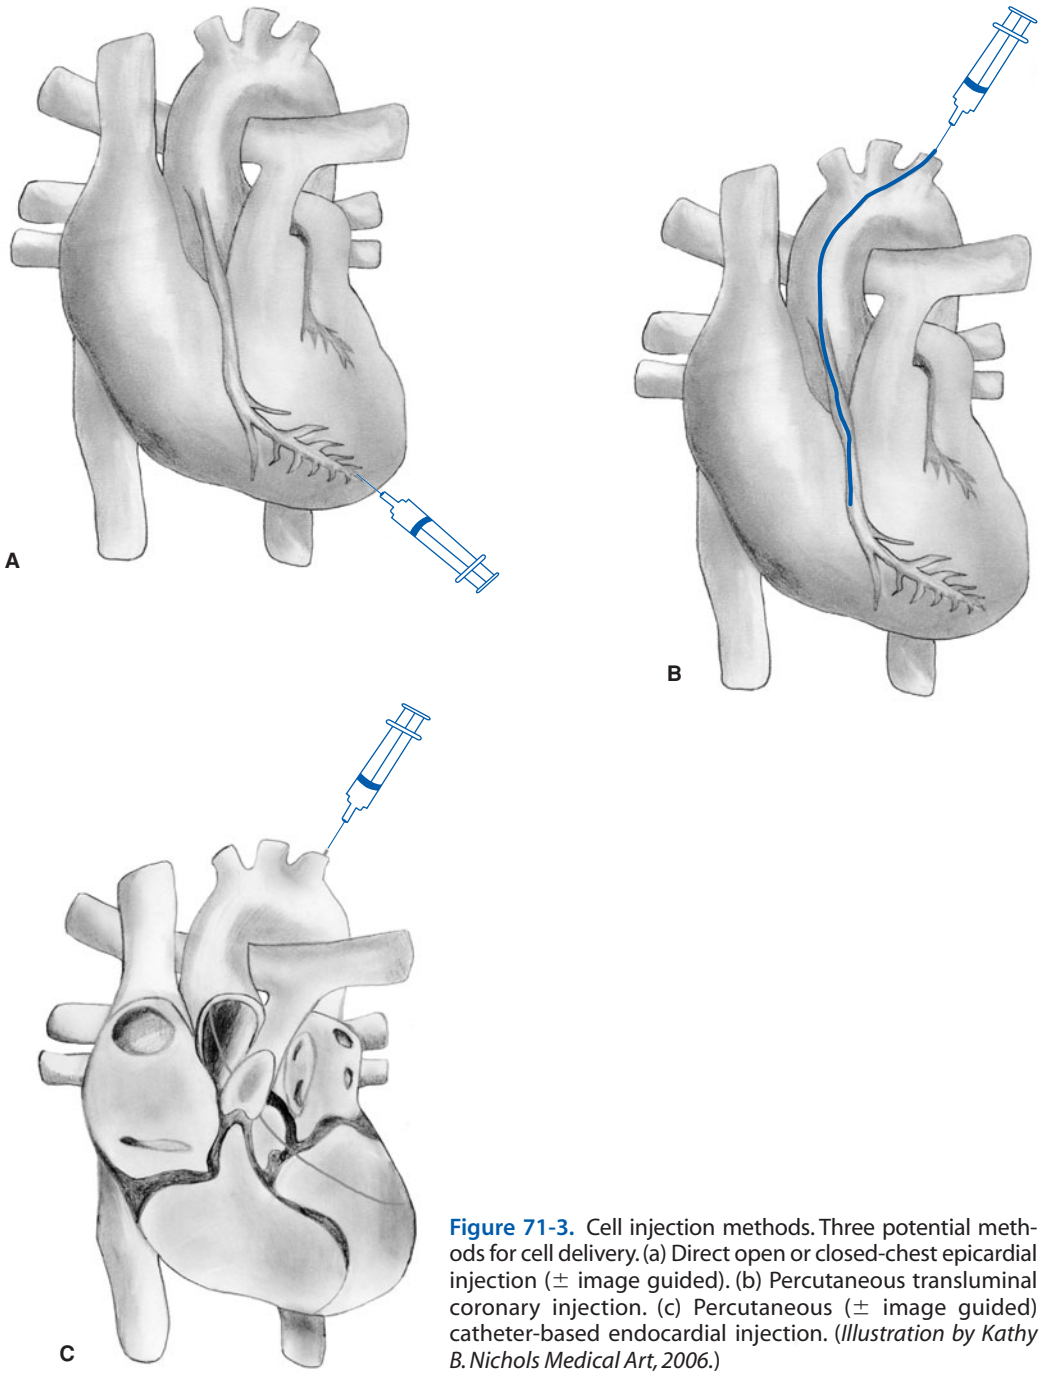

Figure 71-3. Cell injection methods. Three potential methods for cell delivery. (a) Direct open or closed-chest epicardial injection (± image guided). (b) Percutaneous transluminal coronary injection. (c) Percutaneous (± image guided) catheter-based endocardial injection. (*Illustration by Kathy B. Nichols Medical Art, 2006.*)

[CABG]), only limited options are available for chronic myocardial ischemia. This observation strongly suggests that further development of the chronic cardiovascular disease models using cell-based therapy is warranted. This observation has clearly been recognized, as numerous investigators are now incorporating cellular therapy in combination with mechanical assist device insertion.

As with most research, the experimental hypothesis will remain fundamental in choosing the correct animal model. However, the availability of appropriate stem cell lines in the desired species will add additional limitations in the field of cellular cardiovascular therapy. Full characterization of the cell lines is critical to allow for safety evaluation and is advantageous in correctly ascribing functional changes to the appropriate precursor cell. The multiple types of stem cells available for the rodent have made small-animal models effective for investigations of stem cell engraftments. However, significant differences in myocar-

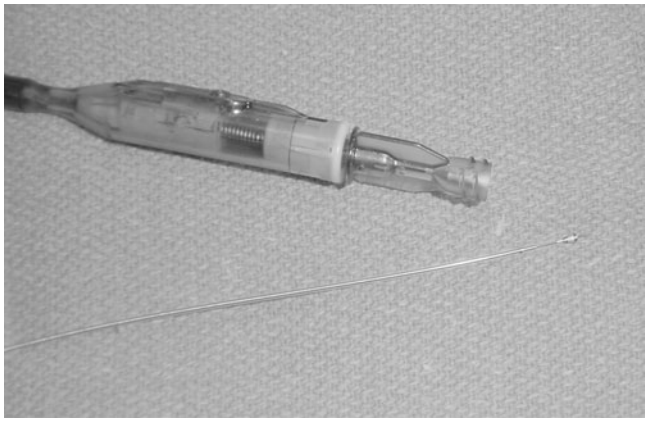

Figure 71-4. Stem cell injection catheter. (*Courtesy Boston Scientific and R. P. Gallegos.*)

