CARDIAC SURGERY IN THE ADULT

Cardiac Surgery in the Adult

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Cardiac Surgery in the Adult

THIRD EDITION

Lawrence H. Cohn, MD
Virginia and James Hubbard Professor of Cardiac Surgery
Harvard Medical School
Division of Cardiac Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Contributors

Tarek S. Absi, MD
Instructor, Department of Cardiac Surgery, Vanderbilt Heart Institute, Vanderbilt University Medical Center, Nashville, Tennessee
Mitral Valve Replacement

Michael A. Acker, MD
William Maul Measey Professor of Surgery, Department of Surgery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Ischemic Mitral Regurgitation

Sanjeev Aggarwal, MD
Professor of Medicine, Department of Cardiothoracic Surgery, University of Louisville, Louisville, Kentucky
Long-Term Mechanical Circulatory Support

Arvind K. Agnihotri, MD
Instructor in Surgery, Division of Cardiac Surgery, Department of Surgery, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts
Surgical Treatment of Complications of Acute Myocardial Infarction: Postinfarction Ventricular Septal Defect and Free Wall Rupture

Rashid M. Ahmad, MD
Assistant Professor of Cardiac Surgery, Director, Cardiovascular Intensive Care Unit, Director, Cardiac Surgery Infomatics, Department of Cardiac Surgery, Vanderbilt Heart Institute, Vanderbilt University Medical Center, Nashville, Tennessee
Reoperative Valve Surgery

Cary W. Akins, MD
Clinical Professor of Surgery, Harvard Medical School, Visiting Surgeon, Department of Cardiac Surgery, Department of Surgery, Massachusetts General Hospital, Boston, Massachusetts
Myocardial Revascularization with Carotid Artery Disease

Michelle A. Albert, MD, MPH
Assistant Professor, Department of Medicine, Harvard Medical School, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts
Preoperative Evaluation for Cardiac Surgery

Robert H. Anderson, MD
Professor, Institute of Child Health and Great Ormand Street Hospital for Children, University College London, London, United Kingdom
Surgical Anatomy of the Heart

Mark P. Anstadt, MD
Associate Professor of Surgery, Department of Surgery, Wright State University School of Medicine, Medical Director, Cardiovascular Surgery, Miami Valley Hospital, Dayton, Ohio
Cardiopulmonary Resuscitation

Elliott M. Antman, MD
Professor of Medicine, Harvard Medical School, Director, Samuel A. Levine Cardiac Unit, Division of Cardiovascular Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Preoperative Evaluation for Cardiac Surgery

Sary F. Aranki, MD
Associate Professor of Surgery, Harvard Medical School, Division of Cardiac Surgery, Brigham and Women's Hospital, Boston, Massachusetts
Mitral Valve Replacement

James M. Bailey, MD, PhD
Associate Professor, Director, Critical Care Service, Department of Anesthesiology, Emory University School of Medicine, Atlanta, Georgia
Cardiac Surgical Pharmacology

Contributors

Donald S. Baim, MD
Executive Vice-President, Chief Medical Officer, Boston Scientific Corporation, Boston, Massachusetts
Percutaneous Aortic Valve Interventions; Percutaneous Catheter-Based Mitral Valve Repair

Jorge M. Balaguer, MD
Assistant Professor of Cardiac Surgery, Department of Cardiac Surgery, Vanderbilt Heart Institute, Vanderbilt University Medical Center, Chief of Cardiac Surgery, Department of Veteran's Affairs Medical Center, Nashville, Tennessee
Reoperative Valve Surgery

William A. Baumgartner, MD
Johns Hopkins Medicine, Baltimore, Maryland
Heart Transplantation

Joseph E. Bavaria, MD
Department of Surgery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Trauma to the Great Vessels

Steven F. Bolling, MD
University of Michigan Hospital, Ann Arbor, Michigan
Nontransplant Surgical Options for Heart Failure

R. Morton Bolman, III, MD
Chief, Division of Cardiac Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Ascending Aortic Aneurysms; Stem Cell-Induced Regeneration of Myocardium

Derek R. Brinster, MD
Medical College of Virginia, Richmond, Virginia
Ascending Aortic Aneurysms

Morgan L. Brown, MD
Department of Surgery, St. Boniface General Hospital, University of Manitoba, Clinical and Translational Research PhD Program, Mayo Clinic Graduate School, Winnipeg, Canada
Indications for Revascularization

John G. Byrne, MD
Chairman of Cardiac Surgery, William S. Stoney Professor of Surgery, Department of Cardiac Surgery, Vanderbilt Heart Institute, Vanderbilt University Medical Center, Nashville, Tennessee
Reoperative Valve Surgery

Richard P. Cambria, MD
Professor of Surgery, Harvard Medical School, Chief, Division of Vascular and Endovascular Surgery, Massachusetts General Hospital, Boston, Massachusetts
Myocardial Revascularization with Carotid Artery Disease

Faisal H. Cheema, MD
Associate Research Scientist, Department of Cardiothoracic Surgery, Columbia-Presbyterian Medical Center, Columbia University College of Physicians & Surgeons, New York Presbyterian Hospital, New York, New York
Long-Term Mechanical Circulatory Support

Frederick Y. Chen, MD
Associate Surgeon, Director, Cardiac Surgery Research Laboratory, Division of Cardiac Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Cardiac Surgical Imaging; Nonischemic Mitral Valve Repair

Albert T. Cheung, MD
Department of Surgery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Cardiac Anesthesia

W. Randolph Chitwood, MD
Department of Surgery, East Carolina University School of Medicine, Greenville, North Carolina
Minimally Invasive and Robotic Mitral Valve Surgery

George T. Christakis, MD
Sunnybrook Health Science Center, Toronto, Canada
Bioprosthetic Aortic Valve Replacement: Stented Pericardial and Porcine Valves

Lawrence H. Cohn, MD
Virginia and James Hubbard Professor of Cardiac Surgery, Harvard Medical School, Division of Cardiac Surgery, Brigham and Women's Hospital, Boston, Massachusetts
Minimally Invasive Aortic Valve Replacement; Nonischemic Mitral Valve Repair

John V. Conte, MD
Associate Director, Division of Cardiac Surgery, Associate Professor of Surgery, Director of Heart and Lung Transplantation, Johns Hopkins Hospital, Baltimore, Maryland
Heart Transplantation

Joseph S. Coselli, MD
Professor and Chief, Division of Cardiothoracic Surgery, Michael E. Debakey Department of Surgery, Baylor College of Medicine, Chief, Adult Cardiac Surger, Texas Heart Institute, Chief, Adult Cardiac Surgery Section, Associate Chief, Cardiovascular Surgery Services, St. Luke's Episcopal Hospital, Houston, Texas
Descending and Thoracoabominal Aortic Aneurysms

Willard M. Daggett, Jr., MD
Department of Surgery, Massachusetts General Hospital, Boston, Massachusetts
Surgical Treatment of Complications of Acute Myocardial Infarction: Postinfarction Ventricular Septal Defect and Free Wall Rupture

Ralph J. Damiano, Jr., MD
John M. Shoenberg Professor of Surgery, Department of Surgery, Division of Cardiothoracic Surgery, Washington University School of Medicine, St. Louis, Chief of Cardiac Surgery, Barnes-Jewish Hospital, St. Louis, Missouri
Surgical Treatment of Atrial and Ventricular Fibrillation

Tirone E. David, MD
Head, Director of Cardiovascular Surgery, Melanie Munk Chair of Cardiovascular Surgery, Professor of Surgery, University of Toronto, Toronto General Hospital, Toronto, Canada
Aortic Valve-Sparing Operations; Surgical Treatment of Aortic Valve Endocarditis

Michael J. Davidson, MD
Instructor in Surgery, Division of Cardiac Surgery, Harvard Medical School, Brigham and Women's Hospital, Boston, Massachusetts
Percutaneous Aortic Valve Interventions; Percutaneous Catheter-Based Mitral Valve Repair

William J. DeBois, MBA, CCP
Chief Perfusionist, Department of Cardiothoracic Surgery, Weill Medical College, New York Presbyterian Hospital of Cornell University, Huntington, New York
Transfusion Therapy and Blood Conservation

Nimesh D. Desai, MD
Cardiac Surgery Resident, Division of Cardiac Surgery, Sunnybrook and Women's College Health Sciences Center, Cardiac Surgery Program, University of Toronto, Toronto, Canada
Bioprosthetic Aortic Valve Replacement: Stented Pericardial and Porcine Valves

Todd M. Dewey, MD
Surgical Director, Heart Transplant and Medical Assist of Device and Technology, Department of Cardiothoracic Surgery, Medical City Dallas Hospital, Cardiopulmonary Research Science and Technology Institute (CRSTI), Dallas, Texas
Myocardial Revascularization without Cardiopulmonary Bypass

Verdi J. DiSesa, MD
Chief, Section of Cardiac Surgery, The Chester County Hospital, West Chester, Pennsylvania
Valvular and Ischemic Heart Disease

Samuel Jerome Durham, MD, FACS, FACC
Associate Professor of Surgery, Chief, Division of Cardiothoracic Surgery, Medical University of Ohio, Toledo, Ohio
Late Complications of Cardiac Surgery

Robert E. Eckart, MD
Cardiac Arrhythmia Service, Cardiovascular Division, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Interventional Therapy for Atrial and Ventricular Arrhythmias

Fred H. Edwards, MD
Professor of Surgery and Chief, Division of Cardiothoracic Surgery, University of Florida, Jacksonville, Florida
Risk Stratification and Comorbidity

Ann M. Emery, RN
Department of Cardiovascular and Thoracic Surgery, Regions Hospital, St. Paul, Minnesota
Aortic Valve Replacement with a Mechanical Cardiac Valve Prosthesis

Robert W. Emery, Jr., MD
Director of Cardiovascular Research, Head, Division of Cardiovascular and Thoracic Surgery, St Joseph's Hospital, Cardiac Surgical Associates, St. Paul, Minnesota
Aortic Valve Replacement with a Mechanical Cardiac Valve Prosthesis

Maurice Enriquez-Sarano, MD, FACC, FAHA
Professor of Medicine, Mayo School of Medicine, Consultant, Cardiovascular Diseases and Internal Medicine, Mayo Clinic, Rochester, Minnesota
Principles and Practice of Echocardiography in Cardiac Surgery

Laurence M. Epstein, MD
Associate Professor of Medicine, Harvard Medical School, Chief, Arrhythmia Service, Division of Cardiovascular Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Interventional Therapy for Atrial and Ventricular Arrhythmias

Volkmar Falk, MD, PhD
Department of Cardiac Surgery, Heart Center, Leipzig University School of Medicine, Leipzig, Germany
Minimally Invasive Myocardial Revascularization

James I. Fann, MD
Associate Professor, Department of Cardiothoracic Surgery, Stanford University School of Medicine, Stanford University Medical Center, Cardiac Surgery Section, VA Palo-Alto Heath Care System, Stanford, California
Pathophysiology of Mitral Valve Disease

R. Saeid Farivar, MD
Instructor in Surgery, Harvard Medical School, Division of Cardiac Surgery, Brigham and Women's Hospital, Boston, Massachusetts
Cardiac Surgical Physiology

Contributors

Suellen P. Ferraris, PhD
Research Assistant Professor, Department of Surgery, University of Kentucky Chandler Medical Center, Lexington, Kentucky
Risk Stratification and Comorbidity

Victor A. Ferraris, MD, PhD
Tyler Gill Professor and Chief, Division of Cardiothoracic Surgery, Co-Director, Linda and Jack Gill Heart Institute, University of Kentucky Chandler Medical Center, Lexington, Kentucky
Risk Stratification and Comorbidity

O. H. Frazier, MD
Tenured Professor, Department of Surgery, University of Texas Health Science Center at Houston, Director, Cardiovascular Surgical Research, Chief, Cardiopulmonary Transplantation, Texas Heart Institue, Chief, Transplan Service, Active Staff, Cardiovascular Surgery Service, St. Luke's Episcopal Hospital, Houston, Texas
Total Artificial Heart

Robert P. Gallegos, MD
Fellow, Division of Cardiac Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Stem Cell-Induced Regeneration of Myocardium

Rose B. Ganim, MD
Resident, Division of Thoracic Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Postoperative Care of Cardiac Surgery Patients

Isaac George, MD
Surgical Research Fellow, Department of Surgery, Columbia University College of Physicians and Surgeons, New-York Presbyterian Hospital, Columbia University Medical Center, New York, New York
Myocardial Revascularization after Acute Myocardial Infarction

Bernard J. Gersh, MD, ChB, PhD
Professor of Medicine, Mayo Medical School, Rochester, Minnesota
Indications for Revascularization

A. Marc Gillinov, MD
Staff Surgeon, Surgical Director of the Center for Atrial Fibrillation, Department of Thoracic and Cardiovascular Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio
Surgical Treatment of Mitral Valve Endocarditis

Thomas G. Gleason, MD
Co-Director, The Center for Heart Valve Disease, Director, The Center for Thoracic Aortic Disease, University of Pittsburgh Medical Center (UPMC), Pittsburgh, Pennsylvania
Trauma to the Great Vessels

Donald D. Glower, MD
Professor of Surgery and Biomedical Engineering, Department of Surgery, Duke University Medical Center, Durham, North Carolina
Left Ventricular Aneurysm

Jeffrey Philip Gold, MD, FACS, FACC
Senior Vice President for Medical Affairs, Dean of the College of Medicine, Medical University of Ohio in Toledo, Toledo, Ohio
Late Complications of Cardiac Surgery

Enrique Góngora, MD
Chief Resident of Cardiothoracic Surgery, Division of Cardiovascular Surgery, Mayo Clinic, Rochester, Minnesota
Myocardial Revascularization with Cardiopulmonary Bypass

G. V. Gonzalez-Stawinski, MD
Associate Staff, Department of Thoracic and Cardiovascular Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio
Coronary Artery Reoperations

Joseph H. Gorman, III, MD, PhD
Assistant Professor of Surgery, Department of Surgery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Ischemic Mitral Regurgitation

Robert C. Gorman, MD
Assistant Professor of Surgery, Department of Surgery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Ischemic Mitral Regurgitation

James P. Greelish, MD
Assistant Professor of Cardiac Surgery, Director of Research and Education for the Department of Cardiac Surgery, Vanderbilt Heart Institute, Vanderbilt University Medical Center, Nashville, Tennessee
Reoperative Valve Surgery

G. Randall Green, MD
Attending Surgeon, Department of Cardiothoracic Surgery, St. Joseph's Hospital Health Center, Rochester, New York
Aortic Dissection

Igor D. Gregoric, MD
Associate Director, Cardiovascular Surgical Research, Director, Mechanical Circulatory Support, Texas Heart Institute at St. Luke's Episcopal Hospital at The Houston, Texas
Total Artificial Heart

Randall B. Griepp, MD
Professor of Cardiothoracic Surgery, Department of Cardiothoracic Surgery, Mount Sinai Medical Center, New York, New York
Anuerysms of the Aortic Arch

Bartley P. Griffith, MD
Professor of Surgery, Chief, Division of Cardiac Surgery, University of Maryland School of Medicine, Baltimore, Maryland
Immunobiology of Heart and Heart-Lung Transplantation

Gary L. Grunkemeier, MD
Director, Medical Data Research Center, Providence Health System, Portland, Oregon
Statistical Treatment of Surgical Outcome Data

Tomas Gudbjartsson, MD
Clinical Professor of Surgery, Landspitali University Hospital, Faculty of Medicine, University of Iceland, Reykjavik, Iceland
Mitral Valve Replacement

Michel Haddad, MD, FRCSC
Fellow in Cardiac Surgery and Transplantation, Division of Cardiac Surgery, University of Maryland Medical Center, Baltimore, Maryland
Immunobiology of Heart and Heart-Lung Transplantation

Nitsan Halevy, MD
Research Assistant, Division of Preventive Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Preoperative Evaluation for Cardiac Surgery

John W. Hammon, Jr., MD
Professor of Surgery, Department of Cardiothoracic Surgery, Bowman Gray School of Medicine at Wake Forest University, Wake Forest University Baptist Medical Center, Winston-Salem, North Carolina
Extracorporeal Circulation

Craig R. Hampton, MD
Cardiothoracic Surgery Associates, St. Luke's Hospital, Duluth, Minnesota
Stentless Aortic Valve Replacement: Autograft/Homograft

Keith A. Horvath, MD
Chief, Department of Cardiac Surgery, Suburban Hospital, Cardiac Surgeon, Department of Cardiac Surgery, The Johns Hopkins Hospital and Health System, Director, Cardiothoracic Surgery Research Program, National Institutes of Health, NHLBI, Bethesda, Maryland
Transmyocardial Laser Revascularization and Extravascular Angiogenetic Techniques to Increase Myocardial Blood Flow

George H. Humphreys, II, MD
Professor of Surgery, Vice-Chair, Research and Information Systems, Division of Cardiothoracic Surgery, Department of Surgery, Columbia University College of Physicians and Surgeons, New York, New York
Surgical Implantation of Pacemakers and Automatic Defibrillators

Neil B. Ingels, Jr., PhD, FAHA
Consulting Professor of Cardiothoracic Surgery, Stanford University School of Medicine, Chairman, Department of Cardiovascular Physiology and Biophysics, Research Institute of Palo Alto Medical Foundation, Palo Alto, California
Pathophysiology of Mitral Valve Disease

O. Wayne Isom, MD
Professor and Chairman, Department of Cardiothoracic Surgery, Weill Medical College of Cornell University, New York Presbyterian Hospital, New York, New York
Transfusion Therapy and Blood Conservation

M. Salik Jahania, MD
Assistant Professor, Department of Cardiothoracic Surgery, University of Kentucky Chandler Medical Center, Lexington, Kentucky
Myocardial Protection

Stuart W. Jamieson, MB, FRCS
Distinguished Professor of Surgery, Chief, Division of Cardiothoracic Surgery, Department of Surgery, University of California Medical Center, San Diego, California
Pulmonary Embolism and Pulmonary Thromboendarterectomy

Ruyun Jin, MD
Postdoctoral Fellow, Medical Data Research Center, Providence Health System, Portland, Oregon
Statistical Treatment of Surgical Outcome Data

Zain I. Khalpey, MD, PhD
Junior Fellow, Division of Cardiac Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Postoperative Care of Cardiac Surgery Patients

Amy Knutsen, MD
Research Fellow, Department of Cardiovascular and Thoracic Surgery, Regions Hospital, St. Paul, Minnesota
Aortic Valve Replacement with a Mechanical Cardiac Valve Prosthesis

Karl H. Krieger, MD
Professor and Vice-Chairman, Department of Cardiothoracic Surgery, Weill Medical College of Cornell University, New York Presbyterian Hospital, New York, New York
Transfusion Therapy and Blood Conservation

Irving L. Kron, MD
Professor and Chairman, Department of Thoracic and Cardiovascular Surgery, University of Virginia Health Sciences Center, Charlottesville, Virginia
Aortic Dissection

Hillel Laks, MD
Professor and Chief, Division of Cardiothoracic Surgery, Department of Surgery, David Geffen School of Medicine at UCLA, UCLA Medical Center, Los Angeles, California
Adult Congenital Heart Disease

Robert D. Lasley, MD
Professor, Division of Cardiothoracic Surgery, Wayne State University School of Medicine, Detroit, Michigan
Myocardial Protection

Martin LeBoutillier, III, MD
Attending Staff, Department of Cardiac Surgery, The Chester County Hospital, West Chester, Pennsylvania
Valvular and Ischemic Heart Disease

Leonard Y. Lee, MD
Assistant Professor, Department of Cardiothoracic Surgery, Weill Medical College of Cornell University, New York Presbyterian Hospital, New York, New York
Transfusion Therapy and Blood Conservation

Scott A. LeMaire, MD
Associate Professor and Director of Clinical and Translational Research, Division of Cardiothoracic Surgery, Michael E. Debakey Department of Surgery, Baylor College of Medicine, Cardiovascular Surgery Staff, the Texas Heart Institute at St. Luke's Episcopal Hospital, Houston, Texas
Descending and Thoracoabominal Aortic Aneurysms

Jerrold H. Levy, MD
Professor and Chairman for Research, Department of Anesthesiology, Emory University School of Medicine, Attending Anesthesiologist, Division of Cardiothoracic Anesthesia, Emory University Hospital, Atlanta, Georgia
Cardiac Surgical Pharmacology

James E. Lowe, MD
Professor of Surgery, Division of Cardiovascular and Thoracic Surgery, Department of Surgery, Duke University Medical Center, Durham, North Carolina
Cardiopulmonary Resuscitation; Left Ventricular Aneurysm

Bruce W. Lytle, MD
Professor of Surgery, Thoracic, and Cardiovascular Surgery, Cleveland Clinic Lerner College of Medicine of Case Western Reserve University, Chairman, Department of Thoracic and Cardiovascular Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio
Coronary Artery Reoperations

Michael J. Mack, MD
COR Specialty Associates of North Texas, PA(CSANT), Cardiopulmonary Research Science and Technology Institute (CRSTI) Dallas, Texas
Myocardial Revascularization without Cardiopulmonary Bypass

Michael M. Madani, MD
Assistant Clinical Professor of Surgery, Division of Cardiothoracic Surgery, University of California Medical Center, San Diego, California
Pulmonary Embolism and Pulmonary Thromboendarterectomy

Joren C. Madsen, MD, PhD
Associate Professor of Surgery, Division of Cardiac Surgery, Harvard Medical School, Department of Surgery, Massachusetts General Hospital, Boston, Massachusetts
Surgical Treatment of Complications of Acute Myocardial Infarction: Postinfarction Ventricular Septal Defect and Free Wall Rupture

Abeel A. Mangi, MD
Clinical Associate, Adult Cardiac Surgery, Mechanical Circulatory Support and Thoracic Organ Transplant, The Cleveland Clinic Foundation, Cleveland, Ohio
Pericardial Disease

Daniel Marelli, MD
Assistant Professor, Division of Cardiothoracic Surgery, Department of Surgery, David Geffen School of Medicine at UCLA, UCLA Medical Center, Los Angeles, California
Adult Congenital Heart Disease

Manu N. Mathur, MD
Consultant Cardiothoracic Surgeon, Royal North Shore Hospital, Sydney, Australia
Anuerysms of the Aortic Arch

John E. Mayer, MD
Professor of Surgery, Harvard Medical School, Senior Associate in Cardiac Surgery, Children's Hospital, CHMC Cardiovascular Surgical Foundation, Inc., Boston, Massachusetts
Tissue Engineering for Cardiac Valve Surgery

Patrick M. McCarthy, MD
Co-Director, Bluhm Cardiovascular Institute, Chief, Division of Cardiothoracic Surgery, Northwestern University's Feinberg School of Medicine, Northwestern Medical Faculty Foundation, Inc., Chicago, Illinois
Temporary Mechanical Circulatory Support

Edwin C. McGee, Jr., MD
Surgical Director of Advanced Heart Failure Therapeutics, Bluhm Cardiovascular Institute, Assistant Professor of Surgery, Northwestern University's Feinberg School of Medicine, Division of Cardiac Surgery, Northwestern Memorial Hospital, Chicago, Illinois
Temporary Mechanical Circulatory Support

Robert M. Mentzer, Jr., MD
Professor of Cardiothoracic Surgery and Physiology, Dean and Senior Advisor to the President of Medical Affairs, Wayne State University School of Medicine, Detroit, Michigan
Myocardial Protection

Hector I. Michelena, MD
Division of Cardiovascular Diseases, Mayo Clinic, Rochester, Minnesota
Principles and Practice of Echocardiography in Cardiac Surgery

Tomislav Mihaljevic, MD
Staff Surgeon, Department of Thoracic and Cardiovascular Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio
Pathophysiology of Aortic Valve Disease

Michael R. Mill, MD
Professor of Surgery and Chief, Division of Cardiothoracic Surgery, University of North Carolina School of Medicine, Chapel Hill, North Carolina
Surgical Anatomy of the Heart

D. Craig Miller, MD
Thelma and Henry Doelger Professor of Cardiovascular Surgery, Department of Cardiothoracic Surgery, Stanford University School of Medicine, Stanford, California
Pathophysiology of Mitral Valve Disease

R. Scott Mitchell, MD
Professor of Cardiovascular Surgery, Department of Cardiothoracic Surgery, Stanford University School of Medicine, Stanford, California
Endovascular Therapy for the Treatment of Thoracic Aortic Disease

Nader Moazami, MD
Assistant Professor of Surgery, Director of Cardiac Transplantation, Division of Cardiothoracic Surgery, Washington University School of Medicine, St. Louis, Missouri
Temporary Mechanical Circulatory Support

Susan D. Moffatt-Bruce, MD, PhD
Assistant Professor of Surgery, Department of Cardiothoracic Surgery, Ohio State University Medical School, Columbus, Ohio
Endovascular Therapy for the Treatment of Thoracic Aortic Disease

Friedrich W. Mohr, MD, PhD
Professor and Chairman of Cardiac Surgery, Medical Director of the Heart Center, Leipzig University School of Medicine, Leipzig, Germany
Minimally Invasive Myocardial Revascularization

Jeff L. Myers, MD, PhD
Chief, Divison of Pediatric Cardiothoracic Surgery, Le Bonheur Children's Medical Center, Memphis, Tennessee
Adult Congenital Heart Disease

Timothy J. Myers, BS, CCRA
Manager, Clinical Research and Regulatory Affairs, Cardiovascular Research Laboratories, Texas Heart Institute at St. Luke's Episcopal Hospital, Center for Cardiac Support, School for Cardiac Support, Houston, Texas
Total Artificial Heart

Yoshifumi Naka, MD, PhD
Herbert Irving Assistant Professor of Surgery, Columbia University College of Physicians and Surgeons, Director, Mechanical Circulatory Support, Division of Cardiothoracic Surgery, Department of Surgery, New York Presbyterian Hospital, New York, New York
Long-Term Mechanical Circulatory Support

Vuyisile T. Nkomo, MD
Assistant Professor of Medicine, Mayo School of Medicine, Consultant, Cardiovascular Diseases, Saint Mary's Hospital, Mayo Clinic, Rochester, Minnesota
Principles and Practice of Echocardiography in Cardiac Surgery

Lois U. Nwakanma, MD
Division of Cardiothoracic Surgery, Department of Surgery, Johns Hopkins Medical Institutions, Baltimore, Maryland
Heart Transplantation

Eric J. Okum, MD
Assistant Professor, Department of Cardiovascular and Thoracic Surgery, Rush University Medical Center, Chicago, Illinois
Cardiac Surgical Physiology

Mehmet C. Oz, MD, MBA
Vice-Chairman and Professor, Department of Surgery, Director, Cardiovascular Institute, Division of Cardiothoracic Surgery, Columbia University College of Physicians and Surgeons, New York-Presbyterian Hospital, Columbia University Medical Center, New York, New York
Myocardial Revascularization after Acute MI; Long-Term Mechanical Circulatory Support

Robert F. Padera, Jr., MD, PhD
Associate Pathologist, Instructor in Pathology, Harvard Medical School, Brigham and Women's Hospital, Boston, Massachusetts
Pathology of Cardiac Surgery

Subroto Paul, MD
Surgical Research Fellow, Department of Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Pathophysiology of Aortic Valve Disease

Marc P. Pelletier, MD, MSc
Assistant Professor, Department of Cardiothoracic Surgery, Stanford University, Stanford, California
Heart-Lung and Lung Transplantation

Michael R. Petracek, MD
Professor of Clinical Cardiac Surgery, Department of Cardiac Surgery, Vanderbilt Heart Institute, Vanderbilt University Medical Center, Nashville, Tennessee
Reoperative Valve Surgery

Gosta Petterson, MD
Vice Chairman, Department of Thoracic and Cardiovascular Surgery, Surgical Director of Lung Transplantation, The Cleveland Clinic Foundation, Cleveland, Ohio
Surgical Treatment of Mitral Valve Endocarditis

Mark D. Plunkett, MD
Assistant Professor, Division of Cardiac Surgery, Department of Surgery, David Geffen School of Medicine at UCLA, Los Angeles, California
Adult Congenital Heart Disease

Robert S. Poston, MD
Assistant Professor of Surgery, Division of Cardiothoracic Surgery, University of Maryland Medical Center, Baltimore, Maryland
Immunobiology of Heart and Heart-Lung Transplantation

René Prêtre, MD
Professor of Surgery, Department of Cardiovascular Surgery, University Hospital Zürich, Zürich, Switzerland
Deep Hypothermic Circulatory Arrest

Goya V. Raikar, MD
Division of Cardiovascular and Thoracic Surgery, Health Partners, St. Paul, Minnesota
Aortic Valve Replacement with a Mechanical Cardiac Valve Prosthesis

James D. Rawn, MD
Intensive Care Unit Director, Division of Cardiac Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Postoperative Care of Cardiac Surgery Patients

Michael J. Reardon, MD
Professor of Surgery, Baylor College of Medicine, University of Texas Medical Center at Houston, Houston, Texas
Cardiac Neoplasms

T. Brett Reece, MD
Chief Resident, Department of Surgery, University of Virginia, Charlotte, Virginia
Aortic Dissection

Robert J. Rizzo, MD
Assistant Professor of Surgery, Harvard Medical School, Division of Cardiac Surgery, Brigham and Women's Hospital, Boston, Massachusetts
Ascending Aortic Aneurysms

Robert C. Robbins, MD
Associate Professor of Cardiothoracic Surgery, Department of Cardiothoracic Surgery, Stanford University School of Medicine, Stanford, California
Heart-Lung and Lung Transplantation

Evelio Rodriguez, MD
Assistant Professor, Division of Cardiac Surgery, East Carolina University, Brody School of Medicine, Greenville, North Carolina
Minimally Invasive and Robotic Mitral Valve Surgery

Frank J. Rybicki, MD, PhD
Co-Director, Cardiovascular Imaging Section, Director, Applied Imaging Science Laboratory, Department of Radiology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Cardiac Surgical Imaging

Edward B. Savage, MD
Medical Director, Heart and Vascular Services, Surgeon, Division of Cardiothoracic Surgery, St. John's Mercy Medical Center, St. Louis, Missouri
Cardiac Surgical Physiology

Joseph S. Savino, MD
Associate Professor of Anesthesia, Section Chief, Cardiovascular Thoracic Anesthesia and Intensive Care, Department of Anesthesia, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Cardiac Anesthesia

Mohammed R. Sayeed, MD, FRCS, DNB
Departments of Cardiology and Cardiothoracic Surgery, Apollo Hospitals, Bangalore, India
Pathophysiology of Aortic Valve Disease

Hartzell V. Schaff, MD
Stuart W. Harrington Professor of Surgery, Chair, Division of Cardiovascular Surgery, Mayo Clinic College of Medicine, Rochester, Minnesota
Multiple Valve Disease

Frederick J. Schoen, MD, PhD
Professor, Department of Pathology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Pathology of Cardiac Surgery

Richard B. Schuessler, PhD
Associate Research Professor of Surgery and Biomedical Engineering, Washington University School of Medicine, St. Louis, St. Louis, Missouri
Surgical Treatment of Atrial and Ventricular Fibrillation

Ashish S. Shah, MD
Assistant Professor of Surgery, Department of Cardiac Surgery, Johns Hopkins Hospital, Baltimore, Maryland
Heart Transplantation

David M. Shahian, MD
Professor of Surgery, Tufts University School of Medicine, Chair, Department of Surgery, Caritas St. Elizabeth Medical Center, Brighton, Massachusetts
Risk Stratification and Comorbidity

Ahmad Y. Sheikh, MD
Postdoctoral Research Fellow, Department of Cardiothoracic Surgery, Stanford University, Stanford, California
Heart-Lung and Lung Transplantation

Prem S. Shekar, MD
Instructor in Surgery, Department of Cardiac Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Minimally Invasive Aortic Valve Surgery

Richard J. Shemin, MD
Chief, Department of Cardiothoracic Surgery, School of Medicine, University of California, Los Angeles
Tricuspid Valve Disease

Tarang Sheth, MD, FRCPC
Cardiovascular Radiologist, Director of Cardiac CT and MR, Department of Diagnostic Imaging, Trillium Health Centre, Mississauga, Canada
Cardiac Surgical Imaging

W. Roy Smythe, MD
Professor and Glen and Rita K. Roney Endowed Chairman of Surgery, Department of Surgery, Scott and White Memorial Hospital, Texas A&M University Health Science Center, Temple, Texas
Cardiac Neoplasms

David Spielvogel, MD
Associate Professor, Division of Cardiothoracic Surgery, Department of Surgery, New York Medical College, West Chester Medical Center, New York Cardiothoracic Group, Valhalla, New York
Anuerysms of the Aortic Arch

Martinus T. Spoor, MD
Section of Cardiac Surgery, University of Michigan Medical Center, University of Michigan Hospitals, Ann Arbor, Michigan
Nontransplant Surgical Options for Heart Failure

Henry M. Spotnitz, MD
Professor, Department of Cardiothoracic Surgery, University of California, Los Angeles, Los Angeles, California
Surgical Implantation of Pacemakers and Authomatic Defibrillators

Sotiris C. Stamou, MD
Clinical Instructor of Surgery, Lerner College of Medicine of Case Western Reserve University, Fellow in Thoracic and Cardiovascular Surgery, The Cleveland Clinic Foundation, Westlane, Ohio
Pathophysiology of Aortic Valve Disease; Surgical Treatment of Mitral Valve Endocarditis

Paul Stelzer, MD
Division of Cardiac Surgery, Mount Sinai Medical Center, New York, New York
Stentless Aortic Valve Replacement: Porcine and Pericardial

Larry W. Stephenson, MD
Ford-Webber Professor of Surgery and Chief, Department of Cardiothoracic Surgery, Wayne State University School of Medicine, Specialist-in-Chief, Cardiothoracic Surgery, Detroit Medical Center, Detroit, Michigan
History of Cardiac Surgery

Thoralf M. Sundt, III, MD
Associate Professor of Surgery, Division of Cardiovascular Surgery, Mayo Clinic, Mayo Clinic College of Medicine, Mayo Foundation, Rochester, Minnesota
Indications for Revascularization; Myocardial Revascularization with CPB

Rakesh M. Suri, MD, PhD
Assistant Professor of Surgery, Mayo Clinic College of Medicine, Rochester, Minnesota
Multiple Valve Disease

Wilson Y. Szeto, MD
Assistant Professor of Surgery, Division of Cardiovascular Surgery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Ischemic Mitral Regurgitation

Kenichi A. Tanaka, MD
Assistant Professor, Department of Anesthesiology, Division of Cardiothoracic Anesthesiology and Critical Care, Emory University School of Medicine, Atlanta, Georgia
Cardiac Surgical Pharmacology

David F. Torchiana, MD
Chief, Division of Cardiac Surgery, Department of Surgery, Massachusetts General Hospital, Boston, Massachusetts
Pericardial Disease

Marko I. Turina, MD
Head of Cardiac Surgery and Professor of Surgery, Division of Cardiovascular Surgery, University Hospital Zürich, Zürich, Switzerland
Deep Hypothermic Circulatory Arrest

Edward D. Verrier, MD
Vice Chairman, Department of Surgery, William K. Edmark Professor of Cardiovascular Surgery, Chief, Division of Cardiothoracic Surgery, University of Washington School of Medicine, Seattle, Washington
Stentless Aortic Valve Replacement: Autograft/Homograft

Rochus K. Voeller, MD
Cardiothoracic Surgery Research Fellow, Department of Surgery, Washington University School of Medicine, St. Louis, Barnes-Jewish Hospital, St. Louis, Missouri
Surgical Treatment of Atrial and Ventricular Fibrillation

Jon-Cecil M. Walkes, MD
Assistant Professor, Division of Cardiovascular and Thoracic Surgery, Weill Medical College, Cornell University, Methodist DeBakey Heart Center, Houston, Texas
Cardiac Neoplasms

Benson R. Wilcox, MD
Professor of Surgery, Division of Cardiothoracic Surgery, University of North Carolina School of Medicine, Chapel Hill, North Carolina
Surgical Anatomy of the Heart

James T. Willerson, MD
President-Elect, Medical Director, Director of Cardiology Research, and Co-Director of the Cullen Cardiovascular Research Laboratories, The Texas Heart Institute at St. Luke's Episcopal Hospital, President, The University of Texas Health Science Center at Houston, Houston, Texas
Myocardial Revascularization with Percutaneous Devices

James M. Wilson, MD
Director of Cardiology Education and Director of Clinical Cardiology, The Texas Heart Institute at St. Luke's Episcopal Hospital, Houston, Texas
Myocardial Revascularization with Percutaneous Devices

Yifu Zhou, MD
Cellular/Molecular Staff Scientist, Cardiothoracic Surgery Research Program, NHLBI, National Institutes of Health, Bethesda, Maryland
Transmyocardial Laser Revascularization and Extravascular Angiogenetic Techniques to Increase Myocardial Blood Flow

Foreword

Heart surgery, as we know it today did not exist when I graduated from medical school in 1944. During the last half of the twentieth century, however, cardiovascular surgery emerged as an important therapeutic discipline, and I am fortunate to have participated in the excitement of the specialty's formative years.

Probably the most stimulating advance in the treatment of congenital heart disease occurred in 1944, when Alfred Blalock and Helen Taussig introduced their technique of systemic-to-pulmonary artery shunting for tetralogy of Fallot. The success of the "blue-baby" operation was so dramatic and promising that cardiac surgery began to grow at a frenzied pace. The early operative procedures for congenital anomalies, including the blue-baby operation, proved that the circulatory system could be altered to improve blood flow and cardiopulmonary function.

With the introduction of temporary cardiopulmonary bypass, intracardiac procedures soon followed. Once open-heart operations became feasible, cardiac surgeons became active explorers of the cardiac chambers. Mechanical and biological prostheses were developed to repair and replace parts of the heart as well as the heart itself. In my opinion, the most exciting of those early years was cardiac transplantation. Although early transplant survival rates were often disappointing, the success of the procedure stimulated surgeons to tackle other difficult cardiovascular problems. Methods to treat coronary artery disease using coronary artery bypass grafts were developed. Surgeons began to use fabric grafts to repair aortic aneurysms, using specialized techniques to preserve cerebral and spinal cord function during surgery. Those investigators involved in device development brought mechanical circulatory support devices from the laboratories to clinical use. As the field of cardiac surgery expanded, so did that of diagnostic testing. Digital, computer-enhanced techniques provided more precise knowledge of cardiac anatomy and function, facilitating surgical treatment.

Even though many of the obstacles confronting surgeons in the past have been successfully overcome, numerous challenges remain, including the refinement of existing surgical techniques. *Cardiac Surgery in the Adult,* edited by L. Henry Edmunds, Jr., was first published in 1997 at a time when cardiovascular surgery was in a period of incredible growth. The original text was a major contribution to the treatment of adult patients, and it remains on my shelf as testament to how much our specialty has changed, yet remains the same. Dr. Larry Cohn became its co-editor for the second edition and is updating the text for the third time. The original chapters have been updated to reflect current thought and trends, and much more has been added. The new edition discusses refinements in less invasive techniques, such as minimally invasive valve repair and replacement, interventional therapy for atrial and ventricular arrhythmias, and use of the surgical robot. These techniques allow surgeons to attain the same therapeutic objectives with less trauma and discomfort for the patient. Also included are chapters that look to the future to describe, for example, the latest treatments for cardiac failure–a remaining challenge for scientists, cardiologists, and cardiac surgeons. Could the ultimate solution be a combination of therapies, for example, stem cells and mechanical cardiac assistance? Both are discussed within the pages of *Cardiac Surgery*.

Thus, this edition of *Cardiac Surgery in the Adult*, with its impressive list of contributors, provides an important progress report and treatment guide for our specialty. But there is an added bonus. Reading the text, which begins with an excellent history of the specialty, should stimulate its readers to think about how far cardiovascular surgery has come since its beginnings and about how each of us can contribute to insuring its continued, successful evolution.

Preface

The third edition of *Cardiac Surgery in the Adult* presents new knowledge and current experience by the world's leading cardiovascular surgeons and physicians for the treatment of adults with congenital, acquired, infectious, and traumatic diseases of the heart and great vessels. The third edition release date in 2007 celebrates the tenth anniversary of the publication of the first edition edited by L. Henry "Hank" Edmunds in 1997. In the short span of ten years there have been enormous changes in the cardiac surgical armamentarium, with new innovations in minimally invasive cardiac surgery, new percutaneous cardiovascular devices, and new approaches in the imaging, diagnosis, and treatment of all forms of cardiac disease. There have also been changes in cardiac surgical demographics, with increasing interest in percutaneous intervention, endovascular graft technology, and concomitant interest in the pursuit of cross-training for endovascular skills. For these reasons we have added six new chapters in areas related to these new technologies: percutaneous valve therapy, minimally invasive valve and coronary artery bypass surgery, updates in percutaneous treatment of coronary artery disease, and the latest data on stem cell technology. Every chapter has been updated with significant new information and a revamped bibliography. In addition to the updated chapters, this edition also includes 6 video-clip demonstrations of complex operative procedures, a totally new feature in this edition.

My goal as editor is to publish information as quickly as possible to maximize the educational aspect of new technology and developments in cardiac surgical expertise; thus, the turnaround time from receipt of chapters to publication was approximately 18 months.

As in any publication of this magnitude I am indebted to many people. First and foremost, thanks to Hank Edmunds for his inspiration and motivation to continue the good work he began, to the editorial staff at McGraw-Hill, especially Karen Edmonson, Marsha Loeb and Peter Boyle, who have been extremely helpful and supportive in every way possible to get this book to press, to Ann Maloney, my executive assistant in the Division of Cardiac Surgery at the Brigham and Women's Hospital, who was extremely helpful in organization and logistics, and a special thanks to Dr. Denton Cooley, cardiac surgical pioneer and innovator who has written a superb foreword to this third edition. To all the chapter authors, who are some of the busiest physicians in the world, profound thanks; their time and energy have produced a superb volume of surgical and perioperative expertise in a timely fashion.

On a sad note, our profound condolences to the University of Michigan transplant team who lost four members and two pilots on June 4, 2007. A member of this team, Martin Spoor coauthored Chapter 69 with Steven Bolling.

Finally and most importantly, thanks and love to my family, Roberta, Leslie, Jennifer, Stephen, Carly, and Rachel, who have again supported me during the production of another edition of *Cardiac Surgery in the Adult.*

CHAPTER 1

History of Cardiac Surgery

Larry W. Stephenson

The development of major surgery was retarded for centuries by a lack of knowledge and technology. Significantly, the general anesthetics, ether and chloroform, were not developed until the middle of the nineteenth century. These agents made major surgical operations possible, which created an interest in repairing wounds to the heart, leading some investigators in Europe to conduct studies in the animal laboratory on the repair of heart wounds. The first simple operations in humans for heart wounds soon were reported in the medical literature.

HEART WOUNDS

On July 10, 1893, Dr. Daniel Hale Williams (Fig. 1-1), a surgeon from Chicago, successfully operated on a 24-year-old man who had been stabbed in the heart during a fight. The patient was admitted to Chicago's Provident Hospital on July 9 at 7:30 P.M. The stab wound was slightly to the left of the sternum and dead center over the heart. Initially, the wound was thought to be superficial, but during the night, the patient experience persistent bleeding, pain, and pronounced symptoms of shock. Williams opened the patient's chest and tied off an artery and vein that had been injured inside the chest wall, likely causing the blood loss. Then he noticed a tear in the pericardium and a puncture wound to the heart, "about one-tenth of an inch in length."[1]

The wound in the right ventricle was not bleeding, so Williams did not place a stitch through the heart wound. He did, however, stitch closed the hole in the pericardium. The patient recovered. Williams reported this case 4 years later.[1] This operation, which is referred to frequently, is probably the first successful surgery involving a documented stab wound to the heart. At the time, Williams' surgery was considered bold and daring, and although he did not actually place a stitch through the wound in the heart, his treatment seems to have been appropriate. Under the circumstances, he most likely saved the patient's life.

A few years after Williams' case, a couple of other surgeons actually sutured heart wounds, but the patients did not survive. Dr. Ludwig Rehn (Fig. 1-2), a surgeon in Frankfurt, Germany, performed what many consider the first successful heart operation.[2] On September 7, 1896, a 22-year-old man was stabbed in the heart and collapsed. The police found him pale, covered with cold sweat, and extremely short of breath. His pulse was irregular, and his clothes were soaked with blood. By September 9, his condition was worsening, as shown in Dr. Rehn's case notes:

> Pulse weaker, increasing cardiac dullness on percussion, respiration 76, further deterioration during the day, diagnostic tap reveals dark blood. Patient appears moribund. Diagnosis: increasing hemothorax. I decided to operate entering the chest through the left fourth intercostal space, there is massive blood in the pleural cavity. The mammary artery is not injured. There is continuous bleeding from a hole in the pericardium. This opening is enlarged. The heart is exposed. Old blood and clots are emptied. There is a 1.5 cm gaping right ventricular wound. Bleeding is controlled with finger pressure. . . .
>
> I decided to suture the heart wound. I used a small intestinal needle and silk suture. The suture was tied in diastole. Bleeding diminished remarkably with the third suture, all bleeding was controlled. The pulse improved. The pleural cavity was irrigated. Pleura and pericardium were drained with iodoform gauze. The incision was approximated, heart rate and respiratory rate decreased and pulse improved postoperatively.
>
> . . . Today the patient is cured. He looks very good. His heart action is regular. I have not allowed him to work physically hard. This proves the feasibility of cardiac suture repair without a doubt! *I hope this will lead*

> *to more investigation regarding surgery of the heart. This may save many lives.*

Ten years after Rehn's initial repair, he had accumulated a series of 124 cases with a mortality of only 60%, quite a feat at that time.[3]

Dr. Luther Hill was the first American to report the successful repair of a cardiac wound, in a 13-year-old boy who was a victim of multiple stab wounds.[4] When the first doctor arrived, the boy was in profound shock. The doctor remembered that Dr. Luther Hill had spoken on the subject of repair of cardiac wounds at a local medical society meeting in Montgomery, Alabama. With the consent of the boy's parents, Dr. Hill was sent for. He arrived sometime after midnight with six other physicians. One was his brother. The surgery took place on the patient's kitchen table in a run-down shack. Lighting was provided by two kerosene lamps borrowed from neighbors. One physician administered chloroform anesthesia. The boy was suffering from cardiac tamponade as a result of a stab wound to the left ventricle. The stab wound to the ventricle was repaired with two catgut sutures. Although the early postoperative course was stormy, the boy made a complete recovery. That patient, Henry Myrick, eventually moved to Chicago, where, in 1942, at the age of 53, he got into a heated argument and was stabbed in the heart again, very close to the original stab wound. This time, Henry was not as lucky and died from the wound.

Another milestone in cardiac surgery for trauma occurred during World War II when Dwight Harken, then a U.S. Army surgeon, removed 134 missiles from the mediastinum, including 55 from the pericardium and 13 from cardiac chambers, without a death.[5] It is hard to imagine this type of elective (and semielective) surgery taking place without sophisticated indwelling pulmonary artery catheters, blood banks, and electronic monitoring equipment. Rapid blood infusion consisted of pumping air into glass bottles of blood.

OPERATIVE MANAGEMENT OF PULMONARY EMBOLI

Friedrich Trendelenburg was the first to attempt a pulmonary embolectomy. In his classic paper that appeared in 1908,[6]

he stated that the clinical picture is characteristic: rapid collapse, frequently accompanied by substernal pain that often causes the patient to suddenly scream wildly. He reported on animal studies in 1907; following rapid exposure of the heart, he quickly incised the conus pulmonalis, inserted a cannula, advanced it into the pulmonary artery, and removed emboli using suction. Further experimentation revealed that a direct incision in the artery with removal of the emboli using forceps (those designed for removal of polyps) was much easier. He describes his first unsuccessful pulmonary embolectomy in a human. That operation became famous and is known as the *Trendelenburg operation.*

Trendelenburg subsequently reported two more cases, both fatal.[7] The first of those two patients died 15 hours postoperatively of cardiac failure; the second, 37 hours postoperatively. Kirschner, Trendelenburg's student, reported the first patient who recovered fully after undergoing pulmonary embolectomy in 1924.[8] In 1937, John Gibbon estimated that nine of 142 patients who had undergone the Trendelenburg procedure worldwide left the hospital alive.[9] These dismal results were a stimulus for Gibbon to start work on a pump oxygenator that could maintain the circulation during pulmonary embolectomy. Sharp was the first to perform pulmonary embolectomy using cardiopulmonary bypass, in 1962.[10]

SURGERY OF THE PERICARDIUM

Morgagni reported seven cases of constrictive pericarditis in 1761 and described the dangers of cardiac compression by stating that the heart was "so constricted and confined that it could not receive a proper quantity of blood to pass through it."[11] Pick presented a paper in 1896 in which he described the course of chronic pericarditis under the guise of cirrhosis of the liver.[12] Weill in 1895 and Delorme in 1898 proposed excision of the thickened fibrous pericardium in constrictive pericarditis.[13,14] Pericardial resection was introduced independently by Rehn[15] and Sauerbruch.[16] Since Rehn's report, there have been few advances in the surgical treatment of constrictive pericarditis. Some operations are now performed with the aid of cardiopulmonary bypass. In certain situations, radical pericardiectomy that removes most of the pericardium posterior to the phrenic nerves is done.

CATHETERIZATION OF THE RIGHT SIDE OF THE HEART

Although cardiac catheterization is not considered heart surgery, it is an invasive procedure, and some catheter procedures have replaced heart operations. Werner Forssmann is credited with the first heart catheterization. He performed the procedure on himself and reported it in *Klrinische Wochenschrift.*[17] In 1956, Forssmann shared the Nobel Prize in Physiology or Medicine with Andre F. Cournand and Dickenson W. Richards, Jr. His 1929 paper states, "One often hesitates to use intercardiac injections promptly, and often, time is wasted with other measures. This is why I kept looking for a different, safer access to the cardiac chambers: the catheterization of the right heart via the venous system." He goes on to say:

> I confirmed these facts by studies on a cadaver, catheterizing any vein near the elbow, the catheter would pass easily into the right ventricle. . . .
>
> After these successful preliminary studies, I attempted the first experiment on a living human, performing the experiment on myself. In a preliminary experiment, I had asked a colleague to puncture my right brachial vein with a large-bore needle. Then I advanced a well-lubricated No. 4 ureteral catheter through the cannula into the vein. . . . One week later I tried it again without assistance this time. I proceeded with vena puncture in my left antebrachial vein and introduced the catheter to its full length of 65 cm. . . .
>
> I checked the catheter position radiologically, after having climbed stairs from the OR to the radiology department. A nurse was holding a mirror in front of the x-ray screen for me to observe the catheter advance in position. The length of the catheter did not allow further advancement than into the right atrium. I paid particular attention to the possible effects on the cardiac conduction system, but I could not detect any effect.

In this report by Forssmann, a photograph of the x-ray taken of Forssmann with the catheter in his heart is presented. Forssmann, in that same report, goes on to present the first clinical application of the central venous catheter for a patient in shock with generalized peritonitis. Forssmann concludes his paper by stating, "I also want to mention that this method allows new options for metabolic studies and studies about cardiac physiology."

In a 1951 lecture, Forssmann discussed the tremendous resistance he faced during his initial experiments.[18] "Such methods are good for a circus, but not for a respected hospital" was the answer to his request to pursue physiologic studies using cardiac catheterization. His progressive ideas pushed him into the position of an outsider with ideas too crazy to give him a clinical position. Klein applied cardiac catheterization for cardiac output determinations using the Fick method a half year after Forssmann's first report.[19] In 1930, Forssmann described his experiments with catheter cardiac angiography.[20] Further use of this new methodology had to wait until Cournand's work in the 1940s.

HEART VALVE SURGERY BEFORE THE ERA OF CARDIOPULMONARY BYPASS

The first clinical attempt to open a stenotic valve was carried out by Theodore Tuffier on July 13, 1912.[21] Alexis Carrel was present at the operation.[22] Tuffier used his finger to reach the stenotic aortic valve. He was able to dilate the valve supposedly by pushing the invaginated aortic wall through the stenotic valve. The 26-year-old patient recovered and

returned to his home in Belgium. One must be skeptical as to what was accomplished. Russell Brock attempted to dilate calcified aortic valves in humans in the late 1940s by passing an instrument through the valve from the innominate or another artery.[23] His results were poor, and he abandoned the approach. During the next several years, Brock[24] and Bailey and colleagues[25] used different dilators and various approaches to dilate stenotic aortic valves in patients. Mortality for these procedures that often were done in conjunction with mitral commissurotomy was high.

Harvey Cushing attempted to create mitral stenoses in dogs but was not successful.[26] He encouraged Elliott Cutler, a young surgeon working with him, to continue. In collaboration with a Boston cardiologist, Samuel Levine, Cutler worked 2 years on a mitral valvulotomy procedure in the laboratory.[27] Their first patient was a desperately ill 12-year-old girl who was confined to bed for 6 months before operation. She underwent successful valvulotomy on May 20, 1923, using a teratomy knife. Unfortunately, most of Cutler's subsequent patients died because he created too much regurgitation with his valvulotome, and he soon gave up the operation. In 1925, Mr. Souttar, an English surgeon, successfully performed a mitral valvulotomy using his finger to fracture the commissures in a young girl who had been bedridden for 6 months.[28] His case was successful, but he did not do more operations.

In 1961, Dr. Dwight Harken wrote Henry Suttar a letter and asked him why he did not continue with his mitral valvuloplasty. He replied: "Thank you so much for your very kind letter. I did not repeat the operation because I could not get another case. Although my patient made an uninterrupted recovery, the physicians declared that it was all nonsense and in fact the operation was unjustifiable. In fact, it is of no use to be ahead of one's time. . . ."[29] Two decades passed before there was a resurgence of interest in valvular surgery.

In Charles Bailey's 1949 paper entitled, "The Surgical Treatment of Mitral Stenosis," he states: "After 1929 no more surgical attempts [on mitral stenosis] were made until 1945. Dr. Dwight Harken, Dr. Horace Smithy, and the author recently made operative attempts to improve mitral stenosis. Our clinical experience with the surgery of the mitral valves has been five cases to date. During the past 8 years, the author and his associates have performed operations on the mitral valves of 60 mongrel dogs."[30] Bailey goes on to state several conclusions from their animal research. He then describes his five patients, four of whom died and only one of whom lived a long life.

Bailey's home base, Hahnemann Hospital, refused to allow him to attempt any more mitral commissurotomies after two deaths. He became known as the "butcher of Hahnemann Hospital."[29] However, his cardiologist, Dr. Durant, continued to support him. On June 10, 1948, Bailey scheduled cases 4 and 5. The patient operated on at Philadelphia General Hospital in the morning died (case 4). The surgical team regrouped and rushed to Episcopal Hospital, where the second operation was started promptly before the bad morning news was known and before the hospital administration forbade the procedure. The surgery was completed, and 1 week later Bailey brought the patient by train 1000 miles to Chicago, where he presented the woman to the American College of Chest Physicians.[31] A few days after Bailey's success, on June 16 in Boston, Dr. Dwight Harken successfully performed his first valvulotomy for mitral stenosis. Three months later, Russell Brock in England did his first successful clinical case. He did not report this, however, until 1950, when he described success with six patients.[32]

The first successful pulmonary valvulotomy was performed by Thomas Holmes Sellers on December 4, 1947. A systemic pulmonary artery shunt was planned on the left side, but the attempt was abandoned in this patient with severe tetralogy of Fallot and advanced bilateral pulmonary tuberculosis.[33] The pericardium was opened. Dr. Sellers could feel the stenotic valve each time it pushed through the pulmonary trunk during ventricular systole. Sellers used a tenotomy knife, which he passed through the right ventricle to perform the valvulotomy. The patient made a good recovery and was markedly improved.

Russell Brock also attempted pulmonary valvulotomies in a number of patients during the same period using various techniques. Brock's first three patients died, but he eventually developed a successful procedure similar to that of Sellers.[34]

In the early 1950s, Charles Hufnagel, in Washington, DC, and J. M. Campbell, in Oklahoma, independently developed and implanted artificial valves in the descending aorta of dogs. The valves consisted of a mobile ball inside a Lucite case.[35,36] After presenting this first model of a mechanical prosthesis at the American College of Surgeons meeting in 1949, Hufnagel applied this concept clinically for the treatment of aortic valvular insufficiency. In his first clinical paper published in *Surgery* in 1954,[37] Hufnagel reported a series of 23 patients starting September 1952 who had this operation for aortic insufficiency. There were four deaths among the first 10 patients and two deaths among the next 13. Hufnagel's caged-ball valve, which used multiple-point fixation rings to secure the apparatus to the aorta, was the only surgical treatment for aortic valvular incompetence until the advent of cardiopulmonary bypass and the development of heart valves that could be sewn into the aortic annulus position.

The first surgical treatment of multiple valvular disease was by Trace and colleagues.[38] After closed mitral commissurotomy on May 2, 1952, in a 24-year-old woman, the surgeon noted that the right auricular appendage was gravely distended and pointed directly toward the left. Its pulsation was noticed, and it was quite blue-purple in color. The purse-string suture was being placed around the appendage in order to explore it when the patient's heart became arrhythmic. It was deemed advisable to terminate the surgical procedure at this point. The patient did poorly postoperatively. In the 2 weeks after the first operation, a tricuspid commissurotomy was performed. The patient made a good recovery and at 1-year follow-up remained improved.

Combined mitral and tricuspid commissurotomy was performed by Brofman in 1953.[39] Likoff and colleagues[40] reported a series of 74 patients who had combined aortic and mitral valve commissurotomies in 1955 with up to a 2-year follow-up. C. Walton Lillehei was the first to report repair of

multiple valvular lesions using cardiopulmonary bypass. On May 23, 1956, he successfully performed an open mitral commissurotomy and aortic valvuloplasty in a 52-year-old man with mitral stenosis and combined aortic stenosis and incompetence.[41] Borman performed a quadruple-valve commissurotomy in October 1973 in a 12-year-old Israeli girl with stenosis of all four valves.[42]

CONGENITAL CARDIAC SURGERY BEFORE THE HEART-LUNG MACHINE ERA

Congenital cardiac surgery began when John Streider at Massachusetts General Hospital first successfully interrupted a ductus on March 6, 1937. The patient was septic and died on the fourth postoperative day. At autopsy, vegetations filled the pulmonary artery down to the valve.[43] On August 16, 1938, Robert Gross, at Boston Children's Hospital, operated on a 7-year-old girl with dyspnea after moderate exercise.[44] Dr. Gross described the ductus as 7 to 8 mm in diameter and 5 to 6 mm in length. A no. 8 braided silk tie was placed around the ductus with an aneurysm needle, and the vessel was occluded temporarily for 3 minutes of observation. During this time, blood pressure rose from 100/35 to 125/90 mm Hg. According to Dr. Gross, "Since there was no embarrassment of the circulation, it was decided to ligate the ductus permanently." The patient made an uneventful recovery.

Modifications of the ductus operation soon followed. In 1944, Dr. Gross reported a technique for dividing the ductus successfully. The next major congenital lesion to be overcome was coarctation of the aorta. Dr. Clarence Crafoord, in Stockholm, Sweden, successfully resected a coarctation of the aorta in a 12-year-old boy on October 19, 1944.[45] Twelve days later he successfully resected the coarctation of a 27-year-old patient. Dr. Gross, in Boston, who had been working on a coarctation model in the laboratory, first operated on a 5-year-old boy with this condition on June 28, 1945.[46] After he excised the coarctation and rejoined the aorta, the patient's heart stopped suddenly. The patient died in the operating room. One week later, however, Dr. Gross operated on a second patient, a 12-year-old girl. This patient's operation was successful. Dr. Gross had been unaware of Dr. Crafoord's successful surgery several months previously, probably because of World War II.

In 1945, Dr. Gross reported the first successful case of surgical relief for tracheal obstruction from a vascular ring.[47] In the 5 years that followed Gross's first successful operation, he reported 40 more cases.[48]

The famous Blalock-Taussig operation also was first reported in 1945. The first patient was a 15-month-old girl with a clinical diagnosis of tetralogy of Fallot with a severe pulmonary stenosis.[49] At age 8 months, the baby had her first cyanotic spell, which occurred after eating. Dr. Helen Taussig, the cardiologist, followed the child for 3 months, and during that time, cyanosis increased, and the child failed to gain weight. She was readmitted and during the next 6 weeks refused most of her feedings, lost weight, and weighed only 4 kg at operation. The operation was performed by Dr. Alfred Blalock at Johns Hopkins University on November 29, 1944. The left subclavian artery was anastomosed to the left pulmonary artery in an end-to-side fashion. The postoperative course was described as stormy; the patient was discharged 2 months postoperatively. Two additional successful cases were done within 3 months of that first patient.

Thus, within a 7-year period, three congenital cardiovascular defects, patent ductus arteriosus, coarctation of the aorta, and vascular ring, were attacked surgically and treated successfully. However, the introduction of the Blalock-Taussig shunt probably was the most powerful stimulus to the development of cardiac surgery because this operation palliated a complex intracardiac lesion and focused attention on the pathophysiology of cardiac disease.

Anomalous coronary artery in which the left coronary artery communicates with the pulmonary artery was the next surgical conquest. The surgery was performed on July 22, 1946, and was reported by Gunnar Biorck and Clarence Crafoord.[50] The patient was a 15-year-old boy who was unable to do gymnastics or play football because of dyspnea shortly after beginning exercise. At operation, the ductus arteriosus was found to be a cord, but there was a thrill over the pericardium. When the pericardium was opened, the anomalous coronary artery was identified and doubly ligated. The patient made an uneventful recovery.

Muller[51] reported successful surgical treatment of transposition of the pulmonary veins in 1951, but the operation addressed a partial form of the anomaly. Later in the 1950s, Gott, Varco, Lillehei, and Cooley reported successful operative variations for anomalous pulmonary veins.

Another of Gross's pioneering surgical procedures was surgical closure of an aortopulmonary window in a 4-year-old girl who had dyspnea with slight exertion and a cardiac murmur that was consistent with a patent ductus.[52] The operation was carried out on May 22, 1948. After dissecting the posterior aspect of the great vessels, a similar plane was developed between the vessels above the shunt, and an aneurysm needle was passed completely around the shunt.[52] A piece of linen tape 1 cm wide was drawn around the vessel so that it encircled the shunt. At this point, arterial blood began to escape from the depths of the wound so that it was evident that the thin posterior wall of the shunt had been torn slightly. Believing that the one hope of controlling the situation might be to quickly tie the tape that had been placed previously, this was now rapidly and tightly drawn down. Fortunately, all bleeding stopped. All the thrill in the pulmonary artery disappeared. The chest was closed, and the patient made a satisfactory convalescence.

Gross stated: "After successfully treating the child, it is felt that the fortunate outcome had been attended by a high degree of luck and that simple ligature might lead to disaster if attempted in all cases of aortopulmonary artery fenestration. As far as is known, this is the first instance of successful surgical correction of this congenital abnormality." Others were soon to follow using various techniques to interrupt the aortopulmonary window. Cooley and colleagues[53] were the first to report on the use of cardiopulmonary bypass to

repair this defect and converted a difficult and hazardous procedure into a relatively straightforward one.

The cavopulmonary anastomosis has had several variations by different designers. Carlon and colleagues[54] are credited with first proposing the anastomosis in 1951. Glenn[55] reported the first successful clinical application in the United States in 1958 for what has been termed the *Glenn shunt.* Similar work was done in Russia during the 1950s by several investigators. On January 3, 1957, Galankin,[56] a Russian surgeon, performed a cavopulmonary anastomosis in a 16-year-old patient with tetralogy of Fallot. The patient made a good recovery with significant improvement in exercise tolerance and cyanosis.

THE DEVELOPMENT OF CARDIOPULMONARY BYPASS

The development of the heart-lung machine made repair of intracardiac lesions possible. To bypass the heart, one needs a basic understanding of the physiology of the circulation, a method of preventing the blood from clotting, a mechanism to pump blood, and finally, a method to ventilate the blood.[57]

Before 1900, physiologists already were interested in isolated organ perfusion and therefore needed a method to oxygenate blood. Von Frey and Gruber[58] described a blood pump in 1885 in which gas exchange occurred as blood flowed into a thin film over the inner surface of a slanted rotating cylinder. In 1895, Jacobi passed blood through an excised animal's lung that was aerated by artificial respiration.[59] In 1926, Professors S. S. Brukhonenko and S. Terebinsky[60] in Russia designed a machine that used an excised lung from a donor animal as an oxygenator and two mechanically actuated blood pumps. Their machine was used initially to perfuse isolated organs but later was used to perfuse entire animals.

Alexis Carrel, a Nobel laureate, and Charles Lindbergh, the famous aviator, developed a device that successfully perfused the thyroid gland of a cat for 18 days, beginning April 5, 1935.[61] A picture of the two investigators with their perfusion apparatus appeared on the June 13, 1938, cover of *Time* magazine.[62] At the end of that time, much of the tissue was partially preserved, and pieces grew epithelial cells in tissue culture. According to Edwards and Edwards,[61] many other organs were perfused over the next few years by Carrel and Lindbergh. Hearts were kept beating for several days. Although perfused organs survived surprisingly well, all showed progressive degenerative changes in a few days. Edema fluid filled tissue spaces, arteries became calcified, and connective tissue cells outgrew the more specialized cells.

One of the key requirements of the heart-lung machine was anticoagulation. Heparin was discovered by a medical student, Jay McLean, working in the laboratory of Dr. William Howell, a physiologist at Johns Hopkins.[63] In 1915, Howell gave McLean the task of studying a crude brain extract known to be a powerful thromboplastin. Howell believed that the thromboplastic activity was caused by cephalin contained in the extract. McLean's job was to fractionate the extract and purify the cephalin. McLean also studied extracts prepared from heart and liver. McLean discovered that a substance in the extract was retarding coagulation. McLean wrote[64]:

> I went one morning to the door of Dr. Howell's office, and standing there (he was seated at his desk), I said, Dr. Howell, I have discovered antithrombin. He smiled and said, "Antithrombin is a protein and you are working with phospholipids. Are you sure that salt is not contaminating your substance?". . . I told him that I was not sure of that, but it was a powerful anticoagulant. He was most skeptical, so I had the diener, John Schweinhand, bleed a cat. Into a small beaker full of its blood, I stirred all of the proven batch of heparphosphotides, and placed this on Dr. Howell's laboratory table and asked him to tell when it clotted. It never did.

McLean described his finding in February 1916 at a medical society meeting in Philadelphia and later reported it in an article entitled, "The Thromboplastic Action of Cephalin."[64,65] Howell and Holt[66] reported their work on heparin in 1918. In the 1920s, animal experiments confirmed that heparin was an effective anticoagulant.[67]

John Gibbon contributed more to the success of the development of the heart-lung machine than anyone else. His interest began as a young doctor one night in 1930 in Boston "during an all-night vigil by the side of a patient with a massive embolus. . . ."[68] Unfortunately, the patient did not survive, but Gibbon thought that if he had a machine that could take over for the heart and lungs while the blood clot was removed surgically from the pulmonary arteries, the patient could have been saved.

Gibbon's work on the heart-lung machine took place over the next 20 years in laboratories at Massachusetts General Hospital, the University of Pennsylvania, and Thomas Jefferson University. In 1937, Gibbon reported the first successful demonstration that life could be maintained by an artificial heart and lung and that the native heart and lungs could resume function. Unfortunately, only three animals recovered adequate cardiorespiratory function after total pulmonary artery occlusion and bypass, and even they died a few hours later.[69] Gibbon's work was interrupted by World War II; afterward, he resumed his work at Thomas Jefferson Medical College in Philadelphia. Meanwhile, other groups, including Clarence Crafoord in Stockholm, Sweden, J. Jongbloed at the University of Utrecht in Holland, Clarence Dennis at the University of Minnesota, Mario Digliotti and coworkers at the University of Turino in Italy, and Forest Dodrill at Harper Hospital in Detroit, also worked on a heart-lung machine.[70]

Clarence Dennis's first clinical attempt at open-heart surgery was in a 5-year-old girl with end-stage cardiac disease.[71] Her heart was already massive, and her only hope was surgical closure of an atrial septal defect. At operation on April 6, 1951, her circulation was supported by a heart-lung machine that Dennis and his coworkers had developed.[72] The atrial septal defect (ASD) was very difficult to close. Although the heart-lung machine functioned well, the patient did not survive, probably because of a combination of blood loss and surgically induced tricuspid stenosis (Table 1-1).

Table 1–1.

Twilight Zone: Clinical Status of Open-Heart Surgery, 1951–1955

1951	*April 6*: Clarence Dennis at the University of Minnesota used a heart-lung machine to repair an ostium primum or AV canal defect in a 5-year-old girl. Patient could not be weaned from cardiopulmonary bypass.[72]
	May 31: Dennis attempted to close an atrial septal defect using heart-lung machine in a 2-year-old girl who died intraoperatively of a massive air embolus. [72] Although unsuccessful, these were probably the first two surgeries where a heart-lung machine was used while the surgeon attempted to correct a human heart defect.
1951	*August 7:* Achille Mario Digliotti, professor of surgery at the University of Turino, Italy, used a heart-lung machine of his own design to partially support the circulation (flow at 1 L/min for 20 minutes) while he resected a large mediastinal tumor compressing the right side of the heart.[74] The cannulation was through the right axillary vein and artery. The patient survived. This was the first successful clinical use of a heart-lung machine, but the machine was not used as an adjunct to heart surgery.
1952	*February* (1952 or 1953 John Gibbon; see February 1953)
	March: John Gibbon used his heart-lung machine for right-sided heart bypass only while surgeon Frank Allbritten at Pennsylvania Hospital, Philadelphia, operated to remove a large clot or myxomatous tumor suspected by angiography.[75] The right atrium and tricuspid valve were very dilated. No tumor or clot was found. The patient died of heart failure in the operating room shortly after discontinuing right-sided heart bypass.
1952	*July 3*: Dodrill used the Dodrill-GMR pump to bypass the left side of the heart while he repaired a mitral valve.[76] The patient survived. This was the first successful use of a mechanical pump for total substitution of the left ventricle in a human being.
	September 2: John Lewis, at the University of Minnesota, closed an atrial septal defect under direct vision in a 5-year-old girl. The patient survived. This was the first successful clinical heart surgery procedure using total-body hypothermia. A mechanical pump and oxygenator were not used. Others, including Dodrill, soon followed, using total-body hypothermia techniques to close atrial septal defects (ASDs) and perform pulmonary valvulotomies. By 1954, Lewis reported on 11 ASD closures using hypothermia with two hospital deaths.[77] He also operated on two patients with ventricular septal defect (VSD) in early 1954 using this technique. Both resulted in intraoperative deaths.
	October 21: Dodrill performed pulmonary valvulotomy under direct vision using Dodrill-GMR pump to bypass the right atrium, ventricle, and main pulmonary artery.[78] The patient survived.
	Although Dr. William Mustard in Toronto would describe a type of "corrective" surgical procedure for transposition of the great arteries (TGA) in 1964, which, in fact, for many years, would become the most popular form of surgical correction of TGA, his early results with this lesion were not good. In 1952 he used a mechanical pump coupled to the lung that had just been removed from a monkey to oxygenate the blood in seven children while attempts were made to correct their TGA defect.[79] There were no survivors.
1953	*February* (or 1952): Gibbon at Jefferson Hospital in Philadelphia operated to close an ASD in a very sick 15-month-old girl weighing 11 lb.[80] He used his heart-lung machine. No ASD was found. The patient died intraoperatively. Autopsy showed a large patent ductus arteriosus.
	May 6: Gibbon used his heart-lung machine to close an ASD in an 18-year-old woman with symptoms of heart failure.[80] The patient survived the operation and became the first patient to undergo successful open-heart surgery using a heart-lung machine.
	July: Gibbon used the heart-lung machine on two 5-year-old girls to close atrial septal defects.[80] Cardiac arrest occurred after the chest was opened in the first patient. The heart and great vessels were cannulated during CPR. Cardiopulmonary bypass was commenced. The patient died intraoperatively. The second patient was found at operation to have AV canal and a small patent ductus arteriosus. The AV canal was partially closed. She died intraoperatively. Gibbon was extremely distressed and declared a moratorium on further cardiac surgery at Jefferson Medical School until more work could be done to solve problems related to heart-lung bypass. This was probably the last heart operation he performed using the heart-lung machine.

(continued)

Table 1–1.

Twilight Zone: Clinical Status of Open-Heart Surgery, 1951–1955 (*continued*)

1954	*March 26*: C. Walton Lillehei and associates at the University of Minnesota closed a VSD under direct vision in a 15-month-old boy using a technique to support the circulation that they called *controlled cross-circulation*. An adult (usually a parent) with the same blood type was used more or less as the heart-lung machine. The adult's femoral artery and vein were connected with tubing and a pump to the patient's circulation. The adult's heart and lungs oxygenated and supported the circulation while the child's heart defect was corrected. The first patient died 11 days postoperatively from pneumonia, but six of their next seven patients survived.[81] Between March 1954 and the end of 1955, 45 heart operations were performed by Lillehei on children using this technique before it was phased out. Although controlled cross-circulation was a short-lived technique, it was an important stepping stone in the development of open-heart surgery. *July*: Clarence Crafoord and associates at the Karolinska Institute in Stockholm, Sweden, used a heart-lung machine of their own design coupled with total-body hypothermia (patient was initially submerged in an ice-water bath) to remove a large atrial myxoma in a 40-year-old woman.[82] She survived.
1955	*March 22*: John Kirklin at the Mayo Clinic used a heart-lung machine similar to Gibbon's, but with modifications his team had worked out over 2 years in the research laboratory, to successfully close a VSD in a 5-year-old patient. By May of 1955, they had operated on eight children with various types of VSDs, and four were hospital survivors. This was the first successful series of patients (i.e., more than one) to undergo heart surgery using a heart-lung machine.[83] Although their mortality was 50% Kirklin continued on in 1955, his open-heart mortality rates dropped.[84] *May 13*: Lillehei and colleagues began using a heart-lung machine of their own design to correct intracardiac defects. By May of 1956, their series included 80 patients.[81] Initially they used their heart-lung machine for lower-risk patients and used controlled cross-circulation, with which they were more familiar, for the higher-risk patients. Starting in March 1955, they also tried other techniques in patients to oxygenate blood during heart surgery, such as canine lung, but with generally poor results.[81] Dodrill had been performing heart operations with the GM heart pump since 1952 and used the patient's own lungs to oxygenate the blood. Early in the year 1955, he attempted repairs of VSDs in two patients using the heart pump, but with a mechanical oxygenator of his team's design. The first patient died day one after surgery when the endotracheal tube became obstructed, which was undetected for several minutes. The other patient had a common ventricle (no ventricular septum), which Dodrill attempted to repair. This patient died on the second postoperative day. On December 1, he closed a VSD in a 3-year-old girl using his heart-lung machine. She survived. In May 1956 at the annual meeting of the American Association for Thoracic Surgery, he reported on six children with VSDs, including one with tetralogy of Fallot, who had undergone open-heart surgery using his heart-lung machine. All survived at least 48 hours postoperatively.[85] Three were hospital survivors, including the patient with tetralogy of Fallot. *June 30*: Clarence Dennis, who had moved from the University of Minnesota to the State University of New York, successfully closed an ASD in a girl using a heart-lung machine of his own design.[86] Mustard successfully repaired a VSD and dilated the pulmonary valve in a 9-month-old with a diagnosis of tetralogy of Fallot using a mechanical pump and a monkey lung to oxygenate the blood.[87] He did not give the date in 1955, but the patient is listed as Human Case 7. Unfortunately, in the same report, cases 1–6 and 8–15 operated on between 1951 and the end of 1955 with various congenital heart defects did not survive the surgery using the pump and monkey lung, nor did another seven children in 1952, all with TGA (see timeline for 1952) using the same bypass technique.

Note: This list is not all-inclusive but likely includes most of the historically significant clinical open-heart events where a blood pump was used to support the circulation during this period. (A twilight zone can mean an ill-defined area between two distinct conditions, such as the area between darkness and light.)

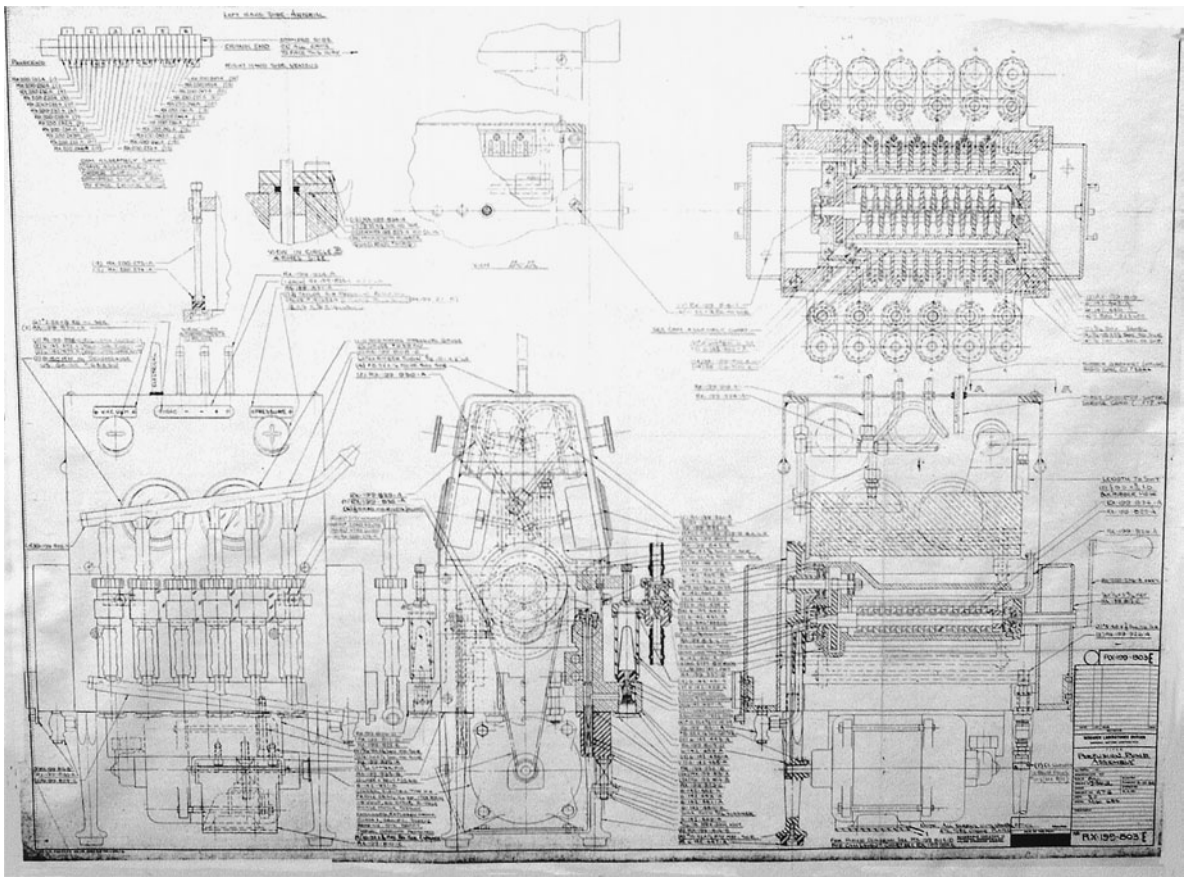

Figure 1-3. Blueprints by General Motors engineers of the Dodrill-GMR mechanical heart. *(Courtesy of Calvin Hughes, M.D.)*

In August of 1951, Mario Digliotti used his heart-lung machine to partially support the circulation of a 49-year-old patient during resection of a large mediastinal tumor.[74] During the operation, the patient developed hypotension and cyanosis. He therefore was placed on partial bypass at 1 L/min for 20 minutes. Although the mass was resected successfully, the Italian machine was never used for open-heart surgery in humans.

Forest Dodrill and colleagues used the mechanical blood pump they developed with General Motors on a 41-year-old man[76] (Fig. 1-3). The machine was used to substitute for the left ventricle for 50 minutes while a surgical procedure was carried out to repair the mitral valve; the patient's own lungs were used to oxygenate the blood. This, the first clinically successful total left-sided heart bypass in a human, was performed on July 3, 1952, and followed from Dodrill's experimental work with a mechanical pump for univentricular, biventricular, or cardiopulmonary bypass. Although Dodrill and colleagues had used their pump with an oxygenator for total heart bypass in animals,[88] they felt that left-sided heart bypass was the most practical method for their first clinical case.

Later, on October 21, 1952, Dodrill and colleagues used their machine in a 16-year-old boy with congenital pulmonary stenosis to perform a pulmonary valvuloplasty under direct vision; this was the first successful right-sided heart bypass.[78] Between July 1952 and December 1954, Dodrill performed approximately 13 clinical operations on the heart and thoracic aorta using the Dodrill–General Motors machine, with at least five hospital survivors.[89] While he used this machine with an oxygenator in the animal laboratory, he did not start using an oxygenator with the Dodrill–General Motors mechanical heart clinically until early 1955.

Hypothermia was another method to stop the heart and allow it to be opened. In 1950, Bigelow and colleagues[90] reported on 20 dogs that had been cooled to 20°C with 15 minutes of circulatory arrest; 11 animals also had a cardiotomy. Only six animals survived after rewarming. Bigelow and colleagues continued to study hypothermia.[91–93]

John Lewis closed an atrial septal defect in a 5-year-old girl on September 2, 1952, using a hypothermic technique[77]:

> She was wrapped in refrigerated blankets until after a period of 2 hours and 10 minutes her rectal temperature had fallen to 28°C. At this point the chest was entered through the bed of the right fifth rib. The cardiac inflow was occluded for a total of 5½ minutes and during this time the septal defect was closed under direct vision. The patient was rewarmed by placing her in hot water kept at 45°C, and after 35 minutes her

> rectal temperature had risen to 36°C, at which time she was removed from the bath. Recovery from the anesthesia was prompt and her subsequent postoperative convalescence was uneventful.

Shortly thereafter, Swan and colleagues[94] reported successful results in 13 clinical cases using a similar technique. But the use of systemic hypothermia for open intracardiac surgery was relatively short-lived; after the heart-lung machine was introduced clinically, it appeared that deep hypothermia was obsolete. However, during the 1960s, it became apparent that operative results in infants under 1 year of age using cardiopulmonary bypass were poor. In 1967, Hikasa and colleagues,[95] from Kyoto, Japan, published an article that reintroduced profound hypothermia for cardiac surgery in infants and used the heart-lung machine for rewarming. Their technique involved surface cooling to 20°C, cardiac surgery during circulatory arrest for 15 to 75 minutes, and rewarming with cardiopulmonary bypass. At the same time, other groups reported using profound hypothermia with circulatory arrest in infants with the heart-lung machine for cooling and rewarming.[96–99] Results were much improved, and subsequently, the technique also was applied for resection of aortic arch aneurysms.

After World War II, John Gibbon resumed his research. He eventually met Thomas Watson, chairman of the board of the International Business Machines (IBM) Corporation. Watson was fascinated by Gibbon's research and promised help. Soon afterward, six IBM engineers arrived and built a machine that was similar to Gibbon's earlier machine, which contained a rotating vertical cylinder oxygenator and a modified DeBakey rotary pump. Gibbon used this new machine successfully for intercardiac surgery on small dogs and had several long-term survivors, but the blood oxygenator was too small for human patients. Eventually, the team developed a larger oxygenator that the IBM engineers incorporated into a new machine.[100]

In 1949, Gibbon's early mortality in dogs was 80%, but it improved gradually.[101] Gibbon operated on a 15-month-old girl with severe congestive heart failure (CHF). The preoperative diagnosis was ASD, but at operation, none was found. She died, and a huge patent ductus was found at autopsy. The next patient was an 18-year-old girl with CHF owing to an ASD. This defect was closed successfully on May 6, 1953, with the Gibbon-IBM heart-lung machine. The patient recovered, and several months later the defect was confirmed closed at cardiac catheterization.[101] Unfortunately, Gibbon's next two patients did not survive intracardiac procedures when the heart-lung machine was used. These failures distressed Dr. Gibbon, who declared a 1-year moratorium for the heart-lung machine until more work could be done to solve the problems causing the deaths.

During this period, C. Walton Lillehei and colleagues at the University of Minnesota studied a technique called *controlled cross-circulation.*[57] With this technique, the circulation of one dog was used temporarily to support that of a second dog while the second dog's heart was stopped temporarily and opened. After a simulated repair in the second dog, the animals were disconnected and allowed to recover.

Lillehei and colleagues[102] used their technique at the University of Minnesota to correct a VSD in a 12-month-old infant on March 26, 1954 (Fig. 1-4). Either a parent or a close relative with the same blood type was connected to the child's circulation. In Lillehei's first clinical case, it was the child's father. The patient had been hospitalized 10 months for uncontrollable heart failure and pneumonitis. The patient made an uneventful recovery until death on the eleventh postoperative day from a rapidly progressing tracheal bronchitis. At autopsy, the VSD was closed, and the respiratory infection was confirmed as the cause of death. Two weeks later, the second and third patients had VSDs closed by the same technique 3 days apart. Both remained long-term survivors with normal hemodynamics confirmed by cardiac catheterization.

In 1955, Lillehei and colleagues[103] published a report of 32 patients that included repairs of VSDs, tetralogy of Fallot, and atrioventricularis communis defects. By May of 1955, the blood pump used for systemic cross-circulation by Lillehei and colleagues was coupled with a bubble oxygenator developed by Drs. DeWall and Lillehei, and cross-circulation was soon abandoned after use in 45 patients during 1954 and 1955. Although its clinical use was short-lived, cross-circulation was an important steppingstone in the development of cardiac surgery.[57]

Meanwhile, at the Mayo Clinic only 90 miles away, John W. Kirklin and colleagues launched their open-heart program on March 5, 1955.[83] They used a heart-lung machine based on the Gibbon-IBM machine but with their own modifications. Dr. Kirklin wrote[104]:

> We investigated and visited the groups working intensively with the mechanical pump oxygenators. We visited Dr. Gibbon in his laboratories in Philadelphia, and Dr. Forest Dodrill in Detroit, among others. The Gibbon pump oxygenator had been developed and made by the International Business Machine Corporation and looked quite a bit like a computer. Dr. Dodrill's heart-lung machine had been developed and built for him by General Motors and it looked a great deal like a car engine. We came home, reflected and decided to try to persuade the Mayo Clinic to let us build a pump oxygenator similar to the Gibbon machine, but somewhat different. We already had had about a year's experience in the animal laboratory with David Donald using a simple pump and bubble oxygenator when we set about very early in 1953, the laborious task of building a Mayo-Gibbon pump oxygenator and continuing the laboratory research.
>
> Most people were very discouraged with the laboratory progress. The American Heart Association and the National Institutes of Health had stopped funding any projects for the study of heart-lung machines, because

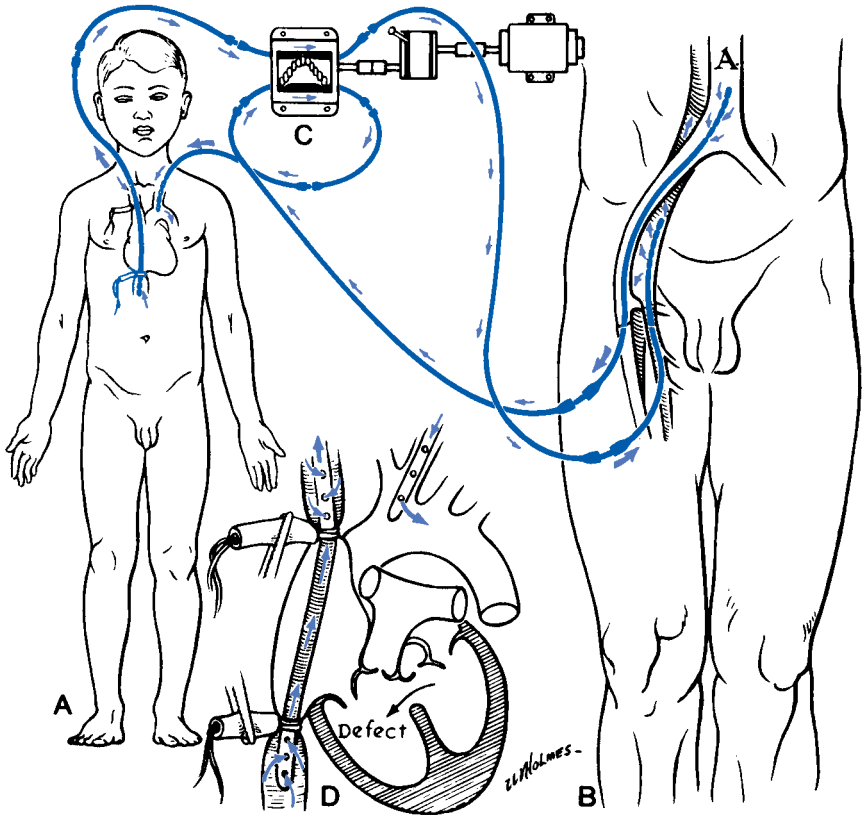

Figure 1-4. A depiction of the method of direct-vision intracardiac surgery using extracorporeal circulation by means of controlled cross-circulation. (*A*) The patient, showing sites of arterial and venous cannulations. (*B*) The donor, showing sites of arterial and venous (superficial femoral and great saphenous) cannulations. (*C*) The Sigma motor pump controlling precisely the reciprocal exchange of blood between the patient and donor. (*D*) Close-up of the patient's heart, showing the vena caval catheter positioned to draw venous blood from both the superior and inferior venae cavae during the cardiac bypass interval. The arterial blood from the donor circulated to the patient's body through the catheter that was inserted into the left subclavian artery. *(Reproduced with permission from Lillehei CW, Cohen M, Warden HE, et al: The results of direct vision closure of ventricular septal defects in eight patients by means of controlled cross circulation. Surg Gynecol Obstet 1955; 101:446. Copyright American College of Surgeons.)*

it was felt that the problem was physiologically insurmountable. David Donald and I undertook a series of laboratory experiments lasting about 1½ years during which time the engineering shops at the Mayo Clinic constructed a pump oxygenator based on the Gibbon model.[105]

. . . The electrifying day came in the spring of 1954 when the newspapers carried an account of Walt Lillehei's successful open-heart operation on a small child. Of course, I was terribly envious and yet I was terribly admiring at the same moment. That admiration increased exponentially when a short time later, a few of my colleagues and I visited Minneapolis and observed one of what was now a series of successful open-heart operations with control cross-circulation.

. . . In the winters of 1954 and 1955 we had nine surviving dogs out of 10 cardiopulmonary bypass runs. With my wonderful colleague and pediatric cardiologist, Jim DuShane, we had earlier selected eight patients for intracardiac repair. Two had to be put off because two babies with very serious congenital heart disease came along and we decided to fit them into the schedule. We had determined to do all eight patients even if the first seven died. All of this was planned with the knowledge and approval of the governance of the Mayo Clinic. Our plan was then to return to the laboratory and spend the next 6 to 12 months solving the problems that had arisen in the first planned clinical trial of a pump oxygenator. . . . We did our first open-heart operation on a Tuesday in March 1955.

Kirklin continued[104]:

> Four of our first eight patients survived, but the press of the clinical work prevented our ever being able to return to the laboratory with the force that we had planned. By now, Walt Lillehei and I were on parallel, but intertwined paths.

By the end of 1956, many university groups around the world had launched into open-heart programs. Currently, it is estimated that more than 1 million cardiac operations are performed each year worldwide with use of the heart-lung machine. In most cases, the operative mortality is quite low, approaching 1% for some operations. Little thought is given to the courageous pioneers in the 1950s whose monumental contributions made all this possible.

Extracorporeal Life Support

Extracorporeal life support is an extension of cardiopulmonary bypass. Cardiopulmonary bypass was limited initially to no more than 6 hours. The development of membrane oxygenators in the 1960s permitted longer support. Donald Hill and colleagues in 1972 treated a 24-year-old man who developed shock lung after blunt trauma.[106] The patient was supported for 75 hours using a heart-lung machine with a membrane oxygenator, cannulated via the femoral vein and artery. The patient was weaned and

recovered. Hill's second patient was supported for 5 days and recovered. This led to a randomized trial supported by the National Institutes of Health to determine the efficacy of this therapy for adults with respiratory failure. The study was conducted from 1972 to 1975 and showed no significant difference in survival between patients managed by extracorporeal life support (9.5%) and those who received conventional ventilatory therapy (8.3%).[107] Because of these results, most U.S. centers abandoned efforts to support adult patients using extracorporeal life support (ECLS), also known as *extracorporeal membrane oxygenation* (ECMO).

One participant in the adult trial decided to study neonates. The usual causes of neonatal respiratory failure have in common abnormal postnatal blood shunts known as *persistent fetal circulation* (PFC).[108–111] This is a temporary, reversible phenomenon. In 1976, Bartlett and colleagues at the University of Michigan were the first to treat a neonate successfully using ECLS. Since that time, two prospective studies have shown the efficacy of ECLS for the management of neonatal respiratory failure.[112,113] More than 8000 neonatal patients have been treated using ECLS worldwide with a survival rate of 82% (ELSO registry data).

MYOCARDIAL PROTECTION

Alexis Carrel reported in 1914 that "The arresting of the circulation of the heart has already been performed in many ways by various experimenters. We ourselves have used all known methods of stopping the circulation through the heart."[114] He also referred to work of Borrel and others, who had experimented with different forms of myocardial preservation. Carrel goes on to state: "When the above-mentioned precautions were taken, it was possible to clamp the pedicle of the heart (aorta and pulmonary artery) for 2½ or 3 minutes without any subsequent trouble. As soon as the clamp was removed, the heart resumed its pulsations, and after a very short time, the pulsations were again normal."

Melrose and colleagues[115] in 1955 presented the first experimental study describing induced arrest by potassium-based cardioplegia. Blood cardioplegia was used "to preserve myocardial energy stores at the onset of cardiac ischemia." These authors state, "Ringer drew attention in 1883 to the effect of the differentiations on the heartbeat and Hooker in 1929 suggested that potassium inhibition induced by an excess of potassium chloride could be used to stop the heart when its beat was disorganized by ventricular fibrillation." Melrose goes on to state that ". . . they have succeeded in evolving a reliable method of stopping and restarting the heart at both normal and reduced body temperatures." Unfortunately, the Melrose solution proved to be toxic to the myocardium, and as a result, cardioplegia was not used widely for several years.

Gay and Ebert[116] and Tyres and colleagues[117] demonstrated that cardioplegia with lower potassium concentrations was safe. Studies by Kirsch and colleagues,[118] Bretschneider and colleagues,[119] and Hearse and colleagues[120] demonstrated the effectiveness of cardioplegia with other constituents and renewed interest in this technique. Gay and Ebert in 1973 demonstrated a significant reduction in myocardial oxygen consumption during potassium-induced arrest when compared with that of the fibrillating heart.[116] They also showed that the problems in the use of the Melrose solution in the early days of cardiac surgery probably were due to its hyperosmolar properties and perhaps not to the high potassium concentration.

In a 1978 publication by Follette and colleagues,[121] the technique of blood cardioplegia was reintroduced. In experimental and clinical studies, these authors demonstrated that hypothermic, intermittent blood cardioplegia provided better myocardial protection than normothermic, continuous coronary perfusion and/or hypothermic, intermittent blood perfusion without cardioplegia solution. The composition of the best cardioplegia solution remains controversial, and new formulations, methods of delivery, and recommended temperatures continue to evolve.

EVOLUTION OF CONGENITAL CARDIAC SURGERY DURING THE ERA OF CARDIOPULMONARY BYPASS

With the advent of cardiopulmonary bypass using either the cross-circulation technique of Lillehei and colleagues or the version of the mechanical heart-lung machine used by Kirklin and colleagues, the two groups led the way for intracardiac repairs for many of the commonly occurring congenital heart defects. Because of the morbidity associated with the heart-lung machine, palliative operations also were developed to improve circulatory physiology without directly addressing the anatomic pathology. These palliative operations included the Blalock-Taussig subclavian–pulmonary arterial shunt[49] with modifications by Potts and colleagues[122] and Waterston and colleagues,[123] the Blalock-Hanlon operation to create an atrial septal defect,[124] and the Galankin-Glenn superior vena cava–right pulmonary arterial shunt.[55]

As the safety of cardiopulmonary bypass improved steadily, surgeons addressed more and more complex abnormalities of the heart in younger and younger patients. Some of the milestones in the development of operations to correct congenital heart defects using cardiopulmonary bypass appear in Table 1-2. These advances coincided with simultaneous advances in the surgery of adult heart disease, and the same surgeons operated on both children and adults. In the 1970s, although depending on the same technology and basic knowledge, pediatric and adult cardiac surgery began to separate. Operations for more complex congenital lesions in younger and younger patients required new techniques, and likewise, the advent of direct operations for ischemic heart disease required new technology and methods to deal with damaged ventricles and acute complications of

Table 1–2.

First Successful Intracardiac Repairs Using Cardiopulmonary Bypass or Cross-Circulation

Lesion	Year	Reference	Comment
Atrial septal defect	1953	Gibbon[101]	May 6, 1953
Ventricular septal defect	1953	Lillehei[102]	Cross-circulation
Complete atrioventricular canal	1954	Lillehei[103]	Cross-circulation
Tetralogy of Fallot	1954	Lillehei[102]	Cross-circulation
Tetralogy of Fallot	1955	Kirklin[83]	Cardiopulmonary bypass (CPB)
Total anomalous pulmonary veins	1956	Kirklin[125]	
Congenital aneurysm sinus of Valsalva	1956	Kirklin[126]	
Congenital aortic stenosis	1956	Kirklin[127]	First direct visual correction
Aortopulmonary window	1957	Cooley[128]	First closure using CPB
Double outlet right ventricle	1957	Kirklin[129]	Extemporarily devised correction
Corrected transposition great arteries	1957	Lillehei[130]	
Transposition of great arteries: atrial switch	1959	Senning[131]	Physiologic total correction
Coronary arteriovenous fistula	1959	Swan[132]	
Ebstein's anomaly	1964	Hardy[133]	Repair of atrialized tricuspid valve
Tetralogy with pulmonary atresia	1966	Ross[134]	Used aortic allograft
Truncus arteriosus	1967	McGoon[135]	Used aortic allograft
Tricuspid atresia	1968	Fontan[136]	Physiologic correction
Single ventricle	1970	Horiuchi[137]	
Subaortic tunnel stenosis	1975	Konno[138]	
Transposition of great arteries: arterial switch	1975	Jatene[139]	Anatomic correction
Hypoplastic left heart syndrome	1983	Norwood[140]	Two-stage operation
Pediatric heart transplantation	1985	Bailey[141]	

ischemia. With the exception of sporadic patients who reached adult life with uncorrected or partially corrected congenital heart defects, cardiac surgery in the adult represents the surgery of acquired heart disease. Nevertheless, a close connection continues because the advances in one subspecialty usually are applicable in the other, and this kinship and interdependence probably will remain for the foreseeable future.

VALVULAR SURGERY: CARDIOPULMONARY BYPASS ERA

Cardiac valve repair or replacement under direct vision awaited the development of the heart-lung machine. The first successful aortic valve replacement (AVR) in the subcoronary position was performed by Dr. Dwight Harken and associates.[142] A caged-ball valve was used. Many of the techniques described in Harken's 1960 report are similar to those used today for AVR.

That same year, Starr and Edwards[143] successfully replaced the mitral valve using a caged-ball valve of their own design. Starr later wrote[144]:

> In 1958, Lowell Edwards presented himself in my office with a proposal to develop an implantable artificial heart. I learned that he was a retired engineer with considerable financial resources. His visit was fortuitous, because just about that time, I had become interested in valvular prostheses. . . . Edwards agreed to begin the project by working on one valve at a time. . . . The obvious direction then was toward the ball valve prosthesis. I drew out for Edwards the general configuration of the Hufnagel valve. He then drew out for me how he thought that particular valve could be adapted for intracardiac use using an open cage. The first animal to have this implant survived for more than a year, but all other subsequent animals died of thrombosis. . . . The big breakthrough came at the end of 1958 when we developed the Silastic shield for the ball valve, which allowed an 80% long-term survival. . . . A Silastic shield over the area where thrombus formed on the valve would give us a chance to have long-term survivors.

The first successful operation was done in September 1960 on a woman in her mid-twenties. The patient was in pulmonary edema on oxygen prior to operation and in excellent condition and wide awake on the evening of the day of the surgery.

By 1967, nearly 2000 Starr-Edwards valves had been implanted, and the caged-ball-valve prosthesis was established as the standard against which all other mechanical prostheses would be compared.

In 1964, Starr and colleagues reported 13 patients who had undergone multiple valve replacement.[145] One patient had the aortic, mitral, and tricuspid valves replaced on February 21, 1963. Cartwright and colleagues, however, on November 1, 1961, were the first to replace both the aortic and mitral valves successfully with ball-valve prostheses that they had developed.[146] Knott-Craig and colleagues,[147] from the Mayo Clinic, successfully replaced all four heart valves in a patient with carcinoid involvement.

In 1961, Andrew Morrow and Edwin Brockenbrough[148] reported a treatment for idiopathic hypertrophic subaortic stenosis by resecting a portion of the thickened ventricular septum. They referred to this as *subaortic ventriculomyotomy.* They gave credit to William Cleland and H. H. Bentall in London, who had encountered this condition unexpectedly at operation and resected a small portion of the ventricular mass. The patient improved, but no postoperative hemodynamic studies had been reported. The subaortic ventriculomyotomy became the standard surgical treatment for this cardiac anomaly, although in some patients systolic anterior motion (SAM) of the anterior leaflet of the mitral valve necessitates mitral valve replacement with a low-profile mechanical valve.

An aortic homograft valve was used clinically for the first time by Heimbecker and colleagues in Toronto for replacement of the mitral valve in one patient and an aortic valve in another.[149] Survival was short, 1 day in one patient and 1 month in the other. Donald Ross reported on the first successful aortic valve placement with an aortic valve homograft.[150] He used a technique of subcoronary implantation developed in the laboratory by Carlos Duran and Alfred Gunning in Oxford.

The technique of AVR with a pulmonary autograft described initially by Ross in 1967 is advocated by some groups for younger patients who require AVR.[151,152] An aortic or pulmonary valve homograft is used to replace the pulmonary valve that has been transferred to the aortic position.

Other autogenous materials that have been used to manufacture valve prostheses include pericardium, fasciae latae, and dura mater. In the 1960s, Binet and colleagues[153] began to develop and test tissue valves. In 1964, Duran and Gunning in England replaced an aortic valve in a patient using a xenograft porcine aortic valve. Early results with formaldehyde-fixed xenografts were good,[153] but in a few years these valves began to fail because of tissue degeneration and calcification.[154] Carpentier and colleagues revitalized interest in xenograft valves by fixating porcine valves with gluteraldehyde. Carpentier also mounted his valves on a stent to produce a bioprosthesis. Carpentier-Edwards porcine valves and Hancock and Angell-Shiley bioprostheses became popular and were implanted in large numbers of patients.[155,156]

Carpentier later wrote: "In 1964 as a young resident in thoracic surgery, I was asked by J. P. Binet, chief of the service, to collect homograft valves from cadavers. Studies of the anatomy of the valves in various animal species showed that the valves from the pigs were the closest to those of humans."[157] Carpentier described the first successful xenograft valve replacement in 1965, followed by 12 other operations,

but within 5 years, all the heterograft valves had to be replaced. Carpentier goes on to state:

> The use of formalin proposed by O'Brien did not significantly improve the results. I began mounting the valves on a stent in 1966, which permitted the use of heterograft valves in the mitral position. It became obvious that the future of tissue valves would depend upon the development of methods of preparation capable of preventing inflammatory cell reaction, and penetration into the tissue. My background in chemistry is obviously insufficient. I decided to abandon surgery for two days a week to follow the teaching program in chemistry at the Faculty of Sciences and prepare a Ph.D. It is certainly not easy to become a student in chemistry when you are 35 and an associate professor of surgery.
>
> I began to investigate numerous cross-linking inducing factors and found that gluteraldehyde was able to almost eliminate inflammatory reaction. . . .

With the development of cardiopulmonary bypass, valves could be approached under direct vision, and for the first time, mitral insufficiency could be attacked by reparative techniques. Techniques for mitral annuloplasty were described by Wooler and colleagues,[158] Reed and colleagues,[159] and Kay and colleagues.[160] The next step forward was development of annuloplasty rings by Carpentier and Duran. In the 1970s, few groups were involved in valve repairs. Slowly, techniques evolved, were tested clinically, and were followed over the years. Carpentier led the field by establishing the importance of careful analysis of valve pathology, described in detail several techniques of valve repair, and reported good results after early and late follow-up, especially with concomitant use of annuloplasty rings.[161]

From 1966 to 1968, a small epidemic of infective endocarditis in Detroit among heroin addicts broke out. Patients were dying of intractable gram-negative tricuspid valve endocarditis, often owing to *Pseudomonas aeruginosa.* Long-term antibiotic administration in combination with tricuspid valve replacement was 100% fatal. These results prompted Agustin Arbulu and colleagues to remove the tricuspid valve entirely without replacing it in seven dogs in 1969. Six survived with satisfactory hemodynamic performance. Starting in 1970, Arbulu operated on 55 patients; in 53, the tricuspid valve was removed without replacing it.[162,163] At 25 years, the actuarial survival is 61%.

CORONARY ARTERY SURGERY

Alexis Carrel remarked in 1910[164]:

> I attempted to perform an indirect anastomosis between descending aorta and the left coronary artery. It was for many reasons a difficult operation. On account of the continuous motion of the heart, it was not easy to dissect and to suture the artery. In one case, I implanted one end of a long carotid artery, preserved in a cold storage, on the descending aorta. The other end was passed through the pericardium and anastomosed to the pericardial end of the coronary near the pulmonary artery. Unfortunately, the operation was too slow. Three minutes after the interruption of the circulation fibrillary contractions appeared, but the anastomosis took five minutes. By massage of the heart, the dog was kept alive, but he died less than two hours afterwards. It shows that the anastomosis must be done in less than three minutes.

In 1930, Claude Beck, a Cleveland surgeon, developed methods to indirectly revascularize the hearts of animals by attaching adjacent tissues in hopes of forming collateral blood flow to ischemic myocardium.[165] These tissues included pericardium, pericardial fat, pectoralis muscle, and omentum. Postmortem examination showed that anastomotic vessels did develop between these tissues and the myocardium. In the first patient, Beck roughened the outer surface of the heart with a burr and then sutured a pedicle graft of pectoralis muscle to the left ventricular wall.[166] The patient made an uneventful recovery and was angina-free after the operation. Beck subsequently performed this operation with modifications on 16 patients.[167]

Arthur Vineberg, a Canadian surgeon, in 1946 reported implanting the internal mammary artery through a tunnel in the myocardium, but he did not actually anastomose the left internal mammary artery to a coronary artery.[168] He showed in animals that communications developed between the internal mammary and the coronary arteries. Contemporary surgeons, however, remained skeptical, but Mason Sones validated Vineberg's concept by demonstrating communications between the graft in the myocardium and the coronary system by angiography in two patients operated on 5 and 6 years earlier. In the middle 1960s, the Vineberg operation with many variations was performed at many institutions in the United States and Canada.[169]

At the same time, other surgeons performed coronary arterial endarterectomies. Longmire and colleagues[170] were the first to report endarterectomy of the coronary arteries for the treatment of ischemic coronary disease. In 1958, they reported five patients, with four hospital survivors. Although the operation was used subsequently by other groups, mortality was high, and the procedure was abandoned as an isolated operation.

Selective coronary angiography was developed by Sones and Shirey at the Cleveland Clinic and reported in their 1962 classic paper entitled, "Cine Coronary Arteriography."[171] They used a catheter to inject contrast material directly into the coronary artery ostia. This technique gave a major impetus to direct revascularization of obstructed coronary arteries.

From 1960 to 1967, several sporadic instances of coronary grafting were reported. All were isolated cases and, for uncertain reasons, were not reproduced. None had an impact on the development of coronary surgery. Dr. Robert H. Goetz performed what appears to be the first

clearly documented coronary artery bypass operation in a human, which was successful. The surgery took place at Van Etten Hospital in New York City on May 2, 1960.[172] He operated on a 38-year-old man who was severely symptomatic and used a nonsuture technique to connect the right internal mammary artery to a right coronary artery. It took him 17 seconds to join the two arteries using a hollow metal tube. The right internal mammary artery–coronary artery connection was confirmed patent by angiography performed on the 14th postoperative day. The patient remained asymptomatic for about a year and then developed recurrent angina and died of a myocardial infarction on June 23, 1961. Goetz was severely criticized by his medical and surgical colleagues for this procedure, although he had performed it successfully many times in the animal laboratory. He never attempted another coronary bypass operation in a human.

Another example involved a case of autogenous saphenous vein bypass grafting performed on November 23, 1964, in a 42-year-old man who was scheduled to have endarterectomy of his left coronary artery.[173] Since the lesion involved the entire bifurcation, endarterectomy with venous patch graft was abandoned as too hazardous. The anterior descending coronary artery was softer distal to the bifurcation. An autogenous saphenous vein graft therefore was placed from the aorta to the left anterior descending. This was probably the first clinical case of successful coronary artery bypass surgery using saphenous vein. The authors, Garrett, Dennis, and DeBakey, however, did not report this case until 1973. The patient was alive at that time, and angiograms showed the vein graft to be patent.

Shumaker[174] credits Longmire with the first internal mammary–coronary artery anastomosis. "It was almost surely Longmire, long-time chairman at UCLA, and his associate, Jack Cannon, who first performed an anastomosis between the internal mammary artery and a coronary branch, probably in early 1958." Longmire wrote:

> At that time we were doing the coronary thromboendarterectomy procedure, we also, I think, performed a couple of the earliest internal mammary–coronary anastomoses. . . . We were forced into it when the coronary artery we were endarterectomizing disintegrated, and in desperation we anastomosed the internal mammary artery to the distal end of the right coronary artery—and later decided it was a good operation.

The reference that Shumaker gives for this quotation from Longmire is a personal communication to Shumaker in 1990, which is 32 years after the fact!

As early as 1952, Vladimir Demikhov, the renowned Soviet surgeon, was anastomosing the internal mammary artery to the left coronary artery in dogs.[175] In 1967, at the height of the Cold War, a Soviet surgeon from Leningrad, V. I. Kolessov, reported his experience with mammary artery–coronary artery anastomoses for the treatment of angina pectoris in six patients in an American surgical journal.[176] The first patient in that series was done in 1964. Operations were performed through a left thoracotomy without extracorporeal circulation or preoperative coronary angiography. The following year, Green and colleagues[177] and Bailey and Hirose[178] separately published reports in which the internal mammary artery was used for coronary artery bypass in patients. Bailey and Hirose carried out the anastomosis on the beating heart and advocated using loupes for magnification. Green and colleagues advocated using cardiopulmonary bypass, fibrillating the vented heart, cross-clamping the aorta, and washing all blood from the coronary system while performing the anastomosis.

Rene Favalaro from the Cleveland Clinic used saphenous vein for bypassing coronary obstructions.[179] Favalaro's 1968 article focused on 15 patients, who were part of a larger series of 180 patients who had undergone the Vineberg procedure. In these 15 patients with occlusion of the proximal right coronary artery, an interpositional graft of saphenous vein also was placed between the ascending aorta and the right coronary artery distal to the blockage. The right coronary artery was divided, and the vein graft was anastomosed end to end. Favalaro states that this procedure was done because of the unfavorable results with pericardial patch reconstruction of the coronary artery. In an addendum to that paper, 55 patients were added, 52 for segmental occlusion of the right coronary and 3 others for circumflex disease.

The contributions by Favalaro, Kolessov, Green and colleagues, and Bailey and Hirose all were important, but arguably, the official start of coronary bypass surgery as we know it today happened in 1969 when W. Dudley Johnson and coworkers from Milwaukee reported their series of 301 patients who had undergone various operations for coronary artery disease (CAD) since February of 1967.[180] In that report, the authors presented their results with direct coronary artery surgery during a 19-month period. They state:

> After two initial and successful patch grafts, the vein bypass technique has been used exclusively. Early results were so encouraging that last summer the vein graft technique was expanded and used to all major branches. Vein grafts to the left side of the arteries run from the aorta over the pulmonary artery and down to the appropriate coronary vessel. Right-sided grafts run along the atrioventricular groove and also attach directly to the aorta. There is almost no limit of potential (coronary) arteries to use. Veins can be sutured to the distal anterior descending or even to posterior marginal branches. Double vein grafts are now used in over 40% of patients and can be used to any combination of arteries.

Johnson goes on to say:

> Our experience indicates that five factors are important to direct surgery. One: Do not limit grafts to proximal portions of large arteries. . . . Two: Do not work with diseased arteries. Vein grafts can be made as long as necessary and should be inserted into distal normal

> arteries. Three: Always do end-to-side anastomoses. . . . Four: Always work on a dry, quiet field. Consistently successful fine vessel anastomoses cannot be done on a moving, bloody target. . . . Five: Do not allow the hematocrit to fall below 35.

In discussing Dr. Johnson's presentation, Dr. Frank Spencer commented: "I would like to congratulate Dr. Johnson very heartily. We may have heard a milestone in cardiac surgery today. Because for years, pathologists, cardiologists, and many surgeons have repeatedly stated that the pattern of coronary artery disease is so extensive that direct anastomosis can be done in only 5 to 7% of patients. If the exciting data by Dr. Johnson remain valid and the grafts remain patent over a long period of time, a total revision of thinking will be required regarding the feasibility of direct arterial surgery for CAD." [180]

The direct anastomosis between the internal mammary artery and the coronary artery was not as popular initially as the vein-graft technique; however, owing to the persistence of Drs. Green, Loop, Grondin, and others, internal mammary artery grafts eventually became the conduit of choice when their superior long-term patency became known.[181]

Denton Cooley and colleagues made two important contributions to the surgery for ischemic heart disease.[182] In 1956, with the use of cardiopulmonary bypass, they were the first to repair a ruptured interventricular septum following acute myocardial infarction. The patient did well initially but died of complications 6 weeks after operation. Cooley and colleagues also were the first to report the resection of a left ventricular aneurysm with the use of cardiopulmonary bypass.[183]

Beck[184] in 1944 was the first to excise a left ventricular aneurysm successfully, and Bailey and colleagues[185] in 1951 had five survivors of six attempts with a clamp and oversew technique.

ARRHYTHMIC SURGERY

Sealy and colleagues at Duke University developed the first successful surgical treatment for cardiac arrhythmias.[186,187] A 32-year-old fisherman was referred for symptomatic episodes of atrial tachycardia that caused CHF. On May 2, 1968, after epicardial mapping, a 5- to 6-cm cut was made extending from the base of the right atrial appendage to the right border of the right atrium during cardiopulmonary bypass. The incision transsected the conduction pathway between the atrium and ventricle. Subsequent epicardial mapping indicated eradication of the pathway. Six weeks after the operation, heart size had decreased and lung fields had cleared. The patient eventually returned to work.

A year earlier, Dr. Dwight McGoon at the Mayo Clinic closed an ASD in a patient who also had the Wolf-Parkinson-White (WPW) syndrome.[187] At operation, Dr. Birchell mapped the epicardium of the heart and localized the accessory pathway to the right atrioventricular groove. Lidocaine was injected into the site, and the delta wave disappeared immediately. Unfortunately, conduction across the pathway reappeared a few hours later. This probably was the first attempt to treat the WPW syndrome surgically. As a result of knowledge gained from the surgical treatment for WPW syndrome, over 95% of all refractory clinical cases now are treated successfully by nonsurgical means.[187]

Ross and colleagues[188] in Sydney, Australia, and Cox and colleagues[189] in St. Louis, Missouri, used cryosurgical treatment of atrial ventricular node reentry tachycardia. Subsequently, James L. Cox, after years of laboratory research, developed the Maze operation for atrial fibrillation.[190] Cox spent years in the animal laboratory at Duke University in Durham, North Carolina, and subsequently Washington University School of Medicine in St. Louis, Missouri, developing a surgical technique for the treatment of atrial fibrillation.[187] That technique, with his subsequent modifications, is now known as the *Cox Maze procedure* and has become the world standard with which other techniques used to treat atrial fibrillation, either surgically or with catheters, are compared.[190]

Guiraudon and colleagues[191] from Paris, France, reported their results with an encircling endomyocardial ventriculotomy for the treatment of malignant ventricular arrhythmias. The following year, in 1979, Josephson and colleagues[192] described a more specific procedure for treatment of malignant ventricular arrhythmias. After endocardial mapping, the endocardial source of the arrhythmia was excised. Although the Guiraudon technique usually isolated the source of the arrhythmia, the incision also devascularized healthy myocardium and was associated with high mortality. Endocardial resection was safer and more efficacious and became the basis of all approaches for the treatment of ischemic ventricular tachycardia.[187]

Stimulated by the death of a close personal friend from ventricular arrhythmias, Dr. Mirowski developed a prototype defibrillator over a 3-month period in 1969. In 1980, Mirowski and colleagues described three successful cases using their implantable myocardial stimulator at Johns Hopkins.[193]

PACEMAKERS

Lidwill and Booth in Australia supposedly revived a stillborn infant with electrical pacing in the 1920s.[194] Hyman temporarily paced the heart using two needle electrodes that were passed through the ribs and an electrical device of his own design. In the early 1950s, Bigelow and colleagues reported controlling the heart rate in dogs using external pacemakers.[90]

Paul Zoll is given credit for ushering in the clinical era of pacemaking. In 1952, he reported on two patients suffering from recurring prolonged ventricular standstill whom he treated with an external pacemaker.[195] The first patient was a 75-year-old man with complete heart block who had been revived with 34 intracardiac injections of epinephrine over a 4-hour period. Zoll applied electric shocks 2 ms in duration that were transmitted through the

chest wall at frequencies from 25 to 60 per minute and increased the intensity of the shock until ventricular responses were observed. After 25 minutes of intermittent stimulation, however, the patient died. Many subsequent patients, however, recovered.

The next step came when Lillehei and colleagues reported a series of patients who had external pacing after open-heart surgery during the 1950s.[196] The field of open-heart surgery gave a major impetus to the development of pacemakers because there was a high incidence of heart block following many intracardiac repairs. The major difference between Zoll's pacing and that of Lillehei and colleagues was that Zoll used external electrodes placed on the chest wall, whereas Lillehei and colleagues attached electrodes directly to the heart at operation. Lillehei and colleagues used a relatively small external pacemaker to stimulate the heart and much less electric current. This form of heart pacing was better tolerated by the patient and was a more efficient way to stimulate the heart. The survival rate of Lillehei's patients with surgically induced heart block was improved significantly.

During this period, progress was made toward a totally implantable pacemaker. Elmquist and Senning[197] developed a pacer battery that was small enough for an epigastric pocket with electrodes connected to the heart. They implanted the unit in a patient with atrioventricular block in 1958. Just before implantation, the patient had 20 to 30 cardiac arrests a day. To avoid publicity, the implantation was done in the evening when the operating rooms were empty. The first pacemaker that was implanted functioned only 8 hours; the second pacemaker implanted in the same patient had better success. The patient survived until January 2002 and had many additional pacemakers. Chardack, Gage, and Greatbatch are perhaps better known for their development of the totally implantable pacemaker.[198] In 1961 they reported a series of 15 patients who had pacemakers that they had developed implanted. The technique for inserting permanent transvenous bipolar pacemaker electrodes was developed in 1962 by Parsonnet and colleagues[199] in the United States and Ekestrom and colleagues[200] in Sweden.

Early implantable pacemakers were fixed-rate, asynchronous devices that delivered an impulse independent of the underlying cardiac rhythm. During the past 35 years, enormous progress has been made in the field of pacing technology. The number of individuals with artificial pacemakers is unknown; however, estimates indicate that approximately 500,000 Americans are living with a pacemaker and that each year another 100,000 or more patients require permanent pacemakers in the United States.

HEART, HEART-LUNG, AND LUNG TRANSPLANTATION

Alexis Carrel and Charles Guthrie reported transplantation of the heart and lungs while at the University of Chicago in 1905.[201] The heart of a small dog was transplanted into the neck of a larger one by anastomosing the caudad ends of the jugular vein and carotid artery to the aorta and pulmonary artery. The animal was not anticoagulated, and the experiment ended about 2 hours after circulation was established because of blood clot in the cavities of the transplanted heart. Carrel also reported in 1906 that he had transplanted the heart and lungs of a 1-week-old cat into the neck of a larger cat.[202] The coronary circulation was reestablished immediately, and the "auricles began to beat. The lungs became red and after a few minutes effective pulsation of the ventricles appeared." Carrel stated that a phlegmon of the neck terminated this observation 2 days later.

Vladimir Demikhov, the great Soviet investigator, described more than 20 different techniques for heart transplantation in 1950.[203] He also published various techniques for heart and lung transplantation. He was even able to perform an orthotopic heart transplant in a dog before the heart-lung machine was developed. This was accomplished by placing the donor heart above the dog's own heart, and then with a series of tubes and connections, he rerouted the blood from one heart to the other until he had the donor heart functioning in the appropriate position and the native heart removed. One of his dogs climbed the steps of the Kremlin on the sixth postoperative day but died shortly afterward of rejection.

Richard Lower and Norman Shumway established the technique for heart transplantation as it is performed today.[204] Preservation of the cuff of recipient left and right atria with part of the atrial septum was described earlier by Brock[205] in England and Demikhov[175] in the Soviet Union, but it became popular only after Shumway and Lower reported it in their 1960 paper. Shumway stated[206]:

> In 1958 when I started work at Stanford, the idea [cardiac transplantation] grew out of our local cooling experiments, since we had one hour of aortic cross-clamping during cardiopulmonary bypass. Accordingly we decided to remove the heart at the atrial level and then to suture it back into position. After several of these experiments, we found it would be easier to remove the heart of another dog and to do the actual allotransplant. Something like 20 to 30 experiments were performed before we had a survivor. All of this was done before chemical immune suppression was available.

The first attempt at a human heart transplantation was made by Hardy and colleagues[207] at the University of Mississippi. Since no human donor organ was available at the time, a large chimpanzee's heart was used; however, it was unable to support the circulation because of hyperacute rejection.

The first human-to-human heart transplant occurred December 3, 1967, at the Groote Schuur Hospital in Capetown, South Africa.[209] The surgical team, headed by Christiaan Barnard, transplanted the heart of a donor who had been certified dead after the electrocardiogram showed no activity for 5 minutes into a 54-year-old man whose heart

was irreparably damaged by repeated myocardial infarctions. The second human heart transplant using a human donor was performed on a child 3 days after the first on December 6, 1967, by Adrian Kantrowitz in Brooklyn, New York. Dr. Kantrowitz's patient died of a bleeding complication within the first 24 hours.[209] Barnard's patient, Lewis Washkansky, died on the eighteenth postoperative day. At autopsy, the heart appeared normal, and there was no evidence of chronic liver congestion, but bilateral pneumonia, possibly owing to severe myloid depression from immunosuppression, was present.[210]

On January 2, 1968, Barnard performed a second heart transplant on Phillip Blaiberg, 12 days after Washkansky's death.[211] Blaiberg was discharged from the hospital and became a celebrity during the several months he lived after the transplant. Blaiberg's procedure indicated that a heart transplant was an option for humans suffering from end-stage heart disease. Within a year of Barnard's first heart transplant, 99 heart transplants had been performed by cardiac surgeons around the world. However, by the end of 1968, most groups abandoned heart transplantation because of the extremely high mortality related to rejection. Shumway and Lower, Barnard, and a few others persevered both clinically and in the laboratory. Their efforts in discovering better drugs for immunosuppression eventually established heart transplantation as we know it today.

A clinical trial of heart-lung transplantation was commenced at Stanford University in 1981 by Reitz and colleagues.[212] Their first patient was treated with a combination of cyclosporine and azathioprine. The patient was discharged from the hospital in good condition and was well more than 5 years after the transplant. Reitz's clinical success was based on earlier experiments with primates using allografts.[213,214] These primate recipients survived for more than 140 days when cyclosporine A was used for immune suppression. Several of these animals lived for more than 5 years after allotransplantation.[215]

The current success with heart, heart-lung, and lung transplantation is related in part to the discovery of cyclosporine by workers at the Sandoz Laboratory in Basel, Switzerland, in 1970. In December of 1980, cyclosporine was introduced at Stanford for cardiac transplantation. The incidence of rejection was not reduced, nor was the incidence of infection. However, these two major complications of cardiac transplantation were less severe when cyclosporine was used. Availability of cyclosporine stimulated many new programs across the United States in the mid-1980s.

Andre Juvenelle showed that animals could survive autologous lung transplantation for many years.[216] Lung transplantation from dog to dog was fatal when attempted in the early 1950s.[217] Some animals, however, survived with an autotransplant up to 29 days before succumbing to rejection.[218] The first human lung transplant was performed by Hardy and colleagues[219] at the University of Mississippi on June 11, 1964. A pneumonectomy for carcinoma with pleural adhesions had to be performed first. The patient died on the seventeenth postoperative day. In 1971, a Belgian surgeon, Fritz Derom, achieved a 10-month survival in a patient with pulmonary silicosis.[220]

Much of the credit, however, for the success of lung transplantation belongs to the Toronto group whose efforts were headed by Joel Cooper. Their successes were based on laboratory experimentation and the discovery of cyclosporine. After losing an early patient to bronchial anastomotic dehiscence in 1978, the group substituted cyclosporine for cortisone and wrapped the bronchial suture line with a pedicle of omentum. They also developed a comprehensive preoperative preparation program that increased the strength and nutritional status of the recipients. In 1986, Cooper and associates presented their first two successful patients, who had returned to normal activities and were alive 14 and 26 months after operation.[221] This success was the culmination of more than 40 previous attempts throughout the world made after Derom's case.

HEART ASSIST AND ARTIFICIAL HEARTS

The concept of intra-aortic counterpulsation was first described by Harken[222] in 1958 and reported by Clauss and colleagues[223] in 1961. This idea proposed removal of blood via the femoral artery during systole and rapid reinfusion of the same blood during diastole to increase coronary perfusion. Technical difficulties and complications secondary to hemolysis delayed clinical use until 1962, when Moulopoulos and colleagues introduced a balloon catheter placed in the thoracic aorta.[224] In 1963, Kantrowitz and colleagues reported the first use of the intra-aortic balloon pump (IABP) in three patients.[225] All were in cardiogenic shock but improved during balloon pumping. One survived to leave the hospital.

Akutsu and Kolff reported the development and first application of a totally artificial heart in an animal model at the Cleveland Clinic in 1957.[226] The authors implanted a totally artificial heart in a living dog that survived for 90 minutes with the mechanical heart.

In 1963, Liotta and colleagues reported a 42-year-old man who had a stenotic aortic valve replaced but suffered a cardiac arrest the following morning.[227] The patient was resuscitated but developed severe ventricular failure. An artificial intrathoracic circulatory pump was implanted. The patient's pulmonary edema cleared, but he died 4 days later with the pump working continuously. In 1966, the same group used a newer intrathoracic pump to support another patient who could not be weaned from cardiopulmonary bypass. This pump maintained the circulation. The patient eventually died before the pump could be removed.[228] Later that year, the same group used a left ventricular assist device (LVAD) in a woman who could not be weaned from cardiopulmonary bypass after double valve replacement.[229] After 10 days of circulatory assistance, the patient was weaned successfully from the device and recovered. This woman was probably the first patient to be weaned from an assist device and to leave the hospital.

The first human application of a totally artificial heart was by Denton Cooley and colleagues as a "bridge" to transplantation.[230] They implanted a totally artificial heart in a patient who could not be weaned from cardiopulmonary bypass. After 64 hours of artificial heart support, heart transplantation was performed, but the patient died of *Pseudomonas* pneumonia 32 hours after transplantation. The first two patients bridged successfully to transplantation were reported at almost the same time and in the same location by different groups. On September 5, 1984, in San Francisco,[231] Donald Hill implanted a Pierce-Donachy LVAD in a patient in cardiogenic shock. The patient received a successful transplant 2 days later and was discharged subsequently. The assist device used by Hill was developed at Pennsylvania State University by Pierce and Donachy. Phillip Oyer and colleagues at Stanford University placed an electrically driven Novacor LVAD in a patient in cardiogenic shock on September 7, 1984.[232] The patient was transplanted successfully and survived beyond 3 years. The device used by the Stanford group was developed by Peer Portner.

The first implantation of a permanent totally artificial heart (Jarvik-7) was performed by DeVries and colleagues at the University of Utah in 1982.[233] By 1985, they had implanted the Jarvik in four patients, and one survived for 620 days after implantation. This initial clinical experience was based heavily on the work of Kolff and colleagues.

THORACIC AORTA SURGERY

Alexis Carrel was responsible for one of the great surgical advances of the twentieth century: techniques for suturing and transplanting blood vessels.[234] Although Carrel initially developed his methods of blood vessel anastomosis in Lyon, France, his work with Charles Guthrie in Chicago led to many major advances in vascular, cardiac, and transplantation surgery. In a short period of time, these investigators perfected techniques for blood vessel anastomoses and transposition of arterial and venous segments using both fresh and frozen grafts. After leaving Chicago, Carrel continued to expand his work on blood vessels and organ transplantation and in 1912 received the Nobel Prize. Interestingly, Carrel's work did not receive immediate clinical application.

Rudolph Matas pioneered clinical vascular surgery. Matas's work took place before drugs were available to prevent blood clotting, before antibiotics, and without reliable blood vessel substitutes.[235] Matas performed 620 vascular operations between 1888 and 1940. Only 101 of these were attempts to repair arteries; most involved ligation. Matas developed three variations of his well-known endoaneurysmorrhaphy procedure. The most advanced was to reconstruct the wall of the blood vessel from within while using a rubber tube as a stent.

Vascular surgery advanced tentatively during World War II as traumatic injuries to major blood vessels were repaired in some soldiers with results significantly better than with the standard treatment of ligation.[236] The successful treatment of coarctation of the aorta by Crafoord and Gross added a major boost to the reconstructive surgery of arteries.

Shumaker reported the excision of a small descending thoracic aortic aneurysm with reanastomosis of the aorta in 1948.[237] Swan and colleagues[238] repaired a complex aneurysmal coarctation and used aortic homograft for reconstruction in 1950. Gross[239] reported a series of similar cases using homograft replacement. In 1951, DuBost and colleagues[240] in Paris resected an intra-abdominal aortic aneurysm with homograft replacement.

In 1953, Henry Bahnson,[241] from Johns Hopkins, successfully resected six saccular aneurysms of the aorta in eight patients. In the same year, DeBakey and Cooley[242] reported a 46-year-old man who had resection of a huge aneurysm of the descending thoracic aorta that measured approximately 20 cm in length and in greatest diameter. The aneurysm was resected and replaced with an aortic homograft approximately 15 cm in length.

During the Korean War, the arterial homograft and autogenous vein graft were used to reconstruct battlefield arterial injuries and reduce the overall amputation rate to 11.1%,[243] compared with the rate of 49.6% reported in World War II. Although the vein autograft remains the first-choice peripheral vascular conduit today, the arterial homograft was superseded by the development of synthetic vascular grafts by Arthur Voorhees at Columbia University in 1952. Voorhees and colleagues developed Vinyon-N cloth tubes to substitute for diseased arterial segments,[244] but because of kinking, these smooth-lined tubes could not be used across joints. Development of the crimped graft by Edwards and Tapp[245] and introduction of the Dacron graft by DeBakey[240] were important milestones. DeBakey's account of his discovery of Dacron reflects the resourcefulness and innovation of these pioneering surgeons[247]:

> We were greatly impressed with the report of Voorhees on the use of a fabric woven of Vinyon-N. On my first trip to obtain some of these fabrics from a department store here, I found that they only had some sheets of Dacron. I purchased several yards and cut them in different sizes to make tubes by sewing on my wife's sewing machine. I had been taught by my mother as a boy to sew and I became an expert not only in the use of the sewing machine, but also on the other aspects of sewing. These tubes proved highly successful in animals, and although we later obtained sheets of Orlon, Teflon, nylon and Ivalon, none of these were as good as the original Dacron fabric. It was rather interesting and an example of serendipity that the first material we obtained (Dacron), the only one available at the store at the time, proved later to be the best. One of these Dacron grafts that I had fabricated as a bifurcation graft was used to replace an aneurysm of the abdominal aorta in September 1954.

Another advance in aortic surgery appeared in 1955 when DeBakey and colleagues[247] reported six cases of aortic

dissection treated by aggressive surgery. This paper included a description of pathologic and hemodynamic factors associated with the dissections and led to a more logical approach to treatment of these lesions. Because mortality of operation for acute dissections remained high, Myron Wheat, Jr., introduced medical therapy for the disease.[248]

During the late 1950s, the Houston group, consisting of Michael DeBakey, Denton Cooley, Stanley Crawford, and their other associates, systematically developed operations for resection and graft replacement of the ascending aorta,[249] descending aorta, and thoracoabdominal aorta.[250] Cardiopulmonary bypass was used for the ascending aortic resections. The high risk of paraplegia highlighted a major complication of thoracoabdominal aortic resections. The Houston group was the first to resect an aortic arch with the use of cardiopulmonary bypass in 1957[251] and replace the arch with a reconstituted aortic arch homograph. More interesting is that Cooley and colleagues, using great ingenuity, resected a large aortic arch aneurysm that also involved a portion of the descending aorta in a 49-year-old patient on June 24, 1955. The surgery was done, without the use of cardiopulmonary bypass, by first sewing in a temporary graft from the ascending aorta to the distal descending aorta and sewing in two more temporary limbs off that graft, which were anastomosed to the left and right carotid arteries, while the aneurysm was resected and a permanent graft was placed.[252]

In 1968, Bentall and De Bono[253] introduced replacement of the ascending aorta and aortic valve with reanastomoses of the coronary ostia to the replacement graft. They described the composite-graft technique for replacement of the ascending aorta with reimplantation of the coronary arteries into the composite Dacron graft containing the prosthetic aortic valve. As mentioned previously, Cooley and DeBakey were first to replace the supracoronary ascending aorta in 1956. In 1963, Starr and colleagues[254] reported replacing the supracoronary ascending aorta and the aortic valve at the same sitting. The technique of fashioning "buttons" of aortic tissue adjacent to the coronary ostia and then incorporating these buttons into the aortic graft along with the aortic valve replacement was described by Wheat and colleagues[255] in 1964. Bentall and De Bono incorporated the aortic prosthesis into the tube graft and used the Wheat technique for implanting the coronary arteries into the composite graft.

Since the early 1990s, stents also have been used for the treatment of aneurysms in both the descending aorta and abdominal aorta.[256,257] The progress in this field is moving rapidly.

SUMMARY

The history of adult cardiac surgery continues to be written and will continue to evolve as long as acquired heart disease shortens lives. In the early days after the introduction of cardiopulmonary bypass, the pace of advance was torrid but, in a way, narrowly focused. Now hundreds of thousands of clinicians, scientists, and engineers are involved in a broad and deep effort to develop new and safer operations and procedures, new valves, new revascularization techniques, new biomaterials, new heart substitutes, new life-support systems, and new methods to control cardiac arrhythmias and ventricular remodeling after injury. This research and development is supported by a vigorous infrastructure of basic science in biology and medicine, chemistry and pharmacology, and engineering and computer technology. The history of cardiac surgery is only a prelude; the moving finger writes and having writ moves on to a bright, exciting future.

CHAPTER 2

Surgical Anatomy of the Heart

Michael R. Mill • Benson R. Wilcox • Robert H. Anderson

A thorough knowledge of the anatomy of the heart is a prerequisite for the successful completion of the myriad procedures performed by the cardiothoracic surgeon. In this chapter we describe the normal anatomy of the heart, including its position and relationship to other thoracic organs. We describe the incisions used to expose the heart for various operations and discuss in detail the cardiac chambers and valves, coronary arteries and veins, and the important but surgically invisible conduction tissues.

OVERVIEW

Location of the Heart Relative to Surrounding Structures

The overall shape of the heart is that of a three-sided pyramid located in the middle mediastinum (Fig. 2-1). When viewed from the heart's apex, the three sides of the ventricular mass are readily apparent (Fig. 2-2). Two of the edges are named. The *acute margin* lies inferiorly and describes a sharp angle between the sternocostal and diaphragmatic surfaces. The *obtuse margin* lies superiorly and is much more diffuse. The posterior margin is unnamed but is also diffuse in its transition.

One-third of the cardiac mass lies to the right of the midline and two-thirds to the left. The long axis of the heart is oriented from the left epigastrium to the right shoulder. The short axis, which corresponds to the plane of the atrioventricular groove, is oblique and is oriented closer to the vertical than to the horizontal plane (see Fig. 2-1).

Anteriorly, the heart is covered by the sternum and the costal cartilages of the third, fourth, and fifth ribs. The lungs contact the lateral surfaces of the heart, whereas the heart abuts onto the pulmonary hila posteriorly. The right lung overlies the right surface of the heart and reaches to the midline. In contrast, the left lung retracts from the midline in the area of the cardiac notch. The heart has an extensive diaphragmatic surface inferiorly. Posteriorly, the heart lies on the esophagus and the tracheal bifurcation and bronchi that extend into the lung. The sternum lies anteriorly and provides rigid protection to the heart during blunt trauma and is aided by the cushioning effects of the lungs.

The Pericardium and Its Reflections

The heart lies within the pericardium, which is attached to the walls of the great vessels and to the diaphragm. The pericardium can be visualized best as a bag into which the heart has been placed apex first. The inner layer, in direct contact with the heart, is the *visceral epicardium,* which encases the heart and extends several centimeters back onto the walls of the great vessels. The outer layer forms the *parietal pericardium,* which lines the inner surface of the tough fibrous pericardial sack. A thin film of lubricating fluid lies within the pericardial cavity between the two serous layers. Two identifiable recesses lie within the pericardium and are lined by the serous layer. The first is the *transverse sinus,* which is delineated anteriorly by the posterior surface of the aorta and pulmonary trunk and posteriorly by the anterior surface of the interatrial groove. The second is the *oblique sinus,* a cul-de-sac located behind the left atrium, delineated by serous pericardial reflections from the pulmonary veins and the inferior vena cava.

Mediastinal Nerves and Their Relationships to the Heart

The vagus and phrenic nerves descend through the mediastinum in close relationship to the heart (Fig. 2-3). They enter through the thoracic inlet, with the phrenic nerve located anteriorly on the surface of the anterior scalene muscle and lying just posterior to the internal thoracic artery (internal mammary artery) at the thoracic inlet. In this position, the phrenic nerve is vulnerable to injury during dissection

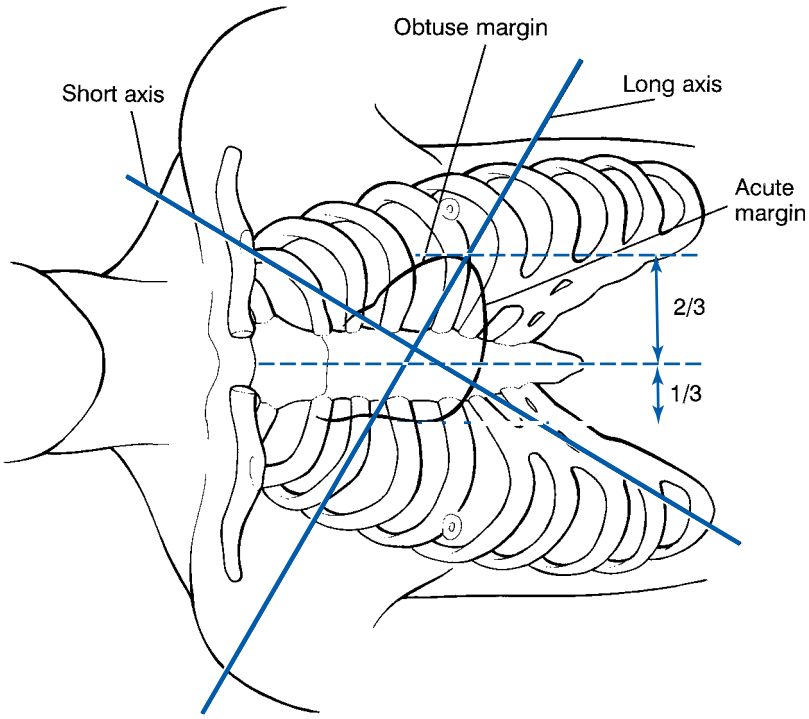

Figure 2-1. This diagram shows the heart within the middle mediastinum with the patient supine on the operating table. The long axis lies parallel to the interventricular septum, whereas the short axis is perpendicular to the long axis at the level of the atrioventricular valves.

and preparation of the internal thoracic artery for use in coronary arterial bypass grafting. On the right side, the phrenic nerve courses on the lateral surface of the superior vena cava, again in harm's way during dissection for venous cannulation for cardiopulmonary bypass. The nerve then descends anterior to the pulmonary hilum before reflecting onto the right diaphragm, where it branches to provide its innervation. In the presence of a left-sided superior vena cava, the left phrenic nerve is applied directly to its lateral surface. The nerve passes anterior to the pulmonary hilum and eventually branches on the surface of the diaphragm. The vagus nerves enter the thorax posterior to the phrenic nerves and course along the carotid arteries. On the right side, the vagus gives off the recurrent laryngeal nerve that

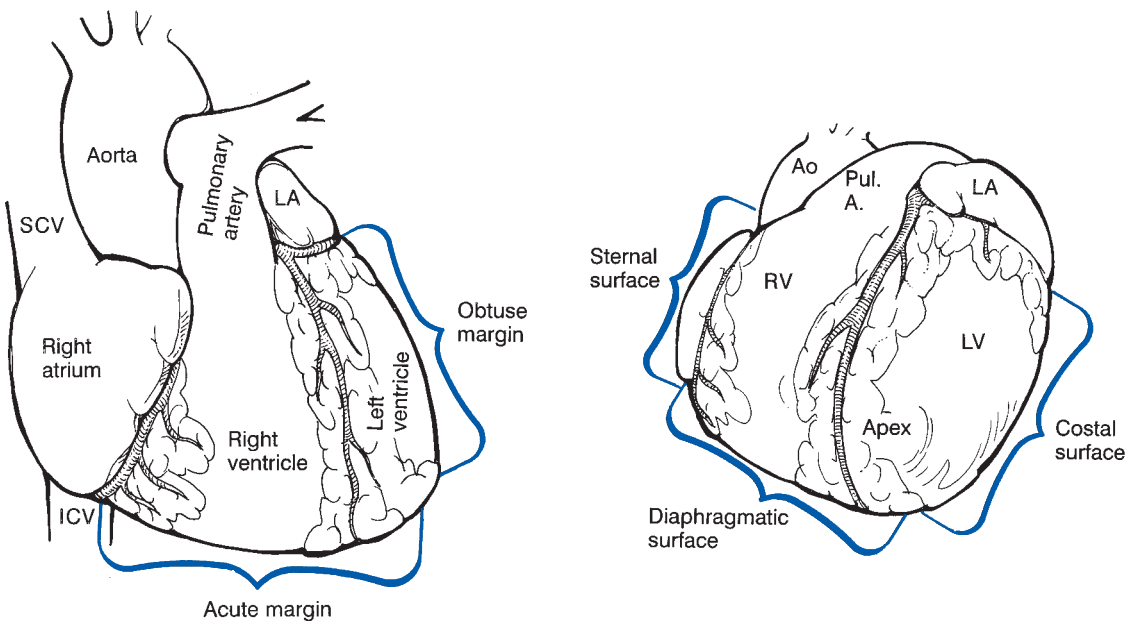

Figure 2-2. This diagram shows the surfaces and margins of the heart as viewed anteriorly with the patient supine on the operating table (*left*) and as viewed from the cardiac apex (*right*).

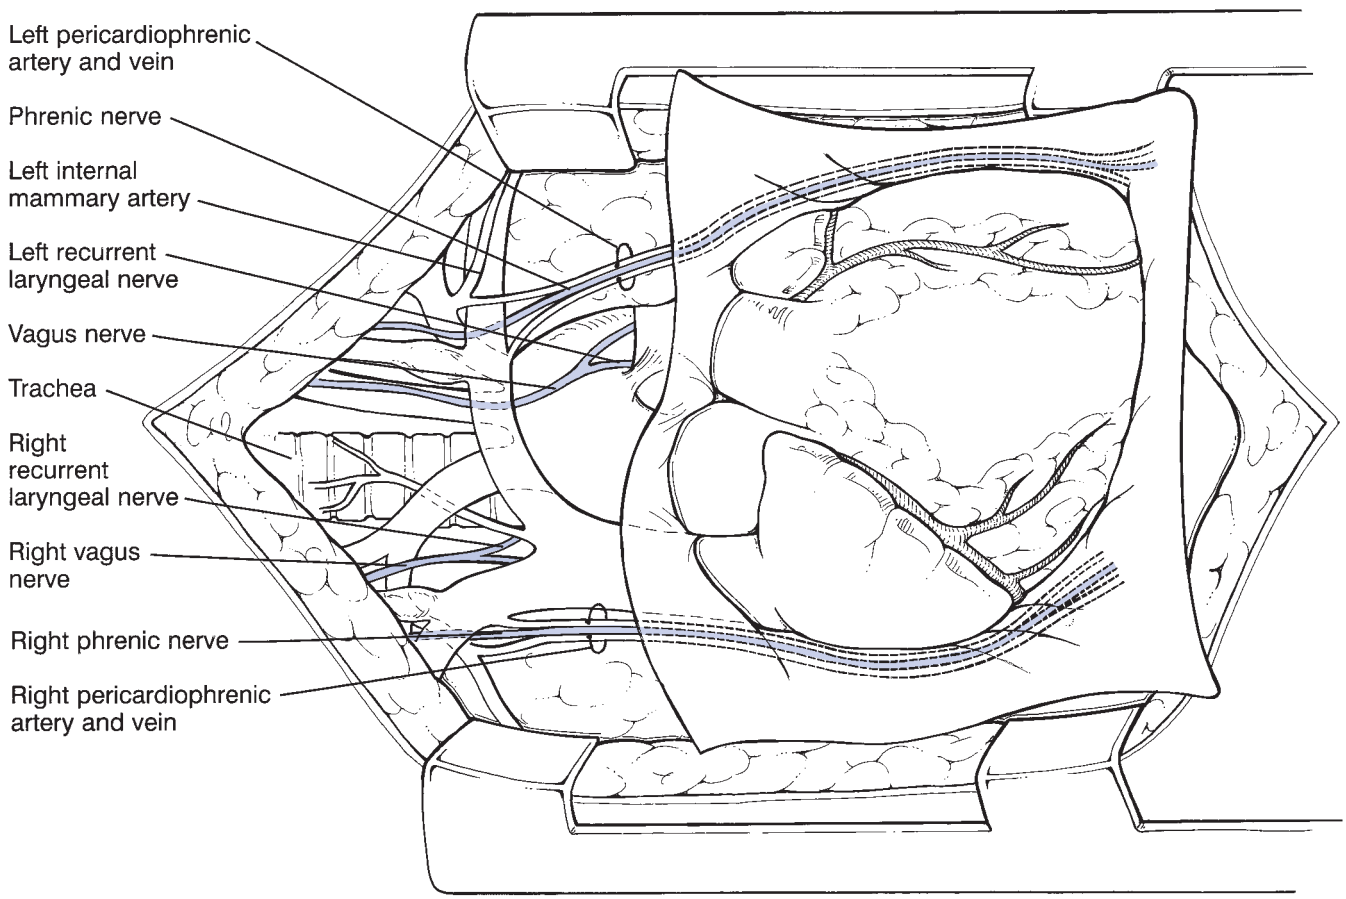

Figure 2-3. Diagram of the heart in relation to the vagus and phrenic nerves as viewed through a median sternotomy.

passes around the right subclavian artery before ascending out of the thoracic cavity. The right vagus nerve continues posterior to the pulmonary hilum, gives off branches of the right pulmonary plexus, and exits the thorax along the esophagus. On the left, the vagus nerve crosses the aortic arch, where it gives off the recurrent laryngeal branch. The recurrent nerve passes around the arterial ligament before ascending in the tracheoesophageal groove. The vagus nerve continues posterior to the pulmonary hilum, gives rise to the left pulmonary plexus, and then continues inferiorly out of the thorax along the esophagus. A delicate nerve trunk known as the *subclavian loop* carries fibers from the stellate ganglion to the eye and head. This branch is located adjacent to the subclavian arteries bilaterally. Excessive dissection of the subclavian artery during shunt procedures may injure these nerve roots and cause Horner syndrome.

SURGICAL INCISIONS

Median Sternotomy

The most common approach for operations on the heart and aortic arch is the median sternotomy. The skin incision is made from the jugular notch to just below the xiphoid process. The subcutaneous tissues and presternal fascia are incised to expose the periostium of the sternum. The sternum is divided longitudinally in the midline. After placement of a sternal spreader, the thymic fat pad is divided up to the level of the brachiocephalic vein. An avascular midline plane is identified easily but is crossed by a few thymic veins that are divided between fine silk ties or hemoclips. Either the left or right or, occasionally, both lobes of the thymus gland are removed in infants and young children to improve exposure and to minimize compression on extracardiac conduits. If a portion of the thymus gland is removed, excessive traction may result in injury to the phrenic nerve. The pericardium is opened anteriorly to expose the heart. Through this incision, operations within any chamber of the heart or on the surface of the heart and operations involving the proximal aorta, pulmonary trunk, and their primary branches can be performed. Extension of the superior extent of the incision into the neck along the anterior border of the right sternocleidomastoid muscle provides further exposure of the aortic arch and its branches for procedures involving these structures. Exposure of the proximal descending thoracic aorta is facilitated by a perpendicular extension of the incision through the third intercostal space.