dial anatomy and physiology raise serious concerns that findings may not be directly translatable to humans. Ultimately, large-animal models that better approximate the diseased human heart will be required to fully assess stem cell engraftment, differentiation, and/or functional improvement. In general, large-animal models are considered better suited for assessment of myocardial function via angiography, echocardiography, or MRI; however, the limited availability of appropriate stem cell lines for use in these models has prevented the widespread use of large-animal models.

Stem Cell Engraftment

The ability to track the implanted cell is critical not only to assess the potential of engraftment, but also for later determination of differentiation and incorporation into the native tissue. Multiple cell-labeling techniques are under investigation, including the use of viral gene transduction (e.g., green fluorescent gene and lacZ), incorporation of dyes, and the use of metallic microparticles.[34,35] Gene insertion can be fairly easily accomplished, allowing for fluorescence microscopy or quantitative polymerase chain reaction identification of the stem cell. However, the exact insertion site into the DNA of the cell cannot currently be well controlled, introducing the possibility for non-expression of the gene or potential disruption of normal cellular transcription and translation processes. The use of dyes incorporated into the cells by pinocytosis has been reported (e.g., 4,6-diamino-2-phenylindole; DAPI). The primary disadvantage of this technique has been the potential for dye incorporation into native cells in vivo. The use of metallic microparticles has received recent attention, in that such particles may allow for real-time identification of cells by MRI imaging and later pathologically by staining. However, information about the potential disruption of cellular function and possible uptake in vivo by native cells has yet to be fully elucidated.