Bilateral Transverse Thoracosternotomy (Clamshell Incision)

The bilateral transverse thoracosternotomy (clamshell incision) is an alternative incision for exposure of the pleural spaces and heart. This incision may be made through either the fourth or fifth intercostal space, depending on the intended procedure. After identifying the appropriate interspace, a bilateral submammary incision is made. The incision is extended down through the pectoralis major muscles to enter the hemithoraces through the appropriate intercostal space. The right and left internal thoracic arteries are dissected and ligated proximally and distally prior to transverse division of the sternum. Electrocautery dissection of the pleural reflections behind the sternum allows full exposure of both hemithoraces and the entire mediastinum. Bilateral chest spreaders are placed to maintain exposure. Morse or Haight retractors are particularly suitable with this incision. The pericardium may be opened anteriorly to allow access to the heart for intracardiac procedures. When required, standard cannulation for cardiopulmonary bypass is achieved easily. This incision is popular for bilateral sequential double-lung transplants and heart-lung transplants because of enhanced exposure of the apical pleural spaces. When made in the fourth intercostal space, the incision is useful for access to the ascending aorta, the aortic arch, and descending thoracic aorta.

Anterolateral Thoracotomy

The right side of the heart can be exposed through a right anterolateral thoracotomy. The patient is positioned supine, with the right chest elevated to approximately 30 degrees by a roll beneath the shoulder. An anterolateral thoracotomy incision can be made that can be extended across the midline by transversely dividing the sternum if necessary. With the lung retracted posteriorly, the pericardium can be opened just anterior to the right phrenic nerve and pulmonary hilum to expose the right and left atria. The incision provides access to both the tricuspid and mitral valves and the right coronary artery. Cannulation may be performed in the ascending aorta and the superior and inferior venae cavae. Aortic cross-clamping, administration of cardioplegia, and removal of air from the heart after cardiotomy are difficult with this approach. This incision is particularly useful nonetheless for performance of the Blalock-Hanlon atrial septectomy or for valve replacement after a previous procedure through a median sternotomy. A left anterolateral thoracotomy performed in a similar fashion to that on the right side may be used for isolated bypass grafting of the circumflex coronary artery or for left-sided exposure of the mitral valve.

Posterolateral Thoracotomy

A left posterolateral thoracotomy is used for procedures involving the distal aortic arch and descending thoracic aorta. With left thoracotomy, cannulation for cardiopulmonary bypass must be done through the femoral vessels. A number of variations of these incisions have been used for minimally invasive cardiac surgical procedures. These include partial sternotomies, parasternal incisions, and limited thoracotomies.

RELATIONSHIP OF THE CARDIAC CHAMBERS AND GREAT ARTERIES

The surgical anatomy of the heart is best understood when the position of the cardiac chambers and great vessels is known in relation to the cardiac silhouette. The atrioventricular junction is oriented obliquely, lying much closer to the vertical than to the horizontal plane. This plane can be viewed from its atrial aspect (Fig. 2-4) if the atrial mass and great arteries are removed by a parallel cut just above the

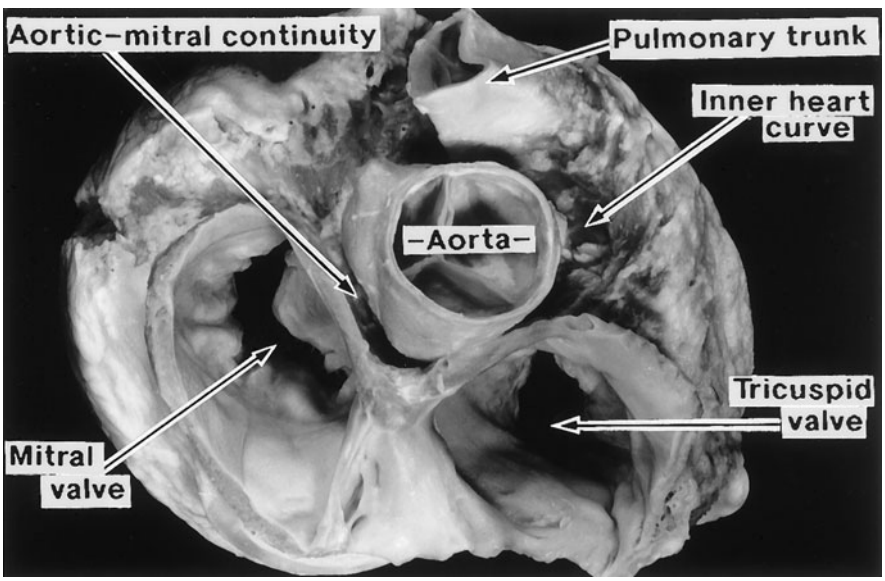

Figure 2-4. This dissection of the cardiac short axis, seen from its atrial aspect, reveals the relationships of the cardiac valves.

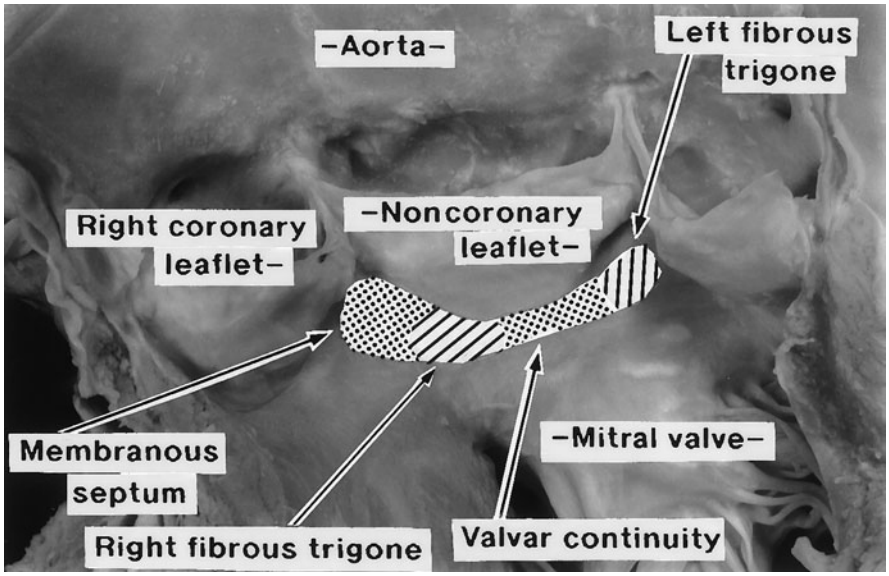

Figure 2-5. This view of the left ventricular outflow tract, as seen from the front in anatomic orientation, shows the limited extent of the fibrous skeleton of the heart.

junction. The tricuspid and pulmonary valves are widely separated by the inner curvature of the heart lined by the transverse sinus. Conversely, the mitral and aortic valves lie adjacent to one another, with fibrous continuity of their leaflets. The aortic valve occupies a central position, wedged between the tricuspid and pulmonary valves. Indeed, there is fibrous continuity between the leaflets of the aortic and tricuspid valves through the central fibrous body.

With careful study of this short axis, several basic rules of cardiac anatomy become apparent. First, the atrial chambers lie to the right of their corresponding ventricles. Second, the right atrium and ventricle lie anterior to their left-sided counterparts. The septal structures between them are obliquely oriented. Third, by virtue of its wedged position, the aortic valve is directly related to all the cardiac chambers. Several other significant features of cardiac anatomy can be learned from the short-axis section. The position of the aortic valve minimizes the area of septum where the mitral and tricuspid valves attach opposite each other. Because the tricuspid valve is attached to the septum further toward the ventricular apex than the mitral valve, a part of the septum is interposed between the right atrium and the left ventricle to produce the muscular atrioventricular septum. The central fibrous body, where the leaflets of the aortic, mitral, and tricuspid valves all converge, lies cephalad and anterior to the muscular atrioventricular septum. The central fibrous body is the main component of the fibrous skeleton of the heart and is made up in part by the right fibrous trigone, a thickening of the right side of the area of fibrous continuity between the aortic and mitral valves, and in part by the membranous septum, the fibrous partition between the left ventricular outflow tract and the right-sided heart chambers (Fig. 2-5). The membranous septum itself is divided into two parts by the septal leaflet of the tricuspid valve, which is directly attached across it (Fig. 2-6). Thus the membranous septum has an atrioventricular component between the right

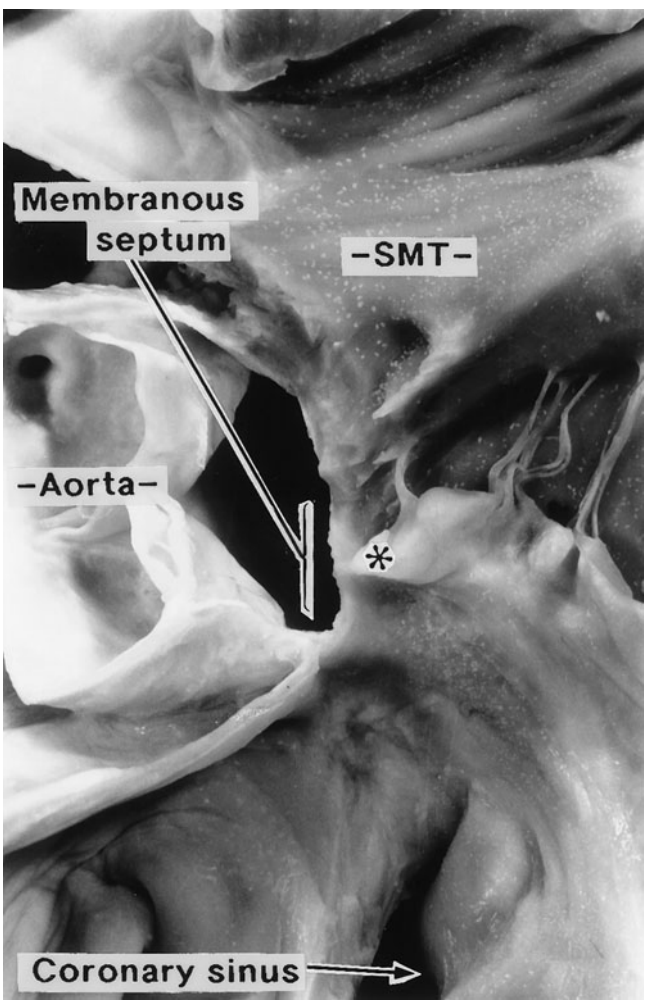

Figure 2-6. This dissection, made by removing the right coronary sinus of the aortic valve, shows how the septal leaflet of the tricuspid valve (*asterisk*) divides the membranous septum into its atrioventricular and interventricular components. SMT = septomarginal trabeculation.

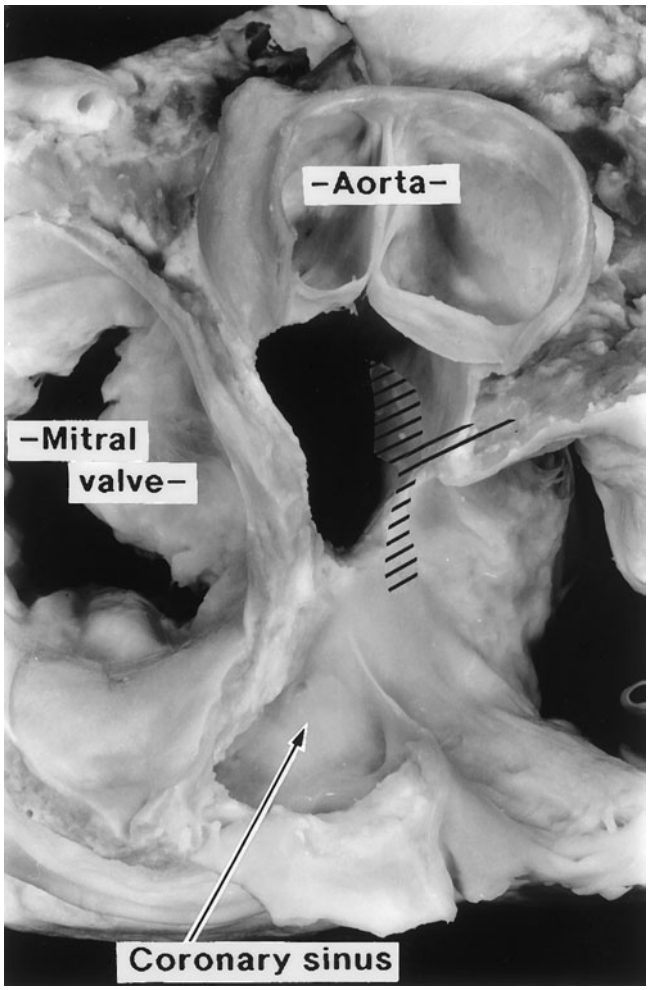

Figure 2-7. This dissection, made by removing the noncoronary aortic sinus (compare with Figs. 2-4 and 2-6), shows the approximate location of the atrioventricular conduction axis (*hatched area*) and the relationship of the mitral valve to the ventricular septum.

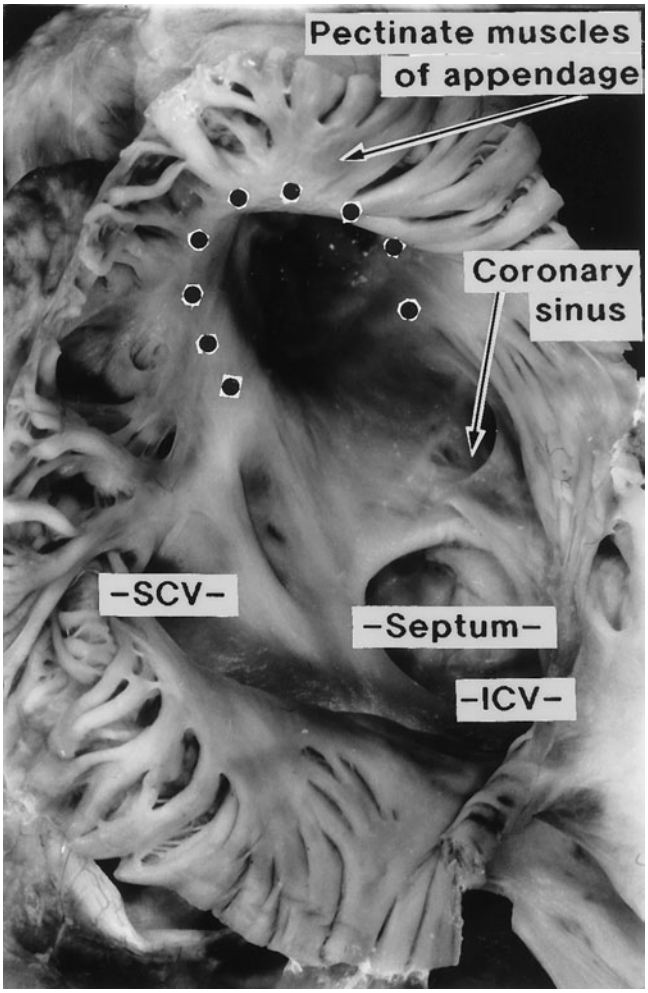

Figure 2-8. This view of the right atrium, seen in surgical orientation, shows the pectinate muscles lining the appendage, the smooth vestibule (*circles*) surrounding the orifice of the tricuspid valve, and the superior vena cava (SCV), inferior vena cava (ICV), and coronary sinus joining the smooth-walled venous component. Note the prominent rim enclosing the oval fossa, which is the true atrial septum (see Fig. 2-11).

atrium and left ventricle, as well as an interventricular component. Removal of the noncoronary leaflet of the aortic valve demonstrates the significance of the wedged position of the left ventricular outflow tract in relation to the other cardiac chambers. The subaortic region separates the mitral orifice from the ventricular septum; this separation influences the position of the atrioventricular conduction tissues and the position of the leaflets and tension apparatus of the mitral valve (Fig. 2-7).

THE RIGHT ATRIUM AND TRICUSPID VALVE

Appendage, Vestibule, and Venous Component

The right atrium has three basic parts: the appendage, the vestibule, and the venous component (Fig. 2-8). Externally, the right atrium is divided into the appendage and the venous component, which receives the systemic venous return. The junction of the appendage and the venous component is identified by a prominent groove, the *terminal groove*. This corresponds internally to the location of the terminal crest. The right atrial appendage has the shape of a blunt triangle, with a wide junction to the venous component across the terminal groove. The appendage also has an extensive junction with the vestibule of the right atrium; the latter structure is the smooth-walled atrial myocardium that inserts into the leaflets of the tricuspid valve. The most characteristic and constant feature of the morphology of the right atrium is that the pectinate muscles within the appendage extend around the entire parietal margin of the atrioventricular junction (Fig. 2-9). These muscles originate as parallel fibers that course at right angles from the

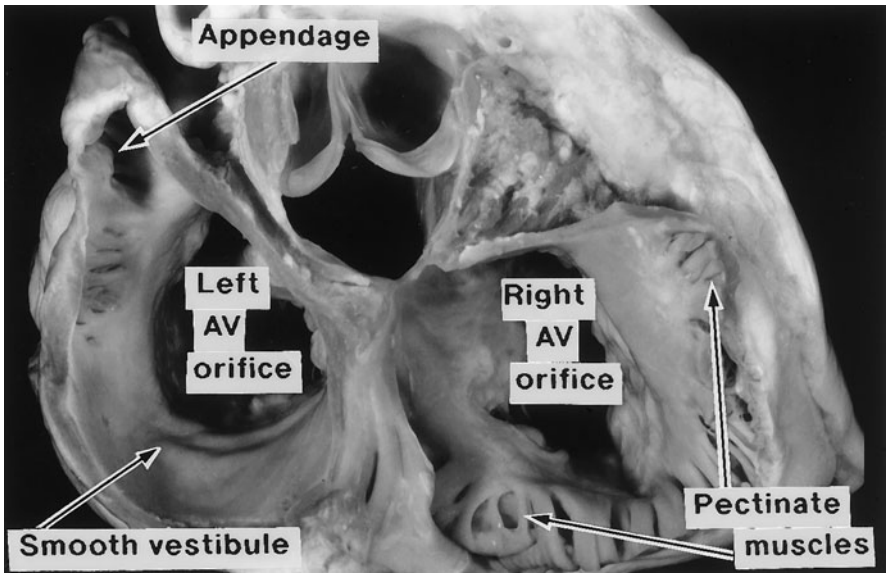

Figure 2-9. This dissection of the short axis of the heart (compare with Fig. 2-4) shows how the pectinate muscles extend around the parietal margin of the tricuspid valve. In the left atrium, the pectinate muscles are confined within the tubular left atrial appendage, leaving the smooth vestibule around the mitral valve confluent with the pulmonary venous component of the left atrium.

terminal crest. The venous component of the right atrium extends between the terminal groove and the interatrial groove. It receives the superior and inferior venae cavae and the coronary sinus.

Sinus Node

The sinus node lies at the anterior and superior extent of the terminal groove, where the atrial appendage and the superior vena cava are juxtaposed. The node is a spindle-shaped structure that usually lies to the right or lateral to the superior cavoatrial junction (Fig. 2-10). In approximately 10% of cases, the node is draped across the cavoatrial junction in horseshoe fashion.[1]

The blood supply to the sinus node is from a prominent nodal artery that is a branch of the right coronary artery in approximately 55% of individuals and a branch of the circumflex artery in the remainder. Regardless of its artery of origin, the nodal artery usually courses along the anterior interatrial groove toward the superior cavoatrial junction, frequently within the atrial myocardium. At the cavoatrial junction, its course becomes variable and may circle either anteriorly or posteriorly or, rarely, both anteriorly and posteriorly around the cavoatrial junction to enter the node. Uncommonly, the artery arises more distally from the right coronary artery and courses laterally across the atrial appendage. This places it at risk of injury during a standard right atriotomy. The artery also may arise distally from the circumflex artery to cross the dome of the left atrium, where it is at risk of injury when using a superior approach to the mitral valve. Incisions in either the right or left atrial chambers always should be made with this anatomic variability in mind. In our experience, these vessels can be identified by careful gross inspection, and prompt modification of surgical incisions can be made accordingly.

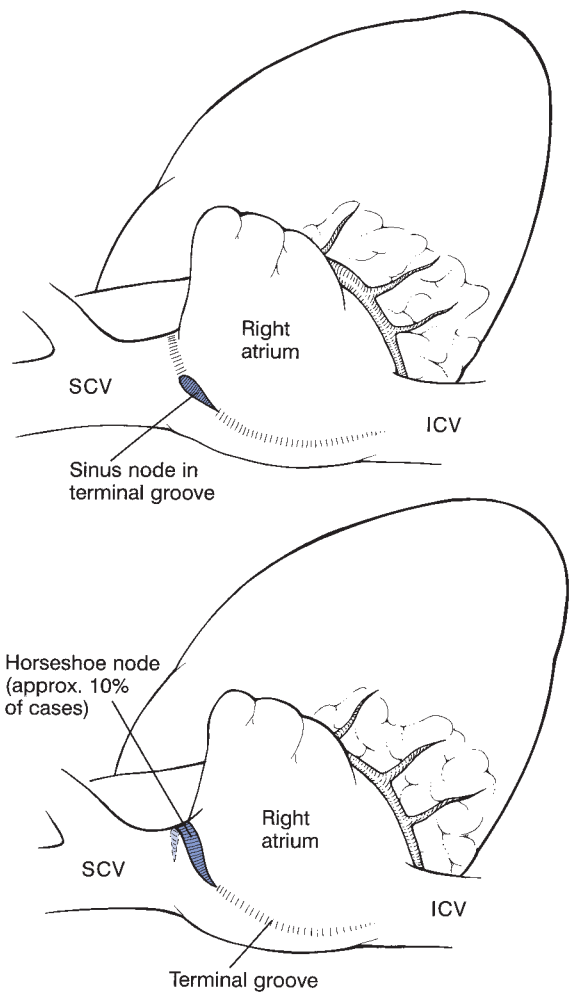

Figure 2-10. This diagram shows the location of the sinus node at the superior cavoatrial junction. The node usually lies to the right (lateral) side of the junction but may be draped in horseshoe fashion across the anterior aspect of the junction. SCV = superior vena cava; ICV = inferior vena cava.

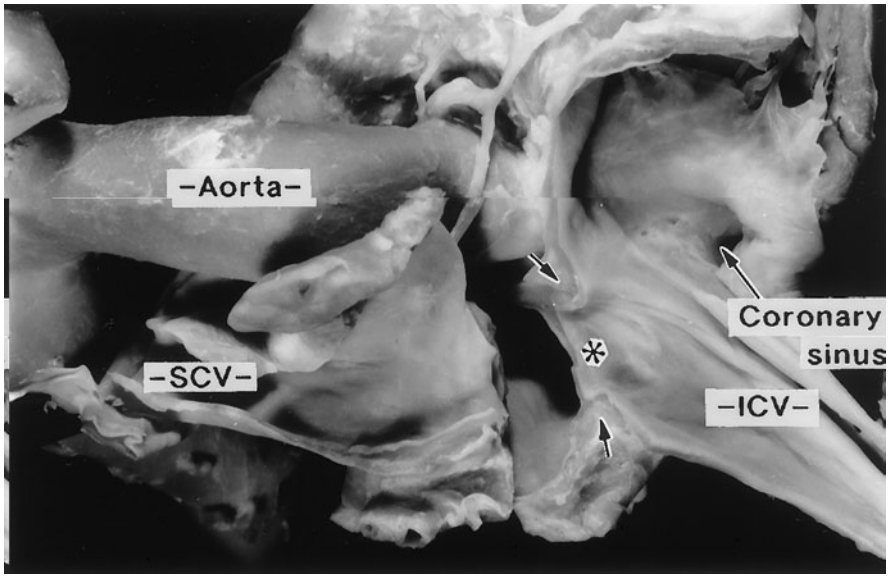

Figure 2-11. This transection across the middle of the oval fossa (*asterisk*) shows how the so-called septum secundum, the rim of the fossa, is made up of the infolded atrial walls (arrows). SCV = superior vena cava; ICV = inferior vena cava.

Atrial Septum

The most common incision into the right atrium is made into the atrial appendage parallel and anterior to the terminal groove. Opening the atrium through this incision confirms that the terminal groove is the external marking of the prominent terminal crest. Anteriorly and superiorly, the crest curves in front of the orifice of the superior vena cava to become continuous with the so-called septum secundum, which, in reality, is the superior rim of the oval fossa. When the right atrium is inspected through this incision, there appears to be an extensive septal surface between the tricuspid valve and the orifices of the venae cavae. This septal surface includes the opening of the oval fossa and the orifice of the coronary sinus. The apparent extent of the septum is spurious because the true septum between the atrial chambers is virtually confined to the oval fossa[2,3] (Fig. 2-11). The superior rim of the fossa, although often referred to as the *septum secundum,* is an extensive infolding between the venous component of the right atrium and the right pulmonary veins. The inferior rim is directly continuous with the so-called sinus septum that separates the orifices of the inferior caval vein and the coronary sinus (Fig. 2-12).

The region around the coronary sinus is where the right atrial wall overlies the atrioventricular muscular septum. Removing the floor of the coronary sinus reveals the anterior extension of the atrioventricular groove in this region. Only a small part of the anterior rim of the oval fossa is a septal structure. The majority is made up of the anterior atrial wall overlying the aortic root. Thus dissection outside the limited margins of the oval fossa will penetrate the heart to the outside rather than provide access to the left atrium via the septum.

Atrioventricular Septum and Node: Triangle of Koch

In addition to the sinus node, another major area of surgical significance is occupied by the atrioventricular node. This structure lies within the triangle of Koch, which is

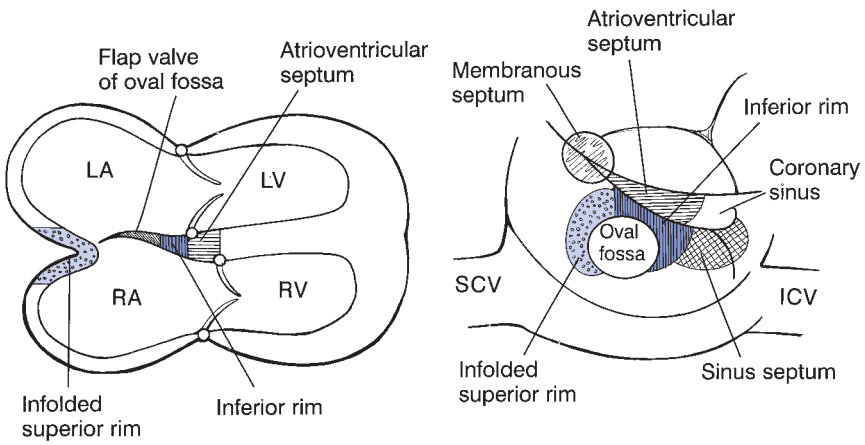

Figure 2-12. This diagram demonstrates the components of the atrial septum. The only true septum between the two atria is confined to the area of the oval fossa. SCV = superior vena cava; ICV = inferior vena cava.

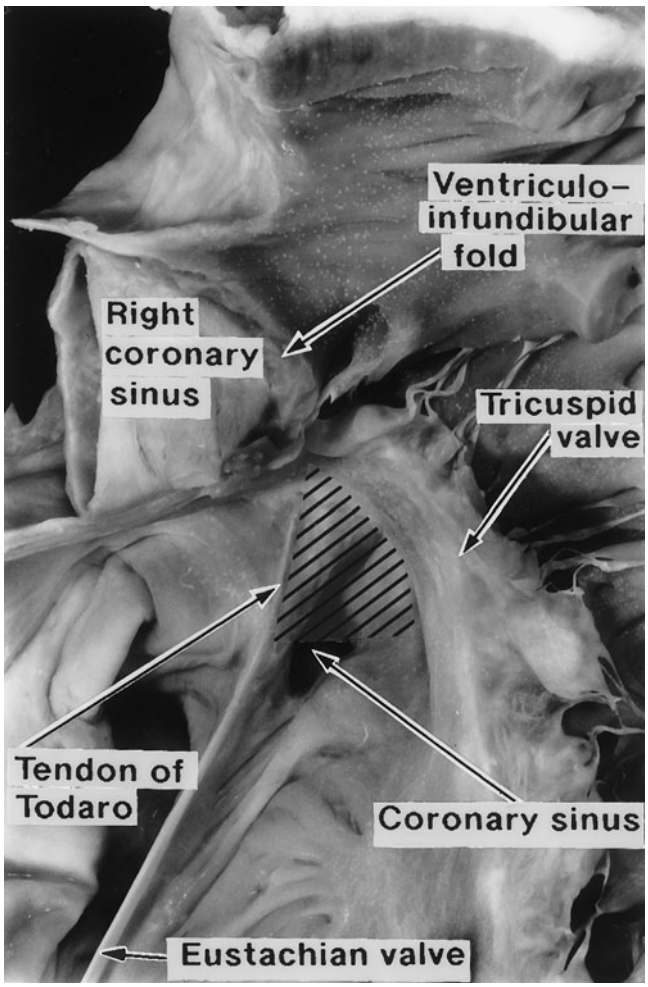

Figure 2-13. This dissection, made by removing part of the subpulmonary infundibulum, shows the location of the triangle of Koch (*shaded area*).

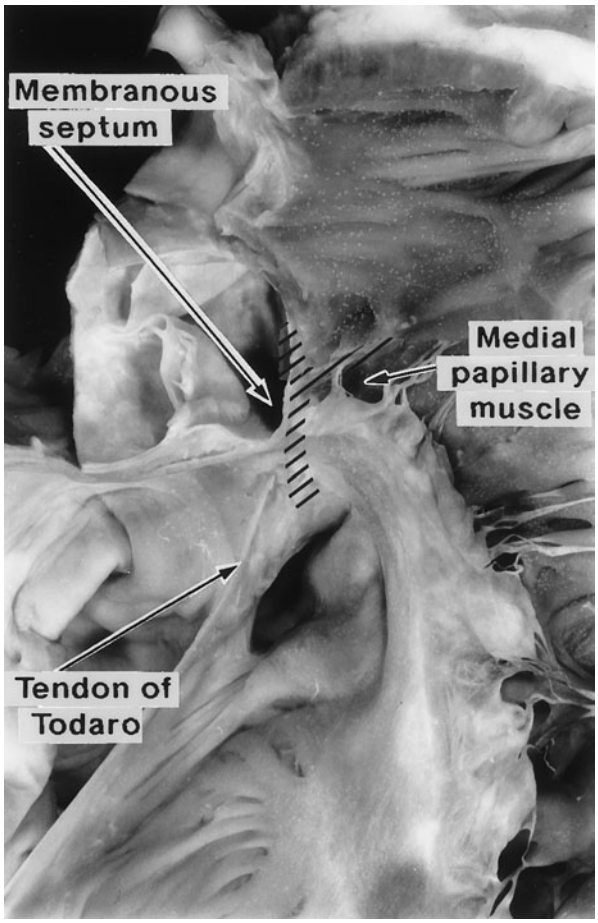

Figure 2-14. Further dissection of the heart shown in Fig. 2-13 reveals that a line joining the apex of the triangle of Koch to the medial papillary muscle marks the location of the atrioventricular conduction axis.

demarcated by the tendon of Todaro, the septal leaflet of the tricuspid valve, and the orifice of the coronary sinus (Fig. 2-13). The tendon of Todaro is a fibrous structure formed by the junction of the eustachian valve and the thebesian valve (the valves of the inferior vena cava and the coronary sinus, respectively). The entire atrial component of the atrioventricular conduction tissues is contained within the triangle of Koch, which must be avoided to prevent surgical damage to atrioventricular conduction. The atrioventricular bundle (of His) penetrates directly at the apex of the triangle of Koch before it continues to branch on the crest of the ventricular septum (Fig. 2-14). The key to avoiding atrial arrhythmias is careful preservation of the sinus and atrioventricular nodes and their blood supply. No advantage is gained in attempting to preserve nonexistent tracts of specialized atrial conduction tissue, although it makes sense to avoid prominent muscle bundles where parallel orientation of atrial myocardial fibers favors preferential conduction (Fig. 2-15).

Tricuspid Valve

The vestibule of the right atrium converges into the tricuspid valve. The three leaflets reflect their anatomic location, being septal, anterosuperior, and inferior (or mural). The leaflets join together over three prominent zones of apposition; the peripheral ends of these zones usually are described as *commissures*. The leaflets are tethered at the commissures by fan-shaped cords arising from prominent papillary muscles. The anteroseptal commissure is supported by the medial papillary muscle. The major leaflets of the valve extend from this position in anterosuperior and septal directions. The third leaflet is less well defined. The anteroinferior commissure is usually supported by the prominent anterior papillary muscle. Often, however, it is not possible to identify a specific inferior papillary muscle supporting the inferoseptal commissure. Thus the inferior leaflet may seem duplicated. There is no well-formed collagenous annulus for the tricuspid valve. Instead, the atrioventricular groove more or less folds directly into the tricuspid valvar leaflets at the vestibule, and

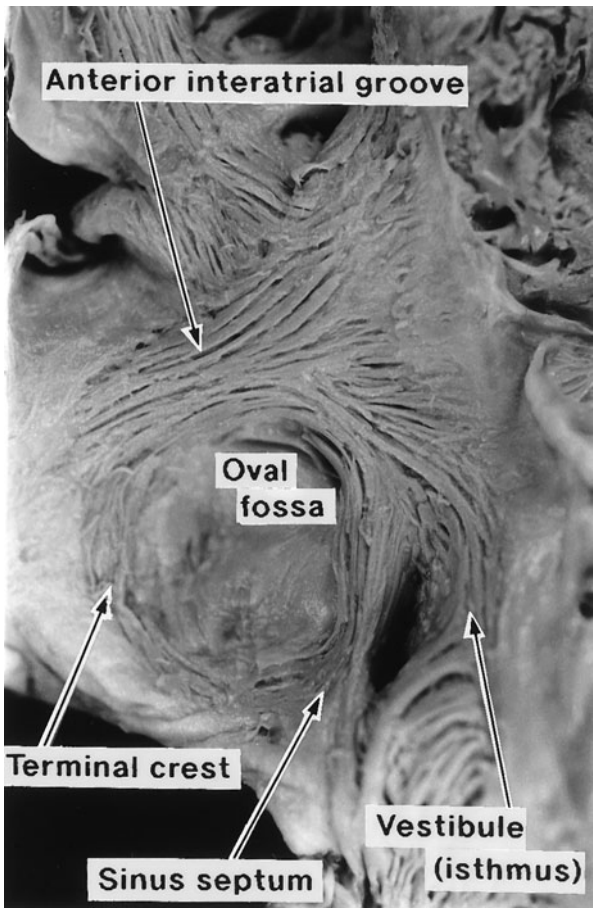

Figure 2-15. This dissection, made by careful removal of the right atrial endocardium, shows the ordered arrangement of myocardial fibers in the prominent muscle bundles that underscore preferential conduction. There are *no* insulated tracts running within the internodal atrial myocardium. (*Dissection made by Prof. Damian Sanchez-Quintana.*)

the atrial and ventricular myocardial masses are separated almost exclusively by the fibrofatty tissue of the groove. The entire parietal attachment of the tricuspid valve usually is encircled by the right coronary artery running within the atrioventricular groove.

THE LEFT ATRIUM AND MITRAL VALVE

Appendage, Vestibule, and Venous Component

Like the right atrium, the left atrium has three basic components: the appendage, the vestibule, and the venous component (Fig. 2-16). Unlike the right atrium, the venous component is considerably larger than the appendage and has a narrow junction with it that is not marked by a terminal groove or crest. There also is an important difference between the relationship of the appendage and vestibule between the left and right atria. As shown, the pectinate muscles within the right atrial appendage extend all around the parietal margin of the vestibule. In contrast, the left atrial appendage has a limited junction with the vestibule, and the pectinate muscles are located almost exclusively within the appendage (see Fig. 2-8). The larger part of the vestibule that supports and inserts directly into the mural leaflet of the mitral valve is directly continuous with the smooth atrial wall of the pulmonary venous component.

Because the left atrium is posterior to and tethered by the four pulmonary veins, the chamber is relatively inaccessible. Surgeons use several approaches to gain access. The most common is an incision just to the right of and parallel to the interatrial groove, anterior to the right pulmonary veins. This incision can be carried beneath both the superior and inferior venae cavae parallel to the interatrial groove to provide wide access to the left atrium. A second approach is

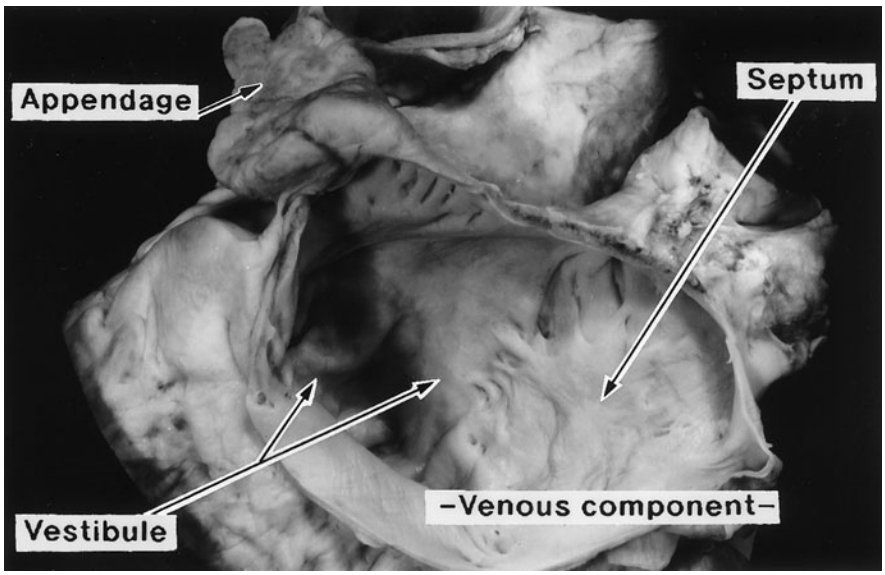

Figure 2-16. Like the right atrium, the left atrium (seen here in anatomic orientation) has an appendage, a venous component, and a vestibule. It is separated from the right atrium by the septum.

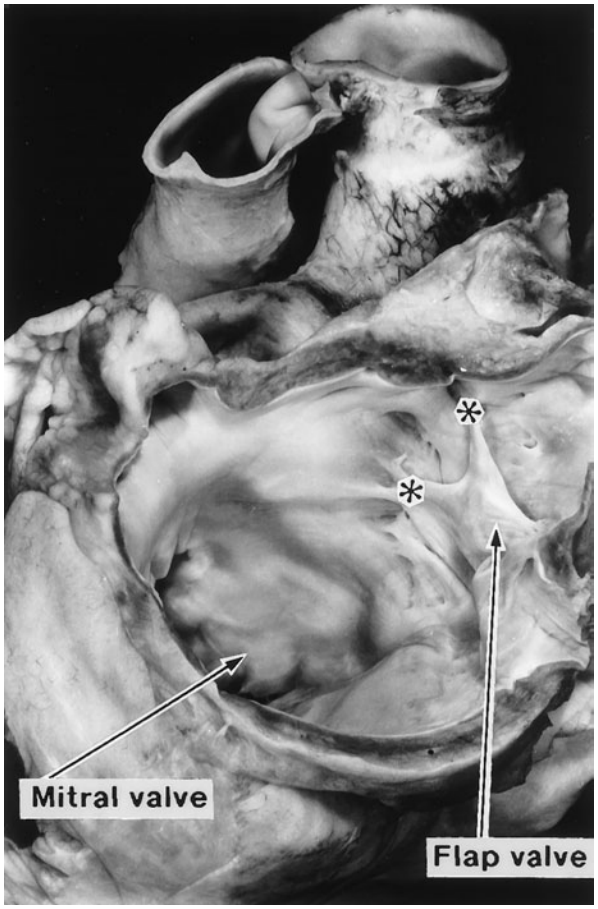

Figure 2-17. This view of the opened left atrium shows how the septal aspect is dominated by the flap valve, which is attached by its horns (*asterisks*) to the infolded atrial groove.

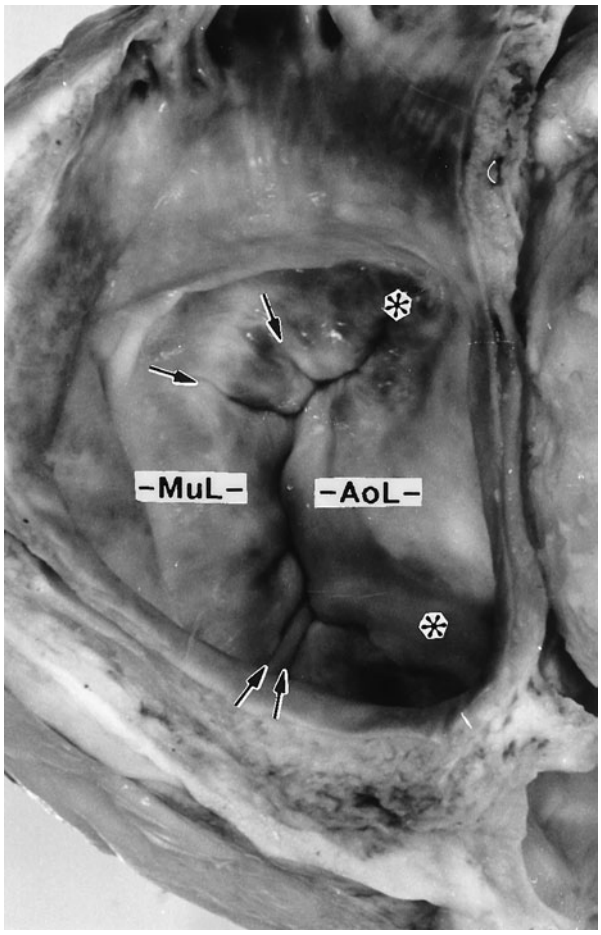

Figure 2-18. This view of the opened left atrium shows the leaflets of the mitral valve in closed position. There is a concave zone of apposition between them (*between asterisks*) with several slits seen in the mural leaflet (MuL). Note the limited extent of the aortic leaflet (AoL) in terms of its circumferential attachments.

through the dome of the left atrium. If the aorta is pulled anteriorly and to the left, an extensive trough may be seen between the right and left atrial appendages. An incision through this trough, between the pulmonary veins of the upper lobes, provides direct access to the left atrium. When this incision is made, it is important to remember the location of the sinus node artery, which may course along the roof of the left atrium if it arises from the circumflex artery. The left atrium also can be reached via a right atrial incision and an opening in the atrial septum.

When the interior of the left atrium is visualized, the small size of the mouth of the left atrial appendage is apparent. It lies to the left of the mitral orifice as viewed by the surgeon. The majority of the pulmonary venous atrium usually is located inferiorly away from the operative field. The vestibule of the mitral orifice dominates the operative view. The septal surface is located anteriorly, with the true septum relatively inferior (Fig. 2-17).

Mitral Valve

The mitral valve is supported by two prominent papillary muscles located in anterolateral and posteromedial positions. The two leaflets of the mitral valve have markedly different appearances (Fig. 2-18). The aortic (or anterior) leaflet is short, relatively square, and guards approximately one-third of the circumference of the valvar orifice. This leaflet is in fibrous continuity with the aortic valve and, because of this, is best referred to as the *aortic leaflet* because it is neither strictly anterior nor superior in position. The other leaflet is much shallower but guards approximately two-thirds of the circumference of the mitral orifice. Since it is connected to the parietal part of the atrioventricular junction, it is most accurately termed the *mural leaflet* but often is termed the *posterior leaflet.* It is divided into a number of subunits that fold against the aortic leaflet when the valve is closed. Although generally there are three, there may be as many as five or six scallops in the mural leaflet.

Unlike the tricuspid valve, the mitral valve leaflets are supported by a rather dense collagenous annulus, although it may take the form of a sheet rather than a cord. This annulus usually extends parietally from the fibrous trigones, the greatly thickened areas at either end of the area of

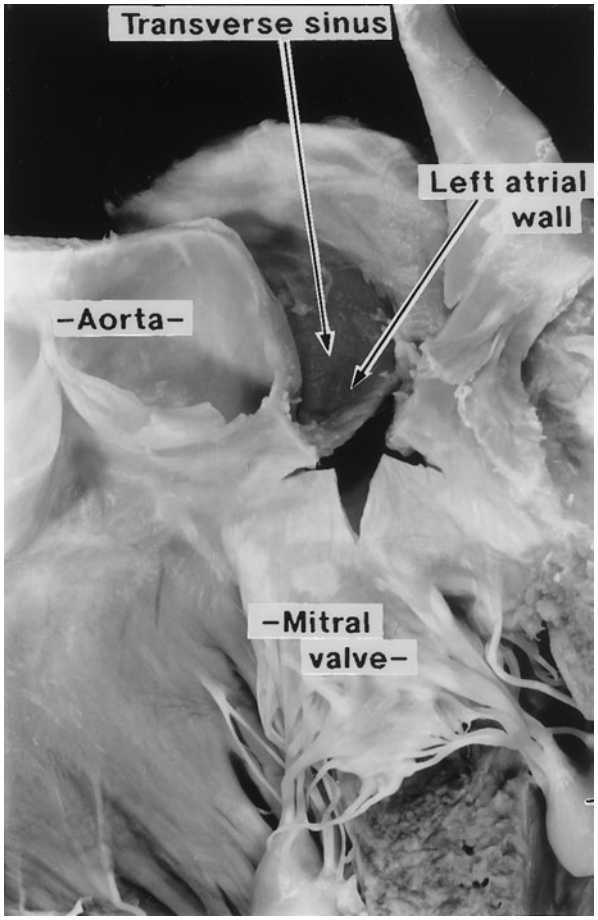

Figure 2-19. This dissection simulates the incision made through the aortic-mitral fibrous curtain to enlarge the orificial diameter of the subaortic outflow tract in a normal heart. (*Dissection made by Dr. Manisha Lal Trapasia.*)

fibrous continuity between the leaflets of the aortic and mitral valves (see Fig. 2-6). The area of the valvar orifice related to the right fibrous trigone and central fibrous body is most vulnerable with respect to the atrioventricular node and penetrating bundle (see Fig. 2-7). The midportion of the aortic leaflet of the mitral valve is related to the commissure between the noncoronary and left coronary cusps of the aortic valve. An incision through the atrial wall in this area may be extended into the subaortic outflow tract and may be useful for enlarging the aortic annulus during replacement of the aortic valve (Fig. 2-19). The circumflex coronary artery is adjacent to the left half of the mural leaflet, whereas the coronary sinus is adjacent to the right half of the mural leaflet (Fig. 2-20). These structures can be damaged during excessive dissection or by excessively deep placement of sutures during replacement or repair of the mitral valve. When the circumflex artery is dominant, the entire attachment of the mural leaflet may be intimately related to this artery (Fig. 2-21).

THE RIGHT VENTRICLE AND PULMONARY VALVE

Inlet and Apical Trabecular Portions

The morphology of both the right and left ventricles can be understood best by subdividing the ventricles into three anatomically distinct components: the inlet, apical trabecular, and outlet portions.[2] This classification is more helpful than the traditional division of the right ventricle into the sinus and conus parts. The inlet portion of the right ventricle surrounds the tricuspid valve and its tension apparatus. A distinguishing feature of the tricuspid valve is the direct attachment of its septal leaflet. The apical trabecular portion of the right ventricle extends out to the apex. Here, the wall of the ventricle is quite thin and vulnerable to perforation by cardiac catheters and pacemaker electrodes.

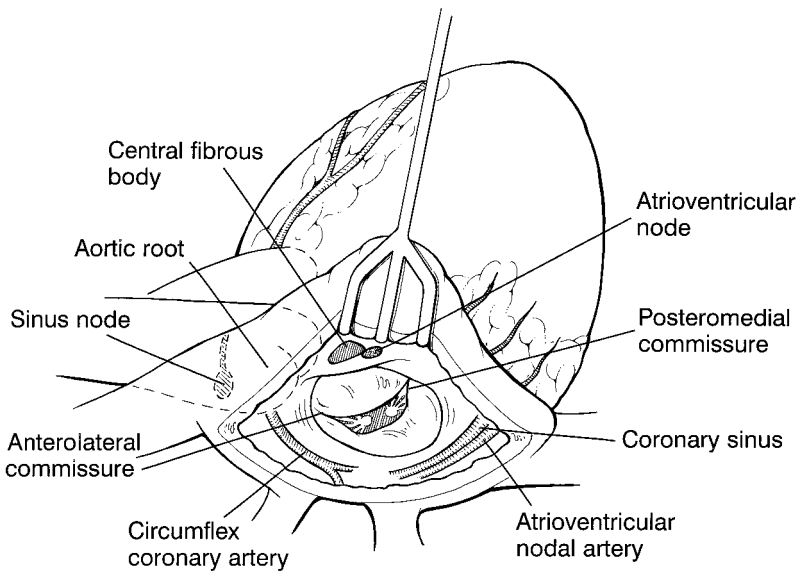

Figure 2-20. This diagram depicts the mitral valve in relationship to its surrounding structures as viewed through a left atriotomy.

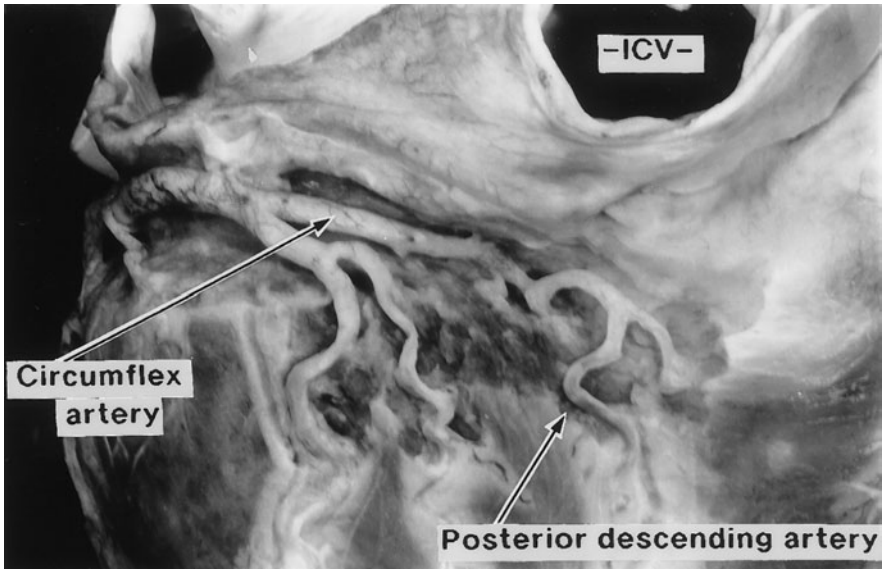

Figure 2-21. The extensive course of a dominant circumflex artery within the left atrioventricular groove shown in anatomic orientation. ICV = inferior vena cava.

Outlet Portion and Pulmonary Valve

The outlet portion of the right ventricle consists of the infundibulum, a circumferential muscular structure that supports the leaflets of the pulmonary valve. Because of the semilunar shape of the pulmonary valvar leaflets, this valve does not have an annulus in the traditional sense of a ringlike attachment. The leaflets have semilunar attachments that cross the musculoarterial junction in a corresponding semilunar fashion (Fig. 2-22). Therefore, instead of a single annulus, three rings can be distinguished anatomically in relation to the pulmonary valve. Superiorly, the sinotubular ridge of the pulmonary trunk marks the level of peripheral apposition of the leaflets (the commissures). A second ring exists at the ventriculoarterial junction. A third ring can be constructed by joining together the basal attachments of the three leaflets to the infundibular muscle. None of these rings, however, corresponds to the attachments of the leaflets, which must be semilunar to permit the valve to open and close competently. In fact, these semilunar attachments, which mark the hemodynamic ventriculoarterial junction, extend from the first ring, across the second, down to the third, and back in each cusp (Fig. 2-23).

Supraventricular Crest and Pulmonary Infundibulum

A distinguishing feature of the right ventricle is a prominent muscular shelf, the supraventricular crest, that separates the tricuspid and pulmonary valves (Fig. 2-24). In reality, this muscular ridge is the posterior part of the subpulmonary muscular infundibulum that supports the leaflets of the pulmonary valve. In other words, it is part of the inner curve of the heart. Incisions through the supraventricular crest run into the transverse septum and may jeopardize the right coronary artery. Although this area is often considered the outlet component of the interventricular septum, in fact, the entire subpulmonary infundibulum, including the ventriculoinfundibular fold, can be removed without entering the left ventricular cavity. This is possible because the leaflets of the pulmonary and aortic valves are supported on separate sleeves of right and left ventricular outlet muscle. There is an extensive external tissue plane between the walls of the aorta and the pulmonary trunk (Fig. 2-25), and the leaflets of the pulmonary and aortic valves have markedly different levels of attachments within their respective ventricles. This feature

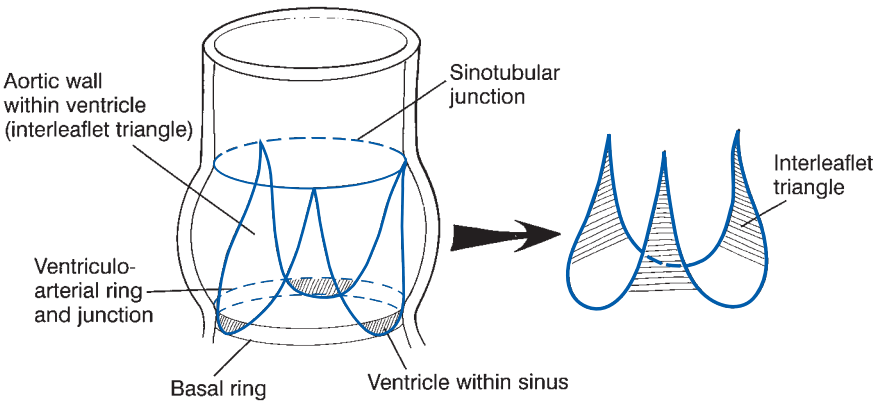

Figure 2-22. The semilunar valves do not have an annulus in the traditional sense. Rather, three rings can be identified anatomically: (1) at the sinotubular junction, (2) at the musculoarterial junction, and (3) at the base of the sinuses within the ventricle.

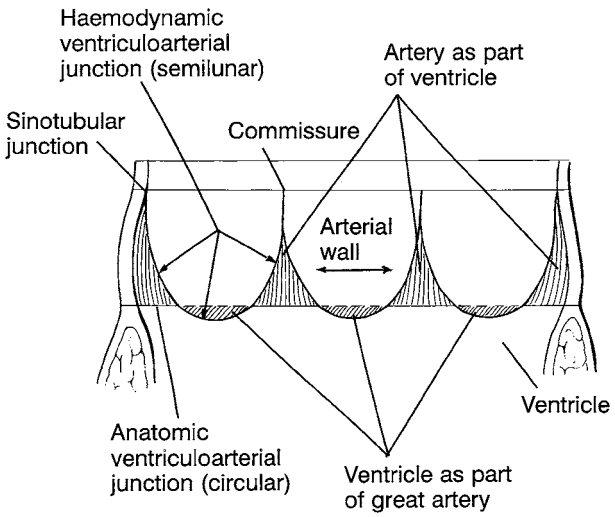

Figure 2-23. The hemodynamic ventriculoarterial junction of the semilunar valves extends from the sinotubular junction across the anatomic ventriculoarterial junction to the basal ring and back in each leaflet (see Fig. 2-22). This creates a portion of ventricle as part of the great artery in each sinus and a triangle of artery as part of the ventricle between each leaflet.

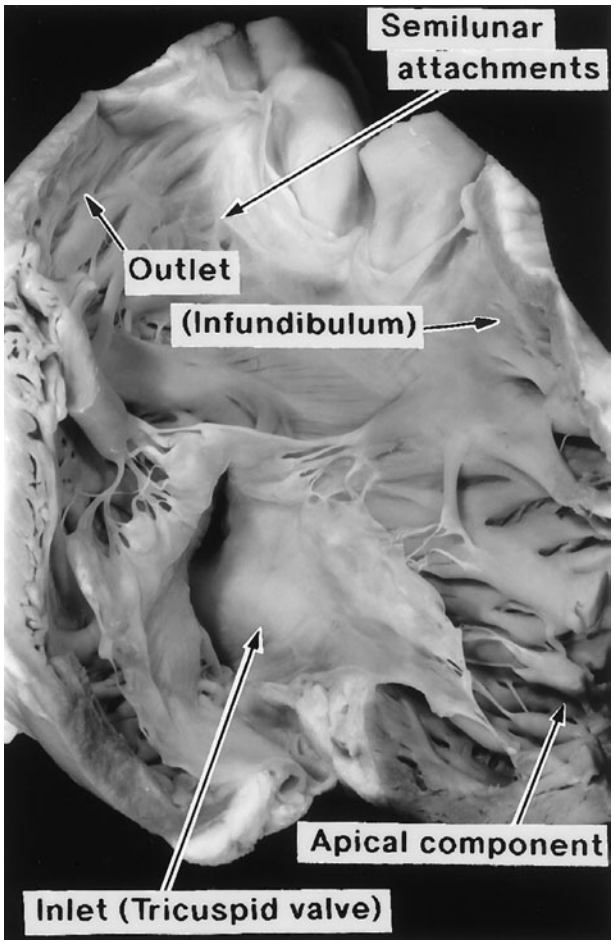

Figure 2-24. View of the opened right ventricle, in anatomic orientation, showing its three component parts and the semilunar attachments of the pulmonary valve. These are supported by the supraventricular crest.

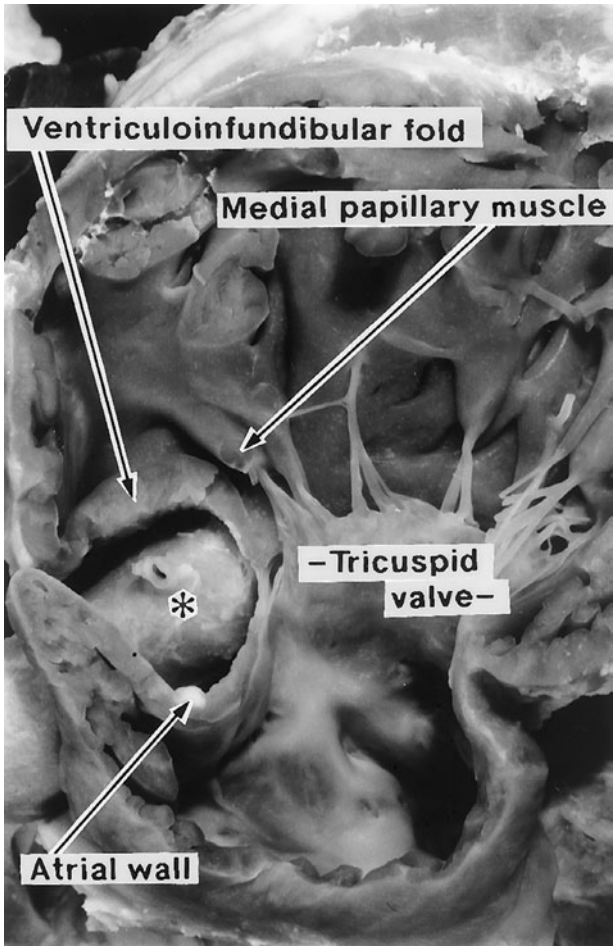

Figure 2-25. This dissection, viewed in surgical orientation, shows how the greater part of the supraventricular crest is formed by the freestanding subpulmonary infundibulum in relation to the right coronary aortic sinus (*asterisk*).

enables enucleation of the pulmonary valve, including its basal attachments within the infundibulum, during the Ross procedure without creating a ventricular septal defect. When the infundibulum is removed from the right ventricle, the insertion of the supraventricular crest between the limbs of the septomarginal trabeculation is visible (Fig. 2-26). This trabeculation is a prominent muscle column that divides superiorly into anterior and posterior limbs. The anterior limb runs superiorly into the infundibulum and supports the leaflets of the pulmonary valve. The posterior limb extends backwards beneath the ventricular septum and runs into the inlet portion of the ventricle. The medial papillary muscle arises from this posterior limb. The body of the septomarginal trabeculation runs to the apex of the ventricle, where it divides into smaller trabeculations. Two of these trabeculations may be particularly prominent. One becomes the anterior papillary muscle, and the other crosses the ventricular cavity as the moderator band (Fig. 2-27).

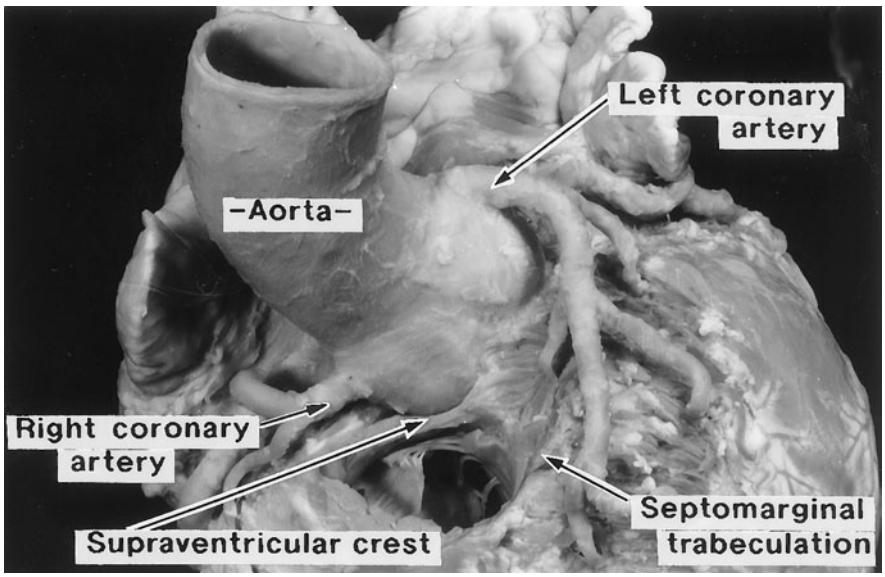

Figure 2-26. Removal of the freestanding subpulmonary infundibulum reveals the insertion of the supraventricular crest between the limbs of the septomarginal trabeculation and shows the aortic origin of the coronary arteries (anatomic orientation).

THE LEFT VENTRICLE AND AORTIC VALVE

Inlet and Apical Trabecular Portions

The left ventricle can be subdivided into three components, similar to the right ventricle. The inlet component surrounds and is limited by the mitral valve and its tension apparatus. The two papillary muscles occupy anterolateral and posteromedial positions and are positioned rather close to each other. The leaflets of the mitral valve have no direct septal attachments because the deep posterior diverticulum of the left ventricular outflow tract displaces the aortic leaflet away from the inlet septum. The apical trabecular component of the left ventricle extends to the apex, where the myocardium is surprisingly thin. The trabeculations of the left ventricle are quite fine compared with those of the right ventricle (Fig. 2-28). This characteristic is useful for defining ventricular morphology on diagnostic ventriculograms.

Outlet Portion

The outlet component supports the aortic valve and consists of both muscular and fibrous portions. This is in contrast to the infundibulum of the right ventricle, which consists entirely of muscle. The septal portion of the left ventricular outflow tract, although primarily muscular, also includes the membranous portion of the ventricular septum. The posterior quadrant of the outflow tract consists of an extensive fibrous curtain that extends from the fibrous skeleton of the heart across the aortic leaflet of the mitral valve and supports the leaflets of the aortic valve in the area of aortomitral continuity (see Fig. 2-5). The lateral quadrant of the outflow tract again is

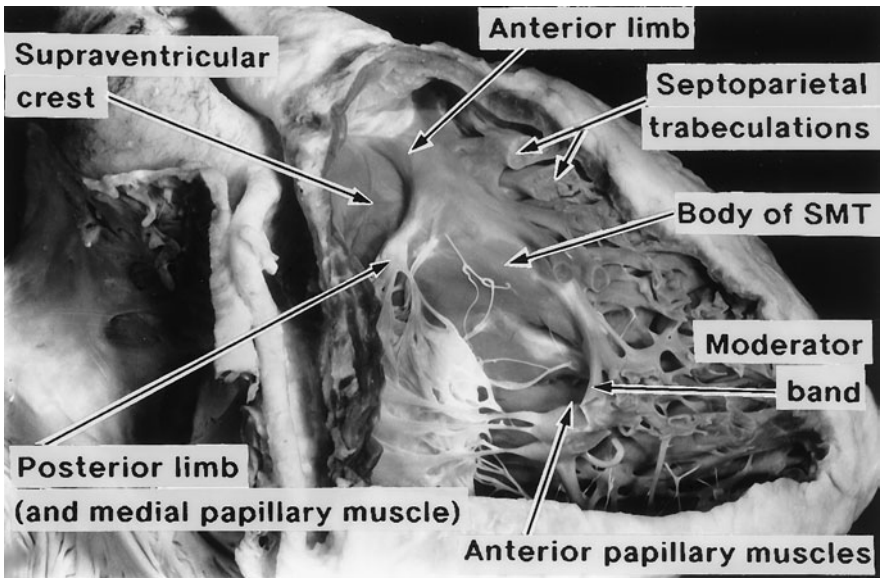

Figure 2-27. This dissection of the right ventricle, in anatomic orientation, shows the relations of supraventricular crest and septomarginal (SMT) and septoparietal trabeculations.

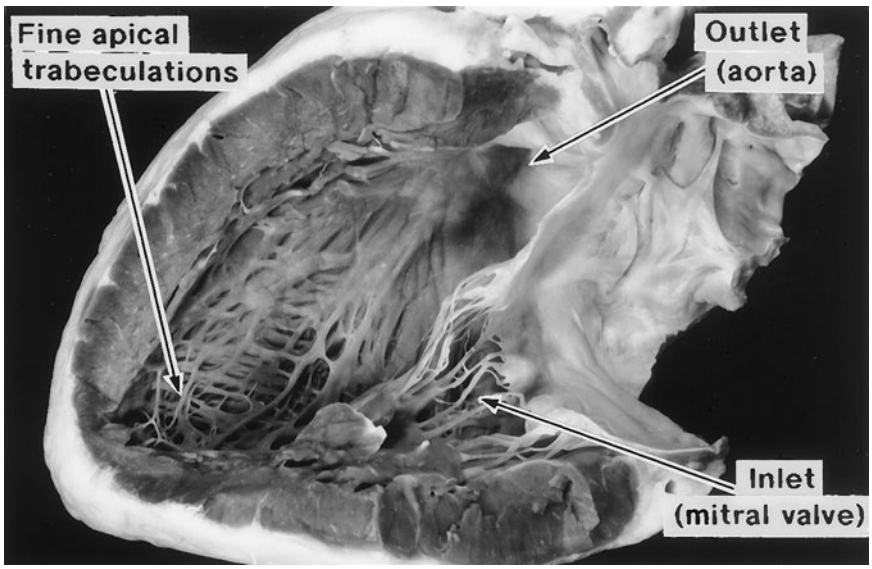

Figure 2-28. This dissection of the left ventricle shows its component parts and characteristically fine apical trabeculations (anatomic orientation).

muscular and consists of the lateral margin of the inner curvature of the heart, delineated externally by the transverse sinus. The left bundle of the cardiac conduction system enters the left ventricular outflow tract posterior to the membranous septum and immediately beneath the commissure between the right and noncoronary leaflets of the aortic valve. After traveling a short distance down the septum, the left bundle divides into anterior, septal, and posterior divisions.

Aortic Valve

The aortic valve is a semilunar valve that is quite similar morphologically to the pulmonary valve. Likewise, it does not have a discrete annulus. Because of its central location, the aortic valve is related to each of the cardiac chambers and valves (see Fig. 2-4). A thorough knowledge of these relationships is essential to understanding aortic valve pathology and many congenital cardiac malformations.

The aortic valve consists primarily of three semilunar leaflets. As with the pulmonary valve, attachments of the leaflets extend across the ventriculoarterial junction in a curvilinear fashion. Each leaflet therefore has attachments to the aorta and within the left ventricle (Fig. 2-29). Behind each leaflet, the aortic wall bulges outward to form the sinuses of Valsalva. The leaflets themselves meet centrally along a line of coaptation, at the center of which is a thickened nodule called the *nodule of Arantius.* Peripherally, adjacent to the commissures, the line of coaptation is thinner and normally may contain small perforations. During systole, the leaflets are thrust upward and away from the center of the aortic lumen, whereas during diastole, they fall passively into the center of the aorta. With normal valvar morphology, all three leaflets meet along lines of coaptation and support the column of blood within the aorta to prevent regurgitation into the ventricle. Two of the three aortic sinuses give rise to coronary arteries, from which arise their designations as *right, left,* and *noncoronary sinuses.*

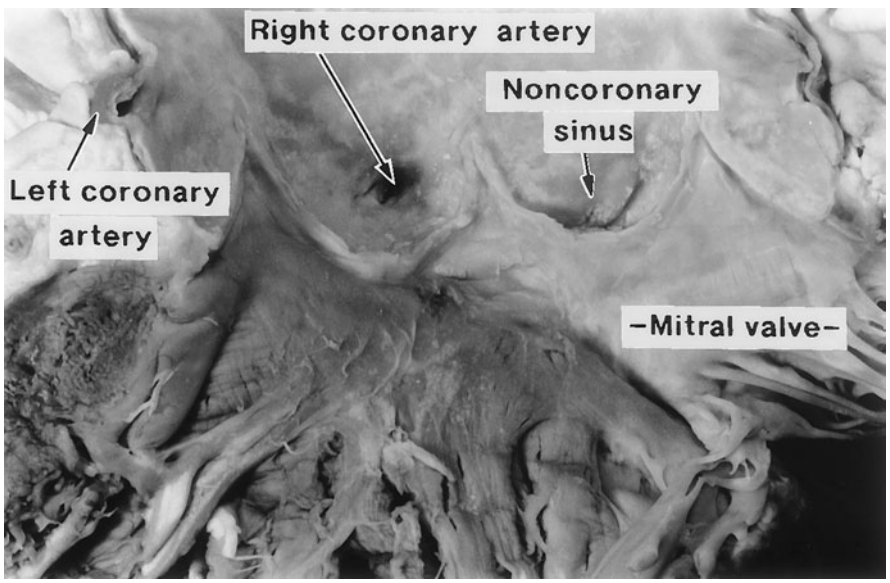

Figure 2-29. This dissection in anatomic orientation, made by removing the aortic valvar leaflets, emphasizes the semilunar nature of the hinge points (see Figs. 2-22 and 2-23). Note the relationship to the mitral valve (see Fig. 2-5).

By sequentially following the line of attachment of each leaflet, the relationship of the aortic valve to its surrounding structures can be clearly understood. Beginning posteriorly, the commissure between the noncoronary and left coronary leaflets is positioned along the area of aortomitral valvar continuity. The fibrous subaortic curtain is beneath this commissure (see Fig. 2-29). To the right of this commissure, the noncoronary leaflet is attached above the posterior diverticulum of the left ventricular outflow tract. Here, the valve is related to the right atrial wall. As the attachment of the noncoronary leaflet ascends from its nadir toward the commissure between the noncoronary and right coronary leaflets, the line of attachment is directly above the portion of the atrial septum containing the atrioventricular node. The commissure between the noncoronary and right coronary leaflets is located directly above the penetrating atrioventricular bundle and the membranous ventricular septum (Fig. 2-30). The attachment of the right coronary leaflet then descends across the central fibrous body before ascending to the commissure between the right and left coronary leaflets. Immediately beneath this commissure, the wall of the aorta forms the uppermost part of the subaortic outflow. An incision through this area passes into the space between the facing surfaces of the aorta and pulmonary trunk (see Fig. 2-30). As the facing left and right leaflets descend from this commissure, they are attached to the outlet muscular component of the left ventricle. Only a small part of this area in the normal heart is a true outlet septum because both pulmonary and aortic valves are supported on their own sleeves of myocardium. Thus, although the outlet components of the right and left ventricle face each other, an incision below the aortic valve enters low into the infundibulum of the right ventricle. As the lateral part of the left coronary leaflet descends from the facing commissure to the base of the sinus, it becomes the only part of the aortic valve that is not intimately related to another cardiac chamber.

Knowledge of the anatomy of the aortic valve and its relationship to surrounding structures is important to successful replacement of the aortic valve, particularly when enlargement of the aortic root is required. The Konno-Rastan aortoventriculoplasty involves opening and enlarging the anterior portion of the subaortic region.[4,5] The incisions for this procedure begin with an anterior longitudinal aortotomy that extends through the commissure between the right and left coronary leaflets. Anteriorly, the incision is extended across the base of the infundibulum. The differential level of attachment of the aortic and pulmonary valve leaflets permits this incision without damage to the pulmonary valve (Fig. 2-31). Posteriorly, the incision extends through the most medial portion of the supraventricular crest into the left ventricular outflow tract. By closing the resulting ventricular septal defect with a patch, the aortic outflow tract is widened to allow implantation of a larger valve prosthesis. A second patch is used to close the defect in the right ventricular outflow tract.

Alternative methods to enlarge the aortic outflow tract involve incisions in the region of aortomitral continuity. In the Manouguian procedure (see Fig. 2-19), a curvilinear aortotomy is extended posteriorly through the commissure between the left and noncoronary leaflets down to and occasionally into the aortic leaflet of the mitral valve.[6] A patch is used to augment the incision posteriorly. When the posterior diverticulum of the outflow tract is fully developed, this incision can be made without entering other cardiac chambers, although not uncommonly the roof of the left atrium is opened. The Nicks procedure for enlargement of the aortic root involves an aortotomy that passes through the middle of the noncoronary leaflet into the fibrous subaortic curtain and may be extended into the aortic leaflet of the mitral valve.[7] This incision also may open the roof of the left atrium. When these techniques are used, any resulting defect in the left atrium must be closed carefully.

As discussed previously, the differential level of attachment of aortic and pulmonary valves, as well as the muscular nature of their support, allows the pulmonary valve to be harvested and used as a replacement for the aortic valve in the Ross procedure.[8,9] This procedure can be combined with the incisions of the Konno-Rastan aortoventriculoplasty to

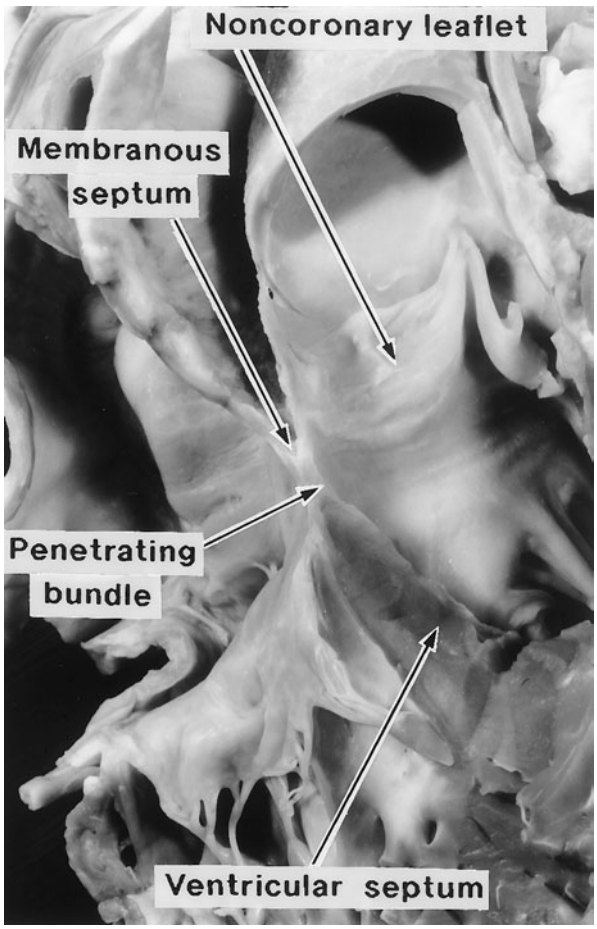

Figure 2-30. Dissection made by removing the right and part of the left aortic sinuses to show the relations of the fibrous triangle between the right and noncoronary aortic leaflets (anatomic orientation).

repair left ventricular outflow tract obstructions in young children with a viable autograft that has potential for growth and avoids the need for anticoagulation.

Accurate understanding of left ventricular outflow tract anatomy is also important in the treatment of aortic valvar endocarditis.[10,11] Because of the central position of the aortic valve relative to the other valves and cardiac chambers (see Fig. 2-4), abscess formation can produce fistulas between the aorta and any of the four chambers of the heart. Patients therefore may present with findings of left-sided heart failure, left-to-right shunting, and/or complete heart block in addition to the usual signs of sepsis and systemic embolization.

THE CORONARY ARTERIES[12–14]

The right and left coronary arteries originate behind their respective aortic valvar leaflets (see Fig. 2-26). The orifices usually are located in the upper third of the sinuses of Valsalva, although individual hearts may vary markedly. Because of the oblique plane of the aortic valve, the orifice of the left coronary artery is superior and posterior to that of the right coronary artery. The coronary arterial tree is divided into three segments; two (the left anterior descending artery and the circumflex artery) arise from a common stem. The third segment is the right coronary artery. The dominance of the coronary circulation (right versus left) usually refers to the artery from which the posterior descending artery originates, not the absolute mass of myocardium perfused by the left or right coronary artery. Right dominance occurs in 85 to 90% of normal individuals. Left dominance occurs slightly more frequently in males than in females.

Main Stem of the Left Coronary Artery

The main stem of the left coronary artery courses from the left sinus of Valsalva anteriorly, inferiorly and to the left between the pulmonary trunk and the left atrial appendage (Fig. 2-32). Typically, it is 10 to 20 mm in length but can extend to a length of 40 mm. The left main stem can be absent, with separate orifices in the sinus of Valsalva for its two primary branches (1% of patients). The main stem

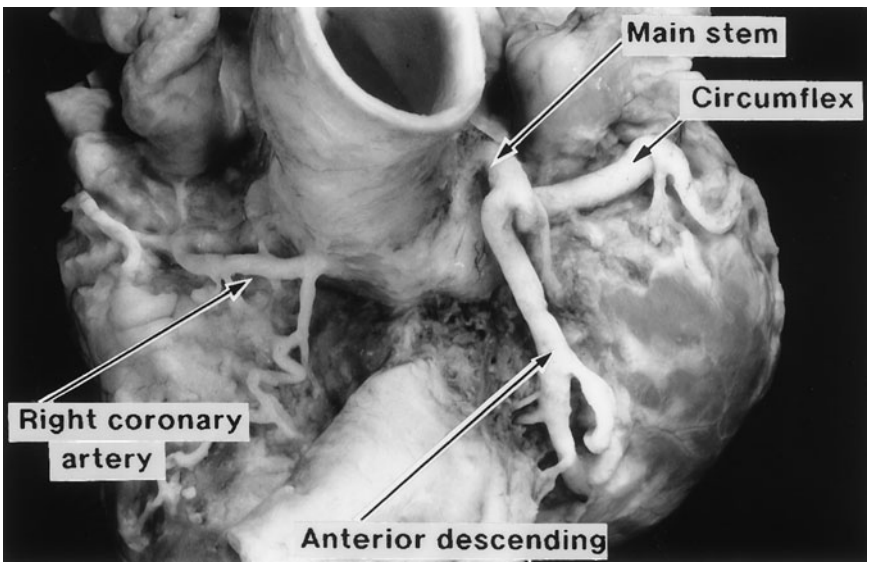

Figure 2-32. The short extent of the main stem of the left coronary artery is seen before it branches into the circumflex and anterior descending arteries. Note the small right coronary artery in this heart, in which the circumflex artery was dominant (see Fig. 2-21).

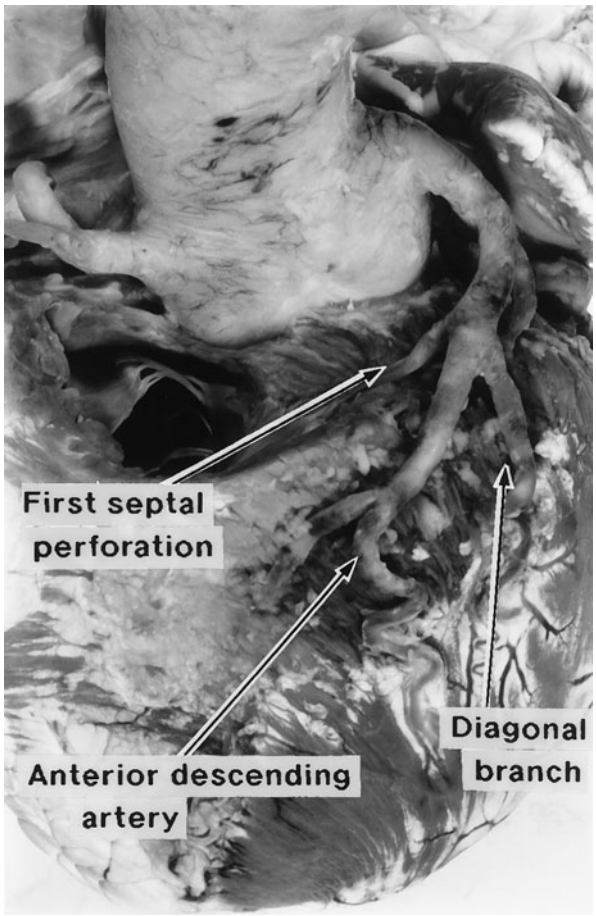

Figure 2-33. The important branches of the anterior descending artery are the first septal perforating and diagonal arteries.

divides into two major arteries of nearly equal diameter: the left anterior descending artery and the circumflex artery.

Left Anterior Descending Artery

The left anterior descending (or interventricular) coronary artery continues directly from the bifurcation of the left main stem, coursing anteriorly and inferiorly in the anterior interventricular groove to the apex of the heart (Fig. 2-33). Its branches include the diagonals, the septal perforators, and the right ventricular branches. The diagonals, which may be two to six in number, course along the anterolateral wall of the left ventricle and supply this portion of the myocardium. The first diagonal generally is the largest and may arise from the bifurcation of the left main stem (formerly known as the *intermediate artery*). The septal perforators branch perpendicularly into the ventricular septum. Typically, there are three to five septal perforators; the initial one is the largest and commonly originates just beyond the takeoff of the first diagonal. This perpendicular orientation is a useful marker for identification of the left anterior descending artery on coronary angiograms. The septal perforators supply blood to the anterior two-thirds of the ventricular septum. Right ventricular branches, which may not always be present, supply blood to the anterior surface of the right ventricle. In approximately 4% of hearts, the left anterior descending artery bifurcates proximally and continues as two parallel vessels of approximately equal size down the anterior interventricular groove. Occasionally, the artery wraps around the apex of the left ventricle to feed the distal portion of the posterior interventricular groove. Rarely, it extends along the entire length of the posterior groove to replace the posterior descending artery.

Circumflex Artery

The left circumflex coronary artery arises from the left main coronary artery roughly at a right angle to the anterior interventricular branch. It courses along the left atrioventricular groove and in 85 to 95% of patients terminates near the obtuse margin of the left ventricle (Fig. 2-34). In 10 to 15% of patients, it continues around the atrioventricular groove to the crux of the heart to give rise to the posterior descending artery (left dominance; see Fig. 2-21). The primary branches of the left circumflex coronary artery are the obtuse marginals. They supply blood to the lateral aspect of the left ventricular myocardium,

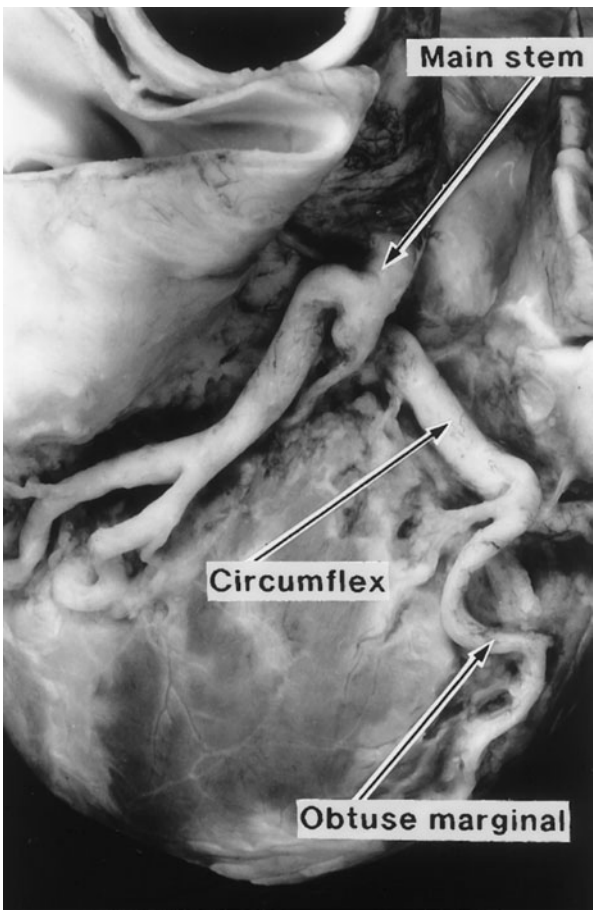

Figure 2-34. The important branches of the circumflex artery, seen in anatomic orientation.

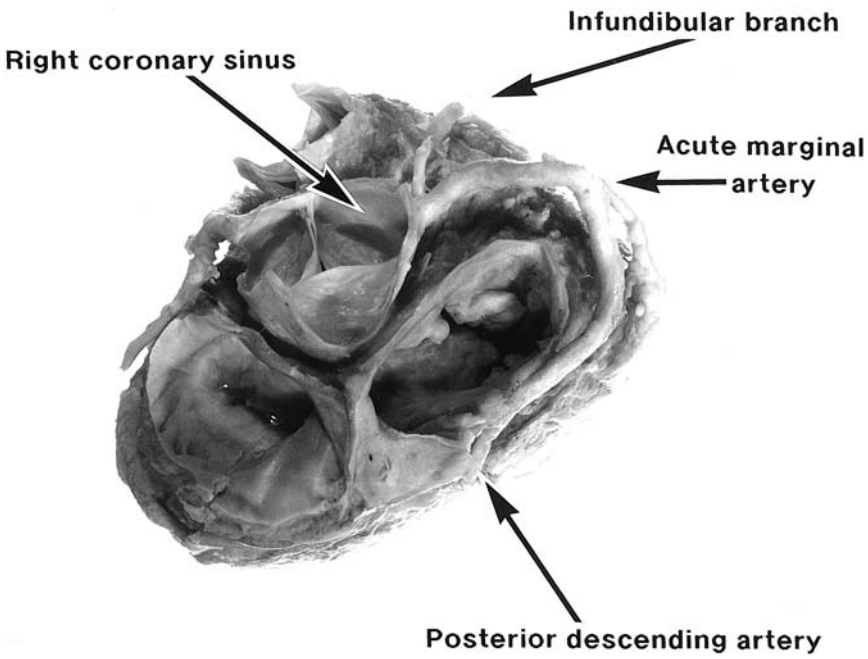

Figure 2-35. This dissection shows the relationships and branches of the right coronary artery.

including the posteromedial papillary muscle. Additional branches supply blood to the left atrium and, in 40 to 50% of hearts, the sinus node. When the circumflex coronary artery supplies the posterior descending artery, it also supplies the atrioventricular node.

Right Coronary Artery

The right coronary artery courses from the aorta anteriorly and laterally before descending in the right atrioventricular groove and curving posteriorly at the acute margin of the right ventricle (Fig. 2-35). In 85 to 90% of hearts, the right coronary artery crosses the crux, where it makes a characteristic U-turn before bifurcating into the posterior descending artery and the right posterolateral artery. In 50 to 60% of hearts, the artery to the sinus node arises from the proximal portion of the right coronary artery. The blood supply to the atrioventricular node (in patients with right-dominant circulation) arises from the midportion of the U-shaped segment. The posterior descending artery runs along the posterior interventricular groove, extending for a variable distance toward the apex of the heart. It gives off perpendicular branches, the posterior septal perforators, that course anteriorly in the ventricular septum. Typically, these perforators supply the posterior one-third of the ventricular septal myocardium.

The right posterolateral artery gives rise to a variable number of branches that supply the posterior surface of the left ventricle. The circulation of the posteroinferior portion of the left ventricular myocardium is quite variable. It may consist of branches of the right coronary artery, the circumflex artery, or both. The acute marginal arteries branch from the right coronary artery along the acute margin of the heart, before its bifurcation at the crux. These marginals supply the anterior free wall of the right ventricle. In 10 to 20% of hearts, one of these acute marginal arteries courses across the diaphragmatic surface of the right ventricle to reach the distal ventricular septum. The right coronary artery supplies important collaterals to the left anterior descending artery through its septal perforators. In addition, its infundibular (or conus) branch, which arises from the proximal portion of the right coronary artery, courses anteriorly over the base of the ventricular infundibulum and may serve as a collateral to the anterior descending artery. Kugel's artery is an anastomotic vessel between the proximal right coronary and the circumflex coronary artery that also can provide a branch that runs through the base of the atrial septum to the crux of the heart, where it supplies collateral circulation to the atrioventricular node.[15]

THE CORONARY VEINS[14]

A complex network of veins drains the coronary circulation. An extensive degree of collateralization among these veins and the coronary arteries and the paucity of valves within coronary veins enable the use of retrograde coronary sinus cardioplegia for intraoperative myocardial protection. The venous circulation can be divided into three systems: the coronary sinus and its tributaries, the anterior right ventricular veins, and the thebesian veins.

Coronary Sinus and Its Tributaries

The coronary sinus predominantly drains the left ventricle and receives approximately 85% of coronary venous blood. It lies within the posterior atrioventricular groove and empties into the right atrium at the lateral border of

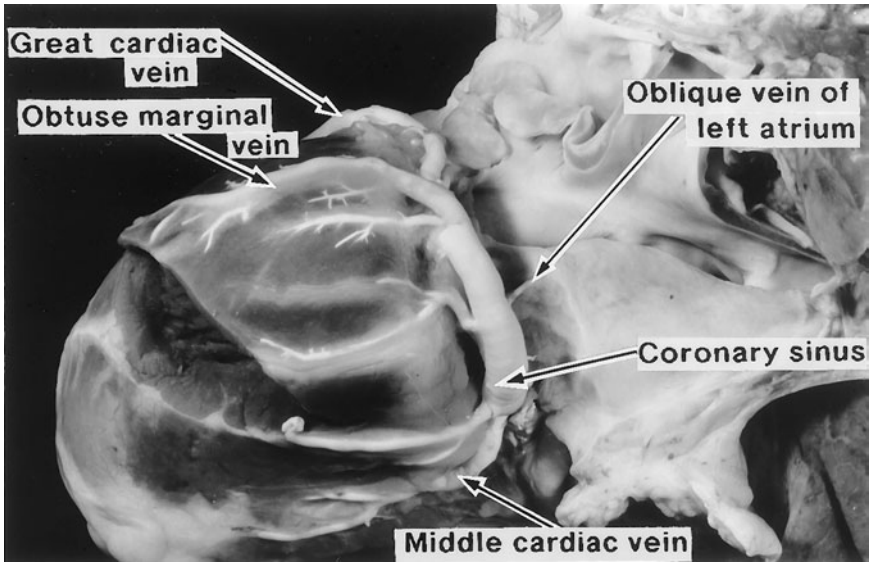

Figure 2-36. The coronary veins on the diaphragmatic surface of the heart, seen in anatomic orientation, have been emphasized by filling them with sealant. The tributaries of the coronary sinus are well demonstrated. Note that, strictly speaking, the sinus does not begin until the oblique vein enters the great cardiac vein.

the triangle of Koch (Fig. 2-36). The orifice of the coronary sinus is guarded by the crescent-shaped thebesian valve. The named tributaries of the coronary sinus include the anterior interventricular vein, which courses parallel to the left anterior descending coronary artery. Adjacent to the bifurcation of the left main stem, the anterior interventricular vein courses leftward in the atrioventricular groove, where it is referred to as the *great cardiac vein*. It receives blood from the marginal and posterior left ventricular branches before becoming the coronary sinus at the origin of the oblique vein (of Marshall) at the posterior margin of the left atrium. The posterior interventricular vein, or *middle cardiac vein,* arises at the apex, courses parallel to the posterior descending coronary artery and extends proximally to the crux. Here, this vein drains either directly into the right atrium or into the coronary sinus just prior to its orifice. The *small cardiac vein* runs posteriorly through the right atrioventricular groove.

Anterior Right Ventricular Veins

The anterior right ventricular veins travel across the right ventricular surface to the right atrioventricular groove, where they either enter directly into the right atrium or coalesce to form the small cardiac vein. As indicated, this vein travels down the right atrioventricular groove, around the acute margin, and enters into the right atrium directly or joins the coronary sinus just proximal to its orifice.

Thebesian Veins

The thebesian veins are small venous tributaries that drain directly into the cardiac chambers. They exist primarily in the right atrium and right ventricle.

CHAPTER 3

Cardiac Surgical Physiology

Edward B. Savage • R. Saeid Farivar • Eric J. Okum

An open cardiac surgical procedure is the most acute application of basic dynamic physiology (principles learned as a medical student) that exists in medical care. Basic physiologic concepts of electromechanical activation and association, loading conditions, inotropy, etc. all have an impact on achievement of a successful outcome. Working knowledge of these fundamental concepts is imperative to maintain and return a patient to normal function. The purpose of this chapter is to present a manageable, working outline of cardiac physiology that can be used in daily practice as a framework against which pathologic processes can be measured, assessed, and treated.

CELLULAR COMPONENTS AND CELLULAR ACTIVATION

The heart beats continuously based on the unique features of its component cells. A cardiac cycle begins when spontaneous depolarization of a pacemaker cell initiates an action potential; this electrical activity is transmitted to atrial muscle cells, which contract, and to the conduction system, which transmits the electrical activity to the ventricle. Activation depends on components of the cell membrane and cell that induce and maintain the ion currents that maintain and promote electrical activation.

Similar to most excitable cells in the body, the activity of cells in the heart is triggered by an *action potential.* An action potential is a cyclic activation of a cell consisting of a rapid change in the membrane potential (the electrical gradient across the cell membrane) and subsequent return to a resting membrane potential. This process depends on a selectively permeable cell membrane and proteins that actively and passively direct ion passage across the cell membrane. The specific components of the myocyte action potential are detailed in Fig. 3-3. The myocyte action potential is characterized by a rapid initial depolarization mediated by *fast channels* (sodium channels) and then a plateau phase mediated by *slow channels* (calcium channels). Further details of this process are introduced as their components are described.

The Sarcolemma

The cardiac cell is surrounded by a membrane (*plasmalemma,* or more specific to a muscle cell, *sarcolemma*). The structural components of the sarcolemma allow for the origination and then conduction of an electrical signal through the heart with subsequent initiation of the *excitation-contraction coupling process.* This leads to depolarization of atrial myocytes and, with an appropriate delay, depolarization of ventricular myocytes. The sarcolemma also participates in the regulation of excitation, contraction, and intracellular metabolism in response to neuronal and chemical stimulation. Each of these functions will be considered, with emphasis on the features of the cardiac sarcolemma that differ from the plasmalemma of other cells.

The Phospholipid Bilayer

A *phospholipid bilayer* provides a barrier between the extracellular compartment and the intracellular compartment, or *cytosol.* It is only two molecules thick, consists of phospholipids and cholesterol aligned so that the lipid, or hydrophobic, portion of the molecule is on the inside of the membrane, and the hydrophilic portion of the molecule is on the outside (Fig. 3-1). The sarcolemma which is a phospholipid bilayer, provides a fluid barrier that is particularly *impermeable to diffusion of ions.* Small lipid-soluble molecules such as oxygen and carbon dioxide diffuse easily through the membrane. The water molecule, although insoluble in the membrane, is small enough that it diffuses easily through the membrane (or through pores in the membrane). Other, slightly larger molecules (e.g., sodium, chloride, potassium, and calcium) cannot diffuse easily through the lipid bilayer and require specialized channels for transport.[1–3]

The specialized ion-transport systems within the sarcolemma consist of *membrane-spanning proteins* that

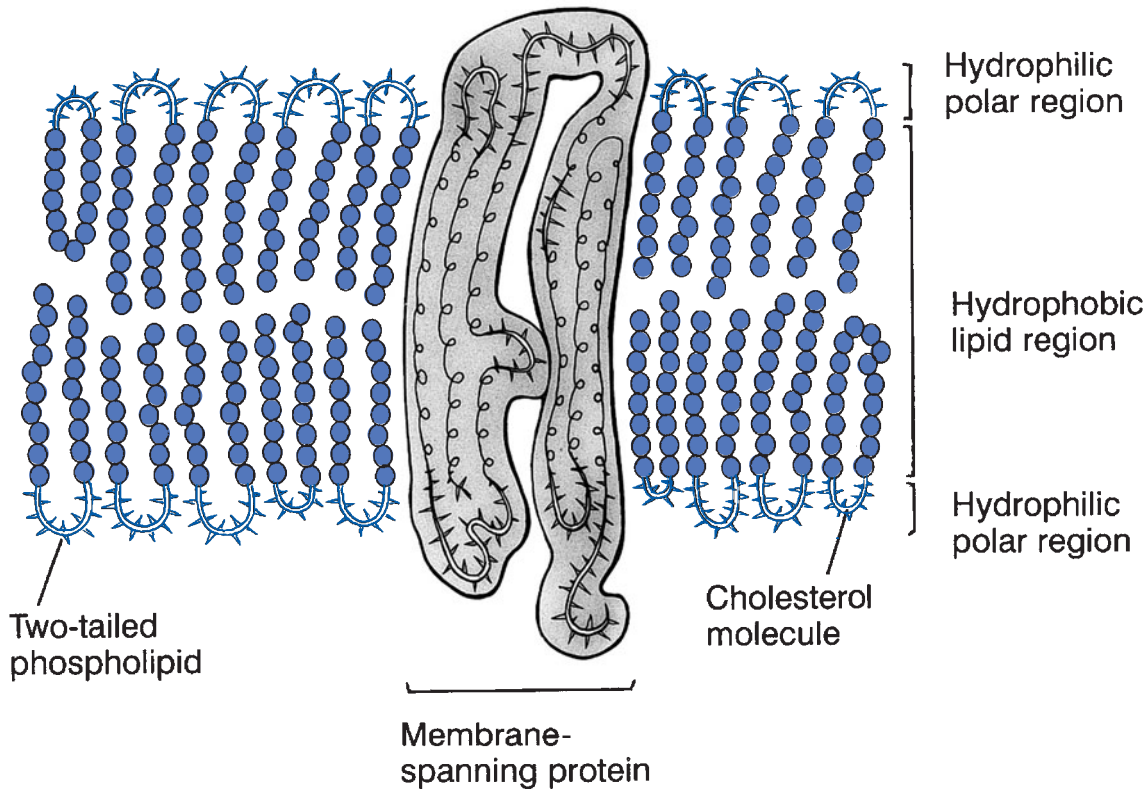

Figure 3-1. The sarcolemma is a bilayer in which phospholipid and cholesterol molecules are arranged with hydrophobic domains within the membrane and hydrophilic domains facing outward. The membrane-spanning protein shown here is similar to many ion channels, with six hydrophobic alpha-helices spanning the membrane and surrounding a central channel.

float in and penetrate through the lipid bilayer. These proteins are associated with three different types of ion transport: (1) *diffusion* through transmembrane channels that can be opened or closed (gated) in response to electrical (*voltage-gated*) or chemical (*ligand-gated*) stimuli, (2) *exchange* of one ion for another with binding of these ions to portions of the transmembrane protein for exchange in response to an electrochemical gradient, and (3) *active (energy-dependent) transport* of ions against an electrochemical gradient.

Other proteins located in the sarcolemma serve as *receptors* for neuronal or chemical control of cellular processes (e.g., beta-adrenergic receptors and muscarinic acetylcholine receptors).

Sarcolemmal channels

Most of the voltage-gated channels consist of tetramers of four subunits that surround the water-filled pore through which ions cross the membrane. A schematic diagram of an ion channel is shown in Fig. 3-2. Each channel contains a *selectivity filter* that selectively allows the passage of particular ions based on pore size and electric charge and an *activation gate* that is regulated by conformational changes induced by either a voltage-sensitive or a ligand-binding region of the protein. Many channels also have an *inactivation gate* that is also controlled either by voltage or by ligands.[1,2,4]

Voltage-gated sodium channels

The voltage-gated sodium channel is prominent in most electrically excitable muscle and nerve cells. Energy-dependent pumps and other ions create a large concentration gradient of sodium (142 mEq/L outside the cell, 10 mEq/L inside the cell) and a large electrical gradient (–70 to –90 mV outside to inside) across the cell membrane. Both the concentration gradient and the electrical force favor the influx of sodium. This influx of positive ions is termed an *inward current.* The inward current of positive sodium ions begins to depolarize (reduce the electrical gradient across) the sarcolemmal membrane. When the membrane potential is raised to between −70 and −50 mV, the activation gate of the sodium channel opens. Once open, sodium ions rapidly rush into the cell, depolarizing the sarcolemmal membrane. The inactivation gate of the sodium channel begins to close at about the same voltage, but with a built-in time delay such that the sodium channel is open for only a few milliseconds. Because these channels open and close so quickly, they have been called *fast channels.* The inactivation gate of the sodium channel remains closed until the cell is repolarized; the resting negative membrane potential of −70 to −90 mV is restored.[5–7]

Voltage-gated calcium channels

There are two important populations of calcium channels. The *type T (transient) calcium channels* open as the membrane potential rises to –60 to –50 mV and then close quickly

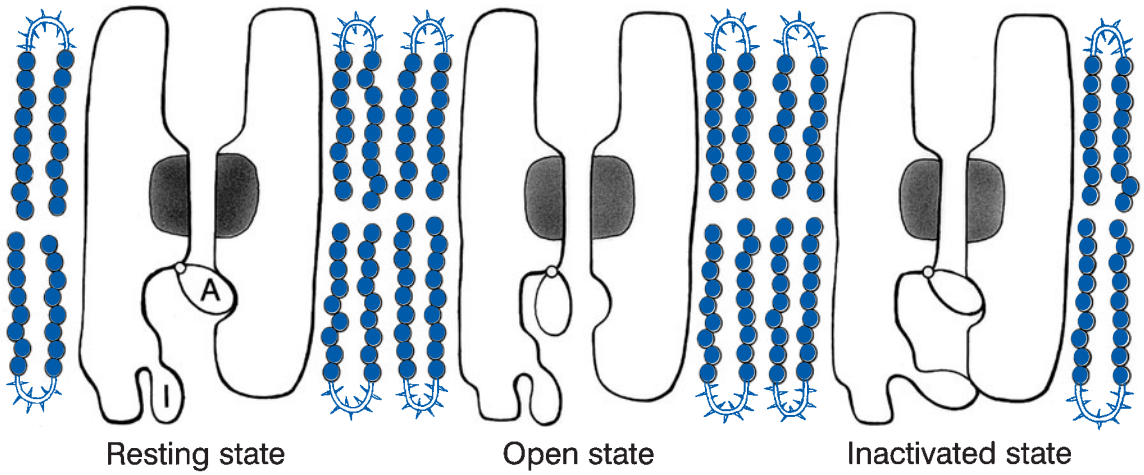

Figure 3-2. A voltage-gated sodium channel is depicted schematically. The shaded region is the selectivity filter. *A* represents the activation gate, and *I* represents the inactivation gate. At rest, the inactivation gate is open, and the activation gate is closed. As the transmembrane potential rises from –80 to –60 mV, the activation gate opens, and sodium ions pass through the channel. Within a few milliseconds, the inactivation gate closes. Once the cell repolarizes, the resting ion channel returns to the resting state.

by action of an inactivation gate. These type T calcium channels are important in early depolarization, especially in atrial pacemaker cells, but they contribute little to the sustained depolarization of the plateau of the action potential and have much less activity in the ventricles.

The second major calcium channel, the *type L (long-lasting) channel,* a *slow channel,* leads to an inward (depolarizing) current that is slowly inactivated and therefore prolonged. These channels open at a less negative potential (–30 to –20 mV). Once open, the slow inactivation allows an inward calcium current (Fig. 3-3) that sustains the action potential. In addition, this increase in cytosolic calcium begins the excitation-contraction sequence. Activity of this channel is altered by catecholamine stimulation. Beta-receptor stimulation induces conformational changes resulting in an increased influx of calcium ions and an associated increase in the strength of sarcomere contraction. This effect is attenuated by stimulation of acetylcholine and adenosine receptors.[8,9]

Potassium channels

A number of potassium channels, both voltage- and ligand-gated, are present in cardiac cells. Three voltage-gated potassium channels moderate the *delayed rectifier current* that repolarizes the cell membrane[10,11] (Fig. 3-3).

Several ligand-gated potassium channels have been identified. *Acetylcholine-* and *adenosine-activated* potassium channels are time-independent and lead to hyperpolarization in pacemaker and nodal cells, thereby delaying spontaneous depolarization. A *calcium-activated* potassium channel opens in the presence of high levels of cytosolic calcium and probably enhances the delayed rectifier current, leading to early termination of the action potential. An *ATP-sensitive* potassium channel is closed in the metabolically normal myocyte but is opened in the metabolically starved myocyte in which ATP stores have been depleted, leading to hyperpolarization of the cell and thereby retarding depolarization and contraction.

Energy-Dependent Ion Pumps and Ion Exchangers

Sodium-potassium-ATP-dependent pump

The sodium-potassium pump uses the energy obtained from the hydrolysis of ATP to move three Na^+ ions out of the cell and two K^+ ions into the cell, each against its respective concentration gradient. Since there is a net outward current (three Na^+ ions for two K^+ ions), the pump contributes about 10 mV to the resting membrane potential. The activity of the pump is strongly stimulated by attachment of sodium to the sodium-binding site on the inside of the membrane. The Na,K-ATPase pump has a very high affinity for ATP, so the pump continues to function even if ATP levels are moderately reduced.

ATP-dependent calcium pump

The ATP-dependent calcium pump transports calcium out of the cell against a strong concentration gradient. This action represents a net outward current, but the magnitude of this current is quite small because the bulk of calcium transferred out of the cell occurs with sodium-calcium exchange (described below). The cytosolic protein *calmodulin* can complex with calcium and facilitate action of the pump; thus increased intracellular calcium levels stimulate the pump.[2,12–14]

Ion exchangers

Multiple proteins that traverse the membrane allow ion exchanges using the potential energy of the electrochemical gradient—the gradient favoring the influx of sodium. The *sodium-calcium exchange pump* exchanges three extracellular sodium ions for one intracellular calcium ion, leading to a net single positive charge transported into the cell with each exchange. The exchange system is sensitive to the concentration of sodium and calcium on both sides of the membrane and to the membrane potential. If external sodium concentrations decrease, the driving force for removal of calcium

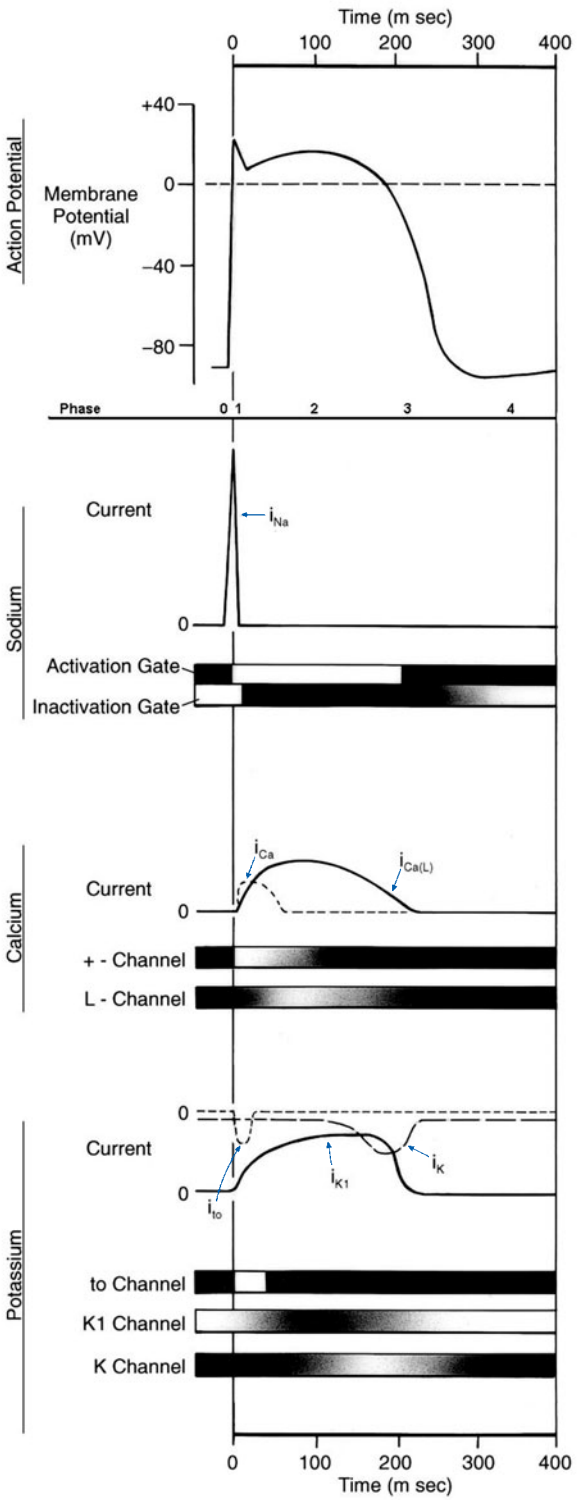

Figure 3-3. A typical ventricular myocyte action potential and the ion currents contributing to it are represented schematically. Inward (depolarizing) currents are depicted as positive, and outward (repolarizing) currents are depicted as negative. The horizontal filled bars show the state of the gate of the ion channel (white = open; black = closed; shaded = partially open). In the case of the sodium channel, both the activation and inactivation gates are shown (*i*, current; Na, sodium; Ca, calcium; K, potassium).

from the cell is decreased, leading to an *increase* in cytosolic calcium (and a consequent increase in contractility). This explains an observation made some years ago that hyponatremia can lead to an *increase* in cardiac contractility. If the intracellular sodium concentration increases, as occurs with ischemia, the gradient for sodium influx is reduced, and the pump slows down or actually reverses, extruding sodium in exchange for an influx (and accumulation) of calcium. This mechanism has been suggested to be central to the accumulation of calcium during ischemia. The sodium-calcium exchange mechanism has a maximum exchange rate that is some 30 times higher than the sarcolemmal ATP-dependent calcium pump described earlier and is likely the primary mechanism for removal of excess cytosolic calcium.[9]

The *sodium-hydrogen exchange pump* extrudes one intracellular hydrogen ion in exchange for one extracellular sodium ion and therefore is electrically neutral. This pump prevents intracellular acidification. Acidification (e.g., during ischemia) increases the affinity of the pump for H^+, promoting the removal of H^+ and preserving intracellular pH at the expense of sodium accumulation. The accumulation of sodium ions then may trigger reversal of the sodium-calcium exchange pump to favor the accumulation of calcium within the cell. This is a purported mechanism underlying injury or cell death during ischemia-reperfusion.

Intracellular Communication Pathways

To allow concurrent activation of all the myofibrils in the muscle cell, the electrical activation signal must be spread rapidly and evenly through all portions of the cell. This is accomplished through the transverse tubules (t-tubules) and the subsarcolemmal cistern and sarcotubular network of the sarcoplasmic reticulum.

T-tubules

The basic contractile unit in a muscle cell is the sarcomere. Sarcomeres are joined together in the myofibril at the z-lines. A system of *transverse tubules* (t-tubules) extends the sarcolemma into the interior of the cardiac cell (Fig. 3-4). These tubules generally are perpendicular to the sarcomere near the z-lines, thus extending the extracellular space into the cell close to the contractile proteins. The t-tubules contain the calcium channels described earlier, which are in close relationship to the *foot proteins* of the *subsarcolemmal cisternae.*

Sarcoplasmic reticulum

The *sarcoplasmic reticulum* is a membrane network within the cytoplasm of the cell surrounding the myofibrils. The primary function of the sarcoplasmic reticulum is *excitation-contraction coupling* by sudden release of calcium to stimulate the contraction proteins and then rapid removal of this calcium to allow relaxation of the contractile elements. The *subsarcolemmal cisternae* and the *sarcotubular network* are the two portions of the sarcoplasmic reticulum that mediate this process.

The *subsarcolemmal cisternae* are beneath the sarcolemma and surround the t-tubules. Specialized bulky proteins are found in the membrane of the sarcoplasmic reticulum

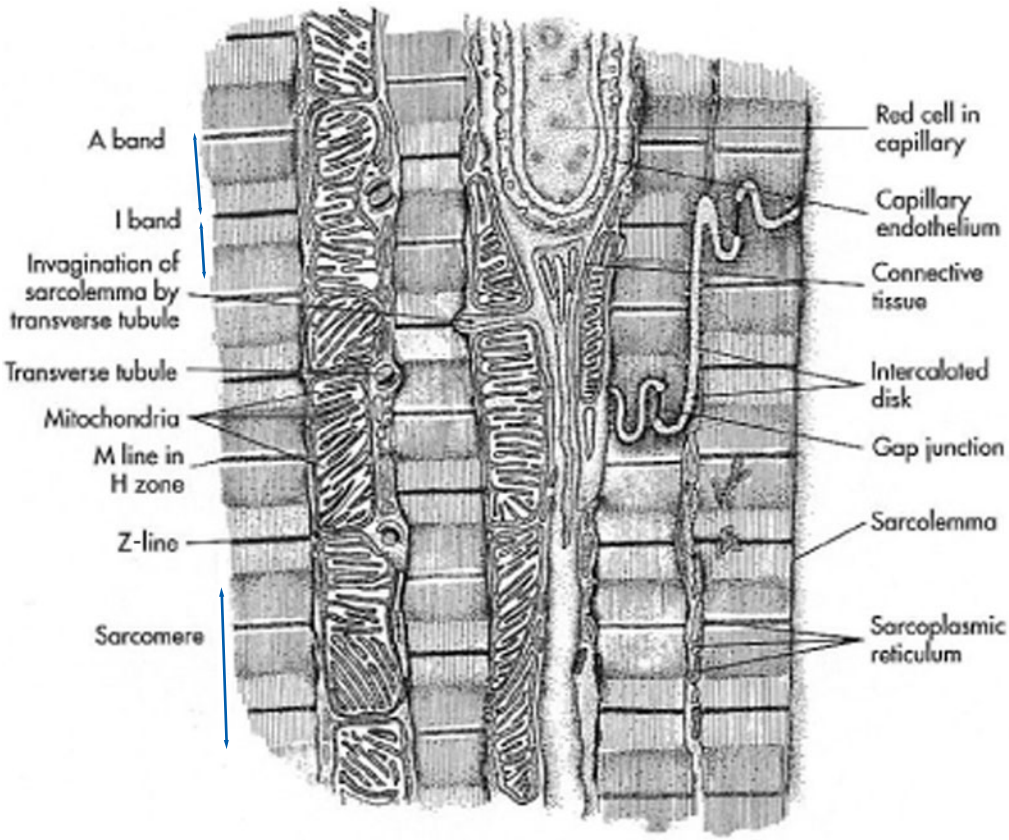

Figure 3-4. Myocyte anatomy. *(From Levy MN: The cardiac pump, in Berne RM, Levy MN, Koeppen BM, Stanton BA, eds: Physiology. St Louis, Mosby, 2004; p 307.)*

with a large protein component extending into the gap between the subsarcolemmal cisternae and the sarcolemma of the t-tubule. These *foot proteins* respond to the release of calcium by the sarcolemma (or t-tubule) by rapid opening of a calcium channel (actually a part of the foot protein), which allows release of a much larger quantity of calcium from the subsarcolemmal cisternae. This is *calcium-triggered calcium release,* with calcium transported across the sarcolemma leading to calcium release from the subsarcolemmal cisternae. The magnitude of calcium release from the subsarcolemmal cisternae appears to be related to the magnitude of the trigger. The calcium channels then close, and the calcium is returned to the sarcoplasmic reticulum by an ATP-dependent calcium pump located primarily in the *sarcotubular network.*[1,2,14] The *sarcotubular network* is the portion of the sarcoplasmic reticulum that surrounds the contractile elements of the sarcomere.

Regulation of calcium transport by the cardiac sarcoplasmic reticulum occurs primarily at the site of the calcium pump. *Phospholamban,* a cytosolic protein, inhibits the basal rate of calcium transport by this calcium pump. This inhibition can be reversed when phospholamban is phosphorylated by a cyclic AMP–dependent or a calcium-calmodulin-dependent protein kinase. This effect appears to be a very important mechanism by which beta-adrenergic stimulation regulates the heart; increased levels of cytosolic cyclic AMP are a consequence of activation of the beta-catecholamine receptor. As phospholamban is phosphorylated, there is accelerated calcium turnover and increased sensitivity of the calcium pump, which facilitates uptake of calcium from the cytosol and relaxation of the heart when the heart comes under the influence of beta-adrenergic agonists. Phosphorylation of phospholamban does not affect the sarcolemmal calcium pump, thereby tending to favor retention of calcium within the cell (increasing the calcium content of the sarcoplasmic reticulum at the expense of calcium removed from the cell through the sarcolemma). This might lead to an increased pulse of calcium within the cell, thereby favoring increased contractility.[9,14]

In this ionic milieu, the importance of maintenance of intracellular pH should be stressed. Regulation of intracellular pH is complex and beyond the scope of this text, but a few simple principles are important to review. Reduced intracellular pH diminishes the amount of calcium released from the sarcoplasmic reticulum and reduces the responsiveness of myofilaments to calcium. Elevation of the pH will have the opposite effect. The clinical relevance of this observation cannot be overstressed.

ELECTRICAL ACTIVATION OF THE HEART

Normal Cardiac Rhythm

The resting membrane potential

The resting state of the cardiac cell is determined by a balance of forces: electrical (based on polarity differences) and chemical (based on gradients across the sarcolemma). At rest

(during diastole), the cardiac cell is polarized. An electrical transmembrane potential across the sarcolemma exists determined primarily by the concentration gradient of potassium across the membrane. This gradient is established by the sodium-potassium pump. However, once this pump shuts off, the steady state is determined by the balance of electrical and chemical forces. As described earlier, the sarcolemma is impermeable to some ions, permeable to others, and selectively permeable to others. Steady-state properties of a mixture of ions of variable permeablities across a membrane are described by the *Gibbs-Donnan equilibrium.*[15] The sarcolemma prevents the diffusion of large anions (e.g., proteins and organic phosphates). At rest, the sarcolemma is relatively permeable to potassium ions owing to the open state of most potassium channels but less permeable to sodium. The concentration gradient established by the sodium-potassium pump promotes the efflux of potassium ions across the sarcolemma. The outward flow of positive ions is counterbalanced by the increasing electronegativity of the interior of the cell owing to the impermeant anions. A Gibbs-Donnan equilibrium is established such that the electronegativity of the cell interior retards potassium ion efflux to the same degree that the concentration gradient favors K^+ efflux. At equilibrium, the forces balance with an intracellular potassium concentration of 135 mM and an extracellular concentration of 4 mM and a predicted resting membrane potential of –94 mV. The actual resting membrane potential is measured at about –90 mV owing to smaller contributions from the current of other less permeable ions (e.g., sodium and calcium). However, the potassium current is the main determinant of the resting membrane potential.[16]

The action potential

The action potential represents the triggered response to a stimulus derived either internally (slow depolarizing ionic currents) or externally (depolarization of adjacent cells). A typical *fast-response* action potential that occurs in atrial and ventricular myocytes and special conduction fibers is depicted in Fig. 3-3. As the transmembrane potential decreases to approximately –65 mV, the "fast" sodium channels open. These channels remain open for a few milliseconds until the inactivation gate of the fast sodium channel closes. The large gradient of sodium ions (extracellular 145 mM, intracellular 10 mM) promotes rapid influx, depolarizing the cell to a slightly positive transmembrane potential. This is *phase 0* of the action potential. A transient potassium current (i_{to}) causes a very early repolarization (*phase 1*) of the action potential, but this fast channel closes quickly. The plateau of the action potential (*phase 2*) is sustained at a neutral or slightly positive level by an inward-flowing calcium current, first from the transient calcium channel and second through the long-lasting calcium channel. The plateau also is sustained by a decrease in the outward potassium current (i_{k1}). With time, the long-lasting calcium channel begins to close, and the repolarizing potassium current (i_k, the delayed rectifier current) leads to the initiation of *phase 3* of the action potential. As repolarization progresses, the stronger first potassium current (i_{k1}) dominates, leading to full repolarization of the membrane to the resting negative potential. During the bulk of the depolarized interval (*phase 4*), the first potassium current predominates in myocytes. Because the sodium channels cannot respond to a second wave of depolarization until the inactivation gates are reopened (by repolarization during phase 3), the membrane is *refractory* to the propagation of a second impulse during this time interval, referred to as the *absolute refractory period.* As the membrane is repolarized during early phase 3 of the action potential, and some of the sodium channels have been reactivated, a short interval exists during which only very strong impulses can activate the cell, which is termed the *relative refractory period.* A drug that acts to speed up the kinetics of the inactivation gate will shorten both the absolute and the relative refractory periods.[1,2,17–19]

Spontaneous depolarization

The action potential of the *slow-response* cells of the nodal tissue [*sinoatrial node* (SA node) and *atrioventricular node* (AV node)] differs from that in the fast-response cells, as shown in Fig. 3-5. The rapid upstroke of *phase 0* is less prominent owing to the absence of fast Na^+ channels. *Phase 1* is absent because there is no rapid inward potassium current. In addition, the plateau phase (*phase 2*) is abbreviated because of the lack of a sustained active Na^+ inward current and the lack of a sustained calcium current. The repolarization phase (*phase 3*) leads to a resting phase (*phase 4*) that begins to depolarize again, as opposed to the relatively stable resting membrane potential of myocytes. The slowly depolarizing phase 4 resting potential is called the *diastolic depolarization current* or the *pacemaker potential.* Continued depolarization of the membrane potential ultimately reduces it to the threshold potential that stimulates another action potential. This diastolic depolarization potential is the mechanism of *automaticity* in cardiac pacemaker cells. Diastolic depolarization is due to the concerted and net actions of (1) a decrease in the outward K^+ current during early diastole (phase 4), (2) persistence of the slow inward Ca^{2+} current, and (3) an increasing inward Na^+ current during diastole. The inward Na^+ current most likely predominates in nodal and conduction tissue. The slope of the diastolic depolarization determines the rate of action potential generation in the pacemaker cells and is the primary mechanism determining heart rate. Of all the cardiac cells, the slope of the diastolic potential is greatest (faster rate of depolarization) in the SA node, and action potentials are generated at a rate of 70 to 80 per minute. The AV node has a slower rate of depolarization, with a frequency of action potential generation of 40 to 60 times per minute. The ventricular myocytes have the slowest rate of depolarization, with a frequency of 30 to 40 times per minute. Once a depolarization is initiated in a pacemaker cell and propagated, it will depolarize the remainder of the heart in a synchronized and sequential manner. If a pacemaker site drops out owing to pathology or drug-induced slowing of the diastolic potential, the next pacemaker site

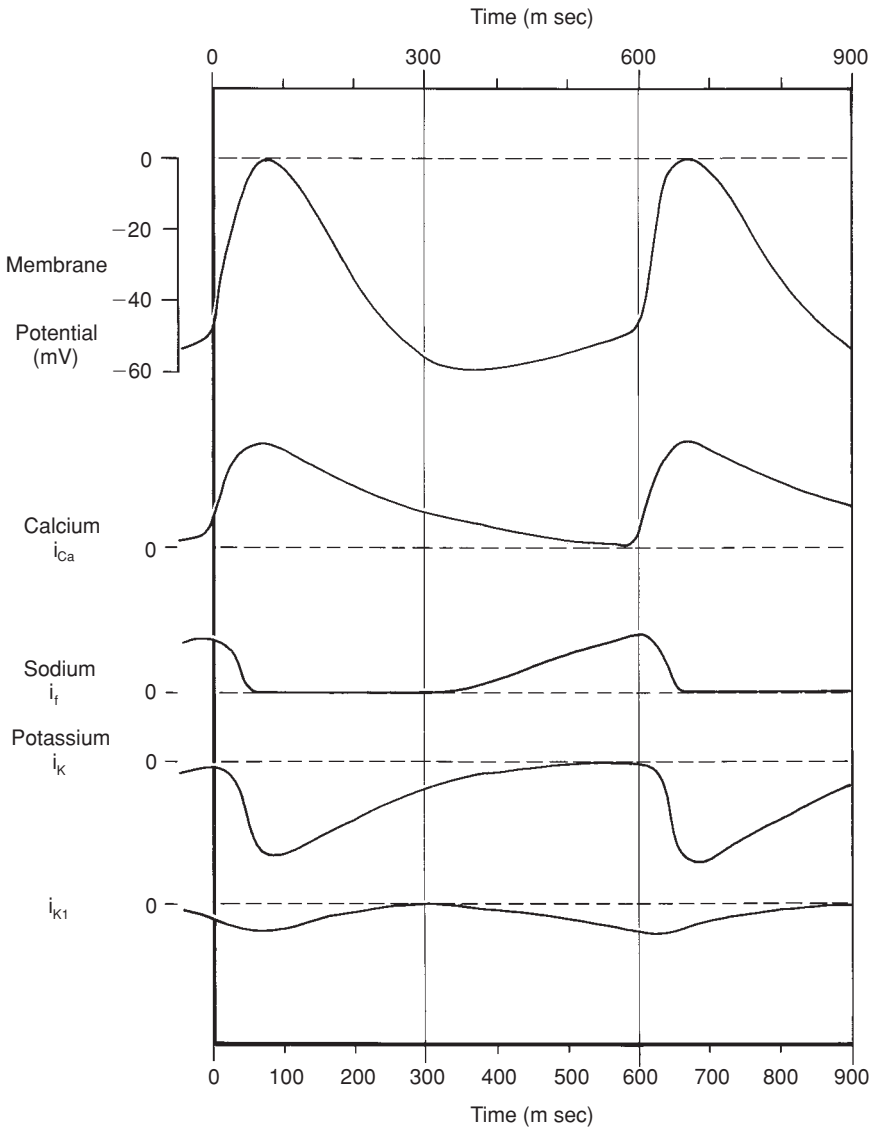

Figure 3-5. The membrane potential of a spontaneously depolarizing cell of the sinoatrial node and the ion currents contributing to it. Inward (depolarizing) currents are depicted as positive, and outward (repolarizing) currents are depicted as negative (*i,* current; Na, sodium; Ca, calcium; K, potassium).

in line will take over, with a heart rate typical for that site. The heart rate can be altered by changing slope of the diastolic depolarization (e.g., acetylcholine decreases the slope and heart rate; beta-adrenergic agonists increase the slope and heart rate). If the slope is unchanged, hyperpolarization (more negative resting potential) or raising the threshold potential will increase the time to reach threshold, resulting in a decrease in heart rate.

Propagation of the action potential

Each myocyte is electrically connected to the next myocyte by an *intercalated disk* at the end of the cell. These disks contain *gap junctions* that facilitate the flow of charged molecules from one cell to the next. These pores in the intercalated disks are composed of a protein, *connexin.* Permeability through the cardiac gap junction is increased by both ATP- and cyclic AMP–dependent kinases. This allows the gap junctions to close if ATP levels fall, thereby reducing electrical and presumably mechanical activity, which is essential in limiting cell death when one region of the heart is damaged. It also allows conduction to increase when cyclic AMP increases in response to adrenergic stimulation.

After spontaneous depolarization occurs in the pacemaker cells of the SA node, the action potential is conducted throughout the heart. Special electrical pathways facilitate this conduction. Three internodal paths exist through the atrium between the SA node and the AV node. After traversing the AV node, the action potential is propagated rapidly through the *bundle of His* and into the *Purkinje fibers* located on the endocardium of the left and right ventricles. Rapid conduction through the atrium causes contraction of most of the atrial muscle synchronously (within 60 to 90 ms). Similarly, the rapid conduction of the signal throughout the ventricle leads to synchronous contraction of the bulk of the ventricular myocardium (within 60 ms). The delay of the propagation of the action potential through the AV node by 120 to 140 ms allows the atria to complete contraction before the ventricles contract. Slow conduction in the AV node is related to a relatively higher internal resistance because of a small number of gap junctions between cells and to slowly

rising action potentials. The nodal delay allows the atrium to pump an aliquot of blood (up to 10% of left ventricular volume) into the ventricle just prior to ventricular contraction, thereby optimizing preload of the ventricle.

Abnormal Cardiac Rhythm

Aberrant pacemaker foci

Many cardiac cells manifest an intrinsic rhythm from spontaneous depolarization. Normally, the SA node spontaneously depolarizes first such that the cardiac beat originates from this primary acemaker site. If the SA node is damaged or slowed by vagal timulation or drugs (e.g., acetylcholine), pacemakers in the AV node or the His-Purkinje system can take over. Occasionally, aberrant foci in the heart depolarize spontaneously, thereby leading to insertion of aberrant beats from either the atrium or the ventricle (noted as premature atrial or ventricular contractions). These beats ordinarily do not interfere with normal depolarization of the heart and have very little tendency to degenerate into disorganized electrical activity.

Reentry arrhythmias

Reentry arrhythmias are perhaps the most common dangerous cardiac rhythm. Under ordinary circumstances, the action potential depolarizes the entire atrium or the entire ventricle in a short enough time interval so that all the muscle is *refractory* to further stimulation at the same time. A reentry arrhythmia is caused by propagation of an action potential through the heart in a "circus" movement. For reentry to occur, there must be a unidirectional block (transient or permanent) to action potential propagation. Additionally, the effective refractory period of the reentered region must be shorter than the propagation time around the loop.[16] For example, if a portion of the previously depolarized myocardium has repolarized before propagation of the action potential is completed throughout the atrium or ventricle, then that action potential can continue its propagation into this repolarized muscle. Such an event generally requires either dramatic slowing of conduction of the action potential, a long conduction pathway, or a shortened refractory period (Fig. 3-6). All these situations occur clinically. Ischemia leads to slowing of the sodium-potassium pump, which leads to a decreased resting membrane potential and *slowing* of propagation of the action potential. Hyperkalemia leads to an increase in the extracellular potassium level, a decrease in the resting membrane potential, and a *slowing* of propagation of the action potential. Progressive atrial dilation creates a *long conduction pathway* around the atrium that can allow a reentry arrhythmia. Adrenergic stimulation leads to a shortened refractory period, which increases the likelihood of a reentry arrhythmia.

A special type of reentry arrhythmia occurs in the Wolff-Parkinson-White (WPW) syndrome in which an *accessory pathway* connects the atrium and the ventricle electrically. This accessory pathway can complete a circular electrical pathway between the atrium and the ventricle: Conduction is unidirectional across the AV node, and the accessory pathway creates a loop that has a propagation time that is greater than the AV node refractory period, resulting in a supraventricular tachycardia. The accessory pathway of the WPW syndrome is dangerous in another way. Because it does not have the inherent delay and refractory period of the AV node, rapid atrial tachycardias can be conducted in a 1:1 manner across the accessory pathway, leading to ventricular rates as fast as 300 beats per minute.

Afterpotentials or parasystole

Most ventricular tachyarrhythmias are reentry arrhythmias. The primary exception to this rule is *parasystole* or

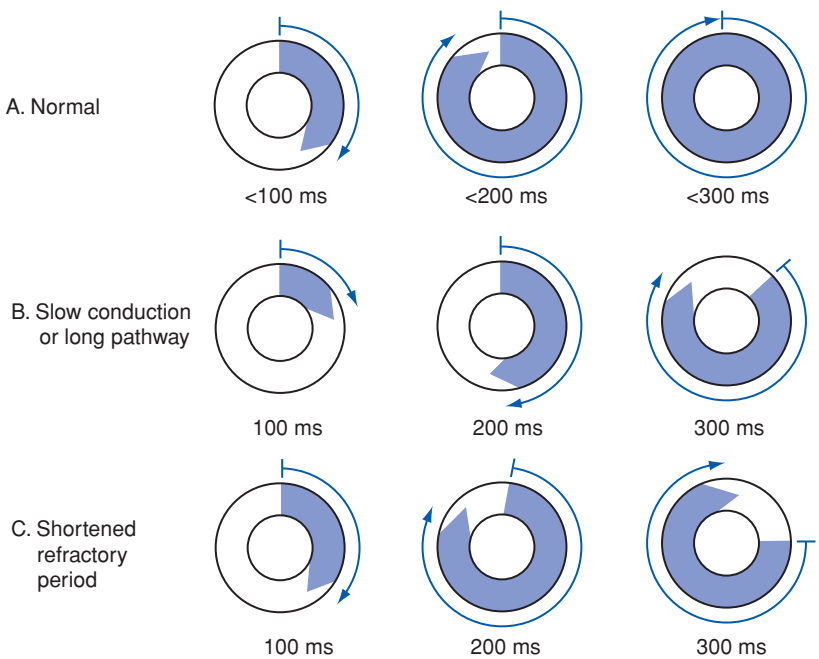

Figure 3-6. Three conditions predisposing to reentry or "circus" pathways for action potential propagation are shown. Muscle that is refractory to action potential propagation is shown as black. Normally, as the action potential travels through the atrium or ventricle, all the muscle is depolarized sufficiently that the action potential encounters no more nonrefractory muscle and stops (*A*). If there is slowed conduction speed or a long pathway (*B*), the action potential may find repolarized (nonrefractory) muscle and continue in a circular path. Similarly, a shortened refractory period (*C*) may lead to rapid repolarization and predispose to a reentry and continuation of the action potential.

afterpotentials. Normally, ventricular action potentials have a flat phase 4 during diastole without spontaneous depolarization. If, however, they have elevated levels of cytosolic calcium, there may be a transient diastolic inward (depolarizing) current, probably related to activity of the sodium-calcium exchange pump. Afterpotentials are thought to underlie the development of ventricular automaticity during digitalis toxicity. The afterdepolarizations associated with digitalis toxicity appear to be *delayed* afterdepolarizations. Another type of afterdepolarization is an *early* afterdepolarization, which occurs *before* the end of complete repolarization. This early afterdepolarization appears to be the mechanism for the ventricular tachycardia called *torsades de pointes,* in which varying QRS complexes appear. A prolongation of the QT interval and the varying QRS complexes in torsades de pointes indicate heterogeneity of the action potential duration within the ventricle, thereby predisposing to ventricular fibrillation.[18]

REGULATION OF CELLULAR FUNCTION BY SARCOLEMMAL RECEPTORS

Parasympathetic Regulation

The parasympathetic nervous system is particularly important in control of the pacemaker cells of the SA node. Acetylcholine released by the nerve endings of the parasympathetic system stimulates *muscarinic receptors* in the heart. These activated receptors, in turn, produce an intracellular stimulatory G-protein that opens *acetylcholine-gated potassium channels.* An increased outward (repolarizing) flow of potassium leads to *hyperpolarization* of the SA node cells. Stimulation of the muscarinic receptors also inhibits the formation of cyclic AMP; decreased cyclic AMP levels inhibit the opening of calcium channels. A decreased inward flow of calcium, combined with an increased outward flow of potassium, leads to a sometimes dramatic slowing of spontaneous diastolic depolarization of the sinoatrial nodal cell (Fig. 3-5). A similar effect in the AV node leads to slowing of conduction through the AV node.[1]

Adrenergic Stimulation and Blockade

Adrenergic receptors affect heart rate, contractility, conduction velocity, and automaticity in cardiac cells and smooth muscle contraction and relaxation in the vasculature. Alpha-adrenergic receptors cause vasoconstriction. There are two types of beta-adrenergic receptors: the $beta_1$-adrenergic receptors, which predominate in the heart, and the $beta_2$-adrenergic receptors, which are present in blood vessels and promote relaxation. The number of beta receptors per unit area (*receptor density*) of the sarcolemma can increase (*upregulation*) or decrease (*downregulation*) in response to various stimuli. Receptor sensitivity also can change depending on ambient conditions and variable stimuli.[20] Cardiopulmonary bypass and ischemia cause downregulation of cardiac beta receptors. Acidemia causes desensitization of beta receptors. This is particularly important in the perioperative period, when acidemia can reduce cardiac contractility, systemic vascular tone, and the response to inotropic agents significantly.

The beta-adrenergic receptor couples with *adenyl cyclase* (Fig. 3-7). When the receptor site is occupied by a catecholamine, a *stimulatory G-protein* is formed that combines with GTP. This activated G-protein–GTP complex then promotes the activity of adenyl cyclase, leading to the formation of *cyclic AMP* from ATP. The G-protein–GTP complex and the cyclic AMP actively promote calcium channel opening. The increased tendency for calcium channels to open during beta-receptor stimulation increases cytosolic calcium and leads to a number of electrophysiologic effects: (1) a positive *chronotropic* (heart rate) effect whereby the heart rate, conduction, and contraction velocity increase and the action potential is shortened leading to a shortening of systole, (2) a positive *dromotropic* (conduction velocity) effect of *accelerated conduction* through the AV node, (3) a positive *inotropic*

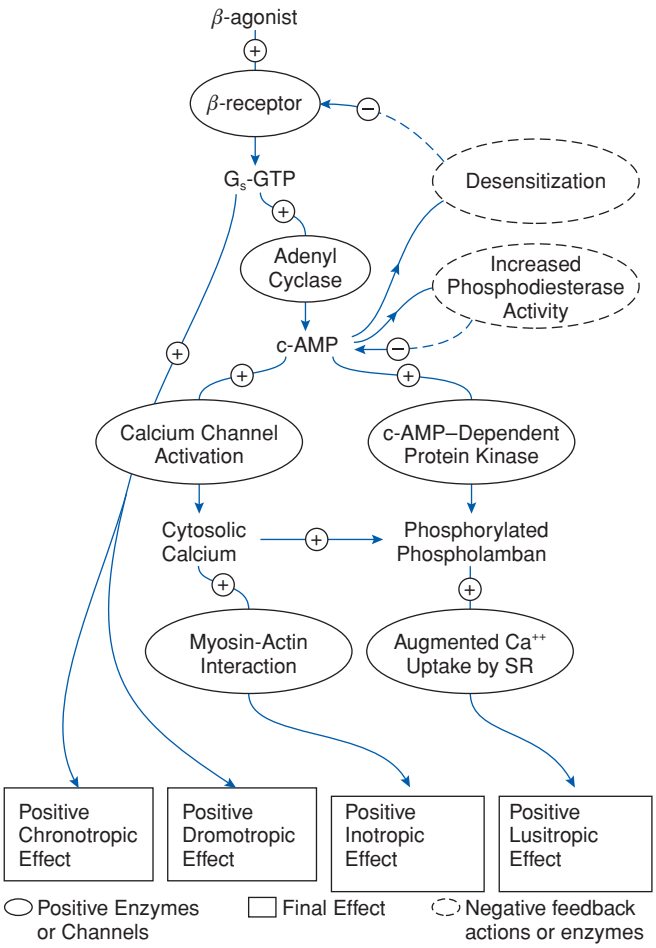

Figure 3-7. Adrenergic stimulation via the action of beta agonists on beta receptors leads to a cascade of events in the myocyte, some of which are shown here. Note that an increase in cAMP causes the activation of two inhibitory pathways, retarding excessively sustained adrenergic stimulation (Gs, stimulatory G-protein; GTP, guanosine triphosphate; SR, sarcoplasmic reticulum; cAMP, cyclic adenosine monophosphate).

(contractility) effect, and (4) increased activity of the sarcoplasmic reticulum calcium pump (more rapid calcium uptake) leading to more rapid relaxation, which facilitates ventricular filling, a positive *lusitropic* (relaxation) effect.[21,22]

Two negative-feedback systems diminish the response to beta agonists when stimulation is repetitive or persistent (tachyphylaxis): Increased cyclic AMP leads to (1) increased phosphorylation of beta receptors, resulting in downregulation, and to (2) increased activity of *phosphodiesterase,* the enzyme that degrades cyclic AMP.

The activity spectrum of adrenergic receptors forms the basis of many therapeutic interventions: perioperatively to support cardiac function and chronically to reduce mortality from myocardial infarction and to treat congestive heart failure. The selectivity of the agonists allows adaptation for various clinical scenarios. $Beta_1$-selective agonists and antagonists are considered *cardioselective.* Some examples are detailed in Table 3-1.

The reduction in inotropy, lusitropy, chronotropy, and dromotropy by beta blockade will reduce myocardial oxygen consumption, contributing to many of its beneficial effects. Since beta blockade will lead to upregulation of sarcolemmal receptors, sudden cessation of beta blockade may cause a temporarily enhanced (and potentially dangerous) sensitivity to adrenergic stimulation.

Phosphodiesterase Inhibition

As discussed previously, cyclic AMP plays a central role in regulation of the cardiac cell. Cytosolic levels of cyclic AMP are increased by activation of receptors other than beta receptors (i.e., for histamine, dopamine, and glucagon) and are decreased by inhibitory G-proteins produced by stimulation of muscarinic receptors by acetylcholine and by stimulation of adenosine receptors. Referring again to Fig. 3-7, one negative-feedback response to the increase in cyclic AMP is an increase in phosphodiesterase, which breaks down cyclic AMP. *Phosphodiesterase inhibitors* (e.g., amrinone and milrinone) inhibit the breakdown of cyclic AMP and thereby increase its level in the cytosol. Their effect is synergistic to that of beta agonists. Since they do not stimulate the production of G-protein–GTP complex, they have a lesser effect on calcium channel activation and therefore fewer of the troublesome positive chronotropic and dromotropic effects of beta-adrenergic stimulation.[22,23]

Adenosine Receptors

There are four types of adenosine receptors. Adenosine receptors are linked to inhibitory and stimulatory G-proteins and various kinases. Activation of adenosine A_1 receptors leads to inhibition of the slow calcium channel and opening of an adenosine-activated ATP-sensitive potassium (K_{ATP}) channel. This leads to hyperpolarization, which delays conduction through the AV node and slows the ventricular response to atrial tachycardia.[1,24] Pretreatment with adenosine (also via A_1-receptor activation) confers a cardioprotective effect during ischemia and can inhibit the inflammatory responses initiated by ischemia and reperfusion.[24]

Table 3–1.

Adrenergic Agonists and Antagonists Correlating Selective Activity with Clinical Usage

	Drug	Alpha	$Beta_1$	$Beta_2$	Clinical usage
Agonists	Epinephrine	Y	Y	Y	Low cardiac output, hypotension
	Norepinephrine	Y	Y		Hypotension
	Phenylephrine	Y			Hypotension
	Dobutamine		Y		Low cardiac output
	Dopamine	Y	Y		Low cardiac output, hypotension
	Isoproterenol		Y	Y	Bradycardia, low cardiac output, pulmonary hypertension
Antagonists (beta blockers)	Metoprolol		Y		Tachycardia, hypertension, MI, angina
	Atenolol		Y		Tachycardia, hypertension, MI, angina
	Esmolol		Y		Tachycardia, hypertension, MI, angina
	Carvedilol	Y ($alpha_1$)	Y	Y	Congestive heart failure

CONTRACTION OF CARDIAC MUSCLE

Molecular Level (The Sarcomere)

The primary contractile unit of all muscle cells is the *sarcomere* (Fig. 3-4). Sarcomeres are connected end to end at the *z-line* to form *myofibrils.* The myocyte contains numerous myofibrils arranged in parallel. A portion of a sarcomere is depicted schematically in Fig. 3-8. *Actin* polymerizes to form the *thin filaments* that are anchored at the z-line. *Myosin* polymerizes to form the *thick filaments* of the sarcomere. Myosin consists of a tail of two "heavy" chains intertwined to form a helix, constituting the rigid backbone of the thick filament. The globular head of myosin is attached to the heavy-chain backbone by a mobile hinge and projects outward. The globular myosin head is an ATPase with a binding sight for actin. Actin monomers polymerize into a double-helical filament with a groove running the length of the filament. Actin binds to the myosin globular head, activating the myosin ATPase to hydrolyze ATP. This leads to a conformational change in the myosin that pulls the filament (Fig. 3-8*B*).

Two proteins modulate the interaction of actin and myosin: *troponin* and *tropomyosin.* Troponin ("T" in Fig. 3-8*A*) is a heterotrimer composed of three units: *Tn-C,* a calcium-binding unit; *Tn-T,* which binds tropomyosin; and *Tn-I,* which facilitates interruption of actin-myosin interaction by tropomyosin. Associated with each troponin complex is tropomyosin, a filamentous protein composed of two tightly coiled helical peptide chains that lies in the groove formed by the two intertwined filaments of actin. The binding of calcium to troponin C removes the troponin I–induced masking of the myosin-binding site on actin, thereby allowing cross-bridge formation between actin and myosin.

During diastole, Ca^{2+} is unavailable to bind troponin C, and the myosin-binding site on actin is blocked. Depolarization of the sarcolemmal membrane and t-tubules leads to an influx of calcium ions. The influx of Ca^{2+} and the subsequent "calcium-triggered, calcium release" from the sarcoplasmic reticulum increase the intracellular Ca^{2+} calcium levels by approximately two orders of magnitude (from 10^{-7} M in diastole to 10^{-5} M in systole). This provides sufficient calcium to bind to troponin C, which causes a conformational change in the troponin molecule, removing the inhibitory effect of troponin I and allowing actin-myosin cross-bridge formation (Fig. 3-8*A*). Cross-bridge formation activates the myosin ATPase and initiates the conformational change in the myosin

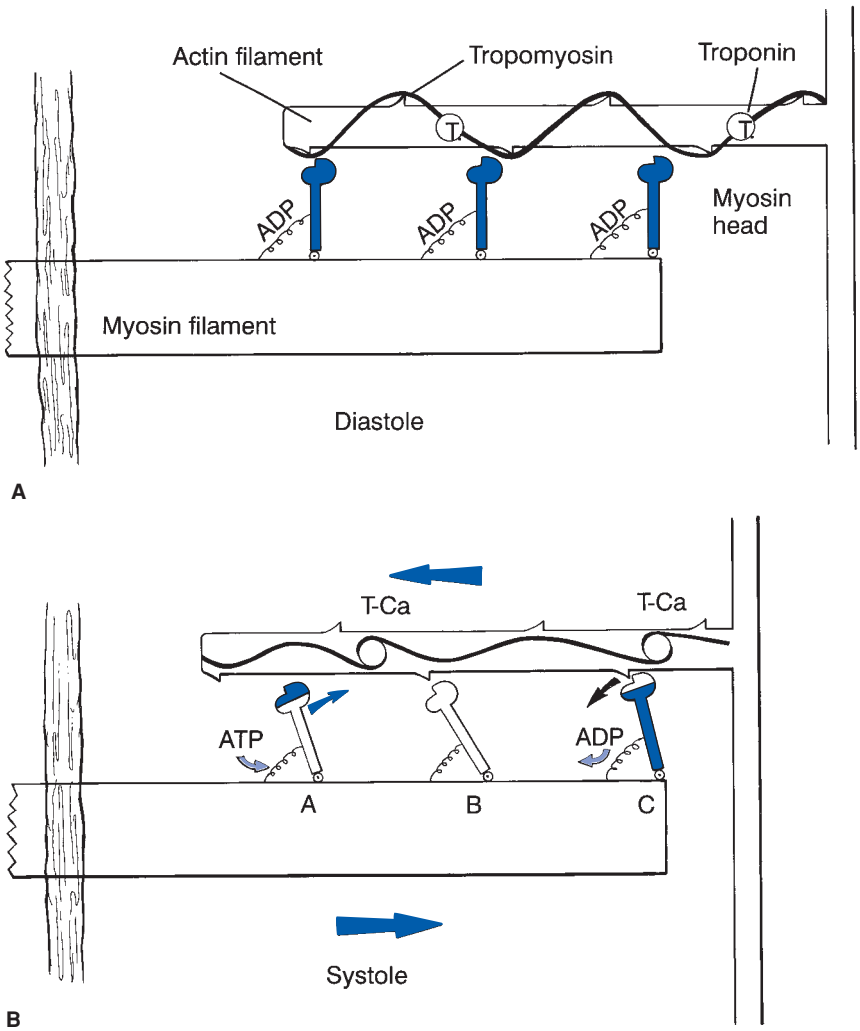

Figure 3-8. The interaction of actin and myosin filaments converts chemical energy into mechanical movement. In diastole, the active sites on the actin filament are covered by tropomyosin. When calcium combines with troponin, the tropomyosin is pulled away from the actin active sites, allowing the energized myosin heads (depicted in solid black and cocked at right angles to the filament) to engage and sweep the actin filament along. The myosin heads are deenergized in this process. Myosin ATPase recocks (reenergizes) the head by using the energy derived from the hydrolysis of ATP. In systole, a deenergizing head (*C*), a deenergized head (*B*), and a reenergizing head (*A*) are shown.

"hinge," drawing the z-lines closer together (Fig. 3-8*B*). ADP and P_i are released, and the myosin head dissociates from the actin. ATP associates with the myosin head, realigning the myosin globular head, preparing it to repeat the process. This process cycles until the end of muscular contraction is signaled by the reduction in intracellular calcium levels by sequestration into the sarcoplasmic reticulum. This is accomplished by sarcoplasmic endoplasmic reticulum calcium ATPase (SERCA) and other energy-dependent pump systems.