Several clinical trials utilizing various cell types and disease models have now been completed (see Table 71-1). Unfortunately, these studies have been limited by the recovery of insufficient postimplantation tissue. This limitation is a direct result of study design—cell-based therapy in patients undergoing revascularization. Few patients having received cell therapy have experienced adverse events resulting in death. As a result, no tissue has been available for autopsy evaluation. Future studies involving end-stage CHF patients utilizing mechanical assist device implantation as a bridge to transplantation may alleviate this limitation.[36] In these patients, myocardial samples will be taken pre–cell implantation at the time of mechanical device insertion or cell injection. Similarly, post–cell-treated myocardium will be available at the time of device explantation or orthotopic heart transplantation.

Functional Assessment of Stem Cell Therapy

Numerous researchers have dedicated their efforts to demonstrating improvement in cardiac function following cell-based therapy. Each author has utilized their preferred method of assessing cardiac function. Regardless of the specific method used by any given investigator (pressure measurements, ultrasonic microcrystal placement, echocardiography, or MRI), all have been able to conclude that cell therapy positively impacts some element of cardiac function. However, long-term follow-up studies directly comparing cardiac assessment techniques specifically for the assessment of cell-based therapy do not currently exist in the literature. Therefore, no conclusions may currently be drawn regarding the superiority of any individual technique of cardiac assessment. It is the authors' opinion that cardiac MRI offers the greatest ability to follow long-term patient outcome. MRI allows for a noninvasive serial assessment of cardiac perfusion, contractility (global and regional), wall motion, infarct size, and chamber size. In addition, the use of real-time MRI may allow for precise delivery of cells using MR-safe injection catheters currently in development.[37] Finally, the use of metallic microparticles, as mentioned above, may allow for cell tracking following cell injection.[34,35] Drawbacks to MRI of course do exist, including the inability to scan patients with newly implanted pacemaker leads and other prohibitive patient contraindications to MRI. More research and further refinements in measurement techniques will likely offer additional strategies that will ultimately be universally applicable.

Mechanism of Myocardial Repair Following Cell Therapy

The concept of myocardial cellular therapy was originally conceived based on the example set by the success of whole organ transplantation—replace what has been lost. However, with the need for whole organ transplantation far exceeding the organs available for donation (see Fig. 71-1),

Table 71–1.

Cell Therapy Clinical Trials, 2001–2005

	Cell source	Delivery	(n)	(Months)	Inclusion criteria	Outcome
Hamano et al[92]	Mononuclear BMCs	IM injection/CABG	5	12	Old MI; no revascularization	↑ perfusion (3/5 pts)
Stamm et al[83]	AC133 bone marrow cells	IM injection/CABG	12	3–9	MI >10 d and <3 mo	↑ EF (4/6 pts), perfusion (5/6 pts)
Strauer et al[80]	Mononuclear BMCs	IC infusion/PTCA	10	3	5–9 days post-MI	↓ Infarct region size ↑ Wall motion/perfusion
Assmus et al[82]	Mononuclear BMCs cultured blood–derived EPCs	IC infusion/PTCA	20	4	<3 days post-MI	↑ LVEF, EDV, perfusion, contractile function
Tse et al[84]	Mononuclear BMCs	Percutaneous IM injection electromechanical mapping	8	3	Severe ischemic heart disease	↓ Anginal symptoms ↑ Perfusion, contractile function
Perin et al[89]	Mononuclear BMCs	Percutaneous IM injection electromechanical mapping	14	2	CHF	↑ LVEF, perfusion, contractile function
Wollert et al[90]	BMCs	IC infusion/PTCA	30	6	<5 days post-MI	↑ LVEF and contractile function
Chen et al[91]	BMSCs	IC infusion 18 days post-PTCA	34	3–6	10 days post-MI	↑ Perfusion, ventricular EDV/ESV, wall movement, and LVEF
Menasche et al[93]	Skeletal myoblasts	IM injection/CABG	10	10.9	CHF	↑ LVEF, contractile function
Menasche et al[93]	Skeletal myoblasts	IM injection/CABG 3 months	12	10.9	Old MI; ischemic CAD	↑ LVEF, contractile function
Pagani et al[87]	Skeletal myoblasts	IM injection/LVAD implant	5	2.25–6.3	Ischemic cardiomyopathy; refractory CHF	Development of myotubes in scarred MI
Smits et al[88]	Skeletal myoblasts	Percutaneous IM injection/ electromechanical mapping	5	6	Ischemic heart failure	↑ LVEF, wall thickening
Kang et al[78]	Peripheral blood SC IV G-CSF	IC infusion after PTCA	10	6	Acute MI (>48 hours) or old MI	↑ in-stent restenosis after G-CSF

↓ = decreased; ↑ = increased; BMC = bone marrow cell; BMSC = bone marrow stem cell; CABG = coronary artery bypass graft; CAD = coronary artery disease; CHF = congestive heart failure; EDV = end-diastolic volume: EF = ejection fraction; EPC, endothelial progenitor cell; ESV = end-systolic volume; G-CSF = granulocyte colony-stimulating factor; IC = intracoronary; IM, intramuscular; LVAD = left ventricular assist device; LVEF = left ventricular ejection fraction; MI = myocardial infarction; PTCA = percutaneous transluminal coronary angioplasty; pts = patients.

the goal of cell-based therapy is to restore cardiac function by the replacement of only the sections of dead myocardium. Here the replacement of lost myocytes would be accomplished by the implantation of a population of readily available cells that integrate into the existing matrix and provide synchronized contractile activity.[38] To date, both animal and human studies have been reported demonstrating improvement in various parameters of heart function in support of this goal. However, the means by which cellular transplantation has provided this benefit to cardiac function remains unclear and hotly debated.[39] A significant problem in understanding the mechanism is undoubtedly related to the limited ability to track implanted cells. No universally reliable technique has thus far allowed tracking of implanted cells, particularly in human trials. Furthermore, as mentioned previously, limited tissue has been available for engraftment studies.

The implantation of adult and fetal cardiomyocytes has been attempted experimentally, with limited success. In these instances, cellular replacement would require only engraftment and integration into the conglomerate contractile apparatus to potentially repair the damaged myocardium. This is not the case for naïve stem cells, which have been intently used for myocardial cell transplantation. In this scenario, implanted stem cells (e.g., embryonic, bone marrow, or skeletal stem cells) would require not only engraftment and integration, but also, most importantly, transdifferentiation into cardiomyocytes. Chiu proposed the notion that transdifferentiation could result from some unknown signaling process commenced by exposure to the local milieu present in the region of injured myocardium.[40,41] This concept does have some support from studies following cardiac transplantation in sex-mismatched pairs where the presence of integrated cardiomyocytes of recipient origin has been identified, presumably following engraftment of circulating stem cells or resident stem cells.[11,12] The importance of the local milieu was highly suggestive, if one considers that the number of engrafted recipient cells increased with the greater incidence of donor organ rejection. This observation emphasized the requirement for myocardial injury as a strong factor involved in the recruitment and engraftment of stem cells.

Several in vitro and in vivo studies exist in the literature that support the hypothesis of the transdifferentiation of stem cells into cardiomyocytes.[28,31,42] At the bench, various forms of bone marrow–derived stem cells (e.g., hematopoietic stem cells, bone marrow mesenchymal stem cells, and multipotent adult progenitor cells) have been successfully induced into a cardiomyocyte phenotype.[43–45] Animal studies using injected cultured stem cells or mobilized stem cells (induced by stem cell factor treatment) have demonstrated rapid regeneration of myocardium, the first being reported by Orlic and colleagues.[31,42,46] In this seminal effort, the expression of cardiomyocyte-specific genes in labeled implanted stem cells was strongly suggestive for integration of the implanted cells with the host myocardium and supported the potential for synchronous contraction. Since the publication of this report, numerous preclinical and clinical trials have demonstrated myocardial repair and regeneration.