The strength of the myocardial contraction is mediated primarily by the degree to which actin-binding sites are exposed. This depends on the affinity of troponin for calcium and the availability of calcium ions. The initial calcium ion influx is altered by cyclic AMP, stimulatory and inhibitory G-proteins, and acetylcholine. The magnitude of the calcium trigger determines the magnitude of the cytosolic calcium release from the sarcoplasmic reticulum. The rate of uptake of calcium from the cytosol is altered by cyclic AMP (Fig. 3-7). Cyclic AMP can phosphorylate a portion of the troponin molecule, facilitating the rapid release of calcium and increasing the rate of relaxation of the actin-myosin complex.[9,25]

Regulation of the Strength of Contraction by Initial Sarcomere Length

In cardiac muscle, the strength of contraction is related to resting sarcomere length (see also "The Frank-Starling Relationship" below). Maximal contraction force occurs when the resting sarcomere length is between 2 and 2.4 μm.[26] At this length, there is optimal overlap of the actin and myosin, maximizing the number of actin-myosin cross-bridges. Force declines at a greater sarcomere length, with decreased overlap of actin and myosin. In the heart, a decrease in contractility related to decreased overlap of the filaments does not seem to occur clinically because the resting length of the cardiac sarcomere rarely exceeds 2.2 to 2.4 μm. Once this length is reached, a stiff parallel elastic element prevents further dilation. If chamber dilation does occur, it appears to be primarily through *slippage* of fibers or myofibers rather than stretching of sarcomeres.[1] Stretching the myocardium increases contractility by increasing the sensitivity of troponin C to calcium. This length-dependent sensitivity to calcium is an important part of the ascending limb of the Starling curve observed in the intact ventricle.

THE PUMP

Mechanics

Clinically observable physiologic parameters

Cardiac surgeons can assess the function of the heart in a number of ways. Most simply, systemic, pulmonary artery, pulmonary capillary wedge, and central venous pressures can be measured directly. Cardiac output can be estimated using thermodilution or based on oxygen saturation measurements. From these direct measurements, other parameters can be derived—though less accurately because of the cumulative error of the measured parameters inherent in the calculation—such as pulmonary and systemic vascular resistance, ventricular stroke work, etc. Ejection fraction—defined as stroke volume/end-diastolic volume—can be estimated by echocardiography and ventriculography but is subject to change based on loading conditions, heart rate, and degree of contractility. Although useful clinically, these parameters do not measure contractility directly.

The Frank-Starling relationship

Almost a century ago, two physiologists (Frank and Starling) simultaneously developed the concept that, within physiologic limits, the heart will function as a sump pump; the more the heart is filled during diastole, the greater the quantity of blood that will be pumped out of the heart during systole. (This relationship was introduced earlier in the section entitled, "Regulation of the Strength of Contraction by Initial Sarcomere Length.")

Under normal circumstances, the heart pumps all the blood that comes back to it without excessive elevation of venous pressures. In the normal heart, as ventricular filling is increased, the strength of ventricular contraction increases as sarcomeres are stretched. The influence of sarcomere length on the force of contraction is called the *Frank-Starling relationship*. This relationship for the left ventricle is depicted in Fig. 3-9. Also depicted in the figure are two other states, a condition of normal adrenergic stimulation and a condition of maximal adrenergic stimulation. Force is increased for the same diastolic left atrial pressure by adrenergic stimulation; this is a positive inotropic effect.

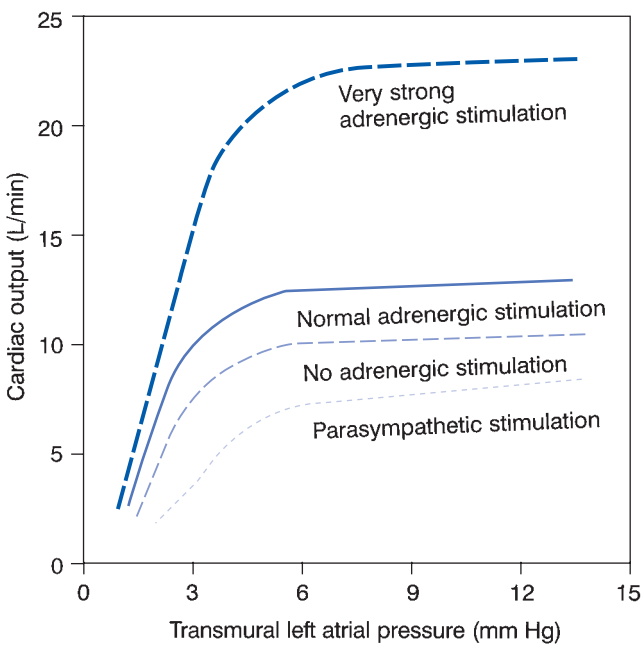

Figure 3-9. Starling curves for the left ventricle. The influence of four different states of neurohumoral stimulation on global ventricular performance is shown.

Preload, diastolic distensibility, and compliance

Preload is the load placed on a resting muscle that stretches it to its functional length. In the heart, preload references the volume of blood in the cavity immediately prior to contraction (at end diastole) because volume determines the degree of stretch imposed on the resting sarcomere. Since volume cannot be assessed easily clinically, pressure is used as a surrogate; thus the concept of preload is represented as the filling pressure of a chamber. The relationship between the end-diastolic pressure and the end-diastolic volume is complex. Several different diastolic pressure-volume relationships are shown in Fig. 3-11 (bold line). As end-diastolic volume increases and the heart stretches, the end-diastolic pressure also increases. The *compliance*, or distensibility, of the ventricle is defined as the change in volume divided by the change in pressure. Conversely, the *stiffness* of the ventricle is the reciprocal of compliance, or the change in pressure divided by the change in volume.

A number of factors affect the diastolic pressure-volume relationship. A fibrotic heart, a hypertrophied heart, or an aging heart becomes increasingly stiff (Fig. 3-11*C* and *E*). In the case of fibrosis, this increasing stiffness is related to the development of a greater collagen network. In the case of hypertrophy, this increased stiffness is related to both stiffening of the noncontractile components of the heart and impaired relaxation of the heart. Relaxation is an active, energy-requiring process. This process is accelerated by catecholamine stimulation but is impaired by ischemia, hypothyroidism, and chronic congestive heart failure. Examination of the diastolic pressure-volume curves in Fig. 3-11 reveals the importance of changes in diastolic distensibility in pathologic cardiac conditions.[27,28]

Afterload: vascular impedance

The *afterload* of an isolated muscle is the tension against which it contracts. In simplest terms, for the heart, the afterload is determined by the pressure against which the ventricle must eject. The greater the afterload, the more mechanical energy must be imparted to the blood mass (potential energy) to begin ejection. In addition to the potential energy imparted to the ejected blood by a change in pressure, the contracting left ventricle generates kinetic energy that overcomes the compliance of the distensible aorta and systemic arterial tree to move the blood into the arterial system. The energy necessary for this flow to occur is relatively small (potential energy >> kinetic energy). *Resistance*, which equals the change in pressure divided by cardiac output, reflects the potential energy imparted to blood. To describe the forces overcome to eject blood from the ventricle accurately, the compliance of the vascular system and kinetic energy imparted also must be considered: the *impedance* of the vascular system (commonly but less accurately referred to as *aortic impedance*). Compliance reflects the capacity of the vascular system to accept the volume of ejected blood. When the vascular system is very compliant, resistance ≈ impedance. As compliance decreases (e.g., with arteriosclerosis), resistance is less than impedance.[29] The interaction of resistance and compliance defines the dicrotic notch marking end systole (ES), closure of the aortic valve, on the aortic pressure tracing (Fig. 3-10).

The cardiac cycle

Multiple parameters of the cardiac cycle are represented in Fig. 3-10. By convention, the cardiac cycle begins at end diastole (ED), just prior to electrical activation of the ventricle. As the heart contracts, intracavitary pressure closes the mitral valve and then increases rapidly until the systemic diastolic pressure is reached (isovolumic contraction) and

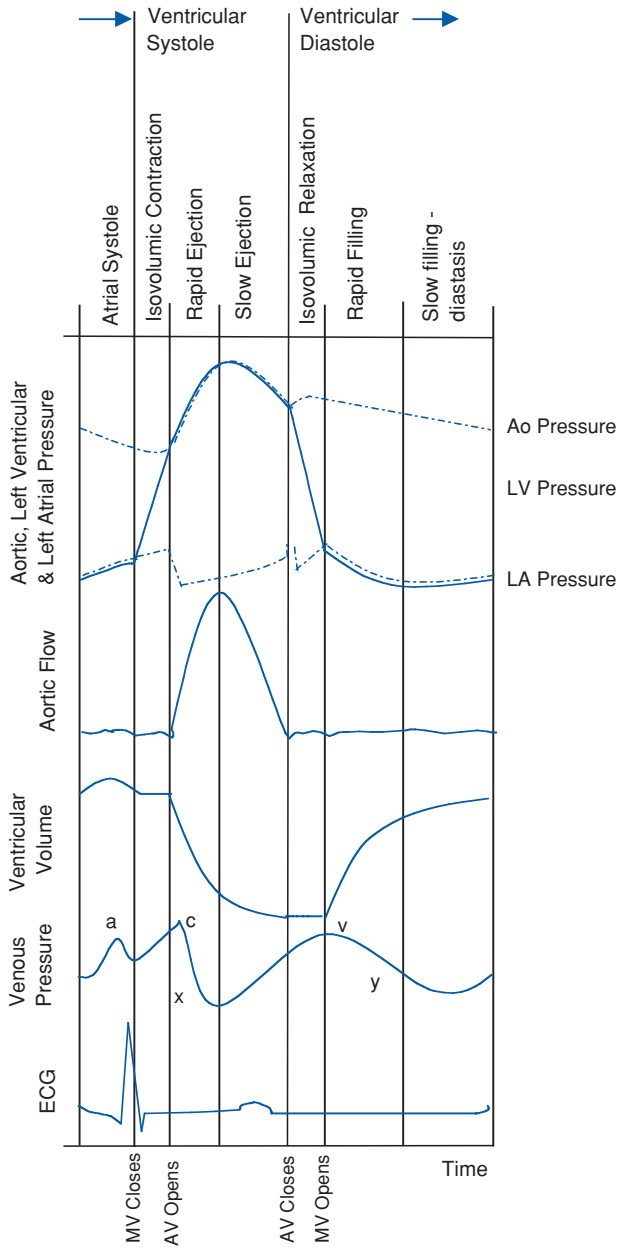

Figure 3-10. Temporal correlation of left atrial and ventricular, aortic, and systemic venous pressures, aortic flow, left ventricular volume, and surface electrocardiogram.

the aortic valve opens. Ejection begins and the intracavitary pressure continues to rise and then fall as the ventricular volume decreases (ejection). When ejection ceases and the aortic valve closes, intracavitary pressure decreases rapidly until the mitral valve opens (isovolumic relaxation). Once the mitral valve opens, the ventricle fills rapidly and then more slowly as the intracavitary pressure slightly increases from distension prior to atrial systole (diastolic filling phase). The completion of atrial systole is the end of ventricular diastole.

A conceptual understanding of the venous pressure changes is important in diagnosing certain pathologic processes. The right atrial pressure is measured easily, and pulmonary capillary wedge pressure is reflective of left atrial pressure. The *a* wave corresponds to atrial systole as pressure increases at ED to complete ventricular filling. The *c* wave reflects pressure pushing the atrioventricular (AV) valve back into the atrium as the ventricular pressure rises and then falls during systole. The *x* descent results from atrial relaxation and downward displacement of the AV valve with ventricular emptying. The *v* wave reflects the increasing atrial pressure from filling before the AV valve opens. The *y* descent is due to rapid emptying of the atrium after the AV valve opens. Characteristic changes in these waveforms are used to diagnose and differentiate constrictive and restrictive processes, as discussed elsewhere in this text. A prominent left atrial *v* wave suggests mitral regurgitation.

Ventricular pressure-volume relationships

The function of the heart can be described and quantified based on the relative intraventricular pressure and volume during the cardiac cycle (Fig. 3-11). Based on this relationship, various measures can be derived to assess cardiac performance (discussed below). The ventricular pressure-volume relationship derives from the Frank-Starling relationship of sarcomere length and peak developed force: The force and extent of contraction (*stroke volume*) is a function of end-diastolic length (*volume*).

ED is represented at the lower right corner of the loop in Fig. 3-11*A*. The pressure-volume loop then successively tracks changes through isovolumic contraction (up to the upper right corner), ejection [left to the upper left corner—which represents ES], isovolumic relaxation (down to the bottom left corner), and then filling (right to the lower right corner). Descriptive data to assess ventricular function are derived from the *end-systolic pressure-volume point* located in the upper left corner of the loop and the *end-diastolic pressure-volume point* located in the lower right corner of the loop. The area within the pressure-volume loop represents the *internal work* of the chamber.

Contractility

The term *contractility* (inotropic state) refers to the intrinsic performance of the ventricle for a given preload, afterload, and heart rate. Although the inotropic state affects cardiac output, it is difficult to quantify in clinically useful terms. For research purposes, the pressure-volume relationship can be used to quantify contractility by deriving the *end-systolic pressure-volume relationship* (ESPVR): Contractility is reflected in the slope (E_{ES}) and volume axis intercept (V_0) of the ESPVR (Fig. 3-12). Holding afterload and heart rate constant, a series of pressure-volume loops is inscribed during transient preload reduction induced by temporary vena caval occlusion; the area of the loops decreases, and the loops are shifted to the left. The progressive pressure-volume points at ES then are linearized to derive the ESPVR. Within a clinical range of systolic pressures (80 to 120 mm Hg), the end-systolic pressure-volume line is largely linear. An increase in inotropic state of the left ventricle is expressed as an increase in E_{ES} and sometimes a decrease in V_0. Conversely, a decrease in inotropic state is expressed as a decrease in E_{ES} and sometimes an increase in V_0 (Fig. 3-12). As the ESPVR describes systolic function, the *end-diastolic pressure volume relationship* (EDPVR; Fig. 3-12) describes ventricular diastolic compliance (specifically, the inverse of the slope of the EDPVR is compliance).

Pressure-volume loops can be used to analyze various physiologic situations. Increased afterload (Fig. 3-11*B*) moves the end-systolic pressure-volume point slightly upward and to the right. If stroke volume is maintained, end-diastolic volume must increase. Thus, although contractility is unchanged, ejection fraction is slightly decreased. Figure 3-11*C* shows the effect of a decrease in ventricular compliance (increased EDPVR) such as may result from hypertrophy, fibrosis, or cardiac tamponade. Systolic function is maintained (E_{ES} and V_0 are unchanged), and stroke volume and ejection fraction can be maintained but require an increased end-diastolic pressure. The positive inotropic (increased E_{ES}) and lusitropic (decreased EDPVR) effects of adrenergic stimulation (Fig. 3-11*D*), at constant stroke volume, shift the pressure-volume loop to the left and increase the ejection fraction. In the hypertrophied heart (Fig. 3-11*E*), in contrast to Fig. 3-11*C*, diastolic compliance is decreased, and systolic contractility is increased. A constant stroke volume leads to an increase in end-diastolic filling pressure and decreased end-diastolic volume. The pressure-volume loop shifts to the left with an increase in ejection fraction. The ability of the hypertrophied heart to increase stroke volume is limited. Acute ischemia (Fig. 3-11*F*) decreases diastolic compliance (increased EDPVR) and contractility. The pressure-volume loop shifts to the right and up to maintain stroke volume, consistent with the clinical observation of an acute decrease in ejection fraction and increase in left ventricular filling pressure. In the dilated heart of chronic congestive heart failure (Figure 3-11*G*), the pressure-volume loop is shifted to the right. Note that the slope of the end-diastolic pressure-volume curve (EDPVR) changes little; rather, the curve shifts to the right. The end-diastolic pressure is not increased owing to a change in compliance; instead, to maintain stroke volume, the pressure-volume loop has moved upward on the compliance curve. Contrast this with the fibrotic process discussed earlier. The effect of afterload reduction on the chronically failing heart from Fig. 3-11*G* is demonstrated in Fig. 3-11*H*. Note that the ESPVR, EDPVR, and stroke volume are unchanged. The

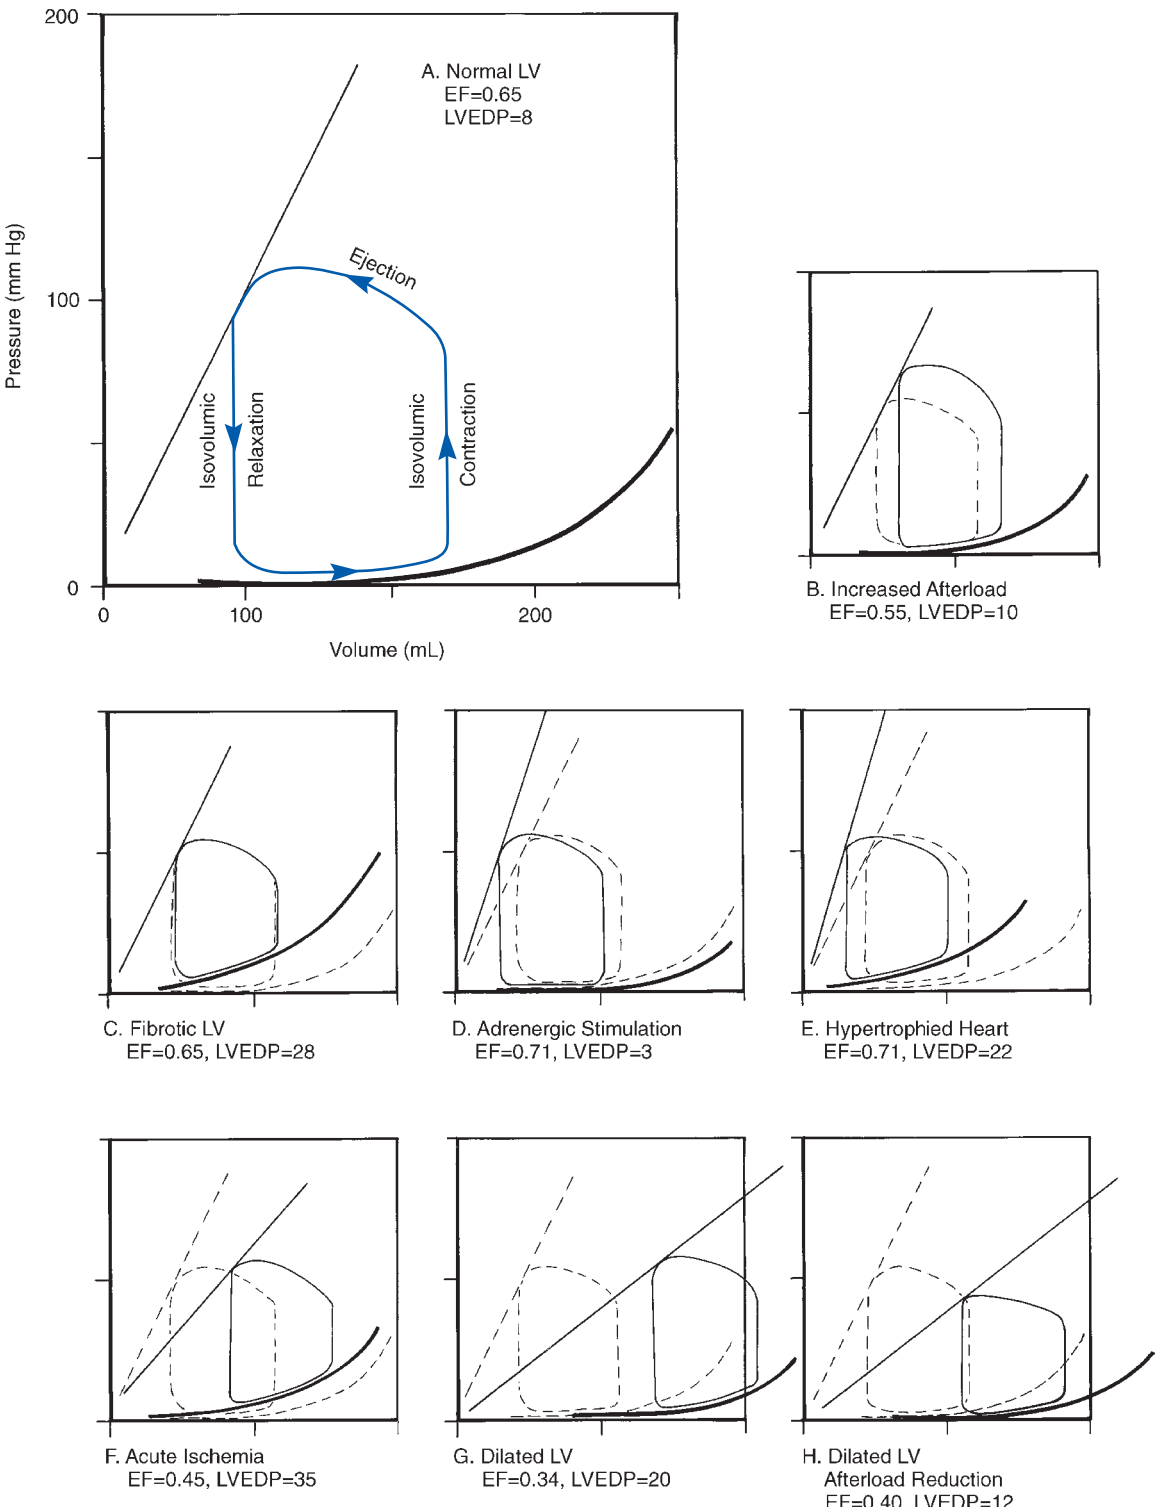

Figure 3-11. Left ventricular pressure-volume curves for various physiologic and pathologic conditions (detailed descriptions are in the text). The bold curved line at the bottom of each loop series represents the diastolic pressure-volume relationship. The straight line located on the upper left side of each loop series is the end-systolic pressure-volume relationship. The stroke volume for each curve has been arbitrarily set at 75 mL. Systolic aortic pressure is 115 mm Hg in all curves except *B* (increased afterload, systolic pressure 140 mm Hg) and *H* (reduced afterload, systolic pressure 90 mm Hg). LV, left ventricle; EF, ejection fraction; LVEDP, left ventricular end-diastolic pressure in mm Hg.

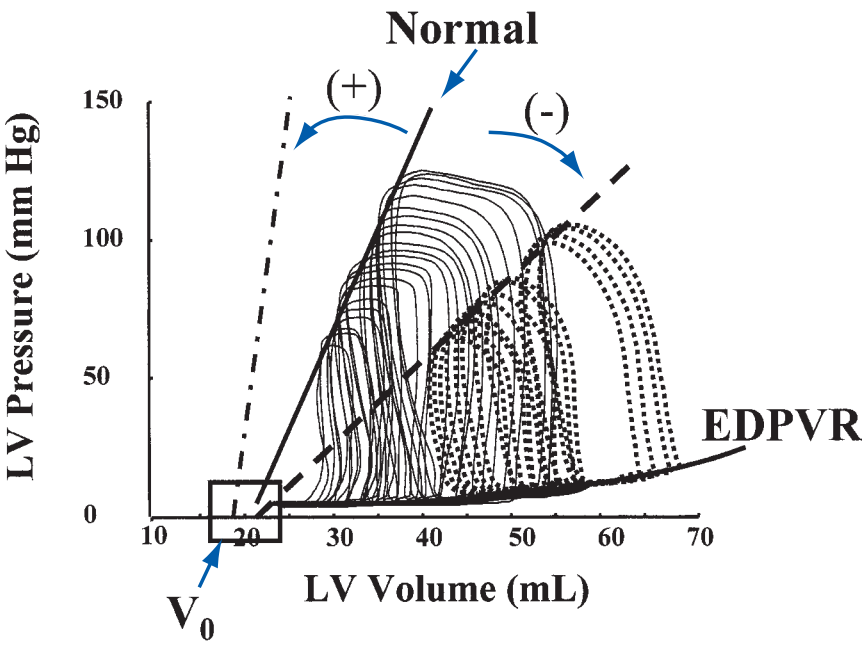

Figure 3-12. Two series of declining left ventricular pressure-volume loops generated during transient bicaval occlusion. Loops were generated in normal left ventricles (Normal) and after 30 minutes of global normothermic ischemia and subsequent reperfusion (*dashed lines*). The end-systolic pressure-volume points from each series are connected by a line generated by linear regression. The end-diastolic pressure-volume relationship indicating chamber stiffness (inverse of compliance) is generated by fitting the end-diastolic point from each loop to an exponential curve. The volume axis intercept (V_0) is shown in the inset. A negative inotropic effect (i.e., ischemia-reperfusion) is characterized by a decrease in the ESPVR slope, whereas a positive inotropic state is characterized by an increase in ESPVR slope. Notice that the V_0 for these conditions are in close proximity (*inset*). In some cases, a negative inotropic state is associated with a decrease in slope and an increase in V_0.

pressure-volume loop has moved back to the left, decreasing the degree of chamber dilatation, the end-diastolic pressure, and the ejection fraction. A positive inotropic agent would shift the ESPVR line to the left (toward the dashed line), the degree of dilatation would be reduced, and both stroke volume and ejection fraction would be increased. It is important to remember that these relationships are idealized and may not reflect true clinical responses. For example, reduced diastolic dilatation from afterload reduction could return the ventricle to a state of improved intrinsic contractility. Despite these interactions, the pure concepts discussed here are very helpful in understanding the response of the heart to clinical interventions.

Another index of contractility, perhaps less influenced by other parameters, is the *preload recruitable stroke work* (PRSW) relationship. *Stroke work* is the area of the pressure-volume loop. For each pressure-volume loop derived by vena caval occlusion, the stroke work is plotted relative to its end-diastolic volume[30] (Fig. 3-13). The slope of the derived linear relationship is a measure of contractility independent (within physiologic ranges) of preload and afterload. The PRSW relationship reflects overall performance of the left ventricle, combining systolic and diastolic components.[31]

Clinical indices of contractility

Clearly, from the preceding discussion, the degree of contractility can be assessed, but unlike blood pressure, an ideal number or range to describe it cannot be derived. Since ESPVR and PRSW are unique for each ventricle, these parameters more accurately measure changes in contractility. The greatest impediment to the clinical application of the ESPVR and PRSW is the difficulty in measuring ventricular volume and inducing preload reduction to derive the pressure-volume loops. More easily measurable indices of contractility have been actively sought.

Ejection fraction is used by many clinicians as a measure of contractility. However, as noted in the discussion of Fig. 3-11, ejection fraction is influenced by preload and afterload alterations without any change in contractility. Depending on loading conditions, hearts with a lower ejection fraction can produce a greater cardiac output. Although roughly indicative of cardiac reserve, ejection fraction is an inconsistent marker for overall cardiac function perioperatively.

Myocardial wall stress

The left ventricle is a pressurized, irregularly shaped chamber. During systole, wall stress develops to overcome afterload and eject the blood. The pressure within the chamber and the geometry of the ventricle determine the tension in the wall. A model of the ventricle as a cylinder can be used to examine the effects of chamber size and wall thickness on

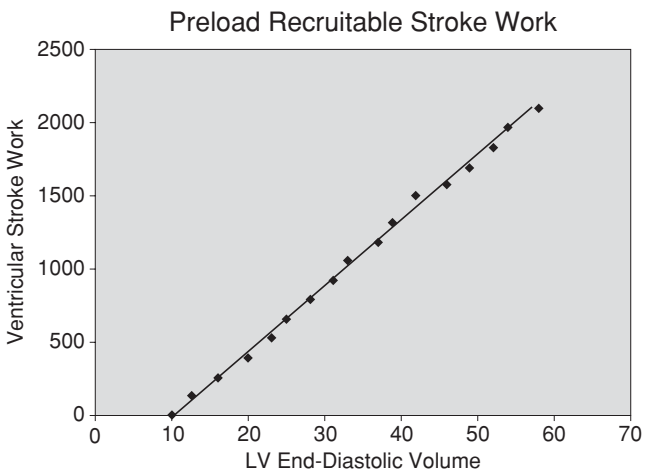

Figure 3-13. Plot of hypothetical measurement of preload recruitable stroke work.

wall stress. In this model, circumferential stress is based on the *law of LaPlace,* that is,

$$\sigma = \frac{Pr}{w}$$

where σ is wall stress, P is transmural pressure, r is radius, and w is wall thickness. This relationship has several important clinical implications. Wall tension must be balanced by the energy available. The only nutrient nearly completely extracted from the blood by the heart is oxygen, and wall tension is the primary determinant of oxygen consumption.

In one scenario, the heart can compensate for changes in wall stress. If systolic pressure within the ventricle is increased chronically (e.g., aortic stenosis or systemic hypertension), then compensatory hypertrophy or thickening of the ventricular wall can return systolic wall stress close to normal. However, as detailed in Fig. 3-11*E,* the price paid is that end-diastolic pressures must be higher.

In another scenario, the function of a heart that has dilated for other reasons is further compromised by the relationship between wall stress and oxygen consumption. As a result of or to compensate for systolic failure, the ventricle will dilate. The increased diastolic diameter proportionally increases wall stress and oxygen consumption. The ability of the heart to increase cardiac output in response to exercise will be limited, leading to symptoms.

Energetics

Chemical fuels

Nearly all chemical energy used by the heart is generated by oxidative phosphorylation. Anaerobic metabolism is very limited because anaerobic enzymes are not present in sufficient concentrations. The major fuels for the myocardium are carbohydrates (i.e., glucose and lactate) and free fatty acids. When sufficient oxygen is present, these fuels are used to generate ATP. Most of the ATP used by the heart (60 to 70%) is expended in the cyclic contraction of the muscle; 10 to 15% is required for maintaining the concentration gradients across the cell membrane; the rest is used in the constant uptake and release of calcium by mitochondria, the breakdown and regeneration of glycogen, and the synthesis of triglycerides.

The heart is quite flexible in the aerobic state in its use of fuels. In the fasting state, lipids may account for 70% of the fuel used by the heart. After a high-carbohydrate meal, blood glucose and insulin levels are high and free fatty acids are low, and glucose accounts for close to 100% of the metabolism. During exercise, elevated lactate levels inhibit the uptake of free fatty acids, and carbohydrates, mostly lactate, can account for up to 70% of the metabolism.[32]

Whatever the fuel source, oxygen is necessary for its efficient utilization. In the absence of oxygen, there are two mechanisms to provide ATP, glycolysis and conversion of phosphate stored in creatine phosphate, because free fatty acids and the by-products of glycolysis cannot be metabolized. Glycolysis is very inefficient—for 1 mol of glucose, 2 mol of ATP is produced by anaerobic glycolysis, compared with 38 mol of ATP with aerobic metabolism. One by-product of glycolysis is lactic acid, which lowers intracellular pH, impairing muscular function. Phosphate stored in creatine phosphate can convert ADP to ATP, but this is not stored in significant amounts.

With ischemia and hypoxia, ATP breaks down to ADP and subsequently to AMP, adenosine, and inosine. The nucleoside building blocks of ATP—adenosine, inosine, and hypoxanthine—are lost from the ischemic myocardium. If oxygen is restored, ATP levels can be restored rapidly in part by salvage pathways with inosine, hypoxanthine, or inosine monophosphate. However, *de novo* synthesis of ATP is also required and can take hours or even days to restore significant ATP levels.

Determinants of oxygen consumption

Since nearly all the energy used by the heart is generated by oxidative metabolism, the rate of oxygen consumption ($M\dot{V}O_2$) is indicative of the metabolic rate of the heart:

$$M\dot{V}O_2 = \frac{(CaO_2 - CvO_2)/CBF}{\text{mass}}$$

where $M\dot{V}O_2$ is myocardial oxygen consumption, CaO_2 is arterial oxygen content in milliliters of O_2 per 100 mL of blood, CvO_2 is coronary venous oxygen content in milliliters of O_2 per 100 mL of blood, and CBF is coronary blood flow in milliliters per minute. Since the bulk of the energy is expended on contraction, changes in the rate of oxygen consumption of the heart are directly related to changes in the contraction cycle and workload. Energy utilization can be increased by an increase in cardiac workload or by a decrease in the efficiency of conversion of chemical to mechanical energy.

Minute work of the heart is the product of heart rate, stroke volume, and developed pressure. A change in each of these factors alters oxygen demand; however, minute work is not the direct determinant of oxygen consumption. As noted earlier, the primary determinant of oxygen demand is the wall tension or stress developed in each cardiac cycle. Indeed, during the period of isovolumic contraction, energy is expended by the heart without the delivery of any kinetic energy to the blood.[33] The energetic cost of ejecting blood from the ventricular chamber is approximately 20 to 30% of that required for isovolumic contraction. To restate this simply, the principal determinant of the cardiac energy requirement is the pressure against which blood is ejected and the volume ejected at that pressure.

Cardiac efficiency relates oxygen consumption to cardiac work. Hence cardiac efficiency = work /$M\dot{V}O_2$. The overall efficiency of the heart ranges from 5 to 40% depending on the type of work (pressure versus volume versus velocity) performed.[34–37] The low efficiency of the heart is due to the expenditure of a predominant portion of the oxygen consumed in generating pressure and stretching internal

elastic components of the myocardium during isovolumic systole (a form of internal work). The velocity of shortening, affected in part by the inotropic state of the myocardium, also is not factored into the work equation but contributes significantly to oxygen consumption.

Following cardiac surgery, cardiac efficiency generally decreases owing to the increase in $M\dot{V}O_2$ relative to the cardiac work performed. The additional oxygen consumed may be due to an increase in basal metabolism and/or an increase in the cost of the excitation-contraction process or inefficiencies of ATP production at the mitochondrial level.

A clear understanding of the role of wall tension and its relation to oxygen demand is essential in cardiac surgery. Excessive systemic pressure may place inordinate energy demands on a compromised ventricle. An intra-aortic balloon pump may shift the energy balance by reducing afterload and improving coronary blood flow. Ventricular distension from an incompetent aortic valve in the absence of left ventricular venting, during the weaning process after removal of the aortic cross-clamp, or with heart failure may create wall stress that outstrips the capacity to deliver oxygen to the myocardium. In the failing heart, where stroke volume is reduced, cardiac output is maintained by increasing heart rate, which increases the percentage of time that the myocardial wall stress is elevated, reduces the time when diastolic blow flow occurs, and creates an imbalance between oxygen demand and delivery.

CORONARY BLOOD FLOW

Normal Coronary Blood Flow

Resting coronary blood flow is slightly less than 1 mL/g of heart muscle per minute. This blood flow is delivered to the heart through large epicardial conductance vessels and then into the myocardium by penetrating arteries leading to a plexus of capillaries. The bulk of the resistance to coronary flow is in the penetrating arterioles (20 to 120 μm in size). Because the heart is metabolically very active, there is a high density of capillaries such that there is approximately one capillary for every myocyte, with an intercapillary distance at rest of approximately 17 μm. Capillary density is greater in subendocardial myocardium than in subepicardial tissue. When there is an increased myocardial oxygen demand (e.g., with exercise), myocardial blood flow can increase to three or four times normal (coronary flow reserve). This increased blood flow is accomplished by vasodilation of the resistance vessels and by recruitment of additional capillaries (many of which are closed in the resting state). This capillary recruitment is important in decreasing the intercapillary distance and thereby decreasing the distance that oxygen and nutrients must diffuse through the myocardium. The blood flow pattern from a coronary artery perfusing the left ventricle, measured by flow probe, is phasic in nature, with greater blood flow occurring in diastole than in systole.[38] The cyclic contraction and relaxation of the left ventricle produce this phasic blood flow pattern by extravascular compression of the arteries and intramyocardial microvessels during systole. There is a gradient in these systolic extravascular compressive forces, being greater or equal to intracavitary pressure in the subendocardial tissue and decreasing toward the subepicardial tissue. Measurement of transmural blood flow distribution during systole shows that subepicardial vessels are perfused preferentially, whereas subendocardial vessels are hypoperfused significantly. Toward the end of systole, blood flow actually reverses in the epicardial surface vessels.[39] Hence the subendocardial myocardium is perfused primarily during diastole, whereas the subepicardial myocardium is perfused during both systole and diastole. A greater capillary density per square millimeter in the subendocardium than in the subepicardial tissue facilitates the distribution of blood flow to the inner layer of myocardium, and myocardial blood flow normally is greater in the subendocardial tissue than in the subepicardial tissue.[40] This places the subendocardium at greater risk of dysfunction, tissue injury, and necrosis during any reduction in perfusion. This is related to (1) the greater systolic compressive forces, (2) the smaller flow reserve owing to a greater degree of vasodilation, and (3) the greater regional oxygen demands owing to wall tension and segmental shortening. If end-diastolic pressure is elevated to 25, 30, or 35 mm Hg, then there is diastolic as well as systolic compression of the subendocardial vasculature. Flow to the subepicardium is effectively autoregulated as long as the pressure in the distal coronary artery is above approximately 40 mm Hg. Flow to the subendocardium, however, is effectively autoregulated only down to a mean distal coronary artery pressure of approximately 60 to 70 mm Hg. Below this level, local coronary flow reserve in the subendocardium is exhausted, and local blood flow decreases linearly with decreases in distal coronary artery pressure. Subendocardial perfusion is further compromised by pathologic processes that increase wall thickness and systolic and diastolic wall tension. Aortic regurgitation in particular threatens the subendocardium because systemic diastolic arterial pressure is reduced and intraventricular systolic and diastolic pressures are elevated.[38,41]

In contrast to the phasic nature of blood flow in the left coronary artery, blood flow in the right coronary artery is relatively constant during the cardiac cycle. The constancy of blood flow is related to the lower intramural pressures and near absence of extravascular compressive forces in the right ventricle compared with the left ventricle.

Control of Coronary Blood Flow

Coronary blood flow is tightly coupled to the metabolic needs of the heart. Under normal conditions, 70% of the oxygen available in coronary arterial blood is extracted, near the physiologic maximum. Any increase in oxygen delivery comes mostly from an increase in blood flow. To maximize efficiency, local coronary blood flow is precisely controlled by a balance of vasodilator and vasoconstrictor mechanisms, including (1) a *metabolic vasodilator system,* (2) a *neurogenic control system,* and (3) the *vascular endothelium.*[42] Blood flow

is controlled by moment-to-moment adjustment of coronary tone of the resistance vessels, i.e., arterioles and precapillary sphincters.

The metabolic vasodilator mechanism responds rapidly when local blood flow is insufficient to meet metabolic demand. The primary mediator is adenosine generated within the myocyte and released into the interstitial compartment. Adenosine relaxes arteriolar smooth muscle cells by activation of A_2 receptors. Adenosine is formed when the oxygen supply cannot sustain the rapid rephosphorylation of ADP to ATP. Once sufficient oxygen is supplied to the myocardium, less adenosine is formed. Adenosine is therefore the coupling agent between oxygen demand and supply. Other local vasodilators that influence coronary blood flow are carbon dioxide, lactic acid, and histamine.

The sympathetic nervous system acts through *alpha receptors* (which cause vasoconstriction) and *beta receptors* (which cause vasodilation). There is direct innervation of the large conductance vessels and lesser direct innervation of the smaller resistance vessels. Sympathetic receptors on the smooth muscle cells of the resistance vessels respond to humoral catecholamines. Alpha receptors predominate over beta receptors such that when norepinephrine is released from the sympathetic nerve endings, vasoconstriction ordinarily occurs.

Endothelium-dependent regulation of coronary artery blood flow is a dynamic balance between vasodilating and vasoconstricting factors. Vasodilators include nitric oxide ($NO^{\bullet}$) synthesized from L-arginine by endothelial nitric oxide synthase and endothelially released adenosine. The principal vasoconstrictor is the endothelially derived constricting peptide endothelin-1. Other vasoconstrictors include angiotensin II and superoxide free radical.[43] $NO^{\bullet}$ is dominant in local regulation of coronary arterial tone by overwhelming the action of endothelium-derived vasoconstrictor substances, which are tonically released by the coronary artery endothelium. $NO^{\bullet}$ is released by the coronary vascular endothelium by both soluble factors (e.g., acetylcholine, adenosine, and ATP) and mechanical signals (e.g., shear stress and pulsatile stress secondary to increased intraluminal blood flow). If the endothelium is intact, acetylcholine from the sympathetic nerves causes vasodilation through generation of $NO^{\bullet}$. If the endothelium is not functionally intact, acetylcholine causes vasoconstriction by direct stimulation of the vascular smooth muscle. $NO^{\bullet}$ is a potent inhibitor of platelet aggregation and neutrophil function (i.e., superoxide generation, adherence, and migration), which has implications in the anti-inflammatory response to ischemia-reperfusion and cardiopulmonary bypass.

Endothelin-1 (ET-1) interacts principally with specific endothelin receptors (ET_A) on vascular smooth muscle and causes smooth muscle vasoconstriction. Endothelin-1 counteracts the vasodilator effects of endogenous adenosine, $NO^{\bullet}$, and prostacyclin (PGI_2). Endothelin-1 is synthesized rapidly in vascular endothelium, particularly during ischemia, hypoxia, and other stress conditions, where it acts in a paracrine fashion. ET-1 has a short half-life (4 to 7 minutes), which exceeds that of adenosine (8 to 12 seconds) and $NO^{\bullet}$ (microseconds). However, the avid binding of ET-1 to ET_A receptors prolongs its effects beyond the half-life. Human coronary arteries demonstrate abundant ET-1 binding sites, suggesting that ET-1 has an important role in the control of coronary blood flow in humans. Changes in coronary blood flow in ischemia-reperfusion, congestive heart failure, hypertension, and atherosclerosis may be, in part, mediated or exacerbated by an overexpression of ET-1, which may overwhelm the vasodilating effects of local autacoids such as adenosine and $NO^{\bullet}$.[44] Increased age may exacerbate the vasoconstrictor responses to ET-1, which are further exaggerated by a concomitant decrease in tonic $NO^{\bullet}$ production. In addition, the levels of ET-1 have been observed to increase with myocardial ischemia-reperfusion and after cardiac surgery.

Under ordinary circumstances, the metabolic vasodilator system is the dominant force acting on the resistance vessels. For example, the increased metabolic activity caused by sympathetic stimulation leads to vasodilation of the coronary arterioles through the metabolic system despite a direct vasoconstriction effect of norepinephrine.[45–47]

Coronary artery blood flow is also determined by perfusion pressure. However, in the coronary vasculature, blood flow can remain constant over a range of perfusion pressures. The control mechanisms described allow *autoregulation* of blood flow, adjusting vascular resistance to match blood flow requirements. The autoregulatory "plateau" occurs between approximately 60 and 120 mm Hg of perfusion pressure. If distal coronary artery perfusion pressure is reduced by a critical stenosis or hypotension, vasodilator capacity will be exhausted, and coronary blood flow will decrease, following a linear relationship with perfusion pressure. Since the subendocardial regional of the left ventricle has a lower coronary vascular reserve, maximal dilation is reached in this region before it occurs in the subepicardial tissue, and a preferential hypoperfusion of the subendocardial tissue results.

Hemodynamic Effect of Coronary Artery Stenosis

Surgically treatable atherosclerotic disease primarily affects the large conductance vessels of the heart. The hemodynamic effect of a stenosis is determined by *Poiseuille's law,* which describes the resistance of a viscous fluid to laminar flow through a cylindrical tube; specifically,

$$Q = \frac{\pi(\Delta P)}{8\eta} \cdot \frac{r^4}{l}$$

where Q is flow, ΔP is the pressure change, η is viscosity, r is radius, and l is the length of the resistance segment. Resistance (pressure change/flow)

$$R = \frac{(\Delta P)}{Q} = \frac{8\eta}{\pi} \cdot \frac{l}{r^4}$$

is inversely proportional to the *fourth* power of the radius and directly proportional to the length of the narrowing. There-

Table 3–2.

Effect of Degree and Length of Stenosis on Resistance to Flow Based on Poisenille's Law

Percent stenosis of a 1-cm–diameter vessel	Radius (cm)	Proportional resistance for various segment lengths (cm)		
		0.25 cm	1 cm	2 cm
0	0.5	1	4	8
50	0.25	16	64	128
60	0.2	39	156	313
70	0.15	123	494	988
80	0.1	625	2500	5000
90	0.25	10,000	40,000	80,000
Proportional increase in resistance 80% vs. 60% stenosis		16		
Proportional increase in resistance 90% vs. 60% stenosis		256		

Note: The value for a reference vessel of length 0.25 cm with 0% stenosis (in the box) is set to 1 for comparison.

fore, a small change in diameter has a magnified effect on vascular resistance (Table 3-2). Conductance vessels are sufficiently large that a 50% reduction in the diameter of the vessel has minimal hemodynamic effect. A 60% reduction in the diameter of the vessel has only a very small hemodynamic effect. As the stenosis progresses beyond 60%, small decreases in diameter have significant effects on blood flow. For a given segment length, an 80% stenosis has a resistance that is 16 times greater than that of a 60% stenosis. For a 90% stenosis, the resistance is 256 times greater than that of a 60% stenosis.[48] Furthermore, for successive stenoses in the same vessel, the resistance is additive. An additional factor in resistance to flow is turbulence. Stenotic lesions can cause conversion from laminar to turbulent flow.[49] With laminar flow, the pressure drop is proportional to flow rate Q; with turbulent flow, pressure drop is proportional to (Q^2). For all these reasons, patients who have had a small progression in the degree of coronary stenosis may experience a rapid acceleration of symptoms.

Atherosclerosis also alters normal vascular regulatory mechanisms. The endothelium is often destroyed or damaged, so vasoconstrictor mechanisms are relatively unopposed by the impaired vasodilator mechanism; constriction is exaggerated, and responses to stimuli that require dilatation are blunted.[50]

As noted earlier, when a stenosis is less than 60%, little change is flow is noted. This is due to compensation by the coronary flow reserve of the resistance vessels distal to the stenotic conductance vessel. Since resistance to flow is additive, a decrease in distal resistance will balance an increase in proximal resistance, and flow will be unchanged. As flow reserve decreases, any stimulus that increases myocardial oxygen demand (such a tachycardia, hypertension, or exercise) cannot be met by dilation of the distal vasculature, and myocardial ischemia results.[42]

In the human, coronary arterial vessels are end vessels with little collateral flow between major branches except in pathologic situations. With sudden coronary occlusion, though, there usually is modest collateral flow through very small vessels (20 to 200 μm in size); this flow generally is insufficient to maintain cellular viability. Collateral flow gradually begins to increase over the next 8 to 24 hours, doubling by about the third day after total occlusion. Collateral blood flow development appears to be nearly complete after 1 month, restoring normal or nearly normal resting flow to the surviving myocardium in the ischemic region. Previous ischemic events or gradually developing stenoses can lead to larger preexisting collaterals in the human heart. The presence of these preexisting collaterals has been shown to be important in the prevention of ischemic damage if coronary occlusion should occur.[51]

Endothelial Dysfunction

As noted previously, NO$^{\bullet}$, adenosine, and endothelin-1 are synthesized and released by the endothelium.[52,53] Ischemia-reperfusion, hypertension, diabetes, and hypercholesterolemia can impair generation of NO$^{\bullet}$, and vasoconstriction may predominate, mediated by the relative overexpression of endothelin-1. Reperfusion after temporary myocardial ischemia is one situation in which NO$^{\bullet}$ production may be impaired, leading to a vicious cycle in which the vasodilator reserve of the resistance vessels is reduced with a consequent and progressive "low flow" or "no flow" phenomenon. The coronary vascular NO$^{\bullet}$ system also may be impaired in some cases after coronary artery bypass surgery.

The endothelium helps to prevent cell-cell interactions between blood-borne inflammatory cells (i.e., leukocytes and platelets) that initiate a local or systemic inflammatory reaction. Inflammatory cascades occur with sepsis, ischemia-reperfusion, and cardiopulmonary bypass. Under normal conditions, the vascular endothelium resists interaction with neutrophils and platelets by tonically releasing adenosine and $NO^{\bullet}$, which have potent antineutrophil and platelet-inhibitory effects. Damage to the endothelium lowers the resistance to neutrophil adhesion. Neutrophils can damage the endothelium by adhesion to its surface and subsequent release of oxygen radicals and proteases. This amplifies the inflammatory response and decreases the tonic generation and release of adenosine and $NO^{\bullet}$, which then permits further interaction with activated inflammatory cells. The products released by activated neutrophils have downstream physiologic consequences on other tissues, notably the heart, including increasing vascular permeability, creating blood flow defects (no-reflow phenomenon), and promoting the pathogenesis of necrosis and apoptosis.[54]

The triggers of these inflammatory reactions in the heart include cytokines [i.e., interleukin 1 (IL-1), IL-6, and IL-8], complement fragments (C3a, C5a, membrane attack complex), oxygen radicals, and thrombin, which upregulate adhesion molecules expressed on both inflammatory cells (CD11a/CD18) and endothelium (e.g., P-selectin, E-selectin, and ICAM-1). The release of cytokines and complement fragments during cardiopulmonary bypass activates the vascular endothelium on a systemic basis, which contributes to the inflammatory response to cardiopulmonary bypass.[55] Both adenosine and $NO^{\bullet}$ have been used therapeutically to reduce the inflammatory responses to cardiopulmonary bypass and to reduce ischemia-reperfusion injury. This treatment has reduced endothelial damage from surgical and nonsurgical ischemia-reperfusion injury and cardiopulmonary bypass.[56–58]

The Sequelae of Myocardial Hypoperfusion: Infarction, Myocardial Stunning, and Myocardial Hibernation

Normally contracting muscle in the left ventricle uses 8 mL of oxygen per 100 g of muscle every minute. Of this, 1.3 mL/100 g of muscle per minute is necessary for cell survival; the rest supports contraction. As oxygen delivery is reduced, contraction strength decreases rapidly (within 8 to 10 heartbeats). This is seen acutely in response to acute ischemia and is reversed rapidly with reperfusion. If the extent of reduction of coronary blood flow is severe, mild to moderate abnormalities in cellular homeostasis occur. Reduced cellular levels of ATP lead to a loss of adenine nucleotides from the cell. If the reduction in coronary blood flow is sustained, progressive loss of adenine nucleotides and elevation of intracellular and intramitochondrial calcium may lead to cellular death and subsequent necrosis. If the myocyte is reperfused before subcellular organelles are irreversibly damaged, the myocyte may recover slowly. A period of days is necessary for full recovery of myocyte ATP levels because adenine nucleotides must be resynthesized. During this time, contractile processes are impaired. This impairment is related to reversible damage to the contractile proteins such that their responsiveness to cytosolic levels of calcium is diminished. The magnitude of the cytosolic pulse of calcium with each heartbeat appears to be nearly normal, but the magnitude of the consequent contraction is greatly reduced. Over a period of 1 to 2 weeks, this myocardium recovers gradually. This viable but dysfunctional myocardium is called *stunned myocardium.*[59,60,65]

Chronic hypoperfusion and oxygen delivery at a reduced level but above the level required for cell viability can cause a chronic hypocontractile state known as *hibernation.* Hibernation appears to be associated with a decrease in the magnitude of the pulse of calcium involved in the excitation-contraction process such that the calcium levels developed within the cytosol during each heartbeat are inadequate for effective contraction to occur. Histologic examination shows islets in the subendocardium where there is a loss of contractile proteins and sarcoplasmic reticulum and alterations in other subcellular structures.[61,62] With reperfusion, hibernating myocardium can resume normal and effective contraction very quickly, although complete recovery may be delayed for several months.[63–66] This is of particular importance for patients with poor ventricular function but viable heart muscle.[67]

Reperfusion of acutely ischemic myocardium may cause further cellular damage and necrosis rather than immediate recovery. The etiology of *reperfusion injury* is multifactorial. Damage to endothelium in the reperfused region fails to prevent adhesion and activation of leukocytes and platelets. Oxygen free radicals are released. Derangement of the ATP-dependent sodium-potassium pump disrupts cell volume regulation with consequent leakage of water into the cell, explosive cell swelling, and rupture of the cell membrane. Techniques attempting to reduce reperfusion injury, minimize adverse sequelae, and preserve myocytes include leukocyte depletion or inactivation, prevention of endothelial activation, free-radical scavenging, reperfusion with solutions low in calcium, and reperfusion with hyperosmolar solutions.[68,69] Both adenosine and low-dose $NO^{\bullet}$ are potent cardioprotective agents that attenuate neutrophil-mediated damage, infarction, and apoptosis.[56,70]

The metabolic changes that occur with ischemia-reperfusion represent a complex system of adaptive mechanisms that allow the myocyte to survive despite a temporary reduction in oxygen delivery. These adaptive mechanisms may be triggered by a very brief coronary occlusion (as short as 5 minutes) such that the negative sequelae of a subsequent prolonged coronary occlusion are greatly minimized. This phenomenon has been called *ischemic preconditioning.* A coronary occlusion that might cause as much as 40% myocyte death in a region subjected to prolonged ischemia may be reduced to only 10% myocyte death if the prolonged period of ischemia is preceded by a 5-minute interval of "preconditioning" coronary occlusion.[68,71,72]

PHYSIOLOGY OF HEART FAILURE

Definition and Classification

Heart failure is the inability of the heart to deliver adequate blood to the tissues to meet metabolic needs at rest or during mild to moderate exercise. Components include low cardiac output, an impaired exercise capacity, neurohormonal activation, enhanced oxidative stress, and premature myocardial cell death. Processes that cause heart failure can impair systolic function (the ability to contract and empty) or diastolic function (the ability to relax and fill) or both. The acute and chronic stages of a myocardial infarction involving a large area of the left ventricle cause systolic heart failure. The acute loss of contractile function compromises the ability of the ventricle to maintain a normal stroke volume (Fig. 3-11*F*). As the infarction heals, the adaptive response of ventricular dilation reduces the heart's systolic functional reserve. Cardiomyopathies affect the myocardium globally, leading to reduced systolic function. In both cases, the left ventricle dilates, which causes the pressure-volume relations of the left ventricle to shift to the right (Fig. 3-11*G*). In this situation, the diastolic portion of the pressure-volume curves is not greatly changed. However, the global systolic performance of the heart (i.e., the ability to pump blood) may be inadequate to meet even resting needs (particularly if there is systolic bulging of a large infarction).[73,74]

Diastolic failure may occur without an impairment of systolic contractility if the myocardium becomes fibrotic or hypertrophied or if there is an external constraint on filling such as with pericardial tamponade.[75] Increased stiffness of the left ventricular myocardium is associated with an excessive upward shift in the diastolic pressure-volume curve (Fig. 3-11*C* and *E*). The most common cause of increased myocardial stiffness is chronic hypertension with consequent left ventricular hypertrophy and diastolic stiffness (related both to myocyte hypertrophy and to increased fibrosis of the ventricle).[76,77]

It should be noted from these examples that although one process may predominate, most patients with heart failure manifest both systolic and diastolic dysfunction.

Early Cardiac and Systemic Sequelae of Heart Failure

The adaptive homeostatic reactions of the body leading to heart failure depend on the duration of the ongoing pathologic process. When cardiac function deteriorates acutely and cardiac output diminishes, neurohumoral reflexes attempt to restore both cardiac output and blood pressure. Activation of the sympathetic adrenergic system in the heart and in the peripheral vasculature causes systemic vasoconstriction (via an alpha-adrenergic effect) and increases heart rate and contractility (via a beta-adrenergic effect). A number of mediators formed during this adaptive stage, including norepinephrine, angiotensin II, vasopressin, brain natriuretic peptide (BNP), and endothelin, not only help in renal retention of salt and water leading to rapid volume expansion but also cause vasoconstriction. Aldosterone output is increased, again helping conserve sodium. The concerted responses of the adrenergic system and the renin-angiotensin system, therefore, recruit changes in the primary determinants of stroke volume and cardiac output—preload, afterload, and contractility. The heart responds to loss of systolic function by dilating progressively. This dilation leads to preservation of stroke volume by Frank-Starling mechanisms, but increased stroke volume is achieved at the expense of ejection fraction, as shown in Fig. 3-11*G* as a right shift in the pressure-volume relationship of the left ventricle with an increase in end-diastolic volume (and pressure). In addition to a global dilatation response, acute alterations in cardiac geometry may occur early after a large myocardial infarction, with thinning of the left ventricular wall in the region of the infarct as well as expansion of overall left ventricular cavity size. This is particularly true if the infarct is apical because of geometric considerations related to the thinness of the left ventricular wall in the region of the apex and to the short radius of curvature of the left ventricular apex. As volume expansion occurs, production of the cardiac atrial natriuretic peptide is increased, which tends to prevent excessive sodium retention and inhibit activation of the renin-angiotensin and aldosterone systems.[78–84]

Cardiac and Systemic Maladaptive Consequences of Chronic Heart Failure

The acute-phase response just described, while acutely beneficial, becomes maladaptive and contributes significantly to long-term problems in patients with heart failure (Figure 3-14). In the latter stages of heart failure, the kidney tends to retain sodium and become hyporesponsive to atrial natriuretic peptide and BNP.[79] Desensitization of beta-adrenergic receptors is a consequence of sustained stimulation with a reduced response to elevated circulating catecholamine levels.[20]

Left ventricular dilation is due to hypertrophy of the myocytes as well as lengthening of the myocytes as sarcomeres are added. However, there is significant slippage of myofibrils, leading to dilation without an increase in the number of myocytes. Progressive dilation of the heart leads to an increase in oxygen consumption during systole. Ventricular remodeling leads to progressive fibrosis.

Angiotensin and aldosterone stimulate collagen formulation and proliferation of fibroblasts in the heart, leading to an increase in the ratio of interstitial tissue to myocardial tissue in the noninfarcted regions of the heart.[85] The impact of aldosterone has been documented by the effectiveness of aldosterone receptor antagonists in improving the morbidity and mortality of patients with heart failure.[86] The progressive fibrosis leads to increased diastolic stiffness, which limits diastolic filling and increases end-diastolic pressure. Fibrosis and increased ventricular size predispose to reentry ventricular arrhythmias that are a common cause of death in the late stages of heart failure. This rapidly deteriorating clinical cycle explains the result in one clinical study in which the 5-year survival rate was only 25% in men and 38% in

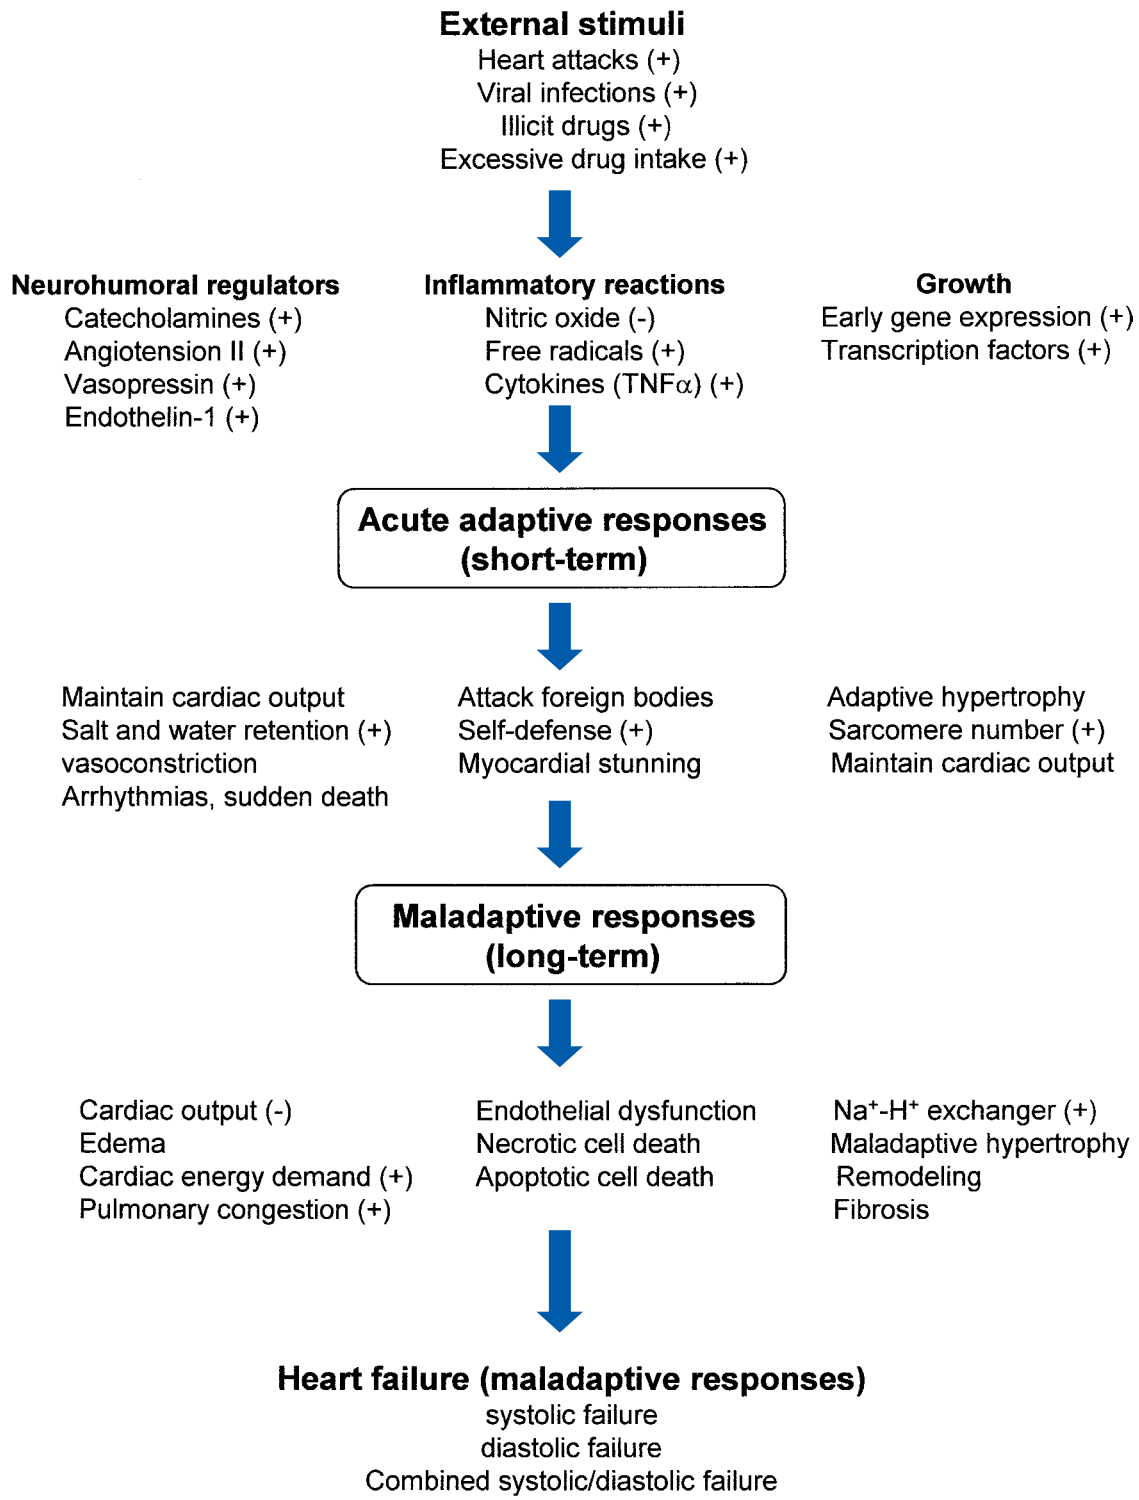

Figure 3-14. Pathophysiology of heart failure from stimulus (etiology) to acute adaptive and chronic maladaptive responses. (+) indicates positive stimulation; (−) indicates negative factors that tend to reduce stimulation of heart failure.

women.[81,83,84,87] Hence heart failure progresses as a result of a vicious cycle of left ventricular dilatation and remodeling, responses that decrease cardiac performance further.

Evidence has accumulated over the past decade that suggests that endothelial dysfunction, release of cytokines, and apoptotic cell death may participate in the development of heart failure as a maladaptive reaction (Fig. 3-14). Reduced availability of nitric oxide and increased production of vasoconstrictor agents such as endothelin and angiotensin II have been reported in failing hearts.[88,89] Heart failure is often accompanied by changes in the endogenous antioxidant defense mechanisms of the heart, as well as evidence of

oxidative injury to the myocardium. Cytokines, released from systemic and local inflammatory responses in the failing heart, directly activate inflammatory cells to release superoxide radicals and cause endothelial dysfunction by augmenting inflammatory cell–endothelial cell interactions. Cytokines also may induce necrotic and apoptotic myocyte cell death directly.[90,91]

Cardiac secretion of B-type natriuretic peptide (BNP) has been shown to be increased with heart failure.[92] BNP is a cardiac neurohormone released as preproBNP that is enzymatically cleaved to N-terminal proBNP and BNP on ventricular myocyte stretch.[93] The physiologic effects of BNP include natriuresis, vasodilation, and neurohumoral changes. Plasma measurement of BNP is emerging as a useful and cost-effective marker for heart failure. A BNP level below 100 pg/mL excludes acutely decompensated heart failure.[94] However, BNP is not specific for heart failure. Other factors rather than stretch may stimulate BNP release, including fibrosis, arrhythmias, ischemia, endothelial dysfunction, and cardiac hypertrophy. BNP levels greater than 20 pg/mL are associated with an increased risk for atrial fibrillation and heart failure. Nesiritide is a synthetic analogue of human BNP. In clinical trials, nesiritide has been shown to decrease cardiac filling pressures, increase cardiac index, and improve the clinical status of patients with acute decompensated heart failure.[95]

ACKNOWLEDGMENT

The authors would like to acknowledge the work of the authors of this chapter in the previous edition, Jacob Vinten-Johansen, Zhi-Qing Zhao, and Robert A. Guyton. The current revision was based on the solid foundation that they had prepared.

CHAPTER 4

Cardiac Surgical Pharmacology

Jerrold H. Levy • Kenichi A. Tanaka • James M. Bailey

Clinical pharmacology associated with cardiac surgery is an important part of patient management. Patients in the perioperative period receive multiple agents that affect cardiovascular and pulmonary function. In this chapter we summarize the pharmacology of the agents commonly used for treating the primary physiologic disturbances associated with cardiac surgery, hemodynamic instability, respiratory insufficiency, and alterations of hemostasis. For cardiovascular drugs, the common theme is that pharmacologic effects are produced by intracellular ion fluxes.

Several basic subcellular/molecular pathways are important in cardiovascular pharmacology, as shown in Fig. 4-1. The action potential in myocardial cells is a reflection of ion fluxes across the cell membrane, especially Na^+, K^+, and Ca^{2+}.[1,2] Numerous drugs used to control heart rate and rhythm act by altering Na^+ (e.g., lidocaine and procainamide), K^+ (e.g., amiodarone, ibutilide, and sotalol), or Ca^{2+} (e.g., diltiazem) currents. Calcium also has a dominant effect on the inotropic state.[3,4] Myocardial contractility is a manifestation of the interaction of actin and myosin, with conversion of chemical energy from ATP hydrolysis into mechanical energy. The interaction of actin and myosin in myocytes is inhibited by the associated protein tropomyosin. This inhibition is "disinhibited" by intracellular calcium. A similar situation occurs in vascular smooth muscle, where the interaction of actin and myosin (leading to vasoconstriction) is modulated by the protein calmodulin, which requires calcium as a cofactor. Thus intracellular calcium has a "tonic" effect in both the myocardium and in vascular smooth muscle.

Numerous drugs used during or around cardiac surgery act by altering intracellular calcium.[3,4] Catecholamines (e.g., norepinephrine, epinephrine, and dobutamine) with beta-agonist activity regulate intramyocyte calcium levels via the nucleotide cyclic adenosine monophosphate (cAMP) (Fig. 4-2). Beta agonists bind to receptors on the cell surface that are coupled to the intracellular enzyme adenylate cyclase via the stimulatory transmembrane GTP-binding protein. This leads to increased cAMP synthesis, and cAMP, in turn, acts as a "second messenger" for a series of intracellular reactions resulting in higher levels of intracellular calcium during systole. Less well known is that drugs with only alpha-adrenergic agonist activity also may increase intracellular Ca^{2+} levels, although by a different mechanism.[5,6] While under investigation, the probable basis for the inotropic effect of alpha-adrenergic drugs is the stimulation of phospholipase C, which catalyzes hydrolysis of phosphatidyl inositol to diacylglycerol and inositol triphosphate (see Fig. 4-2). Both these compounds increase the sensitivity of the myofilament to calcium, whereas inositol triphosphate stimulates the release of calcium from its intracellular storage site, the sarcoplasmic reticulum. There is still some debate about the mechanism for the inotropic effect of alpha-adrenergic agonists and its significance for the acute pharmacologic manipulation of contractility, but there is little debate about the importance of this mechanism in vascular smooth muscle, where the increase in intracellular calcium stimulated by alpha-adrenergic agonists can increase smooth muscle tone significantly. However, intracellular calcium in vascular smooth muscle is also controlled by cyclic nucleotides.[7,8] In contrast to the myocyte, in vascular smooth muscle, cAMP has a primary effect of stimulating the uptake of calcium into intracellular storage sites, decreasing its availability (Fig. 4-3). Thus drugs that stimulate cAMP production (beta agonists) or inhibit its breakdown (phosphodiesterase inhibitors) will cause vasodilation. In addition, cyclic guanosine monophosphate (cGMP) also increases intracellular calcium storage (see Fig. 4-3), decreasing its availability for modulating the interaction of actin and myosin. Several commonly used pharmacologic agents act via cGMP. For example, nitric oxide stimulates the enzyme guanylate cyclase, increasing cGMP levels. Drugs such as nitroglycerin and sodium nitroprusside achieve their effect by producing nitric oxide as a metabolic product. Vasodilation

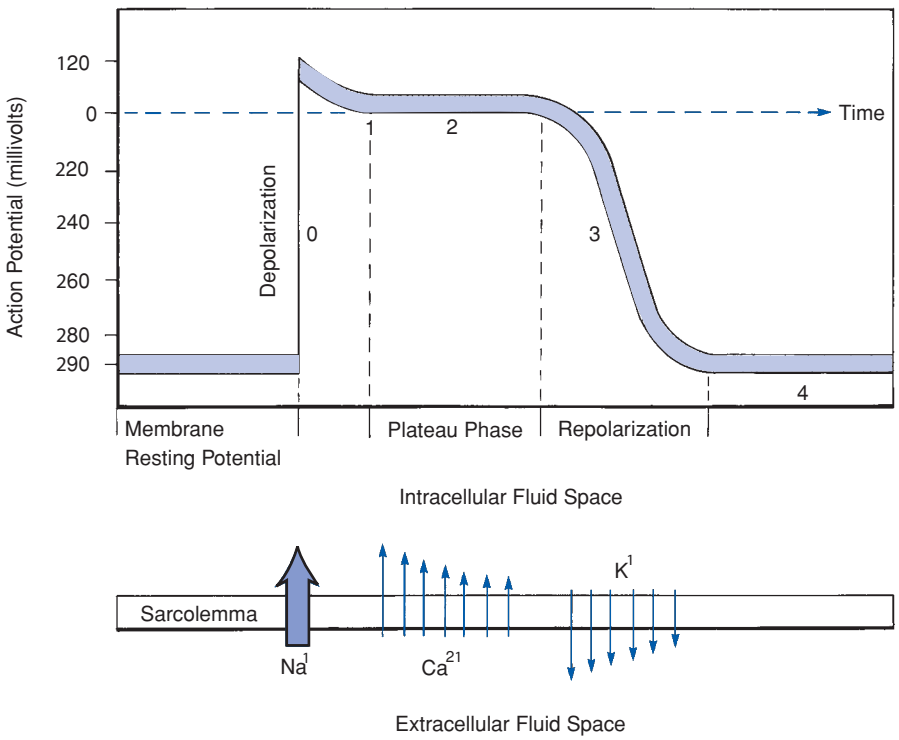

Figure 4-1. Cardiac ion fluxes and the action potential. The resting membrane potential is largely a reflection of the intercellular/intracellular potassium gradient. Depolarization of the membrane during phase 4 triggers an initial fast sodium channel with overshoot (phase 0) followed by recovery (phase 1) to a plateau (phase 2) maintained by an inward calcium flux and then repolarization owing to an outward potassium flux (phase 3).

is also produced by "cross-talk" between K^+ and Ca^{2+} fluxes. Decreased levels of ATP, acidosis, and elevated tissue lactate levels increase the permeability of the ATP-sensitive K^+ channel. This increased permeability results in hyperpolarization of the cell membrane that inhibits the entry of Ca^{2+} into the cell. This results in decreased vascular tone.

The simplistic overview of pathways of cardiac pharmacology as summarized in Figs. 4-1 through 4-3 also suggests the primary cause of difficulty in the clinical use of the drugs discussed in this chapter. The mechanisms of action for control of heart rate and rhythm, contractility, and vascular tone are interrelated. For example, beta-adrenergic agonists not only increase intracellular calcium to increase contractility, but they also alter K^+ currents, leading to tachycardia. Catecholamines not only have beta-adrenergic agonist activity, with inotropic and chronotropic effects, but they also possess alpha-agonist activity, leading to increased intracellular calcium in vascular smooth muscle and vasoconstriction. Phosphodiesterase inhibitors not only may increase contractility by increasing cAMP in the myocyte, but they also may cause excessive vasodilation by increasing cAMP in the vasculature. The interplay of the various mechanisms means the clinical art of cardiac surgical pharmacology lies as much in selecting drugs for their side effects as for their primary therapeutic effects.

ANTIARRHYTHMICS

Arrhythmias are common in the cardiac surgical period. A stable cardiac rhythm requires depolarization and repolarization in a spatially and temporally coordinated manner, and dysrhythmias may occur when this coordination is disturbed. The mechanisms for arrhythmias can be divided into abnormal impulse initiation, abnormal impulse conduction, and combinations of both.[9,10] Abnormal impulse initiation occurs as a result of increased automaticity (spontaneous depolarization of tissue that does not normally have pacemaking activity) or as a result of triggered activity from abnormal conduction after depolarizations during phase 3 or 4 of the action potential. Abnormal conduction often involves reentry phenomena, with recurrent depolarization around a circuit owing to unilateral conduction block in ischemic or damaged myocardium and retrograde activation by an alternate pathway through normal tissue. In this simplistic view, it is logical that dysrhythmias could be suppressed by slowing the conduction velocity of ectopic foci, allowing normal pacemaker cells to control heart rate, or by prolonging the action potential duration (and hence refractory period) to block conduction into a limb of a reentry circuit.

A scheme proposed originally by Vaughan Williams and modified subsequently[11,12] is used often to classify antidysrhythmic agents, and although alternative schemes describing specific channel-blocking characteristics have been proposed and may be more logical,[13] we will organize our discussion using the Vaughan Williams system of four major drug categories. In this scheme, class I agents are those with local anesthetic properties that block Na^+ channels, class II drugs are beta-blocking agents, class III drugs prolong action potential duration, and class IV drugs are calcium entry blockers. Amiodarone will be discussed in detail owing to its expanding role in treating both supraventricular and ventricular arrhythmias and because its use has replaced many of the previously used agents. Because of the efficacy of intravenous amiodarone and its recommendations in Advanced Cardiac Life Support

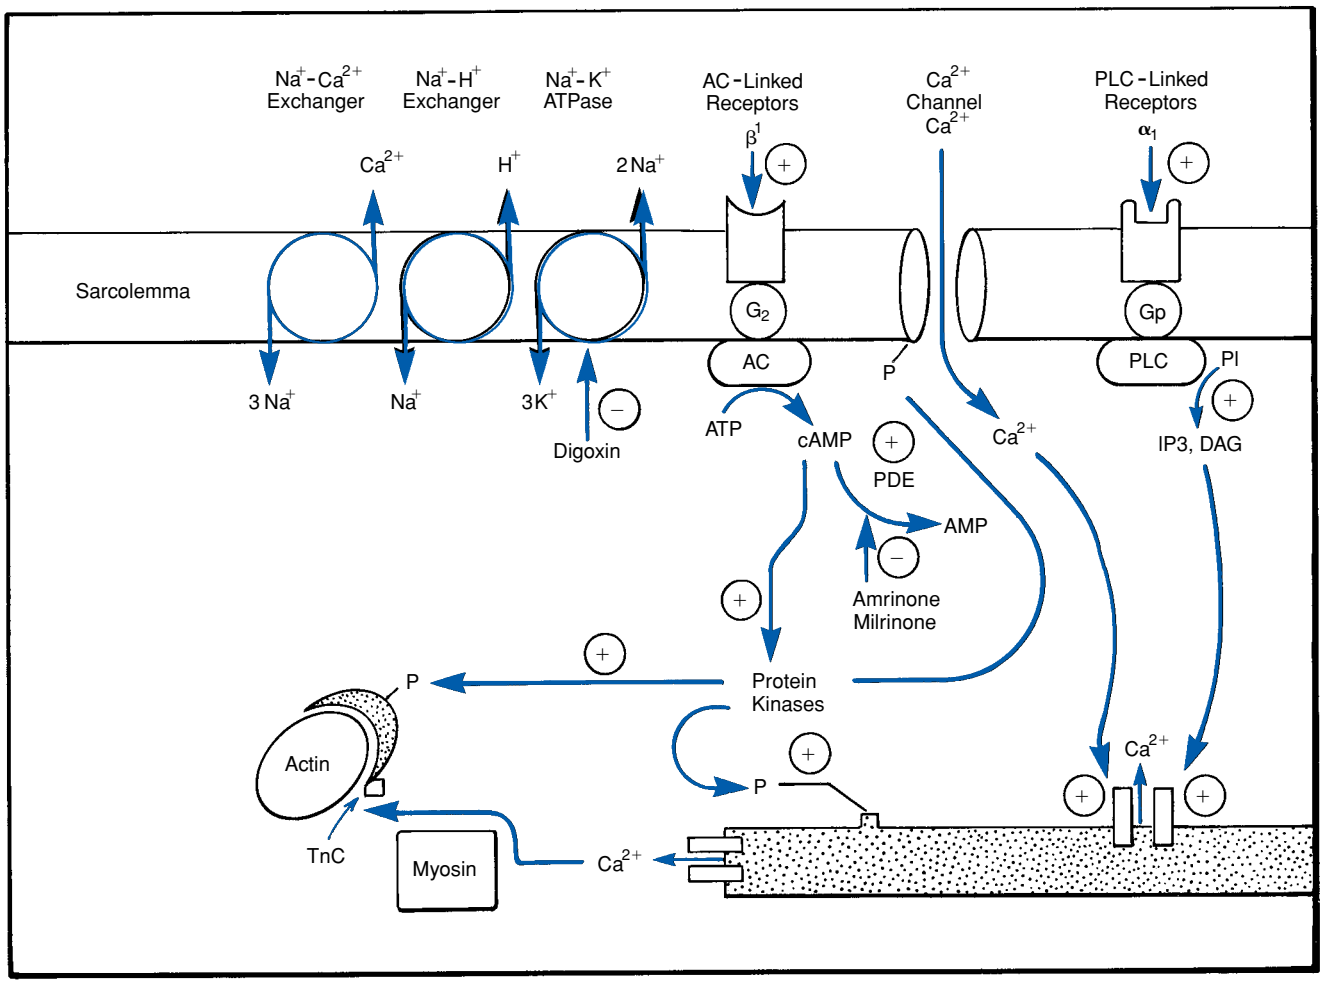

Figure 4-2. Mediators of cardiac contractility. Myocardial contractility is a manifestation of the interaction of actin and myosin, which is facilitated by the binding of calcium to troponin C (TnC). Intercellular calcium levels are controlled by direct flux across the membrane, by cyclic AMP, and by inositol triphosphate (IP_3) and diacylglycerol (DAG) produced by the action of phospholipase C (PLC). The synthesis of cyclic AMP is catalyzed by adenylate cyclase (AC), which is activated by binding of agonist to the beta-adrenergic receptor, and its breakdown is catalyzed by phosphodiesterase (PDE), which is inhibited by amrinone and milrinone. The action of PLC is activated by binding of agonist to the alpha-adrenergic receptor.

(ACLS) guidelines, many of the older drugs used in cardiac surgery have a historical perspective and will be considered briefly.

Class I Agents

While each of the class I agents blocks Na^+ channels, they may be subclassified based on electrophysiologic differences. These differences can be explained, to some extent, by consideration of the kinetics of the interaction of the drug and the Na^+ channel.[14,15] Class I drugs bind most avidly to open (phase 0 of the action potential; see Fig. 4-1) or inactivated (phase 2) Na^+ channels. Dissociation from the channel occurs during the resting (phase 4) state. If the time constant for dissociation is long in comparison with the diastolic interval (corresponding to phase 4), the drug will accumulate in the channel to reach a steady state, slowing conduction in normal tissue. This occurs with class Ia (e.g., procainamide, quinidine, and disopyramide) and class Ic (e.g., encainide, flecainide, and propafenone) drugs. In contrast, for the class Ib drugs (e.g., lidocaine and mexiletine), the time constant for dissociation from the Na^+ channel is short, drug does not accumulate in the channel, and conduction velocity is affected minimally. However, in ischemic tissue, the depolarized state is more persistent, leading to greater accumulation of agent in the Na^+ channel and slowing of conduction in the damaged myocardium.

Procainamide is a class Ia drug that has various electrophysiologic effects.[16] Administration may be limited by the side effects of hypotension and decreased cardiac output.[17,18] The loading dose is 20 to 30 mg/min, up to 17 mg/kg, and should be followed by an intravenous infusion of 20 to 80 mg/kg per minute. Since procainamide prolongs action potential duration, widening of the QRS complex often heralds a potential overdose. The elimination of procainamide involves hepatic metabolism, acetylation to a metabolite with antiarrhythmic and toxic side effects, and

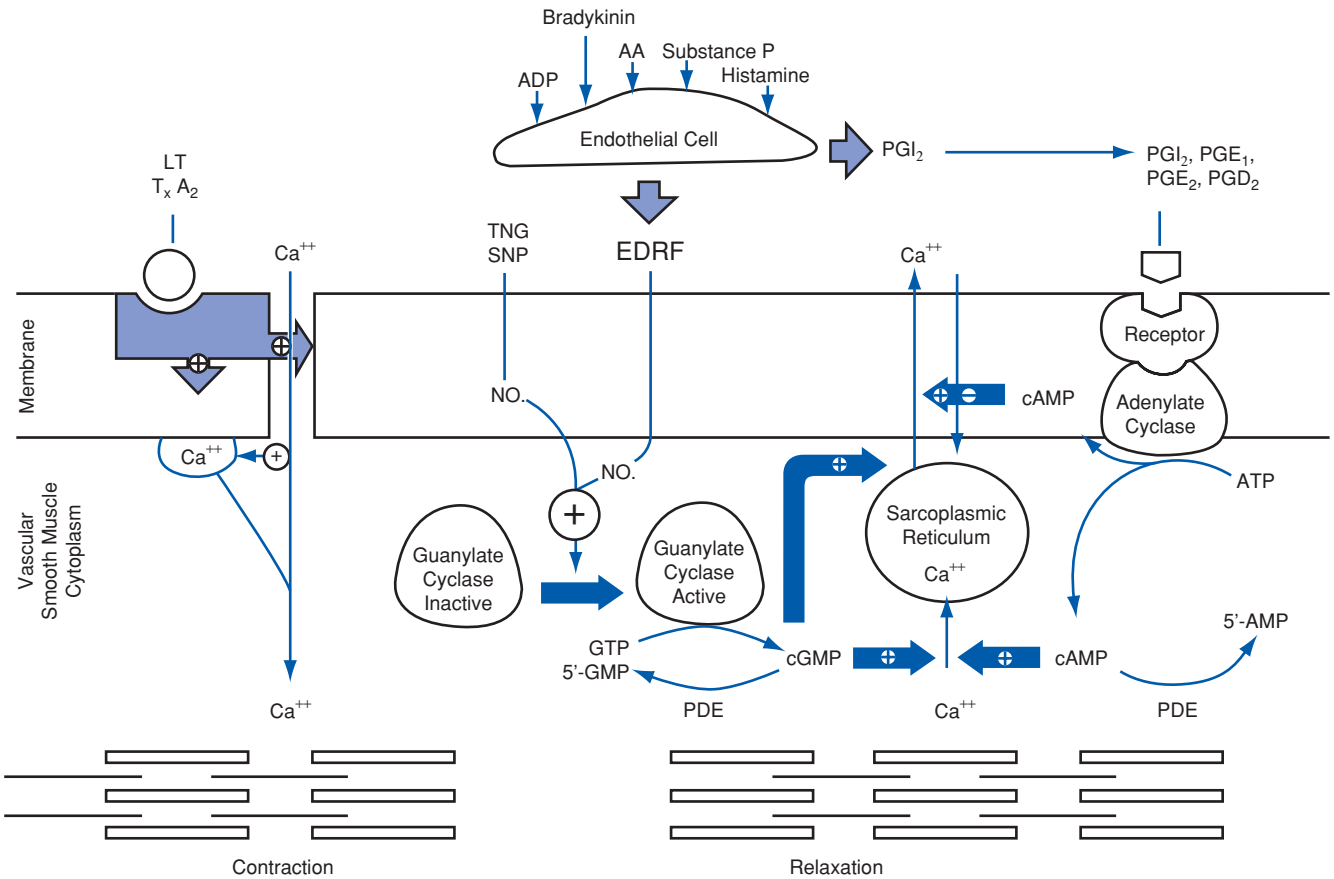

Figure 4-3. Mediators of vascular tone. Cyclic AMP and cyclic GMP increase the uptake of calcium into cellular storage sites in vascular smooth muscle, leading to vasodilation. The synthesis of cyclic GMP is catalyzed by guanylate cyclase, which is activated by nitric oxide (NO), which, in turn, is produced by nitroglycerin (NTG) and sodium nitroprusside (SNP). Excessive vasodilation often is a reflection of other endogenous mediators such as prostaglandins (PGI_2, PGE_1, PGE_2, and PGD_2) and thromboxane A_2 (TxA_2). Several mediators, such as arachidonic acid (AA), bradykinin, histamine, and substance P, stimulate the release of endothelium-derived relaxing factor (EDRF), which is identified with NO. renal elimination of this metabolite. Thus the infusion rate for patients with significant hepatic or renal disease should be at the lower end of this range.

Class Ib drugs include what is probably the best-known antiarrhythmic agent, lidocaine. As noted earlier, lidocaine is a Na^+ channel blocker that has little effect on conduction velocity in normal tissue but slows conduction in ischemic myocardium.[14,15] Other electrophysiologic effects include a decrease in action potential duration but a small increase in the ratio of effective refractory period to action potential duration. The exact role of these electrophysiologic effects on arrhythmia suppression is unclear. Lidocaine has no significant effects on atrial tissue, and it is not recommended for therapy in shock-resistant ventricular tachycardia/fibrillation (VT/VF) in the Guidelines 2000 for Emergency Cardiovascular Care.[19] After an initial bolus dose of 1 to 1.5 mg/kg of lidocaine, plasma levels decrease rapidly owing to redistribution to muscle, fat, etc. Effective plasma concentrations are maintained only by following the bolus dose with an infusion of 20 to 50 mg/kg per minute.[20] Elimination occurs via hepatic metabolism to active metabolites that are cleared by the kidney. Consequently, the dose should be reduced by approximately 50% in patients with liver or kidney disease. The primary toxic effects are associated with the central nervous system, and a lidocaine overdose may cause drowsiness, depressed level of consciousness, or seizures in very high doses. Negative inotropic or hypotensive effects are less pronounced than with most other antiarrhythmics. The other class Ib drugs likely to be encountered in the perioperative period are the oral agents tocainide and mexiletine, which have effects similar to lidocaine.[15]

The class Ic agents, including flecainide, encainide, and propafenone, markedly decrease conduction velocity.[20,21] The Cardiac Arrhythmia Suppression Trial (CAST) study[20,21] of moricizine found that while ventricular arrhythmias were suppressed, the incidence of sudden death was greater than with placebo with encainide and flecainide, and these drugs are not in wide use. Propafenone is available for oral use. The usual adult dose is 150 to 300 mg every 8 hours. It has beta-blocking (with resulting negative inotropic effects) as well as NA^+ channel-blocking activity; lengthens the PR, QRS, and QT duration; and may be used to treat both atrial and ventricular dysrhythmias.[15]

Class II Agents

Beta-receptor blocking agents are another important group of antiarrhythmic (denoted class II in the Vaughan Williams scheme). However, because of their use as antihypertensive as well as antiarrhythmic agents, they are discussed elsewhere in this chapter, and we will move on to consider bretylium, amiodarone, and sotalol, the class III agents in the Vaughan Williams scheme. These drugs have a number of complex ion channel-blocking effects, but possibly the most important activity is K^+ channel blockade.[22] Since the flux of K^+ out of the myocyte is responsible for repolarization, an important electrophysiologic effect of class III drugs is prolongation of the action potential.[23]

Class III Agents

Ibutilide, dofetilide, sotalol, and bretylium are class III agents. Intravenous ibutilide and oral dofetilide are approved for the treatment of atrial fibrillation but carry the risk of torsades de pointes.[24,25] Sotalol is a nonselective beta blocker that also has K^+ channel-blocking activity.[26] In the United States, it is available only for oral administration and has an approved indication for treating life-threatening ventricular arrhythmias, although it is effective against atrial arrhythmias as well. Bretylium is not used widely in 2006 and is not recommended in the Guidelines 2000 for Emergency Cardiovascular Care.[19]

Class IV Agents

Calcium entry blockers (class IV in the Vaughan Williams scheme), including verapamil and diltiazem, are antiarrhythmics. In sinoatrial and atrioventricular nodal tissue, Ca^{2+} channels contribute significantly to phase 0 depolarization, and the atrioventricular (AV) nodal refractory period is prolonged by Ca^{2+} entry blockade.[27,28] This explains the effectiveness of verapamil and diltiazem in treating supraventricular arrhythmias. It is also clear why these drugs are negative inotropes. Both verapamil and diltiazem are effective in slowing the ventricular response to atrial fibrillation, flutter, and paroxysmal supraventricular tachycardia and in converting to sinus rhythm.[29–31] Verapamil has greater negative inotrope effects than diltiazem, and therefore, it is used rarely for supraventricular arrhythmias. The intravenous dose of diltiazem is 0.25 mg/kg, with a second dose of 0.35 mg/kg if the response is inadequate after 15 minutes. The loading dose should be followed by an infusion of 5 to 15 mg/h. Intravenous diltiazem, although useful for rate control, has been replaced by intravenous amiodarone in clinical therapy of supraventricular tachycardia (SVT) and prophylaxis (see "Amiodarone" below).

Other Drugs

One of the difficulties of classifying antiarrhythmics by the Vaughan Williams classification is that not all drugs can be incorporated into this scheme. Three examples are digoxin, adenosine, and magnesium, each of which has important uses in the perioperative period.

Digoxin inhibits the Na^+,K^+-ATPase pump, leading to decreased intracellular K^+, a less negative resting membrane potential, increased slope of phase 4 depolarization, and decreased conduction velocity. These direct effects, however, usually are dominated by indirect effects, including inhibition of reflex responses to congestive heart failure and a vagotonic effect.[10,32] The net effect is greatest at the AV node, where conduction is slowed and the refractory period is increased, explaining the effectiveness of digoxin in slowing the ventricular response to atrial fibrillation. The major disadvantages of digoxin are the relatively slow onset of action and many side effects, including proarrhythmia effects, and it is now used rarely for rate control in acute atrial fibrillation because of the advent of IV amiodarone and diltiazem.

Adenosine is an endogenous nucleoside that has an electrophysiologic effect similar to that of acetylcholine. Adenosine decreases AV node conductivity, and its primary antiarrhythmic effect is to break AV nodal reentrant tachycardia.[33] An intravenous dose of 100 to 200 μg/kg is the treatment of choice for paroxysmal supraventricular tachycardia. Adverse effects, such as bronchospasm, are short-lived because its plasma half-life is so short (1 to 2 seconds). This short half-life makes it ideal for treating reentry dysrhythmia, in which transient interruption can fully suppress the dysrhythmia.

Appropriate acid-base status and electrolyte balance are important because electrolyte imbalance can perturb the membrane potential, leading to arrhythmia generation, as can altered acid-base status, by effects on K^+ concentrations and sympathetic tone. Therapy for dysrhythmia should include correction of acid-base and electrolyte imbalances. Magnesium supplementation should be considered.[34] Magnesium deficiency is common in the perioperative period, and magnesium administration has been shown to decrease the incidence of postoperative dysrhythmia.[35]

AMIODARONE

Intravenous amiodarone has become one of the most administered intravenous antiarrhythmics used in cardiac surgery because of its broad spectrum of efficacy. Amiodarone was developed originally as an antianginal agent because of its vasodilating effects, including coronary vasodilation.[36] It has various ion channel-blocking activities.[10,29,36] The resulting electrophysiologic effects are complex, and there are differences in acute intravenous and chronic oral administration. Acute intravenous administration can produce decreases in heart rate and blood pressure, but there are minimal changes in QRS duration or QT interval. After chronic use, there may be significant bradycardia and increases in action potential duration in AV nodal and ventricular tissue, with increased QRS duration and QT interval.[37–39]

Pharmacokinetics

Amiodarone is a complex drug, markedly lipophilic, that undergoes variable absorption (35 to 65%) after oral administration and is taken up extensively by multiple tissues with interindividual variation and complex pharmacokinetics.[38–40] The short initial context-sensitive half-life after intravenous administration represents drug redistribution. The true elimination half-life for amiodarone is extremely long, up to 40 to 60 days. Because of the huge volume of distribution (~60 L/kg) and a long duration of action, an active metabolite loading period of several months may be required before reaching steady-state tissue concentrations. Further, in life-threatening arrhythmias, intravenous loading often is starting to establish initial plasma levels. Measuring amiodarone plasma concentrations is not useful owing to the complex pharmacokinetics and the metabolites of the parent drug. Plasma concentrations greater than 2.5 mg/L have been associated with an increased risk of toxicity. The optimal dose of amiodarone has not been well characterized and may vary depending on the specific arrhythmias treated. Further, there may be differences in dose requirements for therapy of supraventricular and ventricular arrhythmias.[37–40]

Because of these distinctive pharmacokinetic properties, steady-state plasma levels are achieved slowly. Oral administration for a typical adult consists of a loading regimen of 80 to 1600 mg/d (in two or three doses) for 10 days, 600 to 800 mg/d for 4 to 6 weeks, and then maintenance doses of 200 to 600 mg/d. For intravenous loading, specific studies will be reviewed, but recommended dosing is 150 mg given over 10 minutes for acute therapy in an adult, followed first by a secondary loading infusion of 60 mg/h for 6 hours and then by a maintenance infusion of 30 mg/h to achieve a 1000 mg/d dosing.[37–40]

Electrophysiology

The electrophysiologic actions of amiodarone are complex and incompletely understood. Amiodarone produces all four effects according to the Vaughan Williams classification. It also has been shown to have use-dependent class I activity, inhibition of the inward sodium currents, and class II activity.[10] The antiadrenergic effect of amiodarone, however, is different from that of beta-blocker drugs because it is noncompetitive and additive to the effect of beta blockers. Amiodarone depresses sinoatrial (SA) node automaticity, which slows the heart rate and conduction and increases refractoriness of the AV node, properties useful in managing supraventricular arrhythmia. Its class III activity results in increases in atrial and ventricular refractoriness and in prolongation of the QTc interval. The effects of oral amiodarone on SA and AV nodal function are maximal within 2 weeks, whereas the effects on ventricular tachycardia (VT) and ventricular refractoriness emerge more gradually during oral therapy, becoming maximal after 10 weeks or more.

Indications

The primary indication for amiodarone is ventricular tachycardia or fibrillation refractory to other therapy.[40–48] It is the most efficacious agent for reducing ventricular arrhythmias and suppresses the incidence of post–myocardial infarction sudden death.[37] It is also effective, in doses lower than those used for ventricular dysrhythmia, for the treatment of atrial dysrhythmia and is effective in converting atrial fibrillation to sinus rhythm (see "Atrial Fibrillation" below).

Side Effects

Although there are numerous adverse reactions to amiodarone, they occur with long-term oral administration and have not been associated with acute intravenous administration. The most serious is pulmonary toxicity, which has not been reported with acute administration in a perioperative setting. Some case series have reported an increased risk of marked bradycardia and hypotension immediately after cardiac surgery in patients already on amiodarone at the time of surgery.[49,50] Other case-control studies, however, have not reproduced this finding.[51] None of the placebo-controlled trials of prophylactic amiodarone for perioperative atrial fibrillation prevention found any adverse cardiovascular effects of the drug.[52–56] Thus it is unlikely that amiodarone poses a serious cardiovascular risk to the postoperative patient. Case reports and case series of postoperative acute pulmonary toxicity are similarly lacking in the rigor of randomized, controlled methodology.

PHARMACOLOGIC THERAPY OF SPECIFIC ARRHYTHMIAS

Ventricular Tachyarrhythmias

Intravenous amiodarone is approved for rapid control of recurrent VT or VF. Three randomized, controlled trials of patients with recurrent in-hospital, hemodynamically unstable VT or VF with two or more episodes within the past 24 hours who failed to respond to or were intolerant of lidocaine, procainamide, and (in two of the trials) bretylium have been reported.[42,44,46] Patients were critically ill with ischemic cardiovascular disease, 25% were on a mechanical ventilator or intra-aortic balloon pump before enrollment, and 10% were undergoing cardiopulmonary resuscitation at the time of enrollment. One study compared three doses of IV amiodarone: 525, 1050, and 2100 mg/d.[44] Because of the use of investigator-initiated intermittent open-label amiodarone boluses for recurrent VT, the actual mean amiodarone doses received by the three groups were 742, 1175, and 1921 mg/d. There was no statistically significant difference in the number of patients without VT/VF recurrence during the 1-day study period: 32 of 86 (41%), 36 of 92 (45%), and 42 of 92 (53%) for the low-, medium-, and high-dose groups, respectively. The number of supplemental 150-mg bolus

infusions of amiodarone given by blinded investigators was statistically significantly less in those randomized to higher doses of amiodarone.

A wider range of amiodarone doses (125, 500, and 1000 mg/d) was evaluated by Sheinman and colleagues, including a low dose that was expected to be subtherapeutic.[46] This stronger study design, however, also was confounded by open-label bolus amiodarone injections given by study investigators. There was, however, a trend toward a relationship between intended amiodarone dose and VT/VF recurrence rate ($p = .067$). After adjustment for baseline imbalances, the median 24-hour recurrence rates of VT/VF, from lowest to highest doses, were 1.68, 0.96, and 0.48 events per 24 hours.

The third study compared two intravenous amiodarone doses (125 and 1000 mg/d) with bretylium (2500 mg/d).[42] Once again, the target amiodarone dose ratio of 8:1 was compressed to 1.8:1 because of open-label boluses. There was no significant difference in the primary outcome, which was median VT/VF recurrence rate over 24 hours. For low-dose amiodarone, high-dose amiodarone, and bretylium, these rates were 1.68, 0.48, and 0.96 events per 24 hours, respectively ($p = .237$). There was no difference between high-dose amiodarone and bretylium; however, more than 50% of patients had crossed over from bretylium to amiodarone by 16 hours.

The failure of these studies to provide clear evidence of amiodarone efficacy may be related to the "active-control study design" used, a lack of adequate statistical power, high rates of supplemental amiodarone boluses, and high crossover rates. Nonetheless, these studies provide some evidence that IV amiodarone (1 g/d) is moderately effective during a 24-hour period against VT and VF.

Sustained monomorphic ventricular tachycardia and wide qrs tachycardia

Although the most effective and rapid treatment of any hemodynamically unstable sustained ventricular tachyarrhythmia is electrical cardioversion or defibrillation, intravenous antiarrhythmic drugs can be used for arrhythmia termination if the VT is hemodynamically stable. The Guidelines 2000 for Emergency Cardiovascular Care[19] removed the former recommendation of lidocaine and adenosine use in stable wide QRS tachycardia, now labeled as "acceptable" but not primarily recommended (lidocaine) or not recommended (adenosine). Intravenous procainamide and sotalol are effective, based on randomized but small studies[10]; amiodarone is also considered acceptable.[19]

Shock-resistant ventricular fibrillation

The Guidelines 2000 for Emergency Cardiovascular Care recommend at least three shocks and epinephrine or vasopressin before any antiarrhythmic drug is administered.[10,19] No large-scale controlled, randomized studies have demonstrated efficacy for lidocaine, bretylium, or procainamide in shock-resistant VF,[10,19] and lidocaine and bretylium are no longer recommended in this setting.[19] Two pivotal studies have been reported recently studying the efficacy of agents in acute shock-resistant cardiac arrest.

The Amiodarone in the Out-of-Hospital Resuscitation of Refractory Sustained Ventricular Tachycardia (ARREST) study was randomized, double- blind, and placebo-controlled. The ARREST study in 504 patients showed that amiodarone 300 mg administered in a single intravenous bolus significantly improves survival to hospital admission in cardiac arrest still in VT or VF after three direct-current shocks (44% versus 34%; $p < .03$).[43] Although the highest survival rate to hospital admission (79%) was achieved when the amiodarone was given within 4 to 16 minutes of dispatch, there was no significant difference in the proportional improvement in the amiodarone group compared with the placebo group when drug administration was delayed (up to 55 minutes). Amiodarone also had the highest efficacy in patients (21% of all study patients) who had a return of spontaneous circulation before drug administration (survival to hospital admission increased to 64% from 41% in the placebo group). Among patients with no return of spontaneous circulation, amiodarone only slightly improved outcome (38% versus 33%).

Dorian performed a randomized trial comparing intravenous lidocaine with intravenous amiodarone as an adjunct to defibrillation in victims of out-of-hospital cardiac arrest.[48] Patients were enrolled if they had out-of-hospital ventricular fibrillation resistant to three shocks, intravenous epinephrine, and a further shock or if they had recurrent ventricular fibrillation after initially successful defibrillation. They were randomly assigned in a double-blind manner to receive intravenous amiodarone plus lidocaine placebo or intravenous lidocaine plus amiodarone placebo. The primary endpoint was the proportion of patients who survived to be admitted to the hospital. In total, 347 patients (mean age 67 $\pm$ 14 years) were enrolled. The mean interval between the time at which paramedics were dispatched to the scene of the cardiac arrest and the time of their arrival was 7 $\pm$ 3 minutes, and the mean interval from dispatch to drug administration was 25 $\pm$ 8 minutes. After treatment with amiodarone, 22.8% of 180 patients survived to hospital admission compared with 12.0% percent of 167 patients treated with lidocaine ($p = .009$). Among patients for whom the time from dispatch to the administration of the drug was equal to or less than the median time (24 minutes), 27.7% of those given amiodarone and 15.3% of those given lidocaine survived to hospital admission ($p = .05$). The authors concluded that compared with lidocaine, amiodarone leads to substantially higher rates of survival to hospital admission in patients with shock-resistant out-of-hospital ventricular fibrillation.

Supraventricular Arrhythmias

A supraventricular arrhythmia is any tachyarrhythmia that requires atrial or atrioventricular junctional tissue for initiation and maintenance. It may arise from reentry caused by

unidirectional conduction block in one region of the heart and slow conduction in another, from enhanced automaticity akin to that seen in normal pacemaker cells of the sinus node and in latent pacemaker cells elsewhere in the heart, or from triggered activity, a novel type of abnormally enhanced impulse initiation caused by membrane currents that can be activated and inactivated by premature stimulation or rapid pacing.[56–58] Pharmacologic approaches to treating supraventricular arrhythmias, including atrial fibrillation, atrial flutter, atrial tachycardia, AV reentrant tachycardia, and AV nodal reentrant tachycardia, continue to evolve.[56–60] Because atrial fibrillation is perhaps the most common arrhythmia after cardiac surgery, this condition will be emphasized in detail.

Atrial Fibrillation

Atrial fibrillation (AF) is a common complication of cardiac surgery that increases the length of stay in the hospital with resulting increases in health care resource utilization.[56–61] Advanced age, previous AF, and valvular heart operations are the most consistently identified risk factors for this arrhythmia. Because efforts to terminate AF after its initiation are problematic, current interests are directed at therapies to prevent postoperative AF. Most studies suggest that prophylaxis with antiarrhythmic compounds can decrease the incidence of AF, length of hospital stay, and cost significantly. Class III antiarrhythmic drugs (e.g., sotalol and ibutilide) also may be effective but potentially pose the risk of drug-induced polymorphic ventricular tachycardia (torsades de pointes). Newer promising intravenous agents (RSD1235) are also being investigated. Defining which subpopulations benefit most from such therapy is important as older and more critically ill patients undergo surgery.

Amiodarone is also an effective approach for prophylactic therapy of AF. Intravenous amiodarone is an important consideration because loading with oral therapy is often not feasible in part owing to time required. There also may be added benefits of prophylactic therapies in high-risk patients, especially those prone to ventricular arrhythmias (i.e., patients with preexisting heart failure).

Two studies deserve mention regarding prophylaxis with amiodarone. To determine if IV amiodarone would prevent atrial fibrillation and decrease hospital stay after cardiac surgery, Daoud assessed preoperative prophylaxis in 124 patients who were given either oral amiodarone (64 patients) or placebo (60 patients) for a minimum of 7 days before elective cardiac surgery.[62] Therapy consisted of 600 mg amiodarone per day for 7 days and then 200 mg/d until the day of discharge from the hospital. The preoperative total dose of amiodarone was 4.8 ± 0.96 g over 13 ± 7 days. Postoperative atrial fibrillation occurred in 16 of the 64 patients in the amiodarone group (25%) and 32 of the 60 patients in the placebo group (53%). Patients in the amiodarone group were hospitalized for significantly fewer days than were patients in the placebo group (6.5 ± 2.6 versus 7.9 ± 4.3 days; $p = .04$). Total hospitalization costs were significantly less for the amiodarone group than for the placebo group ($18,375 ± $13,863 versus $26,491 ± $23,837; $p = .03$). Guarnieri evaluated 300 patients randomized in a double-blind fashion to IV amiodarone (1 g/d for 2 days) versus placebo immediately after open-heart surgery.[54] The primary endpoints of the trial were incidence of atrial fibrillation and length of hospital stay. Atrial fibrillation occurred in 67 of 142 (47%) patients on placebo versus 56 of 158 (35%) on amiodarone ($p = .01$). Length of hospital stay for the placebo group was 8.2 ± 6.2 days, and 7.6 ± 5.9 days for the amiodarone group. Low-dose IV amiodarone was safe and effective in reducing the incidence of atrial fibrillation after heart surgery but did not significantly alter length of hospital stay.

In summary, AF is a frequent complication of cardiac surgery. Many cases can be prevented with appropriate prophylactic therapy. Beta-adrenergic blockers should be administered to most patients without contraindication. Prophylactic amiodarone should be considered in patients at high risk for postoperative AF. The lack of data on cost benefits and cost-efficiency in some studies may reflect the lack of higher-risk patients in the study. Patients who are poor candidates for beta blockade may not tolerate sotalol, whereas amiodarone does not have this limitation. Additional studies also need to be performed to better assess the role of prophylactic therapy in off-pump cardiac surgery.

INOTROPIC AGENTS

Some depression of myocardial function is common after cardiac surgery.[63–65] The etiology is multifactorial—preexisting disease, incomplete repair or revascularization, myocardial edema, postischemic dysfunction, reperfusion injury, etc.—and usually is reversible. Adequate cardiac output usually can be maintained by exploiting the Starling curve with higher preload, but often the cardiac function curve is flattened, and it is necessary to use inotropic agents to maintain adequate organ perfusion.

The molecular basis for the contractile property of the heart is the interaction of the proteins actin and myosin, in which chemical energy (in the form of ATP) is converted into mechanical energy. In the relaxed state (diastole), the interaction of actin and myosin is inhibited by tropomyosin, a protein associated with the actin-myosin complex. With the onset of systole, Ca^{2+} enters the myocyte (during phase 1 of the action potential). This influx of Ca^{2+} triggers the release of much larger amounts of Ca^{2+} from the sarcoplasmic reticulum. The binding of Ca^{2+} to the C subunit of the protein troponin interrupts inhibition of the actin-myosin interaction by tropomyosin, facilitating the hydrolysis of ATP with the generation of a mechanical force. With repolarization of the myocyte and completion of systole, Ca^{2+} is taken back up into the sarcoplasmic reticulum, allowing tropomyosin to again inhibit the interaction of actin and myosin with consequent relaxation of contractile force. Thus inotropic action is mediated by intracellular Ca^{2+}.[66] A novel

drug, levosimendan, currently under clinical development in the United States but approved in several countries, increases the sensitivity of the contractile apparatus to Ca^{2+},[67] whereas the positive inotropic agents available for clinical use achieve their end by increasing intracellular Ca^{2+} levels.

The first drug to be considered is simply Ca^{2+} itself. In general, administration of calcium will increase the inotropic state of the myocardium when measured by load-independent methods, but it also will increase vascular tone (afterload) and impair diastolic function. In addition, the effects of calcium on myocardial performance depend on the plasma Ca^{2+} concentration. Ca^{2+} plays important roles in cellular function, and the intracellular Ca^{2+} concentration is highly regulated by membrane ion channels and intracellular organelles.[68,69] If the extracellular Ca^{2+} concentration is normal, administration of Ca^{2+} will have little effect on the intracellular level and will have less pronounced hemodynamic effects. On the other hand, if the ionized plasma calcium concentration is low, exogenous calcium administration may increase cardiac output and blood pressure.[70] It also should be realized that even with normal plasma Ca^{2+} concentrations, administration of Ca^{2+} may increase vascular tone, leading to increased blood pressure but no change in cardiac output. This increased afterload, as well as the deleterious effects on diastolic function, may be the basis of the observation that Ca^{2+} administration can blunt the response to epinephrine.[71] Routine use of Ca^{2+} at the end of bypass should be tempered by the realization that Ca^{2+} may have little effect on cardiac output while increasing systemic vascular resistance, although this in itself may be of importance. If there is evidence of myocardial ischemia, Ca^{2+} administration may be deleterious because it may exacerbate both coronary spasm and the pathways leading to cellular injury.[72,73]

Digoxin, while not effective as acute therapy for low-cardiac-output syndrome in the perioperative period, nevertheless well illustrates the role of intracellular Ca^{2+}. Digoxin functions by inhibiting Na^+,K^+-ATPase, which is responsible for the exchange of intracellular Na^+ with extracellular K^+.[3,4] It is thus responsible for maintaining the intracellular/extracellular K^+ and Na^+ gradients. When it is inhibited, intracellular Na^+ levels increase. The increased intracellular Na^+ is an increased chemical potential for driving the Ca^{2+}/Na^+ exchanger, an ion exchange mechanism in which intracellular Na^+ is removed from the cell in exchange for Ca^{2+}. The net effect is an increase in intracellular Ca^{2+} with an enhancement of the inotropic state.

The most commonly used positive inotropic agents are the beta-adrenergic agonists. The $beta_1$ receptor is part of a complex consisting of the receptor on the outer surface of the cell membrane and membrane-spanning G-proteins (so named because they bind GTP), which, in turn, stimulate adenylate cyclase on the inner surface of the membrane, catalyzing the formation cyclic adenosine monophosphate (cAMP). The inotropic state is modulated by cAMP via its catalysis of phosphorylation reactions by protein kinase A. These phosphorylation reactions "open" Ca^{2+} channels on the cell membrane and lead to greater release and uptake of Ca^{2+} from the sarcoplasmic reticulum.[3,4]

There are many drugs that stimulate $beta_1$ receptors and have a positive inotropic effect, including epinephrine, norepinephrine, dopamine, isoproterenol, and dobutamine, the most commonly used catecholamines in the perioperative period. While there are differences in their binding at the $beta_1$ receptor, the most important differences between the various catecholamines are their relative effects on alpha- and $beta_2$-adrenergic receptors. In general, alpha stimulation of receptors on the peripheral vasculature causes vasoconstriction, whereas $beta_2$ stimulation leads to vasodilation (see the discussion elsewhere in this chapter). For some time it was believed that $beta_2$ and alpha receptors were found only in the peripheral vasculature, as well as a few other organs, but not in the myocardium. However, alpha receptors are found in the myocardium and mediate a positive inotropic effect.[5,6] The mechanism for this positive inotropic effect is probably the stimulation of phospholipase C, leading to hydrolysis of phosphatidyl inositol to diacylglycerol and inositol triphosphate, compounds that increase Ca^{2+} release from the sarcoplasmic reticulum and increase myofilament sensitivity to Ca^{2+}. It is also possible that alpha-adrenergic agents increase intracellular Ca^{2+} by prolonging action potential duration by inhibition of outward K^+ currents during repolarization or by activating the Na^+/H^+ exchange mechanism, increasing intracellular pH and increasing myofilament sensitivity to Ca^{2+}. Just as the exact mechanism is uncertain, the exact role of alpha-adrenergic stimulation in control of the inotropic state is unclear, although it is apparent that onset of the effect is slower than that of $beta_1$ stimulation.

Besides the discovery of alpha receptors in the myocardium, $beta_2$ receptors are present in the myocardium.[74] The fraction of $beta_2$ receptors (compared with $beta_1$ receptors) is increased in chronic heart failure, possibly explaining the efficacy of drugs with $beta_2$ activity in this setting. This phenomenon is part of the general observation of $beta_1$-receptor downregulation (decrease in receptor density) and desensitization (uncoupling of effect from receptor binding) that is observed in chronic heart failure.[75] Interestingly, it has been demonstrated in a dog model that this same phenomenon occurs with cardiopulmonary bypass (CPB).[76] In this situation, a newer class of drugs, the phosphodiesterase inhibitors, may be of benefit. These drugs, typified by the agents available in the United States, amrinone and milrinone, increase cAMP levels independently of the beta receptor by selectively inhibiting the myocardial enzyme responsible for the breakdown of cAMP.[3,4]

In clinical use, selection of a particular inotropic agent usually is based more on its side effects than on its direct inotropic properties. Of the commonly used catecholamines, norepinephrine has alpha and $beta_1$ but little $beta_2$ activity and is both an inotrope and a vasopressor. Epinephrine and dopamine are mixed agonists with alpha, $beta_1$, and $beta_2$ activity. At lower doses, they are primarily inotropes and not

vasopressors, although vasopressor effects become more pronounced at higher doses. This is especially true for dopamine, which achieves effects at higher doses by stimulating the release of norepinephrine.[77] Dobutamine is a more selective beta$_1$ agonist, in contrast to isoproterenol, which is a mixed beta agonist. Selection of a drug depends on the particular hemodynamic problem at hand. For example, a patient with depressed myocardial function in the presence of profound vasodilation may require a drug with both positive inotropic and vasopressor effects, whereas a patient who is vasoconstricted may benefit from some other choice. We recommend an empirical approach to selecting inotropic agents with careful monitoring of the response to the drug and selection of the agent that achieves the desired effect.

Clinical experience suggests that phosphodiesterase inhibitors can be effective when catecholamines do not produce an acceptable cardiac output.[78–80] There are few differences in the hemodynamic effects of the two drugs available for use in the United States, amrinone and milrinone. Both agents increase contractility with little effect on heart rate, and both are vasodilators. There is significant venodilation, as well as arteriodilation, and maintaining adequate preload is important in avoiding significant hypotension.[81,82] If amrinone is used, the bolus dose recommended in the product insert, 0.75 mg/mL, is inadequate to maintain therapeutic plasma levels, and a loading dose of 1.5 to 2.0 mg/mL should be used.[83] With either drug, administering the loading dose over 15 to 30 minutes may attenuate possible hypotension. Plasma levels drop rapidly after a loading dose because of redistribution, and the loading dose should be followed immediately by a continuous infusion.[83,84] Because of their longer half-lives, it is rather more difficult to readily titrate plasma levels than with catecholamines (which have plasma half-lives of a few minutes).

Phosphodiesterase inhibitors, specifically milrinone, facilitate separation from CPB with biventricular dysfunction and are used for treating low-cardiac-output syndrome after cardiac surgery.[82,85–87] Doolan and colleagues also demonstrated that milrinone, in comparison with placebo, significantly facilitated separation of high-risk patients from CPB.[88]

Levosimendan

Levosimendan is a new class of drugs known as *calcium sensitizers*. The molecule is a pyridazinone-dinitrile derivative with additional action on adenosine triphosphate (ATP)–sensitive potassium channels.[67,89,90] Levosimendan is used intravenously for the treatment of decompensated cardiac failure, demonstrating enhanced contractility with no increase in oxygen demands, and produces antistunning effects without increasing myocardial intracellular calcium concentrations or prolonging myocardial relaxation. Levosimendan also causes coronary and systemic vasodilation. In patients with decompensated congestive heart failure, IV levosimendan reduced the incidence of worsening congestive heart failure (CHF) or death significantly. IV levosimendan significantly increased cardiac output or cardiac index and decreased filling pressure in the acute treatment of stable or decompensated CHF in large, double-blind, randomized trials and after cardiac surgery in smaller trials. Levosimendan is well tolerated and has not been shown to be arrhythmogenic. In addition to sensitizing troponin to intracellular calcium, levosimendan has been shown to inhibit phosphodiesterase III and open ATP-sensitive potassium channels (K_{ATP}), which may produce vasodilation. Unlike currently available intravenous inotropes, levosimendan does not increase myocardial oxygen use, has not been shown to be proarrhythmic, and has been used effectively in the presence of beta-blocking medications. Levosimendan also has not been shown to impair ventricular relaxation, which was an initial concern with this class of drugs. Clinical studies have demonstrated short-term hemodynamic benefits of levosimendan over both placebo and dobutamine. While large-scale, long-term morbidity and mortality data are scarce, the Levosimendan Infusion versus Dobutamine in Severe Low-Output Heart Failure (LIDO) study suggested a mortality benefit of levosimendan over dobutamine up to 180 days after treatment. Clinical studies comparing levosimendan with other positive inotropes, namely, milrinone, are lacking. Levosimendan treatment appears to be well tolerated, with the primary adverse events being headache and hypotension.

Clinical Trials

Despite their common use after cardiac surgery, there have been relatively few comparative studies of inotropic agents in the perioperative period. In 1978, Steen and colleagues reported the hemodynamic effects of epinephrine, dobutamine, and epinephrine immediately after separation from CPB.[91] The largest mean increase in cardiac index was achieved with dopamine at 15 μg/kg per minute. However, it should be noted that the only epinephrine dose studied was 0.04 μg/kg per minute. In a later comparison of dopamine and dobutamine, Salomon and colleagues concluded that dobutamine produced more consistent increases in cardiac index, although the hemodynamic differences were small, and all patients had good cardiac indices at the onset of the study.[92] Fowler and colleagues also found insignificant differences in the hemodynamic effects of dobutamine and dopamine, although they reported that coronary flow increased more in proportion to myocardial oxygen consumption with dobutamine.[93] While neither of these groups reported significant increases in heart rate for either dopamine or dobutamine, clinical experience has been otherwise. This is supported by a study by Sethna and colleagues, who found that the increase in cardiac index with dobutamine occurs simply because of increased heart rate, although they found that myocardial oxygen was maintained.[94] Butterworth and colleagues subsequently demonstrated that the older and much cheaper agent, epinephrine, effectively increased stroke volume without as great an increase in heart rate as dobutamine.[95] More recently, Feneck and colleagues compared dobutamine and milrinone and found them to be equally effective in treating low-cardiac-output syndrome after cardiac surgery.[96] This study was a comparison of two drugs,

and the investigators emphasized that the most efficacious therapy is probably a combination of drugs. In particular, phosphodiesterase inhibitors require the synthesis of cAMP to be effective, and thus use of a combination of a $beta_1$-adrenergic agonist and a phosphodiesterase inhibitor would be predicted to be more effective than either agent alone.

Finally, while global hemodynamic goals (i.e., heart rate, blood pressure, filling pressures, and cardiac output) may be achieved with inotropic agents, this does not guarantee adequate regional perfusion, in particular renal and mesenteric perfusion. So far there have been few investigations of regional perfusion after cardiac surgery. There has been more interest in regional (especially mesenteric) perfusion in the critical-care medicine literature, and some of the studies may be relevant to postoperative care of the cardiac surgical patient. Two studies have indicated that epinephrine may impair splanchnic perfusion, especially in comparison with combining norepinephrine and dobutamine.[97,98] Norepinephrine alone has variable effects on splanchnic blood flow in septic shock,[99] although adding dobutamine can improve splanchnic perfusion significantly when blood pressure is supported with norepinephrine.[98] Low-dose dopamine improves splanchnic blood flow,[100] but there is evidence that dopamine in higher doses impairs gastric perfusion.[101] The relevance of these studies of septic patients for the cardiac surgical patient is unclear, although there are similarities between the inflammatory responses to CPB and to sepsis.

VASOPRESSORS

CPB often is characterized by derangements of vascular tone. Sometimes CPB induces elevations in endogenous catecholamines, as well as other mediators, such as serotonin and arginine vasopressin (AVP), leading to vasoconstriction. However, often CPB is characterized by endothelial injury and a systemic inflammatory response, with a cascade of cytokine and inflammatory mediator release and profound vasodilation. The pathophysiology has a striking resemblance to that of sepsis or an anaphylactic reaction. Further, vasodilation after cardiac surgery may be exacerbated by the preoperative use of angiotensin-converting enzyme (ACE) inhibitors and post-CPB use of milrinone.

The mechanisms of vasodilatory shock have been reviewed recently.[102] Vascular tone is modulated by intracellular Ca^{2+}, which binds calmodulin. The Ca^{2+}-calmodulin complex activates myosin light-chain kinase, which catalyzes the phosphorylation of myosin to facilitate the interaction with actin. Conversely, intracellular cGMP activates myosin phosphatase (also via a kinase-mediated phosphorylation of myosin phosphatase), which dephosphorylates myosin and inhibits the interaction of actin and myosin. A primary mediator of vasodilatory shock is nitric oxide (NO), which is induced by cytokine cascades. NO activates guanylate cyclase, with resulting loss of vascular tone. Another mechanism of vasodilation that may be particularly relevant to prolonged CPB is activation of ATP-sensitive potassium (K_{ATP}) channels. These channels are activated by decreases in cellular ATP or increases in hydrogen ion or lactate. All these could result from the abnormal perfusion associated with CPB and/or hypothermia. Increases in potassium channel conductance result in hyperpolarization of the vascular smooth muscle membrane, which decreases Ca^{2+} flux into the cell, leading to decreased vascular tone. A third mechanism of vasodilatory shock that also may be particularly relevant to cardiac surgery is deficiency of vasopressin. As noted earlier, CPB often induces the release of vasopressin, and this may contribute to the excessive vasoconstriction sometimes seen after CPB. However, it has been observed in several experimental models of shock that the initially high levels of vasopressin decrease as shock persists, leading some investigators to suggest that vasopressin stores are limited and are depleted by the initial response to hypotension.

Excessive vasodilation during shock usually is treated with catecholamines, most typically phenylephrine, dopamine, epinephrine, or norepinephrine.[103] Although catecholamines produce both alpha- and beta-adrenergic effects, $alpha_1$-adrenergic receptor stimulation produces vasoconstriction. As noted earlier, stimulation of these receptors activates membrane phospholipase C, which, in turn, hydrolyzes phosphatidylinositol 4,55 diphosphate.[7] This leads to the subsequent generation of two second messengers, including diacyl glycerol and inositol triphosphate. Both these second messengers increase cytosolic Ca^{2+} by different mechanisms, which include facilitating release of calcium from the sarcoplasmic reticulum and potentially increasing the calcium sensitivity of the contractile proteins in vascular smooth muscle.

Mediator-induced vasodilation often is poorly responsive to catecholamines,[103] and the most potent pressor among catecholamines, norepinephrine, is required frequently. Some clinicians are concerned about renal, hepatic, and mesenteric function during norepinephrine administration. However, in septic patients, norepinephrine can improve renal function,[102–107] and there is evidence that it may improve mesenteric perfusion as well.[108] Given the hemodynamic similarities between septic patients and some patients at the end of CPB, these results often are extrapolated to the cardiac surgical patient but have not been confirmed by a systematic study. In some cases of profound vasodilatory shock, even norepinephrine is inadequate to restore systemic blood pressure. In this situation, low doses of vasopressin may be useful. Argenziano and colleagues[109] studied 40 patients with vasodilatory shock (defined as a mean arterial blood pressure of less than 70 mm Hg with a cardiac index greater than 2.5 L/m^2 per minute) after cardiac surgery. Arginine vasopressin levels were inappropriately low in this group of patients, and low-dose vasopressin infusion ($\leq$0.1 units/min) effectively restored blood pressure and reduced norepinephrine requirements without significantly changing cardiac index. These observations were similar to an earlier report of the use of vasopressin in vasodilatory septic shock.[110] Vasopressin also has been reported to be useful in treating milrinone-induced hypotension.[111] In this latter report, vasopressin was reported

to increase urine output, presumably via glomerular efferent arteriole constriction. However, the overall effects on renal function are unclear. In addition, there are still important unanswered questions about vasopressin and mesenteric perfusion. While vasopressin effectively may restore blood pressure in vasodilatory shock, it must be remembered that in physiologic concentrations it is a mesenteric vasoconstrictor, and mesenteric hypoperfusion may be a factor in developing sepsis and multiorgan dysfunction syndrome.

VASODILATORS

Different pharmacologic approaches are available to produce vasodilation (Table 4-1). Potential therapeutic approaches include (1) blockade of alpha$_1$-adrenergic receptors, ganglionic transmission, and calcium channel receptors, (2) stimulation of central alpha$_2$-adrenergic receptors or vascular guanylate cyclase and adenylate cyclase, and (3) inhibition of phosphodiesterase enzymes and angiotensin-converting enzymes.[112] Adenosine in low concentrations is also a potent vasodilator with a short half-life, but it is used, as noted earlier, for its ability to inhibit atrioventricular conduction. Losartan, a novel angiotensin II (AII) antagonist, has just been released for treating hypertension but is not available for intravenous use.

Stimulation of Adenylate Cyclase (Cyclic AMP)

Prostacyclin, prostaglandin E$_1$, and isoproterenol increase cyclic nucleotide formation (e.g., adenosine-3′,5′-monophosphate and cyclic AMP) in vascular smooth muscle to produce calcium mobilization out of vascular smooth muscle. Inhibiting the breakdown of cyclic AMP by phosphodiesterase also will increase cyclic AMP.[112] Increasing cyclic AMP in vascular smooth muscle facilitates calcium uptake by intracellular storage sites, thus decreasing calcium available for contraction. The net effect of increasing calcium uptake is to produce vascular smooth muscle relaxation and hence vasodilation. However, most catecholamines with beta$_2$-adrenergic activity (e.g., isoproterenol) and phosphodiesterase inhibitors have positive inotropic and other side effects that include tachycardia, glycogenolysis, and kaluresis.[113] Prostaglandins (i.e., prostacyclin and prostaglandin E$_1$) are potent inhibitors of platelet aggregation and activation. Catecholamines with beta$_2$-adrenergic activity, phosphodiesterase inhibitors, and prostaglandin E$_1$ and prostacyclin have been used to vasodilate the pulmonary circulation in patients with pulmonary hypertension and right ventricular failure.[113]

Table 4–1.

Vasodilators Used in the Treatment of Hypertension, Pulmonary Hypertension, and Heart Failure

Angiotensin-converting enzyme inhibitors
Angiotensin II Antagonists
Alpha$_1$-adrenergic antagonists (prazosin)
Alpha$_2$-adrenergic agonists (clonidine)
Nitrates
Nitric oxide
Hydralazine
Prostacyclin
Calcium channel blockers
Dihydropyridine agents (nifedipine, nicardipine, felodipine, amlodipine)

Nitrates, Nitrovasodilators, and Stimulation of Guanylyl Cyclase (Cyclic GMP)

The vascular endothelium modulates vascular relaxation by releasing both nitric oxide and prostacyclin.[114–116] Inflammatory mediators also can stimulate the vascular endothelium to release excessive amounts of endothelium-derived relaxing factor (EDRF, or nitric oxide), which activates guanylyl cyclase to generate cyclic GMP.[89,90] Nitrates and sodium nitroprusside, however, generate nitric oxide directly, independent of vascular endothelium.[115,116] The active form of any nitrovasodilator is nitric oxide (NO), in which the nitrogen is in a +2 oxidation state. For any nitrovasodilator to be active, it first must be converted to nitric oxide. For nitroprusside, this is easily accomplished because nitrogen is in a +3 oxidation state, with the nitric oxide molecule bound to the charged iron molecule in an unstable manner, allowing nitroprusside to readily donate its nitric oxide moiety. For nitroglycerin, nitrogen molecules exist in a +5 oxidation state, and thus they must undergo significant metabolic transformations before they are converted to an active molecule. Nitroglycerin is a selective coronary vasodilator and does not produce coronary steal compared with nitroprusside because the small intracoronary resistance vessels, those less than 100 μm thick, lack whatever metabolic transformation pathway is required to convert nitroglycerin into its active form of nitric oxide.[115,116] Chronic nitrate therapy can produce tolerance through different mechanisms, as shown in Table 4-2.[114–118] Sodium nitroprusside and nitroglycerin are effective vasodilators that produce venodilation that contributes significantly to the labile hemodynamic state.[114] Intravenous volume administration often is required with nitroprusside owing to the relative intravascular hypovolemia.

Dihydropyridine Calcium Channel Blockers

Dihydropyridine calcium channel blockers are direct arterial vasodilators.[119] Nifedipine was the first dihydropyridine calcium channel blocker, and the newer second-generation water-soluble agents that are available in intravenous form include isradipine and nicardipine. Isradipine and nicardipine produce arterial vasodilation without any effects on the vascular capacitance bed, no effects on atrioventricular nodal conduc-

Table 4–2.

Mechanisms of Nitrate Tolerance

Classic
Decreased bioconversion to nitric oxide

Increased vasopressin, catecholamines
Novel
Increased superoxide anion production
Increased production of endothelin-1 via protein kinase C–mediated mechanisms

tion, and no depression of ventricular function (i.e., contractility).[120–125] Nicardipine is the first intravenous drug of this class to be available in the United States, and it offers a novel and important therapeutic option to treat perioperative hypertension following cardiac surgery. Because currently available intravenous calcium channel blockers have longer half-lives than nitrovasodilators, rapid loading infusion rates or bolus loading doses need to be administered to obtain therapeutic levels. Bolus nicardipine administration also can be used to treat acute hypertension that occurs during the perioperative period (i.e., intubation, extubation, cardiopulmonary bypass–induced hypertension, and aortic cross-clamping). Clevidipine, a new short-acting agent of this class, is under investigation.

Phosphodiesterase Inhibitors

The phosphodiesterase inhibitors currently available for use produce both positive inotropic effects and vasodilation.[126] When administered to patients with ventricular dysfunction, they increase cardiac output while decreasing pulmonary artery occlusion pressure, systemic vascular resistance, and pulmonary vascular resistance. Because of their unique mechanisms of vasodilation, they are especially useful for patients with acute pulmonary vasoconstriction and right ventricular dysfunction. Multiple forms of the drug are currently under investigation. The bipyridines (e.g., amrinone and milrinone), the imidazolones (e.g., enoximone), and the methylxanthines (e.g., aminophylline) are the ones most widely available. Papaverine, a benzyl isoquinolinium derivative isolated from opium, is a nonspecific phosphodiesterase inhibitor and vasodilator used by cardiac surgeons for its ability to dilate the internal mammary artery.[126]

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors have growing use in managing heart failure, and more patients are receiving these drugs. The ACE inhibitors prevent the conversion of angiotensin I to angiotensin II by inhibiting an enzyme called *kininase* in the pulmonary and systemic vascular endothelium. This enzyme is also important for the metabolism of bradykinin, a potent endogenous vasodilator, and for release of EDRF. Although there are little data in the literature regarding the preoperative management of patients receiving these drugs, withholding them on the day of surgery has been our clinical practice based on their potential to produce excessive vasodilation during CPB. Although Tuman was unable to find any difference in blood pressure during CPB in patients receiving ACE inhibitors, contact activation during CPB has the ability to generate bradykinin and thus amplify the potential for vasodilation.[127] The vasoconstrictor requirements were increased after bypass in his study.

Angiotensin II–Receptor Blockers

ACE inhibitors may not be tolerated in some patients owing to cough (common) and angioedema (rare). Inhibition of kininase II by ACE inhibitors leads to bradykinin accumulation in the lungs and vasculature, which probably causes cough and vasodilation. Alternative treatment with angiotensin II–receptor blockers (ARBs) may be associated less frequently with these side effects because ARBs do not affect kinin metabolism. Six ARBs are currently available for antihypertensive therapy in the United States: losartan (Cozaar), valsartan (Diovan), irbesartan (Avapro), candesartan (Atacand), eprosartan (Teveten), and telmisartan (Micardis). Mortality in chronic heart failure is related to activation of the autonomic nervous and renin-angiotensin systems, and ACE inhibitor therapy seems to attenuate progression of myocardial dysfunction and remodeling. ACE inhibitors do not completely block angiotensin II (A-II) production[128] and even may increase circulating A-II levels in patients with heart failure.[129] It was thought initially that ARBs might offer advantages over ACE inhibitors for heart failure therapy in terms of tolerability and more complete A-II blockade. Although ARBs were better tolerated,[130] all-cause mortality and the number of sudden deaths or resuscitated cardiac arrests were not different when losartan (Cozaar) and captopril (Capoten) were compared in patients (>60 years old, NYHA classes II to IV, LVEF < 40%).[131] Thus the long-term benefits from ACE inhibitor therapy are, at least in part, attributable to increased bradykinin formation.[132,133] For the treatment of heart failure, combination therapies with ACE inhibitors and ARBs are currently being investigated.[134,135] Perioperative hypotension may be encountered in ARB-treated patients as well as ACE inhibitor–treated patients, and increased inotropic support may be required.[136–138]

PHARMACOLOGIC MANIPULATION OF THE HEMOSTATIC SYSTEM DURING CARDIAC SURGERY

Numerous pharmacologic approaches to manipulate the hemostatic system in cardiac surgery include attenuating hemostatic system activation, preserving platelet function,

Table 4–3.

Novel Anticoagulant Agents Affecting the Hemostatic System

Therapeutic class	Agents	Indications
Anti-inflammatory	Adhesion molecule inhibitors Aprotinin complement inhibitors (pexelizumab) Interleukin antagonists P-selection inhibitors	All agents except aprotinin are in clinical development
Antiplatelet inhibitors (intravenous)	Abciximab (ReoPro) Eptifibatide (Integrelin) Tirofiban (Aggrastat)	Percutaneous coronary interventions
Antiplatelet inhibitors (oral)	Clopidogrel (Plavix)	Reduction of atherosclerotic events (myocardial infarction, stroke, and vascular death)
Antithrombotic	Argatroban (Novastan) Bivalirudin (Angiomax) Dermatan surfate (Orgaran) Pentasaccharide (Fondaparinux) Recombinant hirudin (lepirudin)	Anticoagulation in patients with heparin-induced thrombocytopenia (except for pentacaccharide, which is in phase 3 clinical studies)
Broad-spectrum biologicals	Activated protein C Antithrombin Aprotinin (Trasylol)	In phase 3 studies for sepsis For antithrombin-deficiency states Prophylactic use to reduce blood loss and transfusions in patients undergoing CPB

Source: Reproduced with permission from Levy JH: Pharmacologic preservation of the hemostatic system during cardiac surgry. Ann Thorac Surg 2001; 72:1815S

and decreasing the need for transfusion of allogeneic blood products.[139–141] Different approaches currently available or under investigation are shown in Tables 4-3 and 4-4. Pharmacologic approaches to reduce bleeding and transfusion requirements in cardiac surgical patients are based on either preventing or reversing the defects associated with the CPB-induced coagulopathy.

Pharmacology of Anticoagulation

Anticoagulation therapy is based on inhibiting thrombus formation; however, thrombus is due to both thrombin activation and platelet activation (Table 4-5). Because of the complex humoral amplification system linking both hemostatic and inflammatory responses, there are multiple pathways to generate thrombin and platelet activation. During cardiac surgery, multiple aspects of the extracorporeal system can generate thrombin.

Heparin

Heparin is purified from either porcine intestine or beef lung. Heparin that is used for cardiac surgery includes fragments that range from 3000 to 30,000 Da and is also called *unfractionated*.[141] Heparin acts as an anticoagulant by binding to antithrombin III (AT III), enhancing the rate of thrombin–AT III complex formation and also inhibiting other clotting factors.[142] One major advantage of unfractionated heparin is that it can be reversed immediately by protamine. Because heparin also binds to other proteins, it can produce platelet dysfunction. Heparin dosing for CPB ranges from 300 to 500 units/kg. Despotis reported that the maintenance of patient-specific heparin concentrations during CPB was associated with more effective suppression of hemostatic activation.[143,144] Further, Mochizuki has shown that excess protamine can further alter coagulation and coagulation tests, and the careful, exactly titrated reversal of heparin, avoiding excess protamine, may be an important contribution by Despotis.[145] Heparin-induced thrombocytopenia (HIT) is an adverse effect of heparin produced by antibodies (IgG) to the composite of heparin–platelet factor 4 (PF4) that leads to the formation of immune complexes.[146] These immune complexes bind to platelets via platelet Fc-receptors (CD32), producing intravascular platelet activation, thrombocytopenia, and platelet activation with potential thromboembolic complications that can result in limb loss or death.

Table 4–4.

Agents That Improve Hemostatic Function in the Bleeding Patient

Therapeutic class	Agents	Indications
Blood components	Fresh-frozen plasma	Factor deficiency, reversal of warfarin, increased prothrombin time
	Cryoprecipitate	Von Willebrand's disease, hypofibrinogenemia
	Platelets	Thrombocytopenia, platelet dysfunction
Factor concentrates	Recombinant factor VIII	Hemophilia
	Recombinant factor IX	Hemophilia
	Recombinant factor VIIa (NovoSeven)	Hemophilia with factor inhibitors; use reported with intractable, life-threatening bleeding
Fibrinolytic inhibitors	Aprotinin (Trasylol)	All agents used to decrease bleeding during cardiac surgery, but aprotinin is the only drug FDA approved to reduce bleeding
	Epsilon-aminocaproic acid	
	Tranexamic acid	
Pharmacologic agents	Desmopressin	Hemophilia A with factor VIII coagulant activity levels greater than 5%, used also to improve platelet function in renal failure
Protease inhibitors	Protinin (Trasylol)	Prophylactic use to reduce blood loss and transfusions in patients undergoing CPB
Topical agents	Fibrin glue/fibrin tissue adhesives	Tissue sealant applied for refractory bleeding

Low-Molecular-Weight Heparin

Low-molecular0weight heparin (LMWH) is manufactured by depolymerizing unfractionated heparin to produce a mean molecular weight of approximately 5000.[147] A pentasaccharide sequence is required for attachment of a heparin fragment to antithrombin, and additional 13-saccharide residues are necessary to allow the heparin fragment to attach itself simultaneously to the heparin-binding domain of thrombin.[147] LMWH fragments of less than 18 saccharides retain the critical pentasaccharide sequence required for formation of a factor Xa–antithrombin complex; LMWH inhibits both factor Xa and thrombin, but the ratio of factor Xa to thrombin is increased.[147] LMWH is used widely in cardiovascular medicine but poses a problem for cardiac surgical

Table 4–5.

Preoperative Anticoagulants Used in Cardiac Surgical Patient

	Heparin	LMWH	Warfarin
Chemistry	Glycosaminoglycan MW = 15.000	MW = 5.000	4-Hydroxy-coumarin
Mechanism of action	Binds to antithrombin 111 to inhibit thrombin	Inhibition Ila-Xa	Vitamin K antagonist (factors II, VII, IX, X)
Bioavailability	30%	100%	
Half-life	IV: 45–60 min	SC: 4–7 h	40 h
Laboratory evaluation	Act–APTT	Anti-Xa	PT/INR
Reversal	Protamine, 1 mg/100 units heparin	Protamine reverses 60–80%	Vitamin K, FFP (2–4 units)

patients because of its long half-life. Partial thromboplastin time and activated clotting time are not affected by LMWH, and LMWH is not readily reversible with protamine.

Antithrombin

Antithrombin (AT) levels normally are present as approximately 100% activity but decrease approximately 30% in patients receiving heparin.[147] Following initiation of CPB, AT decreases by 40 to 50%, an important consideration that may be critical in determining the extent of thrombin inhibition, especially during CPB.[148] Despotis suggested better anticoagulation during CPB may be associated with less bleeding postprocedure, presumably related to preservation of critical coagulation components. One promising therapy currently under investigation is the use of purified antithrombin III (AT III).[150] Supplemental AT, through improved heparin sensitivity and enhanced anticoagulation, may preserve hemostasis during CPB.[151]

New Anticoagulants

The new intravenous antithrombins recombinant hirudin (Refludan), bivalirudin (Hirulog), and argatroban inhibit fibrin-bound thrombin independent of AT.[152–158] The direct thrombin inhibitors do not require AT or access to the heparin-binding site of thrombin and inhibit fibrin-bound as well as fluid-phase thrombin.[41] Recombinant hirudin (lepirudin), a 65-amino-acid polypeptide, is the most potent antithrombin. Although lepirudin has been used for cardiac surgical patients with HIT, it is nonreversible, its effect is difficult to monitor, it is eliminated by renal mechanisms, and it has been replaced by other agents. Argatroban is a synthetic intravenous direct thrombin inhibitor with a relatively short elimination half-life that is approved for use in patients with HIT and is used in critically ill patients, especially in ICU settings. Argatroban requires hepatic elimination and can be used in patients with renal failure.

When patients with HIT require CPB, although danaparoid (Orgaran), ancrod, recombinant hirudin (Refludan), and several other drug combinations have been used with various degrees of success, one of the major problems with these drugs is their lack of reversibility and thus potential to produce bleeding. Danaparoid has a long half-life ($t_{1/2}$ of anti–factor Xa activity of 24 hours), and monitoring is complicated by the need to measure anti–factor Xa. Recombinant hirudin, a direct thrombin inhibitor modified from a leech salivary protein, is the most potent and specific thrombin inhibitor currently known. Bivalirudin (Angiomax) is a short-acting hirudin analogue that requires infusions to be effective and is the most studied agent in patients with HIT both on pump and off pump for cardiac surgery.[161,162]

Aprotinin

Aprotinin is a naturally occurring polypeptide with a molecular weight of 6512 that reversibly complexes with the active serine site in various proteases in plasma to inhibit the serine proteases trypsin, kallikrein, plasmin, and elastase reversibly. Multiple mechanisms are responsible for aprotinin's ability to reduce bleeding after CPB.[163–170] Aprotinin is the most potent antifibrinolytic agent. The propagation of the "intrinsic" fibrinolysis through factor XII–mediated kallikrein activation and the generation of plasmin through "extrinsic" or tissue plasminogen activator (tPA)–mediated activation of plasminogen is effectively inhibited by approximately 4 μmol/L of aprotinin, which is maintained in plasma with the high-dose regimen. Aprotinin also has multiple anti-inflammatory effects, and inflammation and hemostasis are closely linked. Finally, aprotinin has been studied in multiple placebo-controlled studies and is the only agent approved by the Food and Drug Administration (FDA) to reduce bleeding in cardiac surgical patients.[167–171]

ANTIFIBRINOLYTIC AGENTS AND DESMOPRESSIN

The synthetic lysine analogues epsilon aminocaproic acid (EACA, Amicar) and tranexamic acid inhibit fibrinolysis by attaching to the lysine-binding site of the plasmin(ogen) molecule, displacing plasminogen from fibrin. Levi and colleagues reported a meta-analysis of all randomized, controlled trials of the three most frequently used pharmacologic strategies to decrease perioperative blood loss [aprotinin, lysine analogues (aminocaproic acid and tranexamic acid), and desmopressin].[170] Studies were included if they reported at least one clinically relevant outcome (e.g., mortality, rethoracotomy, proportion of patients receiving a transfusion, or perioperative myocardial infarction) in addition to perioperative blood loss. In addition, a separate meta-analysis was done for studies concerning complicated cardiac surgery. A total of 72 trials (8409 patients) met the inclusion criteria. Treatment with aprotinin decreased mortality almost twofold [odds ratio (OR) = 0.55; 95% confidence interval (CI) = 0.34–0.90] compared with placebo. Treatment with aprotinin and with lysine analogues decreased the frequency of surgical reexploration (OR = 0.37; 95% CI = 0.25–0.55 and OR = 0.44; 95% CI = 0.22–0.90, respectively). These two treatments also decreased significantly the proportion of patients receiving any allogeneic blood transfusion. The use of desmopressin resulted in a small decrease in perioperative blood loss but was not associated with a beneficial effect on other clinical outcomes. Aprotinin and lysine analogues did not increase the risk of perioperative myocardial infarction; however, desmopressin was associated with a 2.4-fold increase in the risk of this complication. Studies in patients undergoing complicated cardiac surgery showed similar results.

Acquired Platelet Dysfunction

Acquired functional platelet disorders are caused by the multitude of potent antiplatelet agents that patients receive for atherosclerotic vascular disease or during percutaneous interventions.[172–173] Clopidogrel (Plavix), a drug that selectively

interferes with ADP-induced platelet aggregation, is used commonly in patients with ischemic heart disease and those undergoing angioplasty.[172] Clopidogrel requires 3 to 5 days for the onset to occur and a similar length of time for the effect to disappear.[172] Because of the pivotal role of the platelet glycoprotein (GP) IIb/IIIa complex in platelet-mediated thrombus formation, three different GP IIb/IIIa antagonists are available currently, but they differ in antagonist affinity, reversibility, and receptor specificity.[172] GP IIb/IIIa (IIbβ3) is a receptor on platelets that binds to key hemostatic proteins, including fibrinogen and von Willebrand factor (vWF), to allow cross-linking of platelets and platelet aggregation. By blocking this final common pathway using GP IIb/IIIa antagonists, these drugs function as inhibitors of platelet participation in acute thrombosis. Various antagonists of GP IIb/IIIa are available and include the monoclonal antibody abciximab (ReoPro); tirofiban (Aggrastat), a nonpeptide fiban molecule; and eptifibatide (Integrelin), a cyclic peptide. Tirofiban and eptifibatide are cleared predominantly through renal mechanisms and have a circulating plasma half-life of approximately 2 to 4 hours, and while abciximab has a relatively short plasma half-life, the monoclonal antibody avidly binds to platelets with a relatively longer duration of action.[171]

Antiplatelet agents are used primarily to treat and prevent arterial thrombosis. Ticlopidine and clopidogrel are believed to inhibit the binding of adenosine 5′-diphosphate (ADP) to its platelet receptor; this ADP-receptor blockade leads to direct inhibition of the binding of fibrinogen to the GP IIb/IIIa complex.[172] Clopidogrel was approved by the FDA for the reduction of ischemic events in patients with recent myocardial infarction, stroke, or peripheral arterial disease with no added risk for neutropenia. Use of the combination of clopidogrel and aspirin, as well as the use of clopidogrel in coronary stenting, is growing rapidly. Many heart centers now administer clopidogrel before anticipated stenting procedures. The variability in bleeding in patients receiving these agents for cardiac surgery may relate to the time and duration of therapy.

Previous recommendations for managing patients receiving antiplatelet agents and requiring cardiac surgery are summarized in Table 4-6. The fact that a patient is receiving antiplatelet agents should not preclude urgent revascularization. Platelets may be needed and should be available when operating on abciximab-treated patients. Platelets should not be administered prophylactically. Although recommendations have been made on reducing heparin dosing, we believe that there are no data to support reductions in heparin dosing during CPB and cardiac surgery. Therefore, standard loading doses should be considered, and additional heparin doses, based on time and duration of bypass or on actual heparin levels, should be maintained. Further, the heparin is reduced at the end of CPB.

Table 4–6.

Recommendations for Managing Patients Receiving Platelet Inhibitors for Cardiac Surgery

Stop therapy.
Do not give platelet transfusions prior to surgery or revascularization.
Give normal doses of heparin.
Platelet transfusions as needed after cardiopulmonary bypass.

Protamine

One of our most unusual clinical practices is to anticoagulate patients with heparin, an extract from bovine lung or porcine intestine, and reverse the heparin with protamine, which is a histone and a basic arginine-rich polypeptide extracted from salmon sperm. Protamine immediately reverses heparin by nonspecific polyionic-polycationic (acid-base) interactions. There are different methods to determine the amount of protamine to be administered: Use a ratio of 1.3 mg protamine per 100 units of heparin administered, determine heparin levels based on heparin-protamine titrations, or use a dose based on the total amount of heparin administered over time.[174]

Protamine, a polypeptide isolated from fish sperm, does have the potential to produce anaphylactic reactions and other potential adverse drug reactions.[175,176] Although rapid protamine administration has the potential to produce hemodynamic instability, the life-threatening reactions to protamine seen clinically represent immediate hypersensitivity reactions.[175,176] The incidence of anaphylaxis appears to be higher in certain patient groups, including patients with diabetes receiving protamine-containing insulin such as neutral protamine Hagedorn (NPH). We have reported that the incidence of anaphylaxis to protamine in NPH insulin–dependent diabetics is 0.6 to 2% compared with 0.06% in most other patients.[175,176] Other patient groups may be at an increased risk for adverse reactions to protamine, including patients with a prior vasectomy or previous fish allergy; however, data do not support this contention.[175,176]

New methods for reversing anticoagulation were once under investigation but may never come to market and include heparin-binding filters, recombinant platelet factor 4, and heparinase.[177]

Antifibrinolytics

As discussed earlier, patients following fibrinolytic therapy have a complex coagulopathic state. Because of the potential half-lives of the fibrinolytic agents, drugs that counteract their effects are potentially useful. Epsilon-aminocaproic acid (EACA, Amicar) and its analogue, tranexamic acid, are derivatives of the amino acid lysine. Both these drugs inhibit the proteolytic activity of plasmin and the conversion of plasminogen to plasmin by plasminogen activators. Although

Table 4–7.

Indications for Blood Product Administration in the Bleeding Cardiac Surgical Patient

Blood product	Indication	Doses
Red blood cells	Low Hct	
Fresh-frozen plasma	Warfarin therapy Documented coagulation factor deficiency Abnormal PT	2–4 units
Platelets	Low platelet count, e.g., <50,000–100,000 Platelet dysfunction, e.g., abnormal TEG	1 unit/10 kg
Cryoprecipitate	Low fibrinogen, e.g., <150 mg/dL Fibrin glue	1–1.5 units/10 kg
Bovine Antithrombin III	Fibrin glue Inadeguate ACT (pt on heparin)	500–1000 units

aprotinin in concentrations used clinically is the most potent inhibitor of fibrinolysis and would represent a useful therapy, it is not approved for this use.[170] Additional coagulation factors and platelets may be required besides to inhibiting fibrinolysis to reverse the coagulopathy.

Blood Products

Blood products are administered widely in cardiac surgical patients and represent a major utilization for hospitals. Once widely administered as part of empirical therapy, specific indications for coagulation factors need to be determined prior to their administration (Table 4-7). In addition to cost, blood products carry significant risks. Although the risk of viral-induced transmission is low, immunosuppressive effects, transfusion-related acute lung injury, and cost need to be considered when administering blood products. The role of fresh-frozen plasma needs to be considered because it represents an often inappropriately used product. Specific indications for blood products are listed in Table 4-7. Each institution needs to develop its own algorithm for blood product administration in cardiac surgical patients. With the use of specific therapies, excessive and inappropriate transfusions can be avoided.

Recombinant Coagulation Products

Coagulation products used to manage bleeding in patients with hemophilia, von Willebrand's disease (vWD), or acquired inhibitors to antihemophilic factor include antihemophilic factor concentrates, factor IX concentrates, factor VIIa concentrate, factor IX complexes, anti-inhibitor coagulant complexes, and desmopressin acetate. These commercially available products are used to manage acute bleeding or to prevent excessive bleeding during cardiac and noncardiac surgery in patients with hematologic disorders. Recombinant activated factor VIIa (rFVIIa, NovoSeven, Novo Nordisk A/S) has been used as a novel and effective treatment for patients with hemophilia with inhibitors for the treatment of bleeding and to secure hemostasis in complex clinical situations.[178–181]

The role of rFVIIa in the treatment of bleeding as a therapeutic approach has been addressed in multiple reports and in a study of high-risk patients. Further, the use of rFVIIa has been reported in patients who refused allogeneic blood products.[181]

The modes of action of rFIIa are multiple, including tissue-factor-dependent mechanisms and generation of factors Xa and IXa on the surfaces of activated platelets. These studies relate thrombin generation on activated platelets to the high level of rFVIIa binding to platelet surfaces. Therapeutic doses of rFVIIa are not established; different doses have been used during surgery in patients with hemophilia and inhibitors and in those with refractory bleeding following cardiac surgery. The off-label use of rFVIIa has been reported to control bleeding in patients with refractory bleeding undergoing cardiac surgery, although current studies are underway to better define its application, especially in relation to its cost. Recommended dose ranges for rFVIIa usually vary from 30 to 90 μg/kg.[178]

Fibrinolytics

Patients also may have received fibrinolytic drugs, including tissue plasminogen activator (tPA), streptokinase, and urokinase. These drugs inactivate fibrinogen and other adhesive proteins and have the potential to affect platelets as well.[181] Patients receiving these drugs within 24 hours of surgery should be considered to be at high risk for coagulopathy, and fibrinogen levels should be measured.

BETA-ADRENERGIC RECEPTOR BLOCKERS

Not surprisingly, most of the effects observed after administration of a beta-adrenergic receptor blocker reflect the

reduced responsiveness of tissues containing beta-adrenergic receptors to cathecholamines present in the vicinity of those receptors. Hence the intensity of the effects of beta blockers depends on both the dose of the blocker and the receptor concentrations of catecholamines, primarily epinephrine and norepinephrine. In fact, a purely competitive interaction of beta blockers and catecholamines can be demonstrated in normal human volunteers as well as in isolated tissues studied in the laboratory. The presence of disease and other types of drugs modifies the responses to beta blockers observed in patients, but the underlying competitive interaction is still operative. The key to successful use of beta-adrenergic receptor blockers is to titrate the dose to the desired degree of effect and to remember that excessive effects from larger than necessary doses of beta-adrenergic receptor blockers can be overcome by (1) administering a catecholamine to compete at the blocked receptors and/or (2) administering other types of drugs to reduce the activity of counterbalancing autonomic mechanisms that are unopposed in the presence of beta-receptor blockade. An example of the latter is propranolol-induced bradycardia, which reflects the increased dominance of the vagal cholinergic mechanism on cardiac nodal tissue. Excessive bradycardia may be relieved by administering atropine to block the cholinergic receptors, which are also located in the sinoatrial (SA) and atrioventricular (AV) nodes.

Table 4–8.

Location and Actions of Beta-Adrenergic Receptors

Tissue	Receptor	Action	Opposing actions
Heart			
Sinus and AV nodes	1	↑ Automaticity	Cholinergic receptors
Conduction pathways	1	↑ Conduction velocity	Cholinergic receptors
		↑ Automaticity	Cholinergic receptors
Myofibils	1	↑ Contractility	—
		↑ Automaticity	—
Vascular smooth muscle (Arterial, venous)	2	Vasodilation	Alpha-adrenergic receptors
Bronchial smooth muscle	2	Bronchodilation	Cholinergic receptors
Kidneys	1	↑ Renin release (juxtaaglomerular cells)	$Alpha_1$-adrenergic receptors
Liver	2	↑ Glucose metabolism ↑ Lipolysis	$Alpha_1$-adrenergic receptors
Fat/adipose tissue	3	↑ Lipolysis	—
Skeletal muscle	2	↑ Potassium uptake glyccogenolysis	—
Eye, ciliary muscle	2	Relaxation	Cholinergic receptors
GI tract	2	↑ Motility	Cholinergic receptors
Gallbladder	2	Relaxation	Cholinergic receptors
Urinary bladder detrusor muscle	2	Relaxation	Cholinergic receptors
Uterus	2	Relaxation	Oxytocin
Platelets	2	↓ Aggregation	$Alpha_2$-adrenergic receptors (aggregation)

Knowledge of the type, location, and action of beta receptor is fundamental to understanding and predicting effects of beta-adrenergic receptor–blocking drugs[183] (Table 4-8). Beta-adrenergic receptor blockers are competitive inhibitors; hence the intensity of blockade depends on both the dose of the drug and the receptor concentrations of catecholamines, primarily epinephrine and norepinephrine.

Beta-adrenergic receptor antagonists (blockers) include many drugs (Table 4-9) that typically are classified by their relative selectivity for $beta_1$ and $beta_2$ receptors (i.e., cardioselective or nonselective), the presence or absence of agonistic activity, membrane-stabilizing properties, alpha-receptor-blocking efficacy, and various pharmacokinetic features (e.g., lipid solubility, oral bioavailability, and elimination half-time).[184] The practitioner must realize that the selectivity of individual drugs for $beta_1$ and $beta_2$ receptors is relative, not absolute. For example, the risk of inducing bronchospasm with a $beta_1$-adrenergic (cardioselective) blocker (e.g., esmolol or metoprolol) may be relatively less than with a nonselective blockers (e.g., propranolol); however, the risk is still present.

Acute Myocardial Infarction

Clinical trials of intravenous beta-adrenergic blockers in the early phases of acute myocardial infarction suggest that mortality decreases by 10%. Following myocardial infarction, chronic oral beta-blocking agents reduce the incidence of recurrent myocardial infarction. A randomized, controlled trial of atenolol (Tenormin) in the perioperative period was performed by Mangano and his group. In their study, the incidence of myocardial ischemia was reduced by 50% in patients receiving atenolol. Overall mortality after discharge was lower in the atenolol group than in the control group over a 2-year period (10% versus 21%).[185] However, atenolol did not result in reducing death during hospitalization or perioperative myocardial infarction. Poldermans and colleagues performed another randomized, controlled perioperative trial using bisoprolol (Zebeta) in high-risk vascular surgical patients. Bisoprolol therapy, started 1 week before a major surgery and continued for 30 days postoperatively, has reduced the rate of death and nonfatal myocardial infarction significantly.[186] The follow-up of this study showed that the

reduction in cardiac events persisted over 2 years in the bisoprolol-treated group (12% versus 32%).[187]

Supraventricular Tachycardias and Ventricular Dysrhythmias

Beta-adrenergic blocking agents are Vaughan Williams class II antidysrhythmics that primarily block cardiac responses to catecholamines. Propranolol (Inderal), esmolol (Brevibloc), and acebutolol (Sectral) are used commonly for this indication. Beta-blocking agents decrease spontaneous depolarization in the SA and AV nodes, decrease automaticity in Purkinje fibers, increase AV nodal refractoriness, increase threshold for fibrillation (but not for depolarization), and decrease ventricular slow responses that depend on catecholamines. Amiodarone, a class III agent, also exerts noncompetitive alpha- and beta-adrenergic blockade, which may contribute its antidysrhythmic and antihypertensive actions.[188] Sotalol is another class III antidysrhythmic with nonselective beta-blocking action. There is evidence that beta-blocking agents also decrease intramyocardial conduction in ischemic tissue and reduce the risks of dysrhythmias to the extent that they decrease myocardial ischemia. Beta-adrenergic blockers are not particularly effective in controlling dysrhythmias that are not induced or maintained by catecholamines.

Hypertension

Hypertension is a major risk factor for developing heart failure and other end-organ damage. Beta blockers, along with diuretics, are considered to be the initial drug of choice for uncomplicated hypertension in patients aged less than 65 years.[189]

During the early phases of therapy, there is a decrease in cardiac output, a rise in systemic vascular resistance (SVR), and relatively little change in mean arterial blood pressure. Within hours to days, SVR normalizes, and blood pressure declines. In addition, the release of renin from the juxtaglomerular apparatus in the kidney is inhibited ($beta_1$ blockade). Beta-blocking agents with intrinsic agonistic activity reduce systemic vascular resistance below pretreatment levels presumably by activating $beta_2$ receptors in vascular smooth muscle. Most beta-adrenergic blockers are used with other agents in treating chronic hypertension. When combined with a vasodilator, beta blockers limit reflex tachycardia. For example, when propranolol is combined with intravenous nitroprusside (a potent arterial dilator), it prevents reflex release of renin and reflex tachycardia induced by nitroprusside.

Acute Dissecting Aortic Aneurysm

The primary goal in managing dissecting aneurysms is to reduce stress on the dissected aortic wall by reducing the systolic acceleration of blood flow. Beta blockers reduce cardiac inotropy and ventricular ejection fraction. Beta blockers also may limit reflex sympathetic responses to vasodilators that are used to control systemic arterial pressure.

Pheochromocytoma

The presence of catecholamine-secreting tissue is tantamount to the continuous or intermittent infusion of a varying mixture of norepinephrine and epinephrine. It is absolutely essential that virtually complete alpha-adrenergic receptor blockade be established prior to administering the beta blocker to prevent exacerbation of hypertensive episodes by unopposed alpha-adrenergic receptor activity in vascular smooth muscle.

Chronic Heart Failure

It is now understood that activation of the autonomic nervous system (ANS) and renin-angiotensin system (RAS) as compensatory mechanisms for the failing heart actually may contribute to deterioration of myocardial function. Mortality in chronic heart failure seems related to activation of ANS and RAS. Progression of myocardial dysfunction and remodeling may be attenuated by the use of beta-blocking agents and ACE inhibitors. Carvedilol (Coreg) is a beta blocker approved by the FDA to treat patients with heart failure. It has an $alpha_1$- and nonselective beta-blocking activity (alpha:beta = 1:10). It is contraindicated in severe decompensated heart failure and asthma. In patients with atrial fibrillation and left-sided heart failure treated with carvedilol, improved ejection fraction and a trend toward a decreased incidence of death and chronic heart failure hospitalization were observed in a retrospective analysis of a U.S. carvedilol study.[190] There are several ongoing clinical trials with carvedilol, metoprolol (Toprol), and bisoprolol (Zebeta). The results of these studies may provide answers as to which beta-blocking agent would be most successful in the treatment of specific patient populations.

Other Indications

The other clinical applications of beta-adrenergic receptor blockers listed in Table 4-10 are based on largely symptomatic treatment or empirical trials of beta-adrenergic antagonists.

Side Effects and Toxicity

The most obvious and immediate signs of a toxic overdose of a beta-adrenergic receptor blocker are hypotension, bradycardia, congestive heart failure, decreased AV conduction, and a widened QRS complex on the electrocardiogram. Treatment is aimed at blocking the cholinergic receptor responses to vagal nerve activity (e.g., atropine) and administering a sympathomimetic to compete with the beta blockers at adrenergic receptors. In patients with asthma and chronic obstructive pulmonary disease (COPD), beta blockers may cause bronchospasm. Beta blockers may increase levels of plasma triglycerides and reduce levels of high-density lipoprotein (HDL) cholesterol.[191] Rarely, beta blockers may mask the symptoms of hypoglycemia in diabetic patients. Other side effects include mental depression, physical fatigue, altered sleep patterns, sexual dysfunction, and gastrointestinal symptoms, including indigestion, constipation, and diarrhea.

Table 4–10.

Clinical Applications of Beta-Adrenergic Receptor Blockers
Angina pectoris
Accute myocardial infarction (prophylaxis)
Supraventricular tachycardia
Ventricular dysrhythmias
Hypertension (usually in combination with other drugs)
Pheochromocytoma (after alpha-receptor blockade is established)
Acute dissecting aortic aneurysm
Hyperthyroidism
Hypertrophic obstructive cardiomyopathy (IHSS)
Dilated cardiomyopathy (selected patients)
Migraine prophylaxis
Acute panic attack
Alcohol withdrawal syndrome
Glaucoma (topically)

Drug Interactions

Pharmacokinetic drug interactions include reduced gastrointestinal absorption of the beta blocker (e.g., aluminum-containing antacids and cholestyramine), increased biotransformation of the beta blocker (e.g., phenytoin, phenobarbital, rifampin, and smoking), and increased bioavailability owing to decreased biotransformation (e.g., cimetidine and hydralazine). Pharmacodynamic interactions include an additive effect with calcium channel blockers to decrease conduction in the heart and a reduced antihypertensive effect of beta blockers when administered with some of the nonsteroidal anti-inflammatory drugs (NSAIDs).

DIURETICS

Diuretics are drugs that act directly on the kidneys to increase urine volume and produce a net loss of solute (principally sodium and other electrolytes) and water. Diuretics and beta blockers are initial drugs of choice for uncomplicated hypertension in patients younger than 65 years.[189] The currently available diuretic drugs have a number of other uses in medicine (e.g., glaucoma and increased intracranial pressure). The principal indications for the use of diuretics by intravenous administration in the perioperative period are (1) to increase urine flow in oliguria, (2) to reduce intravascular volume in patients at risk for acute congestive heart failure from excessive fluid administration or acute heart failure, and (3) to mobilize edema.

Renal function depends on adequate renal perfusion to maintain the integrity of renal cells and to provide the hydrostatic pressure that produces glomerular filtration. There are no drugs that act directly on the renal glomerulus to affect glomerular filtration rate (GFR). In the normal adult human of average size, GFR averages 125 mL/min, and urine production approximates 1 mL/min. In other words, 99% of the glomerular filtrate is reabsorbed. Diuretics act primarily on specific segments of the renal tubule to alter reabsorption of electrolytes, principally sodium, and water.

There are two basic mechanisms behind the renal tubular reabsorption of sodium. First, sodium is extruded from the tubular cell into peritubular fluid primarily by active transport of the sodium ion, which reflects the action of the Na^+,K^+-ATPase pump as well as the bicarbonate reabsorption mechanism (see below). This extrusion of sodium creates an electrochemical gradient that causes diffusion of sodium from the tubular lumen into the tubular cell. Second, sodium moves from the glomerular filtrate in the tubular fluid into the peritubular fluid by several different mechanisms. The most important quantitatively is the sodium electrochemical gradient created by the active extrusion of sodium from the tubular cell into the peritubular fluid. In addition, sodium is coupled with organic solutes and phosphate ions, exchanged for hydrogen ions diffusing from the tubular cell into the tubular lumen, and coupled to the transfer of a chloride ion or a combination of a potassium and two chloride ions (Na^+-K^+-$2Cl^-$ cotransport) from the tubular fluid into the tubular cell. Diuretics are classified by their principal site of action in the nephron and by the primary mechanism of their naturetic effect (Table 4-11).

Osmotic Diuretics

Mannitol is the principal example of this type of diuretic, which is used for two primary indications: (1) prophylaxis and early treatment of acute renal failure that is characterized by a decrease in GFR leading to a decreased urine volume and an increase in the concentration of toxic substances in the renal tubular fluid and (2) to enhance the actions of other diuretics by retaining water and solutes in the tubular lumen, thereby providing the substrate for the action of other types of diuretics. Normally, 80% of the glomerular filtrate is reabsorbed isosmotically in the proximal tubules. By its osmotic effect, mannitol limits the reabsorption of water and dilutes the proximal tubular fluid. This reduces the electrochemical gradient for sodium and limits its reabsorption so that more is delivered to the distal portions of the nephron. Mannitol produces a prostaglandin-mediated increase in renal blood flow that partially washes out the medullary hypertonicity, which is essential for the countercurrent mechanism promoting the reabsorption of water in the late distal tubules and collecting

Table 4–11.

Classification of Diuretics

Site of action	Mechanism	
Osmotic	Proximal convoluted and late proximal for NA^+ diffusion from tubular fluid into tubular cell	↓ Eleectrochemical gradient
	Late proximal tubule	↓ Gradient for Cl^- (accompanying NA^+ diffusion)
	Thick ascending loop of Henle	↓ Na^+-K^+-$2Cl^-$ cotransport
Carbonic	Proximal convoluted tubule anhydrase inhibitors	↓ Na^+-H^+ exchange$^+$
Thiazides	Distal convoluted tubule	↓ Na^+-Cl^- cotransport
High-ceiling loop diuretics	Thick ascending loop of Henle	↓ Na^+-K^+-$2Cl^-$ cotransport
Potassium-sparing diuretics	Late distal tubule and collecting duct	↓ Electrogeenic Na^+ entry into cells (driving force for K^+ ssectretion)

Source: Reproduced with permission from Wener IM: Drugs affecting renal function and electrolyte metabolism, in Gilman AG, Rall TW, Nies AS, Taylor P (eds): The Pharmacological Basis of Therapeutics, 8th ed. New York, Pergamon Press, 1990; p 708.

system under the influence of antidiuretic hormone (ADH). Mannitol is used often (25 to 50 g) as part of the priming solution of cardiopulmonary bypass for the above-mentioned indications. The principal toxicity of mannitol is acute expansion of the extracellular fluid volume leading to CHF in the patient with compromised cardiac function.

High-Ceiling (Loop) Diuretics

Furosemide (Lasix), bumetanide (Bumex), and ethacrynic acid (Edecrin) are three chemically dissimilar compounds that have the same primary diuretic mechanism of action. They act on the tubular epithelial cell in the thick ascending loop of Henle to inhibit the Na^+-K^+-$2Cl^-$ cotransport mechanism. Their peak diuretic effect is far greater than that of the other diuretics currently available. Administered intravenously, they have a rapid onset and relatively short duration of action, the latter reflecting both the pharmacokinetics of the drugs and the body's compensatory mechanisms to the consequences of diuresis. These three diuretics increase renal blood flow without increasing GFR and redistribute blood flow from the medulla to the cortex and within the renal cortex. These changes in renal blood flow are also short-lived, reflecting the reduced extracellular fluid volume resulting from diuresis. Minor actions, including carbonic anhydrase inhibition by furosemide and bumetanide and actions on the proximal tubule and on sites distal to the ascending limb, remain controversial. All three of the loop diuretics increase the release of renin and prostaglandin, and indomethacin blunts the release as well as the augmentation in renal blood flow and naturesis. All three of the loop diuretics produce an acute increase in venous capacitance for a brief period of time after the first intravenous dose is administered, and this effect is also blocked by indomethacin.

Potassium, magnesium, and calcium excretion is increased in proportion to the increase in sodium excretion. In addition, there is augmentation of titratable acid and ammonia excretion by the distal tubules leading to metabolic alkalosis, which is also produced by contraction of the extracellular volume. Hyperuricemia can occur but usually is of little physiologic significance. The nephrotoxicity of cephaloridine, and possibly other cephalorsporins, is increased. A rare but serious side effect of the loop diuretics is deafness, which may reflect electrolyte changes in the endolymph.

Because of their high degree of efficacy, prompt onset, and relatively short duration of action, the high-ceiling or loop diuretics are favored for intravenous administration in the perioperative period to treat the three principal problems cited earlier. Dosage requirements vary considerably among patients. Some may only require furosemide 3 to 5 mg IV to produce a good diuresis. And for some patients, the less potent benzothiazides may be sufficient.

Benzothiazides

Hydrochlorothiazide (HCTZ) is the prototype of more than a dozen currently available diuretics in this class. Although the drugs differ in potency, they all act by the same mechanism of action and have the same maximum efficacy. All are actively secreted into the tubular lumen by tubular cells and act in the early distal tubules to decrease the electroneutral Na^+-Cl^- cotransport reabsorption of sodium. Their moderate efficacy probably reflects the fact that more than 90% of the filtrated sodium is reabsorbed before reaching the distal tubules. Their action is enhanced by their combined administration with an osmotic diuretic such as mannitol. The benziothiazides increase urine volume and the excretion of

sodium, chloride, and potassium. The decreased reabsorption of potassium reflects the higher rate of urine flow through the distal tubule (diminished reabsorption time).

This class of diuretics produces the least disturbance of extracellular fluid composition, reflecting their moderate efficacy as diuretics and perhaps suggesting their usefulness when a moderate degree of diuretic effect is indicated. Their principal side effects include hyperuricemia, decreased calcium excretion, and enhanced magnesium loss. Hyperglycemia can occur and reflects multiple variables. With prolonged use and development of a contracted extracellular fluid volume, urine formation decreases (i.e., tolerance develops to their diuretic actions). These agents also have a direct action on the renal vasculature to decrease GFR.

Carbonic Anhydrase Inhibitors

Acetazolamide (Diamox) is the only diuretic of this class available for intravenous administration. Its use is directed primarily toward alkalinization of urine in the presence of metabolic alkalosis, which is a common consequence of prolonged diuretic therapy. It acts in the proximal convoluted tubule to inhibit carbonic anhydrase in the brush border of the tubular epithelium, thereby reducing the destruction of bicarbonate ions (i.e., conversion to CO_2 that diffuses into the tubular cell). The carbonic anhydrase enzyme in the cytoplasm of the tubular cell is also inhibited, and as a consequence, conversion of CO_2 to carbonic acid is reduced markedly, as is the availability of hydrogen ions for the Na-H exchange mechanism. Hence the reabsorption of both sodium and bicarbonate in the proximal tubules is diminished. However, more than half the bicarbonate is reabsorbed in more distal segments of the nephron, thereby limiting the overall efficacy of this class of diuretics.

Potassium-Sparing Diuretics

Spironolactone (Aldactone) is a competitive antagonist of aldosterone. Spironolactone binds to the cytoplasmic aldosterone receptor and prevents its conformational change to the active form, thereby aborting the synthesis of active transport proteins in the late distal tubules and collecting system where the reabsorption of sodium and secretion of potassium are reduced.

Triamterene (Dyrenium) and amiloride (Midamor) are potassium-sparing diuretics with a mechanism of action independent of the mineralocorticoids. They have a moderate natriuretic effect leading to an increased excretion of sodium and chloride with little change or a slight increase in potassium excretion when the latter is low. When potassium secretion is high, they produce a sharp reduction in the electrogenic entry of sodium ions into the distal tubular cells and thereby reduce the electrical potential that is the driving force for potassium secretion.

Both types of potassium-sparing diuretics are used primarily in combination with other diuretics to reduce potassium loss. Their principal side effect is hyperkalemia. It is appropriate to limit the intake of potassium when using this type of diuretic. It is also appropriate to use this type of diuretic cautiously in patients taking ACE inhibitors, which decrease aldosterone formation and consequently increase serum potassium concentrations.

Other Measures to Enhance Urine Output and Mobilization of Edema Fluid

The infusion of albumin (5 to 25% solutions) or other plasma volume expanders (e.g., hetastarch) is often employed in an attempt to draw water and its accompanying electrolytes (i.e., edema fluid) osmotically from the tissues into the circulating blood and thereby enhance their delivery to the kidney for excretion. In the presence of a reduced circulating blood volume, this approach seems to be a logical method to increase the circulating blood volume and renal perfusion. The limiting feature of this approach to enhancing diuresis relates to the fact that the osmotic effect of albumin and plasma expanders is transient because they can diffuse (at a rate slower than water) from blood through capillary membranes into tissue. The albumin or plasma expander then tends to hold water and its accompanying electrolytes in tissue (i.e., rebound edema). The same limiting feature applies to osmotic diuretics such as mannitol, which may transiently draw water and its accompanying electrolytes from tissues into the circulating blood for delivery to the kidney, where the mannitol passes through the glomerulus and delays the reabsorption of water and its accompanying electrolytes from the proximal tubular fluid. While this mechanism may enhance the actions of other diuretics, it is a transient effect that is limited by the diffusion of mannitol from blood into tissues with the production of rebound edema.

Dopamine (Intropin), at doses 1 to 3 μg/kg per minute, has been used conventionally to support mesenteric and renal perfusion. Its vascular action is mediated via vascular dopamine 1 (D_1) receptors in coronary, mesenteric, and renal vascular beds. By activating adenyl cyclase and raising intracellular concentrations of cyclic AMP, D_1-receptor agonists cause vasodilatation. There are also dopamine 2 (D_2) receptors that antagonize D_1-receptor stimulation. Fenoldopam (Corlopam), a parenteral D_1-receptor-specific agonist, was approved by the FDA recently. The Joint National Commissions VI and VII recommendations include this drug for hypertensive emergencies.[192,193] Infusion of fenoldopam (0.1 to 0.3 μg/kg per minute) causes an increase in GFR, renal blood flow, and Na^+ excretion.

Clinical trials of dopamine failed to show improvement in renal function, which probably is due to the nonspecificity of dopamine. As a catecholamine and a precursor in the metabolic synthesis of norepinephrine and epinephrine, dopamine has inotropic and chronotropic effects on the heart. The inotropic effect is mediated by beta$_1$-adrenergic receptors and usually requires infusion rates higher than those able to produce enhanced renal perfusion and diuresis. However, there are varied pharmacokinetic responses to dopamine infusion even in healthy subjects[194]; therefore, the use of a "renal dose" dopamine regimen may not always result in the desirable effects. Stimulation of catecholamine receptors and D_2 receptors antagonizes the effects of

D_1-receptor stimulation. There are a small number of studies where improved renal outcome was shown with use of the D_1-receptor-specific agonist fenoldopam.[195–197] A further large-scale study is needed to answer whether prophylactic use of fenoldopam reduces the incidence of perioperative renal insufficiency.

HERBAL MEDICINE

A large number of Americans take herbal remedies for their health. Most of these herbal therapies are not supported by clear scientific evidence and are not under rigorous control by the FDA.[198] Patients who take alternative remedies may not necessarily disclose this information to their physicians.[199] There are increasing concerns regarding serious drug interactions between herbal therapy and prescribed medication. Some of the most common herbal remedies and drug interactions are summarized in Table 4-12.[200]

Drugs for airway management

Airway management in cardiovascular surgical patients is very important because these patients often present with coexisting conditions that may complicate endotracheal intubation. For example, a patient with morbid obesity and sleep apnea may require awake intubation with a fiberoptic bronchoscope, or a history of smoking and COPD may make the patient susceptible to rapid desaturation and/or bronchospasm. Airway management in the perioperative period is a primary responsibility of the anesthesiologist, but the surgeon becomes involved in the absence of the anesthesiologist or in assisting the anesthesiologist in difficult situations. Airway management involves instrumentation and mechanics (not discussed here) and employs drugs to overcome pathophysiologic problems that contribute to airway obstruction and to facilitate manipulation and instrumentation of the airway. Most of the drugs used for these purposes are taken from drug classes that have other important therapeutic applications (e.g., sympathomimetics).

Five major challenges may be encountered in airway management. Each of these is described succinctly below to facilitate understanding of the roles that drugs play in meeting the challenges. For the most part, details of pharmacology such as doses, side effects, and toxicity are left to standard textbooks of pharmacology and drug compendia. The five challenges are (1) overcoming airway obstruction, (2) preventing pulmonary aspiration, (3) performing endotracheal intubation, (4) maintaining intermittent positive-pressure ventilation (IPPV), and (5) reestablishing spontaneous ventilation and airway protective reflexes.

Airway Obstruction

Obstruction to gas flow can occur from the entry of a foreign object (including food) into the airway and as a result of pathophysiologic processes involving airway structures (e.g., trauma and edema). In the anesthetized or comatose patient, the loss of muscle tone can allow otherwise normal tissues (e.g., tongue and epiglottis) to collapse into the airway and cause obstruction. The first measure in relieving such obstructions involves manipulation of the head and jaw, insertion of an artificial nasal or oral airway device, and evacuation of obstructing objects and substances (e.g., blood, secretions, or food particles). Except for drugs used to facilitate endotracheal intubation (see below), the only drug useful to improve gas flow through a narrowed airway is a mixture of helium and oxygen (heliox), which has a much reduced viscosity resulting in reduced resistance to gas flow.

Aspiration

The upper airway (above the larynx/epiglottis) is a shared porthole to the lungs (gas exchange) and gastrointestinal tract (fluids and nutrition). Passive regurgitation or active vomiting resulting in accumulation of gastric contents in the pharynx places the patient at risk of pulmonary aspiration, especially under circumstances in which airway reflexes (e.g., glottic closure and coughing) and voluntary avoidance maneuvers are suppressed (e.g., anesthesia or coma). Particulate matter can obstruct the tracheobronchial tree, and acidic fluid ($pH < 2.5$) can injure the lung parenchyma. The resulting pneumonitis can cause significant morbidity (e.g., acute respiratory distress syndrome) and has a high mortality rate. Preoperative restriction of fluids and food (NPO status) does not guarantee the absence of aspiration risks. Similarly, the advance placement of a naso- or orogastric tube may serve to reduce intragastric pressure but does not guarantee complete removal of gastric contents. Nevertheless, both NPO orders and the insertion of a naso- or orogastric tube under some circumstances are worthwhile measures to reduce the risks of pulmonary aspiration. In some circumstances, the deliberate induction of vomiting in a conscious patient may be indicated, but this is done rarely and almost never involves the use of an emetic drug. In fact, more often antiemetic drugs are employed to reduce the risks of vomiting during airway manipulation and induction of anesthesia.

Drug therapy to reduce the risks of pulmonary aspiration is focused on decreasing the quantity and acidity of gastric contents and on facilitating endotracheal intubation (see below). Nonparticulate antacids [e.g., sodium citrate (Bicitra)] are used to neutralize the acidity of gastric fluids. Drugs to reduce gastric acid production include H_2-receptor blockers [e.g., cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid)] and inhibitors of gastric parietal cell hydrogen-potassium ATPase [proton pump inhibitors, e.g., omeprazole (Prilosec), lansoprazole (Prevacid), and esomeprazole (Nexium)]. Metoclopramide (Reglan) enhances gastric emptying and increases gastroesophageal sphincter tone. Cisapride (Propulsid) also increases gastrointestinal motility via the release of acetylcholine at the myenteric plexus.

Antiemetic drugs are used more commonly in the postoperative period and include several different drug classes: anticholinergics [e.g., scopolamine (Transderm Scop)],

Table 4–12.

Commonly Used Herbal Remedies

Name	Common uses	Side effects/drug interactions
Cayenne (paprika)	Muscle spasm, GI disorders	Skin ulcers/blistering
		Hypothermia
Echinacea	Common cold antitussive urinary tract infections	May cause hepatotoxicity May decrease effects of steroids and cyclosporine
Ephedra (ma-huang)	Antitussive, bacteriostatic	Enhanced sympathomimetic effects with guanethedine or monoamine oxidase inhibitor (MAOI)
		Arrhythmias with halothane or digoxin
		Hypertension with oxytocin
Feverfew	Migraine, antipyretic	Platelet inhibition, rebound headache, aphthous ulcers, GI irritation
Garlic	Lipid lowering, antihypertensive antithrombotic	May potentiate warfarin
Ginger	Antinausseant antispasmodic	May potentiate aspirin and warfarin
Gingko	Improve circulation	May potentiate aspirin and warfarin
Ginseng	Adaptogenic enhace energy level, antioxidant	Ginseng abuse synddrome: sleepiness, hypertonia, edema May cause mania in patients on phynelzine
		May decrease effects of warfarin
		Postmenopausal bleeding
		Mastalgia
Glodenseal	Diuretic, anti-inflammatory, laxative hemostatic	Overdose may cause paralysis; aquaretic (no sodium excretion); may worsen edema/hypertension
Kava-kava	Anxiolytic	Potentiates barbiturates and benzodiazepines
		Potentiates ethanol
		May increase suicide risk in depression
Licorice	Antitussive gastric ulcers	High blood pressure, hypokalemia, and edema
Saw palmetto	Benign prostatic hypertrophy, antiandrogenic	Additive effects with other hormone therapy (e.g., HRT)
St. John's wort	Antidepressant, anxiolytic	Possible interaction with MAOIs
		Deecreases metabolism of fentanyl and ondansetron
Valerian	Mild sedative, anxiolytic	Potentiates barbiturates and benzodiazepines

antihistamines [e.g., hydroxyzine (Vistaril) and, promethazine (Pherergan)], and antidopaminergics [e.g., droperidol (Inapsine) and prochlorperazine (Compazine)]. Antidopaminergic agents may cause extrapyramidal side effects in elderly patients. More costly but effective alternatives include the use of antiserotoninergics [e.g., ondansetron (Zofran) and dolasetron (Anzmet)].

Of course, the most widely used measure to minimize the risks of pulmonary aspiration in the anesthetized or comatose patient is endotracheal intubation.

Endotracheal Intubation

Drugs are employed for three purposes in facilitating endotracheal intubation: (1) to improve visualization of the larynx during laryngoscopy, (2) to prevent closure of the larynx, and (3) to facilitate manipulation of the head and jaw.

For bronchoscopy, laryngoscopy, or fiberoptic endotracheal intubation, the reflex responses to airway manipulation can be suppressed by several different methods alone or in combination. Topical anesthesia (2% or 4% lidocaine spray) can be used to anesthetize the mucosal surfaces of the nose, oral cavity, pharynx, and epiglottis. Atomized local anesthetic can be inhaled to anesthetize the mucosa below the vocal cords. The subglottic mucosa also can be anesthetized topically by injecting local anesthetic into the tracheal lumen through the cricothyroid membrane. A bilateral superior laryngeal nerve block eliminates sensory input from mechanical contact or irritation of the larynx above the vocal cords. It must be remembered that anesthesia of the mucosal surfaces to obtund airway reflexes compromises the reflex protective mechanisms of the airway and increases the patient's vulnerability to aspiration of substances from the pharynx. Improvement of visualization of the larynx includes decreasing salivation and tracheal bronchial secretions by administration of an anticholinergic drug (e.g., glycopyrrolate), reducing mucosal swelling by topical administration of a vasoconstrictor (e.g., phenylephrine), and minimizing bleeding owing to mucosal erosion by instrumentation, which also is minimized by topical vasoconstrictors. The use of steroids in minimizing acute inflammatory responses in the airway may have some delayed benefit, but steroids usually are not indicated just before intubation.

Systemic drugs, usually administered intravenously, can be used to obtund the cough reflex. Intravenous lidocaine (1 to 2 mg/kg) transiently obtunds the cough reflex without affecting spontaneous ventilation to any significant degree. The risks of central nervous system (CNS) stimulation and seizure-like activity have to be kept in mind and can be reduced by the prior administration of an intravenous barbiturate or benzodiazepine in small doses. Intravenous opioids are effective in suppressing cough reflexes, but the doses required impair spontaneous ventilation to the point of apnea. A combination of an intravenous opioid and a major tranquilizer (e.g., neuroleptanalgesia) allows the patient to tolerate an endotracheal tube with much smaller doses of the opioid and less embarrassment of spontaneous ventilation. Small doses of opioids are also useful in obtunding airway reflexes during general anesthesia provided either by intravenous (e.g., thiopental) or inhaled anesthetics (e.g., isoflurane). Not only do the opioids obtund the cough reflex that results in closure of the larynx, but they also are useful in limiting the autonomic sympathetic response to endotracheal intubation that typically leads to hypertension and tachycardia.

Skeletal muscle relaxants are used most commonly in conjunction with a general anesthetic to allow manipulation of the head and jaw and to prevent reflex closure of the larynx. Of course, they also render the patient apneic, and two procedures are used commonly to maintain oxygenation of the patient's blood. First, the patient breathes 100% oxygen by mask while still awake to eliminate nitrogen from the lungs, and then a rapid-sequence administration of an intravenous anesthetic (e.g., thiopental) is followed immediately by a rapid-acting neuromuscular blocker [e.g., succinylcholine or rocuronium (Zemuron)], and cricoid pressure is applied (Sellick maneuver). As soon as the muscle relaxation is apparent (30 to 90 seconds), laryngoscopy is performed, an endotracheal tube is inserted, the tracheal tube cuff is inflated, and the position of the tube in the trachea is verified. Second, when there is minimal risk of pulmonary aspiration (e.g., presumed empty stomach), the patient is anesthetized and paralyzed while ventilation is supported by intermittent positive pressure delivered via a face mask. At the appropriate time, laryngoscopy is performed, and the endotracheal tube is inserted.

Normalizing Pulmonary Function during Positive-Pressure Ventilation

Once an endotracheal tube is in place, it is common practice in the operating room to maintain general anesthesia and partial muscular paralysis in order to facilitate positive-pressure ventilation and continued toleration of the endotracheal tube by the patient. Postoperatively, in the PACU and ICU, general anesthesia and partial muscular paralysis may be continued if prolonged positive-pressure ventilation is anticipated, or sedatives may be administered by intravenous infusion to allow toleration of the endotracheal tube in anticipation of recovery of spontaneous ventilation and tracheal extubation.

Three other problems are encountered in the patient whose ventilation is supported mechanically by an endotracheal tube: (1) poor ventilatory compliance, (2) bronchoconstriction, and (3) impaired gas exchange. Poor ventilatory compliance can reflect limited compliance of the chest wall and diaphragm, limited compliance of the lungs per se, or both. Deepening general anesthesia and administration of a skeletal muscle relaxant can be used to reduce intercostal and diaphragmatic muscle tone, but they obviously cannot improve the chest cavity compliance that is fixed by disease (e.g., scoliosis or emphysema).

Poor lung compliance may reflect pulmonary interstitial edema, consolidation, bronchial obstruction (e.g., mucus plugs), bronchoconstriction, or compression of the lung by

intrathoracic substances (e.g., pneumothorax, hemothorax, or tumor mass). Treatment of these involves drug therapy of heart failure and infection and procedures such as bronchoscopy, thoracentesis, etc.

Bronchoconstriction may exist chronically (e.g., asthma or reactive airways disease), and these conditions can be exacerbated by the collection of tracheobronchial secretions in the presence of an endotracheal tube, which reduces the effectiveness of coughing in clearing the airway. Occasionally bronchoconstriction can be induced by mechanical stimulation of the airway by an endotracheal tube or other object in an otherwise normal patient. Drug treatment is focused on reducing bronchial smooth muscle tone (e.g., $beta_2$ sympathomimetic or anticholinergic agents), minimizing tracheal bronchial secretions, and decreasing sensory input from the tracheal bronchial tree (e.g., topical anesthetic, deeper general anesthesia, intravenous lidocaine, or an opioid). Acute treatment of bronchoconstriction may involve any combination of the following: (1) an aerosolized $beta_2$ sympathomimetic and/or anticholinergic agent and (2) systemic intravenous administration of a $beta_2$ sympathomimetic agent, a phosphodiestrerase inhibitor [e.g., theophylline salts (aminophylline)], and/or an anticholinergic agent.

Intravenous steroids are indicated in severe bronchoconstriction, especially in asthmatic patients, for whom they have been effective in the past. With the administration of 100% oxygen, blood oxygenation usually is not the main problem in patients with bronchoconstriction; it is the progressive development of hypercarbia and the trapping of air in lung parenchyma that reduce ventilatory compliance and increase intrathoracic pressure. These, in turn, reduce venous return and may cause a tamponade-like impairment of cardiac function.

Impaired alveolar-capillary membrane gas exchange can result from alveolar pulmonary edema (treated by diuretics, inotropes, and vasodilators), decreased pulmonary perfusion (treated by inotropes and vasodilators), and lung consolidation (antibiotic therapy for infection).

Restoration of Spontaneous Ventilation and Airway Protective Mechanisms

The anesthesiologist attempts to tailor the anesthetic plan according to postoperative expectations for the patient. In the relatively healthy patient for whom tracheal extubation can be anticipated in the operating room, the goal is to have the patient breathing spontaneously with airway reflexes intact and the patient arousable to command immediately on completion of the operation. The challenge for the anesthesiologist is to maintain satisfactory general anesthesia through the entire course of the operation and yet have the patient sufficiently recovered from anesthetic drugs, including hypnotics and opioids, shortly after conclusion of the operation. If this is not possible, then the patient is transferred to the PACU to allow additional time for elimination of drugs that depress spontaneous ventilation and cough reflexes. Another possibility is to administer antagonists to opioids (e.g., naloxone) and benzodiazepines (e.g., flumazenil), but this approach risks sudden awakening, pain, and uncontrolled autonomic sympathetic activity leading to undesirable hemodynamic changes. And there is the risk of recurrent ventilatory depression because it is difficult to match the doses of the antagonists to the residual amounts of anesthetic drugs. On the other hand, it is fairly routine for the effects of neuromuscular blockers to be antagonized by administration of an anticholinesterase (e.g., neostigmine) in combination with an anticholinergic agent (e.g., atropine) to limit the autonomic cholinergic side effects of the anticholinesterase.

When the expectation is for maintenance of mechanical ventilation for some time in the postoperative period, then the patient's tolerance of the endotracheal tube is facilitated by the persistent effect of residual anesthetic drugs subsequently supplemented by administration of intravenous hypnotics (e.g., propofol) and opioids (e.g., fentanyl or morphine). These agents can be associated with side effects, including respiratory depression, especially when they are used concurrently. Dexmedetomidine (Precedex), an $alpha_2$-adrenergic agonist, may offer advantages for sedation during weaning from mechanical ventilation because it provides sedation, pain relief, anxiety reduction, stable respiratory rates, and predictable cardiovascular responses.[201–203] Dexmedetomidine facilitates patient comfort, compliance, and comprehension by offering sedation with the ability to rouse patients. This "rousability" allows patients to remain sedated yet communicate with health care workers.

When the appropriate time comes to have the patient take over his or her own ventilation completely, these sedative and analgesic drugs are weaned to a level allowing satisfactory maintenance of blood oxygenation and carbon dioxide removal, easy arousal of the patient, and at least partial restoration of airway reflex mechanisms.

CHAPTER 5

Pathology of Cardiac Surgery

Robert F. Padera, Jr. • Frederick J. Schoen

In the past several decades, the virtual explosion in the number and scope of surgical and interventional diagnostic and therapeutic procedures performed on patients with cardiovascular diseases has launched cardiovascular pathology into the forefront of high-quality patient care.[1] Quality patient care is informed by the results of pathologic examinations and clinicopathologic studies of patients, procedures, and devices that facilitate informed choices among surgical or catheter-based interventional options and optimize short- and long-term patient management, including recognition of complications. Importantly, beyond implicit clinical benefit, studies of cardiac pathology and pathobiology serve as the cornerstones of modern cardiovascular research and the development of innovative medical devices and other therapeutic options.

This chapter summarizes pathologic considerations most relevant to surgery in the major forms of acquired cardiovascular disease, emphasizing pathologic anatomy, clinicopathologic correlations, and pathophysiologic mechanisms. In view of space limitations, several areas (e.g., aortic disease) are necessarily omitted from discussion and others (e.g., cardiac assist devices) are attenuated, as they are discussed in greater detail elsewhere in the text. Moreover, although we have not included the key pathologic considerations herein, we are mindful that the number of adults with congenital heart disease is increasing rapidly and that they have unique and important clinical and pathologic concerns.[2–4]

GENERAL CONSIDERATIONS

Myocardial Hypertrophy

Hypertrophy is the compensatory response of the cardiac muscle, the myocardium, to increased work (Fig. 5-1).[5] Myocardial hyperfunction induces an increase in the overall mass and size of the heart that reflects increased size of myocytes through addition of contractile elements (sarcomeres) and mitochondria. Since cardiac myocytes are terminally differentiated cells that cannot divide, functionally beneficial augmentation of myocyte number (hyperplasia) in response to stress or injury occurs either little or not at all in the adult heart. Since the vasculature does not proliferate commensurate with increased cardiac mass, hypertrophied myocardium is usually relatively deficient in blood vessels and thereby particularly vulnerable to ischemic damage. Moreover, myocardial fibrous tissue is often increased.

The pattern of hypertrophy reflects the nature of the stimulus. Pressure-overloaded ventricles (e.g., resulting from systemic hypertension or aortic stenosis) develop concentric hypertrophy with an increased ventricular mass, wall thickness, and ratio of wall thickness to cavity radius, without appreciable dilation. In contrast, volume-overloaded ventricles (e.g., resulting from chronic aortic or mitral regurgitation) develop hypertrophy with chamber dilation in which both ventricular radius and wall mass are increased. Pressure-overload hypertrophy is accomplished predominantly by augmentation of cell width via parallel addition of sarcomeres; in contrast, volume overload and/or dilation stimulate augmentation of both cell width and length via both parallel and series addition of sarcomeres. In situations such as myocardial infarction (MI), where there is local myocyte necrosis, the noninfarcted regions of myocardium not only hypertrophy (termed *compensatory hypertrophy*) but also may be overwhelmed by mechanical disadvantage and degenerative changes. The constellation of changes that occur in both infarcted and noninfarcted myocardium is called *ventricular remodeling*.[6] In contrast to the regional changes resulting from MI, the chamber wall is affected globally by the increased chamber pressure of hypertension, the increased pressure or volume workload of valvular heart disease, and in dilated cardiomyopathy.

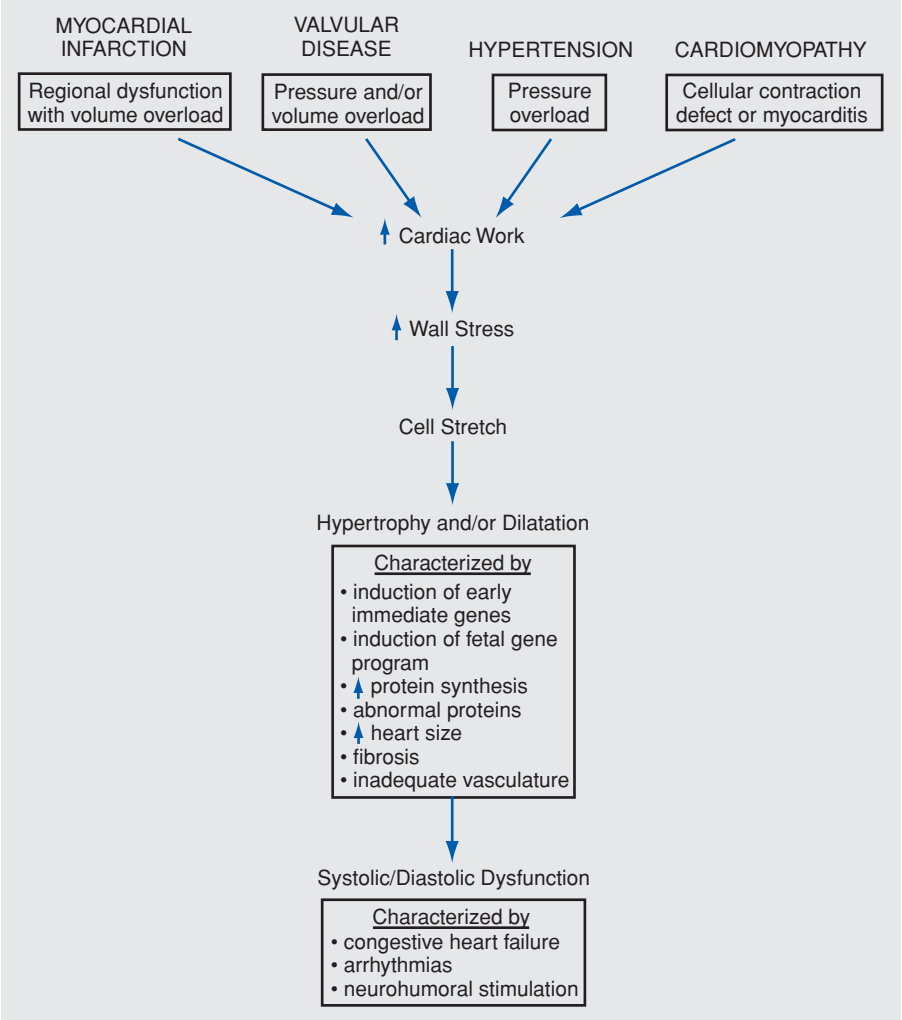

Figure 5-1. Summary of the macroscopic, cellular, and extracellular changes in cardiac hypertrophy and heart failure. (*Modified with permission from Schoen.*[5])

Molecular changes that initially mediate enhanced function in hypertrophied hearts may subsequently contribute to the development of heart failure.[7] Hemodynamic overload alters myocardial gene expression, leading to re-expression of a pattern of protein synthesis similar to that of proliferating cells in general and of fetal cardiac myocytes during development. Proteins comprising contractile elements and those involved in excitation-contraction coupling and energy utilization are altered quantitatively or through production of different isoforms; the variant proteins may be less functional than the normal proteins. Hypertrophied and/or failing myocardium may have additional abnormalities that include reduced adrenergic responsiveness, decreased calcium availability, impaired mitochondrial function, and microcirculatory spasm. Apoptosis of cardiac myocytes, potentially triggered by the same mechanical forces, neurohormonal activation, hypoxia, or cytokines that prompted the adaptive changes, also plays a role in the development of heart failure, and may provide a therapeutic strategy for heart failure treatment.[8]

The changes in the heart described above initially enhance function and are thereby adaptive, but they may ultimately become deleterious and contribute to cardiac failure. Thus, cardiac hypertrophy comprises a tenuous balance between adaptive characteristics and potentially deleterious structural, functional, and biochemical/molecular alterations including enlarged muscle mass with alterations in the cardiac configuration, enhanced metabolic requirements, synthesis of abnormal proteins, decreased capillary:myocyte ratio, fibrosis, microvascular spasm, and impaired contractile mechanisms. Hypertrophy (with or without chamber dilation) also decreases myocardial compliance and may thereby hinder diastolic filling. In addition, left ventricular hypertrophy (LVH) is an independent risk factor for cardiac mortality and morbidity, especially for sudden death.[9,10]

Left ventricular hypertrophy regresses in many cases following removal of the stimulus, but it is uncertain to what extent hypertrophy is capable of resolution in individual patients. Moreover, progressive cardiac failure may ensue following and despite hemodynamic adjustment by valve replacement or repair (Fig. 5-2). In addition, in cardiac surgery with its attendant global ischemia, markedly increased cardiac muscle mass may compromise intraoperative myocardial preservation and render the heart particularly susceptible to ischemic damage.

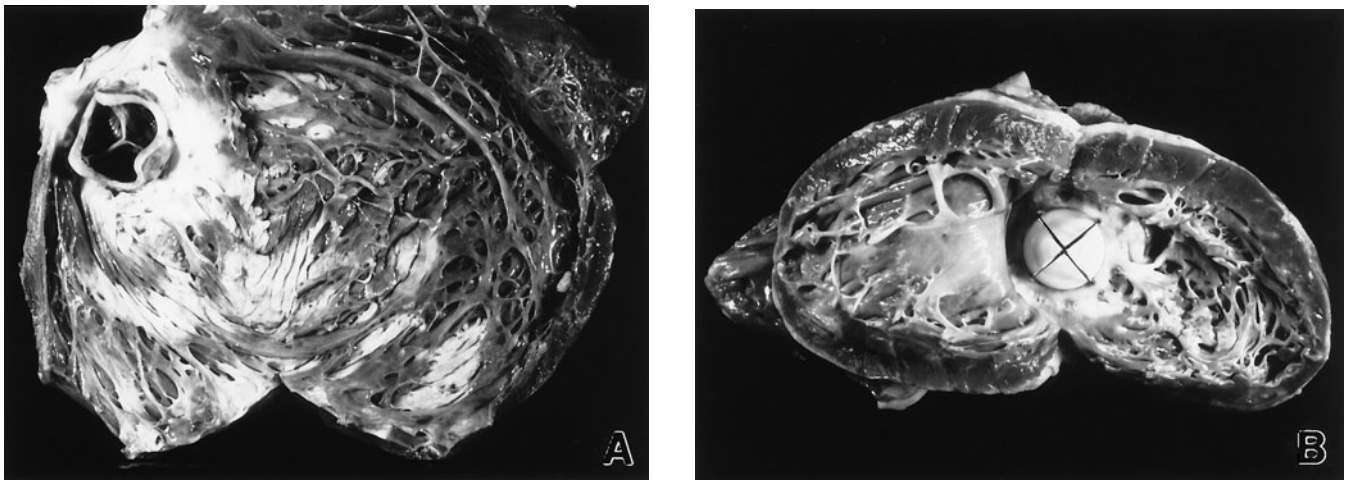

Figure 5-2. Late postoperative cardiac failure necessitating heart transplantation. (A) Four years following mitral valve replacement with a porcine bioprosthesis for congenital deformity causing mitral regurgitation. (B) Twenty-eight years following mitral valve replacement with a caged-disk valve for rheumatic mitral stenosis. In both cases the myocardial degradation secondary to the underlying disease progressed despite an intact valve prosthesis.

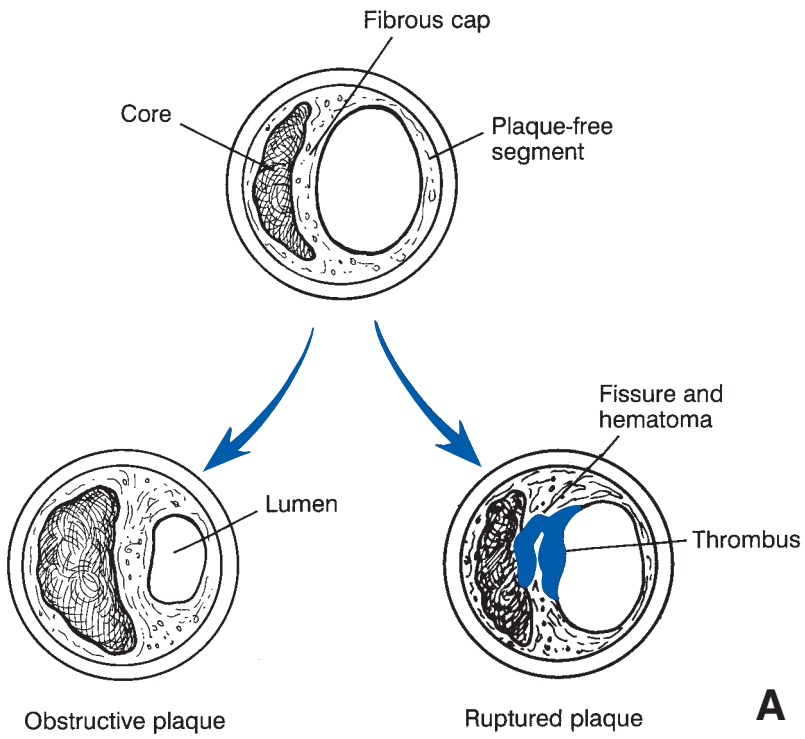
Atherosclerosis

Atherosclerosis is a chronic, progressive, multifocal disease of the vessel wall intima whose characteristic lesion is the atheroma or plaque that forms through the key processes of intimal thickening (mediated predominantly by smooth muscle cell proliferation) and lipid accumulation (mediated primarily by monocyte phagocytosis).[11,12] Atherosclerosis primarily affects the large elastic arteries and large and medium-sized muscular arteries of the systemic circulation, particularly at points of branches, sharp curvatures, and bifurcations. Atherosclerosis of native coronary arteries involves the large epicardial vessels, especially the proximal portions of the left anterior descending and circumflex arteries, and the right coronary artery diffusely, and generally not their intramural branches. In contrast, the arteriosclerosis that affects the coronary arteries of transplanted hearts is a diffuse process that affects distal, intramural vessels as well as the larger epicardial vessels (see later in this chapter). Although normal veins are usually spared from atherosclerosis, venous bypass grafts interposed within branches of the arterial system frequently develop rapidly progressive intimal thickening and ultimately atherosclerotic obstructions. Paradoxically, arterial grafts such as the internal mammary artery are largely spared. Most atheromas in the coronary arteries are eccentric, with a plaque-free segment often occupying a substantial fraction of the vessel wall. In early lesions, the plaque bulges outward at the expense of the media with the arterial lumen remaining circular in cross-section at essentially the same original diameter (a process termed *vascular remodeling*).[13]

The prevailing theory of atherogenesis and atherosclerosis centers around interactions between endothelial cells and smooth muscle cells of the arterial wall, monocytes and platelets in the bloodstream, and plasma lipoproteins. Endothelial cell injury from chronic hypercholesterolemia, homocystinemia, chemicals in cigarette smoke, viruses, localized hemodynamic forces, systemic hypertension, hyperglycemia, or the local effects of cytokines causes phenotypic and hence functional changes in endothelial cells, called *endothelial dysfunction*, which can also contribute to atherosclerosis. Endothelial dysfunction is manifested by: (1) vasoconstriction due to decreased production of the vasodilator nitric oxide, (2) increased permeability to lipoproteins, (3) expression of tissue factor leading to thrombosis, and (4) expression of certain injury-induced adhesion molecules leading to adherence of platelets and inflammatory cells.[14] Progression through an early, subendothelial lesion (often called a fatty streak) to a mature, complex atheromatous plaque involves the following events: (1) monocyte adherence to endothelial cells, migration into the subendothelial space, and transformation into tissue macrophages; (2) smooth muscle cell migration from the media into the intima, and proliferation and secretion of collagen and other extracellular matrix constituents; (3) lipid accumulation, both intracellularly (foam cells) in macrophages and smooth muscle cells as well as extracellularly; (4) lipoprotein oxidation in the vessel wall leading to generation of potent biologic stimuli such as chemoattractants and cytotoxins; (5) persistent chronic inflammation, especially at the junction with the uninvolved arterial wall (the "shoulder"); (6) cell death with release of intracellular lipids (mostly cholesterol esters); and often (7) calcification.

Mature atherosclerotic plaques consist of a central core of lipid and cholesterol crystals and cells such as macrophages, smooth muscle cells, and foam cells along with necrotic debris, proteins, and degenerating blood elements.[15] This core is separated from the lumen by a fibrous cap rich in collagen. The configuration and composition of atheromas



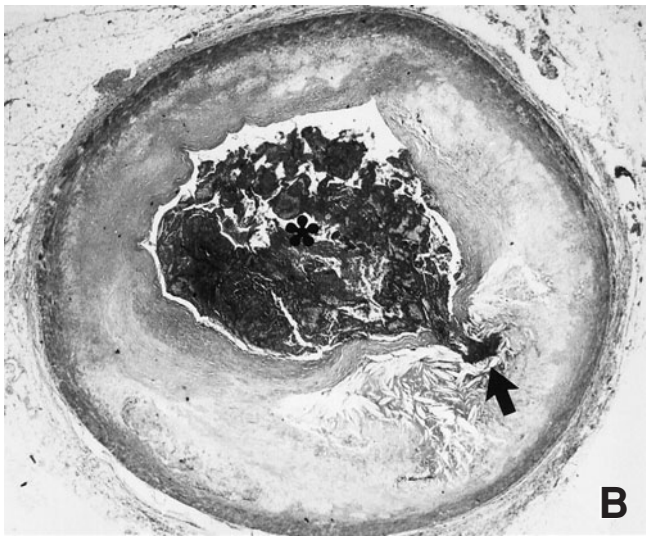


Figure 5-3. Consequences of coronary arterial atherosclerosis. (A) Progression of fibrous atheromatous plaque with a core of extracellular lipid and necrotic debris covered by intact fibrous cap (top) to either severe chronic stenosis (lower left) or acute plaque rupture, fissuring, or erosion, resulting in a complicated lesion with a surface defect, hematoma, or mural thrombus (lower right). (B) Coronary thrombosis, superimposed on atherosclerotic plaque, triggering fatal myocardial infarction. A fissure breaching the fibrous cap and extending into the plaque necrotic core (arrow) presumably initiated the occlusive thrombus (asterisk). Hematoxylin and eosin 15x. (*B: Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

can vary considerably among individuals, among arteries in the same individual, or among regions of one artery, especially with regard to the proportion of lipid to connective tissue. The natural history of atheromatous plaque and the efficacy and safety of interventional therapies depend on relative plaque composition, the spatial distribution of the constituents, the integrity of the fibrous cap, and the local mechanical environment.[16–18] These features of plaque structure can be evaluated using intravascular ultrasound and potentially novel imaging methods, including noninvasive molecular imaging.[19,20]

The clinical manifestations of advanced atherosclerosis in the coronary arteries are generally due to their encroachment of the lumen, leading to progressive stenosis, or to acute plaque disruption with thrombosis (see later discussion in section on ischemic heart disease) (Fig. 5-3). However, slowly developing occlusions over time may stimulate the formation of collateral vessels that protect against distal myocardial ischemia and infarction despite high-grade stenosis. Aneurysms may form secondary to atherosclerosis as a result of atrophy or necrosis of the media, a process more common in the aorta than in the coronary circulation.[21]

The natural history, morphologic features, key pathogenetic events, and clinical complications of atherosclerosis are summarized in Fig. 5-4.

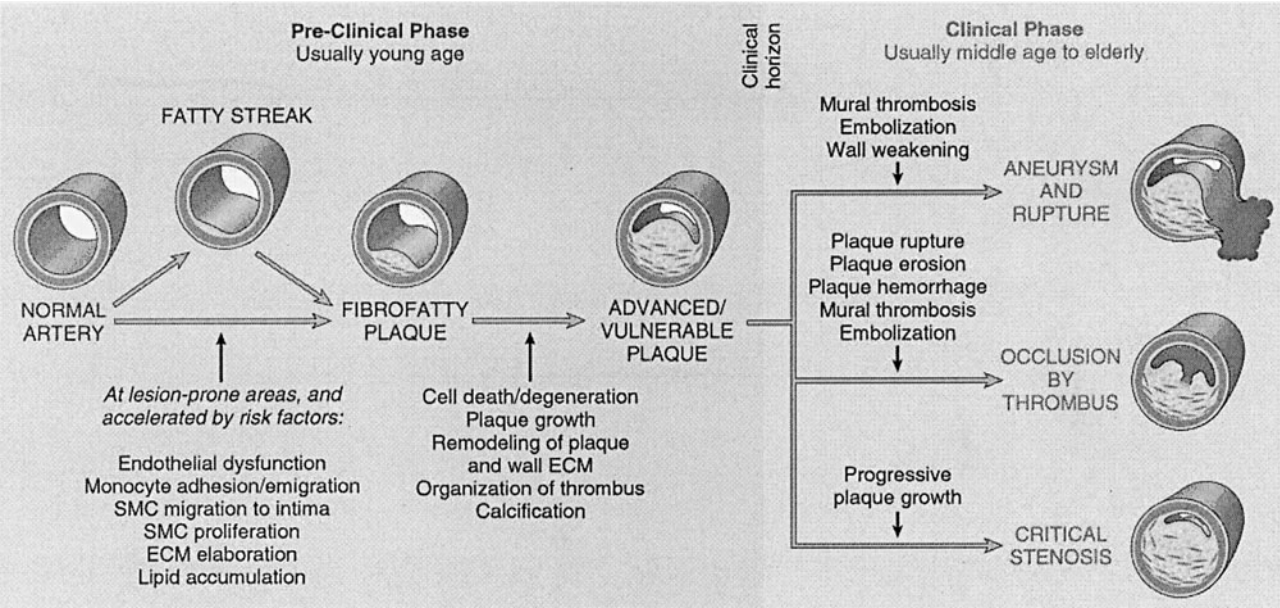

Figure 5-4. Summary of the pathology, pathogenesis, complications, and natural history of atherosclerosis. Plaques usually develop slowly and insidiously over many years, beginning in childhood or shortly thereafter and exerting their clinical effects in middle age or later. As described in the text, they may progress from a fatty streak to a fibrous plaque, and then to plaque complications that lead to disease. The schematic diagram interrelates the morphology, pathogenesis, and complications of atherosclerosis and provides a unified approach to this serious disease process. SMC = smooth muscle cell; ECM = extracellular matrix. Ischemic Myocardial Injury

Cardiac *ischemia* occurs when perfusion is inadequate to meet the metabolic needs of the tissue.[22] Ischemia is most often caused by inadequate local coronary blood flow resulting from obstruction or narrowing secondary to atherosclerosis, thrombosis, embolism, or spasm. Decreased coronary flow leading to global hypoperfusion also follows systemic hypotension, in shock, and during cardiopulmonary bypass. Ischemia can also result from increased cardiac demand secondary to exercise, tachycardia, hyperthyroidism, or ventricular hypertrophy and/or dilation. The effects of ischemia are potentiated when the oxygen supply is decreased secondary to anemia, hypoxia, or cardiac failure.

Progression of damage

The severity and duration of ischemia determine the consequences. The pre-existing adaptive and nutritional/metabolic state of the affected cells and tissues is also a factor.

Intracellular changes following the onset of myocardial ischemia are sequential and complex (Table 5-1). Ischemia induces anaerobic glycolysis in cardiac myocytes within seconds, leading to inadequate production of high-energy phosphates such as adenosine triphosphate and the accumulation of metabolites such as lactic acid, leading to intracellular acidosis. Myocardial function is exquisitely sensitive to these biochemical consequences of severe ischemia; indeed, following the onset of ischemia, a contractility defect is evident within seconds, leading to total loss of contraction within 2 minutes. Ischemic changes in an individual cell are initially sublethal and potentially reversible if the duration of ischemic injury is short and perfusion is restored prior to the onset of irreversible changes (15 to 20 minutes). Irreversible (lethal) injury of cardiac myocytes marked by cell membrane structural defects occurs only after 20 to 40 minutes within the most severely ischemic area. When ischemic injury is of sufficient severity and duration in groups of involved cells, the affected cells die, and *myocardial infarction* results.

Within the region of myocardium made vulnerable by loss of perfusion, termed the *area at risk*, not all cells are equally injured. In particular, a gradient of ischemia exists across the myocardium. The most severely affected regions, and therefore the first to become necrotic, are the subendocardium and papillary muscles in the center of the perfusion defect. However, the myocytes immediately beneath the endocardium to a depth of approximately several hundred microns may be effectively perfused by the well-oxygenated blood in the left ventricular chamber and therefore protected from ischemic damage. As uninterrupted ischemia progresses, there is a *wavefront* of cell death outward from the mid-subendocardial region toward and eventually encompassing the lateral borders and less ischemic subepicardial and peripheral regions. The predominant mechanism of cell

Table 5–1.

Approximate Time of Onset and Recognition of Key Features of Ischemic Myocardial Injury

Event/process	Time of onset
Onset of anerobic metabolism	Within seconds
Loss of contractility	<2 min
ATP* reduced to 50% of normal to 10% of normal	 10 min 40 min
Irreversible cell injury	20–40 min
Microvascular injury	>1 h
Pathologic feature	**Time of recognition**
Ultrastructural features of reversible injury	5–10 min
Ultrastructural features of irreversible damage	20–40 min
Wavy fibers Staining defect with tetrazolium dye Classic histologic features of necrosis	1–3 h 2–3 h 6–12 h
Gross alterations	12–24 h

**ATP = adenosine triphosphate.*

death in MI has traditionally been thought of as coagulation necrosis; however, apoptosis may also play a role.[23,24] In human MI, approximately 50% of the area that has impaired perfusion (i.e., the area at risk) becomes necrotic in approximately 3 to 4 hours. The final transmural extent of an infarct is generally established within 6 to 12 hours. Restoration of flow to a severely ischemic area via therapeutic intervention can alter the outcome depending on the interval between the onset of ischemia and reperfusion.

Within a few minutes of the onset of ischemia, reversible ultrastructural changes can be observed using transmission electron microscopy, including glycogen depletion, cellular and mitochondrial swelling, myofibrillar relaxation, and margination of nuclear chromatin. This is followed by the development of amorphous mitochondrial densities and sarcolemmal disruption as evidence of necrosis. However, neither reversible ischemia nor necrosis existing less than 6 or more hours before patient death can be detected by gross or microscopic analysis. On gross examination at autopsy of a patient who died at least 2 to 3 hours following the onset of infarction, the presence of a necrotic region may often be indicated as a staining defect with triphenyl tetrazolium chloride, a dye that turns viable myocardium a brick-red color on reaction with intact myocardial dehydrogenases.[25] The earliest light microscopic features include clusters of necrotic myocytes that exhibit intense eosinophilia, nuclear pyknosis and loss, and stretched and wavy myocytes. Short-term ischemia short of necrosis cannot be reliably demonstrated by gross or microscopic examination.

The subsequent morphologic changes in the infarcted region follow a largely stereotyped sequence. Inflammatory exudation with polymorphonuclear leukocytes can usually be seen after 6 to 12 hours and peaks within 1 to 3 days. The inflammatory reaction continues with removal of necrotic tissue by macrophages (3 to 5 days) and is followed by a fibroblastic reparative response accompanied by neovascularization (granulation tissue) beginning after approximately 7 to 10 days at the margins of preserved tissue. The infarcted tissue is replaced by scar that reaches maturity by about 6 to 8 weeks. Therefore, neither gross nor microscopic examination can distinguish a scar that is 8 weeks old from one that formed many years before.

The repair sequence following an infarct is similar to that which follows tissue injury of diverse causes and at various noncardiac anatomic sites. However, healing of MI may be altered by reperfusion (see below), mechanical stress, gender, and neurohumoral and other factors.[26] For example, healing of myocardial ischemic injury may be slowed by anti-inflammatory agents administered following MI,[27] or as a component of immunosuppressive therapy following transplantation.[28] Sublethal but chronic ischemic injury is often manifest as myocyte vacuolization, usually most prevalent in the subendocardium.[29]

Although cardiac myocytes are traditionally thought incapable of regeneration, a growing body of evidence suggests that regeneration of cardiac myocytes can occur under certain circumstances at the viable borders of myocardial infarcts.[30,31] Whether this capacity for renewal can be harnessed to therapeutic advantage is not yet known, and is a rapidly evolving and controversial area (discussed later in this chapter).

Effects of reperfusion

The progression of myocardial ischemic injury can be modified by restoration of blood flow (reperfusion) to jeopardized myocardium, since ischemic injury to myocytes is progressive and initially reversible.[32] Reperfusion occurring before the onset of irreversibility (about 20 minutes in the most severely ischemic regions) can prevent cell death, which may substantially limit infarct size or prevent infarction altogether.[33] Later reperfusion after up to 6 to 12 hours does not prevent infarction entirely, but may salvage myocytes located at the leading edge of the "wavefront" that are only reversibly injured.[34] The potential for recovery decreases with increasing severity and duration of ischemia (Fig. 5-5). Whether late

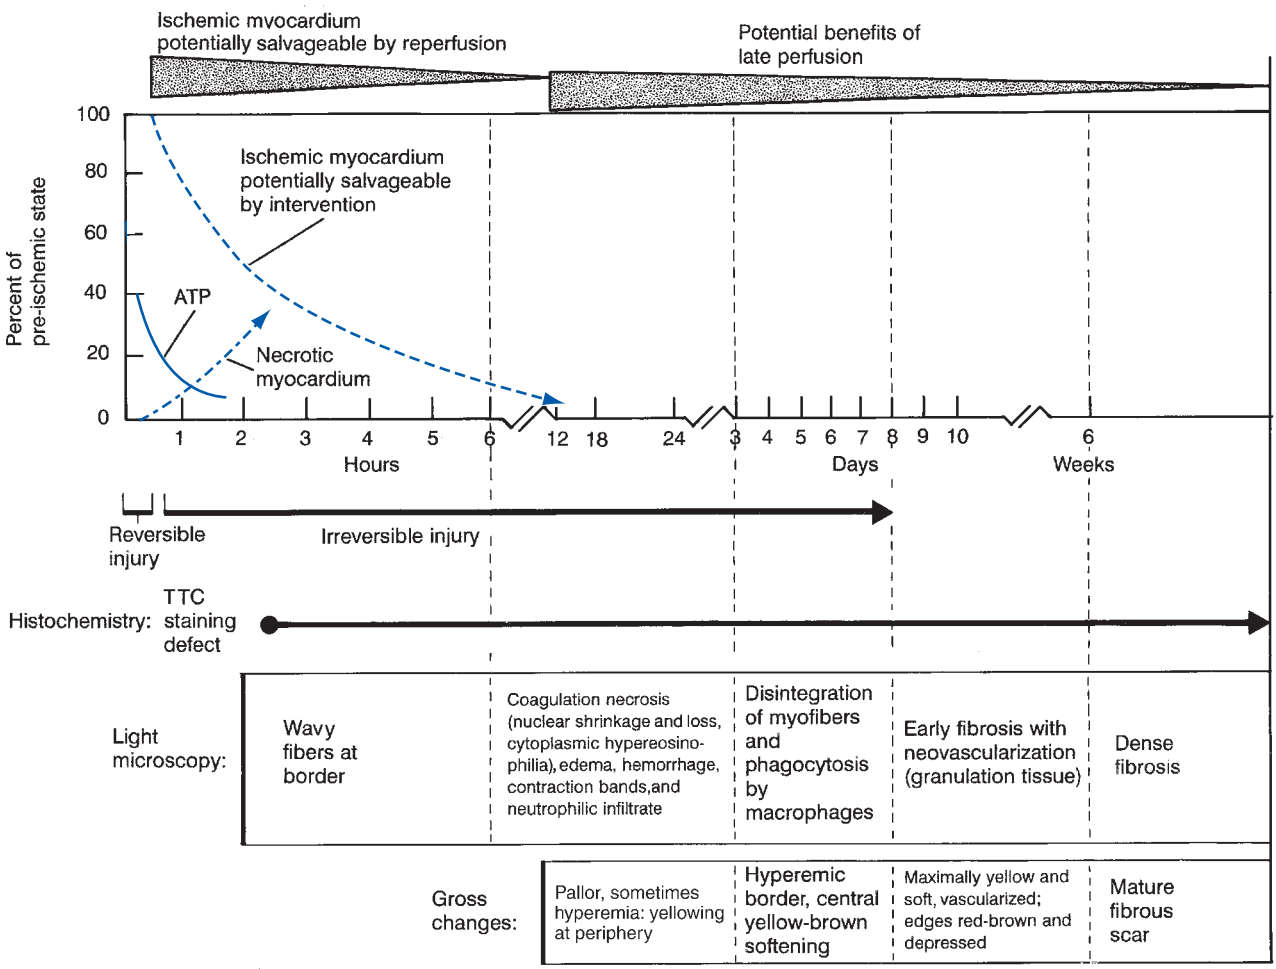

Figure 5-5. Temporal sequence of early biochemical, ultrastructural, histochemical, and histologic findings after onset of severe myocardial ischemia. The time frames for early and late reperfusion of the myocardium supplied by an occluded coronary artery are schematically shown at the top of the figure. For approximately one-half hour following the onset of even the most severe ischemia, myocardial injury is potentially reversible. Thereafter, progressive loss of viability occurs to completion by 6 to 12 hours. The benefits of reperfusion are greatest when it is achieved early, with progressively smaller benefit occurring as reperfusion is delayed. ATP = adenosine triphosphate; TTC = triphenyl tetrazolium chloride. (*Reproduced with permission from Antman and Braunwald*[104] *and Schoen.*[5])

reperfusion beyond the interval at which myocyte salvage continues to be possible may also lead to improved clinical outcomes is not yet resolved.[35]

The gross and microscopic findings of reperfusion of ischemic myocardium are summarized in Fig. 5-6. The microscopic pattern of reperfusion includes hemorrhage and necrotic myocytes with contraction bands, which are transverse eosinophilic lines across the cell that represent clusters of hypercontracted sarcomeres. Contraction bands are a distinct manifestation of irreversible myocyte injury caused by ischemic cell membrane damage followed by a massive influx of calcium from the restored blood flow. This leads to intense sarcomeric contraction.[36] In some cases of reperfusion after severe global ischemia, the left ventricle may undergo a massive tetanic contraction to a small, hard mass; this is termed the stone heart syndrome.[37]

Restoration of systemic pressure to an artery supplying a healthy microvasculature will often restore adequate blood flow. However, microvascular damage often follows severe, prolonged myocardial ischemia and ischemic necrosis, and the effects of ischemic vascular injury followed by reperfusion may include: (1) hemorrhage, visible grossly and microscopically, due to vascular wall incompetence; or (2) microvascular occlusion due to endothelial or interstitial edema, hypercontracted ischemic myocytes, and/or plugging by platelet or neutrophil aggregates, which can cause the *no-reflow phenomenon.* Thus, microvascular occlusions may inhibit the reperfusion of damaged regions.[38]

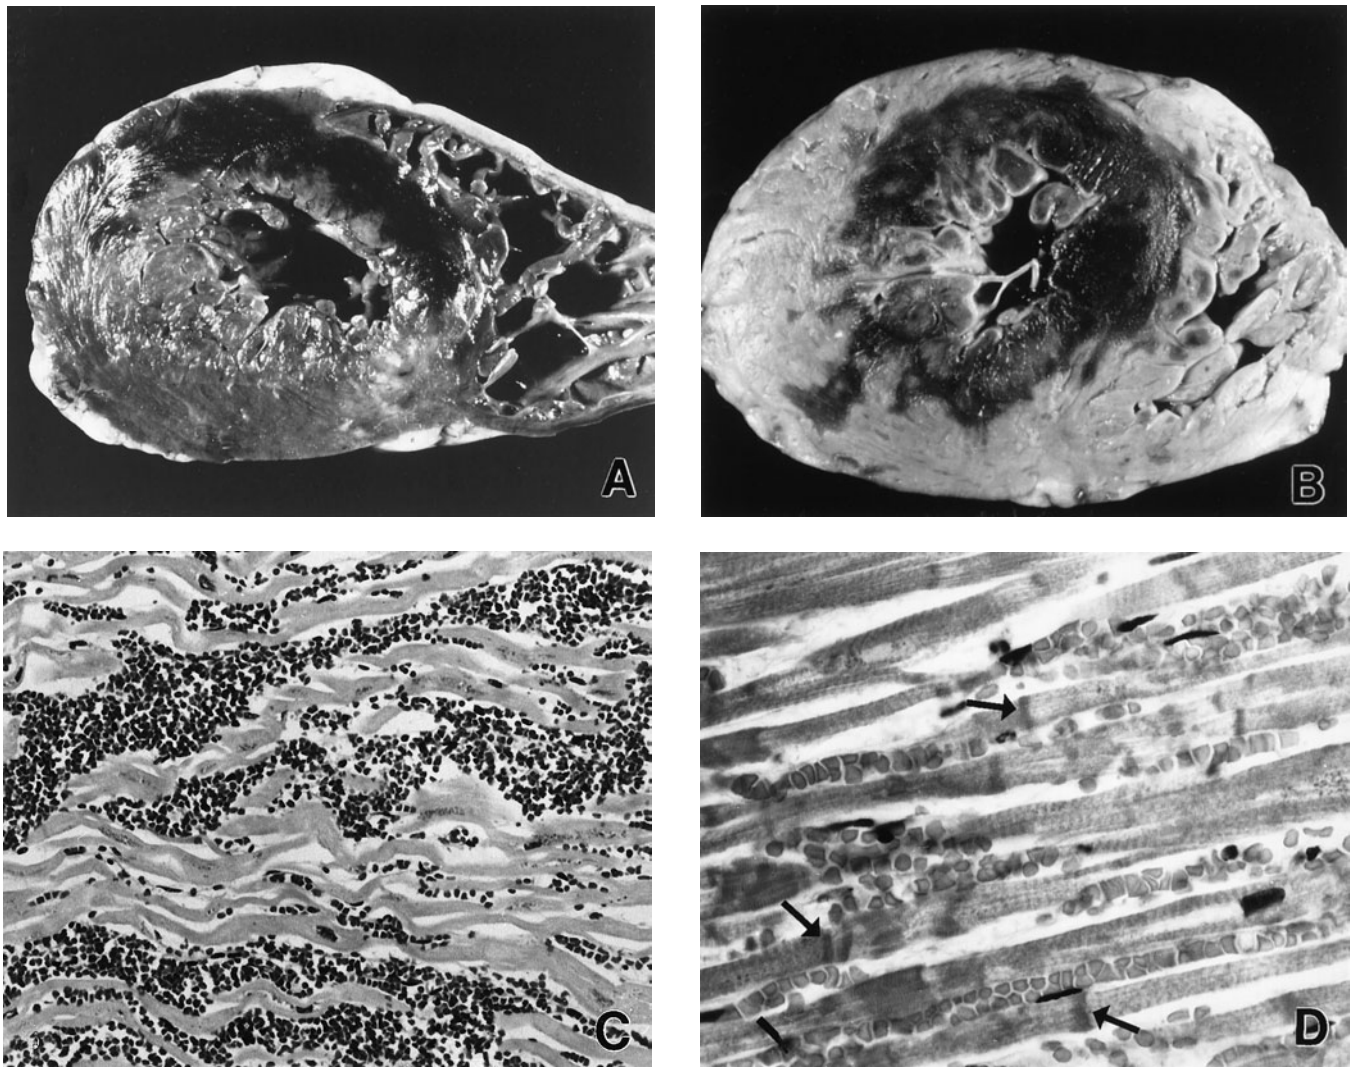

Figure 5-6. Morphologic effects of reperfusion following severe myocardial ischemia. (A) Large, densely hemorrhagic anteroseptal acute myocardial infarct from patient treated by streptokinase intracoronary thrombolysis for left anterior descending artery thrombus, approximately 4 hours following onset of chest pain. (B) Subendocardial circumferential hemorrhagic acute myocardial necrosis in a large hypertrophied heart 2 days postcardiac transplantation. (C) Photomicrograph of myocardial interstitial hemorrhage from heart shown in (A). Hematoxylin and eosin 375x. (D) Photomicrograph of myocardial necrosis with contraction bands (contraction band necrosis). Contraction bands are noted by arrows. Hematoxylin and eosin 375x. (*A, C, and D: Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

Reperfusion may actually damage some of the ischemic but still viable myocytes that have not been irreversibly injured (*reperfusion injury*). However, the amount of salvaged myocardium likely outweighs the extent of this damage. Reperfusion injury is thought to be mediated by toxic oxygen species (such as free radicals) that are overproduced by myocytes, infiltrating polymorphonuclear leukocytes, or complement activation.[39] Arrhythmias also may occur after reperfusion, possibly secondary to myocyte damage by oxygen free radicals and/or increased intracellular calcium.

Although reperfusion may accomplish salvage of myocardial cell viability, metabolic and functional recovery of successfully reperfused myocardium is usually not instantaneous, with contractile dysfunction persisting for hours to days following brief periods of ischemia. Reversible postischemic myocardial dysfunction is termed *myocardial stunning*. Myocardial stunning may occur after percutaneous coronary interventions, cardiopulmonary bypass, or even ischemia related to unstable angina or stress. The use of cardiac assist devices may allow the stunned myocardium to recover in situations of reversible cardiac failure.[40,41]

Viable regions of myocardium with chronically impaired function in the setting of chronically reduced coronary blood flow are termed *hibernating myocardium*.[42,43] Myocardial hibernation is characterized by: (1) persistent wall motion abnormality; (2) low myocardial blood flow; and (3) evidence of viability of at least some of the affected areas. Contractile function of hibernating myocardium can improve if blood flow returns toward normal or if oxygen demand is reduced. Correction of this abnormality is likely responsible for the reversal of long-standing defects in ventricular wall motion that may be observed following coronary bypass graft (CBG) surgery or percutaneous coronary intervention (PCI). Assessment of viable but poorly perfused myocardium may identify those patients who would benefit from restoration of adequate coronary blood flow.[44]

Adaptation to short-term transient ischemia (i.e., duration insufficient to cause cell death) may induce tolerance against subsequent, more severe ischemic insults in a process termed *ischemic preconditioning*.[45,46] Thus, a short (5-minute) period of cardiac ischemia followed by reperfusion may be capable of protecting the affected myocardium against injury from a more intense period of subsequent ischemia. The mechanism of this protection is uncertain, but stimulation of adenosine receptors when adenosine is released during ischemia, enhanced expression of heat-shock proteins (which makes the heart more resistant to prolonged ischemia), and involvement of protein kinase C and adenosine triphosphate–dependent potassium channels have been suggested.[47] Pharmacologic stimulation of these pathways may potentially induce the benefits of preconditioning without actually subjecting the myocardium to dangerous ischemia.

Biomaterials and Tissue Engineering

Biomaterials are synthetic or modified biologic materials that are used in implanted or extracorporeal medical devices to augment or replace body structures and functions.[48,49] Biomaterials include polymers, metals, ceramics, carbons, processed collagen, and chemically treated animal or human tissues, the latter exemplified by glutaraldehyde-preserved heart valves and pericardium. The first generation of biomedical materials (e.g., metals used for early valve substitutes) was generally designed to be inert; the goal was to reduce the host inflammatory responses to the implanted material. By the mid-1980s, bioactive biomaterials were emerging that could interact with the host in a beneficial manner (e.g., biodegradable polymer sutures and drug delivery systems). With a greater understanding of material-tissue interactions at the cellular and molecular levels, advanced materials are being designed to stimulate specific cellular and tissue responses at the molecular level.[50,51]

Biomaterial-tissue interactions comprise effects of both the implant on the host tissues and the host on the implant, and are important in mediating prosthetic device complications (Fig. 5-7).[52] Major morphologic effects of biomaterials on tissues are illustrated in Fig. 5-8. Complications of cardiovascular medical devices, regardless of anatomic site of implantation, can be grouped into six major categories: (1) thrombosis and thromboembolism; (2) device-associated infection; (3) exuberant or defective healing; (4) degeneration, fracture, or other biomaterials failure; (5) adverse local tissue interaction, such as toxicity or traumatic hemolysis; and (6) adverse effects distant from the intended site of the device, such as biomaterial/device migration or systemic hypersensitivity.

Blood-surface interaction

Thromboembolic complications of cardiovascular devices can cause significant mortality and morbidity. Thrombotic deposits can impede the function of a prosthetic heart valve, vascular graft, or blood pump, or cause distal emboli. As in the cardiovascular system in general, surface thrombogenicity, hypercoagulability, and locally static blood flow (called *Virchow's triad*), present individually or in combination, determine the relative propensity toward thrombus formation and location of thrombotic deposits with specific devices. No known synthetic or modified biologic surface is as thromboresistant as the normal, unperturbed endothelium. Like a blood vessel denuded of endothelium, foreign materials in contact with blood spontaneously and rapidly (within seconds) absorb a film of plasma components, primarily protein, followed by platelet adhesion.[53] If conditions of relatively static flow are present, macroscopic thrombus can ensue. Considerable evidence implicates a primary role for blood platelets in the thrombogenic response to artificial surfaces (see Fig. 5-8A).[54] Nevertheless, the clinical approach to control of thrombosis in cardiovascular devices is generally through systemic anticoagulants, particularly warfarin. This agent inhibits thrombin formation but does not inhibit platelet-mediated thrombosis. Antiplatelet agents, such as aspirin or clopidogrel, may also be helpful. The specific physical and chemical characteristics of materials that regulate the outcomes of blood-surface interaction are clearly important but incompletely understood.

Coagulation proteins, complement products, other proteins, and platelets are activated, damaged, and consumed by blood-material interactions. For example, blood contact with the large areas of synthetic surfaces during the extracorporeal perfusion of cardiopulmonary bypass may have at least four consequences: (1) activation and resultant dysfunction of platelets; (2) progressive denaturation of plasma proteins and lipoproteins; (3) activation of coagulation proteins and the fibrinolytic system, and through interaction with inflammatory pathways, production of various bioactive molecules, including bradykinin, a potent vasodilator; and (4) activation of complement through the alternative pathway, with production of C3a and C5a, inducing polymorphonuclear leukocyte stasis in the pulmonary circulation with the occasional sequelae of acute pulmonary hypertension and inflammatory lung injury.[55]

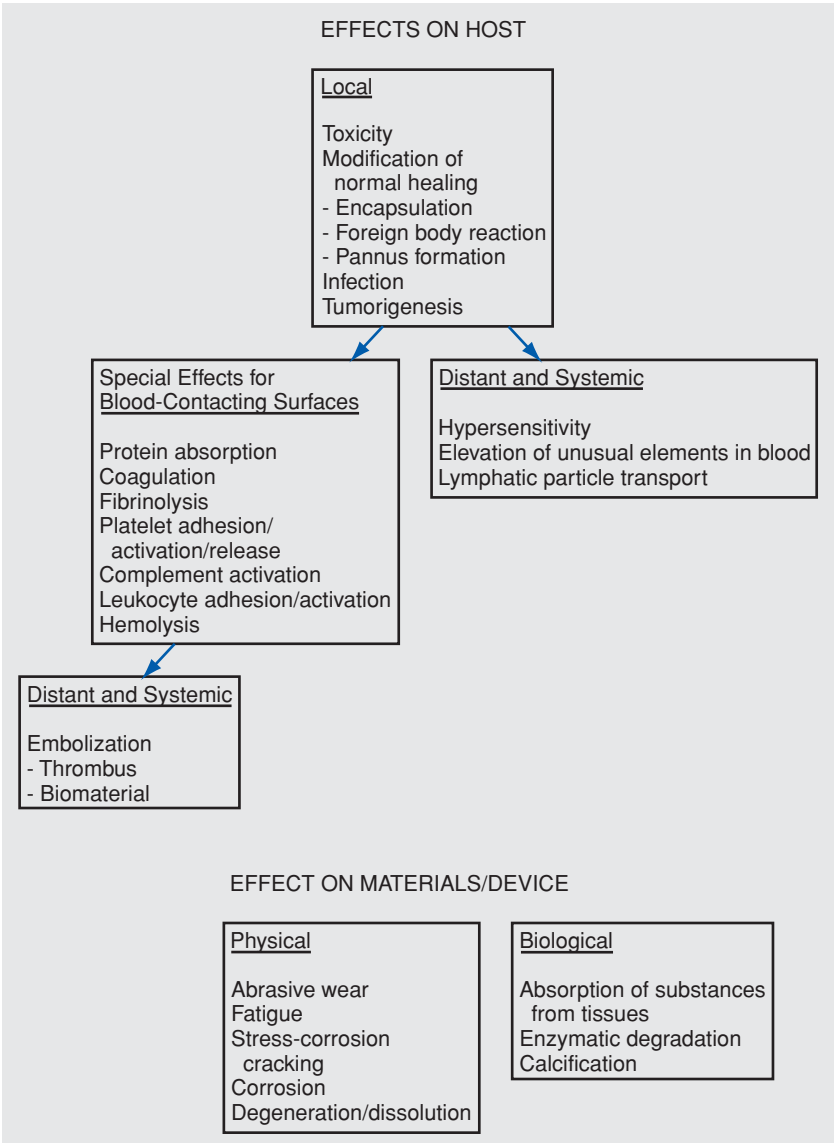

Figure 5-7. Overview of potential interactions of biomaterials with tissue, comprising local, distant, and systemic effects of the biomaterial on the host tissue, as well as the physical and biologic effects of the environment on the materials and the device. These interactions comprise the pathophysiologic basis for device complications and failure modes. (*Modified with permission from Schoen FJ: Introduction to host reactions to biomaterials and their evaluation, in Ratner BD, Hoffman AS, Schoen FJ, Lemons JE, [eds]: Biomaterials Science: An Introduction to Materials in Medicine, 2nd ed. Orlando, Elsevier, Academic Press, 2004; p 293.*)

Hemolysis (damage to red blood cells) in implants and extracorporeal circulatory systems results from both blood-surface interactions and turbulence. Erythrocytes have reduced survival following cardiopulmonary bypass. Also, with earlier model heart valve prostheses, renal tubular hemosiderosis or cholelithiasis occurred in many patients, indicative of chronic hemolysis. With contemporary valves, hemolysis generally is modest and well compensated, but may be accentuated by valve dysfunction.

Tissue-biomaterials interaction

Synthetic biomaterials typically are not immunogenic, but they elicit a foreign body reaction, a special form of nonimmune inflammatory response with an infiltrate predominantly composed of macrophages.[56,57] Nevertheless, immunologic reactions have been proposed rarely for synthetic biomaterial-tissue interactions,[58] and they are possible with tissue-derived biomaterials. Indeed, antibodies can be elicited by implantation of some materials in finely pulverized form. Nevertheless, proven clinical cardiovascular device failure owing to immunologic reactivity is rare. For most biomaterials implanted into solid tissue, encapsulation by a relatively thin fibrous tissue capsule (composed of collagen and fibroblasts) resembling a scar ultimately occurs, often with a fine capillary network at its junction with normal tissue (see Fig. 5-8B). An ongoing inflammatory infiltrate consisting of monocytes/macrophages and multinucleated foreign body giant cells in the vicinity of a foreign body generally suggests persistent tissue irritation (see Fig. 5-8C).

Vascular graft healing

The healing of fabric prostheses or components within the cardiovascular system can yield exuberant fibrous tissue at the anastomosis as an overactive physiologic repair response to vascular injury (Fig. 5-9). Synthetic and biologic vascular grafts often fail because of generalized or anastomotic narrowing mediated by connective tissue

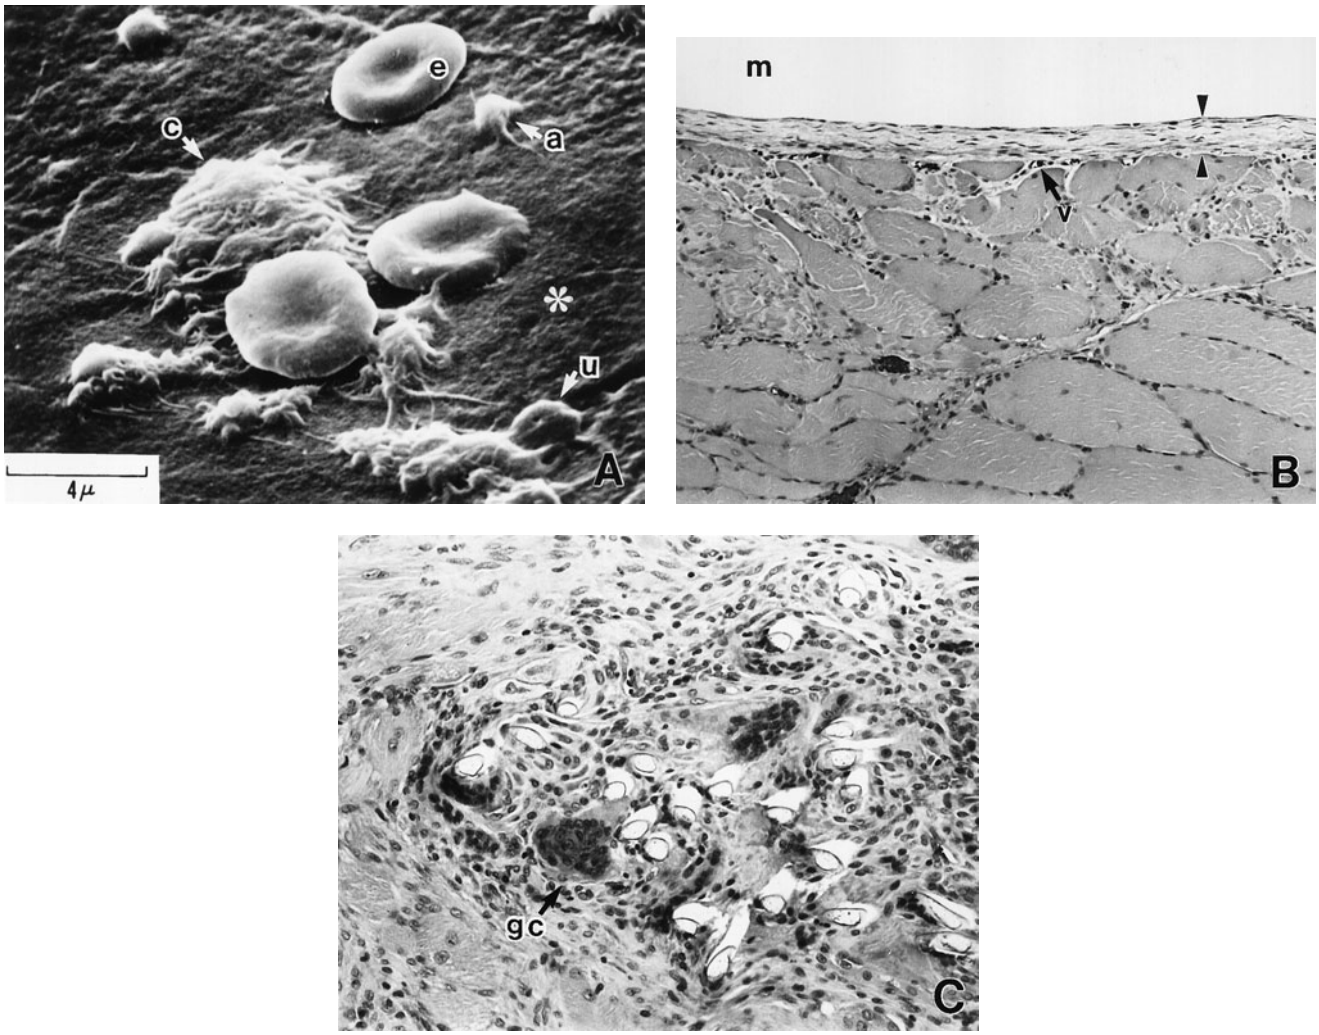

Figure 5-8. Morphology of biomaterials-tissue interactions. (A) Scanning electron photomicrograph of early thrombotic deposits on heart valve material exposed to calf blood for a few minutes in an extracorporeal experiment. Numerous platelets in various stages of adhesion ranging from relatively unaffected (u) to adherent activated (a) forms, some aggregated in clumps (c), are adherent to a background of protein absorption (asterisk). Erythrocytes (e) are probably passively adsorbed in early surface-induced thrombus formation. (B) Photomicrograph of experimental tissue reaction to relatively inert biocompatible material (m), implanted into rabbit muscle. A thin discrete fibrous capsule with virtually no inflammatory cell infiltrate is adjacent to the implant (between arrowheads). Fine vascularity (v) is noted at the interface between the fibrous capsule and the surrounding muscle. Hematoxylin and eosin 150x. (C) Granulomatous inflammatory response to surgically implanted Dacron mesh. This is an intense inflammatory response that includes abundant foreign body giant cells (gc). Hematoxylin and eosin 200x. (*A: Reproduced with permission from Schoen FJ: Cardiac valve prostheses: pathological and bioengineering considerations. J Card Surg 1987; 2:265. B and C: Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

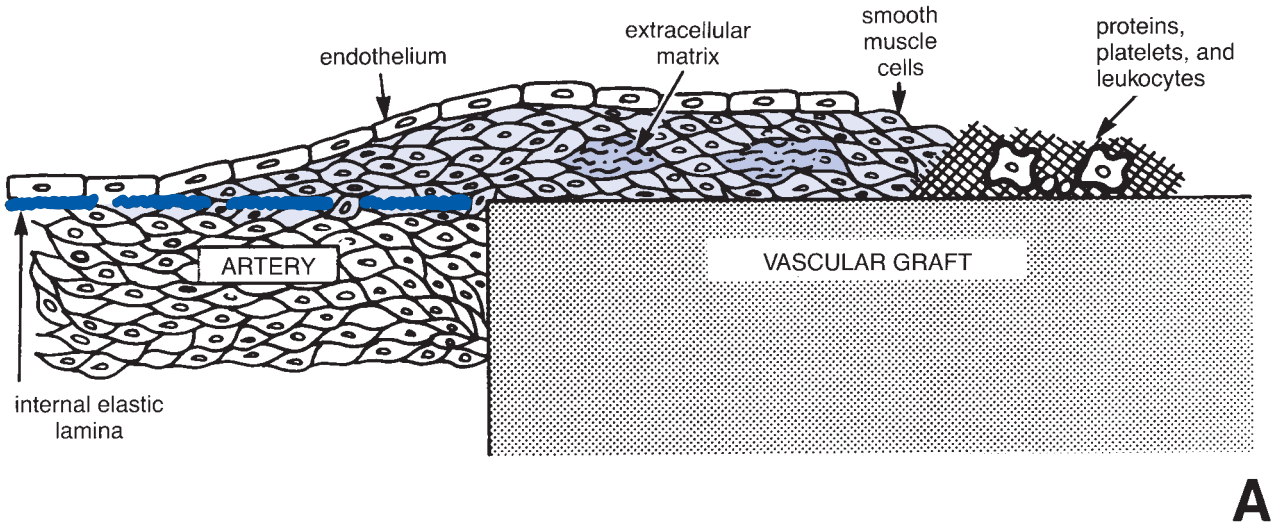
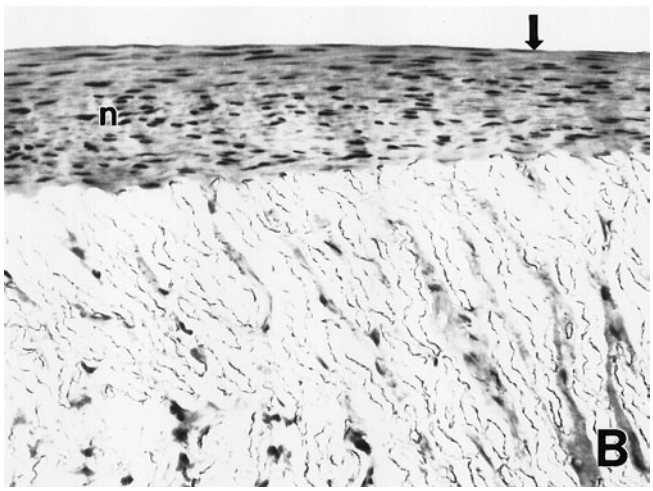
proliferation in the intima, and heart valve prostheses can elicit excessive pannus that occludes the orifice. Intimal hyperplasia results primarily from smooth muscle cell migration, proliferation, and extracellular matrix elaboration following and possibly mediated by acute or ongoing endothelial cell injury. Contributing factors to an exuberant response include: (1) surface thrombogenesis; (2) delayed or incomplete endothelialization of the fabric; (3) disturbed flow across the anastomosis; and (4) mechanical "mismatch" at the junction of the implant and host tissues.

Tissue lining a vascular graft or coating a heart valve sewing cuff derives principally from overgrowth from the host vessel across anastomotic sites. However, tissue ingrowth through the fabric of a graft with interstices large enough to permit ingrowth of fibrovascular elements can arise from capillaries extending from outside to inside the graft. This may permit endothelial cells to migrate to the luminal surface at a large distance from the anastomosis. However, since most clinical vascular grafts are impervious in order to obviate hemorrhage, existing grafts (and other





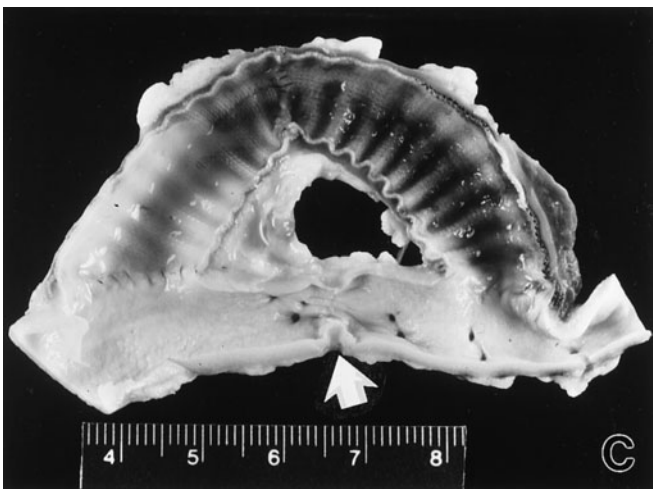


Figure 5-9. Vascular graft healing. (A) Schematic diagram of pannus formation, the major mode of graft healing with currently available vascular grafts. Smooth muscle cells migrate from the media to the intima of the adjacent artery and extend over and proliferate on the graft surface. The thin smooth muscle cell layer is covered by a proliferating layer of endothelial cells. (B) Neointima (n), consisting of smooth muscle cells and extracellular matrix covered by endothelium in an experimental expanded polytetrafluoroethylene graft in the rabbit aorta. The blood-contacting surface is indicated by the arrow. Hematoxylin and eosin 150x. (C) Experimental composite vascular graft composed of dissimilar grafts anastomosed together, used to bypass a surgically-created stenotic segment in the sheep aorta (arrow), from a study of variables in graft healing. The extent of healing is vastly different between the gelatin-coated graft (left) and the albumin-coated graft (right). (*A and B: Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989. C: Reproduced with permission from Kadoba K, Schoen FJ, Jonas RA: Experimental comparison of albumin-sealed and gelatin-sealed knitted Dacron conduits. J Thorac Cardiovasc Surg 1992; 103:1059.*)

fabrics used as cardiovascular implants) heal primarily by ingrowth of endothelium and smooth muscle cells from the cut edges of the adjacent artery or other tissue (*pannus*). A third mechanism exists, deposition of functional endothelial cell progenitors from the circulating blood, but the extent of functional endothelialization via this route is not yet known.[59]

Humans have a limited ability to spontaneously endothelialize cardiovascular prostheses, and full endothelialization of clinical grafts (yielding an intact *neointima*) usually does not occur. For uncertain reasons, endothelial cell coverage generally is restricted to a zone near an anastomosis, typically 10 to 15 mm, thereby allowing healing of intracardiac fabric patches and prosthetic valve sewing rings, but not long vascular grafts. Thus, except adjacent to an anastomosis, a compacted platelet-fibrin aggregate (*pseudointima*) comprises the inner lining of clinical fabric grafts, even after long-term implantation.

Because firm adherence of such linings to the underlying graft may be impossible, dislodgment of the lining and formation of a flap-valve can occur and cause obstruction.[60] Current research centers on the design of novel vascular graft materials that enhance endothelial cell attachment, grafts preseeded with unmodified or genetically engineered endothelial cells, attempts to block smooth muscle cell proliferation, and tissue engineered vascular grafts (see below).[61]

Infection

Infection is a common complication of implanted prosthetic devices and is a frequent source of morbidity and mortality.[62,63] Early implant infections (less than 1 to 2 months postoperatively) most likely result from intraoperative contamination or early postoperative wound infection. In contrast, late infections generally occur by a hematogenous route, and can be initiated by bacteremia induced by therapeutic dental or genitourinary procedures. Antibiotics given prophylactically at device implantation and shortly before subsequent diagnostic and therapeutic procedures may protect against implant infection.

Infections associated with medical devices are characterized microbiologically by a high prevalence of organisms capable of forming a protective *biofilm*.[64] These organisms include gram-positive bacteria such as *Staphylococcus epidermidis*, *Staphylococcus aureus*, *Enterococcus faecalis,* and viridans streptococci, gram-negative bacteria such as *Escherichia coli* and *Pseudomonas aeruginosa*, and fungi such as *Candida albicans*. Some of these organisms, especially *S. epidermidis* and viridans streptococci, are organisms of relatively low virulence in the absence of a foreign body, but are frequent causes of medical device infection.

The presence of a foreign body potentiates infection in several ways. Microorganisms may inadvertently be introduced into deep tissue locations by contamination at device implantation, bypassing natural barriers against infection during implantation. Some devices, such as many of the current left ventricular assist devices (LVADs), require a percutaneous driveline, providing a continuous potential means of entry for microorganisms. The production of a biofilm (a multicellular film of microbial cells that is irreversibly associated with a material surface and enclosed in a self-produced extracellular matrix composed primarily of polysaccharides) by the organisms is protective against the humoral and cellular immune response of the host.[65] The penetration of opsonizing antibodies is delayed by the biofilm, resulting in ineffective uptake and killing by phagocytes. The biofilm also slows the penetration of antibiotics. Moreover, an implanted foreign body could limit phagocyte migration into infected tissue or interfere with inflammatory cell phagocytic mechanisms by release of soluble implant components or surface-mediated interactions with the extracellular matrix of the biofilm. Consequently, an implant-associated infection generally persists until the device is removed.

Tissue engineering and cardiovascular regeneration

As a logical extension of biomaterials science, *tissue engineering* comprises medical devices and therapeutic approaches that use living cells together with natural materials or synthetic polymers to develop or regenerate functional tissues.[66–68] In the most widely used approach to engineering tissues, the first step involves the seeding of cells on a synthetic polymer or natural material (such as collagen or chemically treated tissue) scaffold, and a tissue is matured in vitro. A typical scaffold is a bioresorbable polymer in a porous configuration, adhesive for cells in the desired geometry for the engineered tissue. The cells are either differentiated cells or stem cells. When placed in a metabolically and mechanically supportive environment with growth media (in a *bioreactor*), the cells proliferate and elaborate extracellular matrix in the form of a "new" tissue (the *construct*). In the second step, the construct is implanted in the appropriate anatomic location. Remodeling of the construct in vivo following implantation is intended to replicate the normal functional architecture of an organ or tissue. Key processes occurring during the in vitro and in vivo phases of tissue formation and maturation are (1) cell proliferation, sorting, and differentiation; (2) extracellular matrix production and organization; (3) degradation of the scaffold; and (4) remodeling and potential growth of the tissue.

Progress has been made toward tissue engineered vascular grafts, myocardium, and heart valves. Details are discussed below.

ENGINEERED VASCULAR GRAFTS: Human implantation of a tissue engineered blood vessel (pulmonary artery segment) constructed from cells and polymer has been reported.[69] Engineered tissue blood vessels of small caliber are actively being investigated.[70,71] Clinically employed conventional extended polytetrafluoroethylene vascular grafts have been seeded with endothelial cells at the time of implantation.[72]

A vessel "equivalent" composed of collagen and cultured bovine fibroblasts, smooth muscle, and endothelial cells was unable to withstand burst strengths for in vivo applications, despite reinforcement with a Dacron mesh.[73] Other investigators have improved the mechanical performance of engineered tissue vascular grafts by constructing a cohesive cellular sheet of smooth muscle cells, rolling this sheet to form the media (analogous to a "jelly roll"), and wrapping this sheet of human fibroblasts around the media to serve as an adventitia, and seeding endothelial cells in the lumen.[74] In other work in this area, cultured smooth muscle and endothelial cells isolated from bovine aorta were applied onto tubular scaffolds composed of polyglycolic acid and placed in a bioreactor.[75] Exposure to pulsatile physical forces enhanced the properties of the graft vessels; pulsed grafts were thicker, had greater suture retention, and had higher cell and collagen density than nonpulsed engineered grafts, as well as a histologic appearance similar to that of native arteries. Another approach to vascular graft engineering utilizes naturally derived matrices with or without cell repopulation prior to implantation.[76] Vascular grafts fabricated

from small intestine submucosa used as experimental vascular grafts in dogs were reported to be completely endothelialized and histologically similar to arteries.[77]

Another approach to vascular engineering extends the concept of Sparks' silicone mandril-grown graft used clinically in the 1970s.[78] Sparks grew a vessel substitute inside the subject's own body adjacent to the diseased vessel as the fibrous capsule that forms adjacent to an implanted foreign body (silicone mandril); the mandril was subsequently removed yielding an autologous tissue tube. However, owing to the variability of the quality of tissue generated in older patients in areas of circulatory insufficiency, such vascular replacements developed aneurysms when used clinically. Grafts were recently grown as the tissue that forms around silicone tubing inserted into the peritoneal cavity of rats, rabbits, and dogs.[79] The tissue was removed from the tubing, completely everted (so that mesothelial cells become the blood-contacting surface), grafted into the carotid artery of the same animal, and remained patent up to 4 months.

REGENERATION OF CARDIAC TISSUE: The classic view is that the adult heart responds to mechanical overload by hypertrophy (increase in cell size) and to severe ischemic or other injury by cell death (see earlier). Functional increase in cardiac myocyte number by cell regeneration or hyperplasia has generally not been considered possible. Nevertheless, three lines of research create enthusiasm that clinically-important cardiac regeneration may indeed be possible, including (1) cell-based therapies in which fetal or adult cardiomyocytes, skeletal myoblasts, or nonmuscle stem or differentiated cells are injected into the heart; (2) the possibility that the heart may have endogenous mechanisms of repair; and (3) experimental generation of functional myocardium by tissue engineering approaches, in which cells are seeded on a resorbable biomaterial scaffold, cultured in vitro, and implanted as a prosthetic myocardial patch.

Recent experiments and some early-phase clinical trials lend credence to the notion that cell-based cardiac repair may be an achievable therapeutic target.[80–82] Therapeutic strategies have explored fetal cardiomyocytes; skeletal myoblasts; embryonic-derived endothelial cells; bone marrow–derived immature myocytes; fibroblasts; smooth muscle cells; endothelial progenitor cells; and hematopoietic, mesenchymal, and embryonic stem cells. Clinical trials have used cells derived from skeletal muscle and bone marrow, and basic researchers are investigating sources of new cardiomyocytes, such as resident myocardial progenitors and embryonic stem cells. Structural and functional integration of the graft with the host myocardium may be attainable. Nevertheless, the most appropriate form of cellular therapy for myocardial injury remains to be identified, and it is unclear at present whether the beneficial effects are a result of functional and electrically-integrated myocytes (the ideal), enhancement of angiogenesis owing to a local and nonspecific inflammatory reaction at the site of injection, or a "paracrine" effect, whereby transplanted cells are proposed to produce growth factors, cytokines, and other local signaling molecules that are beneficial to the infarct through neovascularization and/or scar remodeling.

Recent evidence that myocyte regeneration and death occur physiologically, and that these cellular processes are enhanced in pathologic states, have challenged the view of the heart as a postmitotic organ. Heart homeostasis may be regulated by a stem cell compartment in the heart characterized by multipotent cardiac stem cells that possess the ability to acquire the distinct cell lineages of the myocardium, and are capable of regenerating myocytes and coronary vessels throughout life, and have the capacity to adapt to increases in pressure and volume loads.[83] Moreover, adult bone marrow cells may be able to differentiate into cells beyond their own tissue boundary and create cardiomyocytes and coronary vessels. Indeed, myocytes bearing a Y chromosome have been found in the hearts of female donors transplanted to male recipients, raising the possibility that endogenous primitive stem cells, either circulating or resident, may play a role in repair of myocardial infarcts.[84]

Myocardial tissue generated from cells, scaffolds, and bioreactors has been encouraging with respect to construct survival, vascularization, and integration, but functional improvement in clinical implantation has yet to be demonstrated.[85,86] Application of cyclic mechanical stretch and electrical signals have been shown to enhance cell differentiation and force of contraction.[87]

ENGINEERED HEART VALVES: Recent scientific and technological progress has stimulated the goal of creating a living valve replacement that would obviate the complications of conventional valve replacement, adapt to changing environmental conditions in the recipient, and potentially grow with a growing patient.[88–90] Innovative work toward this objective is active in many laboratories, and may eventually lead to clinical application. The long-term success of a tissue engineered (living) valve replacement will depend on the ability of its living cellular components (particularly valvular interstitial cells) to assume normal function with the capacity to repair structural injury, remodel the extracellular matrix, and potentially grow. Three approaches are under consideration: (1) Use the methodology of tissue engineering, combining cells plus a scaffold in a bioreactor environment to generate tissue formed in vitro, which is then implanted in vivo to form an organ or tissue; (2) recruit endogenous cells through the circulation from bone marrow or other source; and (3) harness the intrinsic regenerative potential of the heart valves.

Tissue engineered heart valves grown as valved conduits from autologous cells (either vascular wall cells or bone marrow–derived mesenchymal stem cells) seeded on biodegradable synthetic polymers grown in vitro have functioned in the pulmonary circulation of growing lambs for up to 5 months (Fig. 5-10),[91,92] and evolved in vivo into a

Figure 5-10. Tissue engineered heart valve composed of ovine vascular wall cells seeded on polyglycolic acid polymer scaffold and conditioned in a pulsatile bioreactor in vitro for 14 days. (*Reproduced with permission from Hoerstrup et al.*[91])

specialized layered structure that resembled that of a native semilunar valve. A recent study has shown that pulmonary vascular walls fabricated from vascular wall cells and biodegradable polymer and implanted into very young lambs enlarged proportionally to overall animal growth over a 2-year period.[93]

In an effort to eliminate the need for in vitro cell seeding and culture steps, an alternative tissue engineering strategy has used either a scaffold of a naturally derived biomaterial (such as small intestine submucosa) implanted without prior seeding or a decellularized valve.[94] Tissue-derived valve scaffolds may possess desirable three-dimensional architecture, mechanical properties, and potential adhesion/migration sites for cell attachment and ingrowth. Nevertheless, decellularized porcine valves implanted in humans had a strong inflammatory response and suffered structural failure.[95]

Translation of heart valve tissue engineering and regenerative medicine from the laboratory to the clinical realm has exciting potential, but also formidable challenges and uncertainties. Key hurdles include selection and validation of suitable animal models, development of guidelines for characterization and assurance of the quality of an in vitro fabricated tissue engineered heart valve for human implantation, and strategies to understand, monitor, and potentially control patient variability in wound healing and tissue remodeling in vivo.

ISCHEMIC HEART DISEASE

The ischemic heart disease syndromes are primarily caused by atherosclerosis and its complications, causing diminished coronary perfusion. They are the direct effect on the myocardium of a complex and dynamic interaction among fixed atherosclerotic narrowing of the epicardial coronary arteries, intraluminal thrombosis overlying a ruptured or fissured atherosclerotic plaque, platelet aggregation, and vasospasm.

Pathogenesis

Role of fixed coronary obstructions

In the absence of significant pathology, coronary arterial flow provides adequate myocardial perfusion at rest, and compensatory vasodilation provides flow reserve that is more than sufficient to accommodate the increased metabolic demands during vigorous exertion. When the luminal cross-sectional area is decreased by 75% or more, coronary blood flow generally becomes limited with exertion; with 90% or greater reduction, coronary flow may be inadequate even at rest. Over 90% of patients with ischemic heart disease syndromes have advanced stenosing coronary atherosclerosis (fixed obstructions), and most myocardial infarcts occur in patients with coronary atherosclerosis.

Nonatherosclerotic causes of coronary artery obstruction can also occur. The most common causes are autoimmune diseases (e.g., systemic lupus erythematosus and rheumatoid arthritis), vasculitis (e.g., Buerger disease and Kawasaki disease), fibromuscular dysplasia, dissection, spasm, and embolism. Obstruction of the small intramural coronary arteries is seen in several disease states, including diabetes, deposition diseases such as Fabry disease and amyloidosis, progressive systemic sclerosis (scleroderma), and as a proliferative intimal lesion in the coronary arteries of cardiac allografts (see later).

Role of acute plaque change

The onset and prognosis of ischemic heart disease and other complications of atherosclerosis are not well predicted by the angiographically determined extent and severity of fixed anatomic disease.[96] Dynamic vascular changes are largely responsible for the conversion of chronic stable angina or an asymptomatic state to an *acute coronary syndrome*, most commonly fracture of the fibrous cap leading to hemorrhage into the plaque, followed by platelet aggregation and thrombosis compromising the lumen, and sometimes fissuring and/or ulceration.[97] Plaque alterations precipitating the acute coronary syndrome span a

broad morphologic range from superficial erosion of the intima without a frank rupture through the plaque fibrous cap, to lacerations that extend deep within the plaque.[98] Vasospasm, tachycardia, hypercholesterolemia, and intraplaque hemorrhage are likely contributors, as are stresses induced by blood flow and/or coronary intramural pressure or tone in plaque. Regardless of the extent of injury, the result is flow disruption and exposure of the luminal blood to a thrombogenic surface (collagen, lipid, or necrotic debris), thereby setting the stage for mural or total thrombosis.

Pathologic and clinical studies show that plaques that undergo abrupt disruption leading to coronary occlusion often are those that previously produced only mild to moderate luminal stenosis. Overall, approximately two-thirds of plaques that rupture with subsequent occlusive thrombosis cause occlusion of only 50% or less before plaque rupture, and in 85% of patients, stenosis is initially less than 70%. Thus, there is great interest in predicting plaque disruption or subsequent thrombosis in an individual patient.[99] Although x-ray coronary angiography remains widely used, a noninvasive test is highly desirable. Calcification of the coronary arteries can be detected noninvasively by electron beam computed tomography (CT). Radiographically visible calcium in the epicardial coronary arteries predicts the extent of atherosclerotic disease, but cannot identify features of plaque instability. However, since plaque burden correlates with cardiovascular risk, coronary calcium tends to be a good prognostic indicator of future myocardial ischemic events.[100] Moreover, three-dimensional coronary magnetic resonance angiography (MRA) has the potential to visualize both the coronary lumen and the atherosclerotic plaques in the arterial wall.[101] Intravascular ultrasound also can provide precise information about the degree of stenosis, and the location and nature of atherosclerotic plaque. Molecular imaging techniques that have potential applicability in this setting are emerging.

Plaques considered prone to rupture are termed *vulnerable plaques*. The events that trigger abrupt changes in plaque configuration and superimposed thrombosis of vulnerable plaques are complex and poorly understood. Influences that are both intrinsic to the plaque (e.g., structure and composition) and extrinsic (e.g., blood pressure and platelet reactivity) are important. The fibrous cap is a highly dynamic tissue, and local inflammation regulates the balance of collagen synthetic and degradative activity, which itself determines stability and prognosis. Thus, lesions prone to rupture have a thin collagen layer and few smooth muscle cells (the cells that are responsible for the repair and maintenance of the all-important collagenous matrix and are a rich source of extracellular matrix macromolecules in the artery wall), contain many macrophages which produce matrix metalloproteinases that degrade the collagen that lends strength to the fibrous cap, and contain large areas of foam cells and extracellular lipid.[102] Inflammation also may contribute to coronary thrombosis by altering the balance between prothrombotic and fibrinolytic properties of the endothelium. There is evidence that lipid lowering by diet or drugs such as statins can reduce the onset of coronary thrombotic complications by stabilizing plaque (i.e., increasing the thickness and strength of the fibrous cap) by reducing accumulation of macrophages expressing matrix-degrading enzymes and tissue factor, and reducing activation of smooth muscle cells and endothelial cells.[103]

Potential outcomes for unstable lesions include thrombotic occlusion, nonocclusive thrombosis, healing at the site of plaque erosion, athero- or thromboembolization, organization of mural thrombus (plaque progression), and organization of the occlusive mass with recanalization. Among these outcomes, the most common fate is plaque progression, owing either to resealing of the plaque fissure or to organization of a nonocclusive mural thrombus. Indeed, asymptomatic plaque rupture and its subsequent healing is likely an important mechanism of progressive stenosis.

Coronary and Myocardial Interventions

Revascularization in acute myocardial infarction

The pathophysiologic basis of revascularization in early acute myocardial infarction (AMI) to limit infarct size and improve cardiac function and survival is as follows:[104] (1) Untreated thrombotic occlusion of a coronary artery causes transmural infarction; (2) the extent of necrosis during an evolving MI progresses as a wavefront and becomes complete only 6 hours or more following coronary occlusion (see Fig. 5-5); (3) both early- and long-term mortality following AMI correlate strongly with the amount of residual functioning myocardium; and (4) early reperfusion rescues some jeopardized myocardium. Thus, the benefits of thrombolytic therapy or early percutaneous transluminal coronary angioplasty (PTCA) depend on and are assessed by the amount of myocardium salvaged, recovery of left ventricular function (LVF), and resultant reduction in mortality. These important clinical endpoints are largely determined by the time interval between onset of symptoms and a successful intervention, adequacy of early coronary reflow, and the degree of residual stenosis of the infarct vessel. The maximal time for substantial myocardial salvage is approximately 3 to 4 hours, but some studies suggest that modest benefit can occur following later reperfusion. Spontaneous recanalization, presumably owing to inherent thrombolysis, can be beneficial to LVF but occurs in fewer than 10% of patients within the critical 3 to 4 hours after symptom onset.

Successful thrombolytic therapy or PTCA alone often re-establishes antegrade flow in the infarct-related coronary artery but does not reverse intimal rupture, enhanced platelet adhesiveness, or coronary spasm. Thus, balloon angioplasty with stent placement (see below) or surgical revascularization during infarct evolution constitute more effective management of the underlying disease process than thrombolysis alone.[105]

Angioplasty and stents

PTCA is used in patients with stable angina, unstable angina, or AMI to restore blood flow through a diseased portion of the coronary circulation obstructed by atherosclerotic plaque and/or thrombotic deposits.[106] Angioplasty has also been applied to obstructions in saphenous vein grafts, internal mammary artery (IMA) grafts, and coronary arteries in transplanted hearts. Today, nearly all patients undergoing PTCA will also receive a stent.

ANGIOPLASTY: In PTCA, the plaque splits at its weakest point and enlargement of the lumen and increased blood flow occurs by plaque fracture (the predominant mechanism), and by embolization, compression, redistribution of the plaque contents, and overall mechanical expansion of the vessel wall.[107] The split extends at least to the intimal-medial border and often into the media, with consequent circumferential and longitudinal dissection of the media (Fig. 5-11). Coronary arterial dissection may contribute to the propensity for acute closure that occurs in up to 5% of patients. For example, a dissection that involves a considerable portion of the circumference can generate a flap that may impinge on the lumen. Alternatively, a dissection that involves a substantial proximal-to-distal segment of the vessel, which traverses a large plaque-free wall segment, can induce compression of the vessel at a point of minimal disease. Short-term failure of this procedure (i.e., closure of the treated vessel within hours to days) can occur via several mechanisms, including elastic recoil of the vessel wall, acute thrombosis at the site of ballooning, and acute dissection (i.e., blood within the wall itself) of the vessel beyond the area of angioplasty.

Angioplasty-induced plaque fracture, medial dissection, and stretching of the media beyond the dissection are accompanied by local flow abnormalities and generation of new, thrombogenic blood-contacting surfaces (similar to what is observed with spontaneously disrupted plaque). These features can lead to platelet deposition and occlusive thrombosis. The immediate postangioplasty healing process is not well understood, but dissolution of soft atheromatous material, retraction of the split plaque, thrombus formation, and intimal healing with re-endothelialization likely occur. PTCA is successful in 85 to 95% of cases (including vein grafts and IMAs) and is associated with a mortality rate of 1%.

The long-term success of PTCA is limited by the development of progressive, proliferative restenosis, which occurs in 30 to 40% of patients, most frequently within the first 4 to 6 months[108] (Fig. 5-12). Although vessel wall recoil and organization of thrombus likely contribute, the major process leading to restenosis is excessive medial smooth muscle proliferation as an exaggerated response to angioplasty-induced injury. Medial smooth muscle cells migrate to the intima, where along with existing plaque smooth muscle cells, they proliferate and secrete abundant extracellular matrix. Interest in locally delivered pharmacologic and molecular therapies to mitigate restenosis has been long-standing; regrettably, success has been limited.[109]

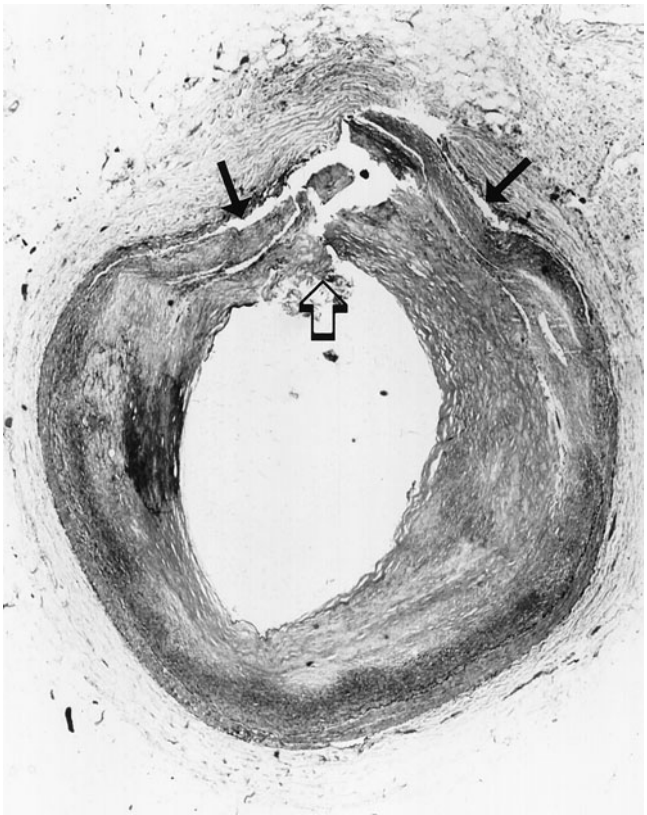

Figure 5-11. Acute changes of percutaneous transluminal coronary angioplasty (PTCA) on coronary arterial atherosclerotic plaque. The changes induced by balloon angioplasty consist of fracture of the plaque (open arrow) with deep extension of the wall defect and partial circumferential dissection (closed arrows). Philadelphia, WB Saunders, 2004; p 511.*)

Coronary atherectomy of primary or restenosis lesions mechanically removes obstructive tissue by excision. Deep arterial resection, including medial and even adventitial elements, occurs frequently but has not been associated with acute symptomatic complications. The morphology of arterial vessel healing after directional or rotational atherectomy is similar to that following angioplasty.

STENTS: Stents are expandable tubes of metallic mesh that are inserted percutaneously at the time of PTCA to preserve luminal patency in both native coronary arteries and vein grafts. They provide a larger and more regular lumen by acting as a scaffold to support the intimal dissections that occur in PTCA, mechanically prevent vascular spasm, and increase blood flow, all of which minimize thrombus formation and reduce the impact of postangioplasty restenosis.

Stenting has been shown to be superior to angioplasty alone in several lesions and situations, including in vessels

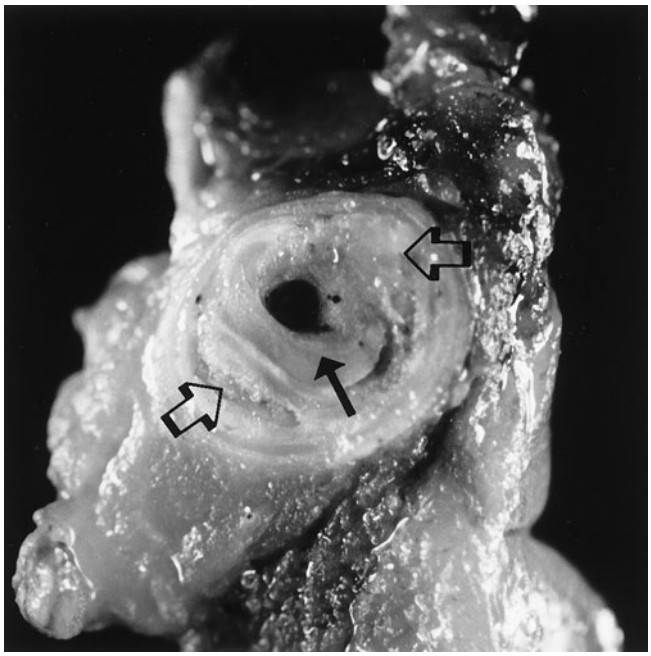

Figure 5-12. Proliferative restenosis after percutaneous transluminal coronary angioplasty. This gross cross-section of a coronary artery from a patient who died several months after angioplasty illustrates both the original, previously disrupted atherosclerotic plaque (open arrows) and markedly occlusive concentric fibrous tissue that formed after the procedure (arrow). >3 mm in diameter, in chronic total occlusions, in stenotic vein grafts, in restenotic lesions after angioplasty alone and in patients with AMI. Complications include acute, subacute, or late stent thrombosis and in-stent restenosis.[110]

The reasons for thrombosis and restenosis are complex and are largely due to tissue interactions with an implanted stent.[111,112] There is early damage to the endothelial lining and stretching of the vessel wall, stimulating adherence and accumulation of platelets and leukocytes. Covered initially by a variable platelet-fibrin coating, stent wires may eventually become completely covered by an endothelium-lined neointima, with the wires embedded in a layer of intimal thickening consisting of smooth muscle cells in a collagen matrix (Fig. 5-13). This tissue may thicken secondary to the release of growth factors, chemotactic factors, and inflammatory mediators from platelets and other inflammatory cells that result in increased migration and proliferation of smooth muscle cells, and increased production of extracellular matrix molecules, narrowing the lumen and resulting in restenosis, which may occur in 50% of patients implanted with first-generation (nondrug eluting) stents.

Many approaches have been used in an attempt to reduce in-stent restenosis. Intracoronary radiotherapy is thought to block cell proliferation, induce cell death, and inhibit migration of smooth muscle cells in the area of the stent to reduce neointimal accumulation. Several studies have shown promising initial results in reducing the restenosis rate, but have also shown some long-term complications including late thrombosis, increased restenosis at the edge of the treated field, and damage to the wall.[113]

The most promising results have been attained with polymer-coated drug-eluting stents, which are now widely used, especially with two drugs, rapamycin (sirolimus) and paclitaxel.[114,115] Rapamycin, a drug used for immunosuppression in solid organ transplant recipients, also inhibits proliferation, migration, and growth of smooth muscle cells and extracellular matrix synthesis. Paclitaxel, a drug used in the chemotherapeutic regimens for several types of cancer, also has similar anti–smooth muscle cell activities. These drugs are embedded in a polymer matrix (such as a copolymer of poly-*n*-butyl methacrylate and polyethylene–vinyl acetate or a gelatin-chondroitin sulfate coacervate film) that is coated onto the stent. The drug is released by diffusion and/or polymer degradation over varying periods of time that can be engineered by the specifics of the polymer-drug system. Despite some risk of late stent thrombosis,[116] coated stents have had excellent long-term success, virtually eliminating restenosis for periods of 2 years and longer, and are felt to represent a major breakthrough in the treatment of coronary artery disease (CAD).[117,118] The impact of the current era of coronary stenting on further surgical and medical treatment has recently been reviewed.[119,120]

Coronary artery bypass graft surgery

Coronary artery bypass graft (CABG) surgery improves survival in patients with significant left main coronary artery disease, with three-vessel (and possibly two-vessel) disease, or with reduced ventricular function.[121] CABG surgery

prolongs and improves the quality of life in patients with left main equivalent disease (the proximal left anterior descending and proximal left circumflex arteries), but does not protect them from the risk of subsequent MI. The main mechanism for these benefits is thought to be the reperfusion of hibernating (i.e., viable but poorly perfused and poorly functioning) myocardium, leading to increased LVF.

The hospital mortality rate for CABG surgery is approximately 1% in low-risk patients, with less than 3% of patients suffering perioperative MI. The most consistent predictors of mortality after CABG are urgency of operation, age, prior cardiac surgery, female gender, low left ventricular ejection fraction (LVEF), degree of left main stenosis, and number of vessels with significant stenoses. The benefit of CABG is greatest in the highest-risk patients with the most severe disease; it is not surprising, therefore, that a recently reported increase in morbidity and mortality has accompanied increased utilization of CABG performed in an older and sicker population.

The most common mode of early death after CABG is acute cardiac failure leading to low output or arrhythmias. Although the underlying cause is massive myocardial damage in some cases, other contributory factors may include: (1) evolving myocardial necrosis either undetectable clinically or too recent to detect at autopsy; (2) postischemic dysfunction of viable myocardium, for which no morphologic markers of the dysfunctional state are known; or (3) a metabolic cause, such as hypokalemia, for which there is no morphologic counterpart. Therefore, although established myocardial necrosis causes cardiac dysfunction in some patients with postoperative failure, it may not be the predominant lesion or the cause of death in all such patients.

Perioperative infarction usually is caused by either perioperative hypotensive episodes or inadequate intraoperative myocardial preservation, potentially exacerbated by severe obstruction of feeding arteries and poor collaterals. Such necrosis usually predominates in the subendocardium and often has the morphology of necrosis with contraction bands. As in cardiac surgery in general, perioperative MI is more likely to occur in patients with cardiomegaly than in those with normal-sized hearts, and in patients who have had preoperative infarctions.

Early thrombotic occlusion of the graft vessel may occur, with inadequate distal run-off from extremely small distal native coronaries (often further compromised by atherosclerosis) comprising the major mechanism. Additional factors may include acute graft dissection at the anastomotic site, atherosclerosis or arterial branching at the anastomotic site, distortion of a graft that is too short or too long for the intended bypass, as well as patient factors. In some cases, thrombosis occurring early postoperatively involves only the distal portion of the graft, suggesting that early graft thrombosis is frequently initiated at the distal anastomosis. Antiplatelet therapy has resulted in improved patency rates, and graft thromboses account for only a minority of early cardiac deaths; indeed, most patients who die early have patent grafts.

The patency of saphenous vein grafts is reported as 60% at 10 years; occlusion results from (with increasing postoperative interval) thrombosis, progressive intimal thickening, and/or obstructive atherosclerosis.[122–124] Between 1 month and 1 year, graft stenosis is usually caused by intimal hyperplasia with excessive smooth muscle proliferation and extracellular matrix production similar to that seen following angioplasty. Atherosclerosis becomes the more dominant mechanism in graft occlusion beyond 1 to 3 years after CABG. As in the native coronary arteries, atherosclerosis in bypass grafts can cause myocardial ischemia through progressive luminal stenosis or plaque rupture with secondary thrombotic obstruction. The potential for disruption and embolization of atherosclerotic lesions in vein grafts exceeds that for native coronary atherosclerotic lesions. Plaques in grafts generally often have poorly developed fibrous caps with large necrotic cores, and develop secondary dystrophic calcific deposits that may extend to the lumen (Fig. 5-14). Thus, atheroembolization is a major risk, often with catastrophic results; PCI or intraoperative manipulation of grafts may stimulate atheroembolism.

In contrast, the IMA has a >90% patency rate at 10 years (Fig. 5-15).[125] Multiple factors likely contribute to the remarkably higher long-term patency of IMA grafts compared to vein grafts. Free saphenous vein grafts sustain not only disruption of their vasa vasora and nerves, but also endothelial damage, medial ischemia, and acutely increased internal pressure. In contrast, the IMA generally requires minimal surgical manipulation, maintains its nutrient blood supply, is accustomed to arterial pressures, needs no proximal anastomosis, and has an artery-to-artery distal anastomosis, as well as having minimal pre-existing atherosclerosis in most cases. The sizes of graft and recipient vessels are comparable with the IMA grafts, but disparate (the graft is substantially larger) with saphenous vein grafts. Radial and gastroepiploic arteries are occasionally also used successfully. With the advent of off-pump and minimally invasive CABG, there have been efforts to facilitate anastomosis of the graft to the aorta. Several sutureless anastomotic devices have been developed to facilitate aortocoronary bypass.[126] An anastomotic device should be easy to use, and produce a geometrically optimal anastomosis with minimal endothelial damage and minimal blood-exposed nonintimal surface.

Transmyocardial laser revascularization

Transmyocardial laser revascularization (TMR) has been used in selected patients to manage CAD that is refractory to conventional revascularization techniques and maximal medical therapy. Performed on a beating heart through a left thoracotomy, the operation employs a high-energy laser to bore transmural channels into the left ventricle. The hypothesis is that blood will flow directly from the left ventricular chamber into the channels and then into the intramyocardial

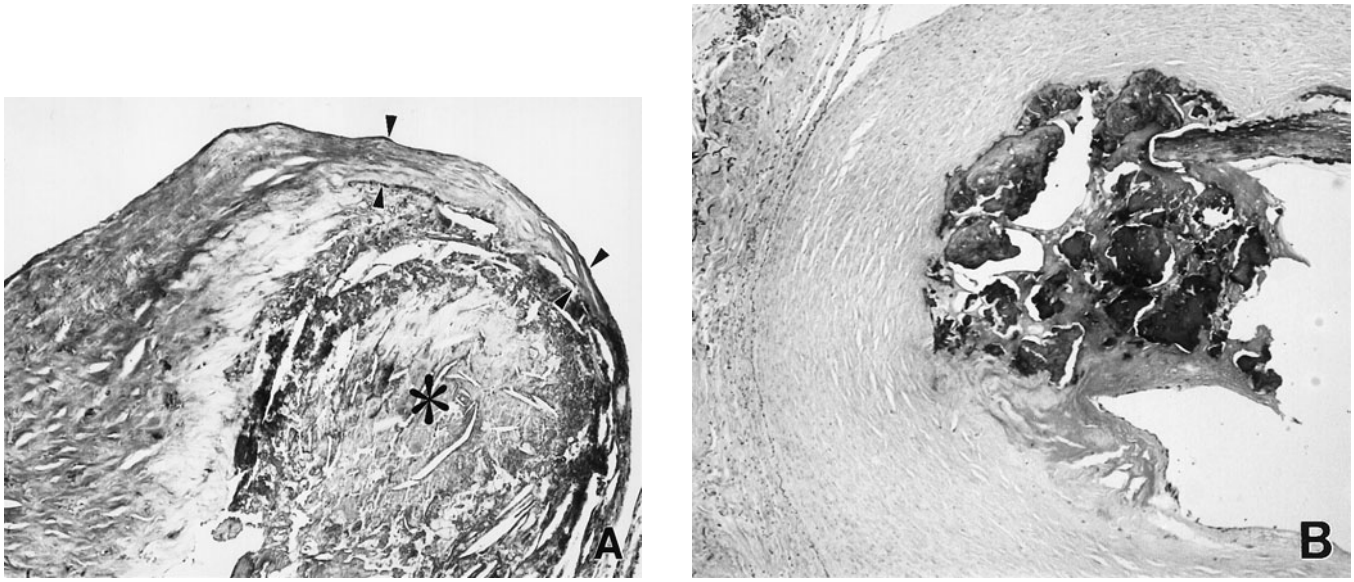

Figure 5-14. Atherosclerosis of saphenous vein bypass grafts. (A) Typical fibrous cap (between arrowheads) is attenuated over the necrotic core (asterisk).100x. vascular plexus, thereby restoring perfusion to potentially viable myocardium in a manner reminiscent of normal reptilian hearts. Although some clinical trials report a decrease in anginal symptoms after TMR, the success of the technique is as yet uncertain.[127,128]

Intramyocardial channels generated by TMR initially have a central region of destroyed myocardium surrounded by a thin rim of necrotic tissue (Fig. 5-16). Over the first 24 hours, the channels fill with blood and fibrin and are surrounded by myocardium with contraction band necrosis (see Fig. 5-16A). After 2 to 3 weeks, the channels are filled with vascularized granulation tissue in keeping with the general time course of wound healing (see Fig. 5-16B). Clinical studies and examination of hearts from patients who have died at various postmortem intervals failed to reveal patent channels.[129] The leading hypothesis for the reported efficacy of TMR is the stimulation of neovascularization in the vicinity of the channels; denervation of these areas may also play a role in the reduction of symptomatic angina.

Myocardial Infarction and Its Complications

Coronary atherosclerosis with acute plaque rupture and superimposed thrombosis typically results in a transmural infarct, where ischemic necrosis involves at least half and usually the full or nearly full thickness of the ventricular wall in the distribution of the involved coronary artery. In contrast, a subendocardial (nontransmural non-Q wave) infarct constitutes an area of ischemic necrosis limited to the inner third to half of the ventricular wall. This process can be multifocal, often extending laterally beyond the perfusion territory of a single coronary artery. Subendocardial infarcts are commonly associated with diffuse stenosing coronary atherosclerosis without acute plaque rupture or superimposed thrombosis in the setting of episodic hypotension, global ischemia, or hypoxemia. A subendocardial infarct can also result from a coronary thrombus that is not completely occlusive or becomes

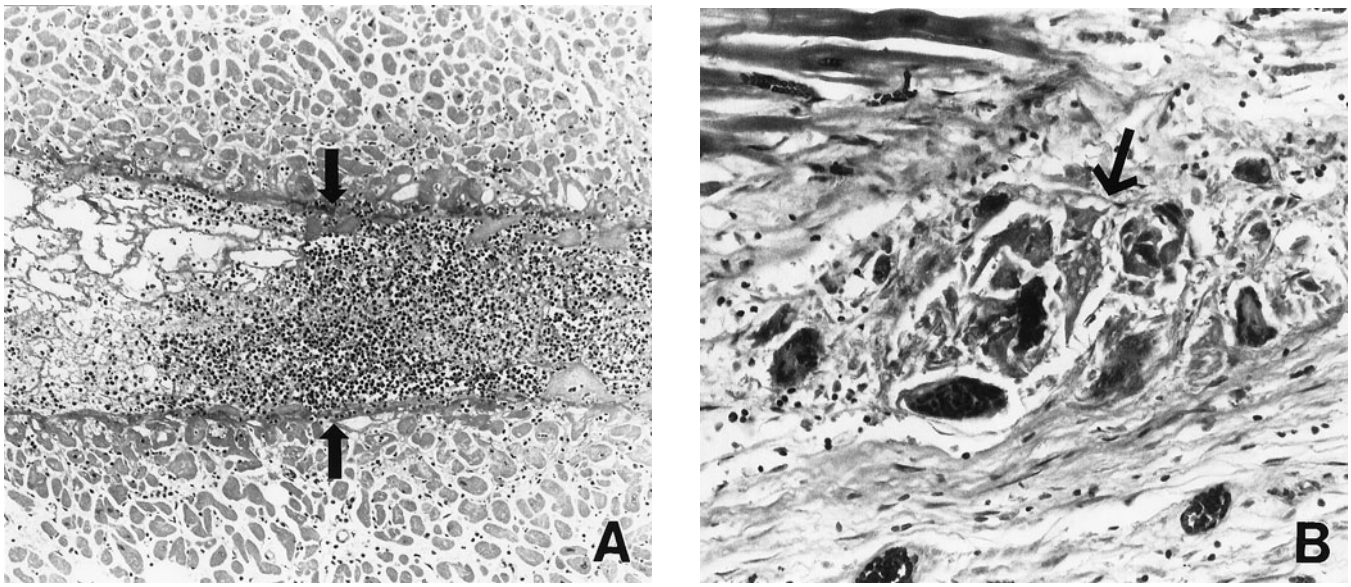

Figure 5-16. Myocardial changes following transmyocardial laser revascularization. (A) Transmyocardial channel (between arrows) filled with fibrin and inflammatory cells from the patient, who died 3 days following the procedure. (B) Transmyocardial channel filled with organizing fibrin (arrow) in a patient who died 18 days following the procedure. No patent channels were noted in either case. Hematoxylin and eosin 150x.

lysed before the progressive myocardial necrosis becomes transmural. In both transmural and subendocardial infarcts, a 1- to 2-mm rim of subendocardium may survive due to diffusion of oxygen and nutrients from the blood in the ventricular cavity.

The short-term mortality rate from AMI has declined from 30% in the 1960s to 7 to 10% or less today, especially for patients who receive aggressive reperfusion, revascularization, and pharmacologic therapy. However, half of all deaths from MI occur within the first hour after the onset of symptoms, often before the individual can reach the hospital. Poor prognostic factors include advanced age, female gender, diabetes mellitus, and a previous MI. The most important factors in long-term prognosis are LVF and the extent of obstructive lesions in vessels perfusing viable myocardium.

Important and frequent complications of MI include ventricular dysfunction, cardiogenic shock, arrhythmias, myocardial rupture, infarct extension and expansion, papillary muscle dysfunction, right ventricular involvement, ventricular aneurysm, pericarditis, and systemic arterial embolism. About one-half of patients with MI will experience one or more of these complications, with outcome dependent on infarct size, location, and transmurality. Patients with anterior infarcts are at greatest risk for regional dilation and mural thrombi and have a substantially worse clinical course than those with inferior-posterior infarcts. In contrast, inferior-posterior infarcts are more likely to have serious conduction blocks and right ventricular involvement. Mechanical complications are more frequent and significant in patients with transmural lesions.

Although many patients have cardiac rhythm abnormalities following MI, the conduction system is involved in only a minority, and heart block following MI usually is transient. These abnormalities require aggressive treatment when they impair hemodynamics, compromise myocardial viability by increasing oxygen requirements, or predispose to malignant ventricular tachycardia or fibrillation. Tachyarrhythmias usually originate in areas of severely ischemic or necrotic myocardium. The proposed mechanisms include the presence of electrically unstable ischemic myocardium, often at the edge of an infarct, causing a micro-reentry phenomenon, and the release of arrhythmogenic metabolites such as lactic acid and potassium from necrotic tissue. Autopsy studies of sudden death victims and clinical studies of resuscitated survivors show that only a minority of patients with ischemia-induced malignant ventricular arrhythmias develop a full-blown AMI. Thus, ischemia caused by severe chronic coronary arterial stenosis can lead directly to lethal arrhythmias owing to myocardial irritability. Tachyarrhythmias that develop long after infarction likely originate at the junction between scar tissue and viable myocardium.

Myocardial infarcts produce functional abnormalities approximately proportional to their size. Large infarcts have a higher probability of cardiogenic shock and congestive heart failure (CHF). Nonfunctional scar tissue resulting from previous infarcts and areas of stunned or hibernating myocardium may also contribute to overall ventricular dysfunction. Cardiogenic shock following MI is generally indicative of a large infarct (often >40% of the left ventricle). The high mortality of myocardial dysfunction and cardiogenic

shock has been alleviated somewhat in recent years by the use of intra-aortic balloon pumps (IABPs) and ventricular assist devices to bridge patients through phases of prolonged but reversible functional abnormalities after MI.