Unfortunately, the number of engrafted cells following injection is typically insufficient to account for the degree of improvement in myocardial function. Furthermore, the mere presence of cardiomyocyte-specific gene products alone is insufficient evidence that the transplanted cells actually regenerate myocardium that electromechanically integrates with host myocardium. Finally, the concept of transdifferentiation itself has been called into question. Opponents point to reports demonstrating stem cell fusion with native parenchymal cells, producing a hybrid cell containing both stem cell and myocyte-specific markers, accounting for prior observation of supposed "neomyogensis."[47–49] Additional negative evidence has recently been offered by recent independent reports where the transdifferentiation of bone marrow stem cells into cardiomyocytes did not occur after implantation.[50–52] The credence of current evidence does not fully support the concept of stem cell transdifferentiation, although sufficient evidence does not exist to dispel this concept. In addition, it is not clear that the observed improvement in cardiac function is the direct consequence of electromechanical integration of the implanted cell. This is certainly the case with skeletal myoblast therapy, in which cell injection results in the formation of isolated skeletal myotubes within the scar. Although the myotubes remain electrically and functionally isolated from the host myocardium, both preclinical and clinical trials have provided documented improvement in cardiac function.[51,53–55]

Alternative Mechanisms of Repair

The lack of absolute evidence to support transdifferentiation of implanted cells into myocytes as the sole mechanism, or even one of the mechanisms, for the observed functional improvement in cardiac function has spawned ongoing interest in both preclinical and clinical research. Regardless of the direct contribution of the injected cells to myocyte mass, it is clear that cellular transplantation results in neomyogenesis, neoangiogenesis, and alterations in ventricular remodeling.[40,56–60]

Recent work has suggested that the mechanisms of cellular therapy may involve cytokines and growth factor–mediated endogenous stem cell mobilization, improved homing of stem cells to sites of injury, and induction of antiapoptotic pathways.[61,62] All mechanisms may contribute to an overall increase in functional myocardial mass salvage in the area of injury. Release of these factors may occur systemically or locally at the site of injury both from and as a result of cellular transplantation. In addition, some have theorized that observed cell fusion could be responsible for the release of factors. Research involving infusion of pharmacologic agents with anti-apoptotic properties (e.g., ursodeoxycholic acid [bear bile]) suggests improvement in survival of ischemically damaged cardiomyocytes, supporting this mechanism. The exact contribution of these mechanisms to the overall effect of cellular therapy remains to be elucidated.

Induction of neovascularization, a crucial component of cellular therapy, is mediated by both cytokine release and potentially by direct cellular contribution of endothelial progenitors, as has been observed following bone marrow stem cell therapy.[10,63,64] Increased angiogenesis provides not only the potential for improved perfusion in the region of myocardial injury, but may also prevent myocyte apoptosis and maladaptive remodeling of the myocardial matrix.[40,57,63,65] Overall, neovascularization could improve cardiac function by preventing cell loss and ventricular dilatation while also recruiting hibernating myocardium. Both preclinical and clinical studies using bone marrow–derived stem cell injections following MI support this theory, with documented increased capillary density in conjunction with an improvement of myocardial contractility.[66,67]