Frequently catastrophic, cardiac rupture syndromes comprise three entities: (1) rupture of the ventricular free wall (most common), usually with hemopericardium and cardiac tamponade; (2) rupture of the ventricular septum (less common), leading to an acquired ventricular septal defect (VSD) with a left-to-right shunt; and (3) papillary muscle rupture (least common), resulting in the acute onset of severe mitral regurgitation (MR). Cardiac rupture is the cause of death in 8 to 10% of patients with fatal acute transmural myocardial infarcts. Ruptures tend to occur relatively early following infarction (mean interval of 4 to 5 days; range, 1 to 10 days) with as many as 25% presenting within 24 hours of MI. Free-wall and septal ruptures almost always involve transmural infarcts. Although the lateral wall is the least common site for left ventricular infarction, it is the most common site for postinfarction free-wall rupture. Acute free-wall ruptures usually are rapidly fatal; repair is rarely possible.[130]

A fortuitously located pericardial adhesion that arrests the rapidly moving blood front and aborts a rupture may result in the formation of a false aneurysm, defined as a contained rupture with a hematoma communicating with the ventricular cavity.[131] False aneurysms contain no myocardial elements in their walls, consisting only of epicardium and adherent parietal pericardium and thrombus; one-half eventually rupture.

Acute VSDs secondary to postinfarction septal rupture complicate 1 to 2% of infarcts. Infarct-related septal defects are of two types: (1) single or multiple sharply localized, jagged, linear passageways that connect the ventricular chambers (simple type), usually involving the anteroapical aspect of the septum; and (2) defects that tunnel serpiginously through the septum to a somewhat distant opening on the right side (complex type), usually involving the basal inferoseptal wall.[132] In simple lesions, neither gross hemorrhage nor peripheral laceration is present. In complex lesions, the tract may extend into regions remote from the site of the infarct. Without surgery, the prognosis following infarct-related septal rupture is poor.

Mitral regurgitation secondary to papillary muscle rupture in either subendocardial or transmural MI reflects loss of the structural or functional integrity of the mitral valve apparatus. Mitral regurgitation in this setting has an acute onset, and its severity varies depending on the location and extent of papillary muscle disruption. If only part of a papillary muscle group is involved, the degree of regurgitation will be less severe than if the entire muscle group ruptures. Since chordae tendineae arise from the heads of the papillary muscles and provide continuity with each of the valve leaflets, interference with the structure or function of either papillary muscle can result in dysfunction of both mitral valve leaflets.

Papillary muscles are particularly vulnerable to ischemic injury. Since the collateral circulation of the posterior myocardium is not as extensive as it is in the anterolateral segments, the posterior medial papillary muscle is more susceptible to widespread necrosis and is more commonly (85%) the site of rupture. Papillary muscle rupture tends to occur later than other rupture syndromes (as late as 1 month after MI).

Other mechanisms can produce MR in the setting of chronic ischemic heart disease. These are discussed later in this chapter in the section on valvular heart disease.

Isolated right ventricular infarction is rare. However, involvement of the right ventricle by extension of an inferoseptal infarct occurs in approximately 10% of transmural infarcts and can have important functional consequences, including right ventricular failure with or without tricuspid regurgitation and arrhythmias.[133]

Infarct *extension* is characterized by new or recurrent necrosis in the same distribution as a completed recent infarct; this increases the amount of necrotic myocardium. Extension most often occurs between 2 and 10 days after the original infarction, forms along the lateral and subepicardial borders, and histologically appears younger than the necrotic myocardium of the original infarct.

In contrast, infarct *expansion* is a disproportionate thinning and dilation of the infarcted region occurring through a combination of (1) slippage between muscle bundles, reducing the number of myocytes across the infarct wall; (2) disruption of the normal myocardial cells; and (3) tissue loss within the necrotic zone.[134] This acute change in the architecture of the left ventricle does not in itself lead to additional necrotic myocardium. However, regional dilation contributes to a significant increase in ventricular volume, increasing the wall stress and workload of noninfarcted myocardium and predisposing to late aneurysm formation. In addition, expansion predisposes to intracardiac mural thrombus formation via myocardial contractility abnormalities, causing stasis and endocardial damage, which causes thrombogenicity. Patients with infarct expansion, which can be detected by echocardiography in 30% of transmural infarcts, have increased morbidity and mortality.

Healing myocardial infarcts have complex structure and mechanisms.[135] Following MI, structural changes occur both in the necrotic zone and in uninvolved areas of the heart (*ventricular remodeling*), which occur by a combination of left ventricular dilation, wall thinning by infarct expansion, compensatory hypertrophy of noninfarcted myocardium, and potentially late aneurysm formation.[136] Ventricular remodeling begins at the time of acute infarction and probably continues for months to years, until either a stable hemodynamic state is achieved or progressively severe cardiac decompensation occurs. Compensatory hypertrophy of noninfarcted myocardium is initially hemodynamically beneficial, but late decreases in ventricular performance with depression of regional and global contractile function may reflect degenerative

changes. Congestive heart failure secondary to CAD occurs when the overall function of nonscarred myocardium (outside the infarct zone) can no longer maintain an adequate cardiac output. Moreover, regions of hyperfunctioning residual myocardium are particularly vulnerable to additional ischemic episodes.

Ventricular aneurysms paradoxically bulge during ventricular systole and most commonly result from a large transmural infarct that undergoes expansion and heals as scar tissue.[137] Even though their walls are frequently as thin as 1 mm, true ventricular aneurysms rarely rupture because of their tough fibrous or fibrocalcific nature. Markedly hypertrophied myocardial remnants as well as necrotic but inadequately healed (i.e., mummified) myocardium often are present in aneurysm walls, indicating incomplete healing of an infarct. Although 50% of patients with chronic fibrous aneurysms have mural thrombus contained within the ventricle, systemic embolization occurs in only approximately 5% of cases. Some pharmacologic approaches to limiting infarct size, such as steroids and other anti-inflammatory agents, could exacerbate infarct expansion and aneurysm formation.

VALVULAR HEART DISEASE

Normal valve function requires structural integrity and coordinated interactions among multiple anatomic components. For the atrioventricular valves (mitral and tricuspid), these elements include leaflets, commissures, annulus, chordae tendineae (tendinous cords), papillary muscles, and the atrial and ventricular myocardium. For the semilunar valves (aortic and pulmonary), the key structures are the cusps, commissures, and their respective supporting structures in the aortic and pulmonary roots.

Structure-Function Correlations in Normal Valves

The anatomy of the mitral and aortic valves is illustrated in Fig. 5-17.

Mitral valve

Of the two leaflets of the mitral valve (see Fig. 5-17A), the anterior (also called septal, or aortic) leaflet is roughly triangular and deep, with the base inserting on approximately one-third of the annulus. The posterior (also called mural, or ventricular) leaflet, although more shallow, is attached to about two-thirds of the annulus and typically has a scalloped appearance. The mitral leaflets have a combined area approximately twice that of the annulus; they meet during systole with apposition to approximately 50% of the depth of the posterior leaflet and 30% that of the anterior leaflet. Each leaflet receives chordae tendineae from both anterior and posterior papillary muscles.

The mitral valve orifice is D-shaped, with the flat anteromedial portion comprising the attachment of the anterior mitral leaflet in the subaortic region. This part of the annulus is fibrous and noncontractile; the posterolateral portion of the annulus is muscular and contracts during systole to asymmetrically reduce the area of the orifice. The edges of the mitral leaflets are held in or below the plane of the orifice by the chordae tendineae, which themselves are pulled from below by the contracting papillary muscles during systole. This serves to draw the leaflets to closure and maintain competence. The orifice of the tricuspid valve is larger and less distinct than that of the mitral valve; its three leaflets (anterior, posterior, and septal) are larger and thinner than those of the mitral valve.

Aortic valve

The three aortic valve cusps (left, right, and noncoronary) attach to the aortic wall in a semilunar fashion, ascending to the commissures and descending to the base of each cusp (see Fig. 5-17B). Commissures are spaced approximately 120° apart and occupy the three points of the annular crown, representing the site of separation between adjacent cusps. Behind the valve cusps are dilated pockets of aortic root, called the sinuses of Valsalva. The right and left coronary arteries arise from individual orifices behind the right and left cusps, respectively. At the midpoint of the free edge of each cusp is a fibrous nodule called the nodule of Arantius. A thin, crescent-shaped portion of the cusp on either side of the nodule, termed the lunula, defines the surface of apposition of the cusps when the valve is closed (approximately 40% of the cuspal area). Fenestrations (holes) near the free edges commonly occur as a developmental or degenerative abnormality, are generally small (less than 2 mm in diameter), and have no functional significance, since the lunular tissue does not contribute to separating aortic from ventricular blood during diastole. In contrast, defects in the portion of the cusp below the lunula are associated with functional incompetence; such holes also suggest previous or active infection. When the aortic valve is closed during diastole, there is a back pressure on the cusps of approximately 80 mm Hg. The pulmonary valve cusps and surrounding tissues have architectural similarity to but are more delicate than those of the corresponding aortic components, and lack coronary arterial origins.

Valve histology

All cardiac valves essentially have the same microscopically inhomogeneous architecture, consisting of well-defined tissue layers covered by endothelium. Using the aortic valve as an example (see Fig. 5-17C), the *ventricularis* faces the left ventricular chamber, and is comprised predominantly of collagenous fibers with radially aligned elastic fibers. The rich elastin of the ventricularis enables the cusps to have minimal surface area when the valve is open, but stretch during diastole to form a large coaptation area. The *spongiosa* is centrally located and is composed of loosely arranged collagen and abundant proteoglycans. This layer has negligible structural strength, but accommodates relative movement

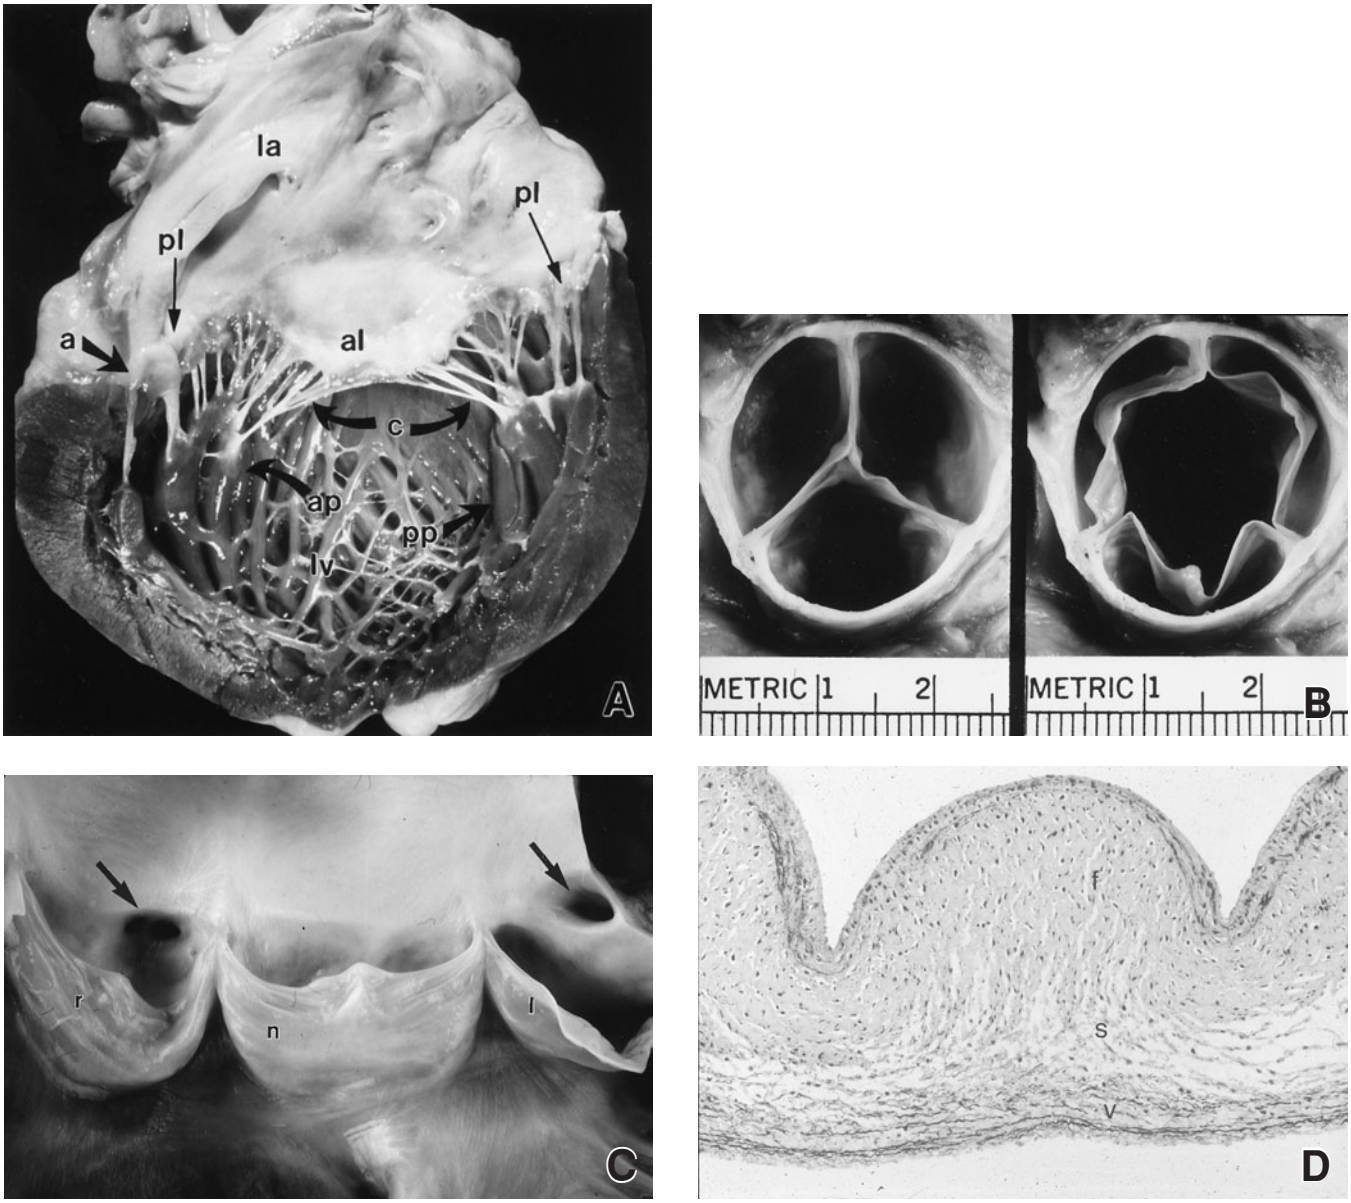

Figure 5-17. Normal mitral and aortic valves. (A) An opened left ventricle of the normal heart reveals the various components of the mitral apparatus. al = anterior leaflet; pl = posterior leaflet; a = annulus; c = chordae tendineae; ap = anterior papillary muscle; pp = posterior papillary muscle; la = left atrium; lv = left ventricle. (B) Aortic valve viewed from the distal aspect in closed (left) and open (right) phases. The closed cusps are closely opposed during ventricular diastole and open against the aortic wall during systole. (C) Aortic valve, opened anteriorly to reveal the relationships of the anterior mitral leaflet (lower right) to the aortic valve cusps (lrn = left/right/noncoronary cusps, respectively) and coronary arterial orifices (arrows). (D) Normal aortic valve histology, demonstrating layered structure, including the fibrosa (f), spongiosa (s), and ventricularis (v). The inflow surface is at bottom. Verhoeff van Giesen elastic tissue stain 150x. (*A: Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989. B, C, and D: Reproduced with permission from Schoen and Edwards.*[185])

between layers during the cardiac cycle, and absorbs shock during closure. The *fibrosa* is a thick fibrous layer that provides structural integrity and mechanical stability and is composed predominantly of circumferentially aligned, densely packed collagen fibers, largely arranged parallel to the cuspal free edge. Normal human aortic and pulmonary valve cusps have few blood vessels; they are sufficiently thin to be perfused from the surrounding blood. In contrast, the mitral and tricuspid leaflets contain a few capillaries in their most basal thirds.

During diastole, adjacent cusps coapt with a substantial area of surface-to-surface contact. This involves,

for example, nearly one-third of the atrioventricular valve leaflets. Thus, normal cusp and leaflet areas are substantially greater than are needed to simply close the valve orifice.

The orientation of connective tissue and other architectural elements is nonrandom in the plane of the cusp, yielding greater compliance in the radial than circumferential direction (anisotropic behavior). With specializations that include crimp of collagen fibers along their length, bundles of collagen in the fibrous layer oriented toward commissures, and grossly visible corrugations, cusps are extremely soft and pliable when unloaded, but taut and stiff during the closed phase. Moreover, the fibrous network within the cusps effectively transfers the stresses of the closed phase to the annulus and aortic wall. This minimizes sagging of the cusp centers, preserves maximum coaptation, and prevents regurgitation. For the mitral valve, the subvalvular apparatus including tendinous cords and papillary muscles is the critical mechanism of valve competency.

Cell Biology of Cardiac Valves

Recent studies have enhanced our understanding of how valves form embryologically, mature in the fetus, and function, adapt, maintain homeostasis, and change throughout life. These essential relationships facilitate an understanding of valve pathology and mechanisms of disease, foster the development of improved tissue heart valve substitutes, and inform innovative approaches to heart valve repair and regeneration.[138,139]

During normal development of the heart, the heart tube undergoes looping, following which the valve cusps/leaflets originate from mesenchymal outgrowths known as endocardial cushions.[140,141] A subset of endothelial cells in the cushion-forming area, driven by signals from the underlying myocardium, change their phenotype to mesenchymal cells and migrate into the acellular extracellular matrix called cardiac jelly to form the endocardial cushions. Likely regulated by transforming growth factor-β (TGF-β) and vascular endothelial growth factor (VEGF), the activated endothelial cells lose cell-cell contacts and invade the cardiac jelly. This transformation of endocardial cells to mesenchymal cells and migration away from the endothelial layer is termed transdifferentiation or endothelial-to-mesenchymal transformation.

Two types of cells are present in the fully-formed aortic valve: endothelial cells located superficially and interstitial cells located deep to the surface. Aortic valve endothelial cells have a different phenotype than those in the aorta,[142,143] and different transcriptional profiles are expressed by the endothelium on the aortic side versus ventricular side of normal adult pig aortic valves.[144] The implications of these differences are not yet known.

The second cell type comprises the valvular interstitial cells (VICs). VICs have variable properties of fibroblasts, smooth muscle cells, and myofibroblasts. Valvular extracellular matrix (ECM) is produced and maintained by VICs, and its quality is the overwhelming determinant of valve durability. To maintain integrity and pliability throughout life, the aortic valve must undergo repetitive physiologic remodeling that entails synthesis, degradation, and reorganization of its ECM, which depends on matrix-degrading enzymes such as matrix metalloproteinases. Although interstitial cells are predominantly fibroblast-like in normal valves, VICs can become activated[145] when valves or their cells are exposed to environmental (i.e., mechanical and chemical) stimulation in vitro and in vivo.[146,147] Activated VICs assume a myofibroblast-like phenotype and mediate connective tissue remodeling. Aortic valves also seem to have contractile properties that are modulated by the VICs,[148] but the relevance of valve contraction to in vivo function is uncertain.

Subsequent to morphogenesis, embryonic fetal valves possess a dynamic structure composed of a nascent ECM and cells with characteristics of myofibroblasts.[149] These changes in cell phenotype and ECM remodeling continue throughout human fetal and postnatal development, and indeed, throughout life. Moreover, ongoing changes in valve cells and ECM lead to changes in properties and potentially function, as evidenced by increasing valve stiffness with increasing age.[150]

Etiology and Pathologic Anatomy of Valvular Heart Disease

Cardiac valve operations usually are undertaken for dysfunction caused by calcification, fibrosis, fusion, retraction, perforation, rupture, stretching, dilation, or congenital malformations of the valve leaflets/cusps or associated structures. Valvular stenosis, defined as inhibition of forward flow secondary to obstruction caused by failure of a valve to open completely, is almost always caused by a primary cuspal abnormality and a chronic disease process. In contrast, valvular insufficiency, defined as reverse flow caused by failure of a valve to close completely, may result from either intrinsic disease of the valve cusps or from damage to or distortion of the supporting structures (e.g., the aorta, mitral annulus, chordae tendineae, papillary muscles, and ventricular free wall) without primary cuspal pathology. Regurgitation may appear either acutely, as with rupture of cords, or chronically, as with leaflet scarring and retraction. Both stenosis and insufficiency can coexist in a single valve, usually with one process predominating. The most commonly encountered morphologies of valvular heart disease are illustrated in Figs. 5-18 and 5-19.

Changing disease patterns and an aging U.S. population have altered the relative frequency of the major causes of valve disease in the late twentieth century. Degenerative (senile) calcific aortic valve disease is the most common cause of aortic stenosis; calcification of congenitally bicuspid aortic valves comprises the second most common cause. Postinflammatory (rheumatic) disease has continued to decline as a cause of aortic valve

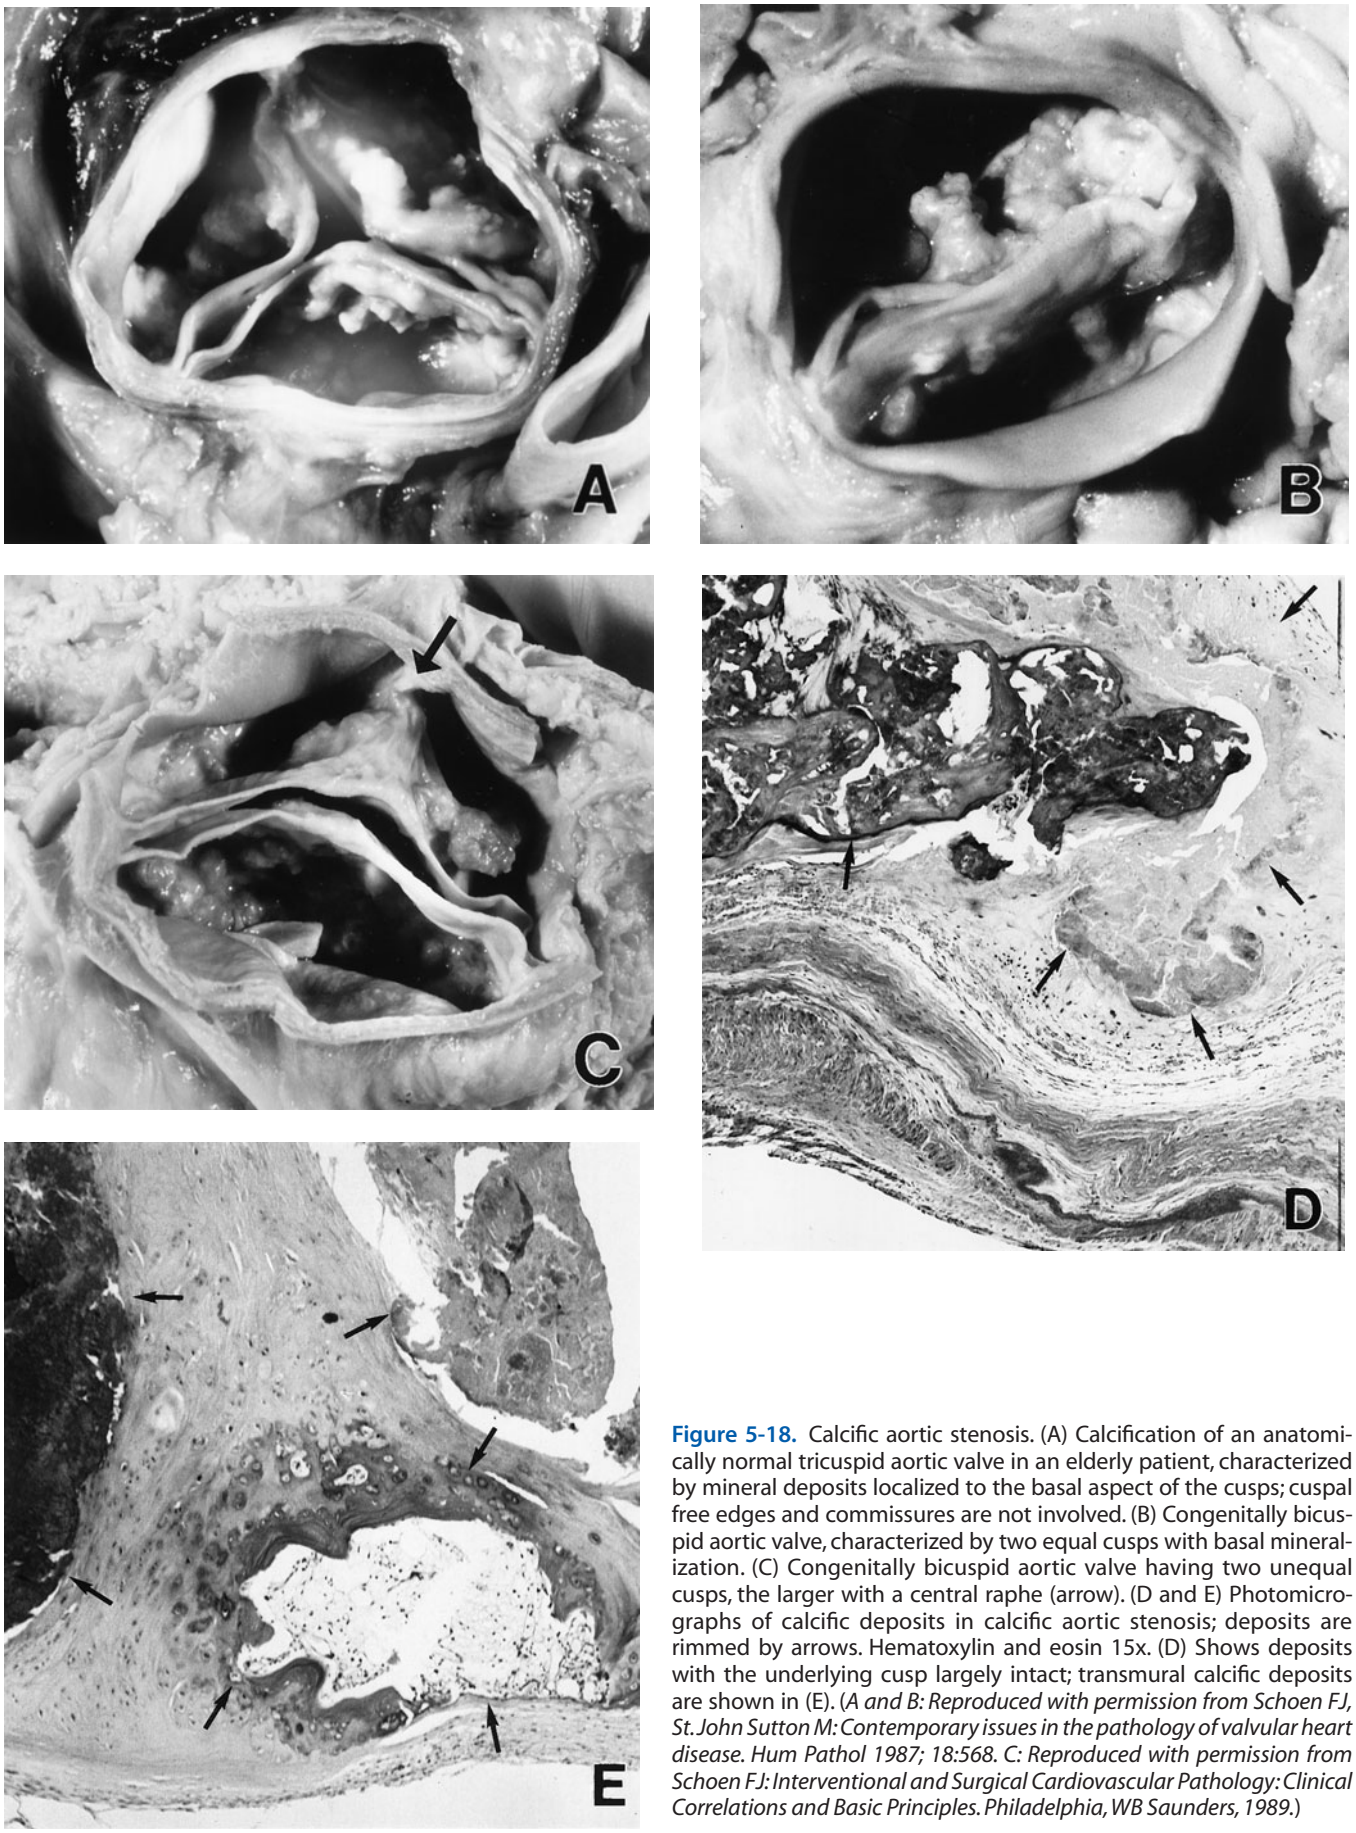

Figure 5-18. Calcific aortic stenosis. (A) Calcification of an anatomically normal tricuspid aortic valve in an elderly patient, characterized by mineral deposits localized to the basal aspect of the cusps; cuspal free edges and commissures are not involved. (B) Congenitally bicuspid aortic valve, characterized by two equal cusps with basal mineralization. (C) Congenitally bicuspid aortic valve having two unequal cusps, the larger with a central raphe (arrow). (D and E) Photomicrographs of calcific deposits in calcific aortic stenosis; deposits are rimmed by arrows. Hematoxylin and eosin 15x. (D) Shows deposits with the underlying cusp largely intact; transmural calcific deposits are shown in (E). (*A and B: Reproduced with permission from Schoen FJ, St. John Sutton M: Contemporary issues in the pathology of valvular heart disease. Hum Pathol 1987; 18:568. C: Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

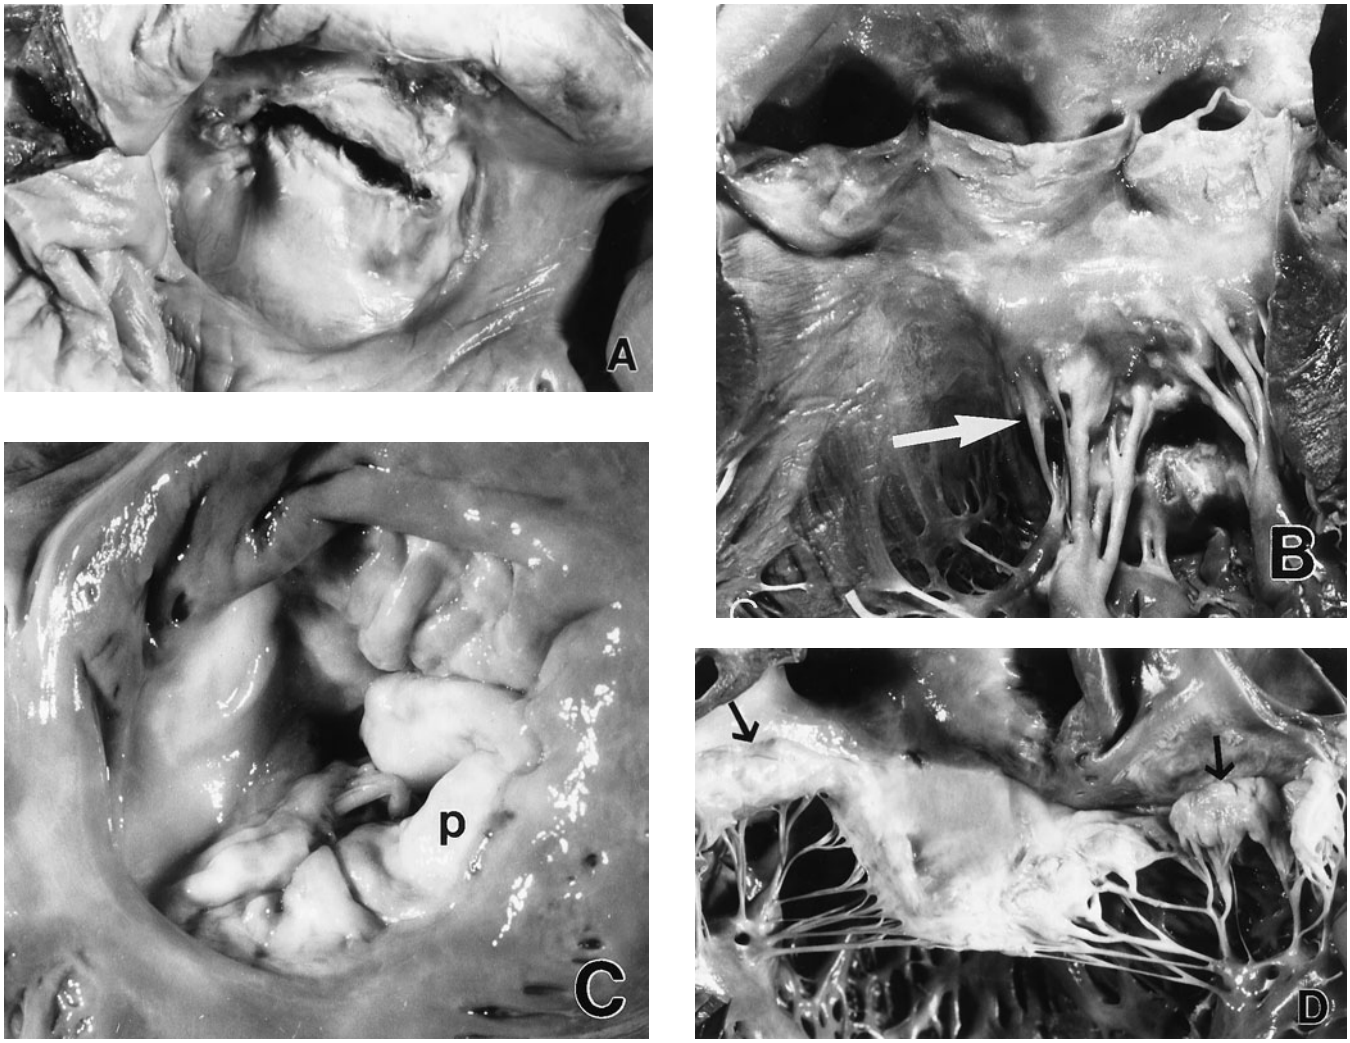

Figure 5-19. Major etiologies of mitral valvular disease. (A) Atrial view, and (B) subvalvular and aortic aspect of a valve from a patient with rheumatic mitral stenosis. There are severe valvular changes, including diffuse leaflet fibrosis and commissural fusion and ulceration of the free edges of the valve, as well as prominent subvalvular involvement with distortion (arrow in [B]). (C and D) Myxomatous degeneration of the mitral valve. In (C) (left atrial view), there is prolapse of a redundant posterior leaflet (p), whereas in (D) from another case, the opened annulus reveals a redundant posterior mitral leaflet (arrows), with thin elongated chordae tendineae. The patient with the valve shown in (D) had chronic mitral regurgitation with prolapse noted clinically, and Marfan syndrome. (*Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

dysfunction. Indeed, the leading cause of chronic aortic insufficiency is aortic root dilation, causing stretching and outward bowing of the commissures and a lack of cuspal coaptation. Over the age of 40, aortic root dilation is most often due to age-related aortic degeneration, or less commonly, aortitis. Under 40 years of age, root dilation occurs most frequently in association with Marfan syndrome, other connective tissue disorders, or operated congenital heart disease. Moreover, whereas postrheumatic deformity remains the leading cause of mitral stenosis, its incidence continues to decline. Moreover, myxomatous mitral valve disease and ischemic MR are the leading causes of pure mitral valve regurgitation; these pathologies are often amenable to and comprise the major indications for mitral valve repair.

Calcific aortic valve stenosis

The most frequent valvular abnormality requiring surgery, acquired aortic stenosis, usually is the consequence of age-related calcium phosphate deposition in either anatomically normal aortic valves or in congenitally bicuspid valves (see Fig. 5-18A).[151,152] With the rising average age of the population, the prevalence of aortic stenosis, estimated at 2%, is increasing. Stenotic, previously normal tricuspid valves come to clinical attention primarily in the eighth to ninth decades of life, while bicuspid valves with

superimposed age-related degenerative calcification generally become symptomatic earlier (usually in the sixth to seventh decades).[153]

Nonrheumatic, calcific aortic stenosis is characterized by heaped-up, calcified masses initiated in the cuspal fibrosa at the points of maximal cusp flexion (the margins of attachment); they protrude distally from the aortic aspect into the sinuses of Valsalva, inhibiting cuspal opening. The dystrophic calcification process generally does not involve the free cuspal edges. In contrast to rheumatic aortic stenosis, appreciable commissural fusion is absent in calcific aortic stenosis and the mitral valve generally is uninvolved. Aortic valve sclerosis comprises a common, earlier, and hemodynamically less significant stage of the calcification process. Nevertheless, aortic sclerosis is associated with an increase of approximately 50% in the risk of death from cardiovascular causes and the risk of MI, even in the absence of hemodynamically significant obstruction of left ventricular outflow.[154]

Aortic stenosis leads to a gradually increasing pressure gradient across the valve, which may reach 75 to 100 mm Hg in severe cases, necessitating a left ventricular pressure of 200 mm Hg or more. Cardiac output is maintained by the development of concentric LVH secondary to pressure overload. The onset of symptoms such as angina, syncope, or heart failure in aortic stenosis heralds the exhaustion of compensatory cardiac hyperfunction, and carries a poor prognosis if not treated by aortic valve replacement (AVR) (approximately 50% mortality within 3 to 5 years).[155] If cardiac output is low, as may occur in heart failure or in the elderly, then neither the gradient nor the resultant murmur may appear significant and aortic stenosis can be missed clinically. Other complications of calcific aortic stenosis include embolization that may occur spontaneously or during interventional procedures, hemolysis, and extension of the calcific deposits into the ventricular septum, causing conduction abnormalities.

The mechanisms of aortic valve calcification are traditionally believed to be degenerative, dystrophic, and passive accumulation of hydroxyapatite mineral in the setting of sclerosis.[156] However, recent studies suggest active regulation of calcification in aortic valves similar to that in the atherosclerotic process in arteries, with inflammation, lipid infiltration, and phenotypic modulation of VICs to an osteoblastic phenotype,[157] and risk factors in common with atherosclerosis. This has stimulated interest in the possibility that statin drugs may decrease the rate of aortic stenosis progression, but studies to date have not supported this contention.[158,159]

Bicuspid aortic valve

With a prevalence of approximately 1%, bicuspid aortic valve (BAV) is the most frequent congenital cardiovascular malformation in humans.[160] Men are affected three to four times more frequently than are women. The two cusps are typically of unequal size, with the larger (conjoined) cusp having a midline raphe, representing an incomplete separation or congenital fusion of two cusps. Less frequently, the cusps are of equal size (see Figs. 5-18B and 5-18C). When a raphe is present, the most commonly fused cusps are the right and left, accounting for about 75% of cases. Neither stenotic nor symptomatic at birth or throughout early life, bicuspid valves are predisposed to accelerated calcification, with about 85% becoming stenotic. About 15% of the time, they become purely incompetent, complicated by infective endocarditis, or associated with acute aortic dissection. Bicuspid aortic valves underlie over two-thirds of aortic stenosis in children and 50% of adults. Aortic abnormalities commonly accompany BAV, even when the valve is hemodynamically normal, and can cause dilation or dissection. Rarely, an uncomplicated bicuspid valve is encountered at autopsy.

Recent studies have confirmed previous reports of familial clustering of BAV and left ventricular outflow tract obstruction malformations, and their association with other cardiovascular malformations.[161,162] The high genetic determination suggests that these common valvular malformations are primary to defective valvulogenesis or secondary to other elements of cardiogenesis. Particularly interesting in this regard is the recent report that mutations in the signaling and transcriptional regulator NOTCH1 caused a spectrum of developmental aortic valve abnormalities and severe calcification in two families with nonsyndromic familial aortic valve disease.[163]

Mitral annular calcification

Degenerative calcific deposits also can develop in the ring (annulus) of the mitral valve of elderly individuals, especially women. Although generally asymptomatic, the calcific nodules may lead to regurgitation by interference with systolic contraction of the mitral valve ring, or very rarely stenosis, by impairing mobility of the mitral leaflets during opening. Occasionally, the calcium deposits may penetrate sufficiently deeply to impinge on the atrioventricular conduction system and produce arrhythmias (and rarely sudden death). Patients with mitral annular calcification have an increased risk of stroke, and the calcific nodules can be the nidus for thrombotic deposits or infective endocarditis.

Rheumatic heart disease

Rheumatic fever is an acute, often recurrent, inflammatory disease that generally follows a pharyngeal infection with group A beta-hemolytic streptococci, principally in children. In the past several decades, rheumatic fever and rheumatic heart disease have declined markedly but not disappeared in the United States and other developed countries. Evidence strongly suggests that rheumatic fever is the result of an immune response to streptococcal antigens, inciting either a cross-reaction to tissue antigens, or a streptococcal-induced autoimmune reaction to normal tissue antigens. The cardiac surgical implications of rheumatic fever primarily relate to chronic rheumatic heart

disease, characterized by chronic, progressive, deforming valvular disease (particularly mitral stenosis) that produces permanent dysfunction and severe, sometimes fatal, cardiac failure decades later.

Chronic rheumatic heart disease most frequently affects the mitral and to a lesser extent the aortic and/or the tricuspid valves. Chronic rheumatic valve disease is characterized by fibrous or fibrocalcific distortion of leaflets or cusps, valve commissures, and chordae tendineae, with or without annular or papillary muscle deformities (see Figs. 5-19A and 5-19B). Stenosis results from leaflet and chordal fibrous thickening and from commissural and chordal fusion, with or without secondary calcification. Regurgitation usually results from scarring-induced retraction of chordae and leaflets, and less commonly, fusion of a commissure in an opened position. Combinations of lesions may yield valves that are both stenotic and regurgitant. Although considered the pathognomonic inflammatory myocardial lesions in acute rheumatic fever, Aschoff nodules are found infrequently in myocardium sampled at autopsy or at valve replacement surgery, most likely reflecting the extended interval from acute disease to critical functional impairment.

Myxomatous degeneration of the mitral valve (mitral valve prolapse)

Myxomatous mitral valve disease (mitral valve prolapse) is the most frequent cause of chronic, pure, isolated mitral regurgitation.[164] Over the last decade, due to improved technology and large community studies, a prevalence of mitral valve prolapse (MVP) of 2.4% and a rate of the serious complications, namely heart failure, MR, infective endocarditis, stroke or other manifestations of thromboembolism, progressive CHF, sudden death, or atrial fibrillation of no more than 3% have been ascertained.[165] Mitral valve prolapse is the most common cause for surgical repair or replacement of the mitral valve. In MVP one or both mitral leaflets are enlarged, redundant, or floppy, and will prolapse, or balloon back into the left atrium during ventricular systole (see Fig. 5-19C). The three characteristic anatomic changes in MVP are: (1) interchordal ballooning (hooding) of the mitral leaflets or portions thereof (most frequently involving the posterior leaflet), sometimes accompanied by elongated, thinned, or ruptured cords (see Fig. 5-19D); (2) rubbery, diffuse leaflet thickening that hinders adequate coaptation and interdigitation of leaflet tissue during valve closure; and (3) substantial annular dilation, with diameters and circumferences that may exceed 3.5 and 11.0 cm, respectively.[166] Pathologic mitral annular enlargement is usually confined to the posterior leaflet, since the anterior leaflet is firmly anchored by the fibrous tissue at the aortic valve end and is far less distensible. The key microscopic changes in myxomatous degeneration are attenuation or focal disruption of the fibrous layer (with loss of collagen) of the valve, on which the structural integrity of the leaflet depends, and focal or diffuse thickening of the spongy layer by proteoglycan deposition (which gives the tissue an edematous, blue appearance on microscopy called "myxomatous" by pathologists).[167] These changes weaken the leaflet. Concomitant involvement of the tricuspid valve is present in 20 to 40% of cases, and the aortic and pulmonary valves also may be affected.

Secondary changes may occur, including: (1) focal pad-like fibrous thickening along both surfaces of the valve leaflets; (2) linear thickening of the subjacent mural endocardium of the left ventricle as a consequence of friction-induced injury by chordal hamstringing of the prolapsing leaflets; (3) thrombi on the atrial surfaces of the leaflets, particularly in the recesses behind the ballooned leaflet segments; (4) calcification along the base of the posterior mitral leaflet; and (5) chordal thickening and fusion with some features that resemble postrheumatic disease.

The pathogenesis of myxomatous degeneration is uncertain, but this valvular abnormality is a common feature of Marfan syndrome and occasionally occurs with other hereditary disorders of connective tissues such as Ehlers-Danlos syndrome, suggesting an analogous but localized connective tissue defect.[168] In these heritable disorders of connective tissue including Marfan syndrome, MVP is usually associated with mutations in fibrillin-1, and recent evidence has implicated abnormal TGF-β signaling (similar to the aortic abnormalities in the pathogenesis of Marfan syndrome and related disorders).[169,170] However, it is unlikely that more than 1 to 2% of patients with MVP have an identifiable connective tissue disorder. Nevertheless, studies utilizing genetic linkage analysis have mapped families with autosomal dominant MVP to the X chromosome, chromosomes 11p15.4, 16p11.2–p12.1 and 13q31.3–q32.1. The latter locus is particularly interesting in that there are at least 16 known genes in the region, several of which could be involved in valvular tissue remodeling.

Ischemic mitral regurgitation

There has been renewed interest in ischemic mitral regurgitation (IMR), also called functional mitral regurgitation. In IMR the leaflets are intrinsically normal while myocardial structure and function are altered by ischemia.[171,172] IMR is present in 10 to 20% of patients with CAD and worsens prognosis following MI, with reduced survival directly related to the severity of the regurgitation. These mechanisms include an ischemic papillary muscle that fails to tighten the chordae during systole, and a fibrotic, shortened papillary muscle that fixes the chordae deeply within the ventricle. Nevertheless, papillary muscle dysfunction alone is generally insufficient to produce IMR. The key causal factor is dilation and increasing spherical shape of the left ventricle, which pulls the papillary muscles down and away from the center of the chamber. Although there is substantial interest in developing surgical and/or percutaneous approaches to the repair of MR, none of the strategies developed so far have resulted in clearly improved patient outcomes.[173]

Drug-induced valve disease

Patients with the carcinoid syndrome often develop plaque-like intimal thickenings of the endocardium of the tricuspid valve, right ventricular outflow tract, and pulmonary valve superimposed on otherwise unaltered endocardium.[174] The left side of the heart is usually unaffected. These lesions are related to elaboration by carcinoid tumors of bioactive products, including serotonin, which cause valvular endothelial cell proliferation but are inactivated by passage through the lung.

Left-sided but similar valve lesions, usually causing regurgitation, have been reported to complicate the administration of fenfluramine and phentermine (fen-phen), appetite suppressants used for the treatment of obesity, which may affect systemic serotonin metabolism.[175] Typical diet drug–associated plaques have proliferation of myofibroblast-like cells in a myxoid stroma with variable vascular channels and lymphocytic and deep fibroelastic tissue. Similar left-sided plaques may be found in patients who receive methysergide or ergotamine therapy for migraine headaches; these serotonin analogs are metabolized to serotonin as they pass through the pulmonary vasculature. Moreover, drug-related valve disease has been reported in patients taking pergolide mesylate, an ergot-derived dopamine receptor agonist used to treat Parkinson disease and restless leg syndrome.[176]

Infective endocarditis

Infective endocarditis is characterized by colonization or invasion of the heart valves, mural endocardium, aorta, aneurysmal sacs, or other blood vessels by a microbiologic agent, leading to the formation of friable vegetations laden with organisms.[177] Virtually any type of microbiologic agent can cause infective endocarditis, but most cases are bacterial.

The so-called Duke criteria provide a standardized assessment of patients with suspected infective endocarditis that integrates factors predisposing patients to the development of infective endocarditis, blood-culture evidence of infection, echocardiographic findings, and clinical and laboratory information.[178] The previously important clinical findings of petechiae, subungual hemorrhages, Janeway lesions, Osler nodes, and Roth spots in the eyes (secondary to retinal microemboli) have now become uncommon owing to the shortened clinical course of the disease as a result of antibiotic therapy.

The clinical classification into acute and subacute forms is based on the range of severity of the disease and its tempo, on the virulence of the infecting microorganism, and on the presence of underlying cardiac disease. Acute endocarditis is a destructive infection, often involving a previously normal heart valve, with a highly virulent organism, and leads to death within days to weeks in over 50% of patients. In contrast, in a more indolent lesion often called subacute endocarditis, organisms of low virulence cause infection on previously deformed valves; the infection pursues a protracted course of weeks to months and may be undetected and untreated.

Vegetations in both acute and subacute endocarditis are composed of fibrin, inflammatory cells, and organisms. *Staphylococcus aureus* is the leading cause of acute endocarditis and produces necrotizing, ulcerative, invasive, and highly destructive valvular infections. The subacute form is usually caused by viridans streptococci. Cardiac abnormalities, such as rheumatic heart disease, congenital heart disease (particularly anomalies that have small shunts or tight stenoses creating high-velocity jet streams), myxomatous mitral valves, BAVs, and artificial valves and their sewing rings, predispose to endocarditis. In intravenous drug abusers, left-sided lesions predominate, but right-sided valves are commonly affected; the usual organism is *S. aureus.* In about 5 to 20% of all cases of endocarditis, no organism can be isolated from the blood (culture-negative endocarditis), often because of prior antibiotic therapy.

The complications of endocarditis include valvular insufficiency (or rarely stenosis), abscess of the valve annulus (ring abscess), suppurative pericarditis, and embolization. With appropriate antibiotic therapy, vegetations may undergo healing, with progressive sterilization, organization, fibrosis, and occasionally calcification. Regurgitation generally occurs on the basis of cusp or leaflet perforation, chordal rupture, or fistula formation from a ring abscess into an adjacent cardiac chamber or great vessel. Ring abscesses tend to be associated with virulent organisms, are technically difficult to deal with surgically, and are associated with a relatively high mortality rate.

Valve Reconstruction and Repair

Reconstructive procedures to eliminate mitral insufficiency of various etiologies and to minimize the severity of rheumatic mitral stenosis are now highly effective and commonplace. Reconstructive therapy of selected patients with aortic insufficiency and aortic dilation may also be done occasionally, but repair of aortic stenosis has been notably less successful. The major advantages of repair over replacement relate to the elimination of both prosthesis-related complications and the need for chronic anticoagulation. Other reported advantages include a lower hospital mortality, better long-term function owing to the ability to maintain the continuity of the mitral apparatus, and a lower rate of postoperative endocarditis. Figures 5-20 and 5-21 illustrate the pathologic anatomy of various mitral valve reconstruction procedures, and Fig. 5-22 illustrates aortic valve repairs for aortic stenosis.

Endovascular approaches to valvular heart disease include balloon valvuloplasty, percutaneous placement of a mitral annular constraint device in the coronary sinus, and double-orifice edge-to-edge mitral valve repair without cardiopulmonary bypass for the treatment of mitral regurgitation.[179,180] Percutaneous valve repair is most likely to be used in patients with severe disease deemed inoperable and in patients with early-stage regurgitant lesions in whom valve repair may

prevent progressive ventricular dilation. Percutaneous transluminal balloon dilation of stenotic valves has been used successfully to relieve some congenital and acquired stenoses of native pulmonary, aortic, and mitral valves, and stenotic right-sided porcine bioprosthetic valves.[181,182]

Mitral stenosis

Commissurotomy may be employed in the operative repair of some stenotic mitral valves in which fibrosis and shortening of both chordae and leaflets have markedly decreased leaflet mobility and area. Since the annular portions of the leaflet are normally devoid of chordal support, splitting them to a point 2 to 3 mm from the annulus may avoid the potential complication of a new or residual regurgitant jet. Anterior leaflet mobility often is sufficient to allow an acceptable mitral opening despite posterior leaflet immobility. Five factors compromise the late functional results of mitral commissurotomy: (1) left ventricular dysfunction; (2) pulmonary venous hypertension and right-sided cardiac factors, including right ventricular failure, tricuspid regurgitation, or a combination of these; (3) systemic embolization; (4) other coexistent cardiac disorders, such as coronary artery or aortic valve diseases; and (5) residual or progressive mitral valve disease, including valve restenosis, residual (unrelieved) stenosis, or regurgitation induced at operation. Progressive degrees of leaflet (especially commissural) calcification, subvalvular (predominantly chordal) fibrotic changes, and significant regurgitation owing to retraction may limit the ability to perform reconstructive surgical repair, and thereby necessitate valve replacement.

Percutaneous balloon mitral valvuloplasty has been used to treat mitral stenosis for over two decades, with

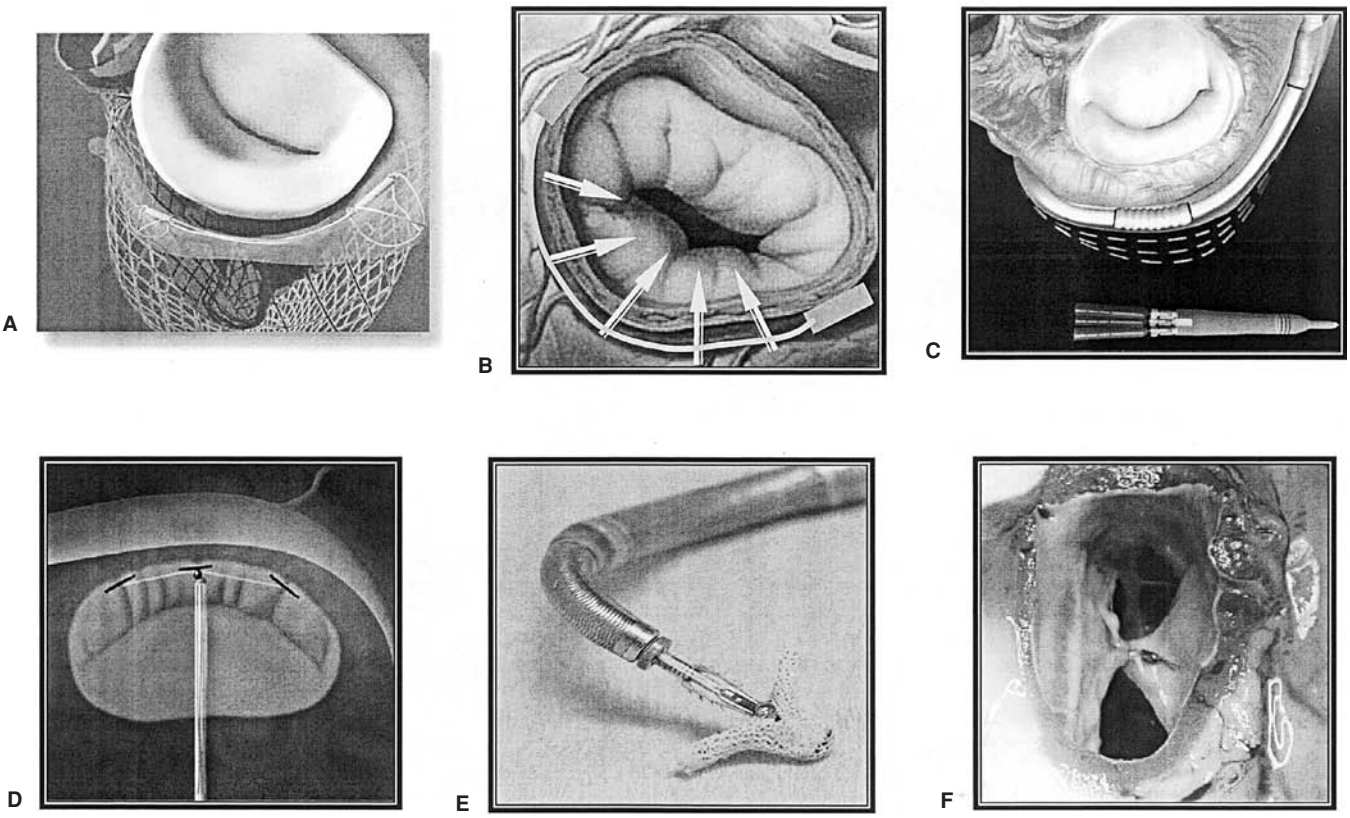

Figure 5-21. Percutaneous correction of mitral regurgitation. The Cardiac Dimensions Carillon (A), the Edwards Viking (B), and the Viacor device (C) all utilize the proximity of the coronary sinus to the posterior mitral annulus to effect a simulated annuloplasty. Other devices such as Mitralign (D) perform direct mitral annuloplasty using a percutaneous approach to the ventricular aspect of the annulus. Edge-to-edge approximation of the A2 and P2 portions of the mitral valve is achieved by either deployment of an eValve clip (E) or direct suture (Edwards Milano II, F). (*Reproduced with permission from Davidson and White.*[180])

excellent success in patients with suitable valvular and subvalvular morphology. However, since balloon valvuloplasty largely involves commissural separation, this procedure is unlikely to provide significant alteration in the subvalvular pathology of the chordae and papillary muscles of patients with rheumatic mitral stenosis.

Mitral regurgitation

Reconstructive techniques are widely used to repair mitral valves with nonrheumatic MR. Structural defects primarily responsible for MR include: (1) dilation of the mitral annulus; (2) leaflet redundancy and prolapse into the left atrium with or without elongation or rupture of chordae tendineae; (3) leaflet perforations or defects; (4) leaflet retraction; (5) chordal rupture or shortening; or (6) dilation of the left ventricle. The posterior leaflet is more delicate, has a shorter annulus-to-free-edge dimension than the anterior leaflet, and is therefore more prone to postinflammatory fibrous retraction.

Following surgical resection of excess anterior or posterior leaflet tissue in valves with redundancy, annuloplasty with or without a prosthetic ring is used to reduce the annulus dimension to correspond to the amount of leaflet tissue available. Edge-to-edge (Alfieri stitch) mitral valve repair has also been used.[183] Tissue substitutes such as glutaraldehyde-pretreated xenograft or autologous pericardium can be used to repair or enlarge leaflets. Ruptured or elongated chordae may be repaired by shortening or replacement with pericardial tissue or thick suture material.

Percutaneous approaches currently being evaluated for MR attempt to emulate one or more of the components of surgical mitral valve repair, including annular reduction and edge-to-edge mitral leaflet apposition (see Fig. 5-21). However, leaflet resection and chordal modification cannot be easily done via catheter. Percutaneous approaches in various stages of development and clinical evaluation include implantation of a device in the coronary sinus, left atrium (or both), or by device placement behind the posterolateral leaflet of the mitral valve, and at least three devices employing these concepts are in clinical trials. The goal is to plicate or straighten the posterior mitral annulus. A major challenge of coronary sinus approaches relates to anatomic variability of the coronary sinus.[184] Additional annuloplasty approaches presently in preclinical testing include a suture annuloplasty from the ventricular side of the mitral annulus,

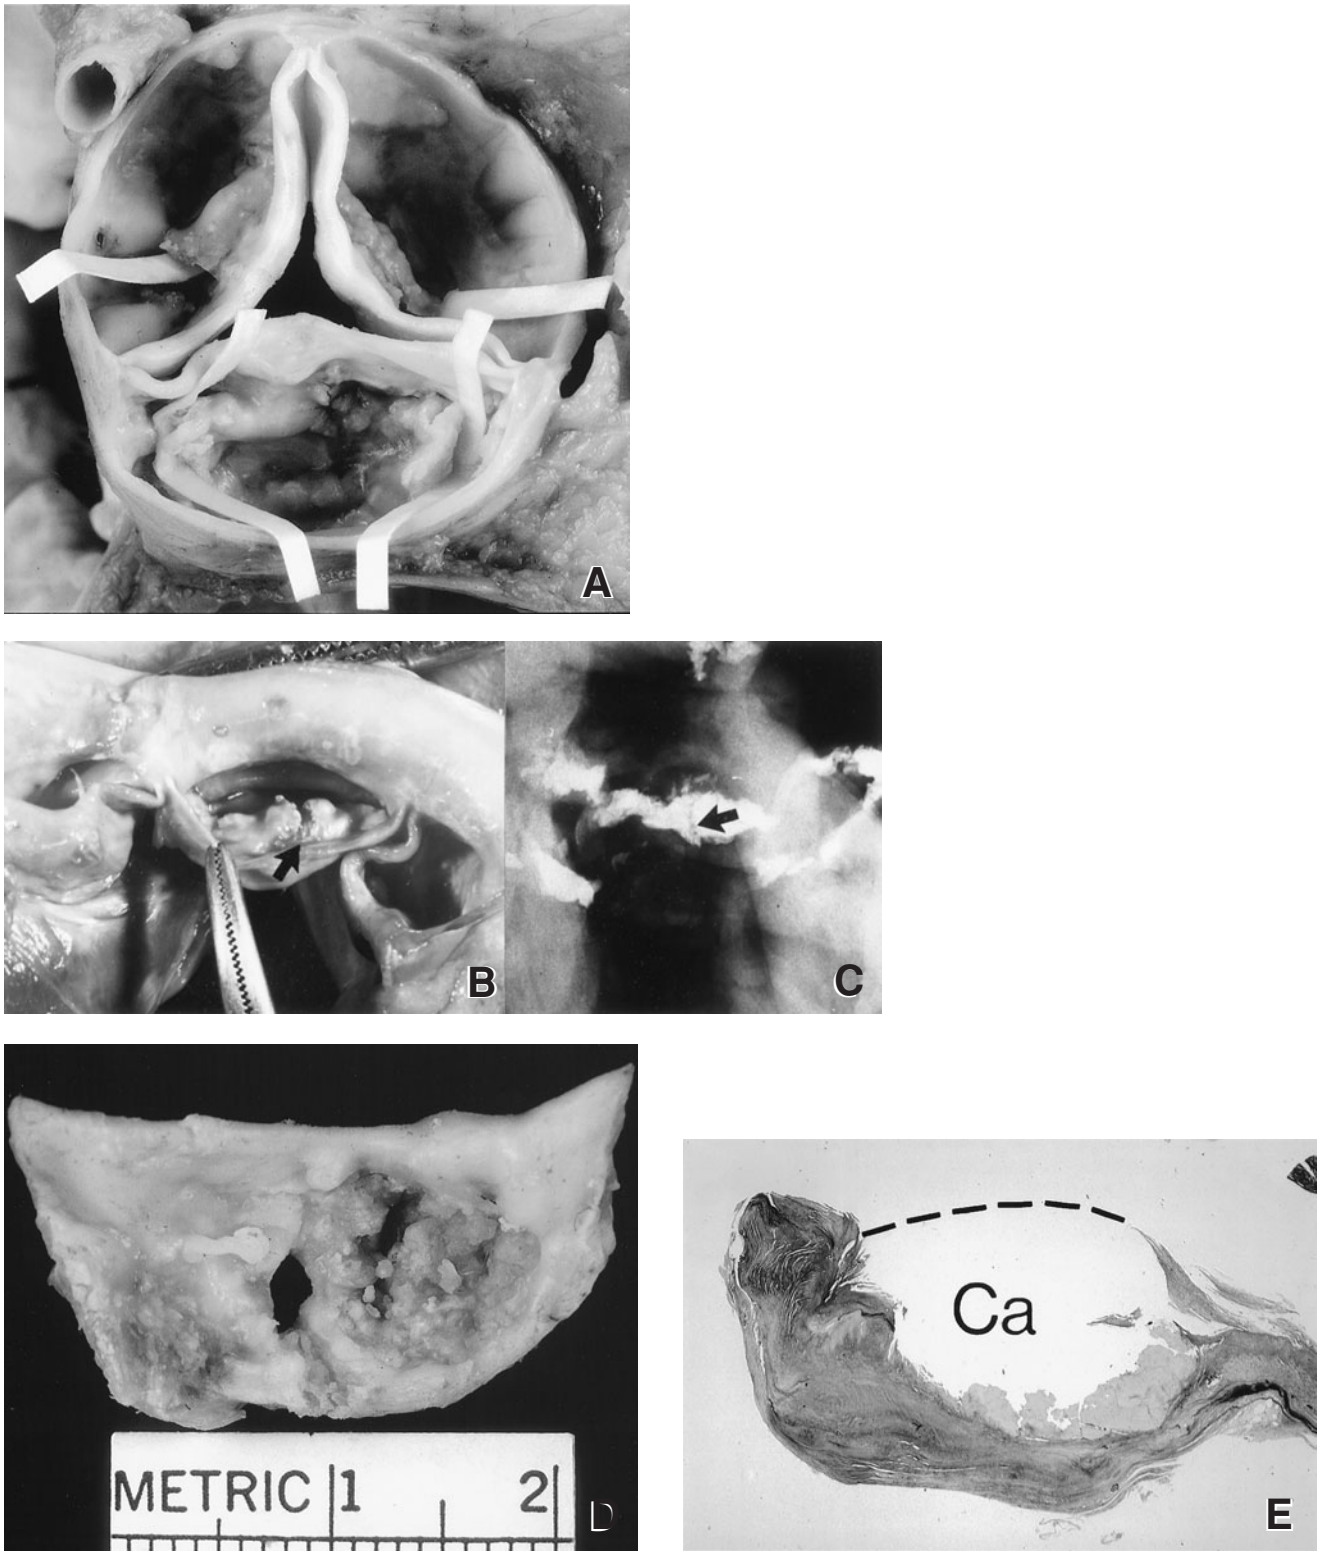

Figure 5-22. Reconstructive procedures for aortic stenosis. Philadelphia, WB Saunders, 1989.*)

thermal modification of the annulus to obtain shrinkage, and a percutaneous ventricular restraint system that attempts to reshape the left ventricle. Another approach uses an edge-to-edge clip prosthesis emulating the edge-to-edge surgical (Alfieri stitch) repair in which the midportions of the anterior and posterior mitral leaflets are clipped together.

Aortic stenosis

Since valvular aortic stenosis in most patients over 60 years of age is characterized by calcific deposits superimposed upon a valve largely free of either congenital or rheumatic deformities, the leaflets are immobilized by extensive deposits of calcium. However, because the calcific deposits arise deep in the valve fibrous layer (see Fig. 5-18D and E), their removal by sharp dissection or ultrasonic débridement generally removes the fibrosa and may cause damage to the spongiosa and ventricularis, resulting in severe compromise of cuspal mechanical integrity (see Fig. 5-22D and E).[185]

In balloon dilation of acquired calcific aortic stenosis, individual functional responses vary considerably and data suggest a modest incremental benefit, high early mortality, and high restenosis rate.[186] The major complications of balloon valvuloplasty include cerebrovascular accident secondary to embolism, massive regurgitation owing to valve trauma, cardiac perforation with tamponade, and with mitral valvuloplasty, creation of an atrial septal defect owing to septal dilation.

Improvement following catheter balloon valvuloplasty of aortic stenosis derives from commissural separation, fracture of calcific deposits, and displacing and stretching of the valve cusps (see Fig. 5-22A). Fractured calcific nodules can themselves prove dangerous (see Fig. 5-22B and C).[187] In pediatric cases in which the cusps are generally pliable, cuspal stretching, tearing, or avulsion may also occur.

Valve Replacement

Severe symptomatic valvular heart disease other than pure mitral stenosis or incompetence is most frequently treated by excision of the diseased valve(s) and replacement by a functional substitute. Pathologic considerations in valve replacement have been reviewed.[188]

Five key factors determine the results of valve replacement in an individual patient: (1) technical aspects of the procedure; (2) intraoperative myocardial ischemic injury; (3) irreversible and chronic structural alterations in the heart and lungs secondary to the valvular abnormality; (4) coexistent obstructive CAD; and (5) valve prosthesis reliability and host-tissue interactions.

Valve types and prognostic considerations

Cardiac valvular substitutes are of two generic types, mechanical and biologic tissue (Fig. 5-23 and Table 5-2).[189] Prostheses function passively, responding to pressure and flow changes within the heart. Mechanical valves are usually composed of nonphysiologic biomaterials that employ a rigid, mobile occluder (composed of pyrolytic carbon in contemporary valves) in a metallic cage (cobalt-chrome or titanium alloy) as in the Bjork-Shiley, Hall-Medtronic, or OmniScience valves, or as two carbon hemidisks in a carbon housing (e.g., the St. Jude Medical and CarboMedics CPHV prostheses). Pyrolytic carbon has high strength and fatigue and wear resistance and good thromboresistance.[190] Tissue valves are more anatomically similar to natural valves, compared to mechanical prostheses, and their pseudoanatomic central flow and relative nonthrombogenicity usually obviate chronic anticoagulant therapy in the absence of another indication. Approximately one-half of all valves implanted in the present era are mechanical (mostly bileaflet tilting disk); the remainder are tissue, mostly bioprosthetic as xenografts fabricated from porcine aortic valve or bovine pericardium that have been preserved in a dilute glutaraldehyde solution, and a small percentage of cryopreserved allografts. In the past decade, innovations in tissue valve technologies and design have expanded indications for their use (Fig. 5-24).[191]

Early mortality after elective cardiac valve replacement now is generally in the range of 3 to 5%, with the majority of deaths owing to hemorrhage, pulmonary failure, low cardiac output, and sudden death with or without myocardial necrosis or documented arrhythmias. Early prosthetic valve–associated complications are unusual.[192] Potential complications related to valve insertion include hemorrhagic disruption and dissection of the atrioventricular groove, perforation or entrapment of the left circumflex coronary artery by a suture, and pseudoaneurysm or rupture of the left ventricular free wall.

Improvement in late outcome has derived predominantly from earlier referral of patients for valve replacement, decreased intraoperative myocardial damage, and improved surgical technique and cardiac valve prostheses. Following valve replacement with currently used devices, the probability of 5-year survival is about 80% and of 10-year survival about 70%, dependent on overall functional state, preoperative LVF, left ventricular and left atrial size, and extent and severity of CAD. Preservation of the subvalvular apparatus has also been an important advance in mitral valve replacement.[193]

Valve-related complications

Prosthetic valve–associated pathology becomes an important consideration beyond the early postoperative period. In the few randomized studies of mechanical prosthetic and bioprosthetic valves, approximately 60% or more patients had an important device-related complication within 10 years postoperatively.[194,195] Valve-related complications frequently necessitate reoperation, now accounting for approximately 15% of all valve procedures,

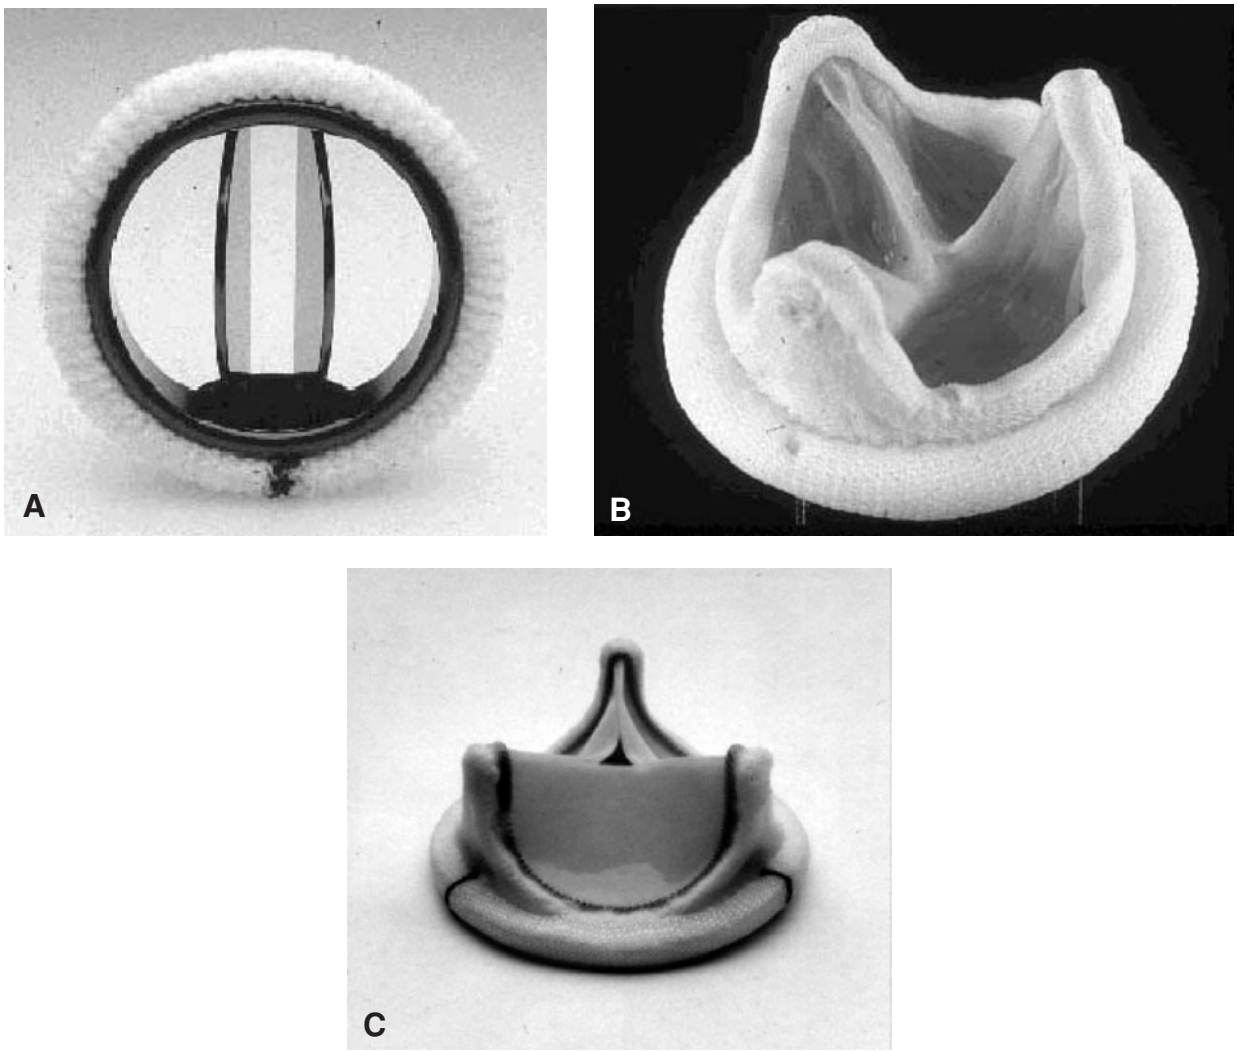

Figure 5-23. Photographs of the widely used generic types of valve substitutes. (A) Bileaflet tilting disk mechanical heart valve (St. Jude Medical, St. Jude Medical Inc., St. Paul, MN). (B) Porcine aortic valve bioprosthesis (Hancock, Medtronic Heart Valves, Santa Ana, CA). (C) Bovine pericardial bioprosthesis (Carpentier-Edwards, Edwards Life Sciences, Santa Ana, CA). (*A and B: Reproduced with permission from Schoen FJ: Approach to the analysis of cardiac valve prostheses as surgical pathology or autopsy specimens. Cardiovasc Pathol 1995; 4:241, and Schoen.*[188])

and they may cause death. Late death following valve replacement results predominantly from either cardiovascular pathology not related to the substitute valve or prosthesis-associated complications. In studies with prior generation valves late death was caused by a device-related complication in 25 to 61% of patients.[196] Autopsy studies generally reveal a higher rate of valve-related pathology than clinical investigations. One-fifth or more of valve recipients will ultimately die suddenly; in one autopsy study, 40% of valve recipients who died suddenly had a valve-related cause.[197]

Four categories of valve-related complications are most important: thromboembolism and related problems, infection, structural dysfunction (i.e., failure or degeneration of the biomaterials comprising a prosthesis), and nonstructural dysfunction (i.e., miscellaneous complications and modes of failure not encompassed by the other groups) (see Table 5-3).[198,199] The clinico-morphologic features of these problems have been widely described in the literature. The relative performance and risk of complications of various types of widely used substitute heart valve types are summarized in Table 5-3. The risk of some valve-related complications (particularly thromboembolism) is potentiated by preoperative or postoperative functional impairment.

THROMBOSIS AND THROMBOEMBOLISM: *Thromboembolic complications* are the major cause of mortality and morbidity after cardiac valve replacement with mechanical valves, and patients with them require chronic therapeutic anticoagulation with warfarin derivatives.[200] Thrombotic deposits can

immobilize the occluder or shed emboli (Fig. 5-25). Tissue valves are less thrombogenic than mechanical valves, with most patients not requiring long-term anticoagulation unless they have atrial fibrillation or another specific indication. Nevertheless, the rate of thromboembolism in patients with mechanical valves on anticoagulants is not widely different from that in patients with bioprosthetic valves without anticoagulation (2 to 4% per year). The thrombotic and thromboembolic problems that frequently complicate mechanical valves tend to occur earlier than the structural failures that complicate tissue valve prostheses.[201] Chronic oral anticoagulation also induces a risk of hemorrhage.

"Virchow's triad" of factors promoting thrombosis (surface thrombogenicity, hypercoagulability, and locally static blood flow) largely predicts the relative propensity toward and locations of thrombotic deposits. For example, with caged-ball prostheses, thrombi formed distal to the poppet at the cage apex. Tilting disk prostheses are particularly susceptible to total thrombotic occlusion or emboli from small thrombi, both generally initiated in a flow stagnation zone in the minor orifice of the outflow region of the prosthesis; bileaflet tilting disk valves are most vulnerable near the hinges where the leaflets insert into the housing. In contrast, late thrombosis of a bioprosthetic valve is marked by large thrombotic deposits in one or more of the prosthetic sinuses of Valsalva. Usually, no causal underlying cuspal pathology can be demonstrated by routine microscopic studies. Some valve thromboemboli, especially early postoperatively with any valve type, are initiated at the valve sewing cuff before it is incorporated by pannus, thus providing the rationale for early antithrombotic therapy regardless of the type of replacement valve. Noninvasive visualization of prosthetic valve thrombi is aided by transesophageal endocardiography.[202]

As with other devices in which nonphysiologic artificial surfaces are exposed to blood at high fluid shear stresses, platelet deposition dominates initial blood-surface interaction and prosthetic valve thromboembolism correlates strongly with altered platelet function. Nevertheless, although platelet-suppressive drugs largely normalize indices of platelet formation and partially reduce the frequency of thromboembolic complications in patients with mechanical prosthetic valves, antiplatelet therapy alone is generally considered insufficient to adequately prevent thromboembolism. The friability and susceptibility to embolization of thrombi that form on bioprosthetic or mechanical valves are prolonged because lack of adjacent

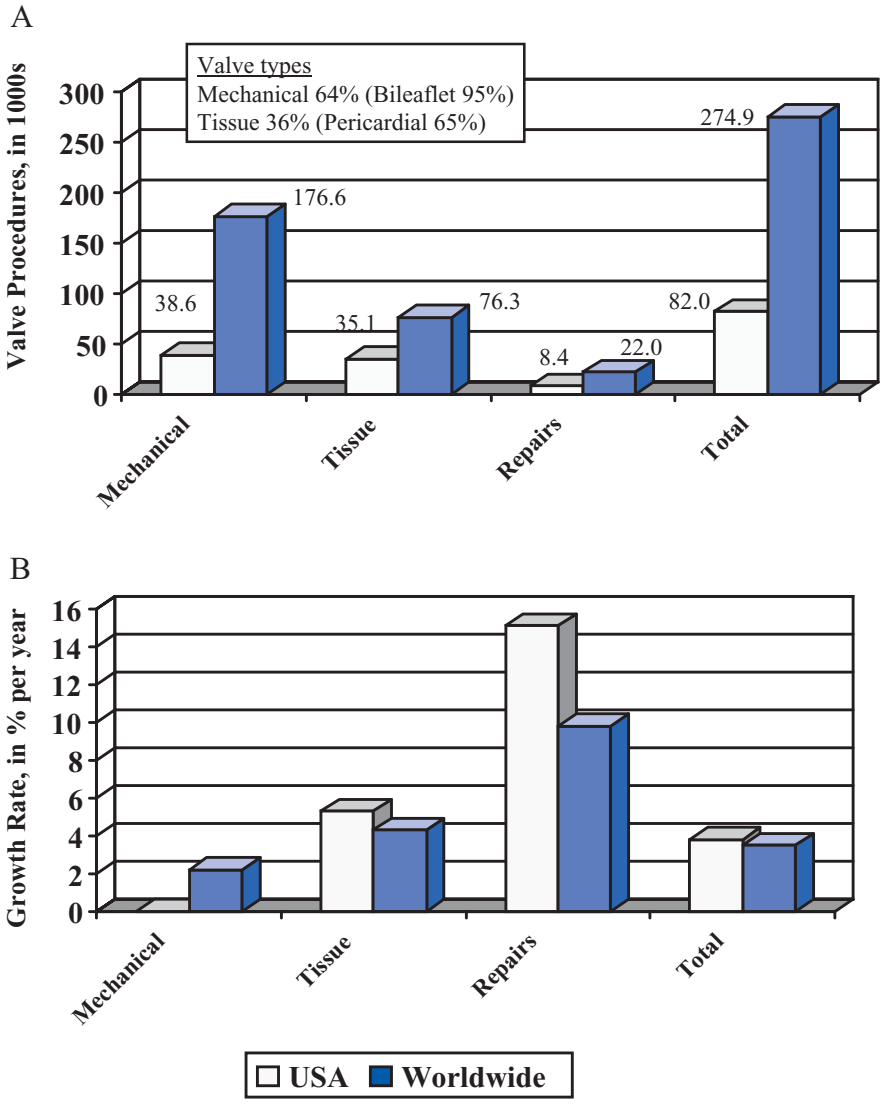

Figure 5-24. U.S. and worldwide use of substitute heart valves and heart valve repairs, estimated for the year 2000. (A) Usage. (B) Growth rate. While mechanical valves are implanted more frequently than tissue valves, the growth rate of tissue valves is approximately 4%, much more than that of mechanical valves. Ninety-five percent of mechanical valves are bilateral tilting disk valves; 65% of tissue valves are pericardial bioprostheses. The overall growth rate of repair operations is more than 10%. Approximately 7000 cryopreserved valves are implanted in the United States with a growth rate of approximately 5% per year (worldwide data not available). (*Data courtesy of St. Jude Medical, Inc., St. Paul, MN.*)

vascular tissue retards their histologic organization. Thus, in selected circumstances, thrombolytic therapy may be a practical nonsurgical option.[203,204] For similar reasons, the age of such thrombi is difficult to determine microscopically.

PROSTHETIC VALVE ENDOCARDITIS: *Prosthetic valve infective endocarditis* (Fig. 5-26) occurs in 3 to 6% of recipients of substitute valves.[205] Infection is generally categorized into early (usually less than 60 days postoperative) and late. The microbial etiology of early prosthetic valve endocarditis is dominated by the staphylococcal species *S. epidermidis* and *S. aureus,* even though prophylactic regimens used today are targeted against these microorganisms. The clinical course of early prosthetic valve endocarditis tends to be fulminant, with rapid deterioration of hemodynamic status due to valvular or annular destruction or persistent bacteremia. In late endocarditis, a probable source of infection can often be found, and the most frequent initiators are dental procedures, urologic infections and interventions, and indwelling catheters. The most common organisms in these late infections are *S. epidermidis, S. aureus,* viridans streptococci, and enterococci. Surgical reintervention usually is indicated for large highly mobile vegetations or cerebral thromboembolic episodes. Transesophageal echocardiography also enhances diagnosis of prosthetic valve endocarditis and its intracardiac complications.[206] Rates of infection of bioprostheses and mechanical valves are similar, and previous endocarditis on a natural or substitute valve markedly increases the risk.

Infections associated with mechanical prosthetic valves and some with bioprosthetic valves are localized to the prosthesis–tissue junction at the sewing ring, and accompanied by tissue destruction around the prosthesis (see Fig. 5-26A). This comprises a ring abscess, with potential paraprosthetic leak, dehiscence, fistula formation, or heart block caused by conduction system damage. Bioprosthetic valve infections may involve, and are occasionally

Table 5–3.

Complications of Substitute Heart Valves

Generic	Specific

limited to, the cuspal tissue, sometimes causing secondary cuspal tearing or perforation with valve incompetence or obstruction (see Fig. 5-26B). Cases without annular involvement have a better prognosis than those associated with an infected annulus. Embolization of vegetations and CHF secondary to obstruction or regurgitation may also occur.

STRUCTURAL VALVE DYSFUNCTION: *Prosthetic valve dysfunction* owing to materials degradation can necessitate reoperation or cause prosthesis-associated death (Fig. 5-27). Durability considerations vary widely for mechanical valves and bioprostheses, for specific types of each, for different models of a particular prosthesis (utilizing different materials or having different design features), and even for the same model prosthesis placed in the aortic rather than the mitral site. Mechanical valve structural failure is often catastrophic and may be life-threatening; in contrast bioprosthetic valve failure generally causes slowly progressive symptomatic deterioration.

Fractures of metallic or carbon valve components occur rarely. Of approximately 86,000 Bjork-Shiley 60- and 70-degree Convexo-Concave heart valves implanted, a cluster of over 500 cases have been reported in which the welded outlet strut fractured because of metal fatigue, leading to disk escape (see Fig. 5-27A).[207] Complete strut fracture is usually fatal. A cineangiographic imaging technique

may facilitate detection of single leg strut fractures at a presymptomatic stage in some patients.[208] Fractures of carbon components (disks or housing) are unusual in most single leaflet or bileaflet tilting disk valves. However, a group of 37 fractures of an estimated 20,000 Edwards-Duramedics bileaflet tilting valves has occurred, possibly a combined result of carbon coating defects and cavitation bubbles impacting on the carbon surfaces during function.[209,210] Fracture of the St. Jude bileaflet tilting disk valve has been rare.[211]

In contrast, structural dysfunction of tissue valves is the major cause of failure of the most widely used bioprostheses (flexible-stent-mounted, glutaraldehyde-preserved porcine aortic valves, and bovine pericardial valves) (see Fig. 5-27B, C and D).[212] Within 15 years following implantation, 30 to 50% of porcine aortic valves implanted as either mitral or aortic valve replacements require replacement because of structural dysfunction manifested as primary tissue failure.[213] Cuspal mineralization is the major responsible pathologic process, with regurgitation through secondary tears the most frequent failure mode, particularly in porcine aortic bioprosthetic valves. Nevertheless, there is increasing recognition that noncalcific structural damage owing to collagen fiber disruption contributes to bioprosthetic heart valve failure.[214] Pure stenosis owing to calcific cuspal stiffening and noncalcific cuspal tears or perforations (reflecting direct mechanical destruction of collagen) occurs less frequently. Calcific deposits are usually localized to cuspal tissue (intrinsic calcification), but calcific deposits extrinsic to the cusps may occur in thrombi or endocarditic vegetations. Calcification is markedly accelerated in younger patients, with children and adolescents having an especially accelerated course. Bovine pericardial valves can also suffer tearing and calcification.[215,216] Abrasion of the pericardial tissue has been an important contributing factor.[217]

The morphology and determinants of calcification of bioprosthetic valve tissue have been widely studied in experimental models. The process is initiated primarily within residual membranes and organelles of the nonviable connective tissue cells that have been devitalized by glutaraldehyde pretreatment procedures. This dystrophic calcification mechanism involves reaction of calcium-containing extracellular fluid with membrane-associated phosphorus, causing calcification of the devitalized cells. Collagen calcification may occur later. The pathologic changes in bioprosthetic valves that occur following implantation are to a large extent rationalized on the basis of changes induced by the preservation and manufacture of a bioprosthesis, including: (1) denudation of endothelial cells, (2) loss of viability of the interstitial cells; and (3) locking of the cuspal microstructure in a static geometry.

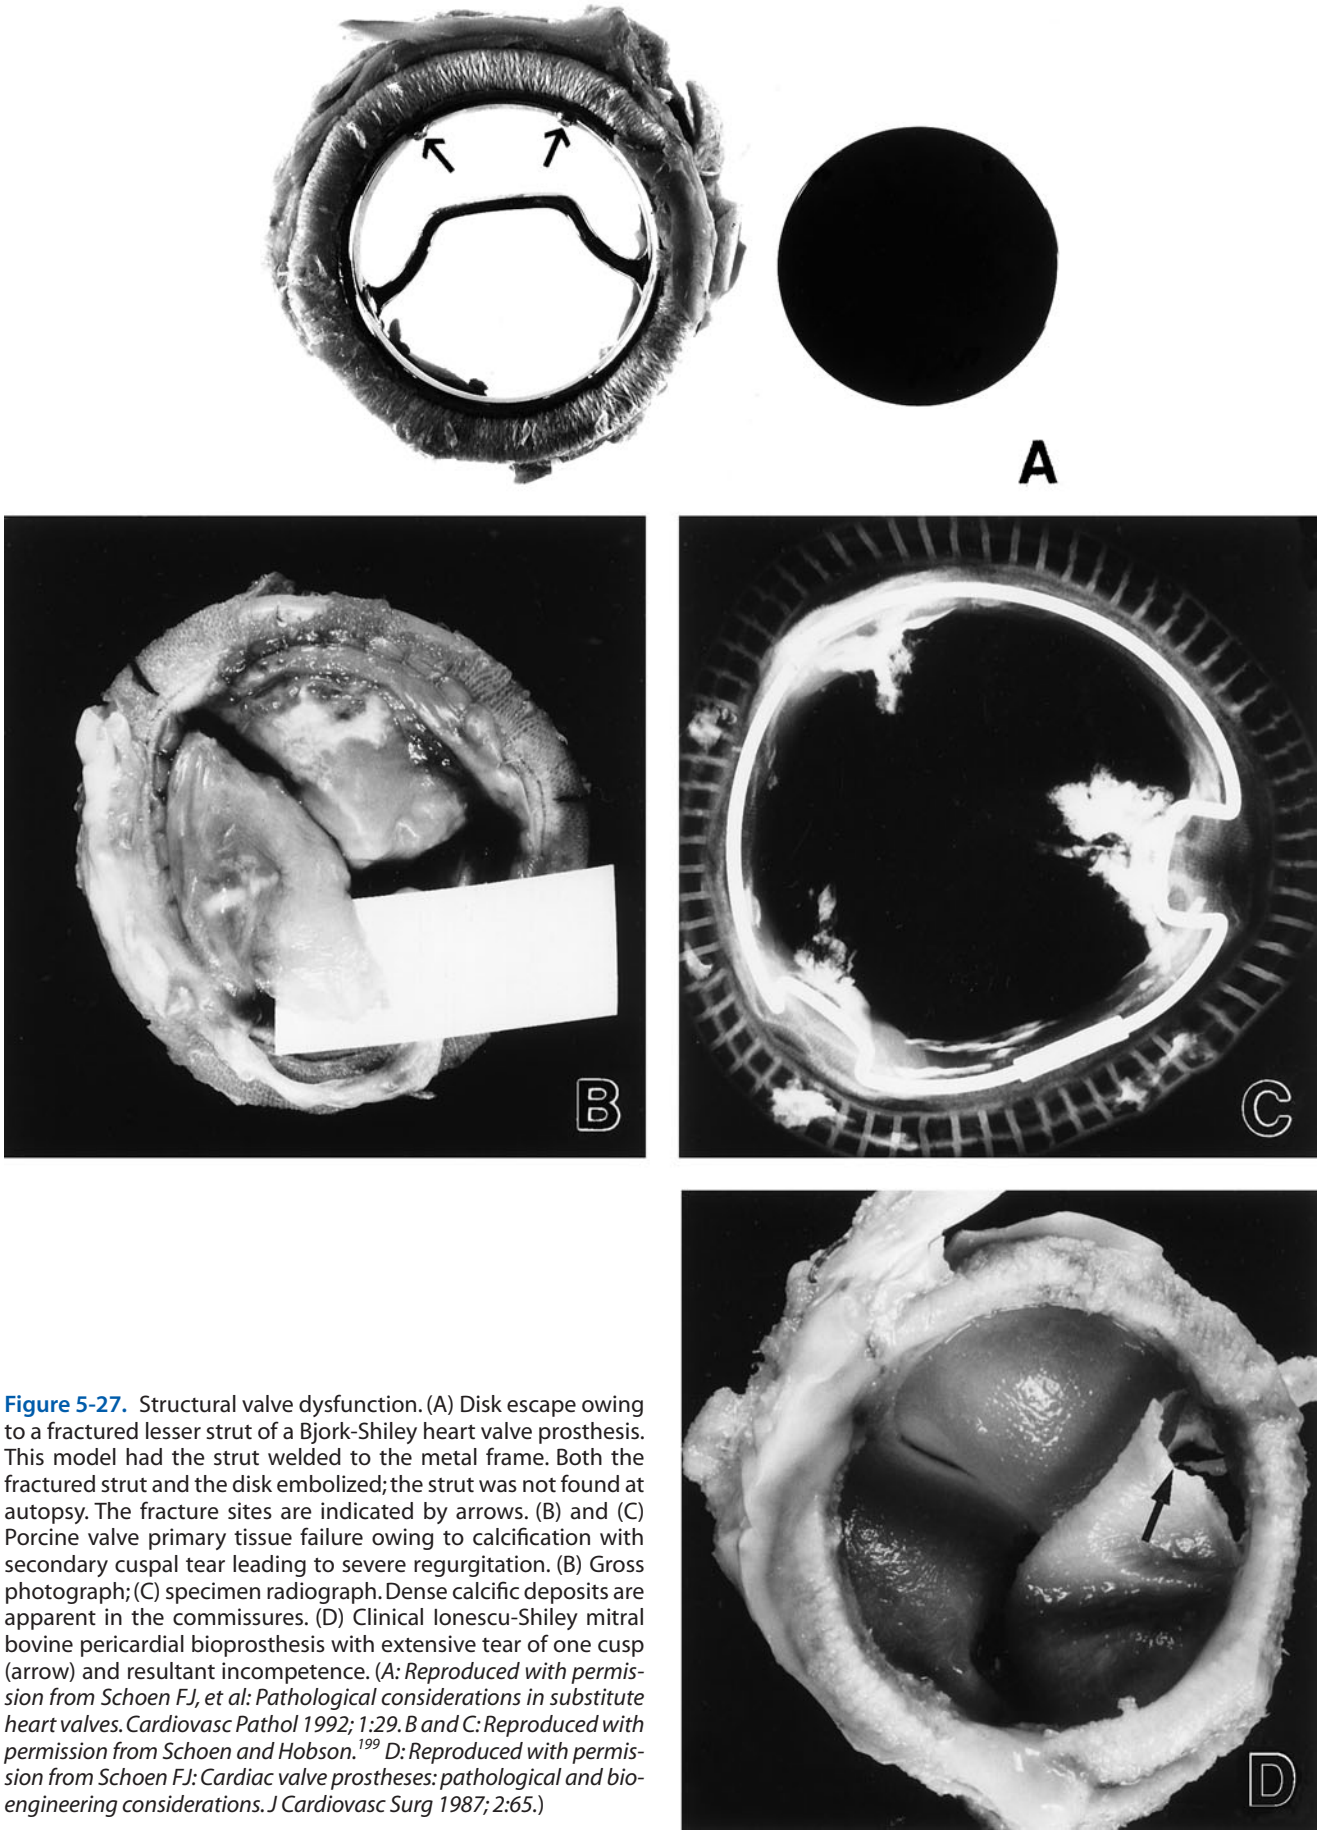

Figure 5-27. Structural valve dysfunction. (A) Disk escape owing to a fractured lesser strut of a Bjork-Shiley heart valve prosthesis. This model had the strut welded to the metal frame. Both the fractured strut and the disk embolized; the strut was not found at autopsy. The fracture sites are indicated by arrows. J Cardiovasc Surg 1987; 2:65.*)

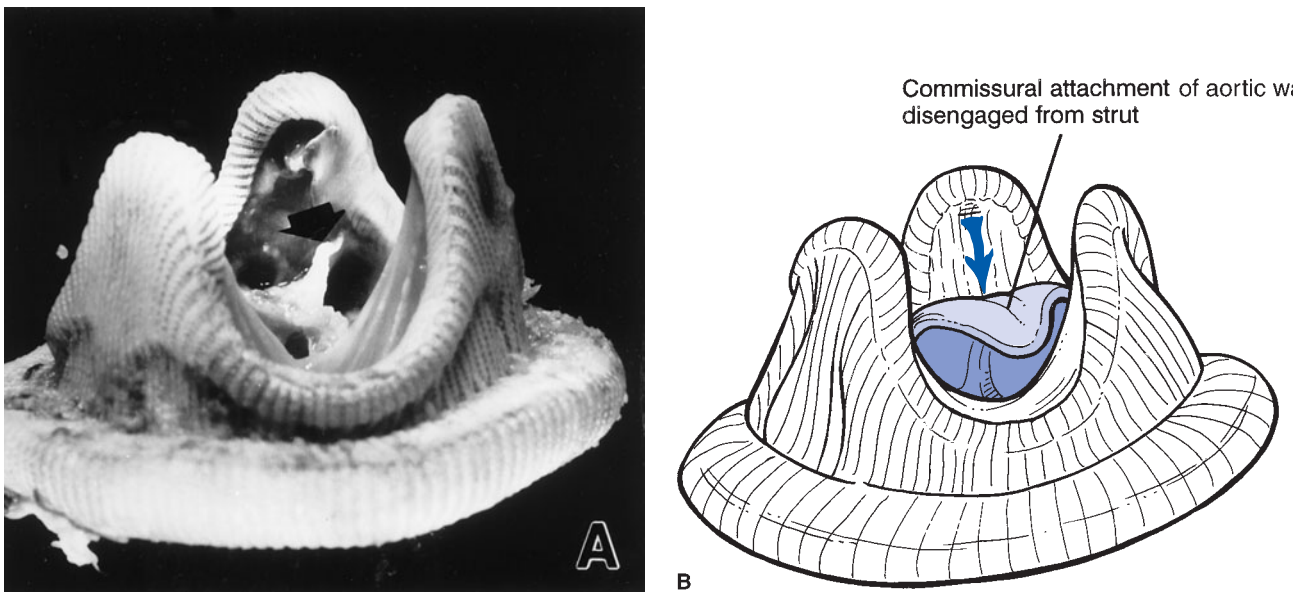

Figure 5-28. Dehiscence of commissural region of Hancock Standard porcine bioprosthetic valve. (A) Gross photograph. (B) Schematic diagram (arrow denotes loss of attachment of commissural support). Removed for regurgitation, this valve had prolapse of one cusp, minimal calcification, and no cuspal tears.

Commissural region dehiscence of the aortic wall tissue from the inside of porcine bioprosthetic valve stents causing insufficiency has also been described in several valve models (Fig. 5-28).

NONSTRUCTURAL DYSFUNCTION: *Extrinsic (nonstructural) complications* of substitute heart valves are illustrated in Fig. 5-29. The most common, paravalvular defects, may be clinically inconsequential or may aggravate hemolysis or cause heart failure through regurgitation. Early paravalvular leaks may be related to suture knot failure, inadequate suture placement, or separation of sutures from a pathologic annulus in endocarditis with ring abscess, myxomatous valvular degeneration, or calcified valvular annulus as in calcific aortic stenosis or mitral annular calcification. Late small paravalvular leaks usually are caused by anomalous tissue retraction from the sewing ring between sutures during healing. They tend to be small and difficult to locate by surgical or pathologic examination (see Fig. 5-29A).

The St. Jude Medical bileaflet tilting disk valve with a silver coating (Silzone) was introduced to prevent bacterial colonization of the valves and consequent prosthetic valve endocarditis. This valve has a conventional polyethylene terephthalate polyester sewing ring coated with metallic silver by an ion beam vapor deposition process. Some studies have suggested that this modification yields a higher-than-expected rate of paravalvular leak and thromboembolism,[218–220] hypothesized to be a result of inhibition of normal fibroblast response and incorporation of the fabric of the sewing cuff into host tissues in some patients.

Hemolysis owing to turbulent flow and blood–material surface interactions has resulted in renal tubular hemosiderosis or cholelithiasis in many patients with earlier model heart valve prostheses. Severe hemolytic anemia is unusual with properly functioning contemporary valves; paravalvular leaks or dysfunction owing to materials degeneration may induce hemolysis.

Extrinsic factors can mediate late prosthetic valve stenosis or regurgitation, including a large mitral annular calcific nodule, septal hypertrophy, exuberant overgrowth of fibrous tissue (see Fig. 5-29B), interference by retained valve remnants (such as a retained posterior mitral leaflet or components of the submitral apparatus; see Fig. 5-29C), or unraveled, long, or looped sutures or knots (see Fig. 5-29D, E, and F). With bioprosthetic valves, cuspal motion can be restricted by sutures looped around stents, and suture ends cut too long may erode into or perforate a bioprosthetic valve cusp.

Valvular allografts/homografts

Aortic or pulmonary valves (with or without associated vascular conduits) transplanted from one individual to another have exceptionally good hemodynamic profiles, a low incidence of thromboembolic complications without chronic anticoagulation, and a low reinfection rate following valve replacement for endocarditis.[221,222] Early valvular allografts sterilized and/or preserved with chemicals (using propiolactone or ethylene oxide) or irradiation suffered a high rate of leaflet fibrosis, calcification, and rupture, resulting in failure rates of nearly 50% at 10 to 12 years and 50 to 90% at 15 to 20 years.[223] Subsequent

technical developments have led to cryopreserved allografts, in which freezing is performed with protection from crystallization by dimethylsulfoxide; storage until valve use is done at –196°C in liquid nitrogen. Contemporary allograft valves are free from degeneration and have durability equal to or better than those of conventional porcine bioprosthetic valves (approximately 50 to 90% valve survival at 10 to 15 years, compared with 40 to 60% for bioprostheses).

We studied 33 explanted left- and right-sided cryopreserved human allograft heart valves/conduits in place several hours to 9 years in children and adults.[224] Cryopreserved human allograft heart valves/conduits implanted more than 1 day had progressively severe loss of normal structural demarcations. Long-term explants were generally devoid of both surface endothelium and deep connective tissue cells, and had hyalinized collagen, laminated elastin, and minimal inflammatory cellularity (Fig. 5-30). Our studies and most others have demonstrated that the function of cryopreserved allograft heart valves/conduits is primarily related to the largely preserved collagen network, rather than cellular viability.

Pulmonary valvular autografts

Often called the Ross operation in recognition of its originator (Sir Donald Ross), pulmonary autograft replacement of the aortic valve is technically difficult but yields excellent hemodynamic performance, avoids anticoagulation, and carries a low risk of thromboembolism.[225,226]

We studied the structural features, cell viability, and ECM remodeling of pulmonary autograft valves in place for 15 days to 6 years.[227] Throughout the postoperative period pulmonary autograft cusps showed (1) near-normal trilaminar structure, (2) near-normal collagen architecture, (3) viable endothelium and interstitial cells, (4) usual outflow surface corrugations, (5) sparse inflammatory cells, and (6) absence of calcification and thrombus. Most valves also had an irregular layer of intimal thickening (up to 1 mm), particularly on the ventricular aspect, and they maintained remarkably preserved semilunar valve morphology, cell viability, and collagen microstructure up to 6 years. The arterial walls showed considerable transmural damage (probably perioperative ischemic injury caused by disruption of the vasa vasorum) with scarring and loss of medial smooth muscle cells and elastin. The early necrosis and healing with probable resultant loss of strength and elasticity of the aortic wall may potentiate late dilation.

Stentless porcine aortic valve bioprostheses

Nonstented (stentless) porcine aortic valve bioprostheses comprise glutaraldehyde-pretreated pig aortic root and valve cusps that have no supporting stent.[228] Three such models approved by the FDA are the St. Jude Medical Toronto SPV (St. Jude Medical Inc., St. Paul, MN), Medtronic Freestyle (Medtronic Heart Valves, Santa Ana, CA) and

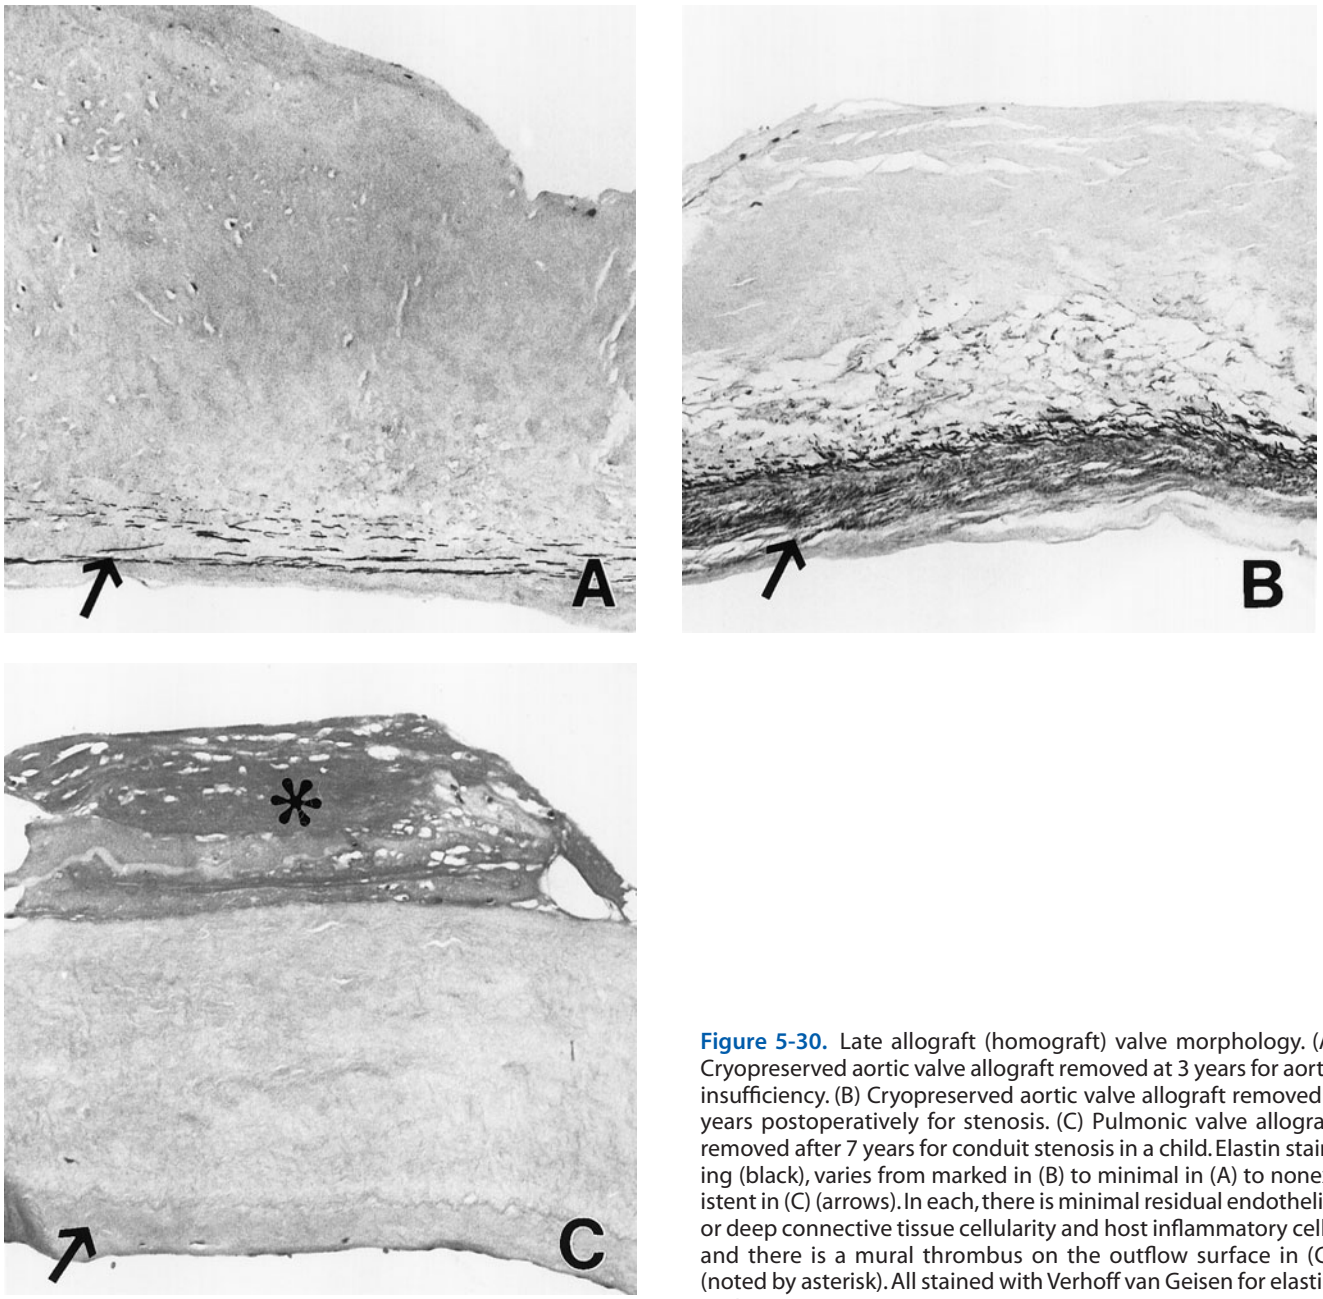

Figure 5-30. Late allograft (homograft) valve morphology. (A) Cryopreserved aortic valve allograft removed at 3 years for aortic insufficiency. (B) Cryopreserved aortic valve allograft removed 5 years postoperatively for stenosis. (C) Pulmonic valve allograft removed after 7 years for conduit stenosis in a child. Elastin staining (black), varies from marked in (B) to minimal in (A) to nonexistent in (C) (arrows). In each, there is minimal residual endothelial or deep connective tissue cellularity and host inflammatory cells, and there is a mural thrombus on the outflow surface in (C); (noted by asterisk). All stained with Verhoff van Geisen for elastin, each 100x.

the Edwards Prima stentless porcine bioprostheses (Fig. 5-31).[229,230] They differ slightly in overall configuration (particularly the amount of aortic wall included), details of glutaraldehyde pretreatment conditions, and overall fabrication, and whether anticalcification technology is used (the Freestyle valve is treated with 2-amino-oleic acid). The principal advantage of a stentless porcine aortic valve is that it generally allows for the implantation of a larger bioprosthesis (than a stented valve) in any given aortic root, which may enhance hemodynamics and thereby regression of hypertrophy and patient survival.[231–233] However, at least one study that compared stented (bovine pericardial) valves implanted in the supra-annular position and stentless valves implanted in the subcoronary position found no difference in hemodynamic function or clinical events between the two groups.[234]

The available evidence suggests that the durability of stentless bioprostheses is comparable to that of contemporary stented bioprostheses; however, similarly to the results for stented bioprostheses, younger recipients have a higher vulnerability to structural valve deterioration. The potential and observed complications with nonstented bioprostheses are comparable to those of stented valves. However, nonstented porcine aortic valves have greater portions of aortic wall

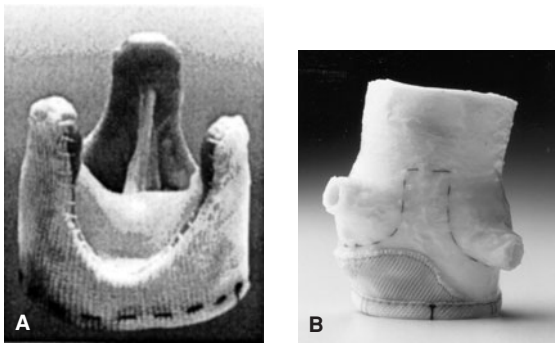

Figure 5-31. Stentless porcine bioprosthetic heart valves. (A) Toronto SPV. (B) Edwards Prima.

exposed to blood than in currently used stented valves, and calcification of the aortic wall and inflammation at the junction of aortic wall with the recipient's tissue may develop, owing to the large area of this interface and may potentially be deleterious. Calcification of the wall portion of a stentless valve could stiffen the root, altering hemodynamic efficiency; may cause nodular calcific obstruction or wall rupture; or provide a nidus for emboli. Pathologic analyses of nonstented valves shows pannus and tissue degeneration, manifest as tears and cuspal calcification, but not substantial aortic wall calcification.[235,236]

Percutaneous valve replacement

New catheter techniques for inserting foldable prosthetic valves within stenotic aortic and pulmonary valves, and for emulating surgical repair of regurgitant mitral valves, are in various stages of preclinical development and clinical testing.[237–239] Percutaneous implantation of a heart valve that can be mounted on an expandable stent, delivered percutaneously through standard catheter-based techniques, and implanted within a diseased valve annulus has been demonstrated to be feasible. Percutaneous valve replacement is most likely to be used in patients with severe aortic stenosis deemed otherwise inoperable, and in congenital heart disease, in which percutaneous pulmonary valve replacement may find a distinct niche to obviate the morbidity of reoperation to replace malfunctioning pulmonary conduits.

Percutaneous valve replacement uses (1) an outer stent-like structure, which (2) contains leaflets; these two components together constitute a functioning valvular prosthesis. Representative designs under development are illustrated in Fig. 5-32. The stent holds open a valve annulus or segment of a prosthetic conduit and resists the tendency of a vessel, valve annulus, and diseased native leaflets to recoil following balloon dilation, supports the valve leaflets, and provides the means for seating the prosthesis in the annulus or vessel. In patients with repaired congenital heart disease, complications of a right ventricle-to-pulmonary artery conduit are frequent, and the opportunity for palliation to delay or prevent surgery is attractive in many cases. For aortic valve disease, the excellent clinical success with surgical AVR restricts the use of balloon valvuloplasty/percutaneous valve replacement to nonsurgical candidates, or as a bridge to valve replacement in patients in whom surgery needs to be delayed.

Several valve designs for endovascular implantation are under development and testing. Valve assemblies composed of either a shape-memory nitinol alloy stent (which is self-expandable) housing a valve constructed of porcine pericardial leaflets, a platinum-iridium alloy stent with a bovine jugular vein valve, and a stainless steel cage (which is balloon-expandable) with equine pericardial leaflets have had the most extensive clinical application, comprising more than 100 patients.[240,241] This early clinical experience demonstrates the feasibility of percutaneous valve replacement in both aortic and pulmonary locations, and the potential and challenges of transcatheter valve replacement. Given the overall clinical success of this approach to date, as well as the morbidity associated with reoperative surgery in repaired congenital heart disease, percutaneous pulmonary valve replacement is the most likely of all the catheter-based valve technologies to achieve near-term broad clinical application.

Key challenges are associated with the use of stent-mounted prosthetic valves. Valved stents are significantly larger than most existing percutaneous cardiac catheters and devices, and presently are on the order of 22 to 24F. In the aortic position, there is the potential to impede coronary flow, or interfere with anterior mitral leaflet mobility, the conduction system, or the diseased native leaflets. Stent architecture may also preclude future catheter access to the coronaries for possible interventions. Secure seating within the aortic annulus or a pulmonary conduit and long-term durability of both the stent and the valve tissue are also major considerations.

MYOCARDIAL DISEASE

A new classification for the cardiomyopathies[242] updates the 1995 World Health Organization/International Society and Federation of Cardiology schema.[243] The proposed system distinguishes broadly between "primary cardiomyopathies" (solely or predominantly confined to heart muscle) and "secondary cardiomyopathies" (myocardial involvement as part of generalized systemic or multisystem disorders). Primary cardiomyopathies are subdivided into genetic, mixed, and acquired categories, underscoring the role of recently elucidated molecular and genetic factors that may lead to cardiomyopathy (Fig. 5-33).[244] Genetic causes of primary cardiomyopathy include hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, left ventricular noncompaction, and the ion channel disorders (e.g., long QT syndrome and Brugada syndrome). The mixed category of primary cardiomyopathies represents diseases that are often acquired, but also have important genetic contributions, and include both dilated and restrictive patterns. Acquired causes of primary cardiomyopathy include

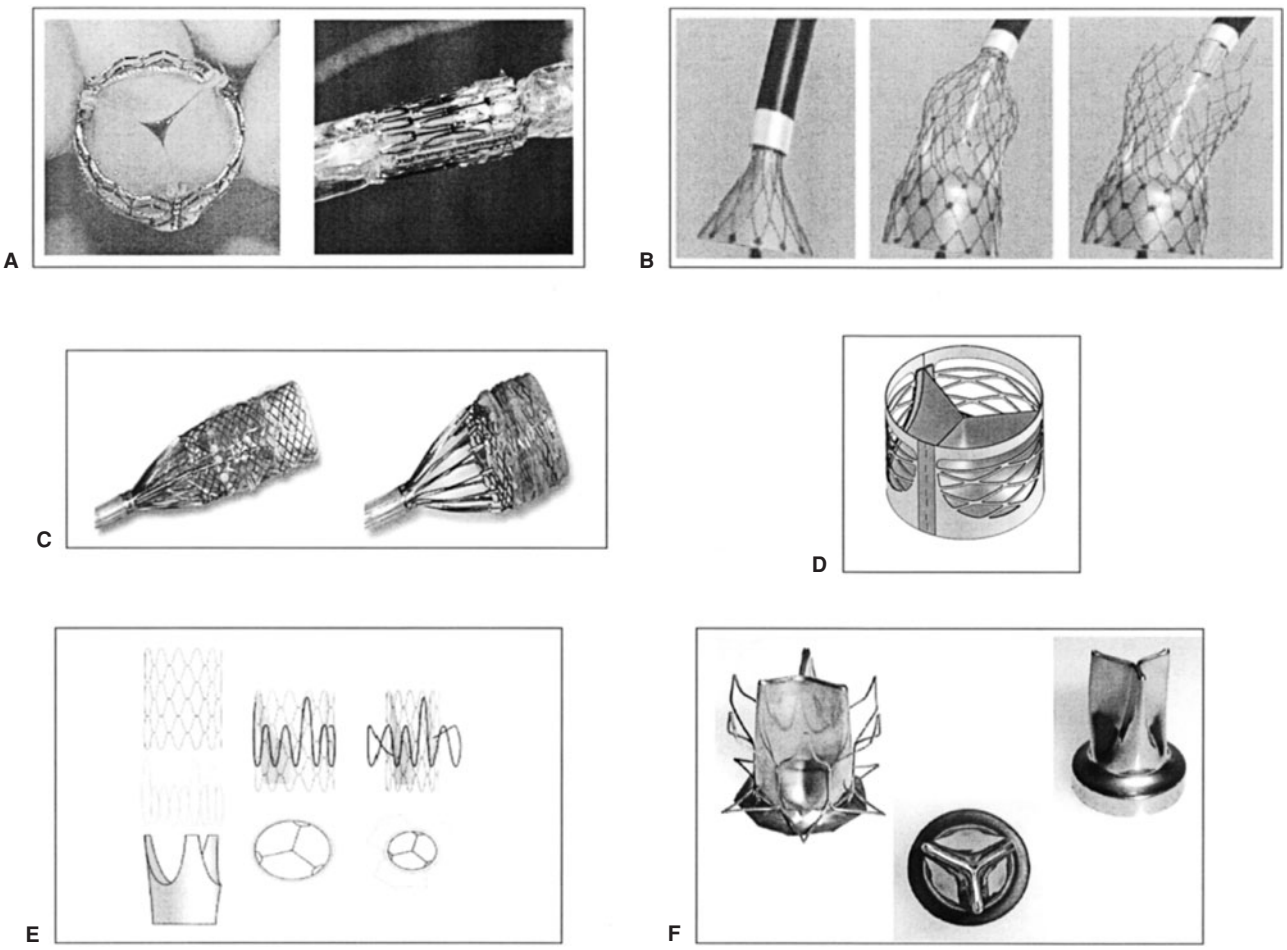

Figure 5-32. Percutaneous valve devices and concepts. (A) The Cribier-Edwards valve consists of three equine pericardial leaflets fixed to a balloon-expandable steel stent. It is hand-crimped over a delivery balloon prior to deployment. (B) The Corevalve system is a self-expanding nitinol cage housing three porcine pericardial leaflets. Devices in preclinical development include (C) the Sadra self-expanding Lotus valve (D), the Aortx valve (E), the Bonhoeffer valve (F), and the eNitinol thin membrane PercValve. (*Reproduced with permission from Davidson et al.*[180])

myocarditis ("inflammatory cardiomyopathy"), stress-provoked ("tako-tsubo"), and tachycardia-induced and peripartum cardiomyopathy. The secondary cardiomyopathies consist of systemic diseases that may have myocardial involvement leading to dysfunction, such as amyloidosis and other infiltrative diseases, hemochromatosis and other storage diseases, drug and other toxic reactions, sarcoidosis, autoimmune/collagen vascular diseases, and neuromuscular/neurologic diseases (e.g., Duchenne-Becker muscular dystrophy). The terms "ischemic cardiomyopathy," "valvular cardiomyopathy," and "hypertensive cardiomyopathy" have been eliminated from the classification. The heart disease seen in these conditions more likely reflects compensatory and remodeling changes, rather then a cardiomyopathy as currently defined, so the terms "ischemic heart disease," "valvular heart disease," and "hypertensive heart disease" are preferred.

The cause of a cardiomyopathy is often revealed by light and/or electron microscopic examination. Myocarditis, sarcoidosis, amyloidosis, hemochromatosis, and many other diseases may be apparent on evaluation of endomyocardial biopsy, and other conditions such as arrhythmogenic right ventricular cardiomyopathy and hypertrophic cardiomyopathy have characteristic gross and microscopic morphologies upon evaluation of the heart at the time of transplantation or autopsy. However, microscopic features are generally nonspecifically abnormal in dilated cardiomyopathy, and the severity of the morphologic changes does not necessarily correlate with the severity of dysfunction or the patient's prognosis. The understanding and potential treatment of myocardial disease have advanced substantially over the last decade as a result of genetic studies and their correlations with clinical features.[245–248]

Endomyocardial biopsy is used in the diagnosis and management of patients with myocardial disease and in the ongoing surveillance of cardiac transplant recipients.[249] The bioptome, inserted into the right internal jugular or

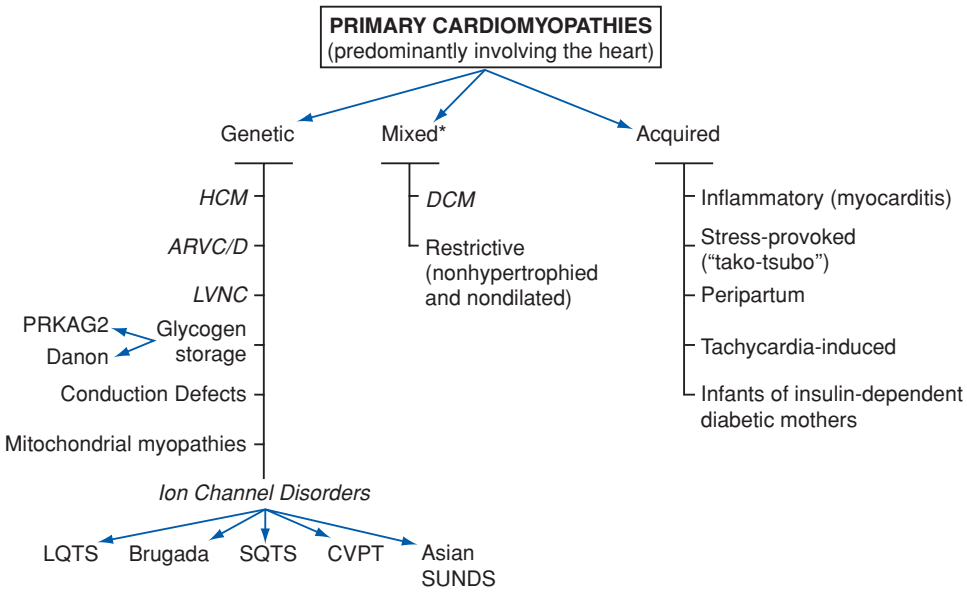

Figure 5-33. Primary cardiomyopathies in which the clinically relevant disease processes solely or predominantly involve the myocardium. The conditions have been segregated according to their genetic or nongenetic etiologies. * = predominantly nongenetic; familial disease with a genetic origin has been reported in a minority of cases; ARVC/D = arrhythmogenic right ventricular cardiomyopathy/dysplasia; CVPT = catecholaminergic polymorphic ventricular tachycardia; DCM = dilated cardiomyopathy; HCM = hypertrophic cardiomyopathy; LQTS = long-QT syndrome; LVNC = left ventricular nonconpaction; SQTS = short-QT syndrome; SUNDS = sudden unexplained nocturnal death syndrome. (*Reproduced with permission from Marron et al.*[242])

femoral vein and advanced under fluoroscopic or echocardiographic guidance through the tricuspid valve, obtains 1- to 3-mm fragments of endomyocardium, most frequently from the apical half of the right side of the ventricular septum. Since most myocardial diseases affect both ventricles, correlation between right- and left-sided findings generally is good.

Cardiomyopathies

The most common variants of primary cardiomyopathy are the dilated and hypertrophic types. Both are illustrated in Fig. 5-34, as is right ventricular cardiomyopathy.

Dilated cardiomyopathy

Dilated cardiomyopathy is characterized by hypertrophy, dilation, and systolic ventricular dysfunction. Dilated cardiomyopathy has a familial basis in approximately 30 to 50% of cases, with autosomal dominant (most common), autosomal recessive, X-linked, and mitochondrial inheritance all described. Mutations in several different genes can cause autosomal dominant dilated cardiomyopathy, including the cytoskeletal protein-encoding genes δ-sarcoglycan, desmin, and lamin A/C, as well as the sarcomeric protein-encoding genes actin, β-myosin heavy chain, cardiac troponin T, and α-tropomyosin. X-linked disease is most often the result of mutations in dystrophin, and mutations in cardiac troponin I have shown autosomal recessive inheritance patterns. Secondary cardiomyopathies such as alcoholic cardiomyopathy and myocarditis manifest as cardiac dilation. Pregnancy-associated nutritional deficiency or immunologic reaction is another possible contributory factor.

The primary functional abnormality in dilated cardiomyopathy is impairment of left ventricular systolic function, as measured by the ejection fraction (<25% in end-stage and normal in approximately 50 to 65%). Pathologic findings include cardiomegaly with heart weight two to three times normal and four-chamber dilation (see Fig. 5-34A). Cardiac mural thrombi, a potential source of thromboemboli, are sometimes present and predominate in the left ventricle, but may occur in any chamber. The histologic changes include myocyte hypertrophy and interstitial and endocardial fibrosis of variable degrees; the myocardial histology in dilated cardiomyopathy is indistinguishable from that in myocardial failure secondary to ischemic or valvular heart disease (see Fig. 5-34B).

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy is characterized by massive myocardial hypertrophy without dilation (see Fig. 5-34C).[250] The classic pattern has disproportionate thickening of the ventricular septum relative to the free wall of the left ventricle (ratio >1.5), termed asymmetric septal hypertrophy, and is usually localized to the subaortic region. When the basal septum is markedly thickened at the level of the mitral valve, the outflow of the left ventricle may be narrowed during systole. Endocardial thickening in the left ventricular outflow tract and thickening of the anterior mitral leaflet result from

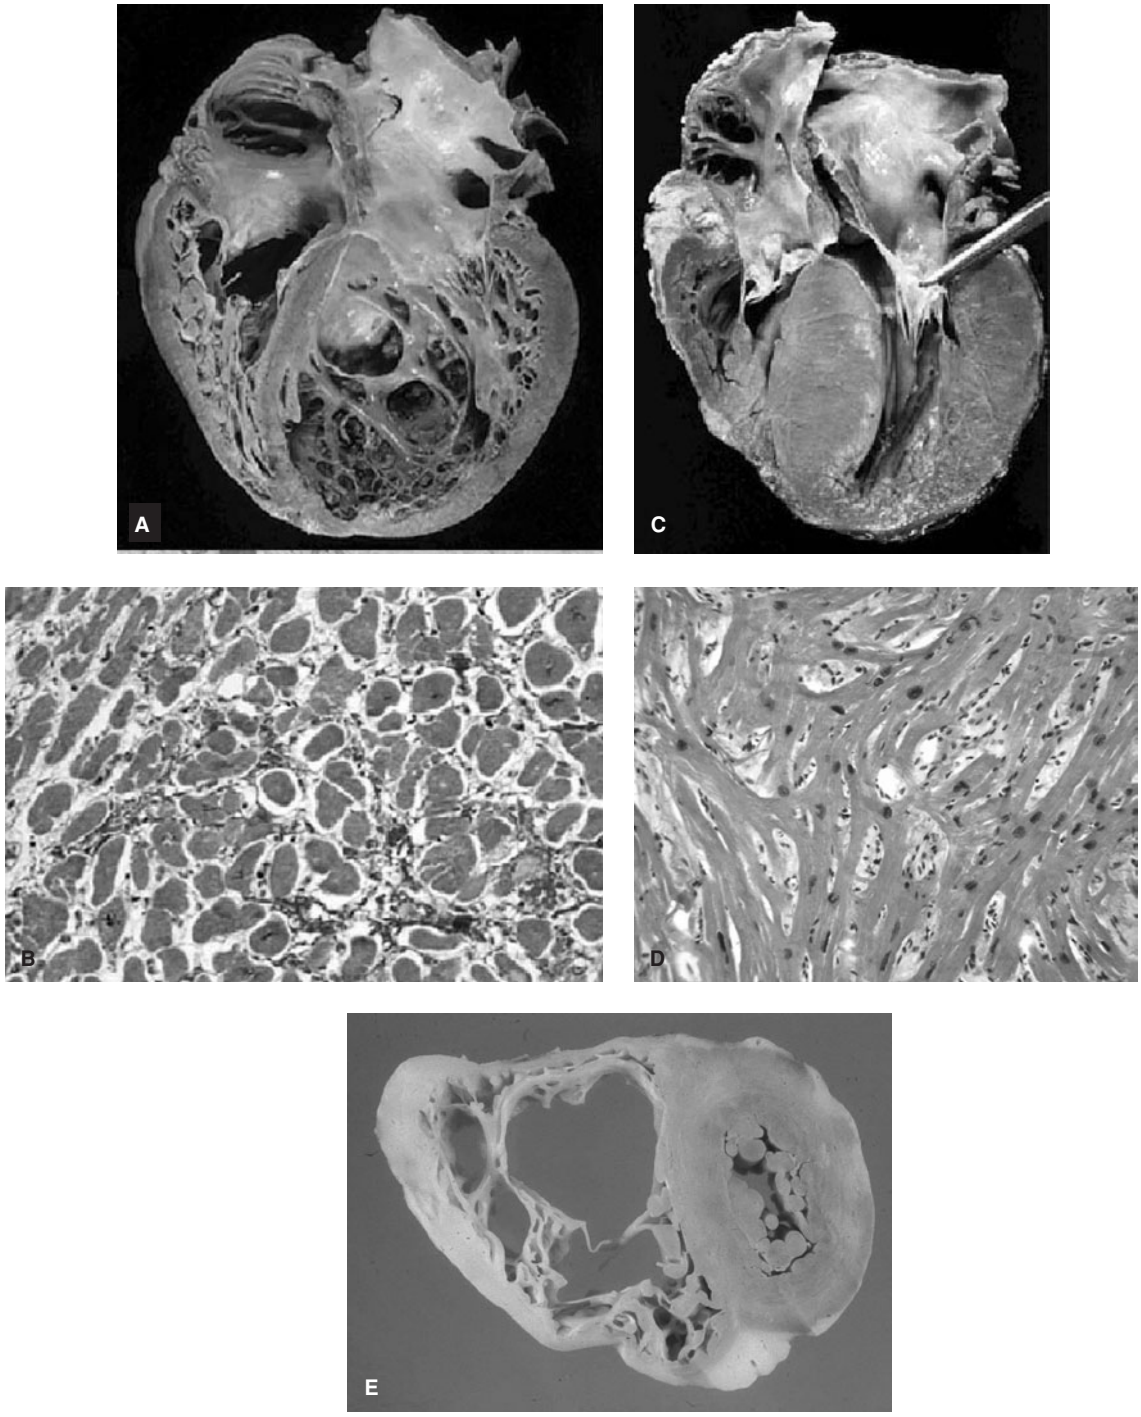

Figure 5-34. Cardiomyopathy. (A) and (B) Dilated cardiomyopathy. (A) Gross photo showing four-chamber dilation and hypertrophy. There is granular mural thrombus at the apex of the left ventricle (on the right in this apical four-chamber view). The coronary arteries were unobstructed. (B) Histology demonstrating irregular hypertrophy and interstitial fibrosis. (C and D) Hypertrophic cardiomyopathy with asymmetric septal hypertrophy. (C) Gross photo. The septal muscle bulges into the left ventricular outflow tract, and the left atrium is enlarged. The anterior mitral leaflet has been moved away from the septum to reveal a fibrous endocardial plaque (see text). (D) Histologic appearance demonstrating disarray, extreme hypertrophy, peculiar branching of myocytes, and interstitial fibrosis characteristic of hypertrophic cardiomyopathy. (E) Right ventricular cardiomyopathy, gross photograph, showing right ventricular dilation and wall thinning, with replacement of the right ventricular wall by fibrosis and fat. (*Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989, and Schoen FJ: The heart, in Kumar V, Fausto N, Abbas A [eds]: Robbins & Cotran Pathologic Basis of Disease, 7th ed. Philadelphia, WB Saunders, 2004; p 555.*)

contact between the two during ventricular systole (observed by echocardiography as systolic anterior motion of the mitral valve), correlating with systolic left ventricular outflow tract obstruction. In about 10% of cases, LVH is symmetric, and in other cases disproportionate hypertrophy involves the mid-ventricular or apical septum, extends onto the left ventricular free wall anteriorly or inferiorly, or causes right ventricular outflow tract obstruction.

The most important microscopic features in hypertrophic cardiomyopathy include: (1) disarray of myocytes and contractile elements within cells (myofiber disarray) typically involving 10 to 50% of the septum; (2) extreme myocyte hypertrophy, with transverse myocyte diameters frequently more than 40 μm (normal approximately 15 to 20 μm); and (3) interstitial and replacement fibrosis (see Fig. 5-34D).

Hypertrophic cardiomyopathy has an extremely variable course, with potential complications including atrial fibrillation with mural thrombus formation and embolization, infective endocarditis of the mitral valve, intractable cardiac failure, and sudden death. Sudden death occurs in approximately 2 to 3% of adults and 4 to 6% of children per year, is the most common cause of death from hypertrophic cardiomyopathy, and is particularly common in young males with familial hypertrophic cardiomyopathy or a family history of sudden death. The risk is related to the degree of hypertrophy.[251,252] Cardiac failure from hypertrophic cardiomyopathy results from reduced stroke volume due to decreased diastolic filling of the massively hypertrophied left ventricle. Although symptoms are not solely a result of ventricular septal thickening, some patients benefit from thinning of the septum by surgical myotomy/myectomy.[253,254] More recently, the technique of chemical septal ablation appears to be a safe and effective procedure, with hemodynamic and functional improvement.[255–257] End-stage heart failure can be accompanied by dilation, for which cardiac transplantation may be recommended.

Hypertrophic cardiomyopathy has a genetic basis in almost all cases. In approximately one-half or more of patients the disease is familial, and the pattern of transmission is autosomal dominant with variable expression; remaining cases appear to be sporadic. Hundreds of mutations have been identified in 11 genes in patients with hypertrophic cardiomyopathy; all are genes for sarcomeric proteins including β-myosin heavy chain, troponin T and I, α-tropomyosin, and titin. Different responsible gene mutations carry vastly differing prognoses, and certain genetic defects indicate a relatively high likelihood of sudden death.

The mechanism by which defective sarcomeric proteins produce the phenotype of hypertrophic cardiomyopathy is incompletely defined.

Restrictive cardiomyopathy

Restrictive cardiomyopathy is characterized by impeded diastolic relaxation and left ventricular filling, with systolic function often unaffected (*diastolic dysfunction*). Any disorder that interferes with ventricular filling can cause restrictive cardiomyopathy (including eosinophilic endomyocardial disease, amyloidosis, hemochromatosis, or postirradiation fibrosis) or mimic it (constrictive pericarditis or hypertrophic cardiomyopathy). The ventricles are of approximately normal size or slightly enlarged, but the cavities are not dilated and the myocardium is firm. Biatrial dilation is commonly observed. Distinct morphologic patterns indicative of specific heart muscle disease may be revealed by light or electron microscopy of endomyocardial biopsy specimens, including deposition of amyloid or of products of an inborn error of metabolism such as trihexosylceramide in Fabry disease.[258]

Arrhythmogenic right ventricular cardiomyopathy

A recently described variant of dilated cardiomyopathy is arrhythmogenic right ventricular cardiomyopathy, characterized by a dilated right ventricular chamber and severely thinned right ventricular wall, with extensive fatty infiltration, loss of myocytes with compensatory myocyte hypertrophy, and interstitial fibrosis (see Fig. 5-34E).[259,260] Clinical features of right ventricular cardiomyopathy include right-sided heart failure and arrhythmias. The arrhythmias are often brought on by exertion, explaining the association of this condition with sudden death in athletes.[261,262] Mutational analysis of patients with right ventricular cardiomyopathy has identified several genes involved in desmosomal cell adhesion, including plakoglobin, desmoplakin, plakophilin-2, and desmoglein-2. Recent studies have shown the high prevalence of plakophilin-2 mutations in this condition (particularly in the familial form of the disease), and the earlier onset of symptoms and arrhythmias when mutations in this gene are present.[263,264]

CARDIAC ASSIST AND REPLACEMENT

Cardiac Transplantation

Cardiac transplantation provides long-term survival and rehabilitation for many individuals with end-stage cardiac failure.[265] Overall predicted 1-year survival is presently approximately 86% and 5-year survival is about 70%.[266] The most common indications for cardiac transplantation, accounting for 90% of the patients, are idiopathic cardiomyopathy and end-stage ischemic heart disease; other recipients have congenital, other myocardial, or valvular heart disease.[267]

Hearts explanted at the time of transplantation typically have the expected pathologic features of the underlying diseases. However, previously undiagnosed conditions and unexpected findings may be encountered. Most frequent is eosinophilic or hypersensitivity myocarditis, seen in from 7 to 20% of explants and characterized by a focal or diffuse mixed inflammatory infiltrate, rich in eosinophils, and generally associated with minimal associated myocyte necrosis.[268,269] In virtually all cases, the myocarditis represents hypersensitivity to one or more of the many drugs taken by

transplant candidates, including dobutamine, and is unrelated to but superimposed on the original disease necessitating transplantation. Several diseases responsible for the original cardiac failure can recur in and cause dysfunction of the allograft, including amyloidosis, sarcoidosis, giant-cell myocarditis, acute rheumatic carditis, and Chagas disease.

Recipients of heart transplants undergo surveillance endomyocardial biopsies on an institution-specific schedule, which typically evolves from weekly during the early postoperative period, to twice weekly until 3 to 6 months, and then approximately one to four times annually, or at any time when there is a change in clinical state. Histologic findings of rejection frequently precede clinical signs and symptoms of acute rejection. Optimal biopsy interpretation requires four or more pieces of myocardial tissue; descriptions of technical details and potential tissue artifacts are available.[270]

The major sources of mortality and morbidity following cardiac transplantation are perioperative ischemic injury, infection, allograft rejection, lymphoproliferative disease, and obstructive graft vasculopathy.

Early ischemic injury

Ischemic injury can originate in the ischemia that accompanies procurement and implantation of the donor heart. Several time intervals are potentially important: (1) the donor interval between brain death and heart removal, perhaps partially related to terminal administration of pressor agents or the release of norepinephrine and cytokines associated with brain death; (2) the interval from warm ischemia between donor cardiectomy to cold storage; (3) the interval during cold transport; and (4) the interval during warming, trimming, and reimplantation. Hypertrophy and coronary obstructions tend to enhance injury, whereas decreased tissue temperature and cardioplegic arrest slow chemical reactions and thereby protect myocytes from progressive ischemic damage. As in other situations of transient myocardial ischemia, frank necrosis or prolonged ischemic dysfunction of viable myocardium or both may be present. Myocardial injury can cause low cardiac output in the perioperative period.

Perioperative myocardial ischemic injury may be detectable in endomyocardial biopsies early after heart transplantation.[271] Because of the anti-inflammatory effects of immunosuppressive therapy, the histologic progression of healing of myocardial necrosis in transplanted hearts may be delayed (Fig. 5-35). Therefore, the repair phase of perioperative myocardial necrosis frequently confounds the diagnosis of rejection in the first postoperative month, and in some cases for as long as 6 weeks. In contrast, ischemic necrosis noted after 3 to 6 months postoperatively is usually secondary to occlusive graft vasculopathy. There is evidence that early ischemic injury may accelerate the progression of graft vasculopathy.[272]

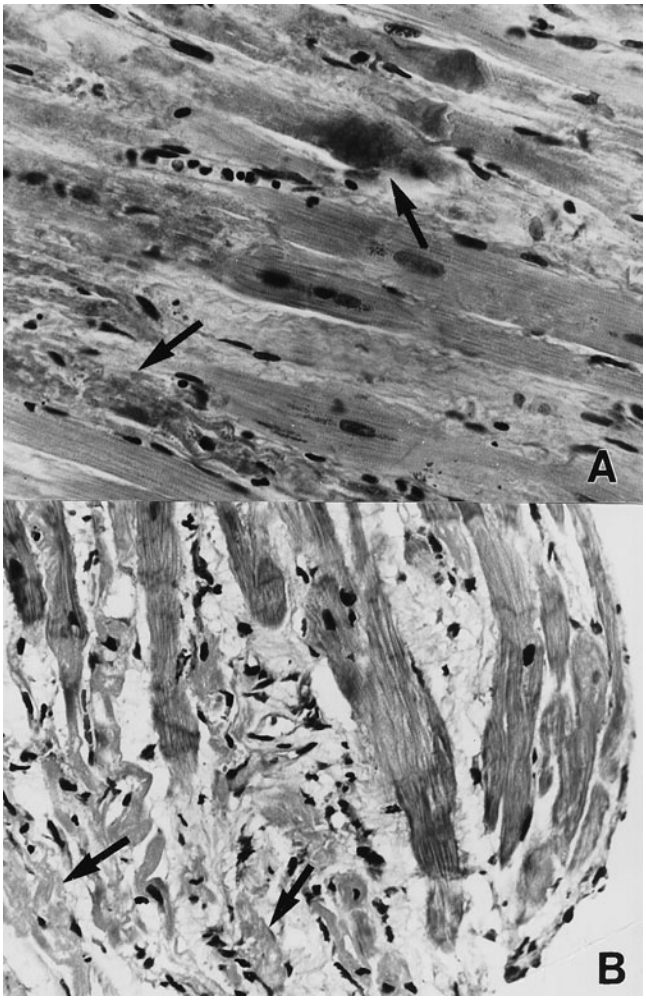

Figure 5-35. Perioperative ischemic myocardial injury demonstrated on endomyocardial biopsy. (A) Coagulative myocyte necrosis (arrows). (B) Healing perioperative ischemic injury with predominantly interstitial inflammatory response (arrows), not encroaching on and clearly separated from adjacent viable myocytes. The infiltrate consists of a mixture of polymorphonuclear leukocytes, macrophages, lymphocytes, and plasma cells. Hematoxylin and eosin 200x. (*Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

Rejection

Improved immunosuppressive regimens in heart transplant patients have substantially decreased the incidence of serious rejection episodes. Nonetheless, rejection phenomena still cause cardiac failure or serious arrhythmias in some patients. Hyperacute rejection occurs rarely, most often when a major blood group incompatibility exists between donor and recipient, and acute rejection is unusual earlier than 2 to 4 weeks postoperatively. Acute rejection episodes occur largely but not exclusively in the first several months after transplantation; rejection can occur years postoperatively, validating the practice of many transplant centers to continue late surveillance biopsies at widely spaced intervals.[273]

Acute cellular rejection is characterized histologically by an inflammatory cell infiltrate, with or without damage to cardiac myocytes; in late stages, vascular injury may become prominent (Fig. 5-36). Until recently, the International Society for Heart and Lung Transplantation (ISHLT) working

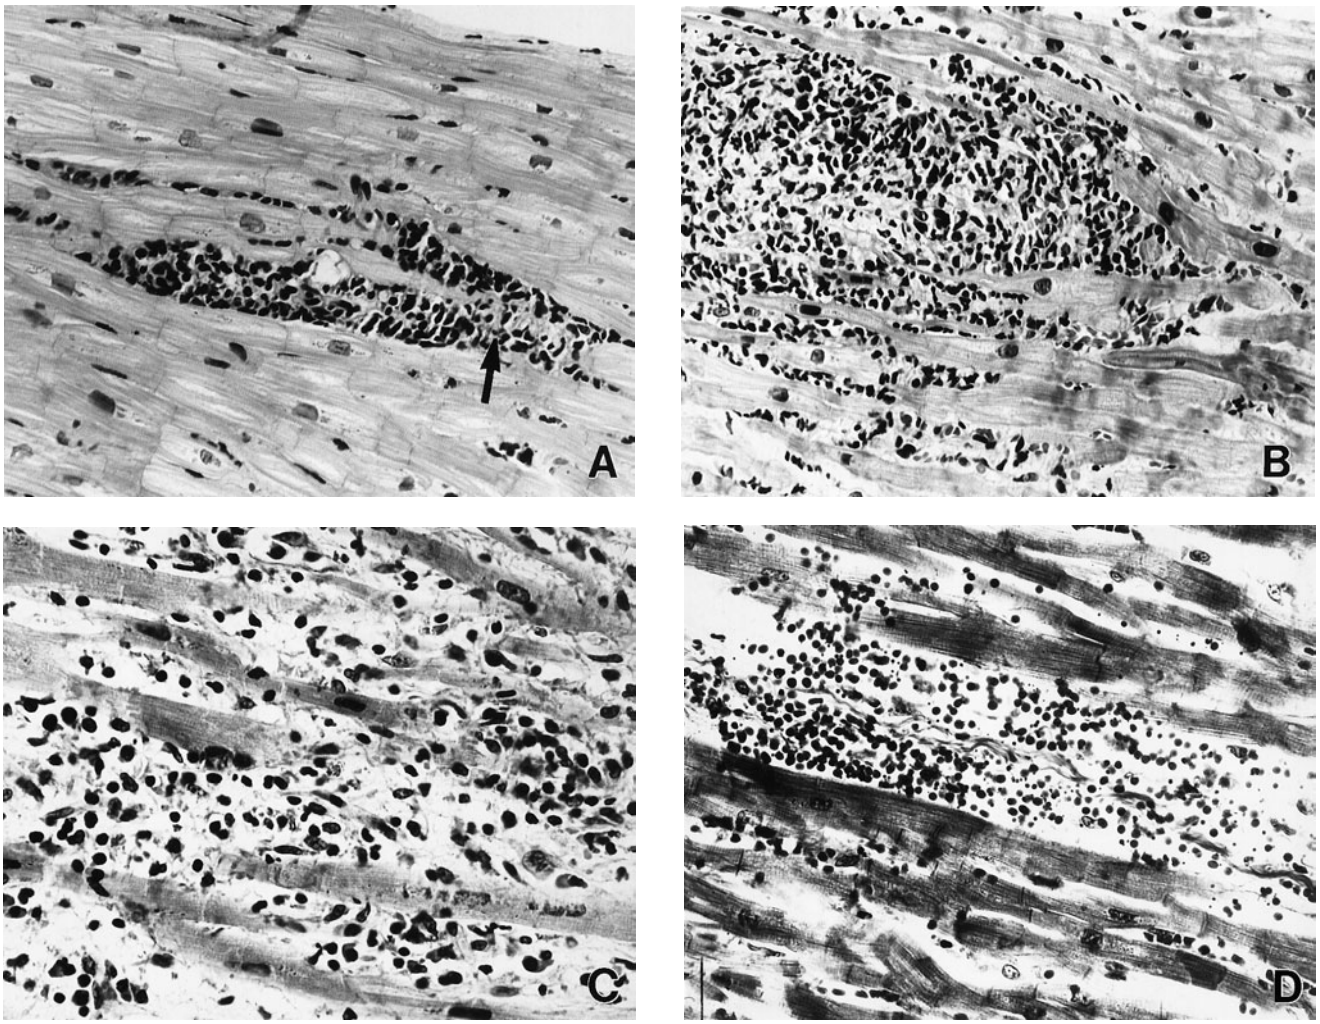

Figure 5-36. Histologic features of rejection. (A) Focal moderate rejection with necrosis. The area of myocyte necrosis is indicated by an arrow. (B) More intense focus of inflammatory infiltrate, with large focus of myocyte necrosis. (C) Fatal rejection with extensive infiltrate and myocyte necrosis. (D) Fatal rejection with widespread myocardial hemorrhage, and necrosis edema. Hematoxylin and eosin 375x. (*Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

formulation from 1990 was the most widely accepted and was used to guide immunosuppressive therapy in heart transplant recipients.[274,275] In this grading system, grade 0 represents no evidence of acute cellular rejection. Mild acute cellular rejection (grades 1A and 1B) is characterized by a focal or diffuse, respectively, mild perivascular or interstitial lymphocytic infiltrate without myocyte damage. Lymphocytic inflammatory infiltrates with associated myocyte encroachment or damage, generally called moderate rejection, can be limited to a single focus (grade 2), present in a multifocal pattern (grade 3A), or be distributed diffusely (grade 3B). In severe rejection (grade 4), myocyte necrosis is more evident, there is often patchy interstitial hemorrhage due to vascular damage, and vasculitis (usually arteriolitis) may be prominent. The increased inflammatory infiltrate often also includes neutrophils or eosinophils, presumably in response to myocyte necrosis or vascular damage. In 2004, the grading system was revised as follows (with the "R" reflecting the revised system): grade 0R—no rejection (no change from 1990); grade 1R—mild rejection (1990 grades 1A, 1B, and 2); grade 2R—moderate rejection (1990 grade 3A); and grade 3R—severe rejection (1990 grades 3B and 4). The 1990 and 2004 formulations are compared in Table 5-4.