In addition to improved myocardial perfusion, cellular therapy appears to be an integral factor in the preservation of the integrity of the extracellular matrix (ECM) following myocardial injury. Myocyte loss results not only from the initial acute ischemic injury, but also from degradation and maladaptive remodeling of the ECM. As a result, disruption of the matrix network impairs support for heart cells, leading to further cell loss and ventricular dilatation, ultimately culminating in CHF.[57,68,69] Cellular transplantation may prevent ECM degradation or may induce the restoration of the ECM, or a combination of both scenarios. This may result from direct secretion of new matrix elements by the injected cells or by secretion of cytokines that result in activation of the biochemical cascades ultimately responsible for ECM stabilization.[53,70–72] In any event, stabilization of the ECM provides structural support for host heart cells, limiting infarct expansion and improving regional ventricular compliance and function.[57,73–75] Numerous reports offer evidence of a beneficial effect following cellular therapy on the ECM, not only in the infarct zone but also in regions of normal myocardium.[57] Functional improvement has been reported following the injection of various types of cells, in spite of a lack of a complete understanding of the true mechanism by which stem cells improve cardiac function. Certainly much more additional investigation at the bench side and bed side is required before the true mechanism is elucidated.

CLINICAL TRIALS IN CELLULAR THERAPY

Scattered individual case reports of patients receiving "cell injections" rapidly appeared in the literature following positive reports in preclinical animal studies.[76–78] This rapid transition of bench-side research into the clinical realm was felt to be justified based on the need for a broadly applicable approach to counteract the ever-increasing incidence of CHF following MI. Though numerous authors reported significant improvement in cardiac function, most of these case studies were severely limited, being confounded by concomitant revascularization and poor characterization of the injected cells. Furthermore, follow-up periods were short and conclusions regarding improvement in cardiac function were based on a variety of clinical nonstandardized end points.

Despite the questionable validity of these preliminary case reports, interest in cellular therapy has steadily increased. The first results from an organized human cellular therapy trial were reported by Menasche and colleagues.[79] Since its publication in 2001, 13 trials involving over 170 enrolled patients have been reported (see Table 71-1) and are discussed in the remainder of this section. As with the animal trials that proceeded, various cell delivery methods, cell types, disease states, and cardiac function assessment methods were utilized in these preliminary phase I feasibility trials (Table 71-2).[78,80–93] Again, all trials supported the feasibility of cell therapy, indicating a positive impact on cardiac function after cell implantation.

Despite the positive conclusions, the strength of many of the authors' conclusions has been questioned due to the potential confounders associated with concomitant revascularization and by the absence of appropriate randomized, double-blind, placebo-controlled experimental protocols. In addition, the potential for serious adverse sustained tachycardia (primarily with skeletal myoblasts) raised significant safety concerns. Although preliminary trials are encouraging, the technique remains in its infancy with little known of the true mechanism associated with improved cardiac function. Significant research is still required to ultimately elucidate the mechanisms of repair and overall long-term results of cell therapy. Clinical trials will undoubtedly assist with

Table 71–2.

Summary of Cell Therapy Clinical Trial Models

Cell delivery method	Cell type	Disease state
Direct epicardial injection	Skeletal myoblasts	Acute myocardial infarction
Percutaneous endocardial intramyocardial injection ± image or NOGA-catheter–guided	Peripheral blood stem cells	Chronic congestive heart failure
Intracoronary infusion with angioplasty	Bone marrow stem cells	

**NOGA Cardiac Guidance System, Biosense Webster, Inc., Diamond Bar, California.*

this endeavor and will answer additional important questions that include (but are not limited to) the identification of the appropriate candidates for cell therapy, and to assess for the appropriate cell type, number, and route of delivery. Only then will the expected benefits and potential side effects be thoroughly appreciated.

Skeletal Myoblast Trials

Skeletal myoblasts (SMs) are primordial cells that are precursors to skeletal myocytes. These cells can be obtained readily by small biopsy of peripheral skeletal muscle and can be expanded by in vitro culture to obtain an adequate number of cells for use in cellular therapy.[94] The first patients to be involved in human cellular therapy trials received direct epicardial SM injections following MI. In this pivotal trial, Menasche and associates injected autologous SMs into a segment of non-revascularizable, nonviable infarcted myocardium in 10 patients with ischemic heart failure who were undergoing planned CABG.[93] At the end of the 11-month follow-up period, all patients demonstrated an improvement in the New York Heart Association functional class and left ventricular ejection fraction (LVEF) with an associated increased viability of the grafted scar. No immediate perioperative deaths were reported, with only one late death occurring secondary to stroke more than a year after transplant. Most concerning was the development of sustained ventricular tachycardia in four patients. These results were supported by Herreros and coworkers, demonstrating similar improvements in cardiac function by 3 months following injection in 12 patients undergoing CABG after MI.[85] Here only 1 of 12 patients developed a nonsustained ventricular tachycardia. Both trials suffered significantly from the inability to rigorously evaluate the cell-treated region, as little tissue was available for pathologic review.

This problem was ameliorated by Pagani and associates who injected SMs in five patients undergoing left ventricular assist device (LVAD) implantation for severe ischemic cardiomyopathy and refractory heart failure.[87] Following explantation of the hearts, histologic evaluation demonstrated the formation of viable islands of muscle grafts in the scarred myocardial tissue where SM injection was performed. Again, 3 of 5 patients experienced documented ventricular tachyarrhythmias. Nonsurgical catheter-based percutaneous injection of SMs have also been successfully accomplished in humans. Using this technique, mapping of damaged regions of myocardium can be performed, allowing for precisely guided injection of cells using stem cell injection catheters. Smits and colleagues treated five patients with ischemic CHF after MI in this fashion, injecting SMs using a catheter-based endocardial approach.[88] On follow-up 6 months after treatment, imaging demonstrated improved myocardial wall thickening within the injection region and an overall improvement in LVEF. As seen with the open surgical technique, 1 of 5 patients developed nonsustained ventricular tachycardia, reflecting that the cell injection and not technique was likely responsible for the dysrhythmia. In summary, these early feasibility trials in humans supported the potential efficacy of SM-based cellular therapy. Importantly, the LVAD trial conducted by Pagani identified the ideal initial candidates for future trials. Critical histologic data not previously obtainable with outpatient death are possible now for the entire heart following heart transplantation rather than relying on small tissue biopsies. The trials have not yet provided data supportive of any apparent obvious superiority of one delivery method over another. Most concerning, the trials also raised serious safety concerns with regard to the induction of severe ventricular arrhythmias, necessitating the use of antiarrhythmics or automated implantable defibrillators.

Blood- and Bone Marrow–Derived Stem Cell Trials

Shortly after the reports of success with SM injection, bone marrow– and blood-derived stem cells were explored as a new potential cell source. The first group trial was reported by Hamano and colleagues, who performed autologous mononuclear bone marrow cell injection in 5 patients undergoing CABG.[81] One year following cell injection, 3 of 5 patients demonstrated improved perfusion in the region of injury. Benefit to cardiac function was suggested by Strauer and Assmus and their coworkers (Transplantation of Progenitor Cells and Regeneration Enhancement in Acute Myocardial Infarction; TOPCARE-AMI), who performed separate nonrandomized trials of autologous cell injection with concomitant percutaneous transluminal coronary angioplasty for recent acute ST-elevation myocardial infarction (MI).[80,82] Strauer infused autologous bone marrow mononuclear cells (n = 10 patients), while Assmus evaluated the use of either autologous circulating blood-derived or bone marrow–derived progenitor cells (n = 20 patients). All patients were evaluated 3 to 4 months post–cell infusion and were compared with matched historical control patients. Cell infusion was associated with a reduction in infarct size and left ventricular end-systolic volume, and was coupled with an improvement in myocardial perfusion and contractility (global and regional). The TOPCARE-AMI trial offered additional conclusions regarding the need for exact stem cell characterization. In this trial, serial contrast-enhanced MRI and ex vivo migratory capacity assay of the implanted cells confirmed that implantation of cells with high migratory capacity was associated with higher beneficial effects on infarct size and left ventricular remodeling.[95] Importantly, no death was directly attributed to cell injection. No significant morbidity attributable to arrhythmia was reported.