Acute antibody-mediated rejection, also called humoral rejection, is recognized as a clinical entity in the transplanted heart, but remains problematic, as no clear consensus has been reached on its recognition or diagnosis either histopathologically or immunologically. If there is suspicion of antibody-mediated rejection, either clinically or by proposed histologic criteria, biopsies may be analyzed by immunofluorescence or immunohistochemistry for (1) immunoglobulin (IgG, IgM, and/or IgA) plus complement deposition (C3d, C4d, and/or C1q) in capillaries, (2) CD68 staining of macrophages within capillaries, and/or (3) C4d staining of capillaries. Treatment of

Table 5–4.

ISHLT Standardized Cardiac Biopsy Grading of Acute Cellular Rejection: Clinicopathologic Comparison of 1990 and 2004 Formulations

Rejection level	Histologic findings	Rejection grade 1990	Rejection grade 2004	Clinical response
None	Normal	0	0	No change
Mild	Lymphocytic inflammation ± one focus of myocyte damage	1A, 1B, 2	1R	No/minimal change to chronic immunosuppressive regimen
Moderate	Lymphocytic inflammation + multiple foci of myocyte damage	3A	2R	Steroid bolus ± change in chronic immunosuppressive regimen
Severe	Lymphocytic inflammation + diffuse myocyte damage ± vascular injury	3B, 4	3R	Aggressive therapy (e.g., steroids ± monoclonal antibodies [OKT3])

ISHLT = International Society for Heart and Lung Transplantation.

patients with antibody-mediated rejection typically requires the presence of hemodynamic compromise and the presence of circulating human leukocyte antigen antibodies in addition to positive biopsy findings.

Immunosuppressive protocols and the threshold for treatment of histologic rejection vary greatly among heart transplant centers; in particular, the clinical significance of mild to moderate rejection is controversial.[276,277] ISHLT grades 1A, 1B, and 2 (from the 1990 system) have been shown to resolve without specific change in management in over 80% of cases, and therefore these levels of rejection remain untreated in many (but not all) heart transplant centers (and they were merged into a single category in the 2004 grading system). Progression of lower rejection grades to advanced rejection on subsequent biopsies becomes less likely with increasing postoperative interval, and is especially unusual beyond 2 years.

Other important findings in surveillance endomyocardial biopsies that must be distinguished from rejection include lymphoid infiltrates, either confined to the endocardium or extending into the underlying myocardium and often accompanied by myocyte damage (so-called Quilty lesions, which have no known clinical significance), old biopsy sites, and healing ischemic injury either in the perioperative period or resulting from the development of graft vasculopathy. Lymphoproliferative disorders and infections may also be seen in biopsies. Apoptosis of myocytes occurs during rejection, with its prevalence paralleling the severity of rejection.[278]

Infection

The immunosuppressive therapy required in all heart transplant recipients confers an increased risk of infection with bacterial, fungal, protozoan, and viral pathogens, with cytomegalovirus and *Toxoplasma gondii* remaining the most common opportunistic infections. Prophylaxis in the form of oral ganciclovir is typically given to patients at high risk of primary cytomegalovirus infection (donor seropositive, recipient seronegative). Viral and parasitic infections can present a challenge in endomyocardial biopsies, as the multifocal lymphocytic infiltrates with occasional necrosis seen with these infections can mimic rejection.

Graft vasculopathy (graft coronary arteriosclerosis)

Graft vasculopathy is the major limitation to long-term graft and recipient survival following heart transplantation.[279] Up to 50% of recipients have angiographically evident disease 5 years after transplantation, while intravascular ultrasound identifies graft vasculopathy in 75% of patients at 3 years posttransplant.[280,281] However, graft vasculopathy may become significant at any time and can progress at variable rates. We have encountered numerous instances of graft coronary disease within 6 to 12 months postoperatively at the Brigham and Women's Hospital.

Graft vasculopathy (Fig. 5-37) occurs diffusely within small distal vessels and ultimately involves both intramyocardial and epicardial allograft vessels, potentially leading to MI, arrhythmias, CHF, or sudden death.[282] Although this process has been called accelerated atherosclerosis, the morphology of the obstructive lesion of graft vasculopathy is distinctive in comparison to typical atherosclerosis (Table 5-5).

The vessels involved have concentric occlusions characterized by marked intimal proliferation of myofibroblasts and smooth muscle cells with deposition of collagen, ground substance, and lipid. Lymphocytic infiltration varies from almost none to quite prominent, with the lymphocytes often noted in a subendothelial location. The internal elastic lamina often is almost completely intact, with only focal fragmentation. The resulting myocardial pathology includes subendocardial myocyte vacuolization (indicative of sublethal

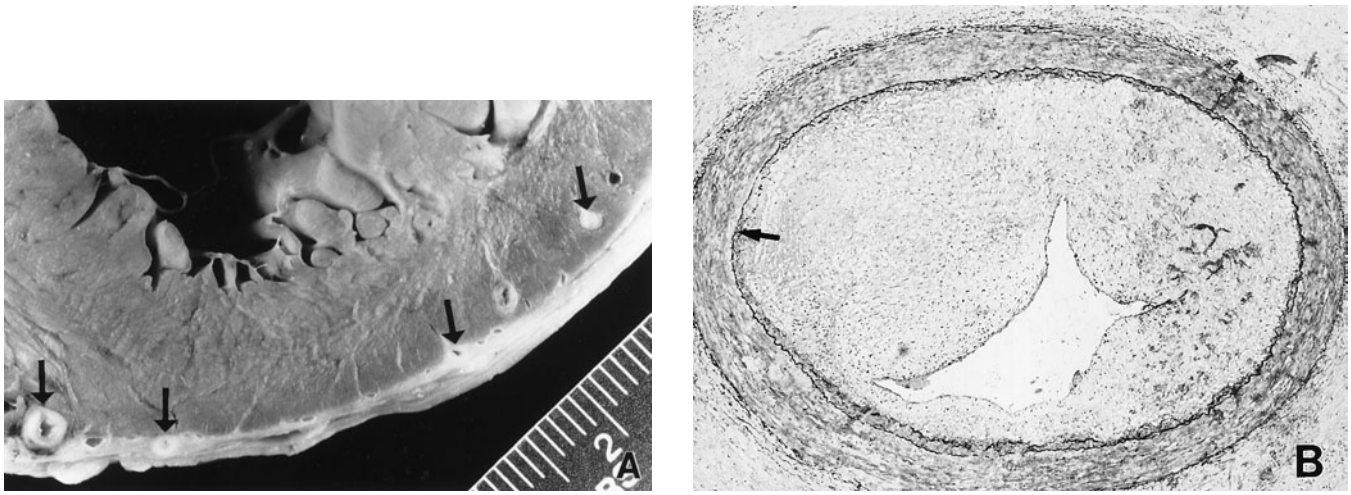

Figure 5-37. Gross and microscopic features of graft coronary disease. (A) Gross photograph of transverse cross-section of heart from a patient who died of graft arteriosclerosis. Severe concentric stenosis of epicardial and large intramural coronaries is apparent (arrows). (B) Histologic appearance of graft arteriosclerosis in low-power photomicrograph of vessel cross-section, demonstrating severe, near-complete, and predominantly concentric intimal proliferation with nearly intact internal elastic lamina (arrow). Verhoeff-van Gieson stain (for elastin) 60x. (*A: Reproduced with permission from Schoen FJ, Libby P: Cardiac transplant graft arteriosclerosis. Trends Cardiovasc Med 1991; 1:216. B: Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

ischemic injury) and myocardial coagulation necrosis (indicative of infarction).

Although the precise mechanisms of graft vasculopathy are not definitely established, there is mounting evidence that graft vasculopathy is caused by both chronic allogenic immune response to the transplant and nonimmunologic factors that contribute to vascular injury. Endothelial injury, both cell-mediated and humoral, is likely the initiating event; endothelial cell dysfunction precedes the angiographic manifestations of graft vasculopathy. Alloreactive T cells, activated by major histocompatibility complex class II molecules on donor endothelium, secrete cytokines that amplify the immune response and result in upregulation of endothelial cell adhesion molecules, leading to accumulation of macrophages in the vessel wall and a localized, sustained inflammatory response. Activated macrophages, foam cells that have taken up oxidized low-density lipoprotein cholesterol, and lymphocytes express cytokines and growth factors such as platelet-derived growth factor, fibroblast growth factor, and transforming growth factor-β, that promote proliferation of smooth muscle cells and myofibroblasts and extracellular matrix synthesis. Hyperlipidemia, specifically high levels of oxidized low-density lipoprotein cholesterol, can predict the development of graft vasculopathy. Advanced donor age, cytomegalovirus infection, perioperative graft ischemia, diabetes, and hyperhomocysteinemia have been associated with graft vasculopathy, but their roles in the evolution of the disease remain uncertain. There is no apparent difference in the frequency with which graft vasculopathy develops in patients who were transplanted for end-stage CAD and those operated for idiopathic cardiomyopathy. Recent studies suggest that the intimal cells present in the intima in graft arteriosclerosis may be at least partially derived from the bone marrow of the recipient.[283]

Early diagnosis of graft vasculopathy is limited by the lack of clinical symptoms of ischemia in the denervated allograft, by the relative insensitivity of coronary angiography, which frequently underestimates the extent and severity of this diffuse disease, and by the exclusive or predominant involvement of small intramyocardial vessels. Histologic changes of chronic ischemia such as subendothelial myocyte vacuolization can be seen on surveillance biopsies and may suggest graft vasculopathy (Fig. 5-38). Although not usually amenable to angioplasty, endarterectomy, or CABG because of their diffuse distribution, stenoses may be alleviated by these procedures in occasional cases. For most cases, however, retransplantation is the only effective therapy for established graft atherosclerosis.

Posttransplant lymphoproliferative disorders

Posttransplant lymphoproliferative disorders (PTLDs) are a well-recognized complication of the high-intensity long-term immunosuppressive therapy required to prevent rejection in cardiac allografts. Several factors increase the risk of developing PTLD, including pretransplant Epstein-Barr virus (EBV) seronegativity (10- to 75-fold increase), young recipient age, and cytomegalovirus infection or mismatching (donor-positive, recipient-negative).[284,285] The incidence of PTLD in cardiac transplant recipients is approximately 3%, and the mortality can be as high as 55% at 1 year following the diagnosis of PTLD.[286]

PTLDs can present as an infectious mononucleosis-like illness or with localized solid tumor masses, especially in extranodal sites (e.g., heart, lungs, and gastrointestinal tract). The vast majority (>90%) of PTLDs derive from the B-cell lineage and are associated with EBV infection, although T- or NK-cell origin and late-arising EBV-negative lymphoid

Table 5–5.

Characteristics of Graft Arteriosclerosis versus Typical Atherosclerosis

Graft arteriosclerosis	Typical atherosclerosis
Rapid onset (months to years)	Slow onset (many years)
Risk factors uncertain	Hypertension, lipids, smoking, etc.
Usually silent/congestive heart failure, sudden death	Chest pain, etc.
Diffuse	Focal
Epicardial/intramural	Epicardial
Concentric	Eccentric
Lesions rarely complicated	Lesions often complicated
Smooth muscle cells, macrophages, lymphocytes	Smooth muscle cells, macrophages, foam cells
Primary immunologic mechanism(s)	Complicated stimuli
Difficult to treat; retransplant usually only option	Revascularization by angioplasty, stents, aortocoronary bypass

malignancies have been described. There is strong evidence that the lesions progress from polyclonal B-cell hyperplasias ("early lesions") to lymphomas ("monomorphic PTLDs") in a short period of time, in association with the appearance of cytogenetic abnormalities. Therapy centers on a stepwise approach of antiviral treatment and reduction of immunosuppression, and then progression to lymphoma chemotherapy. Monoclonal antibodies (rituximab) against the B-cell marker CD20 have yielded impressive initial results and may become an important component of PTLD therapy.[287] As the understanding of the risk factors and pathogenesis of PTLDs has expanded, pre-emptive or prophylactic therapies may help prevent this complication of transplantation.

Cardiac Assist Devices and Total Artificial Hearts

Continuing and increasing discrepancy between the number of available donor hearts and therefore transplants performed (less than 2300 annually in the United States, and declining)[288] and the number of patients in the terminal phase of heart failure and refractory to medical management (estimated 250,000 to 500,000 in the United States, and rising)[289] has prompted efforts in the development of ventricular assist devices (VADs), total artificial hearts, and cardiomyoplasty techniques.[290–292] These areas are briefly reviewed in the following sections, from the perspective of cardiac pathology.

Mechanical cardiac assist devices and artificial hearts have traditionally been used in two settings: for ventricular augmentation sufficient to permit a patient to survive postcardiotomy or postinfarction cardiogenic shock while ventricular recovery is occurring, and as a bridge to transplantation when ventricular recovery is not expected and the

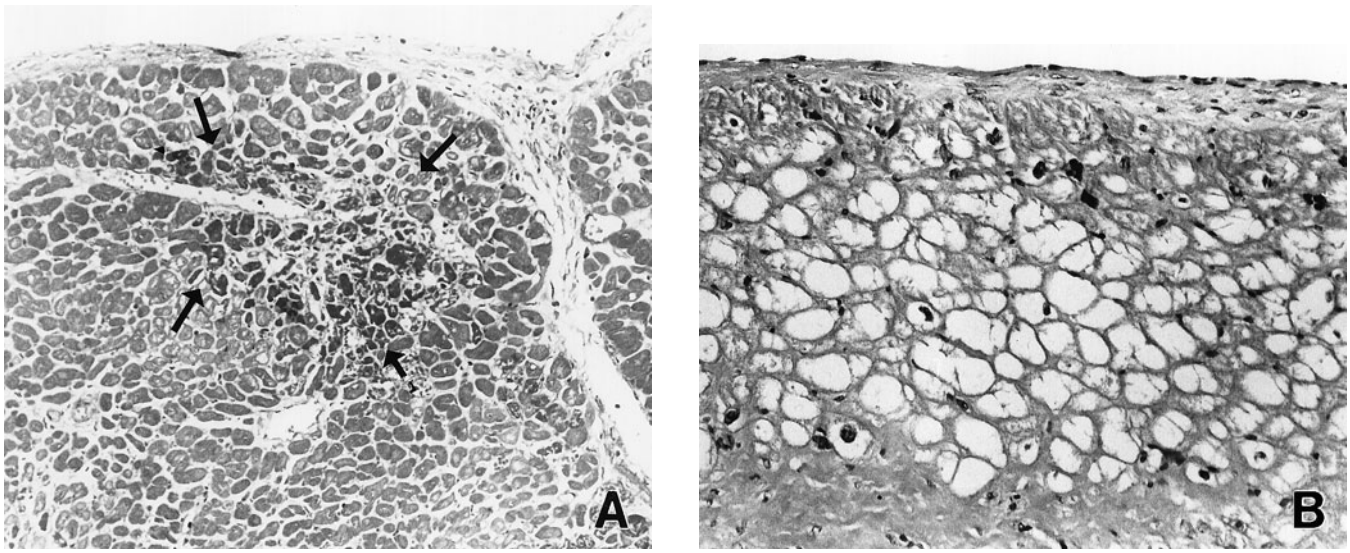

Figure 5-38. Graft arteriosclerosis–induced myocardial pathology in heart transplant recipients. (A) Myocardial microinfarct indicative of disease of small intramural arteries (outlined by arrows) and (B) subendocardial myocyte vacuolization indicative of severe chronic ischemia. Hematoxylin and eosin, 375x.

goal is hemodynamic support until a suitable donor organ is located.[293,294] More recently, LVADs have been shown to provide long-term cardiac support with survival and quality-of-life improvement over optimal medical therapy in patients with end-stage CHF who are not candidates for transplantation.[295,296] LVADs are also being investigated as a bridge to recovery in patients with CHF to induce reverse ventricular remodeling leading to an improvement in cardiac function that would eventually allow device removal.[297] Many types of pumps are currently under development or in clinical use as VADs.[298] Mechanical devices that entirely replace the native heart are currently in use or under development as a bridge to transplant (e.g., CardioWest Total Artificial Heart)[299] or as destination therapy (e.g., AbioCor).[300,301]

The major complications of cardiac assist devices are hemorrhage, thrombosis/thromboembolism, and infection (Fig. 5-39).[302–305] Hemorrhage continues to be a problem in device recipients, although the risk of major hemorrhage has been decreasing with improved therapies and methods. Many factors predispose to perioperative hemorrhage including: (1) coagulopathy secondary to hepatic dysfunction, poor nutritional status, and antibiotic therapy; (2) platelet dysfunction and thrombocytopenia secondary to cardiopulmonary bypass; and (3) the extensive nature of the required surgery.

Nonthrombogenic blood-contacting surfaces are essential for a clinically useful cardiac assist device or artificial heart. Indeed, thromboembolism occurred in most patients having long-term implantation of the Jarvik-7 artificial heart and is a major design consideration for current devices. Thrombi form primarily in association with crevices and voids, especially in areas of disturbed blood flow such as near connections of conduits, valves and other components to each other and to the natural heart (see Fig. 5-39A and B). Most pumps have used smooth polymeric pumping bladders; these are frequently associated with thromboembolic complications. One approach (HeartMate, Thoratec, Pleasanton, CA) to the design of the blood pump is the use of textured polyurethane and titanium surfaces, which accumulate a limited platelet/fibrin pseudointimal membrane that is resistant to thrombosis, allowing only antiplatelet therapy for anticoagulation in most device recipients.[306,307]

Infectious complications have been a major limiting factor in the prolonged use of cardiac assist devices. Infection can occur within the device (see Fig. 5-39C), but may also be associated with percutaneous drive lines. Susceptibility to infection is not only potentiated by the usual prosthesis-associated factors, but also by the multisystem organ damage from the underlying disease, the periprosthetic culture medium provided by postoperative hemorrhage, and by prolonged hospitalization with the associated risk of nosocomial infections. Accounting for significant morbidity and mortality following device use, these infections are often resistant to antibiotic therapy and host defenses. However, infection is not an absolute contraindication to subsequent cardiac transplantation.[308] In the REMATCH trial, sepsis accounted for 21 of the 57 deaths among the patients receiving LVADs. Novel device designs, including alternative sites for driveline placement[309] and the elimination of the driveline altogether with transcutaneous energy transmission technology[310] may play a role in further decreasing this devastating complication.

Other complications include hemolysis, pannus formation around anastomotic sites, calcification (see Fig. 5-39D and E), and device malfunction.[311] Device failure can occur secondary to fracture or tear of one of the prosthetic valves within the device conduits, as this application provides a particularly severe test of valve durability (see Fig. 5-39F). Device failure can also occur secondary to damage or dehiscence of the pumping bladder (see Fig. 5-39G). There is evidence that patients on VADs are more likely to develop allosensitization, which can pose a significant risk to post-transplantation outcome in the bridge-to-transplant patients.[312] These complications not only have significant morbidity and can be fatal in themselves, but they may make a patient ineligible for future transplantation.

To what extent recovery of myocardial function can occur during VAD implantation is uncertain. Many pathophysiologic changes occur during the progression to end-stage heart failure, ranging from the subcellular (e.g., abnormal mitochondrial function and calcium metabolism) to the organ and system level (e.g., ventricular dilation, decreased ejection fraction, and neurohormonal changes), leading to the signs and symptoms of congestive failure. Implantation of an LVAD can reverse many of these changes ("reverse remodeling"), leading to increased cardiac output, decreased ventricular end-diastolic volume, and normalization of neurohormonal status such that a small fraction of patients can be weaned from the device without the need for subsequent cardiac transplantation. Current research focuses on the mechanisms of cardiac recovery, identification of patients who could achieve recovery, and specifics such as the timing and duration of therapy.[313–315]

Skeletal Muscle Augmentation of Cardiac Function

Autologous skeletal muscle has been used to provide active cardiac assist in the form of both cardiomyoplasty and skeletal muscle ventricles for patients with heart failure.[316] In cardiomyoplasty, the latissimus dorsi is wrapped around the ventricles, and this has been shown to stabilize left ventricular size and prevent further dilation. Skeletal muscle can adapt its physiologic, biochemical, and structural characteristics to overcome fatigue and adjust to a more demanding pattern of use by increases in capillary density, activity of oxidative enzymes, and increased mitochondrial volume. While these procedures had some promising experimental and clinical results,[317] interest in their application has waned due to several factors, including the improvement in medical therapy for CHF, the development of the mechanical cardiac assist devices discussed above, and the hesitancy of clinicians to refer patients for this procedure given the alternative therapies. Recent investigations have shown improvement in

long-term muscle function using stimulation protocols in which the skeletal muscle is not stimulated with every heartbeat, or is given rest during periods of low demand such as during sleep.[318,319] In addition, this procedure is an alternative in regions without access to cardiac transplantation and mechanical assist,[320] especially given the improvements with new stimulation protocols.

ARRHYTHMIAS

Arrhythmias generally occur as a result of disorders of electrical impulse formation, disorders of electrical impulse conduction, or a combination of the two. The underlying anatomic substrates for arrhythmogenesis are many. Many of the primary cardiomyopathies can present with arrhythmias, including the genetic (e.g., hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and the ion channelopathies), mixed (e.g., dilated cardiomyopathy) and acquired (e.g., myocarditis) groups. Many secondary cardiomyopathies also may have arrhythmias as a predominant feature (e.g., sarcoidosis). A common cause of arrhythmias and sudden death (especially in the older adult population) is ischemic heart disease, both in patients with and without a prior MI. Myocardial hypertrophy and fibrosis of any etiology (e.g., secondary to valvular heart disease, hypertension, or a remote infarction) also can provide the anatomic and functional substrate for the development of an arrhythmia. These underlying processes and pathologic anatomy increase the risk of spontaneous lethal arrhythmias in the setting of acute initiating events such as acute ischemia, neurohormonal activation, changes in electrolytes, and other metabolic stressors.[321]

Treatments for arrhythmias and their complications include pharmacologic therapy, device therapy[322] (pacemakers and implantable defibrillators), and ablation therapy.

Pacemakers and Implantable Cardioverter-Defibrillators

Modern cardiac pacing (Fig. 5-40) is achieved by a system of interconnected components consisting of (1) a pulse generator that includes a power source and electric circuitry to initiate the electric stimulus and to sense normal activity; (2) one or

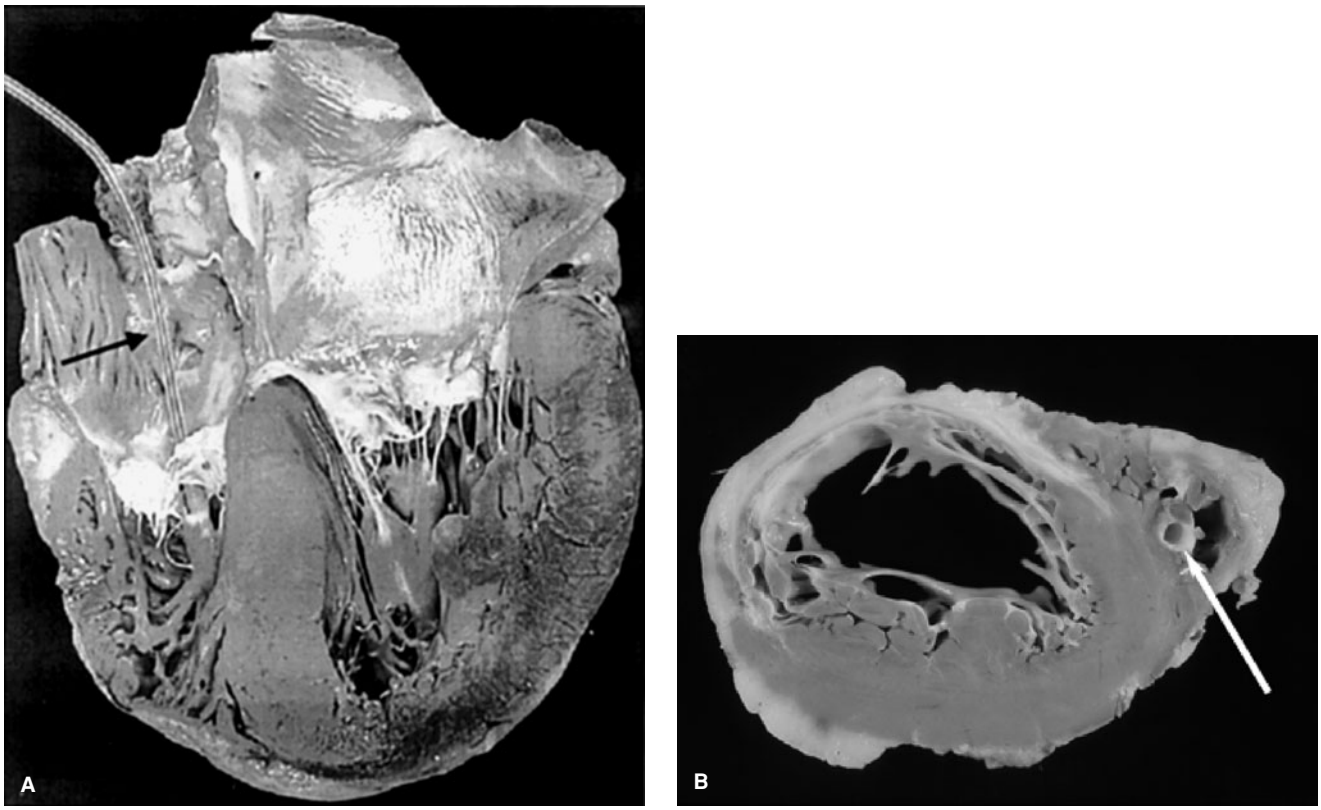

Figure 5-40. Cardiac pacemaker leads in the heart. (A) Pacemaker coursing through right atrium (arrow) and tricuspid valve, ending in right ventricle of heart of patient with hypertensive concentric thickening of the left ventricular wall. (B) Low ventricular section demonstrating fibrosis (arrow) around a pacemaker lead (removed) in the right ventricle of the heart of a patient with an anterior/septal scar (remote transmural myocardial infarction). (A) Reproduced by permission from Schoen FJ: The heart, In: Robbins/Cotran Pathologic Basis of Disease, 7th ed., Kumar V, Fausto N, Abbas A [eds.] Philadelphia, WB Saunders, 2004. pp.555–618.

more electrically insulated conductors leading from the pulse generator to the heart, with a bipolar electrode at the distal end of each; and (3) a tissue, or blood and tissue, interface between the electrode and adjacent stimulatable myocardial cells, which is of critical importance in the proper functioning of the pacemaker. Typically, a layer of nonexcitable fibrous tissue forms around the tip of the electrode (see Fig. 40-B). This fibrosis may be induced by the electrode itself or may be due to myocardial scarring from some other cause, most commonly a healed MI. The thickness of this nonexcitable tissue between the electrode and excitable tissue determines the stimulus threshold, or the strength of the pacing stimulus required to initiate myocyte depolarization, and thus the amount of energy required from the pacemaker. Attempts to reduce the thickness of this layer (thereby extending battery life) include improved lead designs[323] with active fixation, and the use of slow, local release of corticosteroids from the lead tip.[324] Implantable cardioverter-defibrillators (ICDs) are used in the treatment of patients who have life-threatening ventricular arrhythmias that are refractory to medical management and unsuitable for other surgical or ablative therapy. They have similar components to the pacemaker described above. These devices sense arrhythmias that can lead to sudden death and deliver therapy in the form of rapid ventricular pacing and/or a defibrillation current to terminate the dysrhythmic episode. ICDs also must overcome the barrier posed by the interfacial fibrosis at the electrode tip.

Complications from the use of pacemakers include lead displacement; vascular or cardiac perforation leading to hemothorax, pneumothorax, or tamponade; lead entrapment; infection; erosion of the device into adjacent tissues due to pressure necrosis; rotation of the device within the pocket; thrombosis and/or thromboembolism; and lead fracture, in addition to malfunctions of the device itself. If the lead needs to be extracted for chronic infection or device-related defects, damage to the myocardium and/or tricuspid valve may occur secondary to encasement of the lead in fibrous tissue. Similar complications affect ICDs, with additional considerations being the consequences of repeated defibrillations on the myocardium and vascular structures including myocardial necrosis, and the risk of oversensing (with resultant unnecessary shocks) or undersensing (with resultant sudden death). Increased attention has been paid of late to malfunctioning ICDs because of electrical flaws in a specific model that resulted in failure to terminate fatal arrhythmias.[325] It should be noted that it was through the performance of an autopsy on a patient with hypertrophic cardiomyopathy and sudden death (finding no other cause of sudden death) and the subsequent evaluation of the device by the manufacturer that the flaw in this device was brought to light. As a result, there have been many discussions on the topics of postmarket surveillance, device reliability, and the responsibilities of industry, physicians, and regulators. Diligent postmarket surveillance is especially important for ICDs in particular, as the majority of patients who die suddenly are unfortunately not autopsied and it is unknown how many of these deaths may be device related.

Ablation

Ablation involves the directed destruction of arrhythmogenic myocardium, accessory pathways, or conduction system structures to control or cure a variety of arrhythmias, including atrial flutter and fibrillation, ventricular tachycardias and paroxysmal supraventricular tachycardias, that are refractory to medical management.[326–328] Ablation can be carried out as part of a surgical procedure or via percutaneous catheter. Electrophysiologic studies can be used to (1) provide information on the type of rhythm disturbance, (2) terminate a tachycardia by electrical stimulation, (3) evaluate the effects of therapy, (4) ablate myocardium involved in the tachycardia, and (5) identify patients at risk for sudden cardiac death.

Radiofrequency ablation acutely produces coagulation necrosis within the myocardium directly underneath the source tip, eliminating the source or pathway of the arrhythmia (Fig. 5-41). The characteristic histologic changes include loss of myocyte striations, loss or pyknosis of nuclei, hypereosinophilia, and contraction bands. The edge of the fresh lesion is often hemorrhagic with interstitial edema and inflammation. The area undergoes the usual progression of healing similar to that in an infarct, with an early neutrophilic infiltrate, followed by macrophages to handle the necrotic debris, followed by granulation tissue formation and eventual scarring. Through the use of irrigated, cooled catheters, the lesions can penetrate deeply into the myocardium. Techniques using other forms of energy, including cryoablation, microwave, and lasers have been used to create lesions in the myocardium for the treatment of arrhythmias.

NEOPLASTIC HEART DISEASE

Although metastatic tumors to the heart are present in 1 to 3% of patients dying of cancer, primary tumors of the heart are unusual.[329–331] The most common tumors, in descending order of frequency, are: myxomas, lipomas, papillary fibroelastomas, angiomas, fibromas, and rhabdomyomas, all benign and accounting for approximately 80% of primary

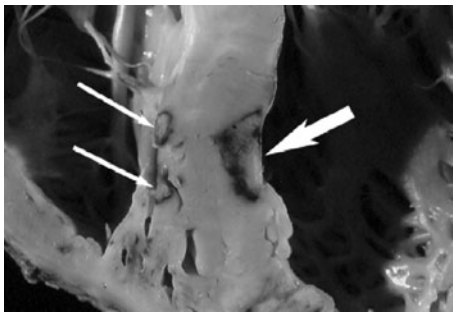

Figure 5-41. Ablation of arrhythmogenic foci by radiofrequency ablation. Recent endocardial ablation site on right (2 small arrows) and left (single arrow) ventricular sides of interventricular septum.

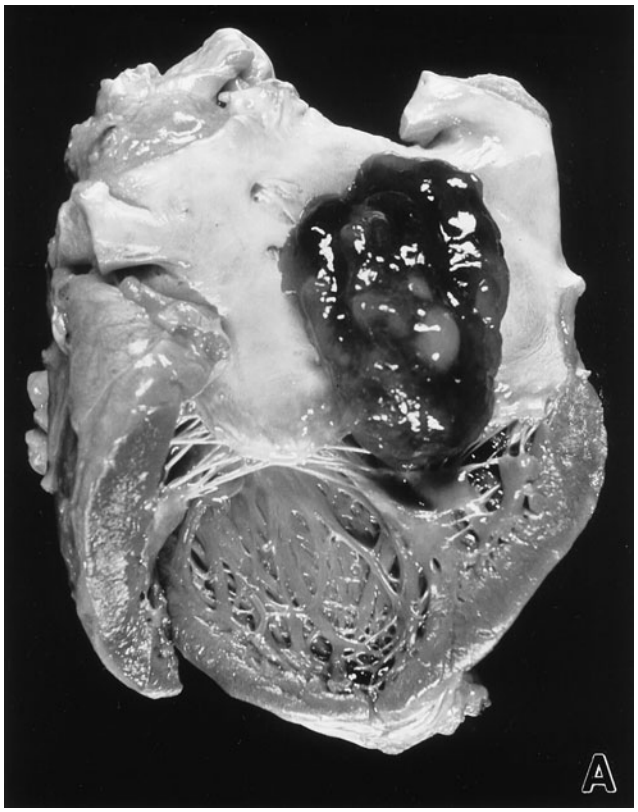
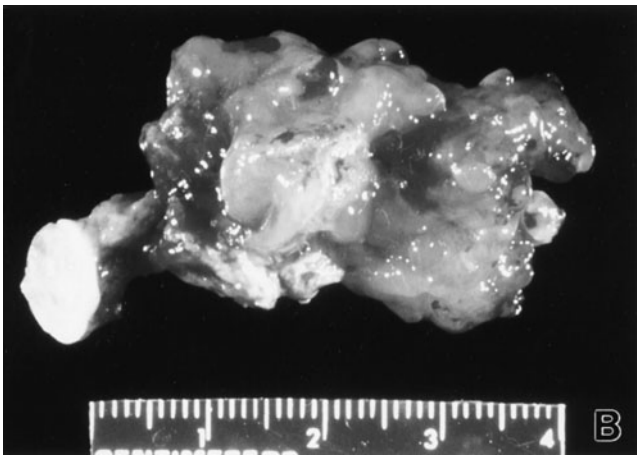
tumors of the adult heart. The remaining 20% are malignant tumors, including angiosarcomas, other sarcomas and lymphomas. Many cardiac tumors have a genetic basis.[332]

Myxoma

Myxomas are the most common primary tumor of the heart in adults, accounting for about 50% of all benign cardiac tumors.[333] They typically arise in the left atrium (80%) along the interatrial septum near the fossa ovalis. Occasionally, myxomas arise in the right atrium (15%), the ventricles (3 to 4%), or valves. These tumors arise more frequently in women and usually present between the ages of 50 and 70 years. Sporadic cases of myxoma are almost always single, while familial cases can be multiple and present at an earlier age.

Myxomas range from small (<1 cm) to large (up to 10 cm) and form sessile or pedunculated masses that vary from globular and hard lesions mottled with hemorrhage to soft, translucent, papillary, or villous lesions having a myxoid and friable appearance (Fig. 5-42). The pedunculated form frequently is sufficiently mobile to move into or sometimes through the ipsilateral atrioventricular valve annulus during





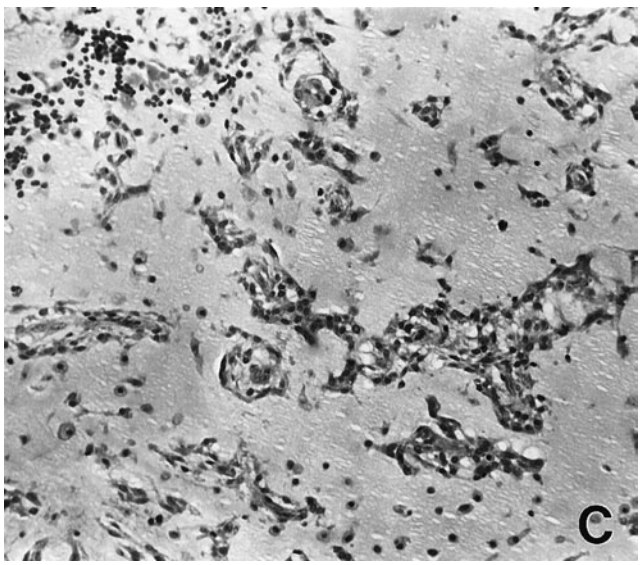


Figure 5-42. Gross and histologic features of cardiac myxomas. (A) Smooth, round, hemorrhagic left atrial myxoma, noted at autopsy. The tumor mass nearly fills the left atrium and extends into the mitral valve orifice. (B) Irregular polypoid, gelatinous friable myxoma mass that was surgically removed. The resection margin that surrounds the proximal portion of the stalk is at left. (C) Characteristic histologic features of myxoma, including individual tumor cells and clusters and islands scattered throughout the characteristic granular extracellular matrix. Hematoxylin and eosin 50x. (*A: Reproduced with permission from Schoen FJ: The heart, in Cotran RS, Kumar V, Collins T [eds]: Pathologic Basis of Disease, 6th ed. Philadelphia, WB Saunders, 1989.*)

ventricular diastole, causing intermittent and often position-dependent obstruction. Sometimes such mobility exerts a wrecking ball effect, causing damage to and secondary fibrotic thickening of the valve leaflets.

Clinical manifestations are most often determined by tumor size and location; some myxomas are incidentally detected in patients undergoing echocardiography for other indications, while others may present with sudden death. Symptoms are generally a consequence of valvular obstruction, obstruction of pulmonary or systemic venous return, embolization, or a syndrome of constitutional symptoms. Intracardiac obstruction may mimic the presentation of mitral or tricuspid stenosis with dyspnea, pulmonary edema, and right-sided heart failure. Fragmentation of a left-sided tumor with embolization may mimic the presentation of infective endocarditis with transient ischemic attacks, strokes, and cutaneous lesions; emboli from right-sided lesions may present as pulmonary hypertension. Constitutional symptoms such as fever, erythematous rash, weight loss, and arthralgias may be due to the release of the acute phase reactant interleukin-6 from the tumor, leading to these inflammatory and autoimmune manifestations. Echocardiography, including transesophageal echocardiography, provides a means to noninvasively identify the masses and their location, attachment, and mobility. Surgical removal usually is curative with excellent short- and long-term prognosis. Rarely, the neoplasm recurs months to years later, usually secondary to incomplete removal of the stalk.

The Carney complex, as it is now known, is a multiple neoplasia syndrome featuring cardiac and cutaneous myxomas, endocrine and neural tumors, as well as pigmented skin and mucosal lesions. Previously described cardiac myxoma syndromes such as LAMB (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxomas, and *b*lue nevi) and NAME (*n*evi, *a*trial myxomas, *m*ucinosis of the skin, and *e*ndocrine overactivity) are now encompassed by the Carney complex. The Carney complex is inherited as an autosomal dominant trait, and is associated with mutations in the *PRKAR1α* gene encoding the R1α regulatory subunit of cyclic adenosine monophosphate–dependent protein kinase A.[334–338] A careful history and physical examination in patients with cardiac myxoma is therefore important to identify other signs of the Carney complex, as this diagnosis carries implications for family members of the patient.

Histologically, myxomas are composed of stellate or globular cells ("myxoma cells"), often in formed structures that variably resemble poorly formed glands or vessels, endothelial cells, macrophages, mature or immature smooth muscle cells, and a variety of intermediate forms embedded within an abundant acid mucopolysaccharide matrix and covered by endothelium. Although it had long been questioned whether cardiac myxomas were neoplasms, hamartomas, or organized thrombi, it is now widely believed that they represent benign neoplasia. These tumors are thought to arise from remnants of subendocardial vasoformative reserve cells or multipotential primitive mesenchymal cells that can differentiate along multiple lineages, giving rise to the mixture of cells present within these tumors.

Other Cardiac Tumors and Tumor-Like Conditions

Cardiac lipomas are discrete masses that are typically epicardial, but may occur anywhere within the myocardium or pericardium. Most are clinically silent, but some may cause symptoms secondary to arrhythmias, pericardial effusion, intracardiac obstruction, or compression of coronary arteries. Magnetic resonance imaging is useful in the diagnosis of adipocytic lesions due to its ability to identify fatty tissues. Histologically, these tumors are comprised of mature adipocytes, identical to lipomas elsewhere. A separate, non-neoplastic condition called lipomatous hypertrophy of the interatrial septum is characterized by accumulation of unencapsulated adipose tissue in the interatrial septum that can lead to arrhythmias. Histologically, this tissue is composed of a mixture of adipose tissue and cardiac myocytes, in contrast to the pure adipose tissue of a proper lipoma.

Papillary fibroelastomas[339,340] are usually solitary and located on the valves, particularly the ventricular surfaces of semilunar valves and the atrial surfaces of atrioventricular valves. The most common site is the aortic valve, followed by the mitral valve. They constitute a distinctive "sea anemone" cluster of hair-like projections up to 1 cm or more in length, and can mimic valvular vegetations echocardiographically (Fig. 5-43).[341] Histologically they are composed of a dense core of irregular elastic fibers coated with myxoid connective tissue and lined by endothelium. They may contain focal platelet-fibrin thrombus and serve as a source for embolization, commonly to cerebral or coronary arteries. Surgical excision is recommended to eliminate these embolic events. Although classified with neoplasms, fibroelastomas may represent organized thrombi, similar to the much smaller, usually trivial, whisker-like Lambl's excrescences that are frequently found on the aortic valves of older individuals.

Rhabdomyomas comprise the most frequent primary tumor of the heart in infants and children.[342] They are usually multiple and involve the ventricular myocardium on either side of the heart. They consist of gray-white myocardial masses up to several centimeters in diameter that may protrude into the ventricular or atrial chambers, causing functional obstruction. These tumors tend to spontaneously regress, so surgery is usually reserved for patients with severe hemodynamic disturbances or arrhythmias refractory to medical management. Most cardiac rhabdomyomas occur in patients with tuberous sclerosis, the clinical features of which also include infantile spasms, skin lesions (hypopigmentation, shagreen patches, and subcutaneous nodules), retinal lesions, and angiomyolipomas. In its familial form, this disease exhibits autosomal dominant inheritance, but about one-half of cases are sporadic, owing to new mutations. Histologically, rhabdomyomas contain characteristic "spider cells," which are large, myofibril-containing rounded or polygonal cells with numerous glycogen-laden vacuoles separated by strands of cytoplasm running from the plasma membrane to the centrally located nucleus.

Figure 5-43. Papillary fibroelastoma. Gross photograph demonstrating resemblance of this lesion to a sea anemone, with papillary fronds arising from the chordae tendineae and near the mitral leaflet (large arrow). In this case multiple lesions were present, all associated with the mitral valve apparatus (small arrowheads). (*Reproduced with permission from Sabatine M, Colucci WS, Schoen FJ: Primary tumors of the heart, in Braunwald E, Libby P, Zipes DP [eds]: Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia, WB Saunders, 2005; p 1741.*)

Cardiac fibromas, while also occurring predominantly in children and presenting with heart failure or arrhythmias, or incidentally, differ from rhabdomyomas in being solitary lesions that may show calcification on a routine chest radiograph.[343] Fibromas are white, whorled masses that are typically ventricular. There is an increased risk of cardiac fibromas in patients with Gorlin syndrome (nevoid basal cell carcinoma syndrome),[344] an autosomal dominant disorder characterized by skin lesions, odontogenic keratocysts of the jaw, and skeletal abnormalities. Gorlin syndrome is a result of germline mutations in the *PTC* gene on chromosome 9; the role of this gene product in myocardial growth and development is unknown. Histologically, fibromas consist of fibroblasts showing minimal atypia and collagen with the degree of cellularity decreasing with increasing age of the patient at presentation. While they are grossly well circumscribed, there is usually an infiltrating margin histologically. Calcifications and elastin fibers are not uncommon in these lesions.

Sarcomas, with angiosarcomas, undifferentiated sarcomas, and rhabdomyosarcomas being the most common, are not distinctive from their counterparts in other locations. They tend to involve the right side of the heart, especially the right atrioventricular groove (Fig. 5-44). The clinical course

Figure 5-44. Massive pericardial angiosarcoma with deep myocardial invasion at multiple sites, particularly at the right atrium (arrow). (*Reproduced with permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989.*)

is rapidly progressive as a result of local infiltration with intracavity obstruction and early metastatic events.

Recently described, and of importance only insofar as they need to be distinguished from primary cardiac tumors or metastatic carcinoma, are peculiar microscopic-sized cellular cardiac lesions that have been noted incidentally as part of endomyocardial biopsy, surgically removed tissue specimens, or at cardiac surgery, and are free-floating or loosely attached to a valvular or endocardial mass.[345] Termed mesothelial/monocytic incidental cardiac excrescences, they appear histologically largely as clusters and ribbons of mesothelial cells and entrapped erythrocytes and leukocytes, embedded within a fibrin mesh. Some represent reactive mesothelial and/or monocytic (histiocytic) hyperplasia, whereas others are now considered to be artifacts formed by compaction of mesothelial strips (likely from the pericardium) or other tissue debris and fibrin, which are transported via catheters or around an operative site on a cardiotomy suction tip.

CHAPTER 6

Cardiac Surgical Imaging

Frank J. Rybicki • Tarang Sheth • Frederick Y. Chen

Over the last decade, advances in computed tomography (CT) technology have revolutionized the diagnosis of cardiovascular disease. As illustrated in this chapter, CT has reduced dramatically and, for some clinical indications, eliminated the need for diagnostic arterial catheterization. In the process, CT has become invaluable in cardiac diagnosis and surgical planning.

CT is based on a source of x-rays and a system to detect those x-rays that pass though a patient. The x-ray source and detector are mounted on the CT gantry that rotates around the patient. Two major technological advances have enabled CT to image the beating heart. The first is the speed at which the CT gantry rotates. The second is the incorporation of an increasing number of detectors that can resolve small anatomic detail. One of the great promises of modern CT is the ability to exclude coronary artery disease noninvasively in less than 1 minute with a single CT acquisition (Fig. 6-1). However, the role of CT extends far beyond the coronary arteries alone. Using the same CT acquisition, native coronary imaging can be extended to coronary bypass grafts, the beating myocardium, valve motion, ventricular outflow tracks, and cardiac lesions.

In order to understand the clinical contribution of CT and to avoid pitfalls in image interpretation, it is essential for the surgeon to appreciate the basic principles of CT used in cardiac imaging. This chapter is divided into two parts. The first part describes the technical considerations for cardiac CT. By understanding each component, the surgeon will be better able to distinguish image artifacts from pathology. The second part reviews the CT examinations that are performed most frequently in the Cardiovascular Imaging Section at Brigham and Women's Hospital (BWH), detailing the strengths and limitations of each examination.

CARDIAC CT PROTOCOLS

Most advances in cardiac CT, e.g., in coronary artery CT angiography (CTA), have focused on the development of protocols consistent with the rapid incremental improvements in the technology. One of the major technological advances has been the incorporation of multiple elements into the CT detector system, called *multidetector CT* (MDCT). MDCT is synonymous with *multislice CT*. Data from each of the detectors are used to reconstruct an axial slice perpendicular to the long axis, or *z* axis, of the patient. The width of the detectors determines the width of the slices and thus the ability of the scanner to resolve small anatomic detail (spatial resolution). Thinner slices yield superior spatial resolution; however, comparing two scanners that produce the same number of slices, the scanner with thinner slices will have less *z*-axis coverage per gantry rotation and thus will have a longer scan time.

Temporal Resolution

Successful cardiac imaging by any modality relies on the ability of the hardware to produce motion-free images or, in other words, to image faster than the heart beats. Because it requires that the gantry be rotated around the patient, CT is inherently slower than digital subtraction angiography (DSA), in which each frame corresponds to a single projection image. As described below, CT recently has become much faster, and thus cardiac CT now can be performed routinely.

Temporal resolution is the metric that measures imaging speed. For a CT scanner with a single photon source, the temporal resolution is one-half the CT gantry rotation time. This is so because image reconstruction requires CT data acquired from one half (180 degrees) of a complete gantry rotation. All manufacturers have gantry rotation times of less than 500 ms; at the time of publication, the minimum (or fastest) gantry rotation time is 330 ms (Siemens Sensation 64 Cardiac, Siemens Medical Solutions, Forchheim, Germany). With this gantry rotation, an electrocardiogram (ECG)–gated cardiac image can be reconstructed (using

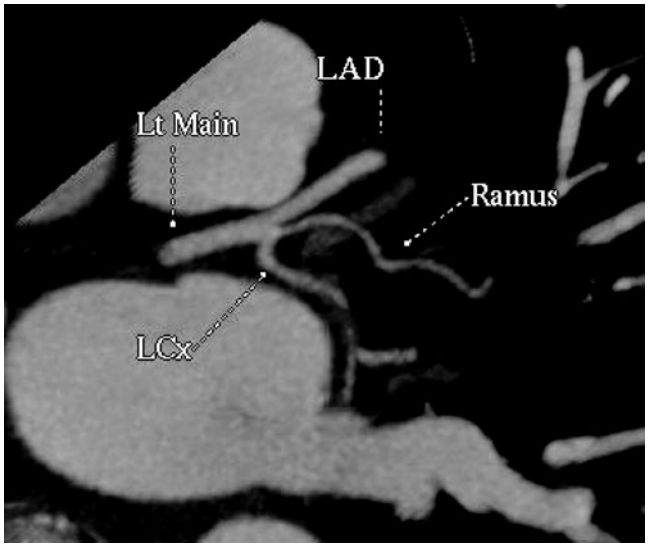

Figure 6-1. Selected coronary computed tomography angiography (CTA) image of the proximal left coronary arterial system in a patient scheduled for isolated mitral valve surgery. Using the protocol detailed in this chapter, CT demonstrated normal coronary arteries in this patient, eliminating the need for arterial catheterization.

single-segment reconstruction, described below) with CT data acquired over 165 ms of the cardiac cycle. Thus the reconstructed images inherently display the average of the cardiac motion over the 165 ms during which the data were acquired. This is how ECG gating enables cardiac CT. Without gating, cardiac images are nondiagnostic because the reconstruction "averages" the motion over the entire RR interval, e.g., over 1000 ms for a patient with a heart rate of 60 bpm.

There are two main strategies to improve temporal resolution. The more recent uses two independent sources and two independent (64-slice) detector systems built into the CT gantry (Siemens Definition, Siemens Medical Solutions, Forchheim, Germany). The second x-ray source is positioned 90 degrees from the first x-ray source, and the second detection system is positioned 90 degrees from the first detection system. With respect to temporal resolution, the practical consequence of this CT configuration is that 180 degrees of gantry rotation can be achieved in half the time (e.g., 82.5 ms as opposed to 165 ms). This halves the temporal resolution (to 82.5 ms), and thus, for this "dual-source" CT configuration, motion is averaged over only 82.5 ms.

For single-source scanners, temporal resolution can be improved by adopting a so-called multisegment image reconstruction. The difference between single-segment and multisegment reconstruction is that in the former, 180 degrees of data are acquired from a single heartbeat, whereas multisegment reconstruction uses several heartbeats to obtain the one-half gantry CT data. For example, in a two-segment reconstruction, two heartbeats are used to generate a single axial slice, and thus the temporal resolution is halved. Similarly, if four heat beats are used (four-segment reconstruction), only 45 degrees of data are used from each heartbeat. This yields a fourfold reduction in the effective temporal resolution, making it theoretically possible to perform high-spatial-resolution cardiac CT in patients with a rapid (e.g., >70 bpm) heart rate. However, since multiple heartbeats are used to fill the 180 degrees of gantry rotation necessary for the reconstruction, stable periodicity of the heart is essential. When beat-to-beat variations in heart rate occur, image quality is degraded significantly. In our experience, multisegment reconstruction works well in patients with high heart rates who are being studied for clinical indications, in whom the highest image quality may not be required (e.g., studies of graft patency, pericardial calcification). For more demanding applications (e.g., native coronary CTA), we still routinely employ beta blockade for heart rates greater than 60 bpm.

Beta Blockade for Heart Rate Control

As suggested earlier, beta blockade is an important component of most cardiac CT examinations. A useful rule of thumb for the target heart rate is, "The first number is a 5"—i.e., an ideal heart rate between 50 and 59 bpm. While this goal is not achieved in every patient, it provides a useful frame of reference. Many surgical patients come to imaging beta blocked as part of their medical therapy. When this is not the case, IV metoprolol is administered routinely in 5-mg increments, given every 5 minutes up to a maximum dose of 25 mg. Doses greater than 15 mg rarely are needed.

ECG Gating

ECG gating refers to the simultaneous acquisition of both the patient's ECG tracing and CT data (Fig. 6-2). With the acquisition of both pieces of information, CT images can be reconstructed using only a short temporal segment periodically located in the R-R interval over multiple cardiac cycles. The duration of the temporal segment is equal to the temporal resolution of the scanner, e.g., 165 ms (330 ms/2) for the Siemens Sensation 64 Cardiac scanner. Each temporal segment of the RR interval is named by its "phase" in the cardiac cycle; the most commonly used nomenclature is to name the percentage of a specific phase with respect to its position in the R-R interval. For example, if a manufacturer enables reconstruction of 20 (equally spaced) phases, they typically would be named 0%, 5%, 10%, . . . 95% beginning with one R wave and ending with the following R wave. The period in which the heart has the least motion usually (but not always) is in middiastole, near a phase between 55% and 75%. Thus, under the assumption that the position of the heart remains consistent over the R-R intervals during which CT data are reconstructed, cardiac motion is minimized by producing images from the same phase over multiple cardiac cycles. This explains why ECG gating typically fails to freeze cardiac motion in patients with an irregular rhythm, such as atrial fibrillation. Consequently, ECG-gated cardiac CT is rarely beneficial in atrial fibrillation patients.

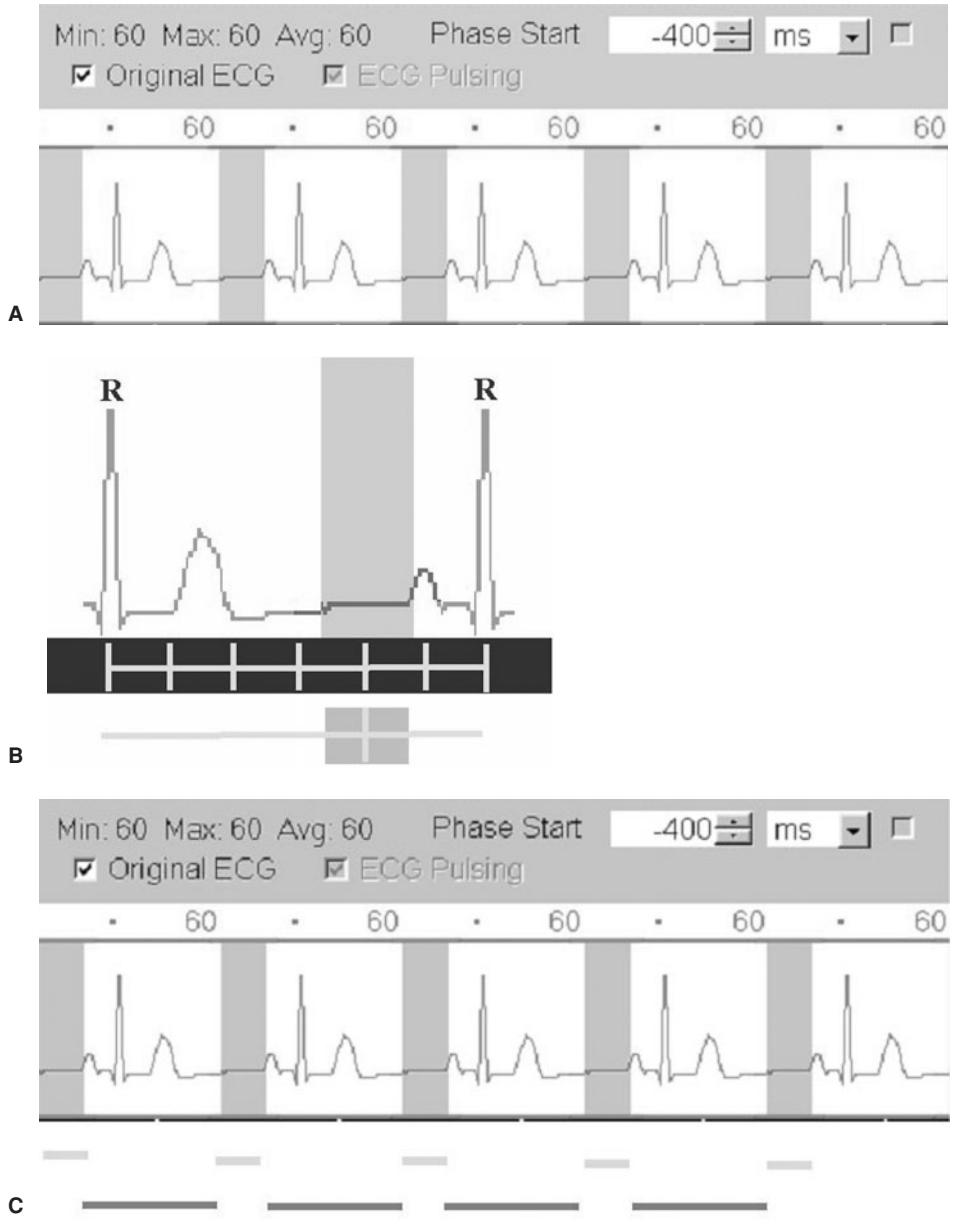

Figure 6-2. (*A*) In gating, the continuous ECG tracing is displayed on the console. In this case, the minimum, maximum, and average heart rate is 60 bpm (R-R interval = 1000 ms). The gray vertical bars indicate that portion of the cardiac cycle used in the reconstruction. As discussed in the text, the width of the gray bar is the temporal resolution of the scan. For this single-segment reconstruction, the width is half the gantry rotation time, or 165 ms. The term "–400 ms" refers to the fact that the center of the gray bars is located 400 ms before the second of the two R waves in the R-R interval. (*B*) Enlarged view of a single R-R interval. To provide a simple demonstration of how the R-R interval is divided, six segments are illustrated. In clinical imaging, CT scanners divide the R-R interval into a number of segments between 10 and 20. The gray block at the very bottom emphasizes that each reconstructed image uses only a small portion of the cardiac cycle. The gray block is positioned in diastole; its center is approximately 65% between the R waves; i.e., for an R-R interval of 1000 ms, 650 ms elapses between the first R wave and the center of the block. This reconstruction is one used most commonly to visualize the left coronary arterial system. If this reconstruction does not provide the most optimal images, additional reconstructions, in either earlier or later phases, are performed. Since the right and left coronary arteries are asynchronous, it is sometimes the case that evaluation of the right side is best performed using images closer to systole. (*C*) Tube current modulation or ECG pulsing. The ECG tracing is identical to the one illustrated in part *A*. The colored bars under the tracing correspond to the gray bars and correlate with current modulation; the optimal (high) tube current will be used. The red lines show times that correspond to portions of the cardiac cycle where the x-ray CT tube current is minimized. ECG pulsing can reduce the patient dose by 30 to 50%.

If only static (as opposed to cine) images are desired, image reconstruction usually can be performed over a small number of phases for which motion is minimized. For native coronary imaging, the reconstructions must account for a synchronous movement of the left and right coronary arterial systems. That is, the phase of the cardiac cycle that proves best for diagnosis of the left main and left anterior descending (LAD) arteries often is different from the phase that proves most diagnostic for the right coronary artery (RCA). Thus it is sometimes the case, particularly when beta blockade is suboptimal, that the reconstruction must include several phases. Within the cardiac cycle, periodic displacement of both saphenous vein grafts (SVGs), radial grafts, and internal mammary artery (IMA) grafts is far less than the motion of the native coronary arteries. Thus, for these vessels, a single reconstruction at middiastole usually is sufficient (Fig. 6-3). However, it is *essential* that the surgeon not only recognizes that motion has degraded image quality but also realizes that additional reconstructions in different phases *can and should be performed.* If the entire course of the graft is not clear to the surgeon on a single image (e.g., 65%), it is almost always the case that another phase can be reconstructed from the CT data (e.g., 50%) for motion-free depiction of the graft segment that was poorly seen. At BWH, open communication between the radiologist and surgeon for every patient has eliminated this pitfall and ensures that the maximum amount of imaging data are incorporated into preoperative planning.

In cine CT, such as imaging the aortic valve over the entire R-R interval, images are reconstructed throughout the cardiac cycle and then played, in cine mode, to demonstrate function. Each individual image (Fig. 6-4) offers an outstanding assessment of the aortic valve and root structure. Cine CT also can be used to assess ventricular wall motion. In comparison with magnetic resonance imaging (MRI), the "gold standard" for global and regional wall motion abnormalities, CT

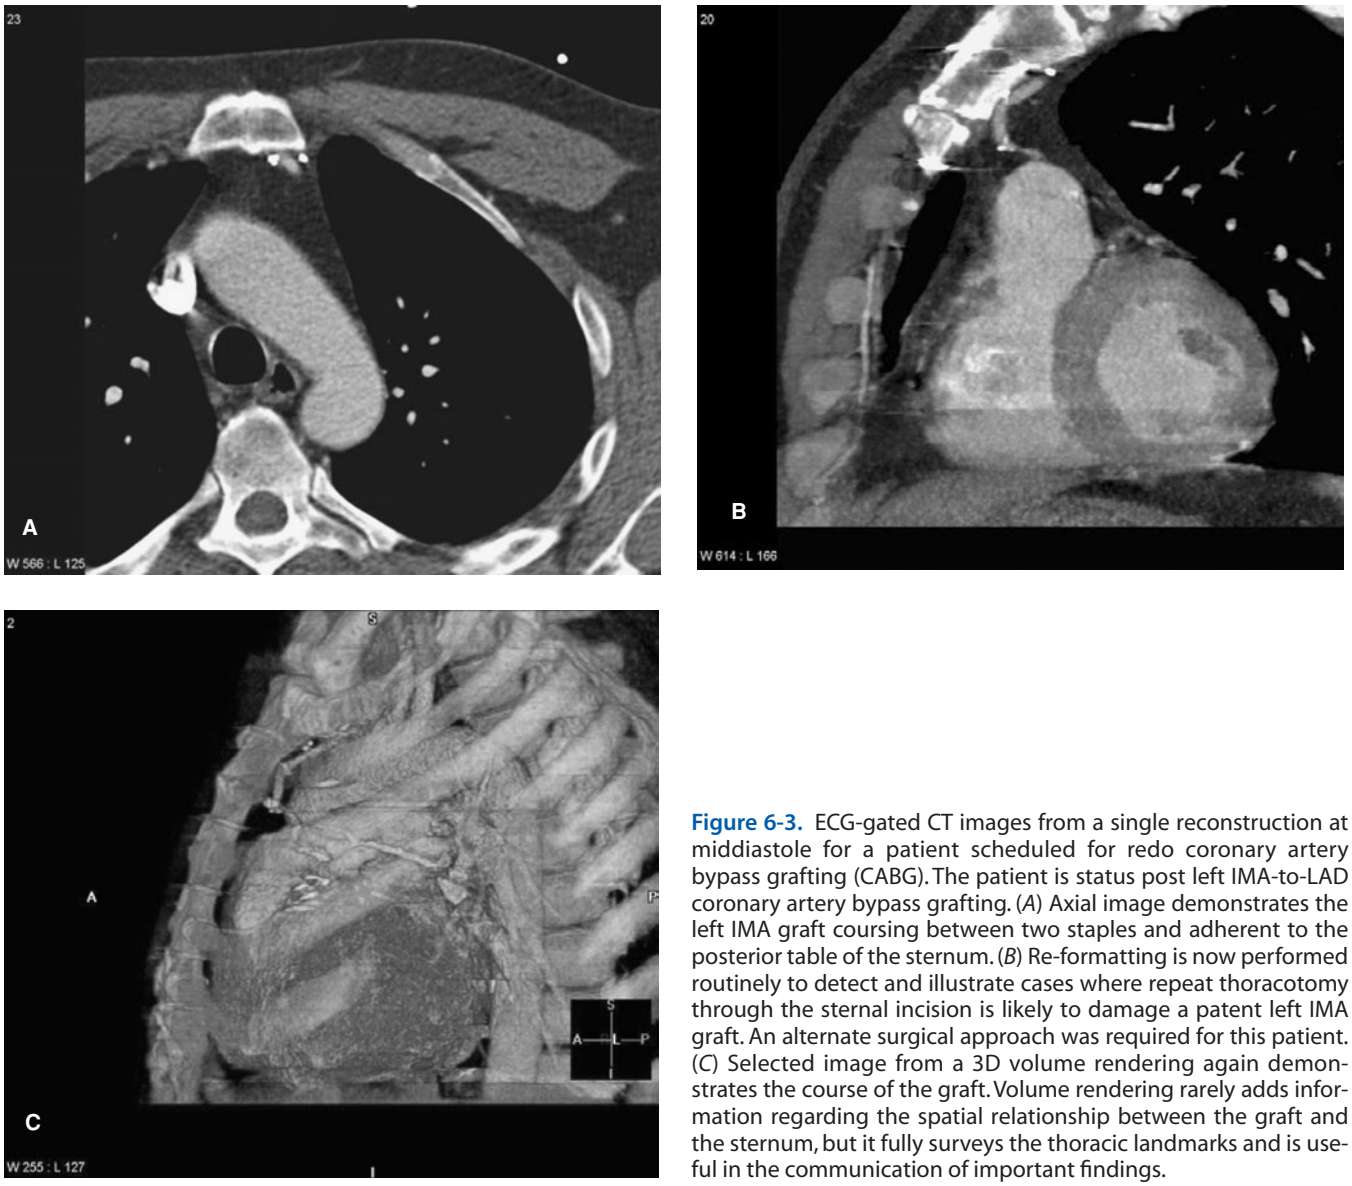

Figure 6-3. ECG-gated CT images from a single reconstruction at middiastole for a patient scheduled for redo coronary artery bypass grafting (CABG). The patient is status post left IMA-to-LAD coronary artery bypass grafting. (*A*) Axial image demonstrates the left IMA graft coursing between two staples and adherent to the posterior table of the sternum. (*B*) Re-formatting is now performed routinely to detect and illustrate cases where repeat thoracotomy through the sternal incision is likely to damage a patent left IMA graft. An alternate surgical approach was required for this patient. (*C*) Selected image from a 3D volume rendering again demonstrates the course of the graft. Volume rendering rarely adds information regarding the spatial relationship between the graft and the sternum, but it fully surveys the thoracic landmarks and is useful in the communication of important findings.

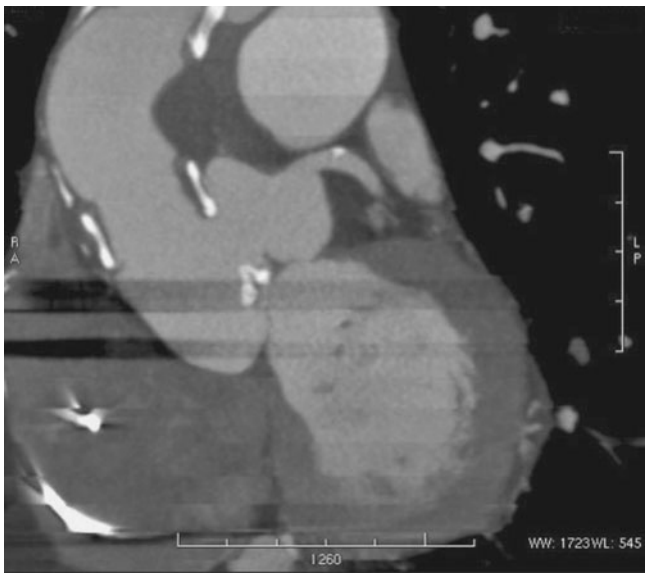

Figure 6-4. ECG-gated CT image through the left ventricle and the aortic valve in a patient status post aortic root repair. Note the pacemaker (right heart wires); MRI was contraindicated. The repair is well visualized and without complication, with only mild aortic valve calcification (cine images showed a tricuspid valve with no significant stenosis). This image also demonstrates a punctate calcified plaque along the superior course of the proximal left main coronary artery without a significant stenosis.

has less contrast to noise, and images typically have greater artifact from the poorer temporal resolution. However, it is important to emphasize that cine CT does not require a separate image acquisition. The entire CT data set (i.e., coronary, valve, myocardium, and pericardium) is acquired in a single breath hold; cine CT is simply part of the image postprocessing.

For surgical patients, CT has the distinct advantage over MRI in that it is by far the best imaging modality to identify and quantify calcification. Also, the most common contraindications for cardiac CT (e.g., impaired renal function as measured by glomerular filtration rate or, alternatively, by serum creatinine) differ from those for MRI (e.g., pacemaker), and thus CT often can be used for patients who cannot have MRI. Finally, newer and future CT equipment with up to 256 slices is expected to perform whole-heart coverage with a single half-gantry (180-degree) rotation. This approach holds the promise of a subsecond cardiac scan. In addition to the fact that patient radiation is decreased, multiple scans can be performed with the same injection of iodinated contrast material, creating the opportunity for a host of additional studies (e.g., myocardial perfusion) that are, at present, largely in the domain of cardiac MRI and nuclear cardiology.

Patient Irradiation

Because ECG gating is required, ascending aorta and cardiac CT delivers more patient irradiation than CT of any other body part. While details regarding cardiac CT dosimetry are beyond the scope of this chapter, discussions regarding CT dose must be based on sound principles. The radiation risk most commonly quoted relates to the probability that the CT scan will result in the development of a fatal radiation-induced neoplasm. Human data for radiation at this low level (the level delivered in ECG-gated cardiac CT) are very sparse; all anecdotal reports support a latency period of no less than 20 years for a radiation-induced neoplasm. For this reason, patients should be separated into two groups: those with a life expectancy of roughly 20 years or less and those with a longer life expectancy. In the former group, the only dose consideration is whether the radiation could cause a skin burn (the only short-term complication of any consequence). X-ray skin burns are extremely uncommon, particularly in CT (even for ECG-gated studies), and typically result from multiple examinations repeated at short-term intervals. Thus, for this subset of patients, *radiation dose should not be a consideration* in determining a modality for coronary imaging.

Current modulation is a strategy to lower the radiation dose for patients with a longer life expectancy and for whom multiple cardiac scanning is anticipated. The tube current (expressed as the milliamperes) is modulated over the course of the cardiac cycle (see Fig. 6-2C) so that the desired (high) diagnostic current is delivered only in diastole. The patient dose is decreased because the tube current is reduced for the remainder of the cardiac cycle. While current modulation is helpful in many cases (e.g., in pediatric patients), the decision to use it should be made after consultation between surgeon and radiologist because the potential drawbacks are significant. Most important, when current modulation is used, images reconstructed during phases with low tube current are noisy (Fig. 6-5) because less tube current is used to generate them. Moreover, current modulation eliminates the potential to reconstruct high-quality cine images. Thus, current modulation is useful only for patients with a long life expectancy in whom repeated imaging is expected and for whom it is anticipated that only static images over a small number of cardiac phases will be sufficient.

Scanning Parameters

The *scan time* refers to the time required to complete the CT acquisition along the *z* axis of the patient. As described earlier, better temporal resolution decreases the scan time, not only decreasing cardiac motion but also enabling breath-hold CT. This is important in cardiac CT because in comparison with nongated CT, ECG gating not only increases patient radiation but also increases the scan time.

In practical terms, a 64-slice ECG-gated cardiac CT scan (i.e., craniocaudal or *z*-axis imaging over ~15 cm) can be performed in roughly 10 seconds versus 20 to 25 seconds with a 16-slice scanner. This is one great benefit of scanners equipped with a larger number of detectors. The number of detectors determines the number of slices obtained per rotation of the CT gantry. Increasing the number of slices, the thickness of the detectors, or both increases the *z*-axis coverage per rotation and thus decreases the scan time.

For example, in a patient who cannot perform the breath hold, using thicker detectors (e.g., 1-mm thickness as

Figure 6-5. Comparison of images obtained without (*left*) and with (*right*) ECG-based tube current modulation or ECG pulsing. The left-hand two-chamber (left atrium and ventricle) view is reconstructed at 65% of the R-R interval. Note that the normal mitral valve is well demonstrated with ECG gating. The right image was reconstructed at 10% of the R-R interval, where the x-ray CT tube current was reduced dramatically. As a result, the right-hand image suffers from high image noise.

opposed to 0.5 mm thickness) will decrease the scan time by providing more *z*-axis coverage per rotation. However, routinely increasing the width of the detectors for cardiac applications is undesirable because it degrades the spatial resolution of the examination. In general, *spatial resolution* refers to the ability to differentiate two structures. In practical terms, the spatial resolution refers to the thinnest axial slices that can be reconstructed from the configuration of the detectors, and thinner detectors translate into better spatial resolution.

Routine consultation between the surgeon and the radiologist is essential to best understand and optimize the tradeoff between scan time and slice thickness. In some cases, as in native coronary CTA, the best spatial resolution is required, and thus the scan time must remain long. To illustrate, consider that the thinnest slices that can be reconstructed are approximately 0.4 mm wide. Therefore, for a perfectly ECG-gated native coronary CTA with no respiratory motion, a normal 3-mm coronary artery spans seven or eight high-quality pixels (3 mm/0.4 mm). If the thinnest slices were 1 mm wide instead of 0.4 mm, the coronary artery would be fully seen on at most three pixels, and thus stenosis evaluation would be severely compromised. On the other hand, myocardial and ascending aortic imaging almost never requires 0.4-mm slices because the pathology is larger. Thus, for dyspneic patients who require only imaging of the ascending aorta, thicker slices are used to cut the scan time. For these more complex cases, routine communication between the surgeon and the radiologist is critical to ensure that imaging meets the diagnostic need for surgical planning or follow-up.

The scanning parameters that primarily determine the number of photons used to create a CT image are termed *effective milliampere-seconds* (effective mA · s) and *kilovolts* (kV). The former is proportional to the x-ray tube current; the latter refers to the voltage applied within the tube. For the surgeon, choosing the best numbers (typical values are 550 to 700 effective mA · s and 120 kV) is far less important than understanding the fact that modern cardiac CT pushes the limits of technology and thus creates tradeoffs with respect to the x-ray CT source. The source generates photons that are either attenuated by the patient or reach the detectors. When more photons reach the detectors, the image quality is higher because there is less noise. The decision to image with thinner slices (e.g., 0.5 mm as opposed to 1 mm) means that fewer photons reach the detector; thus thinner slices have more noise. This is especially important in obese patients because patients with increased body mass absorb more photons than thin patients. For the same scanning parameters, images of obese patients can be degraded dramatically by greater image noise.

If there were no limit to the number of photons that an x-ray CT source could produce, the solution would be simply to increase the number of photons (and the radiation dose) until image noise was satisfactory. Unfortunately, because the x-ray CT tube heats excessively when pushed to its maximum, there is a limit to the number of photons that can be produced. This is why image noise becomes problematic with thin-slice imaging of obese patients. When this is the case, consultation between surgeon and radiologist is important because diagnostic images often can be obtained by increasing the image thickness, scanning a smaller *z*-axis field of view (FOV), or both. The latter can be particularly useful if the examination can be tailored to the most important structure. Scanning a smaller *z* axis means that more photons can be generated and used before the x-ray CT tube reaches its heat limit.

On the other hand, whenever possible, the *z*-axis FOV should be generous because unexpected pathology can extend both cranially and caudally. For example, an ECG-gated cardiac and ascending aorta examination to evaluate extension of the intimal flap into the coronary arteries can reveal extension into the great vessels. Also, scanning must allow for variations in the FOV induced by breath holding. As a general rule, for scanning the native coronary arteries alone, the superior border of the FOV is set at the axial slice

corresponding to the top of the carina. This is typically 2 to 3 cm superior to the origin of the left main coronary artery. The inferior border should scan through the entire inferior wall of the heart and should include several slices of the liver to account for cardiac displacement during breath holding. For bypass graft imaging, the superior border of the FOV must include the subclavian arteries and the origins of both IMAs.

Contrast Material

With the exception of scans performed solely for the assessment of cardiac and aortic calcification, CT examinations are performed with iodinated contrast material. Effective communication between surgeon and radiologist is important in optimizing the use of contrast material, particularly in the decision of whether to use a single or a dual injection system. A single system injects only contrast material, whereas a dual system has two reservoirs to inject contrast material followed by saline. Dual injection is essential for many applications, and it is routine in native coronary artery imaging. The contrast material and saline delivery are timed so that the left side of the heart, aorta, and coronary arteries are opacified with contrast material while the right side of the heart is filled with saline. The use and timing of the saline are essential parts of the examination because artifacts that limit interpretation of the RCA will be induced if the right side of the heart and central veins are densely opacified with contrast material (as opposed to saline). However, for patients in whom imaging requires opacification of both the left and right sides of the heart (e.g., assessment of both the mitral and tricuspid valves), saline cannot be used, and less dense contrast material may be chosen to lessen potential artifacts.

Summary

Advances in technology, such as submillimeter spatial resolution, 64 slices per rotation, and gantry rotation times of less than 1/2 second, have enabled ECG-gated CT to make a positive contribution to the care of cardiac surgery patients. The surgeon must recognize that cardiac protocols push the limit of technology and that therefore CT of the heart is more complicated than a scan of any other body part. Consequently, routine and effective communication between the surgeon and the radiologist will result in the best possible patient outcomes.

APPLICATIONS IN CARDIAC SURGICAL PATIENTS

Native Coronary Artery CTA

One of the most common clinical indications for cardiac CT is to evaluate the native coronary arteries for stenosis (Figs. 6-6 through 6-9). Numerous validation studies have evaluated cardiac CT for this purpose. In these studies, data typically are reported on a per-coronary-artery-segment basis, comparing CTA and DSA. A significant stenosis generally is defined as greater than 50%, determined by quantitative coronary artery angiography. Data are also analyzed on a per-patient basis regarding the value of CTA in ruling in or

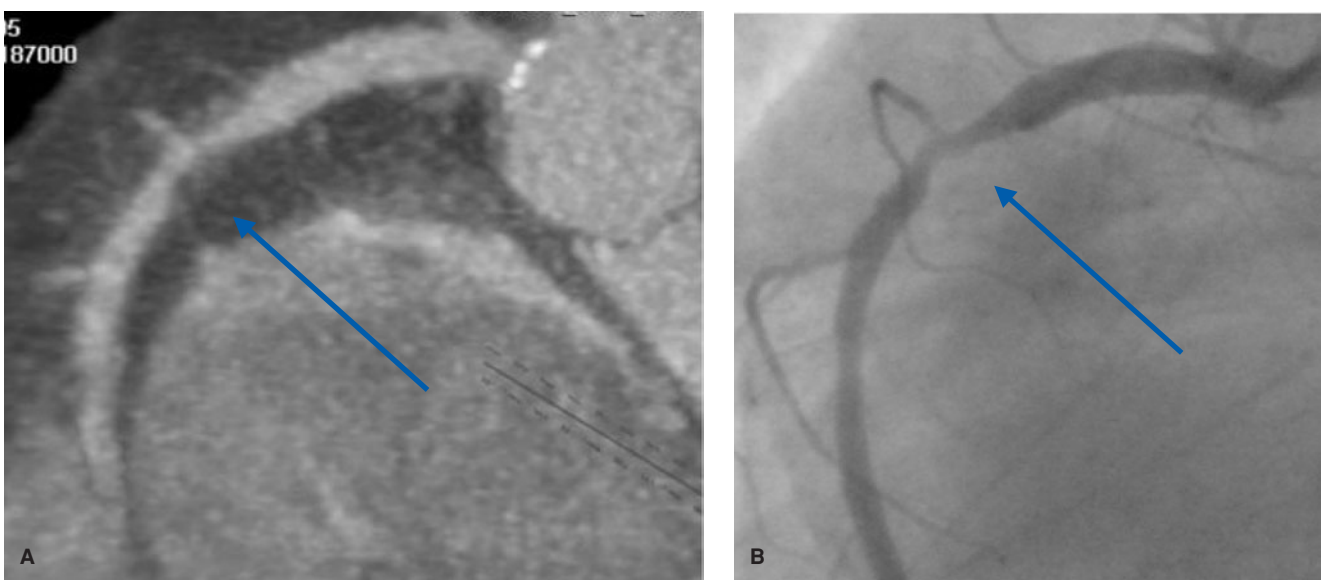

Figure 6-6. Proximal RCA 50% stenosis diagnosed by coronary CTA and confirmed by conventional angiography. Double oblique maximum-intensity projection image (4 mm thick) through proximal RCA (*A*) and LAO projection still image from conventional angiogram (*B*) demonstrate a segment of approximately 50% stenosis (*arrows*).

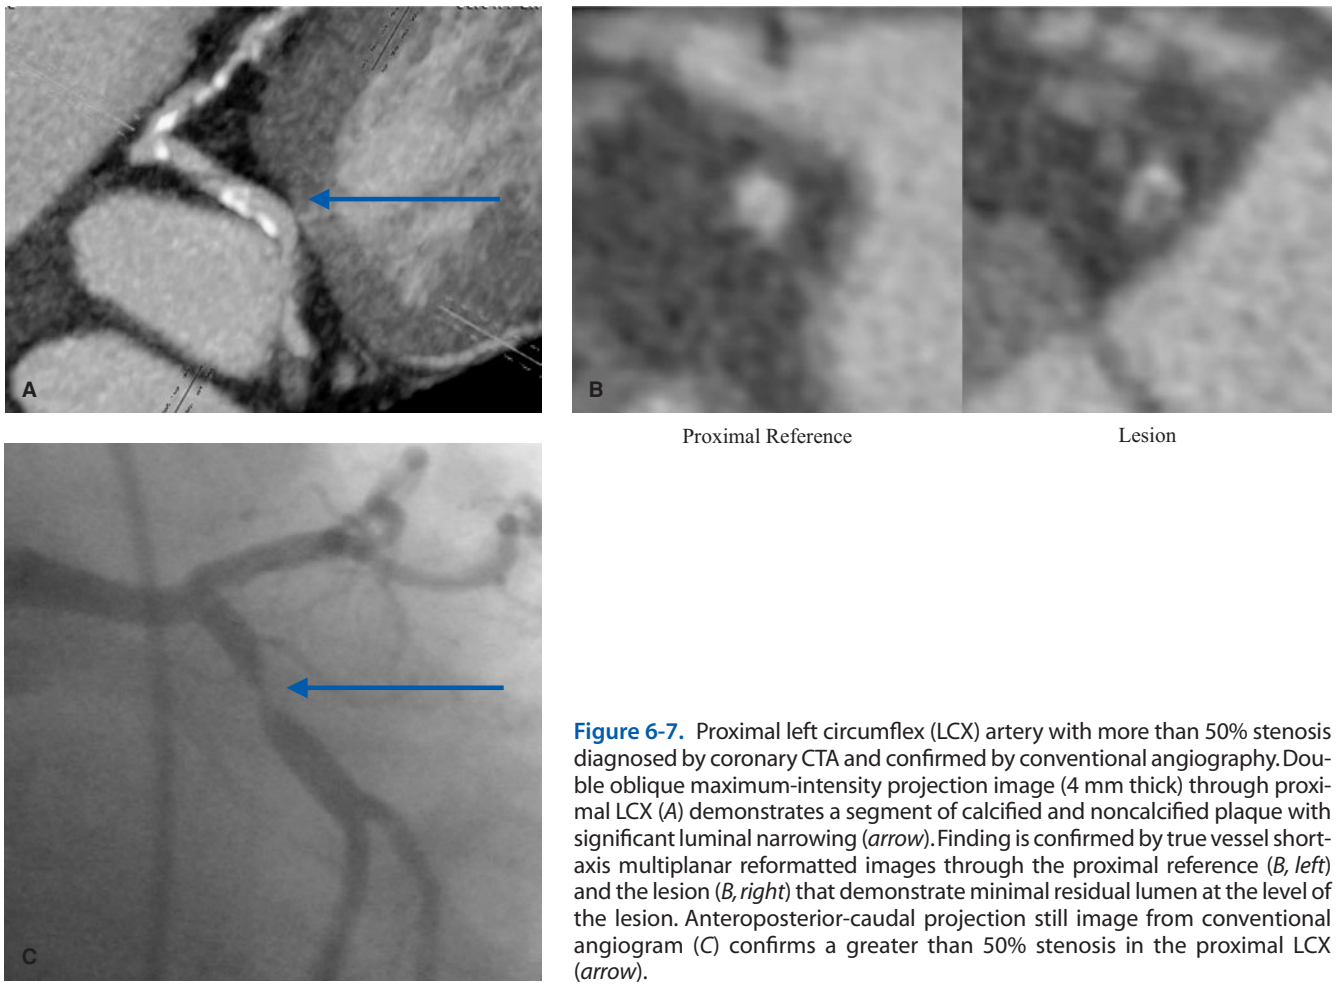

Figure 6-7. Proximal left circumflex (LCX) artery with more than 50% stenosis diagnosed by coronary CTA and confirmed by conventional angiography. Double oblique maximum-intensity projection image (4 mm thick) through proximal LCX (*A*) demonstrates a segment of calcified and noncalcified plaque with significant luminal narrowing (*arrow*). Finding is confirmed by true vessel short-axis multiplanar reformatted images through the proximal reference (*B, left*) and the lesion (*B, right*) that demonstrate minimal residual lumen at the level of the lesion. Anteroposterior-caudal projection still image from conventional angiogram (*C*) confirms a greater than 50% stenosis in the proximal LCX (*arrow*).

excluding coronary artery disease (CAD). Literature to date reports on patient populations with a relatively high prevalence of CAD (i.e., patients already scheduled for DSA).

Table 6-1 summarizes recently published data. The consistently high negative predictive value (NPV) on a per-patient basis (93 to 99%) is the most clinically relevant aspect of presently available data. These data and our experience suggest that cardiac CTA effectively can exclude CAD in patients with a low to intermediate pretest probability of disease. Consequently, CTA has become increasingly useful for the cardiac surgeon in managing patients scheduled for non–coronary artery cardiac surgery. If the clinical suspicion is low but not insignificant, CTA affords the surgeon a method of assessing CAD without subjecting the patient to femoral arterial puncture with its known complications. For example, patients undergoing isolated mitral valve surgery for degenerative myxomatous disease have a low prevalence of CAD, making CTA an ideal alterative to conventional angiography to exclude significant CAD. When the CT protocol described earlier is followed, high-quality imaging is *routine*, and when CTA excludes CAD, some surgeons are beginning to feel comfortable in using CTA alone. In patients in whom image quality is degraded or there is significant disease, CTA then can be followed by DSA and intervention as needed.

Coronary Artery Bypass Graft CTA

Cardiac CT provides the cardiac surgeon with a noninvasive method to assess graft patency after coronary artery bypass grafting (CABG). Studies using 16-slice CT scanners suggest 100% sensitivity and specificity for identifying occluded versus patent grafts.[7–9] In clinical practice, this application is of value in the evaluation of symptomatic patients in the early postoperative period in whom graft failure is being considered (Fig. 6-10). It is particularly useful for the demonstration of patent grafts in patients with a remote surgical history and unknown graft anatomy prior to DSA and in patients in whom conventional angiography fails to demonstrate a known graft (Fig. 6-11). In the reoperative setting, such data have virtually revolutionized decision making and planning prior to surgery in patients who have already undergone CABG.

Patients with recurrent angina after bypass surgery may have developed stenosis or occlusion in bypass grafts or may have progression of native CAD. In these patients, CTA

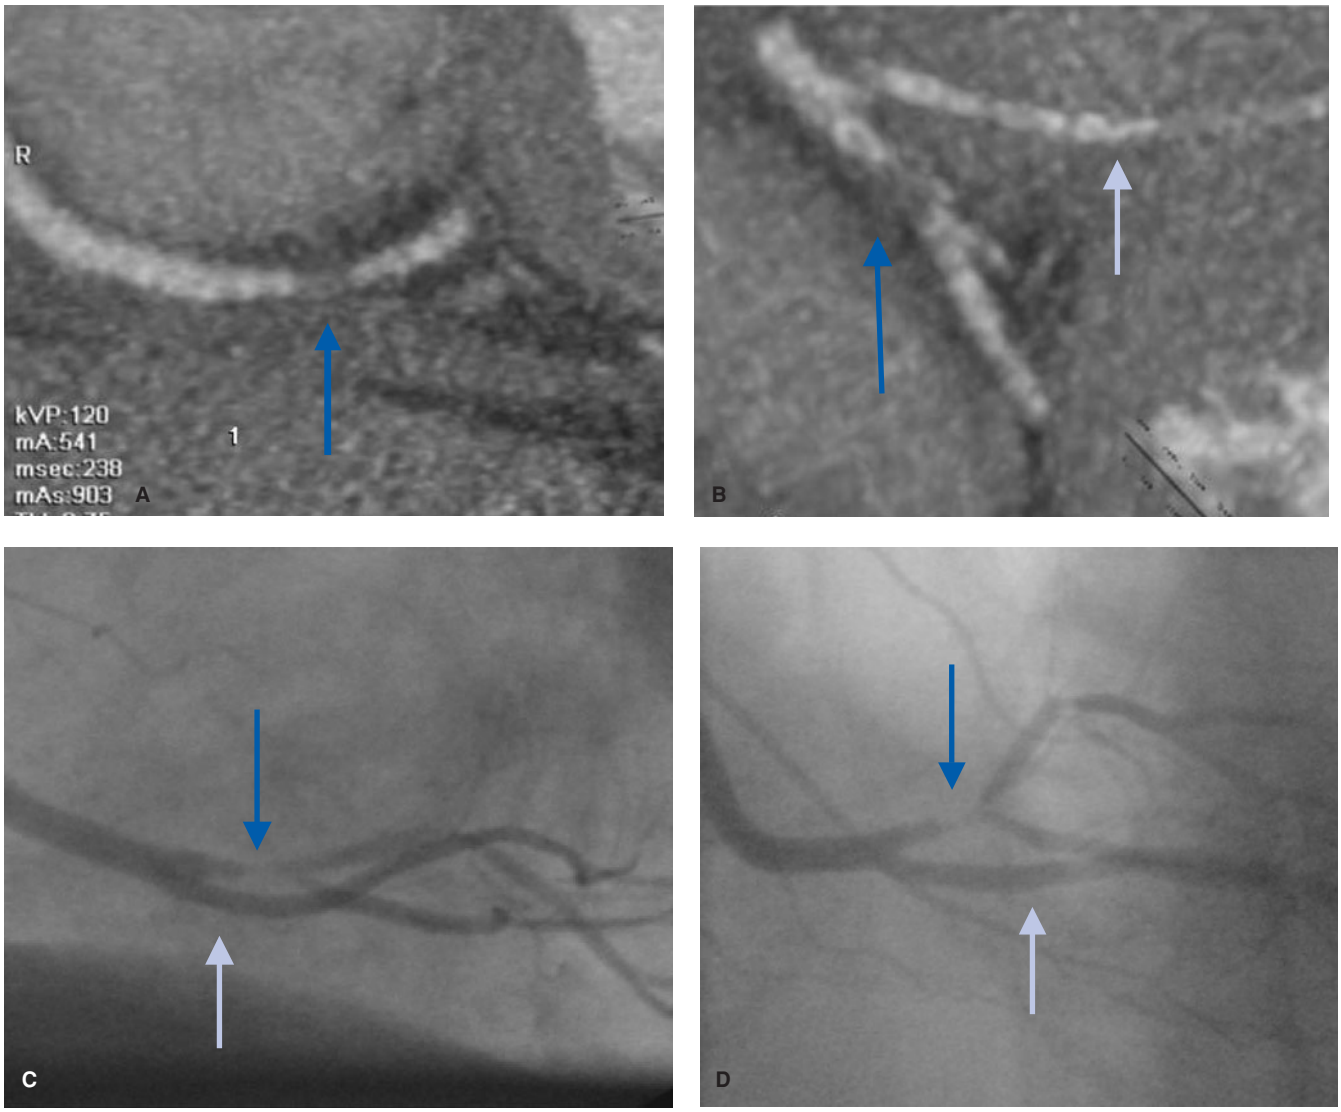

Figure 6-8. Ongoing RCA greater than 50% stenosis diagnosed by coronary CTA and confirmed by conventional angiography. Double oblique maximum-intensity projection images (4 mm thick) through ongoing RCA at 90-degree angles (*A, B*) demonstrate a segment of noncalcified plaque with nonvisualization of lumen (*line arrow*). The PIV is also partially demonstrated (*white arrow*). Finding is confirmed by LAO (*C*) and anteroposterior-cranial (*D*) projection still images via conventional angiogram (*blue arrow*). The PIV is also seen (*white arrow*).

can be more limited. For example, exclusion of significant stenosis in a graft may be problematic owing to metallic surgical clips that cause artifact (Fig. 6-12). Moreover, native CAD in these patients often is advanced and heavily calcified. A large volume of calcium may result in an uninterpretable study for many segments of the native coronary arteries (Fig. 6-13). CTA in such patients may not be definitive; consequently, conventional angiography may be preferred in this population.[10] Obviously, the less calcification and metal artifact present, the more useful CTA is.

In the research context, graft patency is an important outcome in the evaluation of different surgical techniques. Randomized, controlled trials using conventional angiography for assessment of graft patency typically demonstrate a 10 to 20% rate of noncompliance. This noncompliance is at least partly attributable to the invasive nature of the test.[11,12] Cardiac CT is an attractive noninvasive and very accurate method to assess graft patency for clinical trials, again obviating a traditional arterial puncture with its risks and known complications. Cardiac CT also may be used for routine postoperative control of grafts following implementation of a new surgical technique in a local center practice (Fig. 6-14).

The Aorta: The Root, the Ascending Aorta, the Arch, and the Descending Aorta

Surgery of the aortic root, the ascending aorta, the arch, and the descending aorta is becoming increasingly commonplace

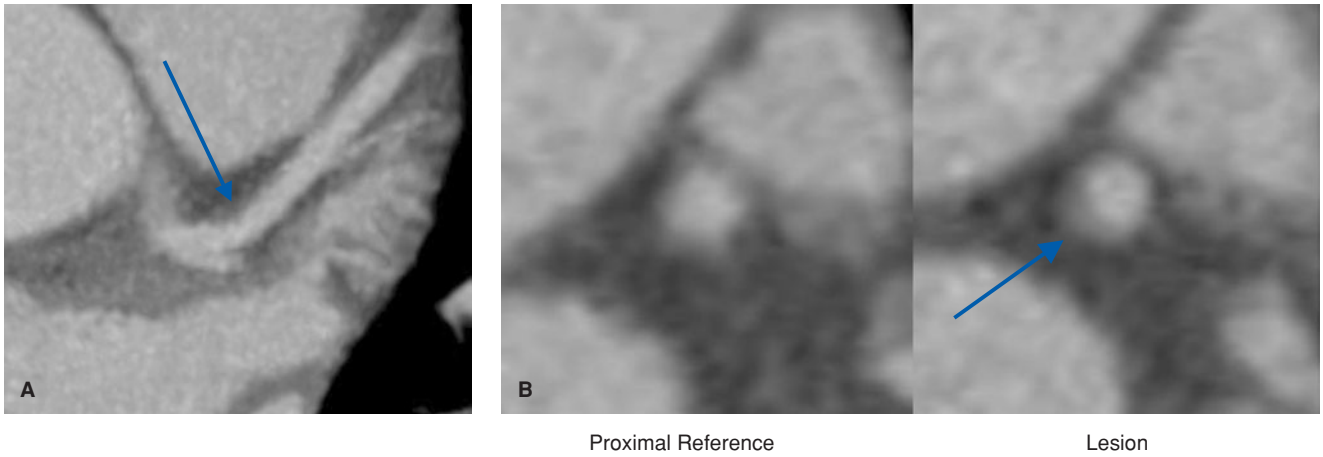

Figure 6-9. Proximal less than 50% stenosis diagnosed by coronary CTA. Double oblique maximum-intensity projection image (4 mm thick) through proximal LAD (*A*) demonstrates a segment of noncalcified plaque that is not associated with any significant luminal narrowing (*arrow*). True vessel short-axis multiplanar reformatted images through the lesion (*B, right*) and through the proximal reference segment (*B, left*) confirm minimal luminal narrowing. Low-density "noncalcified" plaque with positive vessel remodeling is seen (*arrow*). This case highlights the ability of CTA to detect early stages of subclinical atherosclerosis. This lesion may not have been detected during a conventional angiogram.

as the population ages. CT has been used for many years to assess the thoracic aorta. Non–ECG-gated CT is highly accurate in assessment of the aortic arch and descending thoracic aorta because they are not subject to significant cardiac motion. However, ECG-gated cardiac CT adds motion-free imaging of the aortic root and ascending aorta. Without question, any surgery involving the aorta (whether the root, the arch, the ascending, or the descending portion) requires preoperative CTA for surgical decision making. The superior imaging of ECG-gated CTA better defines the pathology and hence facilitates preoperative planning. For example, CTA is by far the best imaging modality to define aortic calcification clearly.

If portions of the aorta are calcified on CTA, then aortic cross-clamping and cannulation for cardiopulmonary bypass at those sites are contraindicated in order to avoid

Table 6–1.

Author	MDCT	Study	*N*	Sens by seg	Spec by seg	Not eval	NPV by patient
Mollet[1]	16	*JACC* 2005 All segments >2 mm	51	95%	98%	n/a	99%
Kuettner[2]	16	*Heart* 2005 All segments	120	85%	98%	7%	96%
Hoffman[3]	16	*JAMA* 2005 All segments >1.5 mm	103	95%	98%	6.4%	95%
Achenbach[4]	16	*Eur Heart J* 2005 All segments >1.5 mm	50	93%	95%	5%	99%
Leschka[5]	64	*Eur Heart J* 2005 All segments	57	94%	97%	n/a	99%
Raff[6]	64	*JACC* 2005 All segments	70	86%	95%	12%	93%

Sens = sensitivity; spec = specificity; seg = segment; eval = evaluable; NPV = negative predictive value.

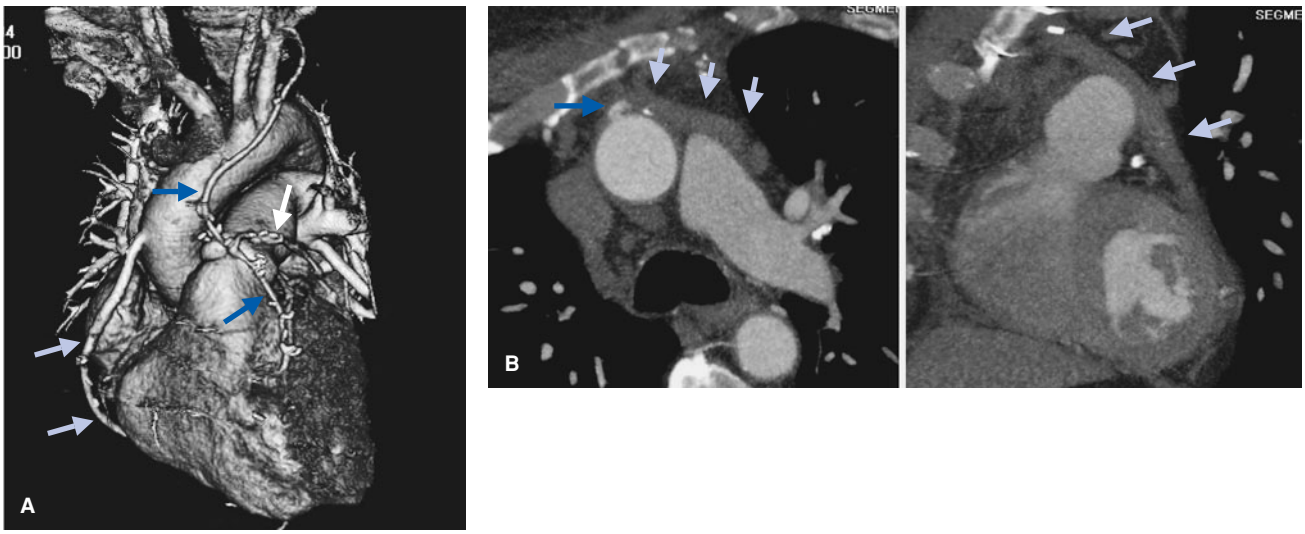

Figure 6-10. Cardiac CT performed for evaluation of graft patency in the postoperative setting. Three-dimensional volume-rendered image demonstrates patent left IMA to LAD (*blue arrows*), T-graft right IMA to obtuse marginal (*white arrow*), and SVG to RCA (*gray arrows*). This study was obtained in a patient 1 day following off-pump CABG. The patient had developed recurrent chest pain and elevated troponin. Cardiac CT ruled out early graft failure as a cause for the patient's presentation. Oblique multiplanar reformatted images (*B*) in a second patient demonstrate an acutely occluded saphenous vein graft to obtuse marginal. Note the patent graft stump (*blue arrow*) and thrombosed graft body (*gray arrows*).

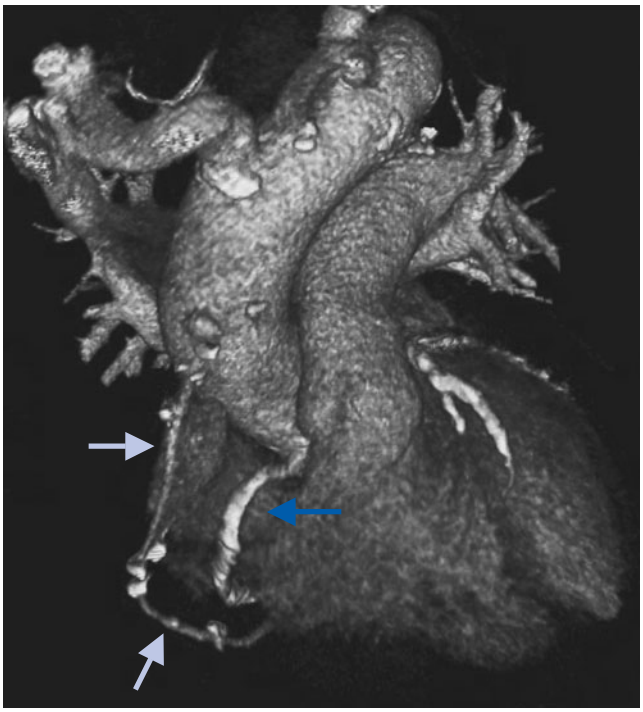

Figure 6-11. Cardiac CT performed to evaluate possible radial graft occlusion. The patient had surgery 1 month prior and presented with recurrent angina. The radial-to-RCA graft could not be selectively catheterized at conventional angiography and also was not seen at aortic root injection. Three-dimensional volume-rendered image demonstrates patent radial graft (*gray arrows*) to RCA (*blue arrow*). The anastomosis is not seen on this orientation.

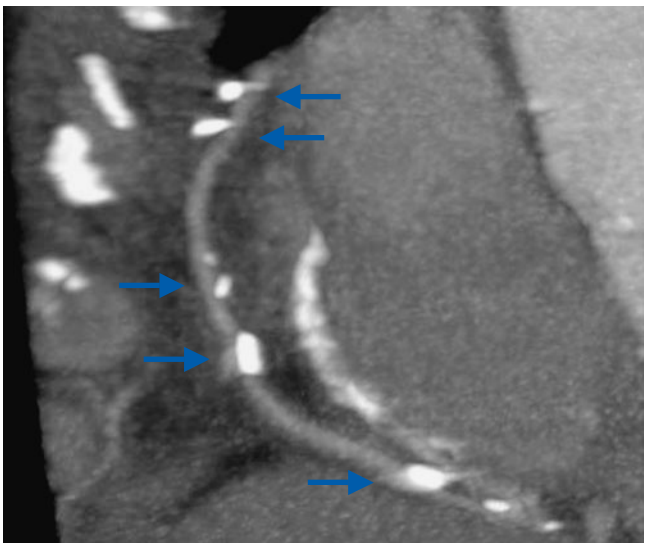

Figure 6-12. Surgical clip artifacts can limit cardiac CT evaluation of coronary bypass grafts significantly. Double oblique maximum-intensity projection image (10 mm thick) demonstrates multiple surgical clips placed along the length of a radial-to-PIV graft (*blue arrows*). Artifact from these metallic clips can partially or completely obscure the adjacent vessel lumen, precluding evaluation of these segments for the presence or absence of stenosis. Although CT can unequivocally demonstrate graft patency, surgical clip artifact usually does not allow complete graft evaluation to rule out graft stenosis.

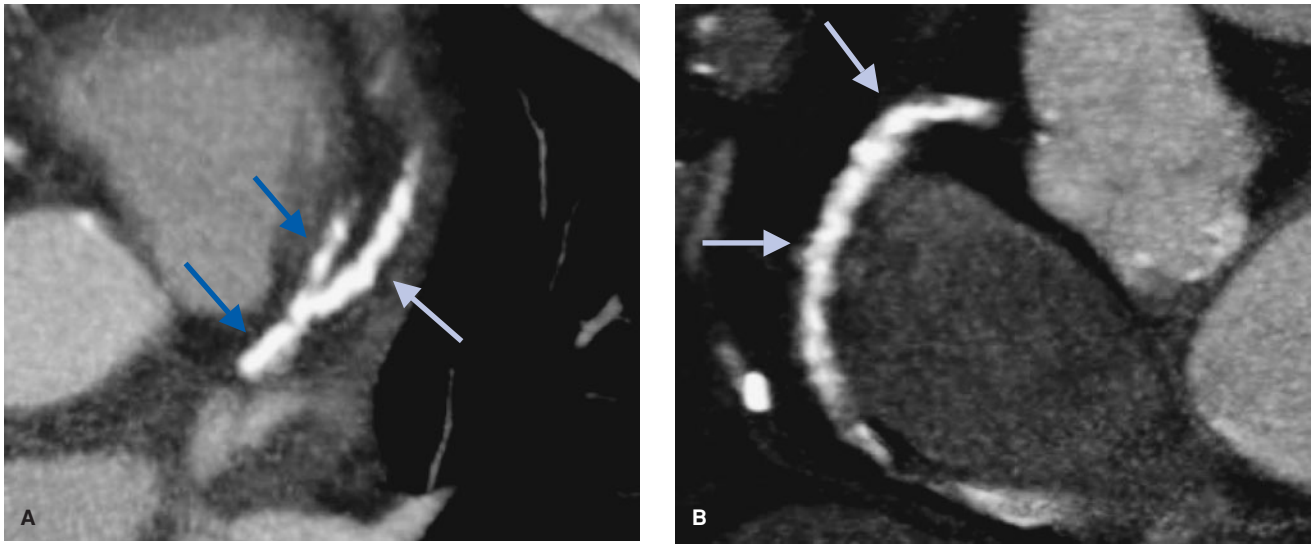

Figure 6-13. Cardiac CT often is limited in its evaluation of native coronary arteries in the post-CABG patient owing to the presence of advanced and heavily calcified coronary atherosclerosis. Double oblique maximum-intensity projection image (4 mm) demonstrates (*A*) the proximal LAD (*blue arrows*) and a large first diagonal branch (*gray arrow*) and (*B*) the proximal right coronary artery (*gray arrows*). The white areas represent calcification. All vessel segments shown are heavily calcified. The extent of calcification completely obscures the vessel lumen, and the presence or absence of stenosis cannot be assessed reliably.

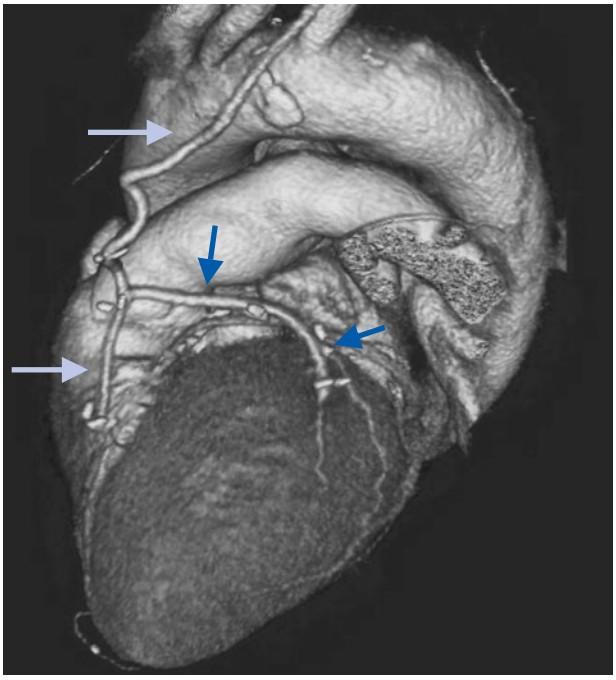

Figure 6-14. Cardiac CT obtained for postoperative graft control in a patient who underwent MVST. Three-dimensional volume-rendered image demonstrates patent left IMA-to-LAD (*gray arrows*) and radial T-graft to obtuse marginal (*blue arrow*).

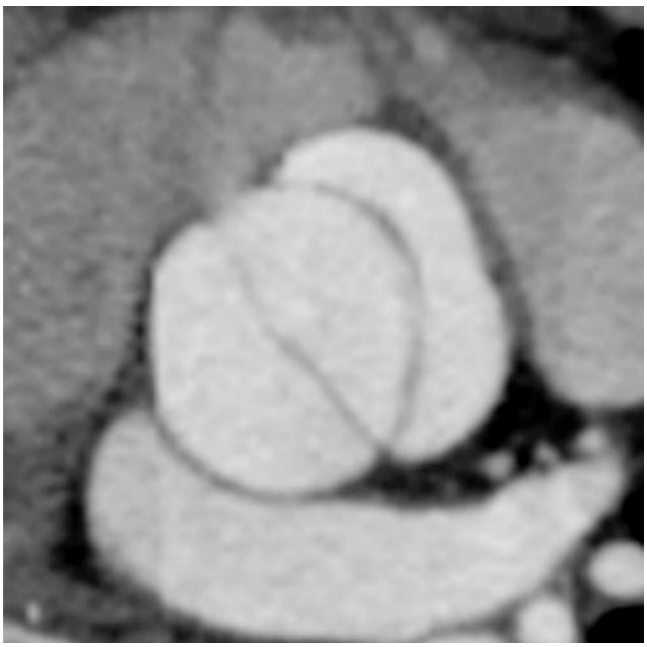

Figure 6-15. Demonstration of aortic root and aortic valve. Axial oblique multiplanar reformatted image from a systolic data set demonstrates an open bicuspid aortic valve. Note the precise definition of the aortic wall, free from the cardiac motion–related artifacts that are present in conventional thoracic CT scanning. Aortic root size measurements are highly accurate owing to a lack of motion artifacts and the high spatial resolution of the cardiac CT scanning (<0.5 mm).

embolic phenomena and stroke. Thus preoperative cardiopulmonary bypass strategy and myocardial protection often are altered critically by preoperative CTA.

As with calcification, CT is the most accurate modality to evaluate the aortic root, with both two-dimensional (2D) and three-dimensional (3D) visualization (Fig. 6-15). Not only can the aortic root be sized from multiple imaging planes, but also the exact location of the aneurysmal pathology with respect to the valve and sinotubular junction often can be defined. This assessment is critical for preoperative decision making and surgical planning. In patients with ascending aortic aneurysms, if the aortic root is determined to be aneurysmal near the coronary ostia, surgical decision making changes from a simple tube-graft repair for the aneurysm to a much more complex composite root repair with coronary reimplantation. In addition, motion-free images obtained with ECG gating allow for definitive exclusion of type A dissection (Fig. 6-16). Three-dimensional volume rendering optimally depicts other aortic root pathologies such as coronary artery anomalies or a sinus of Valsalva

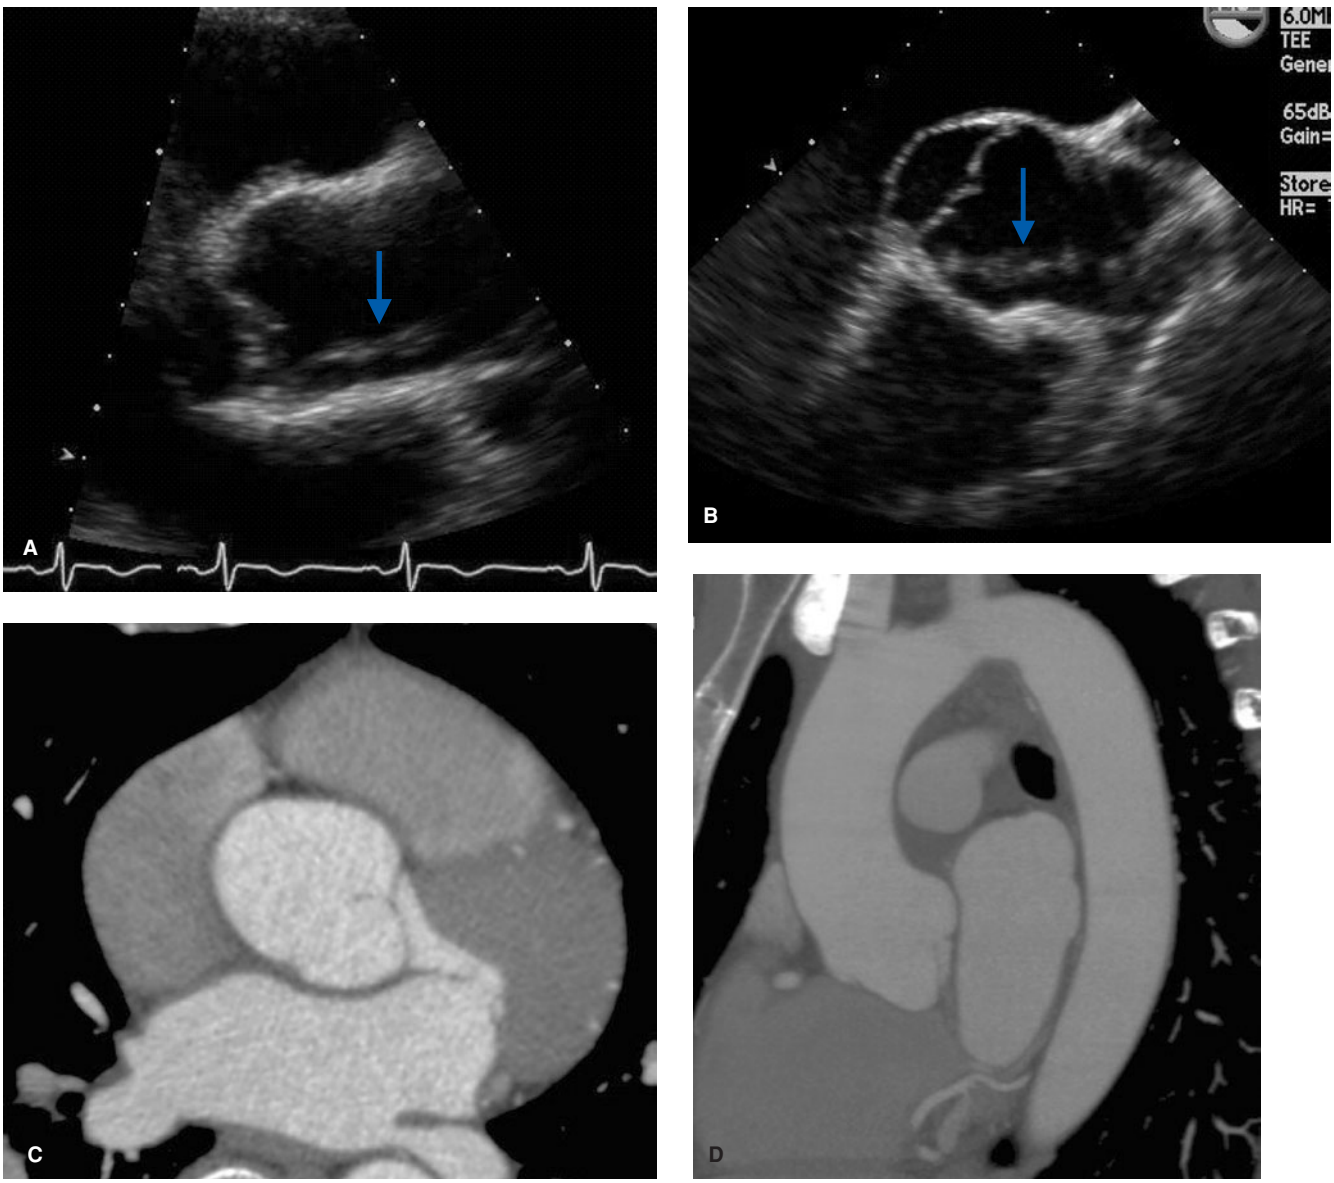

Figure 6-16. Although multiple modalities may be used for evaluation of the aortic root, with recent technical advances, cardiac CT is the "gold standard" for the exclusion of type A dissection. Parasternal long-axis image from transthoracic echocardiogram (*A*) demonstrates a linear area of echogenicity (*white arrow*) above the noncoronary cusp of the aortic valve, concerning for an intimal flap. The finding was detected incidentally in a patient with recent stroke and possible patent foramen ovale. Subsequent transesophageal echocardiogram (*B*) again demonstrates the finding. Axial image from cardiac CT scan (*C*) provides excellent visualization of the aortic root and excludes the presence of an intimal flap. Sagittal oblique maximum-intensity projection image (*D*) shows the aortic root and ascending aorta to be normal. Echocardiographic findings were presumed to be due to artifact.

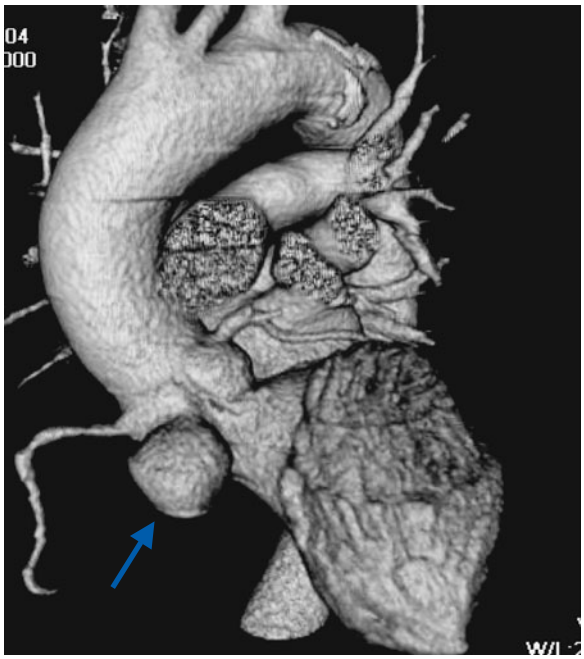

Figure 6-17. Cardiac CT provides optimal visualization of complex aortic root pathology. Prior echocardiogram suggested the entire aortic root to be aneurysmal at more than 4.5 cm in this patient. Three-dimensional volume-rendered image from cardiac CT demonstrates a 2.6-cm sinus of Valsalva aneurysm arising off the right coronary sinus (arrow). The remainder of the aortic root is normal. Using saline flush and thresholding techniques for image display, high-resolution unobstructed visualization of such lesions is possible.

aneurysm (Fig. 6-17). In patients with a sinus of Valsalva aneurysm, as opposed to a root aneurysm, CT alters surgical strategy for repair.

For known ascending aortic aneurysms that do not meet size criteria for surgery, CTA represents the optimal study for periodic assessment of size or change. For patients who require surgery, CTA with 3D volume-rendered images provides the surgeon with preoperative visualization of aneurysm size and extent. The extension of an ascending aortic aneurysm into the arch can be demonstrated, and as mentioned earlier, the expected location of aortic cross-clamping can be determined preoperatively (Fig. 6-18). The location of normal aorta distally and the extent of arch involvement preoperatively will determine the arterial cardiopulmonary bypass cannulation site as well as the need for concomitant arch repair, circulatory arrest, or selective antegrade perfusion. Selective antegrade cerebral perfusion itself depends on intact right axillary and innominate arteries, and CTA is optimal for defining this anatomy. Since the success of a procedure can be compromised by unexpected intraoperative findings, CT has contributed enormously to surgical planning by defining anatomy that would not be visualized preoperatively with any other imaging modality.

In patients with aortic dissection, CTA allows the surgeon to understand the extent of the intimal flap. In particular, ECG-gated CT offers information regarding dissection of the ascending aorta (the proximal extent of the dissection flap and its relationship to the coronary arteries and the aortic valve) that was not available before gating was performed routinely. The location of the true and false lumen is critical in the preoperative planning, the operative sequence, and the extent of repair. For example, in dissection of the descending aorta, end-organ perfusion is assessed by demonstrating contrast enhancement of individual organs and related compromise of the celiac, superior mesenteric, inferior mesenteric, or renal artery. As is the case for a nonsurgical aneurysm, if a descending thoracic aortic dissection is stable and to be followed expectantly, CTA remains the "gold standard" for periodic assessment.

Cardiac Masses

Cardiac MRI is the modality used most commonly for high–spatial-resolution cross-sectional imaging to evaluate cardiac

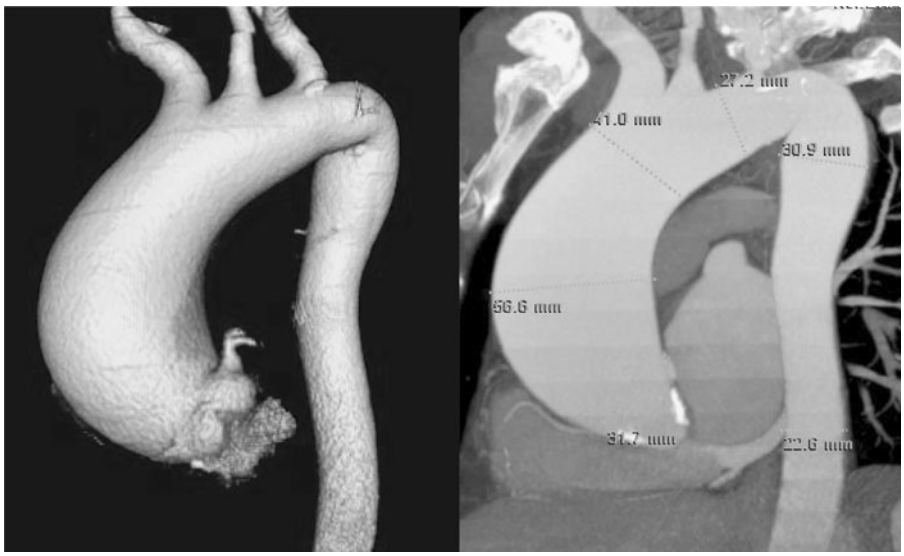

Figure 6-18. Comprehensive evaluation of ascending aortic aneurysm for preoperative planning. On the left, three-dimensional volume-rendered image demonstrates an aneurysmal ascending aorta. Sagittal oblique maximum-intensity projection image (20 mm thick) can be used to demonstrate aortic size measurements. The aneurysm can be seen to extend into the aortic arch. Since the entire ascending aorta and proximal arch needed to be replaced, cross-clamping could not occur proximal to the innominate artery in this patient and would have to occur in the middistal arch, altering the surgical risk of the procedure.

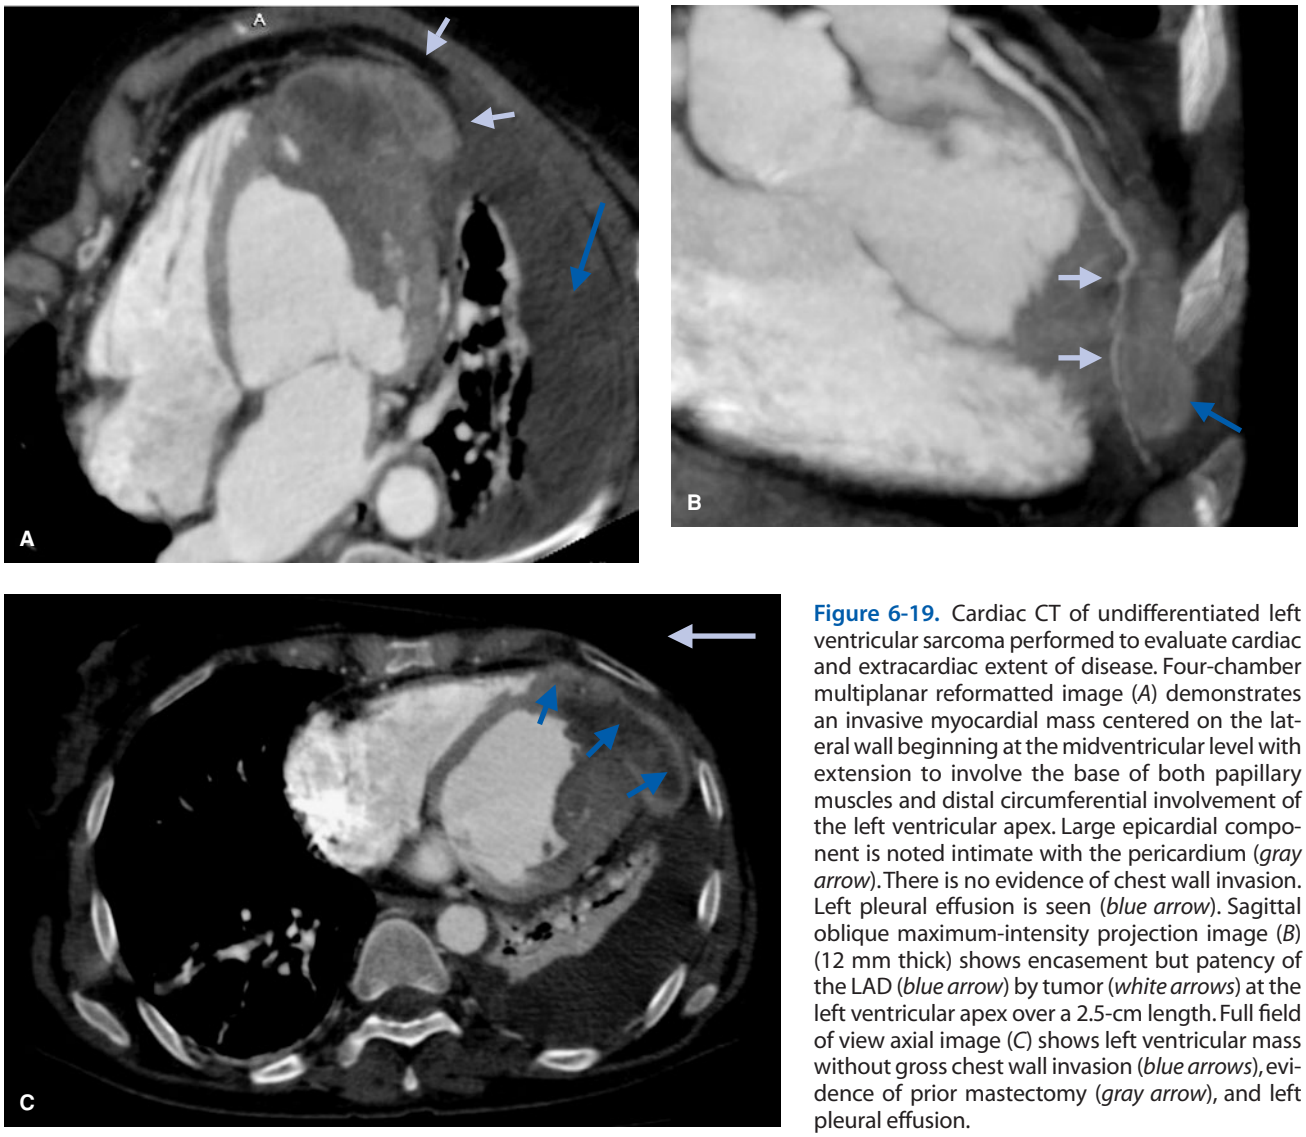

Figure 6-19. Cardiac CT of undifferentiated left ventricular sarcoma performed to evaluate cardiac and extracardiac extent of disease. Four-chamber multiplanar reformatted image (*A*) demonstrates an invasive myocardial mass centered on the lateral wall beginning at the midventricular level with extension to involve the base of both papillary muscles and distal circumferential involvement of the left ventricular apex. Large epicardial component is noted intimate with the pericardium (*gray arrow*). There is no evidence of chest wall invasion. Left pleural effusion is seen (*blue arrow*). Sagittal oblique maximum-intensity projection image (*B*) (12 mm thick) shows encasement but patency of the LAD (*blue arrow*) by tumor (*white arrows*) at the left ventricular apex over a 2.5-cm length. Full field of view axial image (*C*) shows left ventricular mass without gross chest wall invasion (*blue arrows*), evidence of prior mastectomy (*gray arrow*), and left pleural effusion.

and pericardial masses. However, CT may be preferred if the mass is known to extend into the mediastinum, chest wall, or lung or if the patient has a contraindication to MRI. CT also evaluates extracardiac thoracic structures with high spatial resolution; thus it can define the full extent of disease (Fig. 6-19). CT is also useful as a single follow-up examination in patients with metastases to the heart and lungs because it avoids the need for periodic assessment with both conventional chest CT and cardiac MRI. Fat-containing lesions are very amenable to evaluation by CT because lesions have a characteristic appearance, appearing black relative to water (Fig. 6-20).

Imaging of the Pericardium

In patients with clinically suspected constrictive pericarditis, cardiac MRI or CT can be used to confirm and measure pericardial thickening. In comparison with MRI, CT far better demonstrates the presence and extent of calcification. This may be of value in confirming chronic calcific pericardial thickening, supporting the diagnosis of constrictive pericarditis (Fig. 6-21). In these cases, 3D volume rendering to illustrate regional localization of pericardial abnormality functions as an outstanding preoperative planning tool prior to pericardial stripping (Fig. 6-22).

Valve Imaging

In patients with suspected valve dysfunction based on echocardiography, cine CT provides valuable additional data. As discussed earlier, reconstruction is performed for all phases of the cardiac cycle, and the reformatted data can be played in a cine loop. For example, cardiac cine CT permits high-resolution functional evaluation of mechanical aortic valve prostheses (Fig. 6-23).

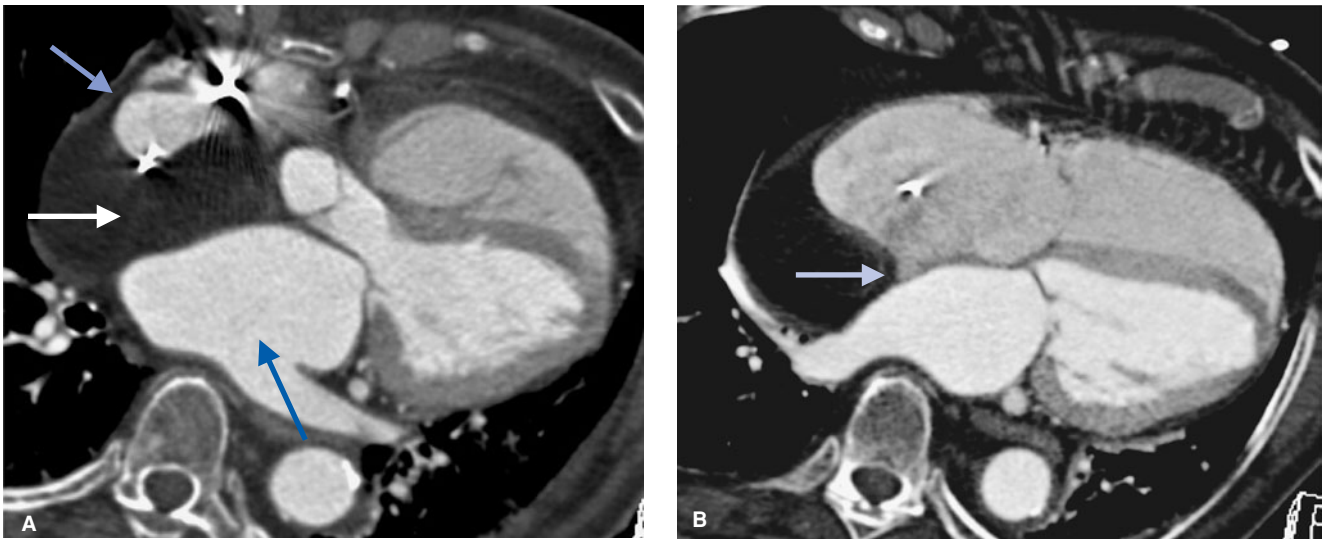

Figure 6-20. Lipomatous hypertrophy of the interatrial septum. Oblique axial multiplanar reformatted image (*A*) demonstrates a low-attenuation mass (*white arrow*) insinuated between the SVC (*gray arrow*) and the left atrium (*blue arrow*). Second more caudal image (*B*) demonstrates characteristic sparing of the fossa ovalis (*gray arrow*). This lesion is nonencapsulated and can be quite extensive, as in this case. Note the presence of leads from pacemaker, which precluded an MRI.

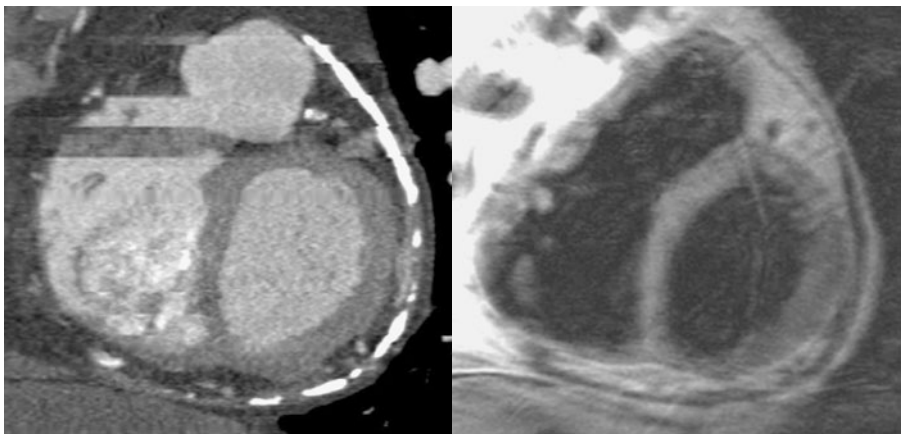

Figure 6-21. Calcific constrictive pericarditis. Short-axis multiplanar reformatted image from cardiac CT demonstrates extensive thickening and calcification involving left-sided pericardium. In the appropriate clinical setting, these findings would support the diagnosis of constrictive pericarditis. Short-axis double inversion recovery fast–spin-echo image from cardiac MRI in the same patient also shows abnormal pericardial thickening but is insensitive to calcification.

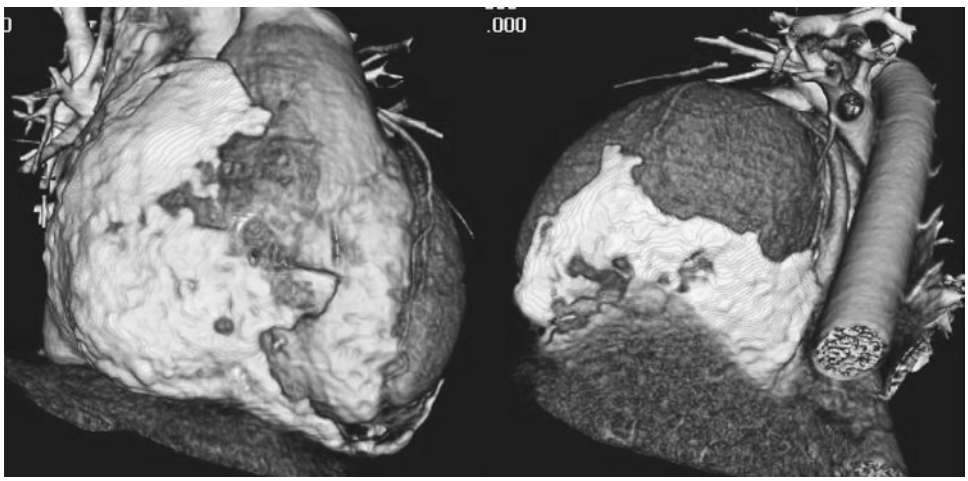

Figure 6-22. Preoperative evaluation of chronic calcific pericardial thickening prior to pericardial stripping. Three-dimensional volume-rendered images from cardiac CT demonstrate extensive regional pericardial calcification (*white areas*). This includes over the right ventricular outflow tract, right ventricle, right atrium, and entire inferior wall extending inferolaterally. Anterior and anterolateral pericardium was normal.

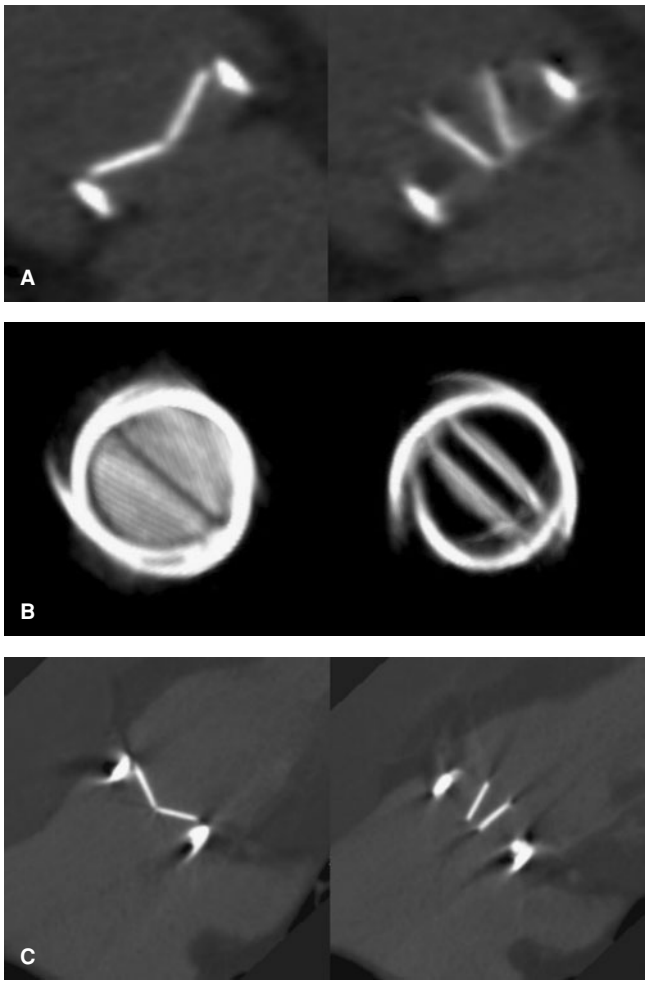

Figure 6-23. Evaluation of mechanical valve function with cardiac CT. Coronal oblique multiplanar reformatted images (*A*) demonstrate closed and open positions of mechanical AVR in a patient with suspected valve dysfunction based on echo-Doppler. Axial oblique slab maximum-intensity projection images (*B*) demonstrate closed and open positions of mechanical AVR in a patient in atrial fibrillation at the time of cardiac CT. Although image quality is degraded by arrhythmia, optimization of the data set with ECG editing can result in diagnostic-quality images. Four-chamber oblique multiplanar reformatted images (*C*) demonstrate closed and open positions of a mechanical MVR. Images can be generated over the cardiac cycle and displayed in a cine movie format to allow dynamic evaluation of valve function. Since the study is performed with contrast material, thrombus or perivalvular abscess also can be identified, if present.

Preoperative Planning and Surgical Guidance

Reoperative surgery

Reoperative cardiac surgery with live coronary artery grafts after previous CABG represents one of the most difficult problems in cardiac surgery. Reoperative sternotomy is challenging secondary to adhesions, loss of tissue planes, and the potential for injury to patent grafts, the aorta, and the right ventricle. Injury to a patent left internal thoracic artery graft to the LAD is associated with a mortality of 50%.[13,14] Cardiac CT has been revolutionary in precisely defining the relationship of important structures (e.g, the aorta, right ventricle, or live grafts) to the midline and sternum for re-entry planning (Fig. 6-24). At BWH, every reoperative surgery includes a preoperative CTA with *z*-axis coverage to include all grafts and the entire course of the IMAs. Preoperative identification of all structures at risk is mandatory, and different, specific operative approaches always remain in consideration.[15] Recent reported experience suggests that preoperative cardiac CT will lead to a modification in surgical strategy for 1 in 5 patients undergoing redo cardiac surgery.[16] For example, if CT demonstrates a patent left IMA is close to the midline or a right ventricle directly adherent to the posterior table of the sternum, cardiopulmonary bypass is instituted prior to reentry. Definition of live grafts with respect to their proximal placement on the aorta is instrumental in determining, *before the operation,* the precise manner in which those grafts will be handled. For example, in reoperative surgery for aortic valve replacement (AVR) in the setting of live grafts, CTA allows the surgeon to plan preoperatively whether or not those grafts will have to be divided in carrying out the aortotomy for the AVR. As described earlier, CT also allows the cardiac surgeon to plan the precise location of the aortotomy itself preoperatively.

Minimally invasive surgery: CABG

Minimally invasive CABG surgery is becoming an alternative to open surgery. With limited intraoperative access for direct visualization, aspects of coronary artery anatomy such as vessel diameter, extent of calcification, and presence of intramyocardial segments become even more important to define preoperatively (Fig. 6-25). In addition, 3D models that combine visualization of a partially transparent thoracic cage over mediastinal structures allow the surgeon to obtain detailed preoperative understanding of the patient's cardiothoracic anatomy (Fig. 6-26). Preoperative CT has demonstrated usefulness for MIDCAB[17] and totally endoscopic coronary artery bypass surgery.[18] CT is also expected to become invaluable for procedures such as multivessel small thoracotomy coronary artery revascularization.

CT versus MRI of the Heart

Throughout this chapter, comparisons between CT and MRI have illustrated the strengths and limitations of each. Both modalities give the surgeon valuable pre- and postoperative information. While the modality best suited for specific clinical indications evolves with the technology, at present, certain generalizations can be made. Cardiac CT is invaluable in reoperative cardiac surgery because it offers higher-quality noninvasive angiography of native coronary arteries and bypass grafts. Since 3D volume rendering with CT has higher quality and better spatial resolution, it is preferred for preoperative planning for reoperative CABG or minimally invasive cardiac surgery. All calcification is poorly seen with MRI and superbly seen with CT, and thus CT is far superior in demonstrating coronary, myocardial,

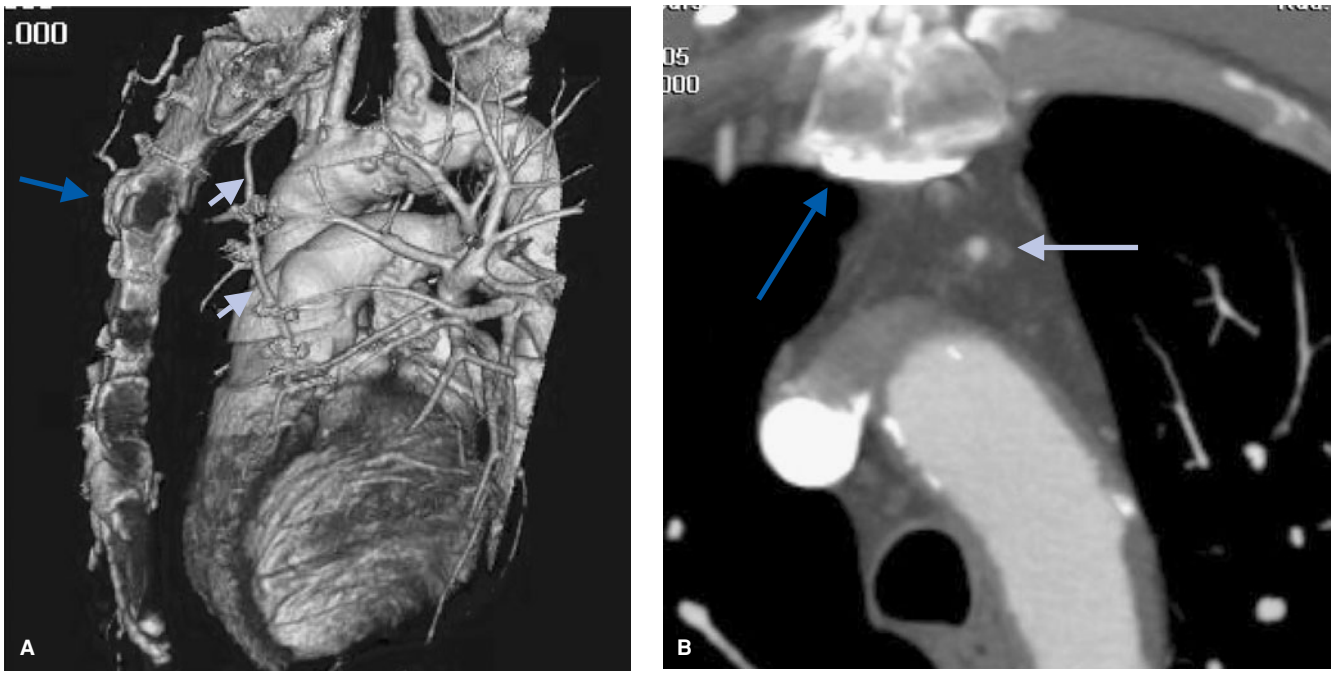

Figure 6-24. Planning for reoperative CABG. Laterally oriented 3-D volume-rendered image (*A*) from a patient who had previously undergone left IMA coronary bypass grafting. The left IMA (*gray arrows*) is grafted to the LAD coronary artery. Note the relatively large distance between the grafted left IMA and the sternum (*blue arrow*). Axial image (*B*) clearly shows the left IMA graft (*gray arrow*) to be clear of the midline and well posterior to the sternum (*blue arrow*). Since the most common surgical approach in a redo CABG is repeat thoracotomy through the sternal incision, this study demonstrates that surgical revascularization through sternal re-entry has no significant risk of damage to the patent left IMA graft.

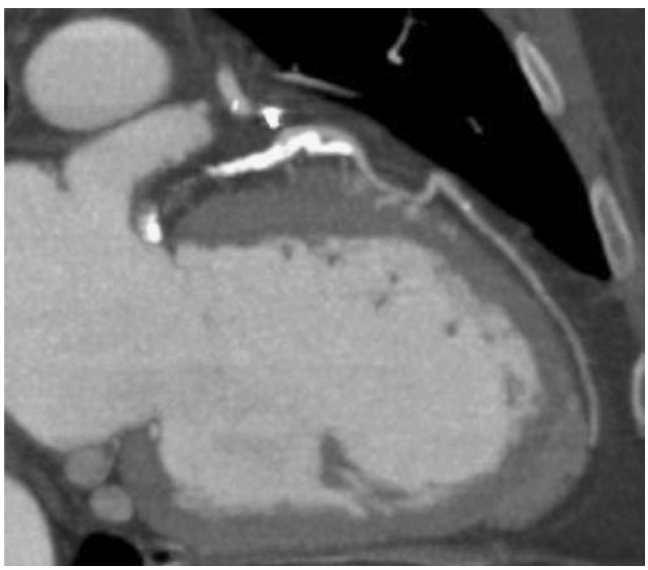

Figure 6-25. Preoperative planning for minimally invasive cardiac surgery (MIDCAB). Two-chamber plane maximum-intensity projection image (6 mm thick) demonstrates the LAD. A segment of heavy calcification is identified in the proximal vessel that corresponds to the site of the stenotic lesion. No significant calcification is present in the remainder of the vessel. An intramyocardial segment is present immediately beyond the calcified segment.

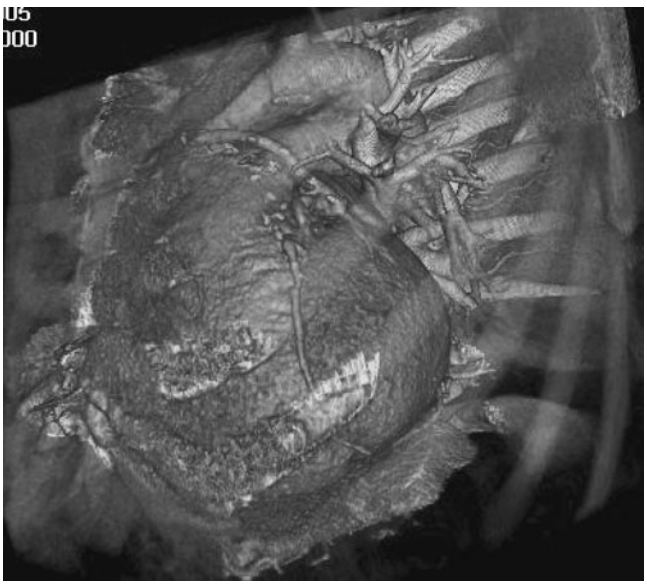

Figure 6-26. Preoperative planning for minimally invasive cardiac surgery (MIDCAB). Specialized display protocols for 3-D volume-rendered images can be used to provide combined visualization of a semitransparent thoracic cage and underlying cardiac and mediastinal structures. These models can be rotated and viewed from any angle or degree of magnification. With cardiac CT, 3-D localization of target vessels, accessibility from proposed incision site, and position of left ventricular apex with respect to chest wall all can be understood preoperatively.

pericardial, and valvular calcification. The same is true for mechanical valve prostheses; because of large areas of artifact on MRI images, functional evaluation is possible only with CT. Finally, all patients with a surgical problem of the aorta require evaluation with CT.

The strengths of MRI include higher temporal resolution, greater blood–myocardial image contrast, multiparametric functional evaluation, and techniques for myocardial tissue characterization. In addition, cardiac MRI is invaluable in assessing myocardial function, contractility, and actual tissue perfusion and viability. For these reasons, MRI remains the "gold standard" to assess biventricular volumes and function and myocardial mass. A number of MRI pulse sequences can delineate areas of chronic myocardial infarction accurately, identify certain specific cardiomyopathies, and confirm the presence of neoplasm. With the use of parallel imaging techniques to increase the speed of the MRI acquisition, very high temporal resolution (20 to 30 ms) can be obtained to study bioprosthetic and native valve function. In addition, measurements of flow parameters through a vessel cross section can be used, for example, to quantify valvular regurgitant lesions accurately.

One distinct advantage of MRI over CT is that MRI delivers no patient radiation. As detailed earlier, the radiation exposure in ECG-gated CT is higher than that for CT of any other body part. In younger patients, who typically have less comorbid disease and may require multiple follow-up examinations over years or decades, MRI should be used when possible.

CONCLUSIONS

Dramatic progress in CT technology has enabled advanced cardiac imaging for cardiac surgery patients. As the newest cardiac imaging modality to enter clinical practice, cardiac CT has rapidly demonstrated broad-ranging applicability, and in particular, CT has revolutionized the preoperative assessment of patients for reoperative surgery. Understanding the technical considerations will allow the surgeon to appreciate the inherent strengths and weaknesses of cardiac CT and to optimally communicate with the radiologist. This, in turn, will result in the best-quality diagnostic examination in the vast majority of cardiac surgery patients.

CHAPTER 7

Risk Stratification and Comorbidity

Victor A. Ferraris • Fred H. Edwards • David M. Shahian • Suellen P. Ferraris

HISTORICAL PERSPECTIVES AND THE PURPOSE OF OUTCOME ASSESSMENT

Hunter, Nightingale, Codman, and Cochrane

> It may seem a strange principle to enunciate as the very first requirement in a Hospital that it should do the sick no harm. It is quite necessary, nevertheless, to lay down such a principle, because the actual mortality in hospitals . . . is very much higher than . . . the mortality of the same class of diseases among patients treated out of hospital.
>
> Florence Nightingale, 1863

From the dark ages until the 1700s, medicine advanced little. Remedies such as blood letting, cathartics, emetics (purges), and blistering were used to treat everything from gunshot wounds to smallpox. These were the only options and not only were ineffective but also often made things worse. As is so often true, before progress can be made, it is necessary to recognize where we stand at present. Arguably, it took at least one person to do this, John Hunter. He was relatively uneducated by the standards of the time. He came to London from his family farm in Scotland to work for his brother, a physician. His brother gave him the task of securing cadavers for anatomy experiments. This often involved illicit actions such as robbing freshly dug graves and associating with the seedier parts of London society. John Hunter had two qualities that allowed him to succeed and become the preeminent surgeon of the time and the father of modern surgery.[1] He had the ability to see things as they really were, and he had great technical skill. He recognized right away that the current remedies of the time were ineffective and that it was often better to do nothing than to subject patients to the current interventions. He was one of the earliest surgeons to recognize that human illness has anatomic causes and explanations. More important, he was unwilling to accept hypothetical abstract explanations of illness such as "humors" or "spirits." He required that he verify causes of illness himself and that he could explain them on the basis of anatomy. For example, treatment of venereal disease was an important part of a physician's practice in the mid-1700s. Hunter was outspoken about the failure of the majority of medications claiming to cure gonorrhea. He was quoted as saying that "gonorrhea could be cured by the most ignorant, since gonorrhea mostly cures itself." He even performed an ingenious test by treating some of his patients with pills made of bread. He recorded the results, and almost all the patients had resolution of gonorrhea. This was one of the first trials documenting the placebo effect. In Hunter's time, gonorrhea and syphilis were thought to be different manifestations of the same infection. Hunter injected himself with what he thought was gonorrhea in order to study the natural history of the disease.[1] Hunter's approach often was unpopular, and it took a person who was not brought up in the mold of the current physicians of the time to stand back and ask these important questions about illness, disease, and outcomes. John Hunter's friends and patients included Benjamin Franklin, Edward Jenner, Lord Byron, Casanova, and Adam Smith. His list of enemies probably was equally distinguished. What is clear is that the assessment of outcomes of illness could not advance without the likes of someone like John Hunter.

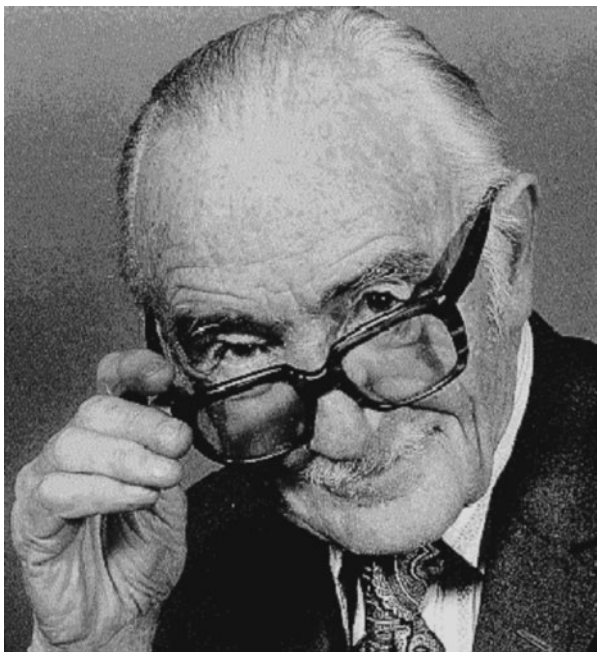
The formal assessment of patient care had its beginnings in the mid-1800s. One of the earliest advocates of analyzing outcome data was Florence Nightingale, who was troubled by observations that hospitalized patients died at higher rates than those treated out of hospital.[2] She also noted that there was a vast difference in mortality rates among different hospitals, with London hospitals having as high as a 90% mortality rate and smaller rural hospitals having a much lower mortality rate (12 to 15%). Although England had tracked hospital mortality rates since the 1600s, the

analysis of these rates was in its infancy. Yearly mortality statistics were calculated by dividing the number of deaths in a year by the average number of hospitalized patients on a single day of that year. Nightingale made the important observation that raw mortality rates were not an accurate reflection of outcome because some patients were sicker when they presented to the hospital and therefore would be expected to have a higher mortality. This was the beginning of risk adjustment based on severity of disease. She was able to carry her observations to the next level by suggesting simple measures such as improved sanitation, less crowding, and location of hospitals distant from crowded urban areas that ultimately would result in dramatic improvement in patient outcomes—an example of a quality improvement project (see below).

Ernest Amory Codman, a Boston surgeon, was one of the most outspoken early advocates of outcome analysis and scrutiny of results. Codman was a classmate of Harvey Cushing and became interested in the issues of outcome analysis after a friendly bet with Cushing about who had the lowest complication rate with the delivery of anesthesia. In the early 1900s as medical students, they were responsible for administering anesthesia. Since vomiting and aspiration were common on induction of anesthesia, many operations were over before they started. Cushing and Codman compared their results and kept records concerning the conduct of anesthesia while they were medical students. This effort not only represented the first intraoperative patient records but also served as a foundation for Codman's later interest in (almost passion for) documentation of outcomes. Codman actually paid a publisher to disseminate the results obtained in his privately owned Boston hospital.[3] Codman was perhaps the first advocate of searching for a cause of all complications. He linked specific outcomes to specific interventions (or errors). He felt that most bad outcomes ultimately were the result of errors or omissions on the part of the physician and completely ignored any contribution to outcome from hospital-based and process-related factors. His efforts were not well received by his peers, and eventually his private hospital closed because of lack of referrals.

Both Codman and Nightingale viewed outcome analysis as an intermediate step in the improvement of patient care. It was not enough to know the rates of a given outcome. For these early clinicians, outcome analysis became meaningful only when it helped to improve patient care. While it is axiomatic that any valid comparison of quality of care or patient outcome must account for patients' severity of illness, this is only the initial step toward improving patient outcome.

Further definition of outcome assessment occurred in the mid-1900s. As more and more therapeutic options became available to treat the diseases that predominated in the early twentieth century (e.g., tuberculosis), a need arose to determine the best alternative of multiple therapies—thus the advent of the controlled, randomized trial and tests of effectiveness of therapy. One of the earliest randomized trials was conducted to determine whether streptomycin was effective against tuberculosis.[4] Although the trial proved the effectiveness of streptomycin against tuberculosis, it stimulated a great deal of controversy. After World War II, several clinicians advocated the use of randomized, controlled trials (RCTs) to better identify the optimal treatment to provide the best outcome. Foremost among these was Archie Cochrane. Every physician should know about Archie Cochrane (Fig. 7-1). He is as close to a true hero as a physician can get, but there may be those who see him as the devil incarnate. As you can see from some of the highlights of his career (see Fig. 7-1), he lived during an exciting time. In the 1930s, Professor Cochrane was branded as a Trotskyite because he advocated a national health system for Great Britain. His advocacy was tempered by 4 years as a prisoner of war in multiple German prisoner of war (POW) camps. He saw soldiers die from tuberculosis,



- 1934–36: Medical student, University College Hospital, London.
- 1936: International Brigade, Spanish Civil War.
- 1939–46: Captain, Royal Army Medical Corps.
- 1941: Taken prisoner of war in June 1941 in Crete; POW medical officer in Salonica (Greece) and Hildburghausen, Elsterhorst, and Wittenberg-am-Elbe (Germany).
- 1947–48: Studied the epidemiology of tuberculosis at Henry Phipps Institute, Philadelphia, USA.
- 1948–60: Member, Medical Research Council Pneumoconiosis Research Unit, Penarth, Wales.
- 1960–69: David Davies Professor of Tuberculosis and Chest Diseases, Welsh National School of Medicine, Cardiff, Wales.
- 1960–74: Director, Medical Research Council Epidemiology Research Unit, Cardiff, Wales.
- 1972: Publication by the Nuffield Provincial Hospitals Trust of his book *Effectiveness and Efficiency—Random Reflections on Health Services.*

Figure 7-1. Portrait of Archie Cochrane with brief biography. (*Used with permission from the Cochrane Collaboration.*)

and he was never sure what the best treatment was. Believe it or not, he did have some alternate therapies to offer the soldiers in the POW camps. He could choose between collapse therapy, bed rest, supplemental nutrition, or even high-dose vitamin therapy. A quote from his book sums up his frustration:

> I had considerable freedom of clinical choice of therapy: my trouble was that I did not know which to use and when. I would gladly have sacrificed my freedom for a little knowledge.[5]

His experience with the uncertainty about the best treatment for tuberculosis and other chest diseases continued after the war when he became a researcher in pulmonary disease for the Medical Research Council of Great Britain. Still with an interest in tuberculosis, now heightened by the fact that he had contracted the disease, Archie wanted to know the best drug therapy for tuberculosis because drugs were now available that could treat this disease—streptomycin being the first really effective drug against *Mycobacterium tuberculosis*.[4] He was a patron of RCTs, to test important medical hypotheses. He used the evidence gained from these RCTs to make decisions about the best therapy based on available evidence—the beginning of *evidence-based practice*. He felt that RCTs are the best form of evidence to support medical decision making (so-called class 1 evidence). Initially, he was a voice in the wilderness, but this changed little by little. In 1979 he criticized the medical profession for not having a critical summary, organized by specialty and updated periodically, of relevant RCTs. In the 1980s at Oxford, a database of important RCTs dealing with perinatal medicine was developed. In 1987, the year before Cochrane died, he referred to a systematic review of RCTs of care during pregnancy and childbirth as "a real milestone in the history of randomized trials and in the evaluation of care" and suggested that other specialties should copy the methods used. This led to the opening of the first Cochrane center (in Oxford, UK) in 1992 and the founding of the Cochrane Collaboration in 1993. Today, the Cochrane Collaboration is a repository of RCTs, both disease-specific and specialty-specific. Clinicians and lay people can go to the Cochrane Web site (www.cochrane.org/) and find summaries of all available RCTs on a wide range of medical subjects. From the preceding discussion, it is fair to call Archie Cochrane the "father of evidence-based medicine." Evidence-based medicine has, at its heart, the imperative to improve outcomes by comparing alternative therapies to determine which is best. Evidence-based studies that involve RCTs have the advantage of being able to infer cause and effect (i.e., a new therapy or drug *causes* improved outcome). On the other hand, observational studies (or retrospective studies) such as those of Hunter, Nightingale, and Codman are only able to define associations between therapies and outcome, not prove cause and effect. The ascendancy of RCTs represents a major step forward in outcome assessment.

DEFINITIONS

Risk Stratification: Arranging Patients According to Severity of Illness

Implicit in the assessment of process of care or of outcomes is the ability to arrange patients according to their severity of illness. In its simplest form, this is *risk stratification*. Implicit in this definition is the ability to predict outcomes from a given intervention based on preexisting risk—i.e., patients who are sicker to start with are expected to have worse outcome from an intervention than are those who are less sick. *Risk stratification* therefore is defined as the ability to predict outcomes from a given intervention by arranging patients according to severity of illness. The usefulness of any risk-stratification system arises from how the system links severity to a specific outcome. Risk stratification is implicit in any assessment of clinical outcomes.

There have been numerous attempts at describing severity of illness by means of a tangible score or number. Table 7-1 is a partial listing of some of the severity measures used commonly in risk assessment of cardiac surgical patients. This list is not meant to be comprehensive but does give an overview of the types of risk-stratification schemes that have been used for cardiac patients. The risk-stratification systems listed in Table 7-1 are in constant evolution, and the descriptions in the table may not reflect current or future versions of these systems. All these severity measures share two common features. First, they are all linked to a specific outcome. Second, all measures view a period of hospitalization as the episode of illness. The severity indices listed in Table 7-1 define severity predominantly based on clinical measures (e.g., risk of death, clinical instability, treatment difficulty, etc.). At least two of the severity measures shown in the table (MedisGroups used in the Pennsylvania Cardiac Surgery Reporting System and the Canadian Provincial Adult Cardiac Care Network of Ontario) define severity based on resource use (e.g., hospital length of stay, cost), as well as on clinical measures.[6,7] Of the nine severity measures listed in the table, only one, the APACHE III system, computes a risk score independent of patient diagnosis.[8] All the others in the table are diagnosis-specific systems that use only patients with particular diagnoses in computing severity scores.

Each of the risk-stratification measures shown in Table 7-1 has been tested against a validation set of patients and found to be an adequate measure of the risk of operative mortality or of other outcome. However, assessing the validity and performance of various risk-adjustment methods entails more than simple cross-validation. No severity tool will ever perfectly describe patients' risks for death, complications, or increased resource use. The most important reason that risk-adjustment methods fail to predict outcomes completely is that the data set used to derive the risk score comes from retrospective, observational data that contain inherent selection bias; i.e., patients were given a certain treatment that resulted in a particular outcome because a clinician had a certain

Table 7–1.

Examples of Risk Stratification Systems Used for Patients Undergoing Cardiac Surgical Procedures

Severity system	Data source	Classification approach	Outcomes measured
APACHE III[8]	Values of 17 physiologic parameters and other clinical information	Integer scores from 0 to 299 measured within 24 hours of ICU admission	In-hospital death
Pennsylvania	Clinical findings collected at time of admission	Probability of in-hospital death ranging from 0 to 1 based on logistic regression model and MediQual's Atlas admission severity score	In-hospital death and cost of procedure
New York	Condition-specific clinical variables from discharge record	Probability of in-hospital death ranging from 0 to 1 based on logistic regression model	In-hospital death
Society for Thoracic Surgeons	Condition-specific clinical variables from discharge record	Bayesian algorithm used to assign patient to risk interval (percent mortality interval); more recently converted to logistic regression model	In-hospital death and morbidity
EuroSCORE	Condition-specific clinical variables from discharge record	Additive logistic regression model with scores based on presence or absence of important risk factors	30-day and in-hospital mortality
Veterans Administration	Condition-specific clinical variables measured 30 days after operation	Logistic regression model used to assign patient to risk interval (percent mortality interval)	In-hospital death and morbidity
Parsonnet	Condition-specific clinical variables from discharge record	Additive multiple regression model with scores between 0 and 158 based on 14 weighted risk factors	Death within 30 days of operation
Canadian	Condition-specific clinical variables entered at time of referral for cardiac surgery	Range of scores from 0 to 16 based on logistic regression odds ratio for six key risk factors	In-hospital mortality, ICU stay, and postoperative length of stay
Northern New England	Condition-specific clinical variables and comorbidity index entered from discharge record	Scoring system based on logistic regression coefficients used to calculate probability of operative mortality from 7 clinical variables and 1 comorbidity index	In-hospital mortality
Cleveland Clinic	Condition-specific clinical variables from discharge record	Range of scores from 0 to 33 based on univariate odds ratio for each of 13 risk factors	In-hospital death or death within 30 days of operation

Pennsylvania = Pennsylvania Cost Containment Committee for Cardiac Surgery; New York = New York State Department of Health Cardiac Surgery Reporting System; Society for Thoracic Surgeons = Society of Thoracic Surgeons Risk Stratification System; Veterans Administration = Veterans Administration Cardiac Surgery Risk Assessment Program; Parsonnet = Parsonnet Risk Stratification Model; Canadian = Ontario Ministry of Health Provincial Adult Cardiac Care Network; Northern New England = Northern New England Cardiovascular Disease Study Group; Cleveland Clinic = Cleveland Clinic Foundation Risk Stratification System.

selection bias about what treatment that particular patient should receive. In observational data sets, patients are not allocated to a given treatment in a randomized manner. In addition, clinician bias is not always founded in evidence-based data. An excellent review of the subtleties of evaluating the performance of risk-adjustment methods is given in the book by Iezzoni, and this reference is recommended to the interested reader.[9] More attention is paid to the quality of risk-adjustment systems in subsequent sections.

Outcomes and Risk Stratification

There are at least four clinical outcomes of interest to surgeons dealing with cardiac surgical patients: *mortality, serious nonfatal morbidity, resource utilization,* and *patient satisfaction.* Which patient characteristics constitute important risk factors may depend largely on the outcome of interest. For example, Table 7-2 lists the multivariate factors and odds ratios associated with various clinical outcomes of interest for patients having cardiac operations.[10–12] The clinical variables associated with increased resource utilization after operation are different from those associated with increased mortality risk. As a generalization, the risk factors associated with in-hospital death are likely to reflect concurrent disease-specific variables, whereas the factors associated with increased resource utilization reflect serious comorbid illness.[13–15] For example, mortality risk after coronary artery bypass grafting (CABG) is associated with disease-specific factors such as ventricular ejection fraction, recent myocardial infarction, and hemodynamic instability at the time of operation, whereas risk factors for increased resource utilization (as measured by length of stay and hospital cost) include comorbid illnesses such as peripheral vascular disease,

Table 7–2.

Multivariate Factors Associated with Various Outcomes of Cardiac Surgery[10,11]

	Relative risk of outcome			
Variable	**Serious morbidity (95% CI)**	**Mortality (95% CI)**	**Decreased cost (95% CI)**	**Decreased LOS (95% CI)**
Congestive heart failure	4.81 (2.16–5.98)	9.20 (6.02–14.0)	0.56 (0.51–0.63)	0.79 (0.73–0.85)
NYS predicted mortality risk		1.28 (1.16–1.41)	0.93 (0.89–0.97)	0.78 (0.76–0.80)
Type of operation		6.04 (3.48–10.5)	0.43 (0.40–0.47)	0.53 (0.48–0.59)
Creatinine > 2.5 mg/100 mL			0.40 (0.33–0.49)	0.47 (0.38–0.58)
Priority		18.6 (7.42–46.6)	0.53 (0.50–0.56)	
Age/RBC volume (per 0.01 unit increase)	6.93 (3.21–11.5)		0.61 (0.55–0.67)	0.32 (0.30–0.36)
Reoperative procedure			0.68 (0.62–0.76)	
Preoperative IABP			0.65 (0.56–0.75)	
Hypertension	5.62 (2.11–15.2)		0.86 (0.81–0.92)	0.83 (0.78–0.89)
More than one prior MI			0.83 (0.75–0.91)	
Dialysis-dependent renal failure			0.61 (0.47–0.78)	
Peripheral vascular disease				0.85 (0.71–0.94)
Prior CNS disease	3.41 (2.99–4.91)			0.81 (0.72–0.92)
COPD				0.87 (0.79–0.94)

CNS = central nervous system; COPD = chronic obstructive pulmonary disease; IABP = intra-aortic balloon counterpulsation; LOS = length of stay; MI = myocardial infarction; RBC = red blood cell.

renal dysfunction, hypertension, and chronic lung disease (Table 7-2). It is not surprising that comorbid conditions are important predictors of hospitalization charges because patients with multiple comorbidities often require prolonged hospitalization not only for treatment of the primary surgical illness but also for treatment of complicating comorbid conditions.

Operative mortality is an easily defined, readily measured outcome, and its value to patients is undeniable. Most studies that have attempted to define effective care have focused on mortality as an outcome for the preceding reasons. Other outcomes such as resource utilization or quality-of-life indicators may be more relevant postoperative outcomes in many instances. Outcome measures other than operative mortality are particularly important when deciding how to spend health care dollars wisely.[16,17]

Measures of Comorbidity

Comorbidities are coexisting diagnoses that are indirectly related to the principal surgical diagnosis but that may alter the outcome of operation. Clearly, physicians or hospitals that care for patients with a higher prevalence of serious comorbid conditions are at significant disadvantage in unadjusted comparisons. The prevalence of comorbid illness in patients with cardiac disease has been well demonstrated. In one series of patients with myocardial infarction, 26% also had diabetes, 30% had arthritis, 6% had chronic lung problems, and 12% had gastrointestinal disorders.[18]

Several indices of comorbidity are available. Table 7-3 compares five commonly used comorbidity measures: the Charlson index, the Rand Corporation index, the Greenfield index, the Goldman index, and the APACHE III scoring system.[18–25] There are many limitations of comorbidity indices, and they are not applied widely in studies of efficacy or medical effectiveness. Perhaps the most serious drawback of comorbidity scoring systems is the imprecision of the databases used to form the indices. Most of the data used to construct the indices come from two sources: (1) administrative databases in the form of computerized discharge abstract data and (2) out-of-hospital follow-up

Table 7–3.

Five Comorbidity Indices

Comorbidity index	Data source and purpose	Classification approach	Most significant comorbidities
Charlson[19]	Abstract of medical records and follow-up data used to predict death at 1 year	Weighted relative risks from Cox proportional hazards model used to create comorbidity index	AIDS, metastatic tumor, and moderate to severe liver disease
APACHE III[21]	In-patient ICU records used to develop chronic health evaluation as part of overall index	Scores ranging from 0 to 299 created from logistic regression model with in-hospital mortality as outcome	AIDS, severe liver failure, lymphoma/leukemia, metastatic tumor
Keeler/RAND[22]	Medicare administrative database used to evaluate 30-day mortality risk	Weights assigned based on regression coefficients of significant logistic regression variables	Cancer, chronic renal failure, hypoalbuminemia, disease of the thorax, and use of nasogastric tube
Goldman[25]	Preoperative examination of patients undergoing noncardiac operations	Weights assigned for comorbidities based on discriminant analysis	Third heart sound, MI within 6 months, nonsinus rhythm, aortic stenosis, type of operation
Greenfield/ ICED[18,23,24]	Abstracts of medical records and outpatient follow-up to assess functional status 1 year after acute event	Combines measures of physiologic derangement and impairment related to comorbidity; variables derived from clinical experience	Functional status, acute exacerbation of comorbid condition, and baseline comorbidities, including metastatic cancer, liver disease, renal failure, and cardiac disease

MI = myocardial infarction.

reports. Discharge abstracts include clinical diagnoses that often are assigned by nonphysicians who were not involved in the care of the patient. Comprehensive entry of correct diagnoses is not a high priority for most clinicians, and problems with discharge coding have been identified by Iezzoni and others.[26–28] These authors found that many conditions that are expected to increase the risk of death actually are associated with a lower mortality. The presumed explanation for this paradoxical finding is that less serious diagnoses are unlikely to be coded for in the most seriously ill patients. Likewise, the accuracy of out-of-hospital follow-up studies is hard to validate, and such studies may contain significant inaccuracies. Despite these shortcomings, analyses that compare physician or hospital outcomes and that do not provide adequate adjustment for patient comorbidity are likely to discriminate against providers or hospitals that treat disproportionate numbers of elderly patients with multiple comorbid conditions. A vivid example of failure to adjust for patient severity occurred when the leaders of the Health Care Financing Administration (HCFA) released hospital mortality figures in March 1986. One hundred and forty-two hospitals had significantly higher death rates than predicted. At the facility with the most aberrant death rate, 87.6% of Medicare patients died compared with a Medicare average of 22.5%. What was not taken into account was that this facility was a hospice caring for terminally ill patients.[29] The HCFA model had not accounted for patient risks and comorbidities adequately.

Risk adjustment for severity of illness and comorbidity is equally important for patients undergoing stressful interventions such as surgical operations or chemotherapy. For example, Goldman and colleagues reported that preexisting heart conditions and other comorbid diseases were important predictors of postoperative cardiac complications for patients undergoing noncardiac procedures.[25] The Goldman scoring system is used commonly by anesthesiologists in assessing patients preoperatively, especially prior to noncardiac procedures.[25,30]

Outcome versus Process and Structural Measures of Quality

In 2000, the Institute of Medicine issued a report that was highly critical of the U.S. health care system, suggesting that between 50,000 and 90,000 unnecessary deaths occur yearly because of errors in the health care system.[31] This Institute of Medicine report created a heightened awareness of more global aspects of quality. For most of the history of cardiac surgery, quality generally was equated with operative mortality (i.e., outcome measure). As the new millennium got underway, a distinct change in the landscape of quality assessment occurred. The narrow focus on operative mortality gave way to a broader analysis that also included operative morbidity. The emphasis on these *outcomes measures* was further expanded to include the *process* of surgical care delivery. *Process measures* were developed to monitor the process of care. These measures typically include the choice of medication, timing of administration, and other interventions considered appropriate for optimal care. *Structural measures* such as health information technology (HIT) and organizational design also were considered important elements in this more global model of medical quality. Donabedian is credited with recognizing that outcome measures, process measures, and structural measures all contribute to quality of care.[32] In keeping with the well-accepted Donabedian model, outcome measures, process measures, and structural measures generally are termed *performance measures.*

The following definitions are adapted from those proposed by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO):

performance measure A quantitative entity that provides an indication of an organization's performance in relation to a specified process or outcome.
outcome measure A measure that indicates the results of process measures. Examples are operative mortality and the frequency of postoperative mediastinitis, renal failure, myocardial infarction, etc.
process measure A measure that focuses on a process leading to a certain outcome. Intrinsic in this definition is a scientific basis for believing that the process will increase the probability of achieving a desired outcome. Examples include the rate of internal mammary artery (IMA) use in CABG patients or the fraction of CABG patients placed on beta-blocking agents postoperatively.
structural measure A measure that assesses whether an appropriate number, type, and distribution of medical personnel, equipment, and/or facilities are in place to deliver optimal health care. Examples include enrollment in a national database or procedural volume.

Although there are numerous proposed criteria for an ideal performance measure, the following are universally accepted attributes:

- The measure must be clearly linked to quality of care.
- The measure must be objective, evidence-based, and risk-adjusted if possible.
- The physician must have the ability to influence the measure in a clinical setting.
- The measure must be sufficiently well defined to permit practical measurement.

Several national organizations are specifically devoted to the rigorous development of performance measures. Perhaps the most visible of these is the National Quality Forum (NQF), a quasi-governmental organization that uses a process of exhaustive, evidence-based scrutiny of candidate measures to determine those that are truly indicative of quality outcome. The value of the NQF process lies in the fact that process measures subject to this "trial by fire" are endorsed at a national level and thereby have a high level of credibility not otherwise possible.

TOOLS OF RISK STRATIFICATION AND OUTCOME ASSESSMENT

Databases

Perhaps the most important tool of any outcome-assessment endeavor is a database that is made up of a representative sample of the study group of interest. The accuracy of the data elements in any such database cannot be overemphasized.[33,34] Factors such as the source of data, the outcome of interest, the methods used for data collection, standardized definitions of the data elements, data reliability checking, and the time frame of data collection are essential features that must be considered when either constructing a new database or deciding about using an existing database.[33,34] The quality of the database of interest must be evaluated.

Data obtained from claims databases are less reliable than those obtained from clinical databases. Because claims data are generated for the collection of bills, their clinical accuracy is inadequate, and it is likely that these databases overestimate complications for billing purposes.[35] Furthermore, claims data underestimate the effects of comorbid illness and contain major deficiencies in important prognostic variables for CABG, namely, left ventricular function and number of diseased vessels.[36] The Duke Databank for Cardiovascular Disease found major discrepancies between clinical and claims databases, with claims data failing to identify more than half the patients with important comorbid conditions such as congestive heart failure (CHF), cerebrovascular disease, and angina.[37] The HCFA used claims data to evaluate variations in the mortality rates in hospitals treating Medicare patients. After an initially disastrous effort at risk adjustment from claims data,[38,39] new algorithms were developed. Despite these advances, the HCFA halted release of the 1993 Medicare hospital mortality report because of concerns about the database and fears that the figures would unfairly punish inner-city public facilities.[40] The quality of databases used to generate comparisons cannot be overemphasized.

Analytic Tools of Risk Stratification

Implicit in risk adjustment is some analytic technique used to develop significant risk factors that are predictive of the outcome of interest. The current shift to outcomes analysis carries with it a more intensive reliance on statistical techniques that are capable of evaluating large populations with multiple variables of interest in an interdependent manner—i.e., multivariate analyses. A modicum of statistical knowledge helps to unravel the intricacies of simple statistics and risk adjustment.[41] This knowledge provides confidence in the results of risk-adjustment methodologies. It is not our intention to provide the reader with exhaustive knowledge of the statistics of outcome analysis but rather to provide a resource for critical assessment of these methods and to stimulate the interest of readers to learn more about this important field. Perhaps the biggest single benefit of risk adjustment for outcome analysis will come from physicians increasing their knowledge base about these analytic techniques and gaining confidence in the methodology such that physician practices will be altered favorably by the results of risk-adjusted outcome assessment, with the ultimate goal being improved patient care.

Regression Analysis

The starting point for understanding multivariate statistical methods is to have a firm grasp of elementary statistics.[41] Several basic texts on statistics are available that are enjoyable reading for the interested health care professional.[42–44] These texts are a painless way to become familiar with the basic terminology regarding variable description, simple parametric (normally distributed) univariate statistics, linear regression, analysis of variance, nonparametric (not normally distributed) statistical techniques, and ultimately, multivariate statistical methods.

A statistical technique that is used commonly to describe how one variable (the dependent or outcome variable) depends on or varies with a set of independent (or predictor) variables is *regression analysis*. The dependent or outcome variable of interest can be either continuous (e.g., hospital cost or length of stay) or discrete (e.g., mortality). Discrete outcome variables can be either dichotomous (two discrete values such as alive or dead) or nominal (multiple discrete values such as improved, unimproved, or worse). The relationship between the outcome variable and the set of descriptor variables can be linear or any other nonlinear mathematical relationship. Two books, one by Glantz and Slinker and the other by Harrell, provide an enjoyable primer on regression analysis and are geared to the biomedical sciences.[44,45] They are recommended to the interested reader.

Regression analysis means determining the relationship (also termed *constructing a model*) that describes how an outcome variable depends on (or is associated with) a set of independent predictor variables. Put in simple terms, multivariate regression analysis is *model building*. The resulting model is useful only if it predicts outcomes accurately for patients by determining significant risk factors associated with the outcome of interest—i.e., risk adjustment of outcome. When the outcome variable of interest is a continuous variable such as hospital cost, linear multivariate regression often is used to construct a model to predict outcome. A multivariate linear regression model contains a set of dependent variables that are linearly related to and can be used to predict an outcome variable. These significant dependent variables are termed *risk factors,* and knowledge of these risk factors allows separation of patients according to their degree of risk—i.e., risk stratification. There are two important features of this linear regression model and any regression model for that matter. First, the model allows one to estimate the expected risk of a patient based on his or her risk characteristics. Second, various health care providers can be compared by comparing their observed outcomes to the expected outcomes that would be predicted from consideration of the risk factors of the patients they treat.

Statistical terminology used to describe variables and variable distribution patterns is particularly important in understanding linear regression statistical modeling. An important concept is *statistical variance* (R^2). R^2 is a summary measure of performance of the statistical model. R^2 often is described by saying that it is the fraction of the total variability of the dependent variable explained by the statistical model. Most investigators routinely report R^2 as a measure of the performance of linear regression risk-adjustment models.[46] For example, the APACHE III risk-adjustment scoring system described in Table 7-1 can be used to predict intensive-care unit (ICU) length of stay. When this is done, the model is associated with an R^2 value of 0.15.[21,46] This implies that 15% of the variability in ICU length of stay can be explained by the variables encompassed in the APACHE III score. Another way of saying this is that 85% of the variability in ICU length of stay is *not* explained by the APACHE III scoring system. This R^2 value does not rate the APACHE III scoring system very highly for predicting ICU length of stay. The APACHE III scoring system uses patient data obtained within 24 hours of admission to the ICU to predict outcome and was developed to predict in-hospital mortality, not hospital costs or length of stay. Ferraris and Propp found that the outcome of patients admitted to the ICU depends on things that happen after admission (especially iatrogenic events occurring in the ICU) more so than patient characteristics present on admission to the ICU.[47] Hence it is not surprising that the APACHE III score does not account for all the variability in ICU length of stay. In addition, it is not clear what level of R^2 can be expected when using APACHE III in a very different context than the one for which it was designed. Shwartz and Ash give an excellent review of evaluating the performance of risk-adjustment methods using R^2 as a measure of model performance, and their work provides an enlightening insight into the tools of risk adjustment.[48] An R^2 value of 0.15, as exhibited by the preceding APACHE III model, is not as horrible as it sounds. Hartz and colleagues point out that it is unlikely that any large multivariate regression model will completely account for all the variability of any complex outcome.[49] These authors constructed a so-called perfect model of simulated mortality data for CABG and found that this model only accounted for 31% of the variation in the mortality rate. The APACHE III value for R^2 looks somewhat better when compared with these standards. Ideally, refinements in any regression model should be an ongoing process that ultimately results in improvement in the regression diagnostics, therefore maximizing the value of R^2.

Logistic Regression

When the outcome variable of interest is a discrete variable (e.g., mortality), then nonlinear regression analysis is used. *Logistic regression* is the nonlinear method used most widely to model dichotomous outcomes in the health sciences. Logistic regression predicts the probability that an indicator variable is equal to 1. To be precise, the logistic regression equation does not directly predict the probability that the indicator is equal to 1. It predicts the log odds that an observation will have an indicator equal to 1. The *odds* of an event are defined as the ratio of the probability that an event occurs to the probability that it fails to occur. Thus

$$\text{Odds (indicator} = 1) = \text{probability (indicator} = 1)/[1 - \text{probability (indicator} = 1)]$$

or

$$\text{Odds (indicator} = 1) = \text{probability (indicator} = 1)/\text{probability (indicator} = 0)$$

The log odds is just the (natural) logarithm of the odds. Probabilities are constrained to lie between 0 and 1, with 1/2 as a neutral value for which both outcomes are equally likely. The constraints at 0 and 1 make it impossible to construct a linear equation for predicting probabilities. Logistic regression equations (i.e., models) compute the set of linear variables that best fits the observed log odds. Unlike a linear least-squares regression equation, which can be solved explicitly, logistic regression equations are solved with computer-intensive iteration steps by trial and error. A trial equation is fitted and adjusted repeatedly in steps until the equation describes the results accurately. Iterations stop when the improvement from one step to the next is very small. A typical logistic regression equation that describes the relationship of age to operative mortality might look as follows:

$$\text{Log odds (death)} = -4.353 + 0.038\ \text{(age)}$$

or

$$\text{Probability (death)}/[1 - \text{probability (death)}] = \exp[-4.353 + 0.038\ \text{(age)}]$$

or

$$\text{Probability (death)} = 1/(1 + \exp^{-[-4.353\ +\ 0.038\ \text{(age)}]})$$

The value –4.353 + 0.038 (age), sometimes called the *logit* or the *log odds,* in the expression is the linear sum of predictor variables (either continuous or discrete) and the value of $1/1 + e^{-x}$ is the probability of outcome between 0 (e.g., survival) and 1 (e.g., death) for any value of predictor variables. With more extensive modeling and with sufficiently large databases, computer iteration techniques produce a model consisting of a set of independent variables that best predicts the occurrence of a dichotomous outcome variable. The significant independent variables identified by the logistic regression model are risk factors that allow risk stratification of patients according to their risk of experiencing the dichotomous outcome (e.g., survival versus death).

The performance of logistic regression models can be assessed in several ways. However, there is less agreement about how best to measure performance for models that predict binary outcomes than there is about the use of R^2 to evaluate linear regression models. One commonly used parameter to evaluate the performance of logistic regression models is the *c*-statistic.[50] The *c*-statistic is equal to the area

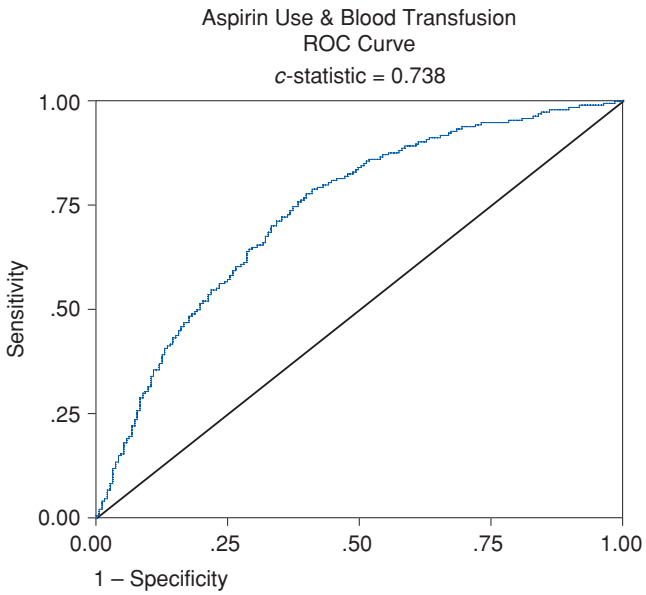


Figure 7-2. Receiver operating characteristics (ROC) curve demonstrating association of preoperative aspirin use in 2606 patients before CABG with postoperative blood transfusion. For this analysis, postoperative transfusion was considered a dichotomous variable (patients either received a transfusion or they did not). The area between the diagonal line and the upper curve represents the *c*-statistic.[51]

under the receiver operator characteristic (ROC) curve (e.g., Fig. 7-2) and can be generated from the sensitivity and specificity of measurements of any dichotomous outcomes. Table 7-4 shows a 2 × 2 table generated from a hypothetical logistic regression model used to predict dichotomous outcomes, and Table 7-5 describes the statistical terms of interest that can be derived from the predicted and observed outcomes.

Figure 7-2 depicts the ability of a logistic regression model to predict patients who will receive a blood transfusion after CABG based on preoperative variables including preoperative aspirin use.[51] This figure is an ROC curve derived from a plot of the sensitivity versus 1 minus the specificity (same as a plot of the correct positive prediction rate on the *y* axis versus the false-positive rate on the *x* axis). The ROC curve in Fig. 7-2 is produced by assuming a particular cutpoint for a predicted probability of one outcome (e.g., patients with a predicted probability of greater than 0.5 of receiving any transfusion after CABG are considered to be positive for receiving a blood transfusion). The *c*-statistic for the prediction model is 0.738, suggesting only a fair ability of the model to predict postoperative blood transfusion. To put this in perspective, a *c*-statistic of 1.0 indicates perfect discrimination of the model, and a *c*-statistic of 0.5 indicates no discrimination. Thus a *c*-statistic of 0.738 is about halfway between perfect and worthless. An excellent critique of the various methods used to assess the performance of regression models of dichotomous outcomes is given by Ash and Shwartz in the book by Iezzoni.[52]

Logistic regression models are used to develop risk profiles for providers (both hospitals and individual surgeons)—so-called report cards.[53–60] This has caused anguish on the part of providers[61] and concern on the part of statisticians and epidemiologists.[53,54] The typical form that report cards take is to grade surgeons by their operative mortality for CABG. In order to grade a provider, the expected number of deaths (*E*, or expected rate), calculated from deaths observed in the entire provider group, is compared with the observed number of risk-adjusted deaths for the provider (*O*, or observed rate). This gives an *O:E* ratio, or a ratio of the risk-adjusted observed mortality rate to the expected mortality rate, based on the group logistic model. In order to make comparisons between providers, a confidence interval (usually the 95% confidence interval) is assigned to the observed mortality rates, and the between-provider mortality rates are presented as a range of values for each provider (Fig. 7-3*A*). The expected mortality rates are assumed to be independent of the observed mortality rates—an incorrect assumption. Furthermore, no sampling error is attached to the expected values—another incorrect assumption. The effect of making these two assumptions is to identify too many outliers (in either direction). Statistical methodology is available and has been available for many years to account for these incorrect assumptions. The methodology involves construction of hierarchical regression models.

Table 7–4.

Two-by-Two Table Comparing Predicted Versus Observed Dichotomous Outcomes

	Observed outcome		
Predicted outcome	**Dead**	**Alive**	**Totals**
Dead	*A*	*B*	*A* + *B*
Alive	*C*	*D*	*C* + *D*
Totals	*A* + *C*	*B* + *D*	*A* + *B* + *C* + *D*

Table 7–5.

Definitions of Important Quantities for Analysis of Risk-Adjusted Dichotomous Outcomes*

Statistical term	Definition from values in Table 7-4
True-positive cases	A
False-positive cases	B
True-negative cases	D
False-negative cases	C
Prevalence	$(A + C)/(A + B + C + D)$
Positive predictive value (PPV)	$A/(A + B)$
Negative predictive value (NPV)	$D/(C + D)$
Sensitivity (rate of correct positive predictions)	$A/(A + C)$
Specificity (rate of correct negative predictions)	$D/(B + D)$

Hierarchical Models versus Logistic Regression

One of the most controversial applications of logistic regression models is *provider profiling,* the determination and comparison of risk-adjusted outcomes for hospitals and physicians.[53,62] Such outcome reports may be mandated by states,[64,65] in which case the results usually are published as report cards. The statistical methodology used previously to develop most such report cards is both simple and straightforward. The probability of mortality for each of a provider's patients during a given time period is estimated using logistic regression, and then these probabilities are aggregated to determine that provider's expected mortality *E.* The observed mortality *O* is simply the counted number of deaths. A ratio of observed to expected mortality (*O:E*) then is calculated, and it has a value close to 1 if the performance is what would be predicted from the model. Ratios greater than 1 imply worse-than-expected performance, and ratios less than 1 suggest better-than-expected performance. Often the *O:E* ratios are multiplied by the state-unadjusted mortality rate to obtain the *risk-adjusted mortality.*

It has long been recognized by statisticians that this intuitively appealing approach, aggregating patient-level data to make inferences about providers, is not appropriate.[65–68] This type of study is inherently multilevel, and in such situations, simply aggregating or disaggregating between levels may lead to erroneous conclusions.[69,70] This was recognized long ago in education, where the analogous situation would be the inappropriate aggregation of pupil test scores to evaluate teacher performance. Multilevel or hierarchical models have been developed for such situations, and these models also found application in longitudinal studies, meta-analyses, and small-area variation studies. These models address most of the major concerns regarding the use of standard models for multilevel scenarios. For example, the sample sizes from various providers often differ substantially and for low-volume providers may be rather small. In the latter situation, the observed point estimates of observed mortality are a much less accurate reflection of their true but unobserved mortality. Hierarchical models "shrink" the observed mortality rates of lower-volume providers toward the mean of the overall population of providers, a way of borrowing strength or pooling the data. The resulting estimates are more accurate and stable. Another concern with the use of nonhierarchical models for profiling is clustering of observations. Standard methods assume independent observations, but patients within a given hospital (and students within a given school) are likely to be more similar to each other than they would be if drawn randomly from the larger population. This "clustering" of patients, referred to mathematically as *intraclass correlation,* reduces the effective sample size, increases standard errors, and makes false outlier identification more likely. Finally, standard logistic models do not partition the various levels of variability (between and within providers) accurately, which is one of the central questions to be answered by profiling. Hierarchical models partition this variability correctly, they account for sample size and clustering, and through their shrinkage effect, they also compensate for multiple comparisons.

Numerous studies have investigated the difference in the results of provider profiling obtained from traditional logistic regression versus hierarchical modeling using data

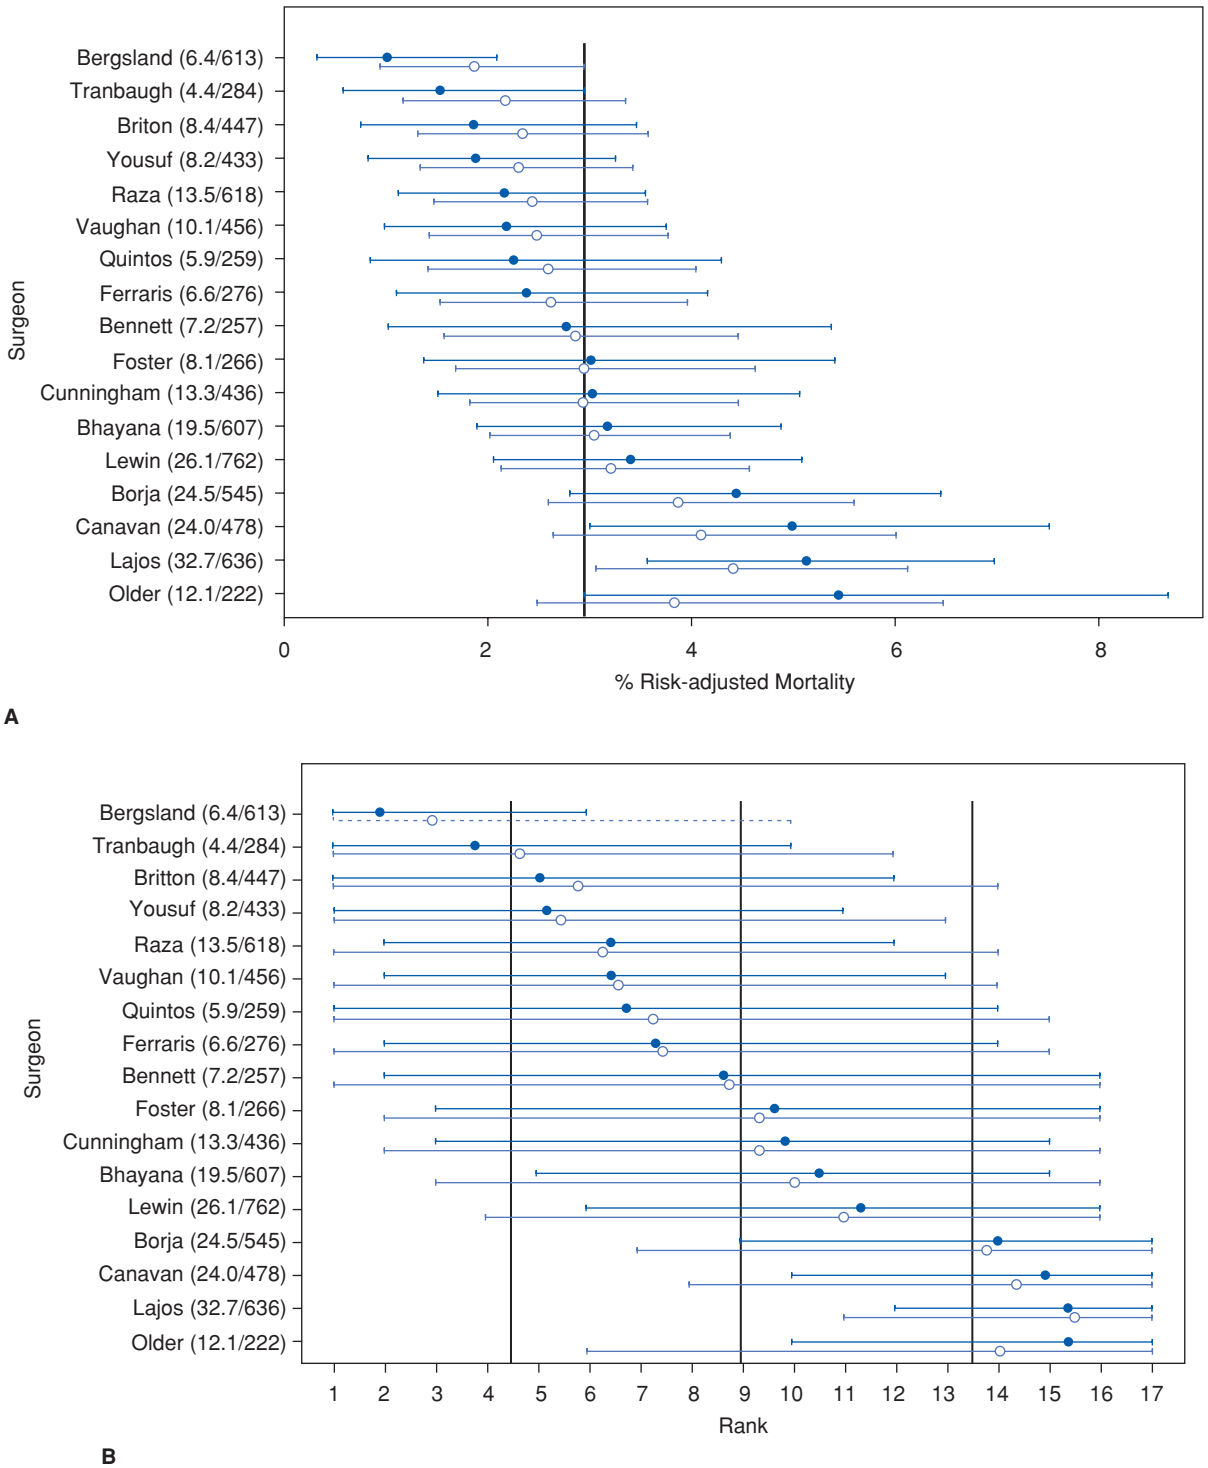

Figure 7-3. Comparison of classic statistical point and interval estimates (*A*) to estimates from hierarchical models (*B*) for a sample of New York surgeons performing coronary artery bypass grafting.[67] (*Used with permission from* Journal of the Royal Statistical Society.)

from New York,[67,71,72] Pennsylvania,[73] Oregon,[54] and Massachusetts.[65] In all but one of these, profiling based on hierarchical models yielded appropriately more conservative results. For example, in the classic work of Goldstein and Spiegelhalter, use of a hierarchical model reduced the number of New York outliers from three to one[67] (see Fig. 7-3*A*, *B*). Hannan's own New York analysis[72] found no significant difference between the results obtained using the two methodologies, but the number of cases per hospital sample was large enough that this is not surprising. The absence of a significant difference in results in this study does not negate the value of hierarchical modeling in other settings, and at

the very least it is comforting to know that the most appropriate model (i.e., a hierarchical model) is being employed. A more significant objection to the use of hierarchical models is that by reducing the chance of false outlier identification, they also may reduce the sensitivity to detect true outliers. Ultimately, this tradeoff is a health policy and regulatory decision.

Two impediments to widespread use of hierarchical models are the absence of the necessary large data sets and the lack of readily available easy-to-use software packages. There are statistical work-arounds that adjust data sets to obtain similar results to those obtained from hierarchical models, but it is unclear if such adjustment produces a qualitatively different result from standard hierarchical analysis. At present, hierarchical regression is the "gold standard" for risk adjustment of dichotomous outcomes and producing provider report cards. Unfortunately, this gold standard is used rarely. Hierarchical models are complex and require not only extensive computer resources but also close planning and oversight by a statistician experienced in these methods. However, most investigators regard them as the best model for profiling providers, and hierarchical modeling has been adopted for use recently both by the state of Massachusetts and by the Society of Thoracic Surgeons.

Statistics of Survival

When the outcome of interest is a time-dependent variable (e.g., hospital length of stay or survival after valve implantation), then regression modeling may be a more complex but still manageable process. Regression models for time-dependent outcome variables can be developed using computer iteration methods. Several excellent texts are available that cover the gamut of technical information from the relatively simple[74,75] to the complex.[76–78] One model that is used extensively in the biomedical sciences is the Cox proportional hazards regression model.[76] In some regression models, such as logistic regression, the dependent or outcome variable is known with precision. With time-dependent outcome variables, the possibility exists that only a portion of the survival time is observed for some patients. Thus the data available for analysis will consist of some outcomes that are incomplete or "censored." Some regression models, such as logistic regression, do not adapt easily to censored data. Cox's model overcomes these technical problems by assuming that the independent (predictor) variables are related to survival time by a multiplicative effect on the hazard function—thus a *proportional hazards* model. The hazard function is defined as the slope of the survival curve (or the time-decay curve) for a series of time-dependent observations. In the Cox model, one assumes that the hazard functions are proportional, a reasonable assumption when comparing survival in two or more similar groups. Hence it is not necessary to know the underlying survival function in order to determine the relative importance of independent variables that contribute to the overall survival curve. Table 7-6 shows an example of the use of Cox regression to evaluate the independent variables that are predictive of hospital length of stay (a time-dependent outcome variable) for patients undergoing CABG.[11] For the purposes of this analysis, hospital deaths were considered censored observations. The independent variables shown in Table 7-6 are considered risk factors for increased length of stay and can be used to stratify patients into groups with varying risk of prolonged hospitalization.

Measures of the performance of Cox regression models are less well developed than those for logistic regression or for multivariate linear regression. Simple methods of checking the predictive value of Cox models usually are reported in the medical literature. One of the most commonly used methods is called *cross-validation,* or *jackknife analysis.* This consists of using Cox regression to determine significant independent variables predictive of outcome in a "training set" of data. The significant variables and their coefficients from the Cox model are then used to compute values of the outcome variables in a different data set (called the *validation set,* or the *jackknife set*). The agreement between the predicted values and the observed values in the validation set is used as an index of the performance of the Cox model. Figure 7-4 shows a cross-validation set of data used to check the results of the Cox regression described in Table 7-6. This figure shows fair "validation" of the Cox model using a relatively small data set (1200 patients operated on during 1994 at a single institution). Performance of Cox models also can be expressed in terms of ROC curves and the *c*-statistic as for logistic regression models.

Bayesian Analysis: Models Based on Experience

Thomas Bayes was a nonconformist minister and mathematician who is given credit for describing the probability of an event based on knowledge of prior probabilities that the same event has already occurred.[79] Using the Bayesian approach, three sets of probabilities are defined: (1) the probability of an event before the presence of a new finding is revealed (*prior probability*), (2) the probability that an event is observed given that an independent variable is positive (*conditional probability*), and (3) the probability of an event occurring after the presence of a new finding is revealed (*posterior probability*). The mathematical relationship between the three probabilities is Bayes' theorem. The prior and posterior probabilities are defined with respect to a given set of independent variables. In the sequential process common to all Bayesian analyses, the posterior probabilities for one finding become the prior probabilities for the next, and a mathematical combination of prior and conditional probabilities produces posterior probabilities. Bayes' theorem can be expressed in terms of the nomenclature of Table 7-5 as

$$P_{\text{Bayes}} = (\text{sensitivity} \times \text{prior probability})/(\text{sensitivity} \times \text{prior probability}) + [\text{false-positive rate} \times (1 - \text{prior probability})]$$

Table 7–6.

Cox Proportional Hazards Regression Model for Significant Predictor Variables Associated with Increased Hospital Length of Stay in 938 Patients Undergoing CABG during 1993[11]

Risk factor (patients with risk factor)	Observed LOS	95% CI	Odds ratio	Chi^2 improvement
None (40 patients)*	5.9 days	0.7 days	1.00	
Age/RBCVOL (385 patients with ≥ mean value of 0.0390)	10.0 days	0.98 days	1.83 per 0.01 unit of age/RBCVOL	72.907
CHF (91 patients)	11.6 days	2.3 days	4.34	17.729
Hypertension (646 patients)	9.0 days	0.6 days	2.31	12.296
Peripheral vascular disease (74 patients)	10.1 days	1.4 days	3.01	8.053
Renal dysfunction (17 patients)†	12.8 days	3.8 days	5.64	6.904
COPD (213 patients)	9.4 days	0.9 days	2.23	7.259
Previous stroke (51 patients)	11.1 days	2.2 days	3.20	5.017

**For purposes of calculating zero risk factor scores, age/RBCVOL was assumed to be less than 0.0250 (one standard deviation below the mean).*
†Serum creatinine ≥ 2.5 mg/% but not dialysis-dependent.
Age/RBCVOL = age in years divided by red blood cell volume obtained from nomogram of patient height, weight, gender, and preoperative hematocrit; CHF = congestive heart failure immediately preceding CABG; COPD = chronic obstructive pulmonary disease; LOS = length of stay.

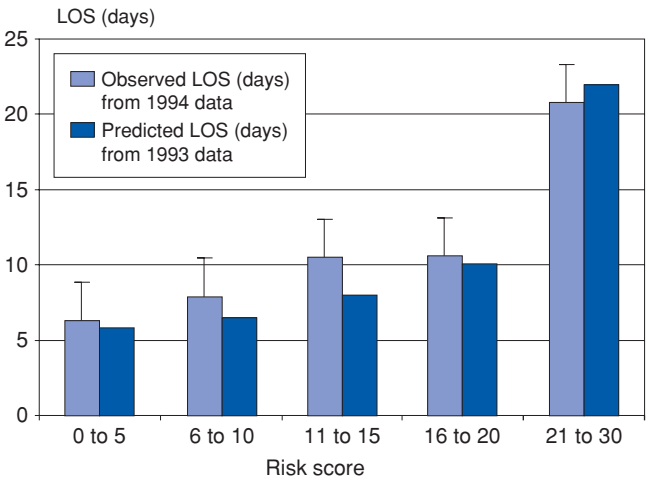

Figure 7-4. Cross-validation of Cox regression model used to predict hospital length of stay (LOS) after CABG. Data from patients operated on in 1993 were used as the "training" data set to predict values for LOS in patients undergoing operation in 1994 ("validation set"). Risk scores were generated by assigning numerical weights to significant variables in the Cox model based on regression coefficients shown in Table 7-8. The methods used to derive the patient risk scores are described in refs. 11 and 278. (*Used with permission from the* Journal of Thoracic and Cardiovascular Surgery.)

where P_{Bayes} is defined as the probability of a given outcome if prior probabilities are known. The principles of Bayesian statistics have been used widely in decision analysis[80] and are also used to generate multivariate regression models based on historical data about independent variables.[81–84] Bayesian multivariate regression models are generated using computer-based iterative techniques[81,84–86] and have been used, in the past but not at present, to develop the risk-stratification analysis for the Society of Thoracic Surgeons National Cardiac Database.[85,87] Evaluation of the performance of the Bayesian statistical regression models usually is done by cross-validation studies similar to those used to validate the Cox survival regression model in Fig. 7-4. Performance of Bayesian models also can be expressed in terms of ROC curves and the *c*-statistic as for logistic regression models. Marshall and colleagues showed that Bayesian models of risk adjustment give comparable results and similar ROC curves to conventional models generated from logistic regression analysis.[88]

Meta-Analysis

An implicit part of assessing outcome is the development of a best standard of care for a given illness or disease process. Once the most efficacious treatment is known, then comparisons with or deviations from the standard can be assessed—a process called *benchmarking* and an important component

in the generation of treatment guidelines. As mentioned earlier, the "best standard" is not always known. Meta-analysis is a quantitative approach for systematically assessing the results of multiple previous studies to determine the best or preferred outcome. The overall goal of meta-analysis is to combine the results of previous studies to arrive at a consensus conclusion about the best outcome. Stated in a different way, meta-analysis is a tool used to summarize efficacy studies (preferably RCTs) of an intervention in a defined population with disease in order to determine which intervention is likely to be effective in a large population with a similar disorder. Meta-analysis is a tool that can relate efficacy studies to effectiveness of an intervention by summarizing available medical evidence.

In summarizing available medical evidence on a given subject, information retrieval is king. Nowhere is this more evident than in the Cochrane Collection of available randomized trials on various medical subjects. For example, a recent Cochrane review (www.update-software.com/abstracts/ab002138.htm) found 17 trials that evaluated postoperative neurologic deficit in patients having hypothermic cardiopulmonary bypass (CPB) compared with normothermic CPB.[89] This compares with a recently published meta-analysis on a similar topic that found only 11 trials on which to perform a similar analysis.[90] It is important to understand how the Cochrane reviewers found these 17 observational studies and RCTs. One has to realize that only about a third of the world's medical literature appears on large computer databases such as MEDLINE, so it is not good enough simply to search MEDLINE for the RCTs of interest. Computerized databases such as MEDLINE are incomplete, especially in areas of subspecialization such as cardiothoracic surgery. The Cochrane reviewers perform an exhaustive search of all available literature, not only MEDLINE but also unpublished trials and so-called fugitive literature (e.g., government reports, proceedings of conferences, published Ph.D. theses). The average thoracic surgeon has not heard of "publication bias," but the Cochrane reviewers are acutely aware of it. They realize that RCTs that have a negative result are less likely to pass the peer-review editorial process into publication than RCTs with a significant treatment effect—so-called publication bias in favor of positive clinical trials.[91] Thus, for each of the Cochrane reviews, attempts are made to find unpublished and/or negative trials to add to the body of evidence about a given subject.

If information retrieval is king in summarizing available medical evidence on a given subject, then statistical analysis of the retrieved studies (including RCTs) shares the throne. It must be obvious that all trials or observational studies that address the same outcomes of a given intervention are not the same. There are almost always subtle differences in study design, sample size, analysis of results, and inclusion/exclusion criteria. The object of comparing multiple observational studies and RCTs on the same treatment outcome is to come up with a single summary estimate of the effect of the intervention. Calculating a single estimate in the face of such diversity may give a misleading picture of the truth. There are no statistical tricks that account for bias and confounding in the original studies. Heterogeneity of the various RCTs and observational studies on the same or similar treatment outcome is the issue. This heterogeneity makes comparison of RCTs a daunting task, about which volumes have been written.[17] There are at least two types of heterogeneity that confound summary estimates of multiple RCTs—clinical heterogeneity and statistical heterogeneity. *Statistical heterogeneity* is present when the between-study variance is large; i.e., similar treatments result in widely varying outcomes in different trials. This form of heterogeneity is easiest to measure. For example, Berlin and colleagues evaluated 22 separate meta-analyses and found that only 14 of 22 had no evidence of statistical heterogeneity.[92] Three of the remaining 8 comparative studies gave different results depending on the type of statistical methods used for the analysis—the more statistical heterogeneity, the less certain are the statistical inferences from the analysis.

Clinical heterogeneity of groups of RCTs that assess similar outcomes is much more difficult to assess. Measurement of treatment outcomes has plagued reviewers who try to summarize RCTs. Many RCTs address similar treatment options (e.g., hypothermic CPB versus normothermic CPB) but measure slightly different outcomes (e.g., stroke or neuropsychological dysfunction). For example, the Cochrane Heart Group found 17 RCTs that addressed the effect of CPB temperature on postoperative stroke.[89] Only 4 of these 17 RCTs measured neuropsychological function, whereas all 17 measured neurologic deficit associated with CPB. In summarizing the results of multiple RCTs comparing a given treatment, it is necessary to match "apples with apples" when looking at outcomes. In this analysis by the Cochrane Heart Group, there was a trend toward a reduction in the incidence of nonfatal strokes in the hypothermic group [odds ratio (OR) 0.68 (0.43, 1.05)]. Conversely, there was a trend for the number of non–stroke-related perioperative deaths to be higher in the hypothermic group [OR 1.46 (0.9, 2.37)]. When pooling all "bad" outcomes (i.e., stroke, perioperative death, myocardial infarction, low output syndrome, and intra-aortic balloon pump use), there was no significant advantage of either hypothermia or normothermia [OR 1.07 (0.92, 1.24)]. This suggests that there is clinical heterogeneity among the various RCTs evaluated. There are statistical "tricks" that can investigate and explore the differences among studies, such things as stratification or regression, but it is unlikely that clinical heterogeneity can be removed completely from the meta-analysis. Importantly, the Cochrane Group concludes from this work that there is no definite advantage of hypothermia over normothermia in the incidence of clinical events following CPB. This constitutes good evidence (i.e., multiple well-done RCTs) to support the notion that normothermic and hypothermic CPB have equal efficacy for most outcomes. An expert panel reviewing the Cochrane evidence might suggest that there is class I evidence [according to the American College of Cardiology/American Heart Association (ACC/AHA) guideline nomenclature shown in Table 7-7] that both normothermic and

Table 7–7.

1999 AHA/ACC Guidelines for CABG in ST-segment elevation (Q-wave) MI

Indication and clinical condition	Definition of level of evidence
Class I None	Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective
Class IIa 1. Ongoing ischemia/infarction not responsive to maximal nonsurgical therapy	Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of a procedure
Class IIb 1. Progressive LV pump failure with coronary stenosis compromising viable myocardium outside the initial infarct area	Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy
2. Primary reperfusion in the early hours (⩽6 to 12 hours) of an evolving ST-segment elevation MI	Class IIb: Usefulness/efficacy is less well established by evidence/opinion
Class III 1. Primary reperfusion late (>12 hours) in evolving ST-segment elevation MI without ongoing ischemia	Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful

AHA = American Heart Association; ACC = American College of Cardiology; MI = myocardial infarction; LV = left ventricle.

hypothermic CPB are equally safe and result in a similar incidence of perioperative complications. This is an entirely different conclusion from that made by Bartels and colleagues in their meta-analysis about the same interventions. These authors suggest that there is little evidence to support the usefulness/efficacy of hypothermia in CPB.[90] Which meta-analysis is closer to the truth is hard to say. Much depends on the details of the meta-analyses, but logic suggests that the higher-quality study including more available RCTs and statistically rigorous analysis such as used by the Cochrane group comes closer to the scientific truth.

There is some concern about the findings of meta-analyses.[93–95] LeLorier and colleagues found significant discrepancies between the conclusions of meta-analyses and subsequent large RCTs.[94,95] On review of selected meta-analyses, Bailar found that "problems were so frequent and so serious, including bias on the part of the meta-analyst, that it was difficult to trust the overall 'best estimates' that the method often produces."[96,97] Great caution must be used in the interpretation of meta-analyses, but the technique has gained a strong following among clinicians because it may be applied even when the summarized studies are small and there is substantial variation in many of the factors that may have an important bearing on the findings.

Breakthrough Statistics[98]

The use of complex statistics is becoming more common in assessing medical data. Arguably, the understanding of this complex material on the part of clinicians has not advanced at a similar rate. In an attempt to address this knowledge gap, Blackstone coined the term *breakthrough statistics* to denote newer methods that are available to handle complex but clinically important research questions.[98] His goal was to acquaint clinicians with the methods in a nontechnical fashion "so that [they] . . . may read reports more knowledgeably, interact with [their] . . . statistical collaborators more closely, or encourage [their] . . . statistician to consider these methods if they are applicable to [their] . . . clinical research."[98] These worthy goals have direct relevance to outcomes assessment and risk stratification.

Balancing scores

One of Blackstone's breakthrough statistical methods deals with a very common problem—the assessment of nonrandomized comparisons. Observational studies, or nonrandomized comparisons, can detect associations between risk and outcome but cannot, strictly speaking, determine which risks *cause* the particular outcome. Traditionally, only RCTs have been able to determine cause and effect. A so-called breakthrough technique to allow nonrandomized comparisons to come closer to inferring cause and effect is the use of *balancing scores.*

Simple comparison of two nonrandomized treatments is confounded by selection factors. This means that a clinician decided to treat a particular patient with a given treatment for some reason (not always obvious and not always

evidence-based). The selection factors used in this nonrandomized situation are difficult to control, and RCTs eliminate this type of bias. However, RCTs often are not applicable to the general population of interest because they are very narrowly defined.[99] Use of nonrandomized comparisons is more versatile and less costly. One of the earliest methods used to account for selection bias was patient matching. Two groups who received different treatments were matched as closely as possible for all factors except the variable of interest. Balancing scores were developed as an extension of patient matching. In the early 1980s, Rosenbaum and Rubin introduced the idea of balancing scores to analyze observational studies.[100] They called the simplest form of a balancing score a *propensity score*. Their techniques were aimed at drawing causal inference from nonrandomized comparisons. The propensity score is a probability of group membership. For example, in a large group of patients having CABG, some receive aspirin before operation and others do not. One might ask whether preoperative aspirin causes increased postoperative blood transfusion. The propensity score is a probability between 0 and 1 that can be calculated for each patient, and this score represents their probability of getting aspirin before operation. If one matches the aspirin and nonaspirin patients by their propensity scores, the patients will be as nearly matched as possible for every preoperative characteristic excluding the outcome of interest. Not all the patients may be included in the analysis because some aspirin users may have a propensity score that is not closely matched with that of a nonaspirin user. But those aspirin users who have a matching propensity score with a nonaspirin user will be very closely matched for every variable except for the outcome variable of interest. This is as close to a randomized trial comparison as you can get without actually doing the randomized trial.

How is the propensity score calculated? The relevant question asked to construct the propensity score is which factors predict group membership (e.g., who will receive aspirin and who will not). The probability of receiving aspirin is a dichotomous variable that can be modeled like any other binary variable. For example, logistic regression can be used to identify factors associated with aspirin use. In the logistic regression analysis to develop the propensity score, as many risk factors as possible are included in the model, and the logistic equation is solved (or modeled) for the probability of being in the aspirin group. This probability is the propensity score. An example of the results obtained from this type of analysis is shown in Table 7-8.[51] In this analysis, 2606 patients (1900 preoperative aspirin users and 606 nonusers) were "balanced" according to their propensity scores. The group was divided into five equal quintiles according to their propensity scores (i.e., their tendency to receive aspirin before operation). Quintile 1 had the least chance of receiving aspirin, whereas quintile 5 had the greatest chance of receiving aspirin before operation. Within each quintile, the patients are matched as closely as possible for all variables except for the outcome variable of interest,

Table 7–8.

Effect of Aspirin (ASA) on Postoperative Blood Transfusion Using Propensity Score–Matched Quintiles.

	Quintile

i.e., receiving any blood transfusion after CABG, almost like a randomized trial. Notice that within each quintile, aspirin users and nonusers are closely matched for other variables such as preoperative renal function, gender, and CPB time. This indicates that the propensity score matching did what it was supposed to—i.e., matched the patients for all variables except for the outcome variable of interest (i.e., postoperative transfusion). The results show that the propensity-scored quintiles are asymmetric—i.e., there is not a consistent association between aspirin and blood transfusion across all quintiles. In the strata that are least likely to receive preoperative aspirin, there are patients who are more likely to receive postoperative transfusion (i.e., patients in quintile 1 have the longest CPB time, the greatest number of women, and the largest number of patients with preoperative renal dysfunction). This implies that some patients may have been recognized as high risk preoperatively and were not given aspirin—i.e., selection bias exists in the data set. The corollary is that if this high-risk cohort received aspirin, there was an increased likelihood of receiving postoperative blood transfusion. These results suggest that certain high-risk aspirin users are at increased risk for receiving a postoperative blood transfusion. These results do not replace RCTs for determining cause and effect, but they do represent an economical and versatile way to address the problem with results comparable with those of RCTs. There is some evidence that well-done observational studies give comparable results to RCTs dealing with similar outcomes,[101,102] and balancing scores provide optimal means of analyzing nonrandomized studies.

Bootstrapping

The importance of risk factor identification for comparing outcomes already has been stressed. Risk factor identification for a given outcome has become commonplace in medicine. A problem arises from this dependence on risk factor analysis, especially logistic regression. Different observers analyzing the same risk factors to predict outcome get different results. Table 7-9 is an example of the variability in risk factor identification that can result. In this table, Grunkemeier and colleagues compared 13 published multivariate risk models for mortality following CABG.[54] The number of independent risk factors cited by any one model varied from 5 to 29! Naftel described 9 factors that contribute to different investigators obtaining different models to predict outcome (i.e., different sets of risk factors associated with the same outcome).[103] Some or all of these factors may affect the risk models listed in Table 7-9. One of Naftel's factors that is important in differentiating various models of CABG mortality is variable selection. In Table 7-9, 13 different groups found 13 different variable patterns that apparently adequately predicted operative mortality. How can this be? Recent breakthrough statistical methods address variable selection in statistical modeling.

In the early 1980s, the ready availability of computers began to surface to the consciousness of investigators. Efron and colleagues popularized computer-intensive computational techniques that were not readily available until computers were on every investigator's desk.[104–107] They coined the term *bootstrap* to describe these computer-intensive methods. *Bootstrap analysis* is a data-based simulation method for statistical inference. Efron's group and others found that by taking repeated random samples from a data set (1000 random samples is typical) and determining risk factors for an outcome from each random new data set using statistical modeling, the predictor variables obtained from all the 1000 random samples usually were different but that some variables were never selected in the model and others were selected consistently. The frequency of occurrence of risk factors among the 1000 or more models provides variables that have a high degree of reproducibility and reliability as independent risk factors of the given outcome. This process is called *bootstrap bagging*[108] and has formalized the development of model building that previously was more of an art than a science. As a result of this work with bootstrap analysis, model building and risk adjustment will be held to a more rigorous scientific standard.

USES OF OUTCOMES ASSESSMENT AND RISK STRATIFICATION

There are multiple areas where the tools of risk stratification and outcome analysis can be used to judge effectiveness of care and to aid providers in quality improvement, including the following: (1) cost containment, (2) patient education, (3) effectiveness-of-care studies, and (4) improving provider practices. Table 7-10 provides an idealized list of some of the potentially beneficial uses and goals of risk stratification.

Improving the Quality of Care

The ultimate goal of risk stratification and outcomes assessment is to account for differences in patient risk factors so that patient outcomes can be used as an indicator of quality of care. A major problem arises in attaining this goal because uniform definitions of quality of care are not available. This is particularly true of cardiovascular disease. For example, there are substantial geographic differences in the rates at which patients with cardiovascular diseases undergo diagnostic procedures, and incidentally, there is little, if any, evidence that these variations are related to survival or improved outcome. In one study, coronary angiography was performed in 45% of patients after acute myocardial infarction in Texas compared with 30% of patients in New York State ($p < .001$ for comparison between states).[109] In these patient populations, the differences in the rate of coronary revascularization were not as dramatic, but the survival in these patients was not related to the type of treatment or diagnostic procedures. Regional variations of this sort suggest that a rigorous definition of the "correct" treatment of acute myocardial infarction, as in other cardiovascular disease states, is elusive and that the definition of quality of care for such patients is imperfect. Similar imperfections exist for

Table 7–10.

Uses of Risk Stratification and Outcome Assessment

Risk-stratification goal	Example of methodology	Potential benefit
Cost containment	Risk-adjusted patient care costs determined and tracked over time	Cost-efficient institution's or physician's benefit from savings and patients benefit from decreased cost
Improve physician practices	Physician-specific risk-adjusted outcomes determined and made available to practitioners in a nonpunitive way	Physicians improve practice patterns by careful analysis of risk-adjusted data
Improve patient education	Risk-adjusted provider profiles (both hospital- and physician-specific) made available to the public in a nonthreatening, nonpunitive manner	Patients understand the risks of a given procedure and have more accurate expectations about given intervention; patients have better understanding of "high risk"
Evaluate effectiveness of care	Risk stratification of population-based retrospective studies used to identify high-risk subsets	Efficacy trials devised and implemented to test benefit in high-risk subsets; with refinements, may allow comparison among providers with goal of improving outliers

nearly all outcomes in patients with cardiothoracic disorders. Risk-adjustment methodologies can isolate patient risk factors that are associated with poor outcome, but what to do about these risk factors and how to improve outcomes based on risk stratification are uncertain. Much more work is required to define optimal outcomes and treatment standards based on risk profile.

Recognizing the difficulties in defining "best practices" for a given illness, professional organizations have opted to promote practice guidelines or "suggested therapy" for given diseases.[63,110,111] These guidelines represent a compilation of available published evidence, including RCTs and risk-adjusted observational studies, as well as consensus among panels of experts proficient at treating the given disease.[112] For example, the practice guideline for CABG is available for both practitioners and the lay public on the Internet (www.acc.org/clinical/guidelines/bypass/execIndex.htm). Table 7-7 summarizes the 1999 AHA/ACC guidelines for CABG in patients with acute (Q-wave) myocardial infarction. These guidelines were developed using a summation of available RCTs, risk-adjusted observational studies, and expert consensus. They are meant to provide clinicians with accepted standards of care that most would agree on, with an ultimate goal of limiting deviations from accepted standards.

Guideline development represents a work in progress. The methodology for developing guidelines for disease treatment is evolving. Many published guidelines do not adhere to accepted standards for developing guidelines.[113] The area where greatest improvement is needed is in the identification, evaluation, and synthesis of the scientific evidence. For example, guidelines for the management of bleeding during cardiac procedures are available but are relatively unsuccessful in limiting nonautologous blood transfusion.[114] There is still marked variability in transfusion practices and blood-conservation interventions.[115] There are at least two reasons for this failure of guidelines. First, accurate and timely information about the platelet and coagulation status of patients in the operating room or in the ICU is difficult to obtain. Second, and possibly most important, patient, physician, and institutional variability in decisions about transfusion (e.g., transfusion trigger) is difficult to control and manage. These limitations in the effectiveness of guidelines in altering physician practices are a drawback of guideline efforts. The most important aspect of practice guidelines is implementation of the guidelines themselves.

Efficacy Studies versus Effectiveness Studies

There are many efficacy studies relating to cardiothoracic surgery. These studies attempt to isolate one procedure or device as beneficial for patient outcome. The study population in efficacy studies is chosen specifically to contain as uniform a group as possible. Typical examples of efficacy studies include randomized, prospective, clinical trials comparing use of a procedure or device in a well-defined population with an equally well-defined control population.

Efficacy studies are different from effectiveness studies.[5] The latter deal with whole populations and attempt to

determine the best treatment option that provides optimal outcome in a population that typically would be treated by a practicing surgeon. An example of an effectiveness study is a retrospective study of outcome in a large population treated with a particular heart valve. Risk stratification is capable of isolating associations between outcome and risk factors. Methodologic enhancements in risk adjustment are capable of reducing biases inherent in population-based retrospective studies[98] but can never eliminate all confounding biases in observational studies.

One reasonable strategy for using risk stratification to improve patient care is to isolate high-risk subsets from population-based retrospective studies (i.e., effectiveness studies) and then to test interventions to improve outcome in high-risk subsets using RCTs. This is a strategy that ultimately should lead to the desired goal of improved patient care. For example, a population-based study on postoperative blood transfusion revealed that the following factors were significantly associated with excessive blood transfusion (defined as more than 4 units of blood products after CABG): (1) template bleeding time, (2) red blood cell volume, (3) CPB time, and (4) advanced age.[116] Cross-validation of these results was carried out on a similar population of patients undergoing CABG at another institution. Based on these retrospective studies, it was reasonable to hypothesize that interventions aimed at reducing blood transfusion after CABG were most likely to benefit patients with prolonged bleeding time and low red blood cell volume. A prospective clinical trial then was performed to test this hypothesis using two blood-conservation techniques, platelet-rich plasma saving and whole-blood sequestration, in patients undergoing CABG. The results of this stratified, prospective clinical trial showed that blood-conservation interventions were beneficial in the high-risk subset of patients.[117] The implications of these studies are that more costly interventions such as platelet-rich plasma saving are only justified in high-risk patients, with the high-risk subset being defined by risk-stratification methodologies. Other strategies have been developed that use risk-adjustment methods to improve quality of care, and these methods will be discussed below.

Other Goals of Outcome Analysis (Cost Containment and Altering Physician Practices)

Financial factors are a major force behind health care reform. America's health care costs amount to 15 to 20% of the gross national product, and this figure is rising at a rate of 6% annually. Institutions that pay for health care are demanding change, and these demands are fueled by studies that suggest that 20 to 30% of care is inappropriate.[118] Charges of inappropriate care stem largely from the observation that there are wide regional variations in the use of expensive procedures.[119,120] This resulted in a shift in emphasis, with health care costs being emphasized on equal footing with clinical outcomes of care. Relman suggested that concern about clinical outcomes will be used by patients, payors, and providers as a basis for distribution of future funding of health care.[121] While wide differences in use of cardiac interventions initially fueled charges of overuse in certain areas,[122] recent evaluations suggest that underuse of indicated cardiac interventions [either percutaneous transluminal coronary angioplasty (PTCA) or CABG] may be a cause of this variation.[122–127] Whether caused by underuse or overuse of cardiovascular services, regional variations in resource utilization make it difficult to use outcomes assessment as an indicator of quality of care.

If the causes of regional variations in the use of cardiac interventions seem puzzling, then physician practice behavior might seem bizarre. One study showed that there were unbelievably large variations in care delivered to patients having cardiac surgery.[128] Among six institutions that treated very similar patients (Veterans Administration medical centers), there were large differences in the percentage of elective, urgent, and emergent cases at each institution, ranging from 58 to 96% elective, 3 to 31% urgent, and 1 to 8% emergent.[128] There was also a 10-fold difference in the preoperative use of intra-aortic balloon counterpulsation for control of unstable angina, varying from 0.8 to 10.6%.[128] Similar variations in physician-specific transfusion practices,[129] ordering of blood chemistry tests,[130] anesthetic practices,[131] treatment of chronic renal failure,[132] and use of antibiotics[133] are observed. This variation in clinical practice may reflect uncertainty about the efficacy of available interventions or differences in practitioners' clinical judgment. Some therapies with proven benefit are underused.[131,132] Whatever the causes of variations in physician practice, they distort the allocation of health care funds in an inappropriate way. Solutions to this problem involve altering physician practice patterns, something that has been extremely difficult to do.[134] How can physician practice patterns be changed in order to improve outcome? Evidence suggests that the principal process of outcome assessment, the case-by-case review [traditionally done in the morbidity and mortality (M&M) conference format], may not be cost-effective and may not improve quality.[135] Health care experts suggest that the M&M conference should be replaced by profiles of practice patterns at institutional, regional, or national levels. One proposed model for quality improvement involves oversight that emphasizes the appropriate balance between internal mechanisms of quality improvement (i.e., risk-adjusted outcomes analysis) and external accountability.[135] Risk adjustment is an essential element of this type of outcomes management and assessment. Quality improvement projects (see below) that employ risk stratification to identify patients at high risk for adverse outcomes are essential components of internal review to improve physician-driven variations in resource utilization. Likewise, external accountability, as painful as it may be, relies on accurate risk assessment for fairness and for acceptance by the stakeholders in the process. It remains for the tools of risk stratification and outcomes assessment to be used accurately and effectively for the full potential of these methods to be recognized.

Rewarding High Performers ("Pay for Performance")

Performance measures are regarded as the cornerstone of a new paradigm in quality assessment. In this approach, a quality initiative takes this general form:

1. A patient population is specified.
2. Process measures are developed to serve as quality metrics for this population.
3. The process measures are collected.
4. Compliance with performance measures is tracked for participating centers.
5. Aggregate results are used to establish norms and benchmarks.
6. Participating centers receive data feedback compared with benchmarks.
7. Participating centers are evaluated through this monitoring process.

It becomes immediately apparent that the validity of this approach depends primarily on the validity of the performance measures. This recognition led to the emergence of several national organizations specifically devoted to the rigorous development of performance measures, most notably the National Quality Forum (NQF).

Using the NQF protocol, the Society of Thoracic Surgeons (STS) played a central role in developing national consensus standards for adult cardiac surgery. This process yielded 21 performance measures (Table 7-11). These measures constitute a unique set of nationally accepted tools that can be used to determine the quality of care in cardiac surgical programs. The significance of this set of measures should be emphasized. Prior to their development, there was no general agreement on the specific parameters that are linked to "quality" in cardiac surgery. With development of the NQF measures, these parameters can be identified using the most objective process currently available. NQF measures provide the "toolbox" for quality measurement in cardiac surgery. Any meaningful quality initiative in cardiac surgery should be based on these performance measures.

The STS Database provides benchmark values for all but three of these performance measures. In the most direct application of NQF measures, an institution simply compares its values against the benchmark values. This process allows providers to pinpoint opportunities for improvement so that resources can be directed specifically to areas of greatest need with the expectation that payors will provide increased resources to the institutions that meet the standards.

More sophisticated approaches involve the development of *quality models* that account for the net impact of some or all of the measures. These quality models can be used to develop rating systems or scorecards that allow relative quality comparisons between individual institutions or between an institution and a national benchmark. Models of this sort are in the early stages of development and, as discussed elsewhere, must be understood fully and applied carefully in this context.

Table 7–11.

National Standards for Cardiac Surgery Based on NQF Consensus

1.	Participation in a systematic database for cardiac surgery
2.	Surgical volume for CABG, valve surgery, and CABG + valve surgery
3.	Timing of prophylactic antibiotic administration
4.	Selection of prophylactic antibiotic
5.	Preoperative beta blockade
6.	Use of internal mammary artery
7.	Duration of prophylactic antibiotic
8.	Prolonged intubation (<24 hours postoperatively)
9.	Deep sternal wound infection rate
10.	Stroke/cerebrovascular accident
11.	Postoperative renal insufficiency
12.	Surgical reexploration
13.	Antiplatelet medications at discharge
14.	Beta blockade at discharge
15.	Antilipid treatment at discharge
16.	Risk-adjusted operative inpatient mortality for CABG
17.	Risk-adjusted operative mortality for CABG
18.	Risk-adjusted operative mortality for aortic valve replacement (AVR)
19.	Risk-adjusted operative mortality for mitral valve replacement (MVR)
20.	Risk-adjusted operative mortality for MVR + CABG
21.	Risk-adjusted operative mortality for AVR + CABG

Many people believe that additional incentives for quality improvement can be obtained by linking quality scores with reimbursement. This concept, commonly called *pay for performance* (P4P), or *value-based purchasing*, has gained a groundswell of support from a variety of organizations. Effective performance-based payments have shown positive results in the private sector, and despite the absence

of convincing evidence, there is widespread belief that similar results can be obtained in medicine.

P4P has become particularly popular among third-party payors. Historically, payment was based on the number and the complexity of services provided to patients, but with P4P, some portion of payment will be determined by the quality rather than the quantity of services. It remains to be seen whether reimbursement incentives will lead to meaningful improvements in quality of care.

There are several reimbursement models, the most common of which is the *tournament model.* In the tournament approach, there are unequivocal winners and losers: Top performers are provided bonuses, which come from reduced payments to the lower performers. Although popular because of its simplicity, this budget-neutral approach, in that one "robs Peter to pay Paul," is subject to considerable criticism because it penalizes precisely the group that most needs financial resources for improvement. Regardless of the mode of implementation, it is obvious that *performance measures* are destined to be an important and intrinsic part of the surgical milieu in upcoming years.

RISKS OF CARDIAC OPERATIONS

Risks for Operative Mortality

By far the bulk of available experience with risk stratification and outcomes analysis in cardiothoracic surgery deals with risk factors associated with operative mortality, particularly in patients undergoing coronary revascularization. Most of the risk-stratification analyses shown in Tables 7-1 and 7-9 are used to evaluate life or death outcomes in surgical patients with ischemic heart disease in part because mortality is such an easy endpoint to measure and track. As mentioned previously, each of the risk-stratification systems shown in Tables 7-1 and 7-9, with the exception of the APACHE III system, computes a risk score based on risk factors that depend on patient diagnosis. For the diagnosis of ischemic heart disease, Table 7-9 shows the significant risk factors found to be important for a spectrum of the risk-stratification systems. The definition of operative mortality varies among the different systems (either 30-day mortality or in-hospital mortality), but the risk factors identified by each of the stratification schemes in Table 7-9 show many similarities. Some variables are risk factors in almost all stratification systems; some variables are never significant risk factors. Each of the models has been validated using separate data sets; hence there is some justification in using any of the risk-stratification methods both in preoperative assessment of patients undergoing CABG and in making comparisons among providers (either physicians or hospitals), but certain caveats exist about the validity and reliability of these models (see below). At present, it is not possible to recommend one risk-stratification method over another. In general, the larger the sample size, the more risk factors can be found. An ideal model would include more variables than even the most robust model in Table 7-9.

There are a large number of patient variables other than those shown in Table 7-9 that have been proposed as risk factors for operative mortality following coronary revascularization. Such variables as serum blood urea nitrogen (BUN) concentration,[136] cachexia,[137] oxygen delivery,[138] human immunodeficiency virus (HIV) infection,[139] case volume,[140] low hematocrit on bypass,[141] use of the internal mammary artery,[142] the diameter of the coronary artery,[143] and resident involvement in the operation[144,145] fit this description. On the surface, the clinical relevance of these variables may seem undeniable in published reports, but very few of these putative risk factors have been tested with the rigor of the variables shown in Table 7-9. The regression diagnostics (e.g., ROC curves and cross-validation studies) performed on the models included in Tables 7-1 and 7-9 suggest that the models are good, but not perfect, at predicting outcomes. In statistical terms, this means that all the variability in operative mortality is not explained by the set of risk factors included in the regression models. Hence it is possible that inclusion of new putative risk factors in the regression equations may improve the validity and precision of the models. New regression models and new risk factors must be scrutinized and tested using cross-validation methods and other regression diagnostics before acceptance. It is uncertain whether inclusion of many more risk factors will improve the quality and predictive ability of regression models significantly. For example, the STS risk-stratification model described in Tables 7-1 and 7-9 includes many predictor variables, whereas the Toronto risk-adjustment scheme includes only five predictor variables. Yet the regression diagnostics for these two models are similar, suggesting that both models have equal precision and predictive capabilities. This suggests that the models are effective at predicting population behavior but not necessarily suited for predicting individual outcomes. Further work needs to be done both to explain the differences in risk factors seen between the various risk-stratification models and to determine which models are best suited for studies of quality improvement.

There are many critical features of any risk-adjustment outcome program that must be considered when determining quality of the risk-stratification method or when comparing one with another (see below). Daley provides a summary of the key features that are necessary to validate any risk-adjustment model.[33] She makes the point that no clearcut evidence exists that differences in risk-adjusted mortalities across providers reflect differences in the process and structure of care.[146] This issue needs further study.

Risk Factors for Postoperative Morbidity and Resource Utilization

Patients with nonfatal outcomes following operations for ischemic heart disease make up more than 95% of the pool of patients undergoing operation. Of approximately 500,000 patients having CABG yearly, between 50% and 75% have what is characterized by both the patient and the provider as an uncomplicated course following operation. The complications

Table 7–12.

Risk Factors Associated with Either Increased Length of Stay (L) or Increased Incidence of Organ Failure Morbidity (M) or Both (L/M) Following Coronary Revascularization

Risk factor	STS[147]	Boston[278]	Albany[11]	VA[194, 279]	Canada[7]
Demographics					
Advanced age	M	L		M	L
Low preoperative red blood cell volume	M		L/M		
Female gender	M				L
Disease-specific diagnoses					
CHF	M	L	L/M	M	
Concomitant valve disease	M			M	L
Reoperation	M			M	L
LV dysfunction (ejection fraction)	M				L
Surgical priority	M			M	L
IABP preop	M	L			
Active endocarditis				M	
Comorbid conditions					
Obesity		L			
Renal dysfunction	M	L	L	M	
Peripheral vascular disease	M		L	M	
Chronic obstructive lung disease	M		L		
Cerebrovascular disease	M		L/M		
Hypertension	M		L/M		

CHF = congestive heart failure; LV = left ventricular; IABP = intra-aortic balloon counterpulsation.

occurring in surviving patients range from serious organ system dysfunction to minor limitation or dissatisfaction with lifestyle and account for a significant fraction of the cost of the procedures. We estimate that as much as 40% of the yearly hospital costs for CABG is consumed by 10 to 15% of the patients who have serious complications after operation.[11] This is an example of a statistical principle called the *Pareto principle* (see below) and also suggests that reducing morbidity in *high-risk* cardiac surgical patients has a significant impact on cost reduction.

A great deal of information exists on nonfatal complications after cardiac operations. Several large databases identify risk factors for both nonfatal morbidity and increased resource utilization. Table 7-12 is a summary of some of the risk factors identified by available risk-stratification models that are associated with either serious postoperative morbidity or increased resource utilization as measures of undesirable outcomes.

The STS Risk Model for Postoperative Morbidity

For many years, operative *mortality* was the sole criterion for a successful CABG procedure. This concept has given way to a broader focus on the entire hospitalization associated with CABG. There is universal agreement that nonfatal complications play a central role in the assessment of CABG quality,

but many morbidity outcomes are relatively difficult to define and track. Risk adjustment is particularly difficult because of the fact that risk factors for most complications are not well established. The low frequency of some complications also creates statistical challenges.

Shroyer and colleagues used part of the large national experience captured in the STS Database to examine five important postoperative CABG complications: stroke, renal failure, reoperation within 24 hours after CABG, prolonged (>24 hours) postoperative ventilation, and mediastinitis.[147] For each of these complications, risk factors were identified using univariate screening followed by multivariate logistic regression analysis (Table 7-12). Predictive models were developed for each of the five complications, thereby allowing one to use specific patient risk factors to adjust for severity of illness and determine *O:E* ratios for providers. This, in turn, allows for meaningful comparisons of risk-matched populations between hospitals or between an institution and a national benchmark.

For the purposes of morbidity estimates, over 500,000 patients from the STS Database were examined.[147] This allowed an accurate estimate of the frequency of each of these five postoperative complications. For example, the morbidity estimates in CABG patients from this large database are as follows: (1) stroke, 1.63%; (2) renal failure requiring dialysis, 3.53%; (3) prolonged postoperative ventilation, 5.96%; (4) mediastinitis, 0.63%; and (5) reoperation within 24 hours, 7.17%. Predictor variables from the logistic regression for each complication demonstrated considerable overlap, but there were substantial differences in odds ratios associated with individual risk factors. The relative importance of specific risk factors differed depending on the outcome measure. For each of the complications, preoperative shock was invariably a major risk factor, as was any form of diabetes. Redo operations were associated with a high odds ratio of most postoperative morbidities, particularly for prolonged postoperative ventilation.

These models were associated with *c*-index values ranging from 0.76 (renal failure) to 0.64 (reoperation within 24 hours), indicating reasonable reliability of the models. The *c*-indices are generally less than those seen with typical models of CABG operative mortality. Nevertheless, the ability to use validated models to risk stratify patients in this context is invaluable. It should be mentioned that NQF and other national quality initiatives clearly have placed a high premium on the need for risk adjustment for most outcome measures, including both mortality and morbidity outcomes.

Risk Factors That Do Not Predict Outcome

Occasionally, studies appear that suggest that a particular patient variable is *not* a risk factor for a particular patient outcome. Care must be exercised in interpreting negative results. Many putative risk factors labeled as "no different from control" in studies using inadequate samples have not received a fair test. For example, Burns and associates studied preoperative template bleeding times in 43 patients undergoing elective CABG.[148] They found no increased postoperative blood loss in patients with prolonged skin bleeding times. Their study reports 5 patients whose bleeding times were prolonged greater than 8 minutes. In this small sample, there was a trend toward more units of blood transfused, but differences between high and low bleeding time groups were reported as "not significant" by the authors at the $\alpha = 5\%$ level (i.e., $p = .05$). Using the authors' data, it is possible to compute a β error for this negative observation of less than 0.5. This means that there is as much as a 50% chance that the negative finding is really a false-negative result. This high false-negative rate occurs because of the small sample size and the wide variation in bleeding time values. We have found elevated bleeding time (>10 minutes) to be a significant multivariate risk factor for excessive blood transfusion after CABG in two different studies.[116,117] Although there is controversy about the value of bleeding time as a screening test,[149,150] it is possible that discarding the bleeding time after an inconclusive negative trial, such as that of Burns and colleagues, may ignore a potentially important risk factor. Care must be taken in the interpretation of a negative finding, especially in a small study group. A similar cautionary note was sounded by Freiman and colleagues after reviewing the medical literature over a 10-year period. These authors found that 50 of 71 "negative" RCTs could have missed a 50% therapeutic improvement from intervention because the sample size studied was too small.[151] Their conclusions were that many therapies discarded as ineffective after inconclusive negative trials still may have a clinically important effect. Negative findings in a literature report require scrutiny and an understanding of type II statistical errors.[41]

Patient Satisfaction as an Outcome

Other post-CABG outcomes, such as patient satisfaction and sense of well-being, have been less well studied. The increasing importance of patient-reported outcomes reflects the increasing prevalence of chronic disease in our aging population. The goal of therapeutic interventions is often to relieve symptoms and improve quality of life rather than to cure a disease and prolong survival. This is especially important in selecting elderly patients for operation. One report from the United Kingdom suggests that as many as a third of patients over the age of 70 did not have improvement in their disability and overall sense of well-being after cardiac operation.[152] Risk-stratification methodology may prove to be important in identifying elderly patients who are optimal candidates for revascularization based on quality-of-life considerations.

Surprisingly little published information is available regarding long-term functional status or patient satisfaction following CABG. One comparative study found no difference between patients older than 65 years and younger than or equal to 65 years with regard to quality-of-life outcomes (e.g., symptoms, cardiac functional class, activities of daily living, and emotional and social functioning).[153] This study also found a direct relationship between clinical severity and quality-of-life indicators because patients with fewer comorbid

conditions and better preoperative functional status had better quality-of-life indicators 6 months after operation. Rumsfeld and colleagues found that improvement in the self-reported quality of life [from the Short-Form Health Survey (SF-36)] was more likely in patients who had relatively poor health status before CABG compared with those who had relatively good preoperative health status.[154] Interestingly, these same authors found that poor preoperative self-reported quality-of-life indicators as measured by the SF-36 questionnaire was an independent predictor of operative mortality following CABG.[155] These findings suggest that the risks of patient dissatisfaction after CABG depend on preoperative comorbid factors, as well as on the indications for and technical complexities of the operation itself. At present, no risk-stratification scheme has been devised to identify patients who are likely to report dissatisfaction with operative intervention following CABG.

There are several difficulties with measurement of patient-reported outcomes, and consequently, cardiothoracic surgeons have not been deeply involved with systematic measurements of patient satisfaction after operation. One problem is that patient-reported outcomes may depend on the type of patient who is reporting them and not on the type of care received. For example, younger Caucasian patients with better education and higher income are more likely to give less favorable ratings of physician care.[156] However, considerable research has been done dealing with instruments to measure patient satisfaction. At least two of these measures, the SF-36[157] and the San Jose Medical Group's Patient Satisfaction Measure,[158] are used to monitor patient satisfaction over time. The current status of these and other measures of patient satisfaction does not allow comparisons among providers because the quality of the data generated by these measures is poor. These instruments are characterized by low response rates, inadequate sampling, infrequent use, and unavailability of satisfactory benchmarks. Nonetheless, available evidence indicates that patient-reported outcomes can be measured reliably[159,160] and that feedback on patient satisfaction data to physicians can improve physician practices significantly.[161] It is likely that managed-care organizations and hospitals will use patient-reported outcome measures to make comparisons between institutions and between individual providers. Risk-adjustment methods for patient-reported outcomes will be required to provide valid comparisons of this type.

Process and Structural Domains of Outcomes Assessment

In 1966, Donabedian suggested that quality in health care was defined as improvement in patient status obtained after accounting for the patient's severity of illness, presence of comorbidity, and the medical services received.[32,162] He further proposed that quality could best be measured by considering three domains: structure, process, and outcome. The notion of measuring quality in this framework is well accepted in most quality-improvement initiatives in place today.

While this general approach has become a modern mainstay in quality programs, the choice of specific measures of structure, process, or outcome can be controversial. *Procedural volume*, for example, is a structural measure that has been used as a surrogate for competent surgical quality. While it may be true that quality and volume are linked for some procedures, it is certainly not the case for all (see "Volume/Outcome Relationship and Targeted Regionalization" below). The practical implications of this structural measure are quite broad and call into play not only clinical considerations but also potentially volatile political ones as well. Likewise, *specialty certification* is a structural measure used often in quality improvement programs. Whereas it is generally true that board-certified individuals usually provide optimal care, it is not invariably true that those not boarded will provide inferior care. One may see readily how inflexible and arbitrary reliance on these structural measures could lead to inappropriate partitioning of care, particularly in small hospitals or underserved regions. Accordingly, it should be emphasized that clinical judgment and perhaps even political judgment should be an integral feature of programs using the Donebedian paradigm.

Birkmeyer pointed out distinct advantages and disadvantages associated with performance measures.[163] For example, the fact that *structural measures* can be tabulated readily in an inexpensive manner using administrative data is a distinct advantage. On the other hand, many structural measures do not lend themselves to alteration. Particularly in smaller hospitals, there simply may be no way to increase procedural volume or to introduce costly design changes in an attempt to create more favorable comparisons with structural measures. *Process measures* often are strongly linked to quality improvement, and they are usually actionable on a practical level. Their major disadvantage lies in the fact that they may not be generally applicable to all patients undergoing a given procedure. To ensure that the right population is examined requires individual clinical assessment and an appreciation for proper exclusionary criteria. This process can be time-intensive and can require sophisticated data-collection systems.

Some practical guidelines have been proposed for using performance measures to assess quality. The major considerations in using performance measures are *volume* and *operative risk*. In general, low-volume, low-risk procedures do lend themselves to a Donebedian-type analysis. Low-volume, high-risk procedures probably should focus primarily on structural measures. High-volume procedures, regardless of risk, can best be assessed with a combination of process and outcome measures.

TOTAL QUALITY MANAGEMENT (TQM) AND OUTCOME ANALYSIS: CASE STUDIES

American health care made almost unbelievable strides in the twentieth century. We are at the brink of being able to treat disease at the molecular level. Cardiac surgeons treat patients who were considered inoperable as recently as a decade ago. Yet almost no one is happy with the health care

Table 7–13.

Principles of Total Quality Management (TQM) Applied to Health Care

Principle	Explanation
Health care delivery is a process.	The purpose of a process is to add value to the input of the process. Each person in an organization is part of one or more processes.
Quality defects arise from problems with the process.	Former reliance on quotas, numerical goals, and discipline of workers is unlikely to improve quality, since these measures imply that workers are at fault and that quality will get better if workers do better. The problem is with the process not with the worker. Quality improvement involves ``driving out fear'' on the part of the worker and breaking down barriers between departments so that everyone may work effectively as a team for the organization.
Customer-supplier relationships are the most important aspect of quality.	A customer is anyone who depends on the organization. The goal of quality improvement is to improve constantly and to establish a long-term relationship of loyalty and trust between customer (patient) and supplier (health care organization) and thereby meet the needs of the patient. The competitive advantage for an organization that can better meet the needs of the customer is obvious. The organization will gain market share, reduce costs, and waste less effort in activities that do not add value for patients.
Understand the causes of variability.	Failure to understand variation in critical processes within the organization is the cause of many serious quality problems. Unpredictable processes are flawed and are difficult to study and assess. Managers must understand the difference between random (or common-cause) variation and special variation in a given outcome.
Develop new organizational structures.	Managers are leaders, not enforcers. Eliminate management by objective numerical goals. Remove barriers that rob workers of their right to pride of workmanship. Empower everybody in the organization to achieve the transformation to a quality product.
Focus on the most "vital few" processes.	This is known as the *Pareto principle* (first devised by Juran) and states that whenever a number of individual factors contribute to an outcome, relatively few of those items account for the bulk of the effect. By focusing on the "vital few," the greatest reward for effort will occur.
Quality reduces cost.	Poor quality is costly. Malpractice suits, excessive use of costly laboratory tests, and unnecessarily long hospital stays are examples of costly poor quality. The premise that it is too costly to implement quality control is incorrect.
Statistics and scientific thinking are the foundation of quality.	Managers must make decisions based on accurate data using scientific methods. Not only managers but all members of the organization use the scientific method for improving processes as part of their normal daily activity.

system. It costs too much, excludes many, is inefficient, and is ignorant about its own effectiveness. This state of confusion has been likened to the conditions that existed with Japanese industry after World War II. Out of the confusion and crisis of post–World War II, Japan has become a monolith of efficiency. Two major architects of this transformation were an American statistician, W. Edwards Deming, and a Romanian-American theoretician, J. M. Juran. They led the way in establishing and implementing certain principles of management and efficiency based on quality. Their efforts are recognized in Japan by the annual awarding of the Deming Prizes in recognition of achievements in attaining high quality. Deming's and Juran's books are some of the "bibles" of quality management in industry.[164,165]

Deming's and Juran's principles are given the acronym of *TQM,* for *total quality management.* The amazing turn-around

Table 7–14.

Steps in a TQM Project

Step	Goal	Tools
1. Definition of problem	List and prioritize problems that affect quality. Define project and identify team to solve problem.	Flow process diagram Pareto chart Customer surveys Risk stratification to identify high-risk subsets
2. Diagnosis of problem	Formulate and test hypotheses about the cause of problem.	Process flow diagram Experimental design methods Statistics to test hypotheses
3. Remedy for problem	Managers and workers participate in training and implementing new or revised process.	Managerial skills in initiating training, implementing solutions, designing controls, and dealing with resistance
4. Check performance of new process	Monitoring process for effectiveness and developing new TQM projects based on results of modifications to the old process.	Sampling methods to get representative sample of outcome Control charts used at every level of the organization—graphs, histograms, stem-and-leaf displays, CUSUM methods, regression analysis, etc.

in Japanese industry led many organizations to embrace the principles of TQM, including organizations involved in the delivery and assessment of health care.[166] Using this approach, health care is viewed as a process requiring raw materials (e.g., sick patients), manufacturing steps (e.g., delivery of care to the sick), and finished products (e.g., outcomes of care). Managerial interventions are important at each step of the process to ensure high-quality product. Table 7-13 outlines the key features of TQM.

An example of application of the principles of TQM to health care delivery is described in the book by Berwick and colleagues.[166] These authors describe the experiences of the National Demonstration Project on Quality Improvement in Health Care in applying the principles of TQM to solve a broad spectrum of health care problems. Twenty-one health care organizations throughout the United States participated in an experiment in the application of TQM to health care. Each organization selected a problem at its institution and, with the aid of an industrial consultant, applied the principles of TQM to attempt to solve the problem. Each institution involved in the project reported that the initiation of TQM practices at that institution was far more valuable than the actual solving of a particular problem in the short term. In the jargon of TQM, the implementation and understanding of TQM principles at every level within an institution produced significant improvement in customer-supplier throughput—i.e., improvement in patient care.

An important component of the TQM process is the use and availability of statistical methods to provide the necessary information to managers and workers who must make decisions about the health care process.[167] While the statistical methods of TQM have a slightly different focus from those outlined earlier for risk adjustment, the goal is the same—i.e., improving the quality of health care. Hence it is reasonable to include a description of the methods of TQM because inevitably they will come up in discussions about health care outcomes and assessing risks for those patient outcomes.

Table 7-14 provides an outline of the sequential steps involved in solving a problem using TQM. Risk stratification plays an important role in the TQM process. One of the most important applications of risk stratification in TQM is in the early stages of the project when definition of the problems that affect quality is being considered. Usually a problem is identified from critical observations—e.g., excessive blood transfusions after operation may result in increased morbidity, including disease transmission, increased infection risk, and increased cost . Tools such as flow diagrams that document all the steps in the process (e.g., steps involved in the blood transfusion process after CABG) are helpful in this phase of the analysis. A logical starting point for efforts to improve the quality of the blood transfusion process would be to focus on a high-risk subset of patients who consume a disproportionate amount of resources. An Italian economist named Pareto made the observation that a few factors account for most of the outcomes of a complex process, and this has been termed the *Pareto principle.* Juran was one of the first to apply this principle to manufacturing in the United States and Japan.[165] The Pareto principle is a valuable tool in improving quality. A graphic method of identifying the spectrum of outcomes in a process is included in most statistics programs and is termed a *Pareto diagram.* Figure 7-5 is an example of a Pareto diagram for blood product transfusion. The data are arranged in histogram format, and the population distribution of patients receiving transfusions is plotted

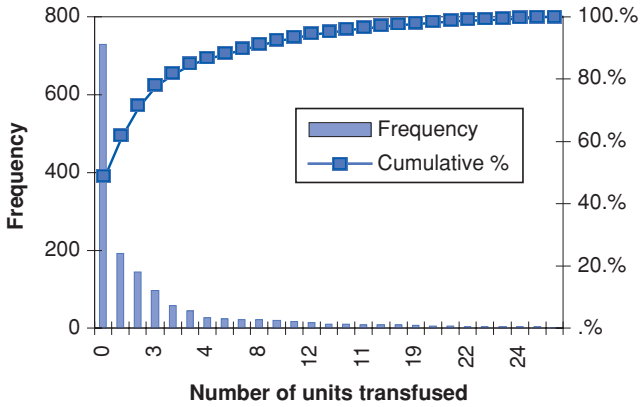

Figure 7-5. Pareto diagram of blood transfusion in 1489 patients undergoing cardiac procedures at Albany Medical Center Hospital during 1994.

simultaneously. The Pareto diagram is an example of a graphic method of risk identification. There are at least three remarkable features of the Pareto diagram in Fig. 7-5. First, over 50% of patients undergoing cardiac procedures receive no homologous blood transfusion. Second, patients who receive more than 10 donor units of blood products are in the 90th percentile of the patient transfusion profile. Third, by looking at the diagram, it is possible to identify a subset of patients who consume more than a certain threshold of blood products. For example, it can be estimated that 20% of the patients consume 80% of the blood products transfused. Substantial savings in cost and possibly other morbidity will result by decreasing the amount of blood transfusion in these 20% of "high-end" users. Strategies can be devised and tested to decrease blood product consumption in the high-risk subset, and ultimately, monitors must be set up to test the effectiveness of the new strategies. Application of the Pareto principle is a valuable tool in risk stratification and TQM, but some of the risk-stratification analytic tools discussed previously can be equally useful in the TQM process. For example, linear regression analysis might be used to identify which of several factors are most important in predicting improved blood transfusion profiles after CABG, or Cox analysis might be used to identify risk factors for increased hospital length of stay in patients at high risk for excessive blood transfusion. Other tools of TQM such as data-sampling strategies and use of control charts play an important role in the process (see below).

Tracking trends using visual aids such as Pareto diagrams and other charts are an important part of quality-improvement interventions. Another type of control-chart technique, *cumulative sum* (CUSUM), has become increasingly popular over the past decade and may help to address some of the problems associated with traditional outcome monitoring. When preparing a performance report, or "report card,"[53] the usual data-collection period is 1 year for hospitals and 2 to 3 years for individual surgeons. Add to this 1 to 1½ years for audit, validation, and analysis, and there may be a several-year delay between the early patients in a series and the ultimate publication of a report. This is clearly an ineffective way to document and address deteriorating trends in performance objectively, particularly if a new procedure is being introduced or if there are subjective concerns regarding outcomes.[168–171]

The CUSUM chart and its various modifications [e.g., sequential probability ratio test (SPRT), cumulative risk-adjusted mortality (CRAM), and variable life-adjusted display (VLAD)] are ideally suited to detecting such trends, particularly when they are small and subtle.[168,169,172,173] In its simplest form, the CUSUM chart is a plot of cumulative failures (e.g., deaths) on the vertical axis against procedure number or date on the horizontal axis. For each failure, the graph advances one unit vertically. For each case not a failure, the graph advances horizontally by one unit. Through visual interpretation of the slope, this simple graphic indicates whether the failure rate is increasing over time. Statistical control limits (e.g., alert and alarm) can be placed around the cumulative failure lines, just as they are in other types of control charts.[168,170,173] One of the earliest and still most widely cited examples of such a CUSUM graph was from de Leval and associates,[171] who described their initial experience with neonatal arterial switch operations. Having experienced only 1 death in their first 52 patients, 7 of the next 16 patients died, resulting in a marked and statistically significant rise in the CUSUM line. After technique modifications, the CUSUM plot again became nearly horizontal.

An important modification of CUSUM charts for surgical cases is the incorporation of individual patient risk, obtained through any of the standard techniques described elsewhere in this chapter. For example, the vertical axis might plot cumulative lives saved (expected minus observed deaths) rather than surgical failures,[173] in which case a gradually rising line indicates good performance, and a line descending below the baseline may indicate poor performance. For each case, a value between –1 and + 1 is added. For example, a patient with a predicted mortality of 20% who survives would have 0.2 added to the cumulative sum, and the line would rise. Conversely, a patient with an expected mortality of 10% who dies would have negative 0.9 added to the cumulative sum line, and the line would go down.[173]

CUSUM charts and their various modifications are used extensively, especially in the United Kingdom, to monitor medical and surgical outcomes. It appears that they may provide earlier detection of performance issues, as well as their remediation, than more traditional report cards. Novick and colleagues used a CUSUM chart to analyze the effect of changing from on-pump CABG to off-pump CABG as a primary means of operative coronary revascularization.[174] These authors found that the CUSUM methodology was more sensitive than standard statistical techniques in detecting a cluster of surgical failures or successes.

Northern New England TQM Project

The paradigm for a TQM-based approach to improving cardiac surgery quality is the Northern New England Cardiovascular Study Group (NNECVDSG). Founded in 1987, this

voluntary consortium of clinicians, scientists, and administrators represents cardiac surgery programs in northern New England. Its mission is to study and improve the quality of cardiovascular care provided to patients through the use of systematic data collection and feedback. Shortly after its formation, this group developed and validated a logistic risk model to account for case-mix differences across its member institutions.[175] Using this model, the group analyzed CABG outcomes for 3055 patients operated on at five medical centers in Maine, New Hampshire, and Vermont between July 1987 and April 1989.[176] Overall unadjusted CABG mortality was 4.3%, but this was found to vary substantially among centers (3.1 to 6.3%). Even after case-mix adjustment, significant variability persisted among medical centers ($p = .021$) and surgeons ($p = .025$). In 1990, the NNECVDSG initiated a regional intervention aimed at reducing both absolute CABG mortality and interinstitutional variability.[177] The three major components of this TQM approach included feedback of outcomes data, training in continuous quality-improvement techniques, and site visits to each program. During the latter, visitors from each discipline focused on the practice of their counterparts at the host institutions. Numerous changes were implemented as a result of these site visits, including technical aspects and processes of care, personnel organization and training, decision making, and methods of evaluating care. Following these interventions, observed mortality declined to less than expected in all categories of patient acuity.

Subsequent to these landmark papers, the consortium has continued to grow in size, now consisting of eight institutions in northern New England. The database currently contains entries for over 150,000 procedures, and data reports and proposed studies are discussed at meetings held three times annually. Over 60 peer-reviewed articles have been published in numerous areas pertaining to cardiac surgical care, ranging from the impact of preoperative variables on hospital and long-term mortality, the optimal conduct of cardiopulmonary perfusion, prevention of specific postoperative complications, on-pump versus off pump CABG surgery, and modes of death following CABG.[178–180] Models also have been developed for valve replacement surgery,[181] and a simplified risk-scoring method for bedside use has been developed[182] and incorporated into the 2004 ACC/AHA guidelines update for CABG. Nineteen years after its formation, the NNECVDSG remains at the forefront of global efforts to improve cardiac surgery quality through voluntary, confidential, and collaborative TQM.

STS Database and Quality Improvement

In the early 1980s, CABG operations were characterized by operative mortality rates typically in the range of 1 to 2%. A few years later, however, the severity of illness of CABG patients began a progressive rise that is still being seen today. Predictably, CABG operative mortality rates reached the 5 to 6% range.[183]

This rise in operative mortality was understood by cardiovascular specialists, but others were unaware of the changes that had produced these higher mortality rates, and surgeons were challenged to justify the increase in CABG mortality. It soon became apparent that databases would be essential for proper investigation of these issues. To truly analyze patient risk factors in a meaningful way required statistical risk models designed to generate a predicted operative mortality based on preoperative clinically significant factors. Clearly, this type of analysis was well beyond the capabilities of the great majority of surgical groups.

In addition, this scrutiny exposed the fact that true national benchmarks did not exist in cardiac surgery. The Society of Thoracic Surgeons (STS) recognized this compelling need for a national standard in cardiac surgery. In 1986, a formal STS committee was formed under the leadership of Dr. Richard E. Clark to develop a national database of cardiac surgery. This committee began to gather and to analyze perioperative patient data in a manner that would establish a national standard of care in cardiac surgery.

The STS Database is a voluntary registry that currently collects data from 70 to 80% of cardiac centers in the United States. Individual participant sites enter extensive clinical data on each patient undergoing cardiac surgery. This information is harvested every 6 months and aggregated at the Duke Clinical Research Institute (DCRI). The data are analyzed, and reports that include benchmark data and risk-adjusted outcomes are provided to each site. This reporting process allows sites to pinpoint areas in need of improvement so that tailored quality-assessment and -improvement programs can be developed.

The STS maintains an active Workforce on National Databases that provides leadership and oversight of database activities. Risk models are developed at periodic intervals using the biostatistical expertise and resources of DCRI in conjunction with STS leadership. Currently, risk models are based on logistic regression techniques and are designed to predict operative mortality for CABG, for mitral and aortic valve replacement, and for CABG combined with mitral and aortic valve replacement. As mentioned earlier, there are also risk models of five common postoperative complications.

The STS data allow one to monitor trends in the patient profiles of cardiac surgery patients over the years. As shown in Fig. 7-6, one can appreciate the progressive

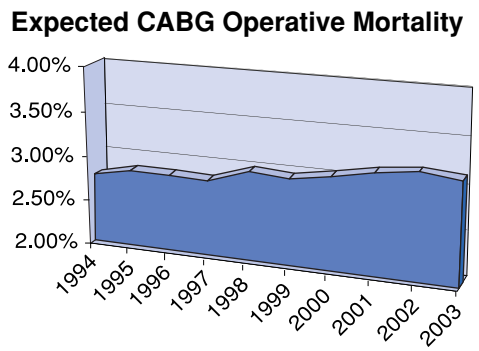

Figure 7-6. Predicted operative mortality from the Society of Thoracic Surgeons risk models between 1994 and 2003.

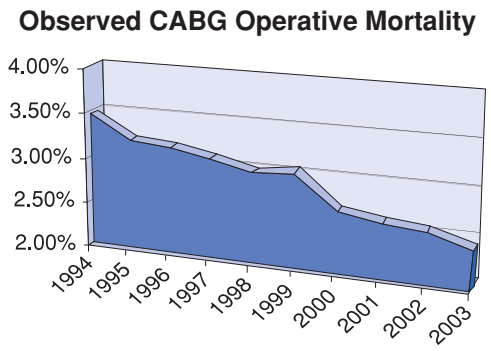

Figure 7-7. Observed operative mortality from the Society of Thoracic Surgeons Database between 1994 and 2003.

increase in operative risk in the 1994–2003 time frame. Information of this sort helps on a clinical level and has an impact on various administrative and regulatory fronts. Negotiations, with the relative value scale update committee for example, traditionally have been based on small surveys, but the use of STS data has allowed a more accurate presentation of objective information that provides a truly fair and meaningful workload analysis.

The reporting and feedback process to individual sites produced impressive improvements in surgical outcomes. As shown in Fig. 7-7, despite the increase in patient risk, there was a progressive drop in operative mortality from 1994 to 2003.

The database plays a central role in the current national quality initiatives. Information from the database allows one to monitor and analyze all but three of the NQF measures specified in Table 7-11. In future revisions, these three missing parameters will be captured in the database entry process. Specific NQF-based reports are being developed to allow users to focus directly on the measures that have been chosen to reflect surgical quality in cardiac surgery.

Third-party payors are expressing renewed interest in developing quality-improvement programs. The STS Database is being proposed as the single source of data for these programs so that surgeons will not be burdened with numerous diverse reporting requirements.

There is a groundswell of public demand for report cards and other hospital/surgeon-ranking systems. The advantages and disadvantages of such reporting systems are addressed elsewhere in this chapter, but it should be mentioned that numerous third-party payors are in the process of developing these scorecard protocols. In order to preempt the development of ill-advised and simplistic scorecards, STS experts are developing a fair and meaningful quality-rating system based on objective information from the STS Database.

The STS Database presently contains records of approximately 3 million patients, thereby making it the largest cardiac surgery database in the world. This clinical database has come to be regarded as an exceptionally valuable resource for cardiac surgeons, and its risk-assessment algorithms generally are accepted as standard quality-assessment tools in cardiac surgery. The database has numerous important practical applications that serve to promote quality improvement and ensure that the specialty is well represented in national regulatory programs.

Massachusetts Cardiac Care Quality Advisory Commission

The Massachusetts experience provides an excellent example of a successfully implemented quality-monitoring effort[65,184] in which cardiac surgeons played an active leadership role. In 2000, the Massachusetts legislature established the Cardiac Care Quality Advisory Commission, one of whose mandates was to implement a transparent, comprehensive report card for invasive cardiac services [CABG and percutaneous intervention (PCI)]. This commission consisted of representatives from the cardiac surgery and PCI communities, statisticians with particular expertise in provider profiling, and regulators from the Department of Public Health. Working together toward their common goal of assessing and improving cardiac care, this group established a collegial and mutually respectful relationship that greatly facilitated subsequent implementation of the program. The STS Database, a unique resource available to our specialty, was mandated as the data-collection instrument for all Massachusetts cardiac programs, and provider performance was analyzed using generalized hierarchical models. Data collection, cleansing, audit, validation, adjudication, and statistical analysis were performed at the Massachusetts Data Analysis Center (Mass-DAC) based at the Harvard Medical School Department of Health Care Policy. Hospital-level reports are released to the public on a yearly basis, whereas 3-year aggregate data on individual surgeons are reviewed confidentially by the commission. It was hoped that this would mitigate the potential for high-risk case avoidance, which is primarily at the discretion of surgeons.

To facilitate information flow, to provide reassurance that monitoring was being conducted in a fair manner, to provide experts for data adjudication and clinical issues, and to coordinate ongoing TQM activities, Massachusetts cardiac surgeons found it useful to form a state STS organization. They also had extensive input from the national STS and the Duke Clinical Research Institute.

Review of CABG data from 2003 revealed that 1 of 14 Massachusetts cardiac programs was a statistical outlier. Because of their close working relationship with the Department of Public Health, Massachusetts STS leaders were asked to conduct a comprehensive evaluation of this program. Because this evaluation was thus a true peer-review process, the results were readily accepted by the surgical community and the involved hospitals, and numerous constructive recommendations were made and implemented. Thus the goals of both public accountability and continuous quality improvement were achieved with little media fanfare.[53]

VALIDITY AND RELIABILITY OF OUTCOME ASSESSMENT METHODS

There is little or no consensus about how to assess the validity of outcome assessment methodology. As pointed out by Daley, the concept of validity is something that everyone understands but for which no single meaning exists.[146] The concept of validity is made up of many parts. According to Daley, five of these parts are as follows: (1) face validity (Will whoever uses the risk model accept it as valid?), (2) content validity (Does the model include risk factors that should have been included based on known risks?), (3) construct validity (How well does the model compare with other measures of the same outcome?), (4) predictive validity (How well does the model predict outcome in patients not used to construct the model?), and (5) attributional validity (Does the model measure the attribute of effectiveness of care, not patient variability?). Of these components, face and content validity are arguably the most important. Clinicians can readily accept the results of risk-stratification efforts if the model uses variables that are familiar and includes risk factors that the clinician recognizes as important in determining outcome. All the risk models shown in Table 7-9 satisfy some or all of these criteria of validity. There is no objective measure that defines validity, but most clinicians would agree that the risk models have relevance to clinical practice and contain many of the features that one would expect to be predictive of morbidity and mortality for CABG.

The issue of reliability of a risk-stratification model is measured more easily than validity. *Reliability* of a risk-adjustment method refers to the statistical term *precision,* or the ability to repeat the observations using similar input variables and similar statistical techniques with resulting similar outcome findings. There are literally hundreds of sources of variability in any risk-stratification model. Some of these include errors in data input, inconsistencies in coding or physician diagnosis, variations in the use of therapeutic intervention, data fragility (i.e., the final model may be very dependent on a few influential outliers), and the type of rater (e.g., physician, nurse, or coding technician), to name a few.[185] The most common measure of reliability is Cohen's kappa coefficient, which measures the level of agreement between two or more observations compared with agreement owing to chance alone.[186] The kappa coefficient is defined as

$$\kappa = P_o - P_c / 1 - P_c$$

where P_c is the fraction representing the agreement that would have occurred by chance, and P_o is the observed agreement between two observers. If two observations agree 70% of the time on an observation where agreement by chance alone would occur 54% of the time (i.e., $P_o = 0.7$ and $P_c = 0.54$), then $\kappa = 0.35$. Landis and Koch have offered a performance estimate of kappa as follows: $\kappa = 0$ to 0.2 signifies slight agreement; $\kappa = 0.2$ to 0.4 signifies fair agreement; $\kappa = 0.4$ to 0.6 signifies good agreement; $\kappa = 0.6$ to 0.8 signifies substantial agreement; and $\kappa = 0.8$ to 1.0 signifies near-perfect agreement.[187] Other methods of measuring the agreement between two models include weighted kappa, the interclass correlation coefficient, the tau statistic, and the gamma statistic. These methods are discussed in the work of Hughes and Ash, and any of these offer an objective means of assessing the reliability of a risk-adjustment model.[185]

Surprisingly little work has been done in assessing the reliability and validity of the risk-adjustment methods used with large cardiac surgical databases. It is absolutely essential that validity and reliability are tested in these models both in order for clinicians to feel comfortable with the comparisons generated by the risk-stratification models and for policymakers (either government or managed-care organizations) to feel confident in making decisions based on risk-adjusted outcomes.

Risk Stratification to Measure the Effectiveness of Care

The biggest single shortcoming of risk-adjustment methodology is its lack of proven effectiveness in delineating quality of care. Even though it may seem obvious that differences in risk-adjusted outcomes reflect differences in quality of care, this is far from proven. What little information there is available on this subject is inconsistent. Hartz and colleagues compared hospital mortality rates for patients undergoing CABG.[188] They found that differences in hospital mortality rates were correlated with differences in quality of care between hospitals. Hannan and colleagues attempted to evaluate the quality of care in outlier hospitals in the New York State risk-adjusted mortality cohort.[189] They concluded, as did Hartz and colleagues, that risk-adjusted mortality rates for CABG were a reflection of quality of care. The measures of quality used in these studies were somewhat arbitrary and did not reflect a complete array of factors that might be expected to influence outcomes after CABG. In TQM jargon, the entire clinical process of surgical intervention for coronary revascularization was not assessed. Other studies have not found a correlation between global hospital mortality rates and quality-of-care indicators.[57,190–192] Indeed, one study suggested that nearly all the variation in mortality among hospitals reflects variation in patient characteristics rather than hospital characteristics,[192] whereas another study found that identifying poor-quality hospitals on the basis of mortality-rate performance, even with perfect risk adjustment, resulted in less than 20% sensitivity and greater than 50% predictive error.[57] These two studies suggest that reports that measure quality using risk-adjusted mortality rates misinform the public about hospital (or physician) performance. At least three ongoing quality-improvement studies are using risk-adjusted outcome measurements to assess and influence the clinical process of CABG: the Northern New England Cardiovascular Disease Study,[193] the Massachusetts Quality Assurance Program,[65] and the Veterans Administration Cardiac Surgery Risk Assessment Program.[194] Results from these studies suggest

that using risk-adjusted outcomes (e.g., mortality and cost) as internal reference levels tracked over time (similar to the control charts of TQM described earlier) can produce meaningful improvements in outcomes. Whether these risk-adjusted outcomes can be used to indicate quality of care or cost-effectiveness of providers across all institutions is another question that remains unanswered. At present, it is not justified to equate risk-adjusted outcome measurements with effective care.[195–199]

Controversy exists as to whether changes in a physician's report card over time reflect changes in care or whether these changes are due to other factors not related to individual provider's care delivery. Hannan and colleagues suggested that the public release of surgeon-specific risk-adjusted mortality rates led to a decline in overall mortality in New York State from 4.17% in 1989 to 2.45% in 1992 and hence improvement in the quality of care.[200] The cause of this decline in operative mortality is uncertain but probably represents a combination of improvement in the process of care (especially in the outlier hospitals), low-volume surgeons retiring, and an overall national trend toward decreased CABG mortality. Ghali and colleagues found that states adjacent to New York that did not have report cards had comparable decreased CABG operative mortality during the same time period.[201] Without any formal quality-improvement initiative or report card, the operative mortality rate in Massachusetts decreased from 4.7% in 1990 to 3.3% in 1994. This occurred while the expected operative mortality of patients increased from 4.7 to 5.7%. The decline in New York State operative mortality over time associated with the publication of surgeon-specific mortality rates was greater than the overall national decrease in CABG death rates. Peterson and colleagues found that the reduction in observed CABG mortality was 22% in New York versus 9% in the rest of the nation, a highly significant difference.[202] An interesting finding in the study of Peterson and colleagues is that the only other area in the United States with a comparable decline in CABG mortality to that of New York was northern New England. The Northern New England Cooperative Group established a confidential TQM approach to improve CABG outcomes[203] at about the same time that New York State report cards were published in the lay press. These two approaches to improving outcomes for CABG represent opposite ends of the spectrum, the New York State approach representing the "stick" and the northern New England approach representing the "carrot." This suggests that the institution of a formal quality-improvement process is the key to improving outcomes and that either the carrot or the stick approach may be effective.[204]

Ethical Implications of Risk Stratification: The Dilemma of Managed Care

An important component of new proposals for health care reform is mandated reports on quality of care.[205] While reporting on quality of care sounds appealing, there are many problems associated with this effort, some of which present the clinician with an ethical dilemma.[206,207] There is general agreement that quality indicators should be risk-adjusted to allow fair comparisons among providers. Risk adjustment in this setting is extremely difficult, may be misleading, and what is worse, may not reflect quality of care at all. The release of risk-adjusted data may alienate providers and result in the sickest patients having less accessibility to care. This may have happened already in New York State[61,208,209] and in other regions where risk-adjusted mortality and cost data have been released to the public. Of even more concern is the selection bias that seems to exist in managed-care health maintenance organization (HMO) enrollment. Morgan and colleagues suggest that Medicare HMOs benefit from the selective enrollment of healthier Medicare recipients and the disenrollment or outright rejection of sicker beneficiaries.[210] This form of separation of patients into unfavorable or favorable risk categories undermines the effectiveness of the Medicare managed-care system and highlights the subtle selection bias that can result when financial incentives overcome medical standards. Careful population-based studies that employ risk adjustment are needed to study this phenomenon.

A major concern of the current move toward market-oriented health care delivery is that health plans will select only the best health risk participants—termed *cream skimming* by van de Ven and colleagues.[211] The result of cream skimming may be to widen the gap between impoverished, underserved patients and affluent patients. In an effort to address these concerns, plans have been proposed that would reward health plans for serving people with disabilities and residents of low-income areas.[212,213] At the heart of these plans is some form of risk adjustment to allocate payments to health care organizations based on overall health risk and expected need for health care expenditures. The use of risk stratification in this setting is new and unproved but offers great promise.

A related problem is that physicians are being rewarded by hospitals and managed-care organizations for limiting costs. Incentives are evolving that threaten our professionalism.[80] On the surface of it, this may seem like a strong statement, but one only has to read some of the "compromise" positions that have been advocated in order to deal with the changing health care climate. "Advice" such as hiring lawyers to optimize care (managed or capitated contracts), recruiting younger patients and discouraging Medicare-age patients away from a managed-care practice, forbidding physicians from disclosing the existence of more costly services not covered by their managed-care plan, and using accounting services to track and limit frequency of office visits have been offered to physicians.[80,214–216] A particular telling indictment is the finding by Himmelstein and colleagues that investor-owned HMOs deliver lower-quality care than not-for-profit plans.[217] Physicians who own managed-care organizations live by a dual standard—the professional standard of providing high-quality patient care and the financial standard of making a profit from this care delivery. Strategies must be devised that allow physicians both to

maintain a professional approach to patients and to participate in the marketplace without compromising patient care.

The Costs of Gathering Data

Collecting risk-adjusted data adds to the administrative costs of the health care system. It is estimated that 20% of health care costs ($150 to $180 billion per year) are spent on the administration of health care.[218] The logistical costs of implementing a risk-adjustment system are substantial. Additional costs are incurred in implementing quality measures that are suggested by risk-stratification methodology. A disturbing notion is that the costs of quality care may outweigh the payors' willingness to pay for those benefits. For example, Iowa hospitals estimated that they spent $2.5 million annually to gather MedisGroups severity data that were mandated by the state. Because of the cost, the state abandoned this mandate and concluded that neither consumers nor purchasers used the data anyway.[219] It is possible that quality improvement may cost rather than save money; although one of the principles of TQM (often quoted by Deming) is that the least expensive means to accomplish a task (e.g., deliver health care) is the means that employs the highest quality in the process. Ultimately, improved quality will be cost-efficient, but startup costs may be daunting, and several organizations already have expressed concerns about the logistical costs of data gathering and risk adjustment.[219,220] It is imperative that part of any cost savings realized by improved quality be factored into the total costs of gathering risk-adjusted data.

Inherent Dangers with Outcome Assessment

It is nearly impossible to assess the accuracy of risk-adjusted outcomes to measure provider quality of care. In a perfect world, differences in observed-to-expected (*O:E*) mortality rates are due to either random variation or to quality of care. The problem is that risk-adjustment methodologies are less than perfect.[221] What if there were perfect risk-adjustment models? Would hospital risk-adjusted mortality rates then reflect quality of care? To answer this question is impossible if currently available clinical databases are used. This is true because there is no valid measure of quality that allows identification of poor- or good-quality providers. No single outcome, process, or structural measure or combination of these measures meets the validity criteria for a quality indicator.

Nonetheless, several researchers investigated the hypothesis that high-quality risk-adjusted outcomes reflect quality of care.[57,190,199,208,222,223] Several authors attempted to circumvent the less than adequate risk-adjustment models and the lack of a recognized quality indicator by simulating mortality experience for a hypothetical set of hospitals with perfect risk adjustment and with prior perfect knowledge of poor-quality providers. These authors used various simulation models, including Monte Carlo simulation,[223] and obtained similar results. Each of the simulations found that under all reasonable assumptions, sensitivity for determining poor quality was less than 20%, and the predictive error for determining high outliers was greater than 50%.[57,222,223] Stated another way, it is likely that 50 to 80% of observed mortality-rate differences between high outliers and nonoutliers are attributable to random variation. Park and colleagues suggest that providers identified as high outliers using conventional risk-adjustment methods do not provide lower-quality care than do nonoutliers.[190] There are two concerns with outcome assessment that must be addressed before clinicians and the public can embrace such assessment: (1) high-quality risk-adjustment models are imperative, and (2) well-defined and well-validated measures of quality of care are needed. Without these two ingredients, there will be natural skepticism and apparent inequalities in the outcome assessment process.

WHAT DOES THE FUTURE HOLD?

Decision Analysis: The Infancy of Risk Stratification and Outcomes Assessment

A great deal of effort has gone into the development of risk models to predict outcomes from cardiac surgical interventions (e.g., Tables 7-1 and 7-9). For populations of patients undergoing operations, the models are fairly effective at predicting outcomes (with certain caveats, as mentioned earlier). The biggest drawback of these risk models is that they exhibit dismal performance at predicting outcomes for an individual patient. Consequently, risk adjustment to predict individual outcomes is extremely difficult to apply at the bedside. For patient-specific needs, risk stratification and outcomes assessment are in their infancy.

What are needed are patient-specific predictors for clinical decision making. On the surface, it would seem that a decision about whether to operate on a patient with coronary artery disease is straightforward. But a decision of this sort is an extremely complex synthesis of diverse pieces of evidence. As mentioned earlier, there are enormous variations in the way that surgeons practice. These variations can increase cost, cause harm, and confuse patients. The tools of decision analysis, similar to how airline pilots make decisions about complicated flight problems, have been applied to the area of physician decision making in an effort to eliminate these variations and to provide accurate and effective decisions at the patient bedside.[17,224] In the decision analytic jargon, the decision to operate for coronary artery diseases is extremely complex because there are more than two alternative treatments, more than two outcomes, and many intervening events that may occur to alter outcomes. Decision models generated to address surgical outcomes typically employ the familiar decision tree. They are commonly perceived as complex and difficult to understand by those unfamiliar with the methods, especially in the context of clinical decision making. Attempts have been made to simplify the methods and to apply them to the medical decision-making process.[224] An important part of creating the decision tree is to estimate the probabilities of each of the various outcomes

for a given set of interventions. This part of the decision analysis tree relies heavily on the results of risk stratification and regression modeling, especially computer-intensive methods such as Bayesian models,[225] to arrive at a probability of risk for a particular outcome. All the diverse pieces of evidence used to form consensus guidelines, including meta-analyses, expert opinions, unpublished sources, randomized trials, and observational studies, are employed to arrive at probabilities of outcome and intervening events. For example, Gage and colleagues performed a cost-effectiveness analysis of aspirin and warfarin for stroke prophylaxis in patients with nonvalvular atrial fibrillation.[226] They used data from published meta-analyses of individual-level data from five randomized trials of antithrombotic therapy in atrial fibrillation to estimate the rates of stroke without therapy, the percentage reduction in the risk of stroke in users of warfarin, and the percentage of intracranial hemorrhages following anticoagulation that were mild, moderate, or severe. Their decision tree suggests that in 65-year-old patients with nonvalvular atrial fibrillation (NVAF) but no other risk factors for stroke, prescribing warfarin instead of aspirin would affect quality-adjusted survival minimally but increase costs significantly. Application of decision analysis methods to clinical decision making can standardize care and decrease risks of therapy, but these methods are in the early developmental phase, and much more work needs to be done before ready acceptance by surgeons.

Volume/Outcome Relationship and Targeted Regionalization

At least 10 large studies addressed the notion that hospitals performing small numbers of CABG operations have higher operative mortality. Seven of these 10 studies found increased operative mortality in low-volume providers.[227–233] In 3 other large studies, there was no such association.[140,234,235] Interestingly, in the 3 studies done more recently (since 1996), there was no clear relationship between outcome and volume. In 2 separate studies done on some of the same patients in the New York State Cardiac Surgery Database, completely opposite results were obtained.[233,235] The Institute of Medicine summarized the relationship between higher volume and better outcome (www.nap.edu/catalog/10005.html) and concluded that procedure or patient volume is an imprecise indicator of quality even though a majority of the studies reviewed showed some association of higher volume and better outcome.[236] Significantly, the largest clinical database dealing with CABG patients, the STS Database, did not find a significant relationship between outcome and provider volume.[237] Many other risk factors are more important determinants of outcome than provider volume in this large clinical database.[147,237,238] The dilemma is that some low-volume providers have excellent outcomes, whereas some high-volume providers have poor outcomes. These observations on operator volume and outcome prompted some authorities to suggest "regionalization" to refer nonemergent CABG patients to large-volume centers.[232,239,240] A role for "selective regionalization" was advocated by Nallamothu and colleagues because they found that low-risk patients did equally well in high-volume or low-volume hospitals.[140,241] They suggest regional referral for elective high-risk patients to high-volume institutions.[140] Other authors pointed out that a policy of regionalized referrals for CABG might have several adverse effects on health care, including increased cost, decreased patient satisfaction, and reduced availability of surgical services in remote or rural locations.[241,242] Furthermore, there is no clearcut proof that a policy of regionalization will have the desired effects. Several published studies reveal the inadequacy of the volume-outcome relationship. Peterson and colleagues reviewed the STS Database to evaluate the relationship of CABG volume to outcome.[237] They found almost no potential benefit in closing low-volume centers. The wide variability in risk-adjusted mortality among hospitals with similar volume precluded the ability of hospital volume to discriminate those centers with significantly better or worse mortality. Hospital procedural volume was only modestly associated with CABG outcomes. They suggested that procedural volume is not an adequate marker of quality for CABG surgery.[237] Similar results were obtained by Rathore and colleagues, who reviewed the Medicare CABG database.[243] Other more important process variables are principal determinants of outcomes in CABG patients. Hannan suggests that regionalization of CABG patients in the New York State system would have detrimental effects on quality of care.[244] It is entirely possible that overcrowding of high-volume centers in a regionalization model would impair outcomes. It is simplistic to suggest that hospital volume is a principal surrogate of outcome, and much more sophistication is required to sort out this relationship. Nonetheless, decisions about utilization of health care resources undoubtedly will be made based on the presumed association between high volume and good outcome.

Medical Errors and Outcomes

The Institute of Medicine (IOM) released a startling report on medical errors that occur in the U.S. health system (http://books.nap.edu/catalog/9728.html). Based mainly on two large studies, one using 1984 data in New York State and the other using 1992 data in Colorado and Utah,[245,246] this report suggested that at least 44,000 Americans die each year from preventable hospital errors.[31] This estimate was not much different from ones obtained from similar analyses on patients in Australia,[247] England,[248] and Israel.[249] This IOM report caused a storm of controversy, with many experts fearing that the report could harm quality-improvement initiatives.[246,250] Some had doubts about the methodology used to derive estimates of medical errors,[251,252] whereas others made an emotional plea for drastic measures to reduce errors.[253]

The airline industry had success in limiting errors by instituting multiple quality-improvement interventions. This industry is used as a model of successful implementation

of error-avoidance behavior and process improvement.[250] These same principles were applied to pediatric cardiac surgery by de Leval and colleagues with some success.[171] These workers evaluated patient and procedural variables that resulted in adverse outcomes. In addition, they employed self-assessment questionnaires and human factors researchers who observed behavior in the operating room, an approach similar to the quality-improvement steps used in the airline industry. Their study highlighted the important role of human factors in adverse surgical outcomes, but more important, they found that appropriate behavioral responses in the operating room can retrieve potential harmful events that occur in the operating room. Studies of this sort that emphasize behavior modification and process improvement hold great promise for future error reduction in cardiac surgery.

Computer applications were applied to the electronic medical record in hopes of minimizing physician errors in ordering. Computerized physician order entry (CPOE) is one of these applications that monitors and offers suggestions when physicians' orders do not meet a predesigned computer algorithm. CPOE is viewed as a quality indicator, and private employer-based organizations used the presence of CPOE to judge whether hospitals should be part of their preferred network (www.leapfroggroup.org/). One of these private groups is the Leapfrog Group, and an initial survey by this group in 2001 found that only 3.3% of responding hospitals currently had CPOE systems in place (www.ctsnet.org/reuters/reutersarticle.cfm?article=19325). In New York State, several large corporations and health care insurers agreed to pay hospitals that meet the CPOE standards a discount bonus on all health care billings submitted. Other computer-based safety initiatives that involve the electronic medical record are likely to surface in the future. The impact of these innovations on the quality of health care is untested, and any benefit remains to be proven.

Information technology used to reduce medical errors has met with mixed success. Innovations that employ monitoring of electronic medical records may reduce errors.[254,255] However, one study that tried to implement guidelines for treating congestive heart failure into a network of physicians' interactive microcomputer workstations found it difficult.[256] The task proved difficult because the guidelines often lack explicit definitions (e.g., for symptom severity and adverse events) that are necessary to navigate the computer algorithm. Another study attempted to implement prophylactic care measures (e.g., update of tetanus immunization in trauma patients) using reminders in the electronic in-patient medical record.[93,257] These investigators were unable to increase the use of prophylactic measures in hospitalized patients with this computer-based approach. Much work needs to be done before computer-aided methods lead to medical error reduction, but the future will see more efforts of this type.

Since the IOM report on medical errors that appeared in 2000,[31] significant energy was expended on reducing medical errors by both physicians and hospitals. Several authors recently expressed dismay that little progress has been made in changing the culture of safety in our hospitals.[258,259] Brennan and colleagues point out that the IOM distinguishes safety from effectiveness. *Effectiveness* is defined as an intervention based on available evidence that improves quality, whereas *safety* encompasses a much narrower definition of limiting accidental injury.[258] These authors suggest a redirection of health care goals toward effectiveness interventions and away from accident-reduction interventions. An important advantage of a focus on effectiveness is the ease with which effectiveness outcomes can be measured compared with safety outcomes. There is some evidence that focus on evidence-based interventions such as providing aspirin to cardiac patients when they leave the hospital has improved the effectiveness of treatment with a secondary benefit of reducing errors.[260] There is still a reluctance to deal transparently with medical mistakes. Health care providers have not spent significantly increased resources on safety and error management largely because the return on this type of investment is very hard to measure. On the other hand, quality-improvement efforts based on evidence of effectiveness are likely to be embraced more readily and may save more lives than will safety-related interventions that lack an evidence base.[258]

Public Access and Provider Accountability

Multiple factors bring surgical results to the public attention. Such things as publication of individual surgeon risk-adjusted mortality rates, limitation of referrals to high-mortality surgeons by insurers, legislative initiatives to reduce medical errors, and abundant proliferation of the Internet as an information resource lead to increased public awareness of surgical outcomes. Like it or not, thoracic surgeons must be prepared to accept this scrutiny and, perhaps, even to benefit from it because the trend of public scrutiny of surgical results is an increasing one.

The World Wide Web provides ready access to medical facts of all sorts, particularly information about thoracic surgery. Everything from access to the thoracic literature, to outcomes of randomized trials, to surgeon-specific risk-adjusted mortality rates, to comparison of hospital outcomes can be obtained by the lay public with rather simple searches on the Internet. This ready public access undoubtedly will increase. Examples of available information sources for the public are listed in Table 7-15. There is very little external scrutiny attached to most of the information sources listed in this table. Almost all information available on these sites is accepted at face value by the public, and quality control of the information sources is limited to self-imposed efforts on the part of the authors of the various information sources. The Agency for Healthcare Research and Quality (AHRQ) attempted to empower the public to critically evaluate the various Web-based sources of health care information in order to limit the spread of misinformation that may creep into various Web sites. The success of these efforts is uncertain but becomes extremely critical as the amount of health care information available on the Web skyrockets.

Table 7–15.

Partial Listing of Publicly Available Information Sources Related to Cardiothoracic Surgery

Source	Targeted audience	Communication media	Information available
American College of Cardiology/ American Heart Association	Patients needing CABG (nationwide)	Internet (www.acc.org/clinical/guidelines/bypass/bypass7.htm)	Literature-based indications for CABG
Agency for Health Care Research and Quality	Broad base of health care consumers and providers	Internet (www.ahcpr.gov/)	Large knowledge base focusing on empowering consumers to judge health care quality
California Office of Statewide Health Planning and Development	Patients who purchase health care insurance in California	Internet (www.oshpd.cahwnet. gov/hpp/ccmrp/ccmrp_summary.pdf)	In-hospital CABG mortality data from 1998
Canadian Health Care System	Provide consumers with hospital outcomes for various procedures that might indicate quality at a given hospital	Internet (www.hcsc.gc.ca/ohihbsi/available/conference/presentations/guerriere_e.pdf)	Risk-adjusted hospital mortality rates for Canadian hospitals
Cochrane Collaboration	All interested consumers	Internet (www.cochraneconsumer.com/)	Summarizes available published evidence about a wide variety of health care interventions, including cardiac surgery
Dartmouth University	Use large health care databases to inform the public of nationwide trends in health care delivery	Internet (www.dartmouthatlas.org/99US/chap_5_sec_12.php)	CABG mortality rates across the United States based primarily on claims databases
Health Care Choices	New York not-for-profit corporation dedicated to educating the public about the nation's health care system	Internet (www.healthcarechoices.org/cardiacsurgery.htm)	Select state CABG mortality rates; primitive attempt to collate all publicly available data about physicians; not nearly complete enough but evolving
HealthFinder	NIH government-sponsored information Web site about a wide variety of medical problems	Internet (www.healthfinder.gov/healthcare/)	General information in fairly specific detail about cardiac procedures (with drawings and diagrams)
Healthoutcomes.com	Patients requiring operation or catheter-based intervention nationwide	Internet (www.healthoutcomes.com)	In-hospital outcome for Medicare patients having selected procedures (e.g., CABG)
Hospital Quality Initiative sponsored by the Center for Medicare and	Provide consumers with a list of performance measures achieved by any hospital in the Medicare and	Internet (www.cms.hhs.gov/quality/hospital)	Hospital rankings for most of the NQF measures; searchable by hospital with comparisons within

Table 7–15.

Partial Listing of Publicly Available Information Sources (Continued)

Source	Targeted audience	Communication media	Information available
Medicaid Services (CMS)	Medicaid system		states and regions
The Leapfrog Group (consortium of Fortune 500 companies and health care insurers)	Provide consumers with list of hospitals that employ Leapfrog-defined quality measures	Internet (www.leapfroggroup.org/index.html)	List of hospitals that use quality measures; hospitals that use these quality measures will be financially rewarded by Leapfrog Group
Medscape, Inc.	Consumer information source for all types of medical conditions and for preventive medicine	Internet (www.medscape.com/px/urlinfo)	Comprehensive, searchable Web site with multiple links to external sites capable of finding comprehensive information about details of cardiac surgery
New Jersey State Department of Health	Health care consumers in the state of New Jersey	By mail (New Jersey Department of Health and Senior Services, Office of Research and Development, P.O. Box 360, Trenton, NJ 08625)	Risk-adjusted hospital mortality rates for CABG
New York State Department of Health	Patients having cardiac procedures in New York State	Internet (www.health. state.ny.us/nysdoh/consumer/heart/1996–98cabg.pdf)	Surgeon- and hospital-specific in-hospital mortality rates for CABG
Pennsylvania Health Care Cost Containment Council	Patients who require CABG in the state of Pennsylvania	Internet (www.phc4.org/reports/cardiaccare.htm)	Hospital- and surgeon-specific CABG mortality rates
Rand Corporation	Provide the public with summary data about health care outcomes for cardiac surgery	Internet (www.rand.org/publications/MR/MR1255/MR1255.app4.pdf)	Summary of publicly available CABG mortality rates with critical appraisal of methods and some estimation of appropriateness of care
Society of Thoracic Surgeons	Provide the public with results of cardiac surgery over as broad of a population as possible (including VA, Northern New England Consortium, and Great Britain)	Internet (www.ctsnet.org/section/outcomes/)	Mortality and other outcomes data for a variety of thoracic procedures; some of the data are presented as raw mortality data without risk adjustment; one of the only databases that includes noncardiac surgery

Table 7–15.