The use of bone marrow– and blood-derived stem cells has also been explored in patients with chronic cardiac disease. Tse and colleagues offered cell therapy to eight patients with stable refractory angina.[84] Patients in this trial received autologous bone marrow mononuclear

cells via percutaneous catheter-based myocardial injections guided by electromechanical mapping. Consistent with the trials completed in the acute MI series, patients demonstrated increased myocardial perfusion and contractility, and reported reduced anginal episodes and nitroglycerin usage by 3-months' follow-up. No adverse events were reported, suggesting a higher degree of relative safety compared with SM injection. However, this conclusion was questioned by Perin and associates, who conducted a similar trial, treating patients (n = 14) with severe chronic ischemic heart failure with autologous mononuclear cells.[89] Cell injection resulted in improved cardiac function at the 4-month evaluation consistent with prior studies; however, one fatality was attributed to sudden cardiac death.

Unlike SMs, blood- and bone marrow– derived stem cells can be mobilized using drug infusion with stem cell colony-stimulating factors. Kang and coworkers randomized patients (n = 27) with MI who underwent percutaneous transluminal coronary intervention into three experimental groups to determine if there was any benefit to granulocyte colony-stimulating factor with or without intracoronary infusion of peripheral blood stem cells compared to the control percutaneous coronary intervention group.[78] At the 6-month follow-up, a high rate of in-stent restenosis was observed in patients who received granulocyte colony-stimulating factor.

Success achieved with initial trials was encouraging and ultimately led to the first true randomized controlled trial examining the safety and efficacy of cell therapy for acute ST-elevation MI, completed by Wollert and colleagues.[90] Patients (n = 60) included in the BOOST trial (Bone Marrow Transfer to Enhance ST-Elevation Infarct Regeneration) were randomized to primary percutaneous intervention with or without intracoronary infusion of autologous bone marrow cells. At the 6-month follow-up, no adverse events were reported. All patients were followed with cardiac MRI, which demonstrated significant improvement in LVEF in the cell treatment group (from 50 to 56.7%) compared to the control group (from 51.3 to 52%). To further explore the conclusions drawn from the BOOST trial, Chen and colleagues randomized patients (n = 69) undergoing primary percutaneous coronary intervention after acute MI to receive intracoronary infusion of autologous bone marrow–derived mesenchymal stem cells or cell-free saline injection.[91] At the 3-month follow-up, patients having received cell therapy were noted to have a greater improvement in LVEF, myocardial perfusion, and wall motion relative to the saline-treated group.

The initial available data involving blood- and bone marrow–derived stem cell therapy are encouraging and should pave the way for larger phase II/III trials aimed at assessing when, how, and to whom cells should be delivered after MI. These future trials will address safety concerns including postimplantation incidence of severe ventricular arrhythmias, though current studies would suggest this to be less concerning with these types of stem cells.

FUTURE DIRECTIONS

Significant translation of bench research in cellular therapy into clinical trials has occurred, offering the cardiovascular physician a new weapon in the armamentarium for prevention and treatment of myocardial injury. Numerous reports in both preclinical and clinical studies demonstrate that cellular therapy is safe and may be efficacious as a treatment option to treat both acute and chronic myocardial injury. Although specific safety concerns remain related to induction of clinically relevant ventricular arrhythmias, preliminary clinical trials suggest that cellular therapy may be routinely engaged for the treatment of myocardial injury with the ultimate goal of prevention of end-stage cardiac failure. Several questions remain to be evaluated, including identification of the ideal cell type or types, the exact cell dose, timing and number of treatments, and most importantly, careful determination of each of these variables as they relate to specific disease states. Certainly both the type (acute versus chronic) and severity of disease will dictate the overall treatment protocol. Additional research is required not only in clinical trials, but also at the bench side to determine the exact mechanism by which cellular therapy improves cardiac function. Cellular therapy likely induces neoangiogenesis, neomyogenesis, anti-apoptotic pathways, and stabilization of the ECM—all contributing to improved cardiac function. Once the specific mechanisms are identified, either the use of purified cytokines or genetic manipulation of the injected cells may add further efficacy while providing an increase in safety by minimizing or eliminating the use of cellular injection itself.