Partial Listing of Publicly Available Information Sources (Continued)

Source	Targeted audience	Communication media	Information available
Solucient Corp., Inc. (top 100 heart hospitals)	Provide the public with rather arbitrary rating of overall quality of cardiac care at hospitals	Internet (www.100tophospitals.com/Media/releases/nr010702_cardio.htm)	Rates all hospitals in the United States that do cardiac surgery and lists the top 100 heart hospitals
Washington Post Medical Web Site	Provider of medical information reports to consumers in North America	Internet (www.medifocus.com/)	General information about cardiac disease
WebMD, Inc.	Provide information to consumers and physicians about a broad spectrum of health care issues	Internet (http://my.webmd.com/content/dmk/dmk_article_53203)	Information about CABG and expected outcomes
Women's Heart Foundation	Provide health-related information for women	Internet (www.womensheartfoundation.org/content/HeartSurgery/state_report_cards_on_ohs.asp)	Links to Internet-available report cards on cardiac surgery

New Risk Stratification Methods: Machine Learning and Other Computer-Intensive Methods

The goal of risk adjustment is to account for the contribution of patient-related risk factors to the outcome of interest. This allows patient outcomes to be used as an indicator of the care rendered by physicians or administered by hospitals. This chapter has outlined some of the risk adjustment methods commonly used for this purpose, including use of multivariate analyses to predict patient outcomes based on patient risk factors. Inevitably, refinements and use of newer techniques will be brought to bear on the problem of risk adjustment. Statistical models are used often in cardiothoracic surgery to describe the relationship between a set of preexisting demographic features or conditions (referred to as *independent variables, input variables, predictor variables,* or *covariates*) and an operative outcome such as morbidity or mortality. Such models usually combine either the original or transformed predictor variables in a linear fashion, along with their associated coefficients, to estimate a continuous (multivariable linear regression) or a binary (multivariable logistic regression) response variable. The use of such linear parametric equations for this purpose is convenient, and the relevant models may be developed and run on any personal computer. In the case of binary logistic regression, the interpretation of coefficients is particularly appealing because they translate readily into odds ratios for each predictor variable.

Notwithstanding their widespread use and easy interpretability, there is no logical reason to believe that simple linear statistical models would be the best way to represent a complex biologic process such as cardiac surgery. Often, many of the assumptions necessary to use traditional regression models are neither fulfilled nor even tested.[44,261] Furthermore, there are significant constraints on the number of predictor variables used in standard logistic regression,[44] especially when the endpoint occurs infrequently, as in cardiac surgery mortality. This results in loss of both valuable information and accuracy.[262] Finally, despite the apparent mathematical precision with which the results of such analyses are often presented, the development and application of these models can be surprisingly subjective. It is a troubling fact that different groups of investigators using the same data likely will derive different statistical models and results. This occurs for a variety of reasons, including choice of statistical technique, variable selection, data management, and clinical interpretation.[98,103,262] Based on standard goodness-of-fit testing, the relationship between predictor and outcome variables often may be described equally well by any number of models, each of which employs a somewhat different subset of the overall available predictors.[98,262] Each of these statistically plausible models, composed of different combinations of variables and their coefficients, tells a somewhat different story of how nature works.[98,262]

With the quantum increases in computational power that have become available over the past decade, many of the practical constraints previously imposed on researchers are no longer relevant. This has led to an entirely new "culture" of modeling called *machine learning* or *algorithmic models*.[98,262] Rather than using classical statistical models with their specific assumptions and limitations, algorithmic modeling is focused more on predictive accuracy and less on trying to constrain nature to a particular parametric equation.

Examples of such algorithmic techniques include neural networks, decision and regression trees, and support-vector machines.[262] Because these models often do not provide an easily understood relationship between predictor and outcome variables, some have referred to them pejoratively as *black boxes*.[262] However, despite this criticism, such models in many instances may provide superior predictive accuracy, even though the mechanism behind the relationship may be less transparent. Furthermore, in machine learning techniques, the number of predictors that can enter the model is not limited as they are in standard regression.[262]

It was postulated over a decade ago that machine learning or artificial intelligence methods such as neural networks would provide the next major advance in predictive modeling for cardiac surgery.[263] However, three studies using relatively small numbers of patients did not reveal substantial differences between the results obtained from these techniques and those from standard logistic regression.[264–266] A much larger study was conducted by Lippmann and Shahian at the MIT Lincoln Laboratory using data from the 1993 STS Database of 80,606 patients who underwent CABG.[267] A two-layer neural network with a single hidden layer, random weight initialization, and backpropagation training did not provide any substantial improvement over standard logistic regression, and this neural network also underestimated risk in the highest-risk groups. Somewhat improved performance was obtained by combining the results of the neural network with those of logistic regression, which overestimated risk in the highest-risk groups, to produce an aggregate "committee classifier." However, the absolute improvement in ROC curve area was relatively small.

Although it was expected that neural networks would improve predictive accuracy because of their ability to use nonlinear parallel processing and to elicit complex patterns and relationships, the results thus far have been disappointing. However, this is more likely a reflection of the imperfect and limited information presented to these models, which is the same information used to develop and evaluate traditional statistical models. No modeling technique is better than the information presented to it for training, and neural networks are no exception. It may well be that if presented with a more comprehensive set of predictor variables, some of which are not even recognized today as being significant, these machine learning techniques ultimately may prove to be more accurate.

INFORMATION MANAGEMENT: ELECTRONIC MEDICAL RECORDS

As mentioned earlier, accurate patient data are essential in order to apply the principles of risk stratification and quality improvement outlined in this chapter. The quality and accuracy of administrative (or claims) databases have been questioned.[26,35,36,38,39,158] Therefore, risk-adjustment methodology has placed greater reliance on data extracted from the medical record. The American College of Surgeons was among the earliest advocates of the utility of medical records for quality review.[268] In the 1960s, Weed advocated standardization and computerization of medical records.[269] Little substantive progress had been made as far as the computerization of medical records until the need arose for management of large amounts of data of the sort required for risk adjustment and outcomes assessment. Medical records are an invaluable source of information about patient risk factors and outcomes. With these facts in mind, more and more pilot studies are being undertaken to computerize and standardize the medical record in a variety of clinical situations.[257,270–276] Iezzoni has pointed out the difficulties with computerized medical records and suggests that they may not adequately reflect the importance of chronic disability and decreased functional status.[277] Nevertheless, it is apparent that the need for data about large groups of patients exists, especially for managed-care and capitation initiatives. It is reasonable to expect that efforts to computerize medical records will expand. Applications of electronic medical records that may be available in the future for cardiothoracic surgeons include monitoring of patient outcomes,[270] supporting clinical decision making with real-time analysis of the electronic medical record[271,273,274] and real-time tracking of resource utilization using computerized hospital records.[257]

CONCLUSION

Risk stratification and outcomes analysis are here to stay. The methods of risk analysis are straightforward but are in their infantile stages. The goal of risk adjustment in the analysis of outcomes is to account for the contribution of patient-related risk factors so that patient outcomes can be used as an indicator of the quality of care rendered by physicians and hospitals. The future undoubtedly will see refinements in risk-adjustment methods and increasing use of these techniques at all levels of health care delivery, including the distribution of health care dollars. Thoracic surgeons have been at the forefront of these methodologies (sometimes unwillingly), but much work remains to be done in the area of education about the use of risk stratification and application of risk-adjusted outcomes analysis toward improving quality of care. We are obliged to have an understanding of the techniques, with the ultimate goal being to improve patient outcomes and maintain high professional quality.

CHAPTER 8

Statistical Treatment of Surgical Outcome Data

Ruyun Jin • Gary L. Grunkemeier

The results (outcome) of cardiac surgery can be measured in several ways. The type of variable used as the measure of a particular outcome determines the statistical methods that should be used for its analysis. For example, some administrative outcomes are captured by continuous variables, such as hospital charges (in dollars) or length of stay (in days). Other outcomes are collected as categorical variables, such as discharge destination (e.g., acute-care facility, specialized nursing facility, or home). Health-related quality of life is another kind of outcome, which is often measured by the Medical Outcome Study (MOS) 36-Item Short-Form Health Survey (SF-36),[1] the Sickness Impact Profile,[2] or disease-specific quality-of-life measures, and can be transferred to quality-adjusted life years (QALYs).[3] Economic endpoints have been used increasingly, such as cost-effective ratio.[4]

However, the major outcomes of interest to clinicians are described by variables that indicate the occurrence of (usually adverse) events, such as death, stroke, infection, or reoperation. Statistically, we must differentiate between two fundamentally different types of events based on their timing: *early (one-time) events* and *late (time-related) events*. Different types of analyses are used for these two types of events. We somewhat arbitrarily divide the areas of statistical inquiry into three major categories based on the goals of the analysis: s*ummarize*, *compare*, and *model*. This chapter will describe and illustrate the statistical methods used most often in each situation.

EVENT TYPES

Early, One-Time Events

In cardiac surgery, early events are those occurring within 30 days of surgery or before hospital discharge, whichever is later. By the time of the analysis, the early outcome of every patient presumably is known. Thus, every patient has a "yes" or "no" value for the event being studied, and an estimate of the probability of the event can be determined by the ratio of patients with the event to total patients, usually multiplied by 100 and expressed as a percentage.

Late, Time-Related Events

Late events are those that occur after discharge and after 30 days. The analysis of these events is complicated by two considerations. First, the time of occurrence must be taken into account because, for example, a death at 6 months will have a different effect on the analysis than a death at 6 years. Second, in the usual ongoing analysis, some patients will have experienced a late event, whereas others will not have experienced an event but are still alive and at risk for the event and may have it in the future. Their event status is termed *censored*, which means that it is known not to have occurred by the time of the latest follow-up. For example, a patient in the study who had surgery 5 years ago and is still alive has a time of death that is not yet known. But we have partial information about his or her survival time, namely, that it exceeds, or is *censored* at, 5 years. When dealing with censored data, it is necessary to use special statistical methods. It is not appropriate, for example, to summarize late mortality by a simple percentage such as the number of late deaths divided by the number of patients. Mortality varies over, and must be related to, postoperative time. The simple "late mortality" percentage in any series of patients will be 100% if the investigator waits long enough.

ANALYSIS GOALS

Statistics are derived for many purposes of varying complexity. The most common ones used for evaluating cardiac surgery are (1) to *summarize* the results from a single series, (2) to *compare* the results between two or more series or subgroups of the same series based on a single discriminating

variable or risk factor, and (3) to construct a multivariable *model* that provides the simultaneous effect of many risk factors.

Summarize

A study usually includes series of patients, and rather than enumerating a particular variable of interest for each individual, the first use of statistics is to summarize the variable for the entire group with a single, representative number (statistic). The *sample average,* or *mean value,* and the *median* (50th percentile) provide a measure of central tendency, and the *standard deviation,* or *interquartile range,* measures the dispersion of the individual values. A single-valued estimate such as this is called a *point estimate,* but acknowledging the imprecision of a single estimated value, a range of values also should be given. The *standard error* (SE) is a measure of the precision of an estimate, and a *confidence interval* (CI), a range of values for the estimate that is consistent with the observed data, can be constructed using its SE or in other, often better ways.

Compare

A study often consists of evaluating subgroups of patients who received different treatments. Thus, in addition to summarizing the outcomes from the subgroups, we are interested in comparing their summary statistics. To do so, we typically compute another statistic that combines data from both groups and that approximately follows some known statistical reference distribution, such as a *normal* (bell-shaped) or other (*chi-square*, *t*, etc.) distribution. We then see how extreme or improbable the value computed from our data would be in that reference distribution if there were in fact no difference between the two groups we are comparing. This probability is called the *p-value*, and when it is smaller than .05 (5%), the difference we have observed is said to be *statistically significant.* This value (.05) is a completely arbitrary number, although in practice it is applied almost universally.

A different paradigm for making comparisons and constructing CIs that has gained much prominence with the availability of computing power and specific software is the *bootstrapping* technique.[5] Instead of using an assumed statistical distribution, it generates many repeated random samples from the data themselves to produce this reference distribution.

Model: Multivariable Regression

Comparing the outcomes between two groups based on a single factor, as described in the preceding section, is called *univariable* (or sometimes *bivariable*) *analysis,* to distinguish it from *multivariable analysis,* in which several characteristics of each subgroup are considered simultaneously. Most clinical studies are based on observational data collected in the normal delivery of care, and the patient subgroups may differ with regard to several influential characteristics. A multiple regression analysis can determine the influence of the treatment under study on the outcome variable after simultaneously adjusting for these potential patient differences. The result is a statistical model that consists of the group of factors that significantly affects the outcome and which may or may not ultimately include the treatment being studied. Each factor is assigned a coefficient that indicates the amount of weight given to that factor in the model. The model hopefully gives us a fuller understanding of the interrelationship among the treatment being studied, the outcome variable, and other important risk factors. One can compute the expected outcome for any patient using these weights applied to the values of that patient's particular set of risk factors.

MATERIALS AND METHODS

Clinical Materials

To describe and illustrate the statistical methods used most frequently in the cardiac surgical literature, we will use a mature data set of isolated mitral valve replacements with Starr-Edwards heart valves. Dr. Albert Starr and his group at the Oregon Health Sciences University and Providence St. Vincent Medical Center in Portland, Oregon, implanted 1255 Starr-Edwards mitral valves in adult patients (age $>$ 20 years old) from 1965 to 1994.[6] A prospective lifetime follow-up service was implemented for every patient. The total follow-up through 2002 was 11,621 patient-years, with a maximum of 37 years. (*Note:* In all figures in this chapter, we have plotted the curves only up the time where more than 20 patients were at risk because the estimates beyond that time are imprecisely determined.) Table 8-1 contains a summary of selected variables used herein to illustrate the statistical methods (*Note:* More variables ordinarily would be considered in a real study than in this simple expository exercise.) Several valve models are represented in this group: "Current valve model" refers to the Model 6120 valve, which is still available; "Previous valve model" refers to all the other models, mostly cloth-covered, which have been discontinued. Patients with the current valve model have a higher mean age, more valve re-replacement surgery, and more concomitant coronary artery bypass grafting (CABG).

Statistical Software

Most of the statistical methods described in this chapter are available in the commonly used statistical software package. The statistical analyses and graphics in this chapter were done using SPSS 11.0 (SPSS, Inc., Chicago, IL), Stata 9.1 (Stata Corp., College Station, TX), S-PLUS 6.1 (Insightful Corp., Seattle, WA), and the open-source program R 2.2.0 (R Foundation for Statistical Computing, Vienna, Austria, www.R-project.org).

The only functionality not found in standard statistical packages is cumulative incidence ("Actual") analysis. Cumulative incidence in the presence of competing events is

Table 8–1.

Mitral Valve Clinical Material and Univariate Comparison of Early Mortality by Valve Model

	Previous model	Current model
Clinical material		
Number of patients	543	712
Mean age ± S.D. (y)	53.0 ± 10.8	60.3 ± 11.3
Female (%)	60.6	61.8
Re-replacement (%)	4.6	6.9
Concomitant CABG (%)	10.1	20.2
Early mortality		
Number of deaths	25	58
Point estimate (%)	4.6	8.1
Standard error (%)	0.9	1.0
95% confidence interval (%)		
Normal approximation	(2.8, 6.4)	(6.4, 10.2)
Exact binomial	(3.0, 6.7)	(6.2, 10.4)
Comparison statistics	*p*-value (2-sided)	
Pearson chi-square	0.012	
With continuity correction	0.017	
Fisher's exact test	0.016	

implemented in the Stata ado file *stcompet*, available at http://econpapers.repec.org/software/bocbocode/s431301.htm (last access at 3/20/2006). Cumulative incidence is also available for S-PLUS and R with the package *cmprsk*, available at http://biowww.dfci.harvard.edu/~gray/ (last access at 3/20/2006). Finally, the NCSS Statistical Analysis System (NCSS, Kaysville, UT) does implement this function directly.

EARLY EVENTS

We will use operative deaths to illustrate the statistical treatment of early events.

Summarize

The *mean* (point estimate) operative mortality is computed as the number of operative deaths divided by the number of patients. Multiplying by 100 converts this decimal to a percentage (P). The SE of a proportion P based on N patients equals the square root of $P(1-P)/N$. Thus, as shown in Table 8-1, the percentages of patients with early death are 4.6% (SE = 0.9%) and 8.1% (SE = 1.0%) for the previous and current valve models, respectively. Table 8-1 also contains the 95% CI, computed by two popular methods. The first method is the simple (asymptotic) method based on the fact that the *binomial* distribution, which governs proportions, can be approximated by the normal (bell-shaped) distribution as the sample size increases.[7] This CI is computed easily as the point estimate plus and minus twice the SE. A second method uses the (exact) binomial distribution directly.[8] Although the "exact" method sounds like it obviously would be the most desirable, there are other methods that actually have better statistical properties.[9]

Compare

To demonstrate a *univariable* comparison, operative mortality between the two valve models was used. This does not seem very interesting clinically because valve model should have little to do with operative mortality; nevertheless, many valve comparison papers attempt to draw clinical conclusions from just such questionable comparisons. Comparing two proportions gives rise to a matrix with two rows and two columns called a *two-by-two contingency table.* Several

Table 8–2.

Univariate and Multivariable (Logistic Regression) Modeling of Early Mortality

	Univariate		Multivariate			
Variable	*p*-Value	Odds ratio	Coefficient	SE	*p*-Value	Odds ratio (95% CI)
Age	<0.001	1.05	0.045	0.012	<0.001	1.04 (1.02, 1.07)
Concomitant CABG	<0.001	3.78	1.016	0.251	<0.001	2.76 (1.69, 4.52)
Current valve model	0.014	1.84			(0.515)	
Female gender	0.361	0.81				
Re-replacement	0.314	1.52				

methods have been used to assess the significance of such tables.[10] The most common method for extracting a *p*-value from such a matrix is the *(Pearson) chi-square test.* This test has an alternative, more conservative form using a *continuity correction.* Validity of the chi-square test depends on having an adequate sample size (technically, each cell of the table should have an expected size of at least 5), and when this is not the case, then *Fisher's exact test* often is used. All three tests find that the current valve model has significantly higher operative mortality because the *p*-values are smaller than the required .05 (see Table 8-1).

Model

Logistic regression

The simple comparison above showed that operative mortality with the current valve model was significantly higher than with the previous valve model. But patients with the current valve model were older and had more concomitant CABG and re-replacement operations (see Table 8-1). Could the apparent difference in operative mortality between valve models be due to these patient characteristics? We explore this possibility using a multivariable analysis.

For binary (dichotomous) outcomes such as operative mortality, the most common method for developing a multivariable model is *logistic regression.*[11] In this model, operative death is the outcome (*dependent variable*), and patient characteristics, plus valve model, are the potential risk factors (*independent variables*). For technical reasons, logistic regression does not use the probability (*P*) of death directly as the dependent variable in the model. Instead, it uses the logarithm of the *odds*, $P/(1 - P)$, of death. To facilitate interpretation of a regression coefficient (*B*) from such a model, it is converted into an *odds ratio* (OR) by using the exponential function. Most statistical programs do this automatically, and the ORs are sometimes labeled exp(*B*). The 95% CI for the OR is computed as the exponential of the normal approximation CI (mean plus and minus twice the SE) for the coefficient itself.

A stepwise regression program begins with a univariable test of each potential risk factor,[11] using a model with a single variable to get the OR and *p*-value associated with that variable. If the OR is greater than 1, that variable is a risk factor (meaning that it adds to the risk). If the OR is less than 1, it is a protective factor. For the heart valve example (Table 8-2), age, concomitant CABG, and valve model are statistically significant (their *p*-values are less than .05). These variables, plus any others showing a trend toward association with operative mortality (usually $p < .2$), would be included in the next step of the stepwise logistic regression. In the final regression model, only age and concomitant CABG were still significant (see Table 8-2). After those effects are accounted for, the effect of valve model is no longer significant ($p = .515$). Thus, by this analysis, the apparent increase in operative mortality with the current valve model is an artifact; current valve model is a surrogate for older age and more bypass surgery, which themselves are primarily responsible for the increased mortality. There are no doubt other clinical variables to consider in this model, but since we used the data only for demonstration purposes, not all possible variables were included. As a rule of thumb, 10 events can support one risk factor considered in a risk model.[12] In our data set, there are 83 operative deaths, so we would have been justified in considering about 8 risk factors. In practice, researchers would reference the published models and study their own data to select more variables for consideration.

The OR of a binary variable such as concomitant CABG (2.76 in Table 8-2) means that the odds of mortality for a patient having concomitant CABG are 2.76 times that of a patient not undergoing concomitant CABG. This is the point estimate; the interval estimate (see Table 8-2) ranges from 1.69 to 4.52. When the lower limit of the 95% CI is greater than 1 (as it is for concomitant CABG, i.e., 1.69), the

OR will be significantly greater than 1. For a continuous variable such as age, the OR of 1.04 means that for each year of age, the odds of dying are multiplied by 1.04.

Evaluating the risk model

HOSMER-LEMESHOW STATISTIC AND ROC CURVE: The performance of a logistic regression risk model needs to be evaluated. Traditionally, the *discrimination* is evaluated by the *c-index*, which is the area under the *receiver operating characteristic* (ROC) curve,[13] and the *calibration* is evaluated by the *Hosmer-Lemeshow (H-L)* statistic.[14] Generally, a *c*-index between 0.7 and 0.8 is considered acceptable discrimination, and a *c*-index between 0.8 and 0.9 is considered excellent discrimination.[15] If the H-L statistic is significant ($p < .5$), it may be a sign of poor calibration. For our final model in Table 8-2, the H-L statistic is $p = .365$, and the *c*-index is 0.710 (95% CI 0.653–0.767). These values can be considered optimistic, however, because the data used to generate the model also were used to test it. Ideally, one would use a different data set, or *bootstrap* resamples of the original data, to test the model.[16]

CUSUM TECHNIQUES: *Cumulative sum* (Cusum) analysis methods also can be used to examine the fit of a model and to examine the influence of variables not in the model.[17] Figure 8-1 shows the cumulative sum of observed minus predicted deaths plotted as a function of predicted mortality. For a model whose observed mortality exactly fit the expected, the line would lie along the horizontal axis. Figure 8-1 shows that patients with predicted mortality of less than about 6% (the lowest point of the curve) have observed mortality of less than predicted and that patients with predicted mortality of greater than about 6% have observed mortality of greater than predicted. When the predicted mortality is greater than about 15%, the risk is underestimated by the model. As a measure of model calibration, the Cusum could be thought of as a continuous version of the H-L test, which is based on the differences in observed minus expected deaths in each of the 10 deciles of risk, shown by shaded vertical bars in Fig. 8-1. Adding more suitable risk factors to our simplistic model hopefully would improve it and make the Cusum curve closer to the horizontal axis throughout the range of observed mortality.

When the dependent (outcome) variable is dichotomous (death), it is difficult to appreciate its relationship to a continuous risk factor, e.g., age, graphically. The Cusum[18] can be used to overcome this difficulty by plotting the Cusum against age. If the continuous factor selected for the horizontal axis is surgery date, the Cusum can be used to detect a learning curve.[19]

O/E RATIO: The predicted (expected) mortality from logistic regression can be used to compare the risk-adjusted performance between groups of patients, e.g., to compare different surgical techniques or different providers. If the ratio of observed (*O*) to expected (*E*) mortality, the *O/E ratio*, is greater than 1, then there are more deaths than expected by the model, and if the *O*/*E* ratio is less than 1, there are fewer deaths than expected. The CI of the *O*/*E* ratio can be calculated by using a normal approximation method, which, as usual, gives a symmetric interval around the point estimate, or by using a logarithmic transformation, which provides a more appropriate asymmetric interval.[20,21] Table 8-3 contains these values for our heart valve example. The CIs for the *O*/*E* ratios for both groups include 1, which means that their risk-adjusted mortalities are not different from those predicted by the model.

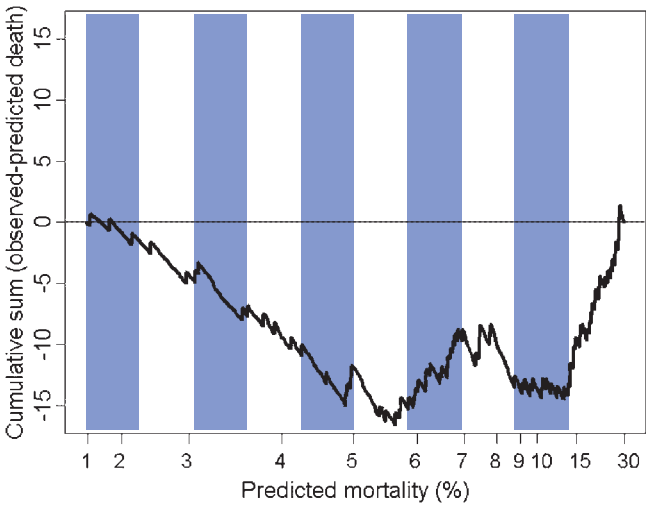

Figure 8-1. Cusum plot of operative death. Vertical axis is the cumulative sum of observed deaths minus predicted deaths by the logistic regression model in Table 8-3. Horizontal axis is scaled in number of patients (ordered by the predicted risk), so it is nonlinear in predicted risk of death. The gray/white bars each contain 10% of the patients.

TIME-RELATED EVENTS

We use both death and thromboembolism (TE) to illustrate methods for the analysis of time-related events.

Summarize

Survival curve

A single percentage is adequate to summarize mortality at a single point in time, such as the operative period (above). To express the pattern of late survival, however, requires a different estimate at virtually every postoperative time, i.e., a survivorship function, whose plot is the familiar survival curve. The most common way to estimate a survival curve is the *Kaplan-Meier* (KM) *method*,[22] called *nonparametric* or *distribution-free* because it does not presuppose any particular underlying statistical distribution. If all the patients in a given series were dead, the survival curve would be very simple to construct, as the percentage that had lived until each point in time. The KM method allows these percentages to

Table 8–3.

Ratio of Observed to Expected Early Mortality (*O*/*E* ratio)

Valve model	Previous	Current
Observed mortality	25/543 = 4.6%	58/712 = 8.1%
Predicted mortality	27.5/543 = 5.1%	55.5/712 = 7.8%
***O*/*E* ratio**	0.91	1.05
95% confidence interval		
Normal approximation	(0.55, 1.27)	(0.80, 1.29)
Log transformation	(0.61, 1.35)	(0.83, 1.32)

be estimated before all the patients have died in an ongoing series, using the assumption that patients who are still alive (whose survival time is censored) will have the same risk of future death as those who have already died. Figure 8-2 shows the KM survival curve for the mitral valve patients. The median survival time can be calculated as the survival time at which the survival curve crosses 0.5 (50%). The mean survival time can be calculated as the area under the completed survival curve. If the observation is not completed, the survival curve could be fitted with a suitable distribution, such as a Gompertz distribution, that could be extrapolated to estimate the uncompleted part.

Hazard function

Besides survival curves, there are several other statistical functions that can characterize the distribution of a time-related event. Survival curves are the easiest to interpret and apply to a patient or a population because they integrate the possibly varying risks over time and produce the probability of being alive at each point in time. The *hazard function* can be considered the fundamental building block of the other functions. The instantaneous hazard measures the risk of the event at each moment for an individual who is so far event-free. For technical reasons, the *instantaneous hazard* is difficult to measure directly, but its integral, the *cumulative hazard function,* is easy to produce either by taking the negative logarithm of the KM estimate[23] or by computing it directly using the *Nelson-Aalen method.*[24] This latter estimate can be derived from the two basic curves in the upper panel of Fig. 8-3. In the modern *counting process* formulation of survival analysis,[25,26] these two curves are the fundamental survival processes. The

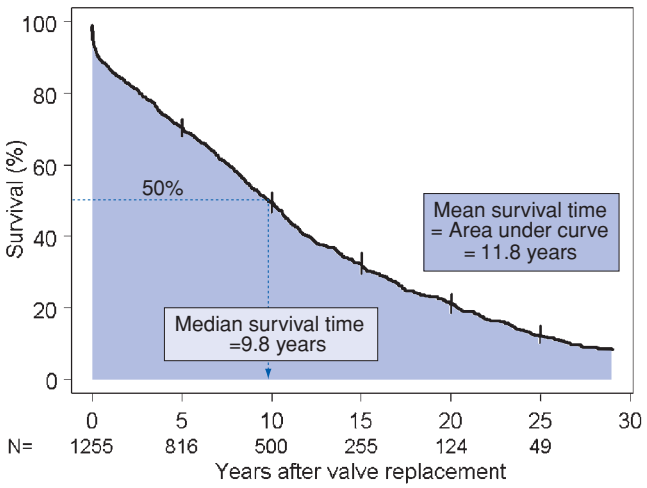

Figure 8-2. Kaplan-Meier survival curve. Vertical lines at 5-year intervals indicate the 95% CIs of the event-free percentages. Numbers below the horizontal axis indicate the number of patients remaining at risk.

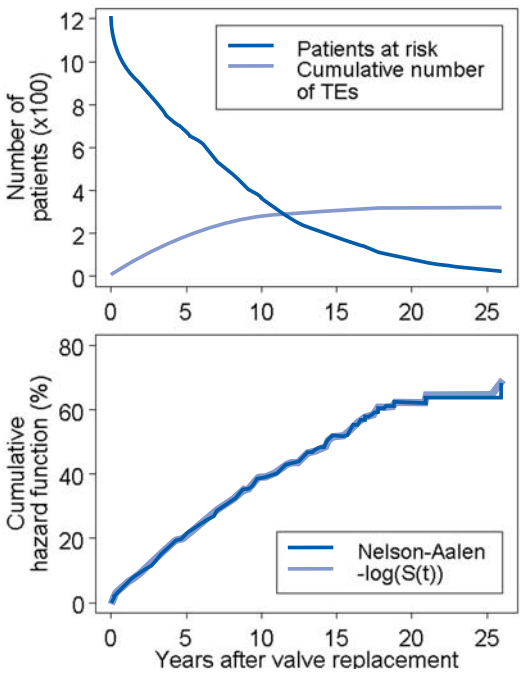

Figure 8-3. Cumulative hazard function of late thromboembolism (TE). The upper panel shows the two basic curves used to create the cumulative hazard function by the Nelson-Aalen method. The lower panel shows that the cumulative hazard function created by two methods are matched very well.

blue curve counts the number of patients still at risk at time t and is called the *at-risk process* $Y(t)$. The gray curve counts the number of events that have happened by time t and is called the *event counting process.* The gray curve rises 1 unit when each event occurs. The cumulative hazard function is similar to the gray curve, except that it rises $1/Y(t)$ each time an event occurs. The lower panel of Fig. 8-3 shows the cumulative hazard function estimated this way and also as the negative logarithm of the KM curve, $-\log[S(t)]$.

Linearized rate

One property of the cumulative hazard function is that it will be a straight line when the event hazard is constant. It is this property that gave rise to the name used in the cardiac literature to measure event rates that are presumed to be constant over time.

If the (instantaneous) hazard is a constant λ, then the cumulative hazard function $H(t)$ is a linear function of postoperative time t with slope λ: $H(t) = \lambda t$. In the cardiac literature, this constant risk parameter is called a *linearized rate.* For a given event in a series of patients, the maximum-likelihood estimate of this rate is the number of events (E) divided by the total follow-up time (T) in patient-years: E/T. Multiplying this by 100 converts it to "events per 100 patient-years," often abbreviated as *percent per patient-year* or *percent per year.* The SE is $\text{sqrt}(E)/T$, where sqrt = square root. Early events usually are not included in the calculation because the risk of most events is higher after operation, so the assumption of a constant hazard would not hold. Figure 8-4 shows that the cumulative hazard functions for two valve groups fit the constant hazard assumption fairly well.

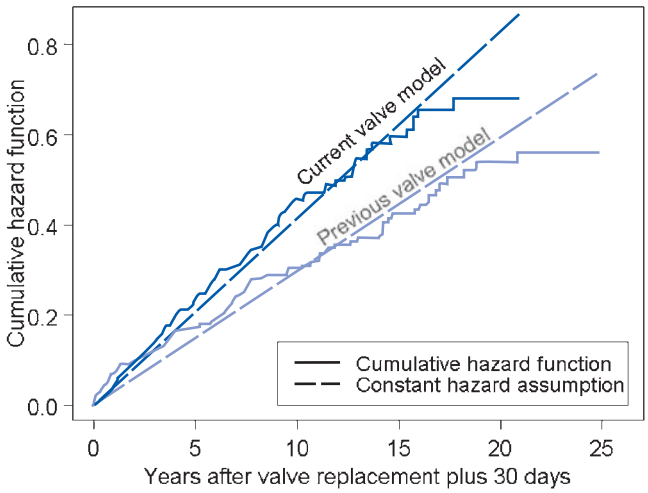

Figure 8-4. Cumulative hazard functions of late thromboembolism (TE) by valve model. The dashed lines depict the constant-hazard assumption. The total follow-up time is 4604 years and 4341 years for current and previous valve models, respectively.

Table 8-4 shows the linearized late TE rates by valve model based on the number of late TEs and late follow-up

Table 8–4.

Summary and Univariable Comparison of Linearized Rates of Late Thromboembolisms by Valve Model

Valve model	Previous	Current
Summarize		
Number of late thromboembolisms	129	191
Late follow-up (patient-years)	4,341	4,604
Linearized rate		
Point estimate (%/year)	2.97	4.15
Standard error (%/year)	0.26	0.29
95% confidence interval (%/year)		
Normal approximation	(2.47, 3.48)	(3.57, 4.72)
Cox's method	(2.49, 3.52)	(3.59, 4.77)
Likelihood ratio	(2.49, 3.50)	(3.58, 4.78)
Compare	*p*-Value (two-sided)	
Normal approximation	0.003	
Cox's method	0.003	
Likelihood ratio	0.003	

(patient-years beyond 30 days). The normal approximation (the mean plus and minus two times of SE) yields approximate 95% CIs. A preferred approximation is based on a suggestion owing to Cox,[27] which was recommended after a comparison of several methods.[28] In this method, the upper and lower 95% confidence limits are given by the 0.025 and 0.975 quantiles, respectively, of the chi-square distribution with $2E + 1$ degrees of freedom divided by $2T$. Another general technique for producing CI that usually is found to have very good properties is the *likelihood-ratio method*.[29] In our example, the CIs given by these three methods agree well, differing from each other only in the second decimal place. Note that the Cox limits and the likelihood-ratio limits are not symmetric around the point estimate, as the normal approximation limits are. (Cox's method also coincides with the probability interval produced by *Bayesian analysis*[30] using a noninformative prior.)

"Actual" analysis

The KM method is used often for events other than death. Figure 8-5 contains a KM TE-free curve for the mitral valve patients. When used for events such as TE that are not necessarily fatal, KM estimates the probability of being event-free given the unrealistic condition that death does not occur. But patients do, in fact, die before such an event has happened to them, so the KM event-free estimate is lower than the real ("actual") event-free percentage. Another method, called *cumulative incidence* in the statistical literature[31] and "*actual*" *analysis* in the cardiac literature, provides a mortality-adjusted event-free percentage.[32–35] The CI of the "actual" curve can be calculated by *Gray's method*.[36,37] The "actual" TE-free curve for this mitral valve series is much higher than the KM TE-free curve (see Fig. 8-5).

Besides providing an unrealistic estimate of the probability of TE, there is another, more technical problem with

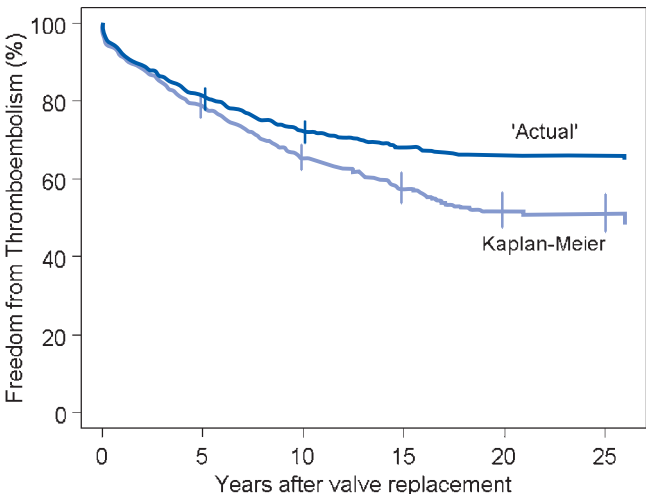

Figure 8-5. Thromboembolism-free curves constructed by the Kaplan-Meier method and the "actual" (one minus the cumulative incidence) method. Vertical lines at selected intervals indicate the 95% CIs of the event-free percentages.

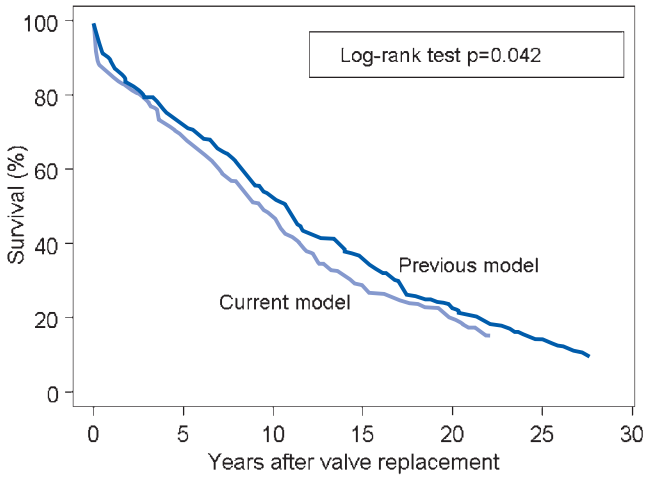

Figure 8-6. Survival by valve model. Overall survival significantly favors the previous valve model based on this univariate analysis that includes the higher mortality risk of the patients with the current valve model.

using the KM method in this situation. Its use is justified only if the risk of future TE for patients who died TE-free would have been the same as for those who actually had a TE. But this assumption cannot be proven from the data, so that the resulting TE estimate generally is regarded as statistically inappropriate.

Compare

The log-rank statistic is chosen most often to compare event-free curves.[38] Figure 8-6 shows the survival curves for the previous and current valve models, including all deaths, early and late. The previous model has significantly better survival according to this univariable comparison (log-rank test $p = .042$). But the difference mostly is due to early deaths; if we only consider late deaths, there is no significant difference between the two groups (log-rank test $p = .172$).

Comparing late TEs using linearized rates (see Fig. 8-4) also shows identical levels of statistical signficance using three different methods of testing: a normal-approximation method, a method recommended by Cox,[27] and a likelihood-ratio method[39] (see Table 8-4).

Model

Cox regression

Analogous to logistic regression, which provides multivariable analysis of the simple percentages associated with operative mortality, there is a widely used method for assessing multivariable influences on late survival: *Cox proportional hazards regression*.[12] This method assumes that the *hazard ratio* (HR) for all risk factors is constant over time. Table 8-5 shows the result of this regression as applied to the valve data for late survival. The univariable comparisons show three variables (i.e., age, concomitant CABG, and female gender)

Table 8–5.

Multivariable Modeling of Late Survival by Cox Regression and Gompertz Regression

	Univariate		Multivariate Cox regression		Multivariate Gompertz regression*	
Variable	***p*-Value**	**Hazard ratio**	***p*-Value**	**Hazard ratio (95% CI)**	***p*-Value**	**Hazard ratio (95% CI)**
Age	<0.001	1.04	<0.001	1.05 (1.04, 1.05)	<0.001	1.05 (1.04, 1.05)
Concomitant CABG	<0.001	1.65	0.052	1.23 (1.00, 1.50)	0.049	1.23 (1.00, 1.50)
Current valve model	<0.172	1.1	0.03	0.85 (0.73, 0.98)	0.03	0.85 (0.73, 0.98)
Female gender	0.005	0.82	0.005	0.81 (0.70, 0.94)	0.004	0.81 (0.70, 0.94)
Re-replacement	0.135	1.25	0.036	1.37 (1.02, 1.83)	0.036	1.37 (1.02, 1.83)

**Additional parameters in the Compertz regression: scale constant = −5.412, shape = 0.055.*

to be significant. The final Cox model includes all five variables, although current valve model and re-replacement were not significant by univariable analysis. This latter finding demonstrates that the practice of allowing only significant (by univariable analysis) variables to enter a stepwise regression may eliminate important risk factors.

The HRs for female and current valve model are less than 1; this means that they are protective factors rather than risk factors. For all the significant factors ($p < .05$) in the model, whether a risk or protective factor, the 95% CI does not include 1. *Note:* The univariable log-rank test shows no significant difference between the survival of previous and current valve models ($p = .172$); the multivariable Cox regression shows that current valve model has a lower risk of death (HR = 0.85, $p = .030$). Thus, the univariable log-rank test and multivariable Cox regression give opposite results. This tells us that if the groups are not compatible, as in this example, a multivariable comparison should be preferred. When the groups are compatible, such as in a randomized clinical trial, univariable comparisons may be appropriate.

Parametric regression

The preceding sections discussed nonparametric methods and nonparametric or semiparametric regression models to describe the survival data, such as KM curves and Cox regression, that do not make any assumptions about the underlying distribution of the survival or hazard functions. Another way

Table 8–6.

Formulas for the Hazard, Cumulative Hazard, and Survival Functions for Three Commonly Used Statistical Distributions

	Exponential	Weibull	Gompertz
h(t)	λ	$\alpha\lambda t^{\alpha-1}$	$\lambda e^{\alpha t}$
H(t)	λt	λt^{α}	$\lambda(e^{\alpha t-1})/\alpha$
S(t)	$\exp(-\lambda t)$	$\exp(-\lambda t^{\alpha})$	$\exp[-\lambda(1\text{-}e^{\alpha t})/\alpha]$
Mean time to event	$1/\lambda$	$\Gamma(1+1/\alpha)/\lambda^{1/\alpha}$	$\int S(t)dt$
Median time to event	$\log(2)/\lambda$	$[\log(2)/\lambda]^{1/\alpha}$	$\mathrm{Log}[1+\log(2)\alpha/\lambda]/\alpha$

Note: $\Gamma()$ is the gamma function. There is not a simple formula for the mean time to event of the Gompertz distribution.

to deal with survival data is to use a *parametric method.* A family of distributions is chosen, and the data are used to select the best-fitting member of that family by estimating the parameters that define the distribution. Three popular distributions used in cardiac surgery research are the *exponential, Weibull,* and *Gompertz distributions.* There are several functions that can be used to characterize a survival distribution. We have already discussed three of them: the *hazard function* $h(t)$, the *cumulative hazard function* $H(t)$, and the *survival function* $S(t)$. The hazard function can be considered the fundamental quantity from which the others are derived. It is the risk of the event at each instant of time t for a patient who is so far event-free. The cumulative hazard is the mathematical integral of the (instantaneous) hazard function. And the survival function is the exponential of the negative cumulative hazard: $S(t) = \exp[-H(t)]$.

Figure 8-7 shows typical plots of these three functions for the *exponential, Weibull,* and *Gompertz distributions,* with a selection of values for their parameters. The upper row of plots contains the hazard functions, the second row is the cumulative hazard functions, and the third row is the survival functions. Table 8-6 contains the formulas used for these functions. The exponential is the simplest lifetime distribution, having only a single parameter λ called the *scale parameter,* which is the (constant) hazard ("linearized") rate. The Weibull distribution is a natural generalization of the exponential distribution that adds a second parameter α called the *shape parameter* to accommodate an increasing ($\alpha > 1$) or decreasing ($\alpha < 1$) risk. The cumulative hazard reduces to the exponential distribution (constant risk) when $\alpha = 1$. The Weibull distribution is used commonly for time to failure and is employed in the cardiac literature to model structural deterioration of prosthetic heart valves. A Gompertz distribution[40] has a scale parameter λ and a shape parameter α. Its hazard function is an exponential function of time. The Gompertz distribution is widely used to model survival, especially in older age groups. Figure 8-8 uses the late death information from the heart valve data to show the fits derived from these 3 distributions. The data fits the Gompertz distribution very well.

Some of the advantages of the parametric method (over nonparametric or semiparametric methods) are

- The hazard function itself can be portrayed easily, which otherwise requires many data points and a complicated smoothing technique.

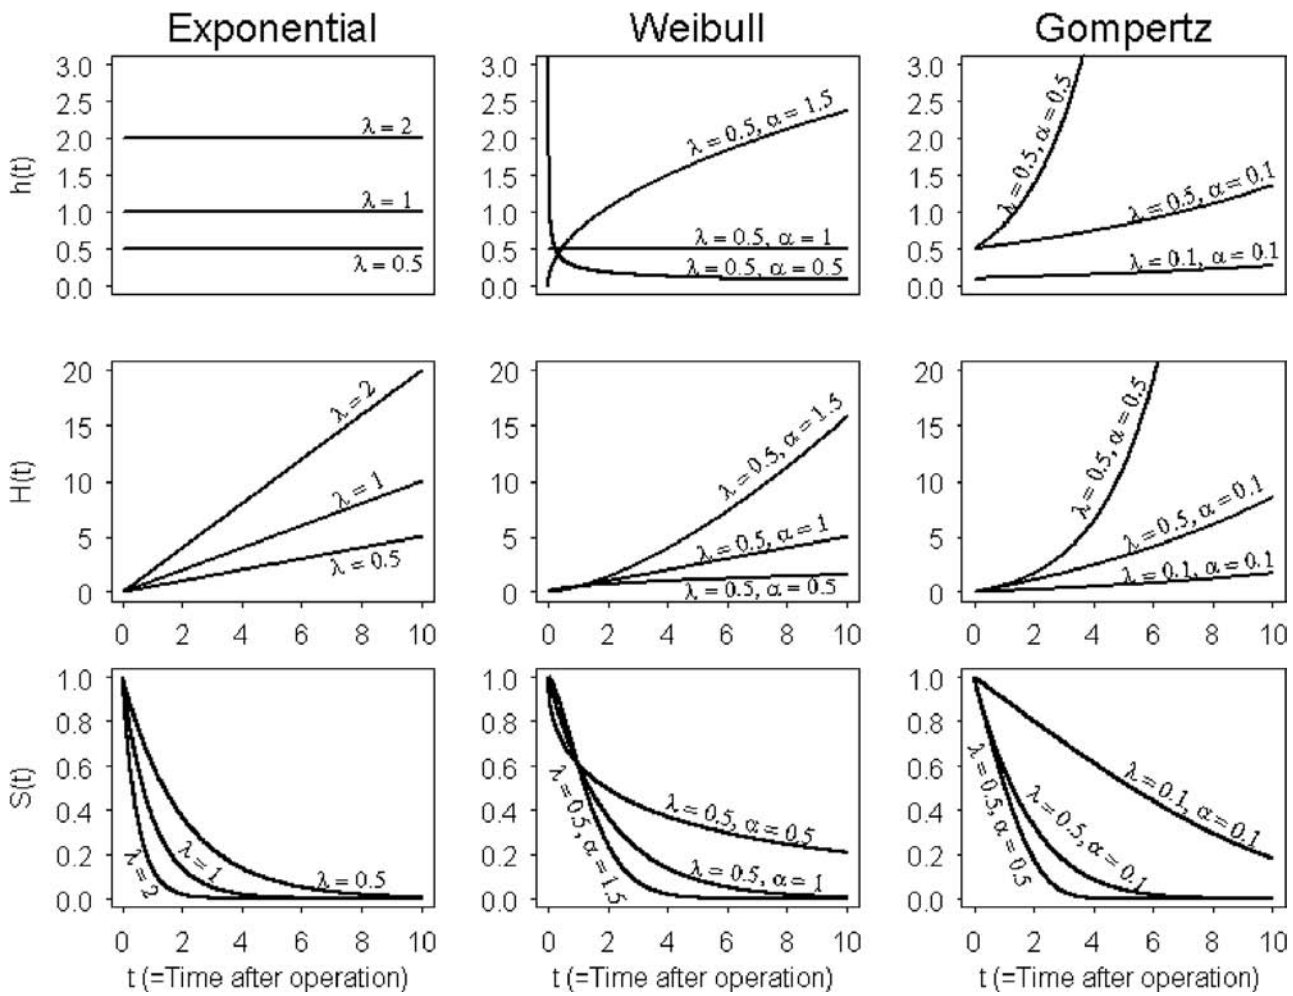

Figure 8-7. Hazard (*top row*), cumulative hazard (*middle row*), and survival function (*bottom row*) for the exponential, Weibull, and Gompertz distributions with different parameters.

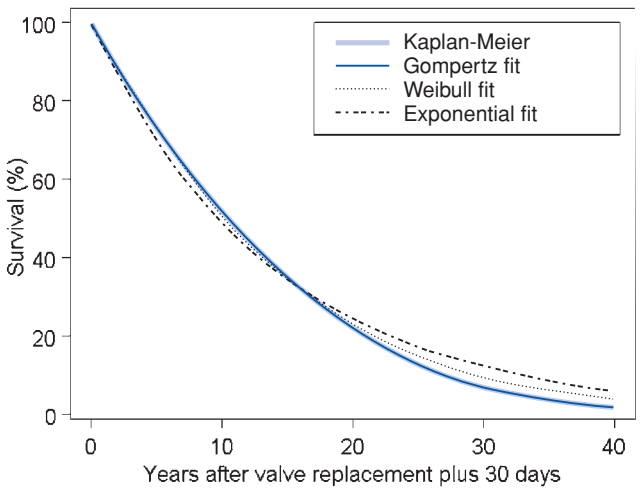

Figure 8-8. Three distributions used to fit late death. The best fit is the Gompertz model.

- The survival curve can be extrapolated into the future (beyond the maximum follow-up time).
- The median time to failure can be given, which otherwise cannot be estimated until the event-free curve reaches 50%.
- The mean time to failure can be given, which otherwise cannot be estimated until the event-free curve reaches 0%.
- The resulting curves may reproduce the underlying mortality process faithfully, which is no doubt smooth over time, unlike the random roughness of the original observed data points, which results in graphic peculiarities.
- The entire survival experience can be summarized with a small number of parameters.

A final and important advantage of fitting parametric models is that there may be a theoretical basis for the model that helps us understand the physical process rather than just describe it. The Weibull distribution has such a theoretical interpretation as the time to failure of a physical system that depends on very many parts (sites) for integrity. Thus, the Weibull distribution is a commonly used distribution for failure analysis and is employed in the cardiac literature to model the structural deterioration of prosthetic heart valves. The Gompertz distribution is used widely to model for human mortality, especially for older populations, based on the assumption that the "average exhaustion of a man's power to avoid death [is] such that at the end of equal infinitely small intervals of time he [loses] equal portions of his remaining power to oppose destruction which he had at the commencement of these intervals."[41]

These parametric distributions also can be used as the basis for regression models; usually the scale parameter is expanded to contain the risk factors. For the mitral valve data, a Gompertz regression produced hazard ratios identical to those of the Cox regression (see Table 8-5).

CONCLUSIONS

1. Different analytical methods must be used for outcome events after surgery depending on whether they are one-time (operative) or time-related (late) events.
2. Factors found significant on univariate analysis often are overturned by multivariate analysis because they are surrogates for other more clinically fundamental variables. This was the case with valve model in both the early and overall analysis of mortality. The converse also can happen; re-replacement was not significant for overall mortality by itself but became so in concert with other risk factors. Multivariable analysis, adjusting with the other risk factor, always should be the first choice.
3. The hazard and cumulative hazard functions measure the instantaneous and cumulative risks of an event, respectively. The cumulative hazard is easier to obtain. The survival curve converts their risks into probabilities of experiencing the events.
4. Linearized rates provide a convenient single-parameter summary of late-event rates but should not be used unless the hazard function is approximately constant.
5. Kaplan-Meier analysis estimates survival probabilities as a function of time after surgery. When used for events that are not necessarily fatal, KM estimates probabilities as if death were eliminated, whereas "actual" analysis gives a true mortality-adjusted estimate of the event probabilities.
6. Parametric regression is a useful tool to analyze long-term outcome. Usually, the Gompertz distribution is good for survival, and the Weibull distribution fits tissue and structural valve deterioration very well.

CHAPTER 9

Preoperative Evaluation for Cardiac Surgery

Michelle A. Albert • Nitsan Halevy • Elliott M. Antman

Improved operative outcomes and advances in surgical techniques have resulted in longer life expectancy for cardiac surgery patients. However, the higher risk profile of patients, including persons who are older, sicker, have multiple comorbidities, and have either failed or do not qualify for advanced percutaneous therapies, has led to increased morbidity and hospital length of stay.[1–3] Furthermore, advances in cardiac surgery using novel approaches (Table 9-1) such as robotically assisted surgery, off-pump coronary artery bypass grafting (OP-CABG), transmyocardial laser revascularization, and minimally invasive valve surgery with robotics extend the operative options for patients.[2–6] As a result, preoperative risk assessment is critical to ensuring safe performance of cardiac surgical procedures. While coronary artery bypass grafting (CABG) is cost-effective and moreover has known benefit in appropriately selected patients such as those with left main disease, three-vessel disease, and severe angina, preoperative risk assessment is nonetheless of critical importance in minimizing perioperative and long-term morbidity and mortality. Additionally, preoperative evaluation can influence hospital quality improvement, hospital/surgeon report cards, and reimbursement. Thus accurate preoperative appraisal can translate into the implementation of proper quality surveillance mechanisms and improve risk-adjusted mortality for CABG to less than 2% for the general population and 3 to 4% for the Medicare population.[7–10] This chapter reviews the information essential to the cardiologist and surgeon in the evaluation and management of patients prior to cardiac surgery.

THE PHYSICAL EXAMINATION AND LABORATORY EVALUATION

The preoperative physical examination is a critical part of a patient's evaluation for CABG because the findings can greatly influence perioperative management. During the physical examination, particular attention should be paid to the patient's risk for endocarditis, the presence of aortic insufficiency, the presence of vascular disease, and the neurologic status. Identification of an aortic regurgitation murmur is important because during cardiopulmonary bypass, regurgitation can worsen, and acute left ventricular distension may develop.

The physical examination also helps to identify potential contraindications to the use of an intra-aortic balloon pump. Also, attention should be paid to the patency of the venous system in the lower extremities because extensive varicosities may necessitate the use of arm veins as conduits; if the latter are needed, then avoidance of intravenous line placement in the arm from which veins will be harvested is necessary. In the event of reoperation, noninvasive imaging of the lower extremities may be desirable, as well as imaging of the left internal mammary artery during cardiac catheterization, to assess patency of potential conduits.

Carotid ultrasound should be performed on all patients to assess the need for timing of carotid revascularization, particularly in individuals with a history of prior stroke, severe bilateral stenoses, or contralateral occlusion and in patients with a history of neurologic symptoms.[11,12]

In women who have had a left radical mastectomy, patency of the left internal mammary artery can be compromised because of alterations in thoracic blood flow. As a result, the left anterior descending artery then becomes ineffective as a conduit.[13]

Basic laboratory testing prior to cardiac surgery is outlined in Table 9-2.

SPECIAL LABORATORY CONSIDERATIONS

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT), or "white clot syndrome," is an immune-mediated, potentially life-threatening thrombotic complication of heparin therapy that

Table 9–1.

Novel Cardiac Surgical Techniques

Technique	Reason/advantage	Mortality (%)	Preoperative considerations
MIDA-AVR	Reduce chest trauma, minimize blood loss, accelerate patient recovery	1.6–2.0*	Body habitus, elderly patients, CXR, defibrillator pads, TEE guidance
MIDA-MVR	Reduce chest trauma, minimize blood loss, accelerate patient recovery	0.8–1.1*	Same as above
MIDA-CABG	Reduce chest trauma, accelerate patient recovery	1.0†	Same as above
Robotic-assisted CABG	Can perform on beating heart	Experimental	–
Off-pump CABG	Elderly patients, COPD, reduces oxidative stress and inflammation, comorbidities, less need for blood transfusions, shorter hospital stay, decrease in deep sternal wound infections, less cerebral dysfunction, less renal dysfunction	1.3‡	Same as above, fewer diseased vessels, absence of LM disease
TMR	Refractory angina despite maximal medical therapy ± revascularization procedures	1–5§	Anginal class III/IV, left ventricular free wall ischemia

MIDA = minimally invasive direct access; AVR = aortic valve replacement; MVR = mitral valve replacement; TMR = transmyocardial laser revascularization.

Source: Adapted from refs. 5, 96, 104, 162, and 164–166.

occurs in 3 to 5% of individuals approximately 5 to 14 days after heparin exposure.[14,15] HIT should be suspected in any patient who experiences a 50% or greater decrease in platelet count from baseline or 30% or greater decrease in platelet count and associated thrombotic complication while on unfractionated heparin for at least 5 days. HIT can occur earlier in patients who are within 3 months of previous exposure to heparin. When testing for platelet factor 4 (PF4)/heparin antibodies in a patient with suspected HIT, it is recommended that the test be repeated on several successive days.[16] Thrombocytopenia usually resolves within 1 week of heparin discontinuation, but thrombotic tendency can persist for up to 1 month. Although HIT can occur with the use of low-molecular-weight heparin (LMWH), the incidence and development of thrombosis are much less frequent.[17] One study demonstrated a higher incidence of saphenous vein graft occlusion among post-CABG patients with HIT compared with non-HIT patients within 2 weeks of surgery (68% versus 20%, $p < .001$). However, the incidence of internal mammary artery graft occlusion was not significantly different between the two groups [HIT patients = 6% (1 patient) and non-HIT patients = 11% (2 patients)].[18]

Antibodies to heparin/PF4 cause platelet activation and aggregation, as well as thrombin formation, resulting most commonly in deep venous thrombosis, pulmonary embolism, or cerebral sinus thrombosis.[19] Following CABG, HIT may present as graft occlusion, left atrial thrombus, valvular thrombosis, or pulmonary embolism.[20] On average, 25 to 50% of cardiopulmonary bypass patients who receive heparin acquire HIT immunoglobulin G (IgG), but only approximately 7% develop HIT.[21,22]

Many surgeons still prefer to use unfractionated heparin (UFH) during cardiopulmonary bypass because of familiarity, the need to employ specialized monitoring when using alternative agents, and the lack of antidotes for alternative agents. Besides the use of lepirudin, an irreversible antithrombin, or argatroban, a reversible direct thrombin inhibitor, reduction of thrombosis during cardiopulmonary bypass in patients with known HIT can be achieved by limiting UFH exposure time or by delaying surgery until 3 months after the patient's UFH exposure.[23] Otherwise, after receiving UFH, platelet counts should be monitored every 3 days from day 3 to day 14 of heparin exposure. In patients with HIT, warfarin initiation should be done in the presence

Table 9–2.

Preoperative Tests for Cardiac Surgery

Preoperative laboratory test	Abnormal finding	Comment
Complete blood count	1. Anemia, especially Hct <35%	1. Anticipate that hemodilution will occur on cardiopulmonary bypass and blood loss will occur intraoperatively. In stable patients, preoperative iron supplementation (weeks) or erythropoietin therapy (days) should be considered. Patients with unstable angina, congestive heart failure, aortic stenosis, and left main coronary artery disease should be advised against autologous donation of blood in the preoperative period.
	2. WBC > 10,000	2. Search for possible infection.
Coagulation screen	1. Prolonged bleeding time 2. Elevated PT and/or PTT 3. Thrombocytopenia	All these laboratory abnormalities suggest that the patient is at risk for bleeding postoperatively and may have excessive chest tube drainage. Corrective measures (e.g., vitamin K, fresh frozen plasma, platelet transfusions) should be considered preoperatively, and surgery may need to be postponed. Hematological consultation may be required if an inherited defect in coagulation (e.g., von Willebrand factor deficiency) is suspected.
Chemistry profile	1. Elevated BUN/creatinine	1. Abnormal renal function that may worsen in the perioperative period (caused by nonpulsatile flow on cardiopulmonary bypass and potential low flow postoperatively); may necessitate temporary or even permanent hemodialysis.
	2. Potassium <4.0 mEq/L and/or magnesium <2.0 mEq/L	2. Electrolyte deficits may place the patient at risk of arrhythmias perioperatively and should be corrected before induction of anesthesia.
	3. Abnormal liver function tests	3. Patient may clear anesthetic agents as well as other cardioactive drugs more slowly. Low albumin level may indicate a state of relative malnutrition that may need to be corrected with nutritional support perioperatively.
	4. Fasting plasma glucose ≥ 126 mg/dL	4. Patients with previously diagnosed or undiagnosed diabetes are at increased risk for postoperative mortality.
Stool hematest	Positive for occult blood	Because heparinization will take place while on the cardiopulmonary bypass apparatus, the patient may be at risk for GI bleeding perioperatively. The source of GI heme loss should be investigated preoperatively if clinical circumstances permit. The potential for bleeding in the future may influence the choice of prosthetic valve inserted.
Pulmonary function	Reduced VC or prolonged FEV_1	Anticipate longer than usual process of weaning from ventilator postoperatively if FEV_1 <65% of VC or FEV_1 <1.5–2.0 L. Obtain baseline arterial blood gas analysis on room air to help guide respiratory management postoperatively.
Thyroid function	These tests are not ordered routinely but should be performed in cases of suspected hypothyroidism or hyperthyroidism, known thyroid dysfunction during replacement therapy, and atrial fibrillation in patients who have not undergone evaluation of thyroid function	Hypothyroid patients require prolonged period of ventilatory support postoperatively because of slower clearance of anesthetic agents. Hyperthyroid patients have a hypermetabolic state that places them at increased risk of myocardial ischemia, vasomotor instability, and poorly controlled ventricular rate in atrial fibrillation.

(continued)

Table 9–2.

Preoperative Tests for Cardiac Surgery *(continued)*

Preoperative laboratory test	Abnormal finding	Comment
PF4/heparin antibody screen.	Positive	In patients exposed to UFH/LMWH within 3 months prior to surgery.
Echocardiography	1. Decreased LV ejection fraction	1. Patients with decreased LV function are at higher perioperative risk for surgery. Selected patients should undergo viability assessment.
	2. Decreased RV function	2. RV dysfunction increases perioperative risk and identification may lead to preoperative assessment of reversibility of pulmonary hypertension.
	3. Aortic stenosis	3. Mild to moderate aortic stenosis (gradient <25 mm Hg) may be treated by prophylactic valve replacement in selected low-risk patients.
	4. Aortic insufficiency	4. Ventricular dimension will help guide decisions to perform valve replacement in addition to revascularization in patients with combined aortic regurgitation and coronary disease.
	5. Mitral insufficiency	5. Moderate or severe mitral regurgitation may warrant valve exploration in patients undergoing coronary revascularization.
	6. LV aneurysm	6. May alert surgeons to the need of aneurysmectomy in selected patients.
	7. Ventricular septal defect	7. Identification will suggest the need for early surgical intervention.
Cardiac catheterization	1. Elevated LV end-diastolic pressure and pulmonary capillary wedge pressure	1. May remain elevated in the early postoperative period and indicate a need for careful attention to maintenance of adequate preload postoperatively.
	2. Elevated right atrial pressure	2. May reflect tricuspid regurgitation or RV dysfunction from prior infarction. Such patients require vigorous volume expansion postoperatively to maintain adequate cardiac output.
	3. Elevated pulmonary artery pressure (and pulmonary vascular resistance)	3. Fixed pulmonary vascular resistance should be suspected when the pulmonary artery diastolic pressure exceeds the mean pulmonary capillary wedge pressure. Vigorous oxygenation and pharmacological support with a pulmonary vasodilator (isoproterenol, prostaglandin E_1) are important in such cases. Patients with a pulmonary artery diastolic pressure equal to the pulmonary capillary wedge pressure usually have more rapid resolution of pulmonary hypertension postoperatively.
	4. LV mural thrombus	4. Increased risk of stroke perioperatively.
	5. Status of internal mammary arteries	5. Highly desirable arterial conduits for planned revascularization surgery. Particular care required during reoperation if patent internal mammary artery bypass is in place from previous surgery.
	6. Status of saphenous vein grafts	6. "Pseudoextravasation" of dye outside the lumen in a patent graft with slow flow probably represents thrombus-filled atherosclerotic aneurysm of the graft.

BUN = blood urea nitrogen; FEV_1 = volume of air expired at 1 second; GI = gastrointestinal; Hct = hematocrit; LMWH; = low-molecular-weight heparin; LV = left ventricular; PT = prothrombin time; PTT = partial thromboplastin time; RV = right ventricular; UFH = unfractionated heparin; VC = vital capacity; WBC = white blood cell count.

of lepirudin or argatroban owing to warfarin's association with limb gangrene when used as the sole agent.[24]

Hypercoagulable Disorders

Management of patients with hypercoagulable syndromes can be especially challenging in the setting of cardiac surgery, where the need to control bleeding postoperatively is crucial in preventing potentially life-threatening complications such as pericardial tamponade. Common (e.g., factor V_{Leiden} and *G20210A* prothrombin gene) and relatively uncommon (e.g., antithrombin deficiency and protein C and protein S deficiency) causes of thrombosis have different risk associations. For example, the relative risk of venous thrombosis in the Caucasian population can range from 2.5 for the prothrombin gene mutation to 25 in the presence of antithrombin deficiency.[25] Furthermore, approximately 50% of cases of venous thrombosis associated with these hereditary disorders are provoked by known risk factors such as surgery. Therefore, aggressive prophylaxis with subcutaneous UFH or LMWH is warranted prior to surgery for patients who are not taking long-term anticoagulation.[26] In contrast, for those on long-term anticoagulation, the decision to continue treatment for thrombosis in the cardiac surgery setting should be individualized. In general, warfarin therapy can be switched to LMWH 3 to 5 days prior to cardiac surgery. Anticoagulation using UFH as a bridge should be resumed as soon as the bleeding risks associated with cardiac surgery have been stabilized, usually within 2 to 3 days postoperatively. The patients at highest risk for venous thrombosis are those within 3 months of an episode of thrombosis and those with conditions that predispose to the highest risk of thrombosis such as antithrombin deficiency.[25]

Patients with antiphospholipid antibody syndrome (e.g., lupus anticoagulant/anticardiolipin antibodies, history of arterial or venous thrombosis, and/or recurrent fetal loss) deserve special mention because this syndrome can be associated with valvular heart disease (32 to 36% requiring replacement).[27–29] Perioperative management, including the choice of prosthetic valve, is challenging and requires a multidisciplinary approach owing to the risk of thrombophilia, abnormal prolongation in clotting times, and the presence of thrombocytopenia. During cardiopulmonary bypass, anticoagulation monitoring is difficult using standard means. Therefore, preoperative in vitro testing to identify the most reliable assay for heparin monitoring during cardiopulmonary bypass may be necessary.[30] Potential heparin assays include protamine titration, kaolin, and the anti-Xa methods that measure heparin's in vitro effects differently.[29]

Multiple Anticoagulants in the Setting of Failed Percutaneous Intervention

Advancements in cardiology have resulted in the almost standard use of glycoprotein IIb/IIIa inhibitors, aspirin, and intravenous (IV) heparin or LMWH in patients with non–ST- and ST-segment elevation myocardial infarction (MI) who undergo early percutaneous intervention (PCI).[31,32] However, prospective, randomized evidence involving patients who have received multiple anticoagulants for PCI who subsequently required urgent or semiurgent cardiac surgery is lacking. Clinical decisions therefore should be based on known bleeding risks/pharmacology associated with individual agents, available subgroup analyses, and surgical urgency.

Although some studies found that the use of aspirin preoperatively increased the need for transfusions,[33,34] others showed that the use of aspirin preoperatively is associated with significantly lower postoperative mortality compared with no aspirin use in the 5 days preceding surgery [odds ratio (OR) = 0.34, 95% confidence interval (CI) 0.15–0.75].[35] Presently, many patients are safely given aspirin in the perioperative period. However, while the use of UFH and aspirin has been the standard of care for acute coronary syndromes (ACS), LMWH has shown superior clinical benefit for ACS.[36,37] Data regarding the preoperative use of enoxaparin compared with UFH are sparse and mixed. Some data demonstrate that the rates of rehospitalization for hemorrhage are higher (7.9% versus 3.7%) for UFH,[38] while other research indicates no increase in risk for postoperative bleeding or blood transfusions.[39] Additional research is needed in this area particularly because only a small number of ACS patients proceed to CABG.

In the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trial, patients who received the glycoprotein IIb/IIIa inhibitor eptifibatide within 30 days of CABG did not experience higher rates of bleeding, probably owing to the short half-life of the drug.[31] Similar findings were noted in the Platelet Receptor Inhibition in Ischemic Syndrome Management (PRISM-PLUS) study.[40] By contrast, retrospective data from the Mayo Clinic show that patients who received abciximab and needed urgent/emergency CABG within 48 hours after PCI tended to have higher rates of major bleeding (90% versus 77%, $p = .68$) and more frequently received red blood cell (RBC) and platelet transfusions than those who were not treated with abciximab.[41] Despite the latter, there were no observed differences in the rates of MI, reoperation for bleeding, mediastinal reexploration, or length of hospitalization between the two groups.

However, the Clopidogrel in Unstable Angina to Prevent Recurrent Ischemic Events (CURE) trial showed that the antiplatelet agent clopidogrel was beneficial in patients with ACS undergoing PCI but was associated with a concomitant increased risk of major bleeding.[42] Although clopidogrel can decrease mortality, it potentially may pose serious problems with major perioperative bleeding. In an analysis of patients in the CURE trial who underwent CABG during the initial hospitalization (average time to procedure 12 days), there was a 19% reduction in the primary outcome of MI, stroke, or cardiovascular death among the clopidogrel-treated patients

compared with the placebo group.[43] Furthermore, the incidences of major and life-threatening bleeding were 27% and 24% higher in the clopidogrel-treated patients, but these rates were not statistically significant. Further comparison of the time to CABG after clopidogrel discontinuation (i.e., ≤5 or ≥5 days) revealed a nonsignificant bleeding excess in patients whose clopidogrel was stopped within 5 days of CABG but no excess bleeding among patients who had discontinued the medication more than 5 days prior to CABG.

By contrast, other data found that among in-hospital referrals for CABG, clopidogrel was associated with higher 48-hour in-hospital mortality, reoperation for bleeding, intubation time, transfusions, and hospital stay.[44,45] Thus data suggest that it is probably best for patients to wait at least 5 days after discontinuing these agents before undergoing cardiac surgery in order to minimize bleeding complications. Nonetheless, emerging data suggest that among patients who require surgery fewer than 5 days after exposure to clopidogrel, aprotinin, a serine protease inhibitor that has multiple effects including platelet aggregation, reduces the rate of postoperative bleeding and blood transfusions.[46,47]

Another area of interest relates to OP-CABG, where hemorrhagic events occur at a lesser frequency than in traditional CABG using cardiopulmonary bypass (CABG-CPB). Research by Kapetanakis and colleagues suggests that clopidogrel administration prior to surgery increases the need for hemostatic reoperation (OR = 5.1, 95% CI 2.47–10.47) and blood transfusions (OR = 2.6, 95% CI 1.94–3.90), thereby possibly extinguishing the advantage of OP-CABG.[48] Still, some argue that this tradeoff between the anti-ischemic benefit of clopidogrel and perioperative bleeding can be balanced by delaying surgery after discontinuing the drug.[49] One exception may be when clopidogrel is being taken in the context of new stent implantation for coronary artery restenosis. In this instance, the risk of stent thrombosis may outweigh the risk of bleeding complications.

Limited data are available regarding the use of thrombolytic agents prior to CABG. However, in a subgroup analysis of the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO I) trial, patients who underwent PCI or CABG after receiving fibrinolytics had a lower rate (0%) of intracranial hemorrhage than those treated with repeat thrombolysis (1.3%) or medical therapy (0.5%; $p = .046$).[50] By contrast, in the Assessment of the Safety of a New Thrombolytic (ASSENT 2) study, no difference in the rate of intracranial hemorrhage was observed among the revascularization, rethrombolysis, and conservative treatment groups.[50] Moreover, an evaluation of the long-term survival in patients who received thrombolysis compared with those who were not given thrombolytic therapy within 7 days of CABG showed no difference in early outcome and increased survival [hazard ratio (HR) = 0.54, 95% CI 0.36–0.81) at 5 years of follow-up, thereby reinforcing the long-term benefit of CABG in decreasing MI and mortality.[51]

PREOPERATIVE ESTIMATION OF MORBIDITY AND MORTALITY RISK: SCORING SYSTEMS

Preoperative risk assessment has important implications for patient well-being, containment of hospital costs, and provision of objective risk stratification data aimed at assessing an accurate potential risk:benefit ratio. Several scoring systems have been developed to assess perioperative risk, particularly in the setting of isolated CABG. The major risk factors for adverse outcome during CABG include advanced age, emergency surgery, history of prior CABG, dialysis dependency, and a creatinine concentration of 2 mg/dL or higher.

Owing to the changing profile of patients undergoing cardiac surgery, accurate preoperative risk stratification has become increasingly difficult. Factors affecting outcome data include surgery type (Table 9-3), follow-up time, medical therapy after hospitalization, and geographic, cultural, social, and economic issues.[52,53] Immer and colleagues compared three different scores (Parsonnet, Higgins, and French scores) used for preoperative risk stratification of postoperative morbidity, mortality, and hospital length of stay for 1299 consecutive patients undergoing CABG and/or heart valve surgery.[54] All three scoring systems performed well, with *c*-statistics between 0.76 and 0.79. The Higgins and French scores were especially useful in predicting postoperative outcome. Both of these scoring systems showed a progressive increase in cardiac risk class with increasing cardiac risk score.

Among European centers, the European System for Cardiac Operative Risk Evaluation (EuroSCORE) algorithm has been used to predict perioperative risk. In a single-center comparison of 19 risk scoring systems, the EuroSCORE algorithm provided the best discriminatory capability for 30-day and 1-year mortality (*c*-statistic 0.84 and 0.76, respectively), closely followed by Cleveland Clinic/Higgins (0.82 and 0.76) and Magovern (0.82 and 0.76) algorithms.[55] For CABG, the EuroSCORE and New York State risk scores best predicted outcome (Fig. 9-1). Unfortunately, risk stratification scoring systems might be somewhat hindered by differences in geographic population, the lack of information related to morbidity, and long-term information on survival.

Rumsfeld and colleagues examined a nontraditional approach to cardiac surgical risk stratification that involved assessment of a patient's self-perceived health status using the Physical Component Summary (PCS) scores from the preoperative Short-Form 36 (SF-36) health status survey.[56] After adjustment for known clinical risk factors of mortality following CABG, the PCS from the preoperative SF-36 was found to be an independent predictor of mortality such that a 10-point or 1-SD decrement in baseline PCS was associated with a 39% increase in 6-month mortality (95% CI 1.11–1.77, $p = .006$). As noted by the authors, this study may have had a selection bias toward lower-risk elective cases and did not determine the predictors of the baseline PCS. While the role of these data in the preoperative evaluation of cardiac surgery patients remains unclear, they illustrate that in addition to

RISK FACTORS FOR MORBIDITY AND MORTALITY

Atrial Fibrillation

Commonly encountered after cardiac surgery, atrial fibrillation occurs in as many as 10 to 40% of patients after CABG and in up to 65% of patients undergoing combined CABG and valve surgery.[57–60] Atrial fibrillation occurs most frequently within 24 to 48 hours after surgery and is associated with prolonged hospitalization (the excess length of stay that was independently attributable to postoperative atrial fibrillation was 4.9 days, with additional costs of $5000 to $6000 per patient), hemodynamic instability, and thromboembolization.[61–65] The risk of stroke increases threefold in patients with postoperative atrial fibrillation.

Risk Scores for In-Hospital Mortality for Coronary Artery Bypass Grafting

Risk Factor	Score
Age (yrs)	
<61	0
61–69	1
70–79	3
80 and older	5

Figure 9-1. Preoperative estimation of risk of mortality, cerebrovascular accident, and mediastinitis, developed by the Northern New England Cardiovascular Disease Study Group.

Atrial fibrillation also was found to be the most common reason for readmission to the hospital after cardiac surgery.[61]

Although usually considered benign and self-limited, postoperative atrial fibrillation is associated with increased early and late mortality, an association that persists after adjustment for existing comorbid conditions and advanced age.[66]

Many patients (25 to 80%) convert spontaneously to sinus rhythm within 24 hours.[67] However, the incidence of atrial fibrillation during the first year following CABG is

greater than in the general population in patients younger than 70 years of age.[68]

The mechanism of atrial fibrillation following cardiac surgery is not well understood, but possible etiologies include multiple wavelet reentry in the atria, rapid firing of an atrial focus, and less likely, atrial ischemia.[60,69] Preoperative clinical predictors of atrial fibrillation after cardiac surgery include increased age, history of hypertension, male sex, previous history of atrial fibrillation or congestive heart failure, peripheral and/or cerebral vascular disease, and severity of coronary artery disease.[58,60,62,70,71] Less well-characterized predictors of postoperative atrial fibrillation include aortic cross-clamp time, pulmonary vein venting, respiratory disease [chronic obstructive pulmonary disease (COPD)], prolonged ventilation,[60] and obesity.[71]

Current guidelines (ACC/AHA/ESC) recommend prophylactic beta-blocker therapy for all patients without contraindications. Therapy with amiodarone or sotalol is reserved for patients at increased risk for postoperative atrial fibrillation (e.g., those with a history of atrial fibrillation, left atrial enlargement, or valvular heart disease).[72] The prophylactic use of beta-blocker therapy decreases the incidence of post-CABG atrial fibrillation by as much as 70 to 80%.[73] Preoperative initiation of beta-blocker therapy probably attenuates the high sympathetic tone associated with cardiac surgery. Unless specifically contraindicated, patients who have received long-term beta blockers should continue receiving them promptly after surgery.[74,75]

Aasbo and colleagues demonstrated a reduction in atrial fibrillation, ventricular tachyarrhythmias, stroke, and length of hospital stay after cardiac surgery attributable to amiodarone prophylaxis. The decrease in atrial fibrillation was similar whether amiodarone therapy was initiated preoperatively or perioperatively. No difference was noted between oral and intravenous administration.[76] The relative merits of adding prophylactic amiodarone compared with beta blockers universally for postoperative atrial fibrillation for all patients is unknown.[75,76] Sotalol, a class III antiarrhythmic drug, also reduces the incidence of postoperative atrial fibrillation compared with placebo and half-dose beta blockade.[77,78] Sotalol may be considered for prophylactic use in high-risk patients, being mindful of potential side effects.[75] Preoperative drug therapy for atrial fibrillation has been shown to decrease hospital length of stay and cost.[79,80] Interestingly, basic science and clinical data show promise for the use of N-3 polyunsaturated fatty acids (PUFAs) in reducing the incidence of postoperative atrial fibrillation and hospital length of stay. PUFAs are believed to decrease the incidence of arrhythmias owing to their effects on rat atrial muscle in experimental models and also have a favorable safety profile.[81] Prophylactic use of calcium channel blockers and digoxin does not reduce the incidence of atrial fibrillation.[56,75] Biatrial pacing may have a role in patients at highest risk for postoperative atrial fibrillation (e.g., those with concomitant mitral valve surgery and CABG).[82,83]

For patients with persistent atrial fibrillation after cardiac surgery, priority should be given to electrolyte repletion and rate control. While beta blockers are considered first-line therapy, calcium channel blockers such as verapamil and diltiazem also are useful in controlling ventricular rate. Amiodarone is also beneficial for rate control, particularly in individuals who are unable to tolerate beta blockers or calcium channel blockers because of hypotension. Antiarrhythmic therapy usually is reserved for individuals who have persistent or recurrent atrial fibrillation. Class IA (e.g., disopyramide, quinidine, procainamide), class IC (e.g., propafenone and flecainide), and class III agents (e.g., sotalol, amiodarone, ibutilide, and dofetilide) all have varying degrees of efficacy for conversion of post-CABG atrial fibrillation.[60] While class IC and class III drugs can be used in the setting of resistant atrial fibrillation, cardiology consultation is prudent prior to their use because they are contraindicated in select patient populations, and the risk for drug-induced proarrhythmia is high. Electrical cardioversion should be performed if the patient demonstrates hemodynamic instability and in patients with persistent symptoms or rapid ventricular rate despite optimal drug therapy. Figure 9-2 outlines an algorithm for the prevention and management of atrial fibrillation after cardiac surgery.

Anticoagulation in patients with postoperative atrial fibrillation for 48 hours or more should be individualized. American College of Chest Physicians (ACCP) guidelines recommend warfarin treatment to therapeutic INR (2 to 3) in select patients with chronic atrial fibrillation or in patients in whom atrial fibrillation persists over 48 hours.[84] Heparin therapy as a bridge to a therapeutic INR with warfarin is troublesome because it is associated with higher rates of large pericardial effusion and cardiac tamponade compared with patients receiving aspirin or placebo.[60] Despite this, heparin should be considered in high-risk patients (e.g., those with a history of stroke or transient ischemic attack).[84]

Although the actual percentage of patients who remain in atrial fibrillation after surgery remains unknown, it is believed that many patients with persistent atrial fibrillation at discharge will convert spontaneously to sinus rhythm within 6 weeks.[85]

Renal Disease

Acute renal failure develops in approximately 1 to 5% patients after cardiac surgery.[86] Morbidity and mortality related to renal disease after cardiac surgery are heavily dependent on comorbid disease. Risk factors for acute renal failure include advanced age, baseline renal dysfunction, left ventricular dysfunction, peripheral vascular disease, and clinical signs of poor cardiac function such as pulmonary rales and the use of an intra-aortic balloon pump.[86–88] Other risk factors include a history of diabetes, hypertension, reoperation, urgent operation, prolonged cardiopulmonary bypass and aortic cross-clamp times, concomitant procedures, and deep sternal or systemic infections.[89]

Additionally, preoperative renal insufficiency is an independent risk factor for postoperative morbidity and mortality.[90–92] Renal insufficiency is associated with greater risk of both 30-day (OR = 3.7) and 1-year mortality

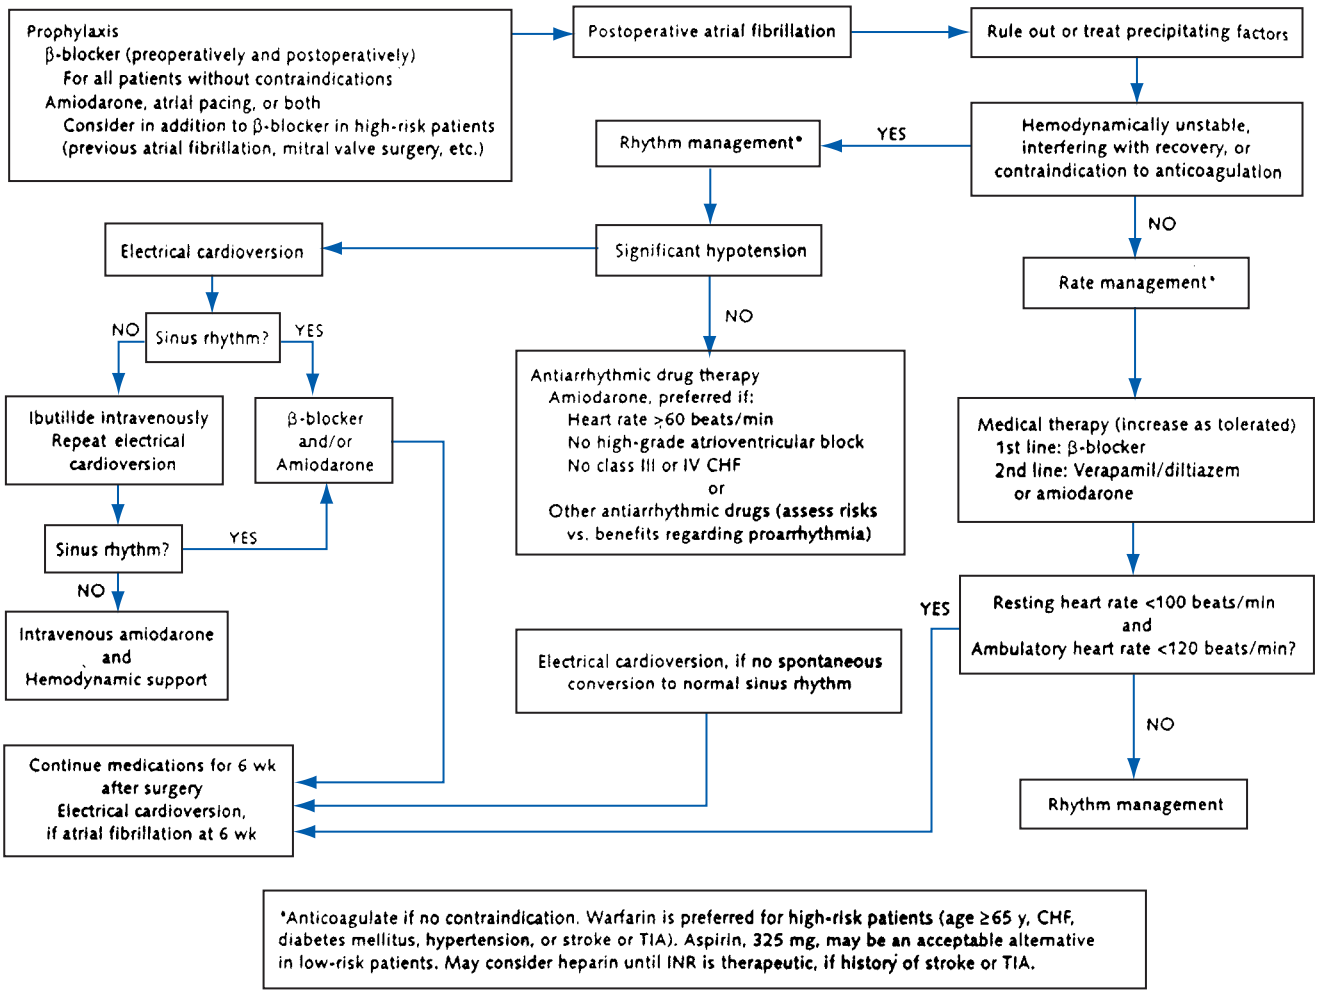

Figure 9-2. Algorithm for the prevention and management of atrial fibrillation after cardiac surgery. *(Adapted with permission from Maisel WH, Rawn JD, Stevenson WG: Atrial fibrillation after cardiac surgery. Ann Intern Med 2001; 135:1061.)*

(OR = 4.6).[90] Even mild renal dysfunction (serum creatinine 1.47 to 2.25 mg/dL) is associated with increased rates of operative and long-term mortality, need for postoperative dialysis, and postoperative stroke.[93]

Dialysis is necessary in 1% of patients who develop acute renal failure; the 30-day mortality is almost 64% for patients with acute renal failure compared with 4.3% for those without acute renal failure.[86] Renoprotective drugs, such as fenoldopam and *N*-acetylcysteine, have no effect on the deterioration of renal function in high-risk patients.[94,95] However, Bucerius and colleagues have demonstrated that OP-CABG was associated with a lower prevalence of the need for postoperative renal replacement therapy compared with CABG-CPB.[96] Thus it seems logical that OP-CABG should be considered in appropriate patients with or at risk for renal failure. Caution must be exercised because analyses that have involved OP-CABG did not include a substantial number of persons with renal dysfunction. The VA Continuous Improvement in Cardiac Surgery Program developed a recursive partitioning clinical risk algorithm that performs well across different patient populations.[94] It helps to identify individuals who are at high risk of developing acute renal failure (Fig. 9-3).

Age

The prevalence of cardiac surgical procedures in the elderly continues to increase as life expectancy improves and procedural benefits outweigh the risks. Moreover, the outcome of surgical coronary revascularization has improved progressively despite increased numbers of elderly patients and worsened preoperative risk profiles over the past several decades. Overall operative mortality in patients over 70 years of age still remains higher than in younger patients, with octogenarians having the highest operative risk.[98,99] While perioperative mortality does not vary significantly by age, 1-year mortality is greater in patients over 75 years of age.[100] Additionally, patients aged 75 years and over are more likely

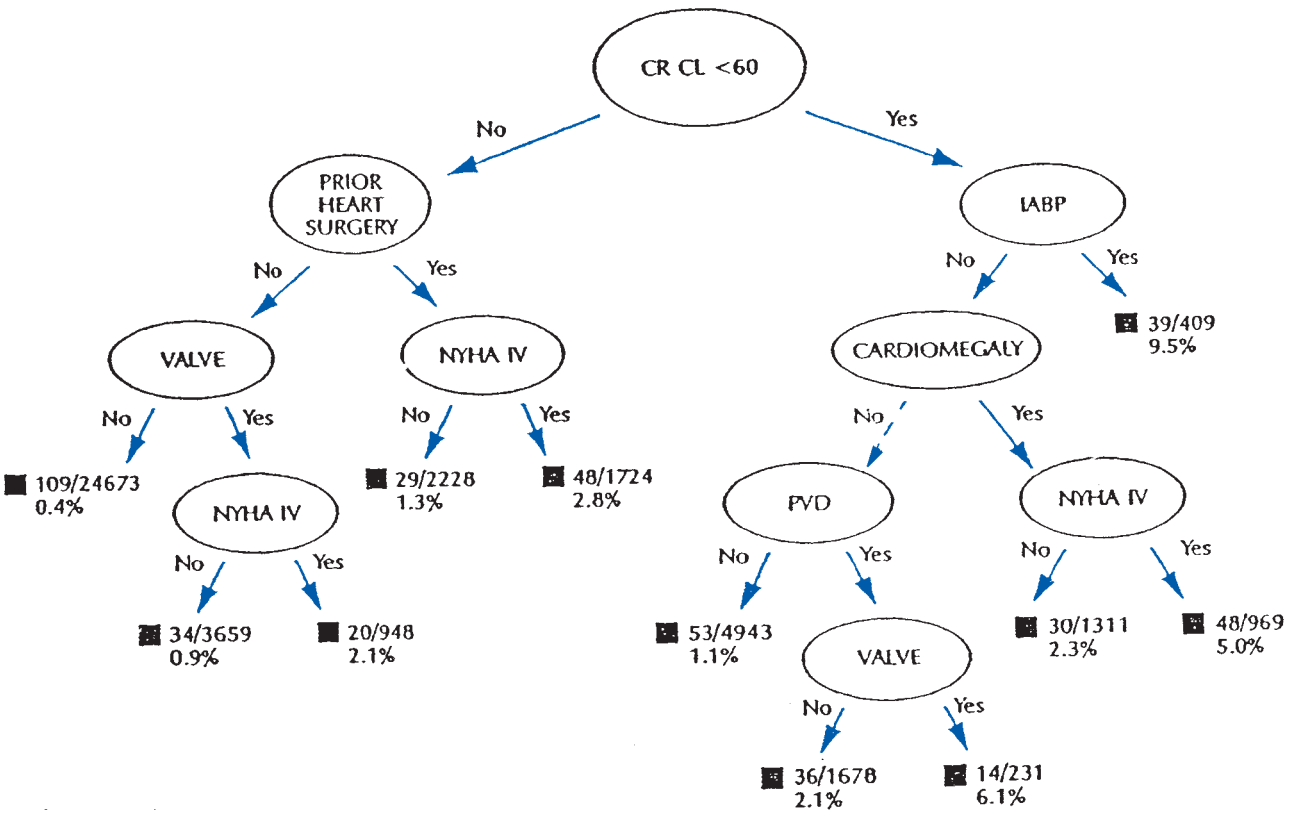

Figure 9-3. Recursive partitioning analysis of the risk of renal failure after CABG. Kidney Int 2000; 57:294.)*

to experience perioperative neurologic and renal complications, tend to require prolonged ventilatory support, and are reoperated on more often owing to bleeding.[99,100] Table 9-4 and Fig. 9-4 demonstrate the effect of age on postoperative morbidity and mortality.

Identified risk factors for poor operative outcome are very similar across age groups[99] and include concomitant CABG and valve replacement (mitral valve in particular); emergency procedure; shock; lower body mass index (BMI); advanced New York Heart Association (NYHA) class; lower ejection fraction[101]; higher prevalence of diabetes, renal dysfunction, and peripheral vascular disease; previous CABG; recent MI; and CABG-CPB.[102] Mortality statistics also may vary based on multiple socioeconomic and demographic factors. For example, whereas a study by Zacek and colleagues reported higher mortality in the 70 years and older versus 70 years and younger age group (7.3% versus 2.3 %, $p < .005$), a Canadian study reported operative mortality declining from 7.2% in 1982–1986 to 4.4% in 1987–1991 in the elderly.[102,103] The latter study also stratified patients by risk and demonstrated that while the prevalence of high-risk elderly patients increased significantly over time, operative mortality decreased for medium- and high-risk patients. Possible reasons for better outcomes include more frequent use of OP-CABG,[102,104] improved myocardial protection and anesthetic techniques perioperatively, as well as greater use of arterial grafts. While some studies demonstrate that patients aged 75 years and over tend to have a higher incidence of mental confusion and reduced quality of life compared with their younger counterparts,[105] others show that they derive similar health status benefits from CABG (e.g., angina relief and quality-of-life improvement) but tend to have a slower rate of recovery following surgery.[100]

Race and Gender

Approximately 28% of all CABG procedures in the United States are performed on women.[106] Some but not all epidemiologic studies suggest that female gender is an independent predictor of postoperative morbidity and mortality.[107,108] Women are more likely to be older when undergoing CABG, have fewer arterial grafts during surgery, and more often undergo emergent CABG than men.[108,109] Moreover, younger women have a higher mortality after CABG compared with their male counterparts. Vaccarino and colleagues reported that despite having higher ejection fractions and fewer diseased coronary arteries, women younger than 50 years of age had in-hospital mortality rates that were three times higher than men (3.4% versus 1.1%).[110] Although reasons for this difference are uncertain, women

had more comorbidities than men in this analysis. Additionally, after adjustment for potential confounders, women undergoing CABG had lower rates of functional gain at 6 months of follow-up (measured by the physical function and mental health scores of the SF-36) compared with their male counterparts.[106] Hospital readmission rates within the first postoperative year also were greater for women.[106,108]

Possible explanations for worse outcomes in women include smaller coronary arteries (which might enhance the difficulty of performing anastomoses and limit graft flow), differences in referral for surgery (i.e., women being referred at later disease stages), and gender differences in self-reported outcomes.[106]

Finally, although crude post-CABG mortality rates differ significantly by race, data suggest that after control for patient and hospital variables, these differences are small.[111,112] However, in the United States, self-described black race is associated with an increased risk of postoperative complications, including prolonged ventilatory support, length of stay, reoperation for bleeding, and postoperative renal failure.[113]

Ventricular Dysfunction

Viable myocardium that has not been revascularized in persons with ischemic heart disease and congestive heart failure promotes the development of further functional and myocardial disability.[114–116] Left ventricular dysfunction is associated with a fourfold increase in operative mortality.[117] Surgical revascularization improves ventricular function in individuals with "hibernating" myocardium.[114] For individuals with ejection fractions of less than 30%, low-cardiac-output syndrome and supraventricular arrhythmias are the most common complications, and in this group, mortality rates approach 10%.[118] However, CABG improves ventricular function and 3-year survival rate, making adequate assessment of myocardial viability via thallium reperfusion imaging, positron-emission tomography, or stress echocardiography necessary prior to surgery.[114,115,119]

Hepatic failure, renal failure, previous MI, reoperation, emergent procedures, female gender, congestive heart failure, and age are all independent predictors of in-hospital mortality in patients with low ejection fraction.[117] Over time, the relative influence of left ventricular dysfunction on operative outcome has declined. Therefore, CABG remains a viable option in patients with low ejection fraction and acceptable perioperative risk.[117,120,121] Despite advances in surgical techniques, 1% of cardiac surgery patients develop postoperative ventricular dysfunction.[122] In these individuals, implantation of ventricular assist

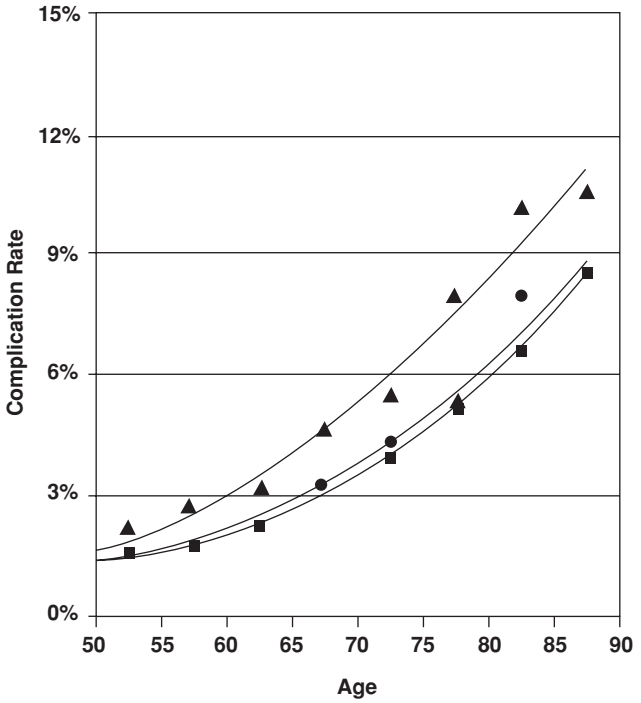

Figure 9-4. In-hospital mortality (circles), postoperative neurologic complications *(triangles)*, and postoperative renal failure (squares) after CABG by age. *(From Alexander KP, Anstrom KJ, Muhlbaier LH, et al: Outcomes of cardiac surgery in patients age ≥ 80 years: Results from the National Cardiovascular Network.* J Am Coll Cardiol *2000; 35:731.)*

devices as a bridge either to recovery or to transplantation can be beneficial, particularly in the bridge to transplant subgroup, often resulting in successful discharge from the hospital.[122]

Patients with left ventricular dysfunction and valvular disease such as mitral regurgitation or aortic stenosis require special preoperative management. Individuals with mitral regurgitation and heart failure should receive preoperative afterload reduction with angiotensin-converting enzyme (ACE) inhibitors or intravenous sodium nitroprusside to maintain systolic blood pressures in the 90 to 100 mm Hg range. While patients with aortic stenosis and hemodynamically significant cerebral or renovascular disease should not receive the latter therapies, intra-aortic balloon counterpulsation (IABP) may be useful in such subgroups. Intra-aortic balloon support also can be used in the setting of acute mitral regurgitation owing to papillary muscle rupture as well as in infarct-related ventricular septal defect. Preoperative IABP use in high-risk patients decreases mortality and shortens ICU stay owing to enhanced hemodynamic performance.[123]

Right ventricular dysfunction also increases perioperative risk, and patients should be assessed for pulmonary hypertension (pulmonary artery systolic pressure > 60 mm Hg), documentation of a history of inferior MI, or chronic tricuspid regurgitation. Right ventricular dysfunction caused by increased pulmonary vascular resistance should be treated with inotropes that have vasodilator properties such as dobutamine (5 μg/kg per minute) and milrinone (5 μg/kg per minute). Intravenous nitrates, aerosolized prostacyclin, and nitric oxide also are effective agents for lowering pulmonary vascular resistance with resulting improvement in right ventricular function.[124]

Pulmonary Disease

In patients with COPD, prolonged weaning from mechanical ventilation postoperatively is common if the forced expiratory volume at 1 second (FEV_1) is less than 65% of vital capacity or if FEV_1 less than 1.5 L. CABG patients with severe COPD are more likely to develop ventilatory failure and have higher mortality rates than those with mild to moderate or no COPD (death: 19% versus 4% versus 2%; $p = .02$).[125] Preoperative screening of arterial oxygen concentration on room air can provide guidance in respiratory management postoperatively. The roles of preoperative spirometry and perioperative bronchodilators remain unclear in stable patients, and these interventions cannot be recommended on a routine basis.

Reoperation

Approximately 3 to 20% of patients who undergo CABG will require reoperation within a decade; reoperations represent roughly 20% of CABG operations performed yearly.[126] Continued aging of the population also is expected to increase the number of reoperations. Generally, operative mortality for reintervention is almost two times higher than the associated mortality for the initial procedure, hovering between 1% and 6% in most case series.[127,128] Furthermore, emergency reoperations increase the baseline operative mortality rate fourfold.[126] Preoperative risk factors for reoperation include female sex, a history of diabetes, hypertension, renal insufficiency, hyperlipidemia, smoking, and reduced ventricular function.

Some studies suggest that improvement in operative techniques and reduced pump time exposure may affect reoperative mortality. For example, data from Sabik and colleagues show that compared with cardiac surgery patients who underwent reoperation prior to 1997, those reoperated on after this date had improved outcomes. However, higher mortality for reoperations was observed if these procedures were performed within 1 year of prior surgery.[129] Interestingly, reoperations in patients 70 years of age or older appear to have an acceptable morbidity and mortality.[130] For example, one study found that reoperative mortality was 7% and survival at 2 to 8 years was 90% in this patient subgroup.

Nutrition and BMI

The postoperative hypermetabolic state requires increased nutrition in order to facilitate wound healing and to meet corporeal metabolic demands. Consequently, patients who are malnourished preoperatively should receive at least 2 to 4

weeks of intensive nutritional bolstering prior to elective surgery, and all patients should resume an oral diet within 24 hours of uncomplicated surgery. Since perioperative stroke may limit the ability of some patients to protect their airway, a swallowing evaluation is mandatory in this subset of patients. Low BMI (<20 kg/m^2) and hypoalbuminemia (<2.5 g/dL) are associated independently with increased risk of morbidity and mortality after cardiac surgery.[131,132] Patients with decreased albumin levels are at increased risk for bleeding, renal failure, prolonged ventilatory support, and reoperation.

While obesity is not associated with increased mortality, patients with a high percent of body fat and poor aerobic capacity are at higher risk for reoperation, increased length of hospitalization, pulmonary edema, renal failure,[133,134] early hospital readmission,[135] higher total costs,[136] sternal wound infection (OR = 2.3; $p < .001$), saphenous vein harvest-site infection, and atrial arrhythmias.[131,137,138]

Diabetes

Diabetes is an important independent risk factor for atherosclerotic heart disease and a significant predictor of in-hospital mortality after CABG.[139] Although the Bypass Angioplasty Revascularization Investigation (BARI) did not evaluate stented patients, it demonstrated that diabetic patients with multivessel disease have greater survival with CABG compared with those who receive PCI.[140] Postoperative mortality does not differ significantly between nondiabetic and diabetic patients without diabetic sequelae. However, diabetic patients with vascular disease and/or renal failure have an increased risk of mortality compared with those without vascular/renal sequelae.[141]

Overall, diabetic patients who undergo CABG have more renal and neurologic complications and longer ICU stays, require more blood transfusions, and have higher reopening rates.[142] Diabetic patients who undergo valve operations have a fivefold increased risk of a major pulmonary complication.

Additionally, patients with undiagnosed diabetes undergoing CABG require more resuscitation and have higher rates of reintubation, longer periods of ventilatory support, and a higher 30-day mortality rate compared with known diabetic and nondiabetic patients.[143] This finding underscores the importance of performing diabetes screening for patients in the preoperative setting.

Neurologic Complications and Carotid Artery Disease

Approximately 1 to 6% of persons develop neurologic complications after cardiac surgery.[144–146] Stroke is the most debilitating of these complications, with an estimated 15,000 victims yearly.[146] It is believed that neurologic complications are related to the effects of cardiopulmonary bypass.[147] Carotid artery disease is responsible for as many as 30% of postoperative strokes. Cerebral microembolization from the

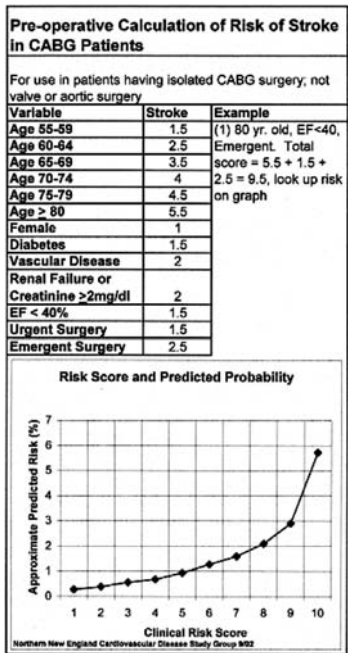

Figure 9-5. Risk prediction card for stroke. CABG = coronary artery bypass grafting; EF = ejection fraction. *(From Charlesworth DC, Likosky DS, Marrin CAS, et al: Development and validation of a prediction model for strokes after coronary artery bypass grafting.* Ann Thorac Surg *2003; 76:436.)*

arterial tree during CABG is likely the most common culprit. In fact, atherosclerosis of the ascending aorta is an independent predictor of long-term neurologic insult and mortality.[148] Moreover, an analysis from Boeken and colleagues showed that among 783 patients undergoing cardiac surgery, the predictors of central nervous system complications include symptomatic cerebrovascular disease, advanced age, type of surgery, and aortic atheroma[149,150] (Fig. 9-5 and Tables 9-5 and 9-6).

For patients undergoing CABG, the incidence of carotid artery disease can be as high as 22% depending on multiple factors, including screening method, age, diabetic status, the presence of left main disease or left ventricular dysfunction, female sex, history of smoking, or prior cerebrovascular attacks.[151] However, whether or not to screen all CABG candidates for carotid stenosis is uncertain. Some data have suggested that selective screening should be performed in patients who are identified to be at high risk, including those with age greater than 65 years, carotid bruit, prior neurologic event, peripheral vascular disease, hypertension, diabetes, and smoking, as a method of decreasing screening burden, cost, and time to surgery.[152,153] However, presently, routine screening of all cardiac surgical candidates via carotid artery ultrasound is advisable to enable detection of significant carotid stenoses prior to surgery.

Indeed, patients with concomitant carotid and coronary artery disease often present a management challenge to physicians because they have decreased long-term survival

Table 9–5.

compared with their counterparts who have only coronary artery disease.[151] Generally, perioperative stroke risk is believed to be highest (>5%) in patients with greater than 80% unilateral stenosis, bilateral stenoses of at least 50%, and unilateral occlusion with at least a 50% carotid artery lesion on the contralateral side.[151] Consequently, previous data suggested that all patients who fall into one of these categories should receive combined carotid endarterectomy (CEA) and CABG. Several authors reported operative mortality rates of between 0% and 5% and perioperative neurologic and myocardial events of approximately 3%.[151–157] However, a systematic review of 97 studies involving 8972 operative outcomes after staged and synchronous CEA and CABG revealed that patients who underwent combined CEA and CABG had higher mortality, stroke, and MI rates (11.5%, 95% CI 10.1–12.9) than those who underwent staged CEA and then CABG (10.2%, 95% CI 7.4–13.1)[158,159] (Table 9-7). Perioperative MI rates were lowest among those who had undergone CABG and then CEA. Overall, although the procedural comparisons did not achieve statistical significance, synchronous procedures were associated with higher rates of stroke or death. To date, randomized trials to guide treatment are lacking, and thus the correct approach remains controversial. Despite this, it presently seems reasonable to perform a staged procedure instead of combined CABG/CEA, although the timing of CEA in relation to CABG is institution-dependent.

Carotid artery stenting also can be performed in close proximity to CABG. Potential advantages of carotid artery stenting include decreasing perioperative risk, hospital cost, and patient discomfort and minimizing the need

for systemic heparinization prior to CABG. Thus carotid artery stenting might be advantageous in patients with stable carotid and coronary artery disease, in elderly patients who are at high risk for thoracotomy, and in patients who have concomitant carotid artery disease and single-vessel left anterior descending artery disease for which minimally invasive surgery is planned. Evidence-based data to support the routine use of carotid stenting among patients who are to undergo cardiac surgical procedures remains sparse, but emerging research suggests that carotid stenting should be considered as a viable alternative. For example, Babatasi and colleagues reported 97% procedural success with coronary artery stenting in a series of 36 patients treated with carotid stenting and CABG.[160] In this study, CABG was performed a mean of 24.3 days after carotid artery stenting, with no embolizations or deaths and a minor stroke rate of 3.6%; two patients developed restenosis at 23 ± 2 months. Other data from Ziada and colleagues demonstrate that in a comparison of patients who had undergone carotid stenting versus CEA and cardiac surgery, while those patients who underwent carotid stenting had a higher baseline risk profile, they suffered fewer adverse myocardial or stroke events than those who underwent CEA. However, of possible concern related to these results is the cutoff for peak MB fraction of creatine kinase of greater than 10 times normal for this study and the retrospective nature of the analysis.[161]

Bradyarrhythmias and Atrioventricular and Intraventricular Block

Preoperative temporary transvenous pacemaker wire insertion is recommended in patients with hemodynamic instability and high-grade heart block (third-degree or Mobitz II). Permanent epicardial pacing lead implantation should be done intraoperatively for patients undergoing tricuspid valve replacement with a mechanical prosthesis owing to the contraindication of passing a transvenous lead through the latter. For individuals with permanent pacemakers, information regarding patient pacemaker dependency, as well as the make, model, and settings of the device, should be clearly documented in the medical record. Previously implanted automatic cardioverter-defibrillator devices should be disabled before surgery to minimize inappropriate shocks caused by electrocautery signal sensing intraoperatively. Bedside external defibrillation equipment must be readily available.

CHAPTER 10

Cardiac Anesthesia

Joseph S. Savino • Albert T. Cheung

The objectives of a general anesthetic are analgesia, amnesia, and unconsciousness while supporting vital physiologic function and creating satisfactory operating conditions. An effective general anesthetic prevents patient movement and blunts the physiologic responses to surgical trauma, nociception, and hemodynamic perturbations and permits recovery at a predictable time after operation. To accomplish this, the anesthesiologist must act as the patient's medical intensivist: support life with mechanical ventilation, control the circulation, and diagnose and treat acute emergencies during surgical incision, rapid changes in body temperature, extracorporeal circulation, and acute shifts in intravascular volume. The task in cardiac surgery is unique because of the nature of the operations and the narrow tolerance for hemodynamic alterations in patients with critical cardiac disease. Furthermore, anesthetic management of the cardiac surgical patient is intimately related to the planned operative procedure and the anticipated timing of intraoperative events.

Anesthetics are chosen based on the patient's preoperative cardiovascular function, drug pharmacokinetics, and the dose-dependent pharmacologic actions. Surgical incision in the presence of inadequate concentrations of a volatile anesthetic produces hypertension, tachycardia, tachypnea, and movement. In the absence of stimulation, the same anesthetic produces cardiovascular depression, hypotension, and apnea. The anesthesiologist titrates the anesthetic to a measurable end point by monitoring cardiovascular effects. Increasing public attention on intraoperative awareness has prompted the American Society of Anesthesiologists to publish a "practice advisory" intended to assist decision making pertaining to this issue.[1] The incidence of intraoperative awareness is approximately 0.2% with general anesthesia.[2] Cardiac surgery is associated with an increased risk of intraoperative awareness.[3–7] Decisions to administer benzodiazepines prophylactically may be prudent in selected patients, such as those with a history of drug resistance or tolerance and young age. High doses of benzodiazepines may preclude early emergence. Alternatives include increasing doses of inhalational agents, propofol, and other sedative hypnotics (e.g., scopolamine). There is no direct method for assessing or monitoring adequacy of analgesia or state of awareness in a paralyzed patient, although the BIS monitor offers some insight. The BIS monitor is an integrated electroencephalographic (EEG) system that relates a bispectral index to depth of general anesthesia and should be considered for select patients.[8,9] Brain function monitors may direct therapy that conflicts with other important anesthesia goals (e.g., preservation of organ function, minimizing risks of aggravating comorbidities, or supporting circulation).

PREOPERATIVE EVALUATION

The preoperative visit by the anesthesiologist is aimed at formulation of an anesthetic plan based on the patient's surgical illness, scheduled operation, and concomitant medical problems. The anesthesiologist is responsible for informing the patient of the conduct of the planned anesthetic and associated risks and obtaining consent for the anesthesia and related procedures. The medical history is elicited by questioning the patient and reviewing the medical records. The nature and severity of the surgical illness and related cardiovascular and pulmonary disease often dictate the choice of anesthetic drugs and monitors. All anesthetic drugs have a direct effect on cardiac function, vascular tone, or the autonomic nervous system. The anesthesiologist must know the status of the cardiovascular system, related morbidity, and concurrent medications to design the anesthetic safely for a patient undergoing heart surgery.

The exchange of information between patient and physician is often a balance between providing sufficient insight regarding possible complications and producing harmful anxiety. An outline of upcoming events accompanied

Table 10–1.

American Society of Anesthesiologists, Physical Status Classification

Class 1: Normal healthy patient
Class 2: Systemic disease without end-organ dysfunction
Class 3: Systemic disease with end-organ dysfunction that is not incapacitating (e.g., diabetes mellitus with abnormal renal function)
Class 4: Systemic disease with end-organ dysfunction that is incapacitating (e.g., diabetes mellitus with renal failure and ketoacidosis)
Class 5: Moribund patient unexpected to survive beyond 24 yours (e.g., diabetes mellitus with renal failure, ketoacidosis, and infarcted bowel requiring vasopressor support)
E*: Emergency surgery

**The E is added to the classification number.*

by an informative discussion of risks and options usually leads to informed consent. Laboratory tests are ordered to complement findings of the medical history and physical examination. Routine preoperative tests for patients scheduled for a cardiac operation include a complete blood and platelet count; electrolyte battery; determination of blood glucose, serum creatinine, and blood urea nitrogen levels; prothrombin time and partial thromboplastin time; chest radiograph; electrocardiogram (ECG); and urinalysis.

The American Society of Anesthesiologists (ASA) has developed a physical status classification as a general measure of the patient's severity of illness[10] (Table 10-1). Concurrent medical illness often defines an acceptable range for monitored parameters that are controlled during cardiac surgery, contributes to postoperative morbidity, or influences the response to a specific drug. Acceptable intraoperative blood pressure is defined by the range of blood pressure before surgery. A severely hypertensive patient may perfuse vital organs inadequately if the blood pressure during surgery is maintained within a "normal" range rather than within the patient's usual range. A previous stroke with apparent recovery may become manifest after general anesthesia without evidence of a new neurologic injury. Chronic obstructive pulmonary disease and its response to bronchodilators permit guided management of perioperative bronchospasm to ensure adequate respiration. Prior surgical and anesthetic procedures are investigated by reviewing medical records. A history of a difficult intubation or adverse response to a specific drug is highly relevant to the anesthesia plan.

Concurrent medications usually are continued until the operation, although the dose may be altered or a shorter-acting preparation substituted. Statins decrease perioperative complications in patients undergoing noncardiac vascular surgery.[11] Their protective effects are less clear for cardiac surgery. Oral medications are administered according to schedule on the day of surgery with a small sip of water. Intravenous heparin given for unstable angina pectoris is not discontinued before surgical incision. For patients scheduled for late afternoon surgery and not receiving maintenance intravenous fluids, preoperative diuretics may be withheld to avoid dehydration. Sudden cessation of certain medications may provoke withdrawal physiology. Caution should be taken when stopping nicotine, benzodiazepines, narcotics, alcohol, beta blockers, alpha agonists (clonidine), and caffeine.

The physical examination includes measurement of vital signs and height and weight and a comprehensive assessment of the heart, lungs, peripheral vasculature, nervous system, and airway. Samsoon's modification of the Mallampati classification to predict a difficult airway is based on the examiner's ability to view intraoral structures[12,13]:

Class 1: Soft palate, tonsillar fauces, tonsillar pillars, and uvula
Class 2: Soft palate, tonsillar fauces, and uvula
Class 3: Soft palate and base of uvula
Class 4: Soft palate not visualized

Classes 1 and 2 represent airway anatomy associated with minimal difficulty with tracheal intubation. Classes 3 and 4 are more likely associated with an inability to intubate the trachea using conventional direct laryngoscopy. Other features associated with difficult intubations include a recessed chin, small mouth, large tongue, and inability to sublux the mandible.

Before the patient enters the operating room, the anesthesiologist formulates a plan to control the circulatory response to anesthesia, secure the airway, and maintain body homeostasis. Emergency operation frequently is incompatible with leisurely preparation but is dictated by a sense of urgency. Rarely is there no opportunity to provide reassurance or to prepare for anesthesia and operation meticulously.

MONITORING PHYSIOLOGIC FUNCTIONS DURING ANESTHESIA

Extensive physiologic monitoring is employed during cardiac operations because virtually every major physiologic system required for life is affected. The reasons for physiologic monitoring are (1) to ensure patient safety in the absence of protective reflexes made ineffective by anesthetic drugs, (2) to enable pharmacologic and mechanical control of vital function, and (3) to diagnose acute emergencies that require immediate treatment. For example, morbidity as a consequence of breathing circuit disconnects, loss of oxygen from the hospital's central supply, or unrecognized

esophageal or main stem intubations can be prevented by capnography, pulse oximetry, airway pressure monitors, oxygen analyzers, and a stethoscope.

The senses of touch, hearing, and sight are the basic monitors. Electronic monitors are vigilance aids that supplement the anesthesiologist's perceptions. In setting up a monitoring and diagnostic system, it is important to establish the sensitivity and specificity for detecting physiologic changes and disease. *Sensitivity* is a measure of the ability of a monitor to detect change in whatever is measured (*measurand*). *Specificity* is the degree that a change in the measurand is peculiar to a singular condition or disease. Sensitivity and specificity of a monitor depend on sensor calibration, accuracy, and precision. A *sensor* is an instrument that detects change in the measurand and provides a corresponding output signal. *Calibration* is the relationship between the measurand and the output signal such that the magnitude of the output signal reflects the magnitude of the parameter being measured. Pressure transducers, light detectors, flowmeters, thermistors, and gas analyzers are examples of sensors used commonly in the operating room. The ideal sensor is accurate during static and dynamic conditions, precise, reliable, safe, practical, and inexpensive. *Accuracy* is defined by how well the output signal agrees with the true value or a calibration quality standard. *Precision* is a measure of repeatability. A sensor is precise if it provides little variability between repeated measures. A pulse oximeter is an accurate monitor of percentage of oxyhemoglobin because it agrees with in vitro measures (between values of 80 to 100%). Thermodilution is an imprecise method of determining cardiac output because successive measurements vary by 20% or more. All monitors are calibrated properly prior to clinical use, and specifications for accuracy and precision must be established to maximize sensitivity and specificity for detecting change.

The selection of monitors is dictated by the utility of the data generated, expense, and risk. Routine or essential monitors that have been deemed cost-effective with low risk:benefit ratios include pulse oximetry, noninvasive blood pressure, capnography, temperature, ECG, precordial or esophageal stethoscope, and oxygen analyzers. These have been defined by the American Society of Anesthesiologists (House of Delegates, 1989) as essential monitors to be used in all surgical patients requiring anesthesia unless there are contraindications (e.g., esophageal stethoscope during esophageal surgery) (Table 10-2). Other noninvasive and invasive monitors are used only with clear indication.

The growth in monitoring technology and sophistication is paralleled by an equal growth in cost. The balance between cost and enhancement of patient safety must be considered when additional monitoring is selected. It is difficult to justify a monitor that provides data that do not influence medical or surgical management. Improved safety decreases patient morbidity and mortality, decreases the direct costs of health care providers, and reduces legal costs, insurance premiums, and possibly the risk of early retirement by physicians. However, monitors do not interpret data and therefore must be monitored by a human being.

Table 10–2.

Physiological Monitors

Organ system	ASA standard operating room monitors	Additional monitoring for cardiac Surgery

Pulmonary	Capnography Pulse oximeter Airway pressure Stethoscope Oxygen analyzer	Arterial blood gases
Nervous system		EEG SSEP Transcranial Doppler CSF Pressure
Metabolic	Temperature Urine output	Serum electrolytes Acid-base Glucose Serum osmolarity Hematocrit

Measurement of Blood Pressure

Blood pressure changes abruptly during anesthesia and surgery and is the most commonly measured index of cardiovascular stability in the perioperative period. Anesthetics and surgery cause changes in blood pressure that may be great enough to cause harm unless anticipated and treated. A change in blood pressure alters perfusion pressure but may not change organ blood flow. Most vital organs have autoregulation of blood flow in response to changes in mean arterial blood pressure, permitting a constant blood flow over a range of perfusion pressures.[14] In hypertensive patients, the boundaries for autoregulation are shifted so that significant decreases in organ perfusion may occur with blood pressures in the "normal" range. Both the type and dose of anesthetic medications affect the relationship between vital organ perfusion and blood pressure. Volatile anesthetics are potent vasodilators that tend to disrupt autoregulation in a dose-dependent manner to render

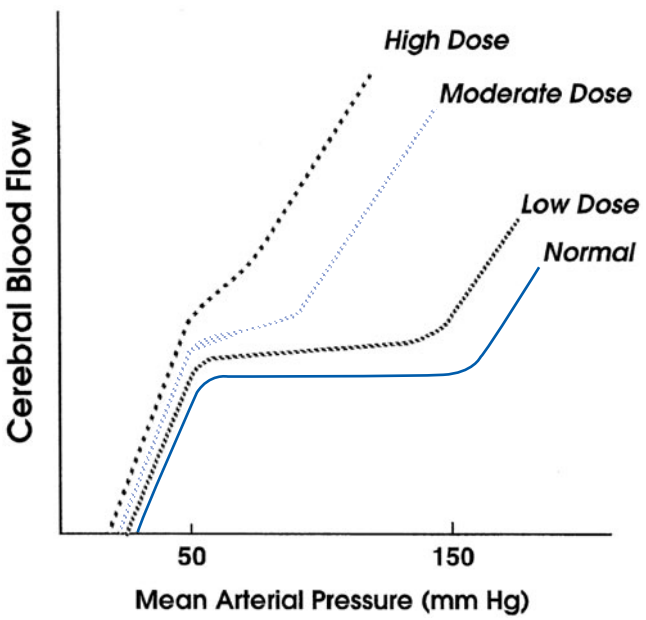

Figure 10-1. Autoregulation maintains a constant cerebral blood flow between mean arterial blood pressures of 50 to 150 mm Hg in the conscious, unanesthetized state. Increasing doses of potent inhalation anesthetics produce a dose-dependent disruption of autoregulation owing to cerebral vasodilatation. (*Modified with permission from Shapiro H: Anesthesia effects upon cerebral blood flow, cerebral metabolism, electroencephalogram and evoked potentials, in Miller RD (ed): Anesthesia, 2d ed. New York, Churchill-Livingstone, 1986; p 1249.*)

blood flow more linearly dependent on blood pressure (Fig. 10-1).

Although noninvasive blood pressure monitoring suffices for most patients during routine noncardiac surgery, direct measure of arterial blood pressure with an indwelling catheter is necessary for cardiac surgery in order to detect changes rapidly, to measure nonpulsatile blood pressure during cardiopulmonary bypass, and to facilitate blood sampling for laboratory analysis. The measuring system includes an intra-arterial catheter and low-compliance saline-filled tubing connected to a transducer with a pressure-sensing diaphragm. The transducer has a strain gauge that converts the mechanical energy (displacement of the diaphragm by a change in pressure) into an electric signal that typically is displayed as a pressure waveform with numeric outputs for systolic, diastolic, and mean pressures. The mean blood pressure is determined by calculating the area under several pulse waveforms and averaging over time. This represents a more accurate measure of mean arterial blood pressure than weighted averages of systolic and diastolic pressures.

The transducer requires a zero reference at the level of the right atrium. Any movement of the patient or the transducer that changes the vertical distance between the transducer and the right atrium affects the value of the blood pressure measured. If the transducer is lowered, the pressure diaphragm senses arterial blood pressure plus hydrostatic pressure generated from the vertical column of fluid contained in the tubing and displays a falsely high blood pressure. A transducer elevated above the zero reference level decreases the displayed blood pressure. A 1-cm column of water (blood) exerts a hydrostatic pressure equal to 0.74 mm Hg. Small changes in patient or transducer position have a relatively insignificant effect on arterial blood pressure measurements but have a more important effect on lower-amplitude pressure measurements, such as central venous, pulmonary artery, and pulmonary artery occlusion pressures.

The intra-arterial cannula, tubing, and transducer assembly are prepared prior to surgery and flushed with heparinized saline. All air bubbles must be cleared from the system to prevent damping and air embolism. The radial artery is the most common site for insertion of an intra-arterial catheter. The increased use of arterial conduits for coronary grafts limits the possible sites for monitoring. Twenty-gauge catheters are preferred because larger catheters are more likely to cause thrombosis. Thrombosis of the radial artery does not produce ischemia of the hand and fingers in the presence of intact ulnar blood flow and a patent palmar arch, although distal emboli remain a risk. The Allen test was designed to assess ulnar and palmar arch blood flow during abrupt occlusion of the radial artery, but its value to predict morbidity with radial artery cannulation is equivocal.[15] Other sites selected for the insertion of an intra-arterial catheter include the brachial, axillary, and femoral arteries.

The contour of the arterial pressure waveform is different in central and peripheral arteries. The propagating pressure waveform loses energy and momentum with a corresponding delay in transmission, loss of high-frequency components such as anacrotic and dicrotic notches, lower systolic and pulse pressures, and decreased mean pressure.[16] The changes in the pulse waveform can be attributed to damping, blood viscosity, vessel diameter, vessel elastance, and the effects of reflectance of the incident arterial waveform by the artery-arteriolar junction.[17,18] The blood pressure waveform measured in the ascending aorta is minimally affected by reflected waves in contrast to measurement of blood pressure in the dorsalis pedis or radial artery. Vasodilators decrease terminal impedance at the artery-arteriolar junction and decrease the resonant frequency of the arterial waveform.

The contour of the pressure waveform is affected by the physical construction of the monitoring system. A hyperresonant response to a change in pressure, or ringing, occurs when the frequency response of the monitoring system (i.e., extension tubing, catheter, and stopcocks) is close to the frequency of the pressure waveform.[16] The natural or resonant frequency f_n of a monitoring system is defined by

$$f_n = \frac{1}{2\pi}\sqrt{\frac{\pi D^2}{4pL \cdot C}}$$

where C is compliance of the measuring system, L is the length of the tubing, D is the diameter of the catheter extension tubing, and p is the density of the solution.

To prevent ringing, the natural frequency of the monitoring system f_n must be greater than the frequencies of the pulse waveform. Any process that decreases f_n, such as narrow, long, compliant tubing, may cause *ringing*.[19] Ringing increases the value of the systolic blood pressure and decreases the value of the diastolic blood pressure but generally does not affect the value of the mean arterial pressure.

Damping is the tendency of the measuring system, through frictional losses, to blunt the peaks and troughs in a signal.[20] Kinks in the pressure tubing or catheter, stopcocks, and air bubbles contribute to damping. Overdamped systems underestimate systolic blood pressure and overestimate diastolic blood pressure. When long lengths of tubing are necessary, deliberate damping may improve the fidelity of the arterial waveform.

Testing a measuring system for ringing and damping ensures that an arterial contour is reproduced faithfully. A simple test is the brief flush of a high-pressure heparinized saline-filled catheter extension assembly. Flush and release should produce a rapid return of the pressure waveform to baseline with minimal oscillations. A gradual return to baseline and loss of higher-frequency components of the waveform suggests overdamping. A rapid return to baseline followed by sustained oscillations suggests ringing.

Electrocardiogram

The intraoperative ECG monitor has evolved from the fading-ball oscilloscope to a sophisticated microprocessor analog display. ECG signals are filtered digitally to eliminate electrical artifact produced by high-frequency (60-Hz) electrical power lines, electrocautery, patient movement, and baseline drift. The bandwidth filter modes are diagnostic, monitor, and filter. The diagnostic mode has the widest bandwidths (least filtered signal) and is preferred for detecting ST-segment changes caused by myocardial ischemia. Monitor and filter modes have progressively narrower bandwidths that effectively eliminate high-frequency interference and baseline drift but decrease the sensitivity of detecting ST-segment changes and decrease the specificity of ST-segment change to diagnose myocardial ischemia. Abnormal ST-segment depression (>1 mV) can occur from excessive low-frequency filtering and result in the misdiagnosis of myocardial ischemia. Filter modes are useful for detecting P waves and changes in cardiac rhythm in the presence of high-frequency interference.

The ECG is the most sensitive and practical monitor for the detection and diagnosis of disorders of cardiac rhythm and conduction and myocardial ischemia and infarction. Continuous monitoring of leads II and V_5 is common (Fig. 10-2). Together these leads detect greater than 90% of ischemic episodes in patients with coronary artery disease who have noncardiac surgery.[21] The ECG leads selected for monitoring of myocardial ischemia can be guided by preoperative testing. Myocardium at risk, identified by exercise testing or coronary angiograms, can be monitored by selecting the lead with the appropriate vector. A

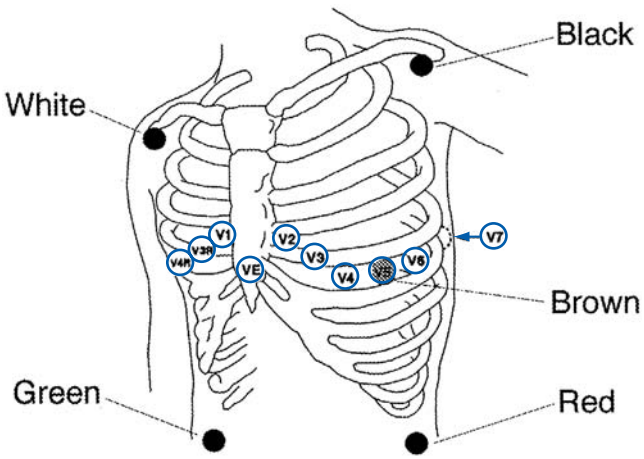

Figure 10-2. Standard intraoperative electrocardiogram (ECG) lead placement. Typically, leads II and V_5 are monitored continuously.

reversible perfusion defect of the inferior wall of the left ventricle during an exercise thallium reperfusion scan may encourage the anesthesiologist to specifically monitor leads II, III, and AVF.

Diagnostic criteria for myocardial ischemia based on the ECG are (1) acute ST-segment depression greater than 0.1 mV 60 ms beyond the J point or (2) acute ST-segment elevation greater than 0.2 mV 60 ms beyond the J point[22] (Fig. 10-3). The normal ST-segment curves smoothly into the T wave. Flat ST segments that form an acute angle with the T wave or downsloping ST segments are worrisome for subendocardial ischemia. ST-segment elevation occurs with transmural myocardial injury but also may occur after direct current (dc) cardioversion and in normal adults. The lack of specificity of ST-T-wave changes for myocardial ischemia is a major limitation of intraoperative ECG monitoring. Pericarditis, myocarditis, mitral valve prolapse, stroke, and digitalis therapy may produce changes in the ST segment that mimic myocardial ischemia.

Digital signal processing handles much larger quantities of information than the unaided eye and may increase the ability to detect ischemic episodes. ST-segment position analyzers automatically measure the displacement of the ST segment from a predetermined reference and enhance the ability to quantify changes in ST-segment position. Appropriate application requires accurate identification of the various loci in the P-QRS-T-wave complex. The operator defines the baseline and the J point of a reference QRS complex by movement of a cursor. New QRS-T-wave complexes are superimposed onto a predefined mean reference complex. Vertical ST-segment displacement is measured in millivolts and displayed graphically in 1-mV increments (see Fig. 10-3). Because the accuracy of automated ST-segment monitoring is vulnerable to baseline drift and dependent on appropriate identification of the PR and ST segments, the diagnosis of myocardial ischemia is always verified by inspecting the actual ECG tracing.

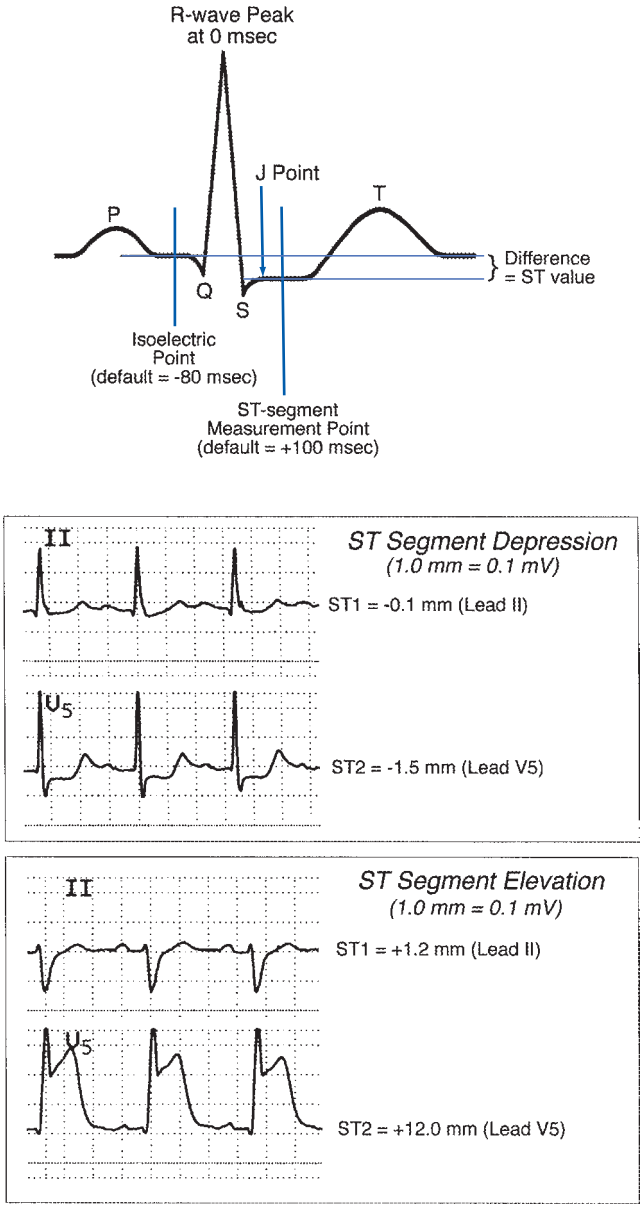

Figure 10-3. Automated ST-segment monitoring of the ECG can be used to detect intraoperative myocardial ischemia. General criteria for myocardial ischemia are ST-segment depression greater than 0.1 mV or ST-segment elevation greater than 0.4 mV that persists for longer than 1 minute. At fast heart rates, the ST-segment measurement point may occur on the upslope of the T wave, causing erroneous indication of ST-segment elevation.

Disturbances of rhythm and conduction are common during anesthesia and especially during cardiac surgery. Instrumentation of the heart, hypothermia, electrolyte abnormalities, myocardial reperfusion, myocardial ischemia, and mechanical factors such as surgical manipulation of the heart affect normal propagation of the cardiac action potential. Heart rate is measured by averaging several RR intervals of the ECG. The ECG may not sense the R wave of the selected lead if the electrical vector is isoelectric. A prominent T wave or pacemaker spike may be miscounted as an R wave by the ECG and artifactually double the rate. Usually, heart rate is best monitored by selecting the lead with an upright R wave and adjusting the sensitivity.

The QT interval can be measured only on hard copy. A normal QT interval is less than half the RR interval, but the QT interval must be corrected for heart rates higher than 90 or lower than 65 beats per minute. A prolonged QT interval increases the risk of reentrant ventricular tachydysrhythmias and may occur from hypokalemia, hypothermia, and toxic drug effect (e.g., quinidine or procainamide). The electrically dormant heart during aortic cross-clamping and perfusion with cold cardioplegia is monitored by the ECG. Hypothermia decreases action potential conduction velocity, and high-dose potassium decreases the transcell membrane potassium concentration gradient to prevent depolarization of cardiac muscle. During cardiopulmonary bypass and aortic cross-clamping, the loss and persistent absence of electromechanical activity suggest that myocardial oxygen consumption is maintained at a minimum.

Monitoring the ECG is most valuable when it begins before induction of general anesthesia. A hard copy of the pertinent leads permits comparison should a change be detected. An abnormal or marginal finding is less worrisome if it was present in the preoperative ECG and remains unchanged during the perioperative period. However, new-onset ST-T-wave changes or disturbances in rhythm and conduction suggest an ongoing active process that usually requires immediate attention.

Capnography

Capnometry is the measure of carbon dioxide (CO_2) concentration in a gas. The capnogram is the continuous graphic display of airway carbon dioxide partial pressure (Fig. 10-4). Changes in its contour reflect disorders of ventilation, carbon dioxide production, or carbon dioxide transport to the lungs. The capnogram is the single most effective monitor for detecting esophageal intubation, apnea, breathing circuit disconnects, accidental extubation of the trachea, and airway obstruction. Tracheal intubation is verified by detection of physiologic carbon dioxide concentrations in the exhaled gas. A steep increase in the phase 3 slope of the exhaled CO_2 concentration suggests partial airway obstruction, either mechanical (e.g., tube kinking) or physiologic (e.g., bronchospasm). A progressive decrease in exhaled

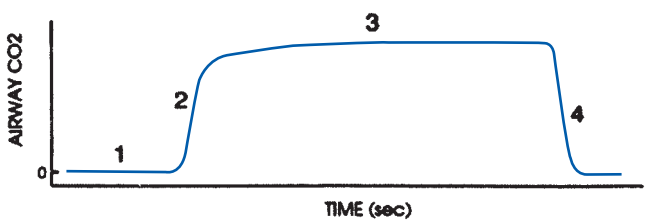

Figure 10-4. The normal capnogram: (1) inspired CO_2 concentration = zero, (2) washout of anatomic dead space, (3) plateau represents alveolar gas CO_2 content, and (4) beginning of inhalation.

carbon dioxide concentration occurs with decreased CO_2 production (e.g., hypothermia), increased minute ventilation, increase in physiologic dead space ventilation (e.g., pulmonary embolus), or low cardiac output. A progressive increase in exhaled carbon dioxide concentration occurs with hypoventilation, increased CO_2 production (e.g., malignant hyperthermia), or increased delivery of CO_2 to the lungs (e.g., during weaning off bypass). The contour of the capnogram is also affected by the expiratory flow rate, distribution of pulmonary blood flow, distribution of ventilation, and use of sidestream or mainstream CO_2 analyzers. Despite the interplay of mechanical and physiologic factors that affect the shape of the capnogram, any abrupt change in contour always signifies an acute change in the patient's cardiovascular, pulmonary, or metabolic state.

Pulse Oximetry

Pulse oximeters were adopted universally into the practice of anesthesia almost immediately after their introduction despite lack of data demonstrating improved outcome with their use. Oxyhemoglobin saturation and arterial oxygen tension are measured routinely during cardiac surgery by intermittent arterial blood sampling. Arterial blood gas analysis does not replace the pulse oximeter, which continuously measures arterial hemoglobin saturation and pulse rate. The pulse oximeter detects decreasing percentages of oxyhemoglobin before changes in the color of the patient's skin or blood are evident.[23] The pulse oximeter is reusable, inexpensive, and noninvasive and provides continuous online data. Its major limitations include electrical interference, motion artifact, high failure rate during periods of low flow or inadequate perfusion, and the need for pulsatile flow for proper operation.[24]

Pulse oximetry measures the percentage of oxyhemoglobin in arterial blood by transillumination and detection of differences in the optical absorption properties of oxy- and deoxyhemoglobin. Transmission oximetry at wavelengths of 660 and 940 nm and photoplethysmography and rapid signal processing permit reliable and rapid determination of the relative proportion of oxy- and deoxyhemoglobin. Oxyhemoglobin has a higher optical absorption in the infrared spectrum (940 nm), whereas reduced hemoglobin absorbs more light in the red band (660 nm). The ratio *R* of light absorbance at the two wavelengths is a function of the relative proportions of the two forms of hemoglobin.

Photoplethysmography permits the measure of arterial hemoglobin saturation by isolating the pulsatile component of the absorbed signal. The peaks and troughs in the blood volume of the finger or ear being transilluminated produce a corresponding pulsatile effect on light absorption, rendering the calculated oxyhemoglobin saturation independent of nonpulsatile venous blood and soft tissue. Calculation of arterial hemoglobin saturation is based on calibration algorithms derived from healthy volunteers. The *R* values were determined by in vitro measures of oxyhemoglobin saturation and are less accurate at oxyhemoglobin saturations below 70%. Motion artifact produces a high absorption of light at both wavelengths and an *R* value of approximately 1 that corresponds to an oxyhemoglobin saturation of approximately 85%.

The pulse oximeter is unable to distinguish other hemoglobin species that absorb light at the emitted wavelengths. Methemoglobin (ferric instead of ferrous hemoglobin) has similar absorption at both 660 and 940 nm with an *R* value of 1 and a corresponding displayed saturation of 85% regardless of the true value. Carbon monoxide poisoning produces carboxyhemoglobin that has significant absorption at 660 nm and is interpreted erroneously by the pulse oximeter as oxyhemoglobin.

Measurement of Temperature

Profound changes in body temperature during cardiac surgery are common, often deliberate, and affect vital organ function (Fig. 10-5). Anesthetized patients are poikilothermic. Intrinsic temperature regulation normally controlled by the hypothalamus fails during general anesthesia. Hypothermia occurs by passive and active heat loss. Passive mechanisms of cooling include radiation, evaporation, convection, and conduction. Active cooling usually occurs with extracorporeal circulation and with the use of cold or iced solutions poured into the chest cavity. Deliberate hypothermia during cardiac surgery is designed to arrest and cool the heart and decrease systemic oxygen consumption. Hyperthermia may result from preexisting fever, bacteremia, malignant hyperthermia, or overzealous rewarming during cardiopulmonary bypass.

Malignant hyperthermia is a rare inherited disorder of muscle that is potentially fatal.[25] It is an autosomal dominant trait with variable penetrance that is almost always quiescent until the patient is exposed to a triggering agent, such as volatile anesthetics or succinylcholine. Malignant hyperthermia is associated with derangements in calcium metabolism. Ineffective uptake of calcium by sarcoplasmic reticulum and abnormal release of calcium from intracellular storage sites occurs with massive skeletal muscle depolarization in response to triggering agents. Clinical manifestations of malignant hyperthermia include increased production of carbon dioxide, tachycardia, and increased cardiac output, followed by fever, metabolic and respiratory acidosis, hyperkalemia, cellular hypoxia, rhabdomyolysis, myoglobinuria, renal failure, and cardiovascular collapse. Serum creatine kinase is increased and may be of diagnostic value. The fever may reach 43°C but may be masked by deliberate hypothermia during cardiopulmonary bypass. Despite increased awareness, improved monitors, and the advent of established treatment algorithms with dantrolene, mortality rates remain high. Treatment is aimed at discontinuing the trigger agent and controlling body temperature through active cooling. Oxygen, hyperventilation, and correction of metabolic acidosis and electrolyte abnormalities are the cornerstone of therapy.

Dantrolene blocks calcium release and is administered at a dose of 2 mg/kg intravenously every 5 minutes for a total

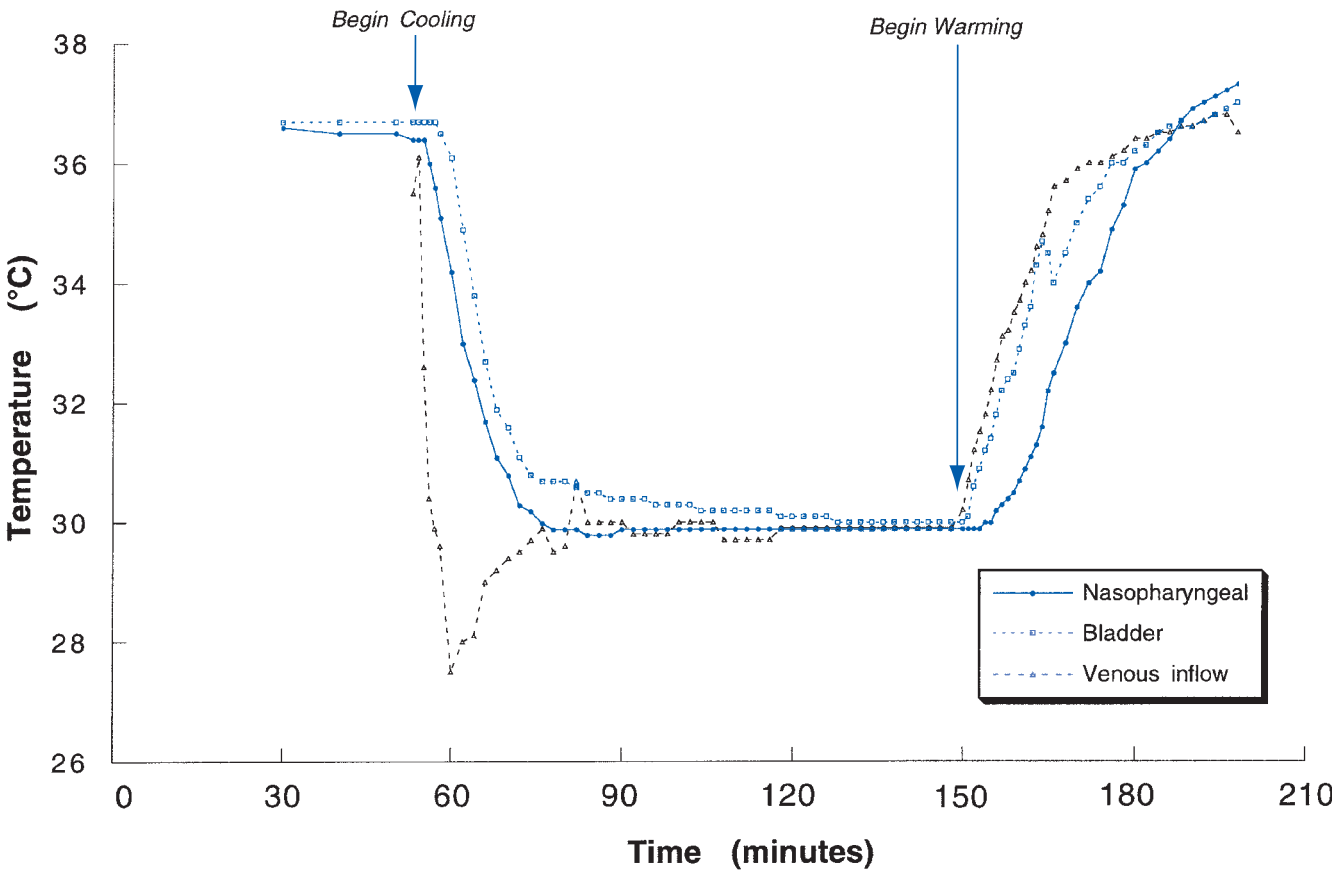

Figure 10-5. Changes in body temperature during hypothermic cardiopulmonary bypass. A brisk diuresis accompanied rewarming, rendering the urine an ultrafiltrate of blood and resulting in the urine (bladder) temperature closely tracking temperature measured in the venous blood in the cardiopulmonary bypass machine.

dose of 10 mg/kg.[26] Intravenous dantrolene generally is continued at 12-hour intervals for a minimum of 24 hours because episodes of malignant hyperthermia may recur even after the trigger agent has been discontinued. The incidence of malignant hyperthermia is approximately 1 in 62,000 anesthetics. Patients with a history of malignant hyperthermia and those with most types of muscular dystrophies are at increased risk. Not all episodes of malignant hyperthermia lead to progressive metabolic and cardiovascular collapse. Unexplained fever after an anesthetic or in the recovery room may identify a patient at increased risk. Testing by in vitro skeletal muscle responses to halothane and/or caffeine is recommended for the preoperative diagnosis of patients suspected to be at increased risk. High-risk patients can be anesthetized safely by using anesthetic drugs such as narcotics, barbiturates, nitrous oxide, local anesthetics, and nondepolarizing muscle relaxants that are not believed to trigger malignant hyperthermia.

Hypothermia after cardiopulmonary bypass is the result of ineffective rewarming; cold operating rooms; cold, wet surgical drapes; a large surgical incision; and administration of cold intravenous fluids. Hypothermia exacerbates dysrhythmias and coagulopathy, potentiates the effects of anesthetic drugs and neuromuscular blockers, increases vascular resistance, decreases the availability of oxygen, and contributes to postoperative shivering. The elderly are especially susceptible because of limited compensatory reserve. Evidence supports the efficacy of mild therapeutic hypothermia for brain protection after cardiac arrest and resuscitation.[27]

Temperature typically is monitored from several sites during cardiac surgery. Blood temperature is measured from the tip of the pulmonary artery catheter and within the cardiopulmonary bypass circuit (typically venous and arterial lines). Blood temperature is the first to change in response to deliberate hypothermia or active rewarming during cardiopulmonary bypass. Nasopharyngeal and tympanic temperatures reflect the temperature of the brain and closely track blood temperature because these sites are highly perfused. Rectal and bladder temperatures provide a measure of core temperature only at equilibrium. Esophageal temperature often underestimates core temperature because of the cooling effects of ventilation in the adjacent trachea. Axillary and inguinal temperature are shell measurements and are impractical.

The degree and site of temperature change are important indicators of an intact circulatory system. A persistent

discrepancy in temperature between two sites may be a sign of malperfusion. Rewarming during cardiopulmonary bypass normally is associated with an increase in nasopharyngeal or tympanic temperature accompanied by a more gradual increase in temperature in organs with low perfusion. A persistently cold nasopharynx with a normal rate of increase in rectal temperature may be due to aortic dissection and hypoperfusion of the head.

Measurement of Cardiac Output and Central Venous and Pulmonary Artery Pressures

Cannulation of the central venous circulation permits central administration of drugs, passage of catheters and pacing electrodes into the heart, rapid administration of fluids through short, large-bore cannulas, and the measure of central venous pressure. The most commonly used site for central venous access is the internal jugular vein because of easy, reliable insertion; easy access from the head of the table; decreased risk of pneumothorax; and decreased risk of catheter kinking during sternal retraction. The subclavian vein is the preferred site for insertion of a central venous catheter for long-term intravenous total parenteral nutrition because of a decreased risk of blood-borne infection.[28] The most important complication of internal jugular vein cannulation is inadvertent puncture or cannulation of the carotid or subclavian artery. Cannulation of the central venous circulation is confirmed by transducing the pressure waveform prior to insertion of a large-bore catheter. Ultrasound-guided cannulation of the internal jugular vein renders the procedure less dependent on anatomic landmarks and is associated with a decrease in the number of unsuccessful cannulation attempts[29] (Fig. 10-6). With the advent and wide availability of portable ultrasound imaging devices, ultrasound-guided central venous cannulation is becoming commonplace to increase the success rate and decrease the risk of complications.[30]

Central venous pressure (CVP) is an index of right ventricular preload. The pulsatile *a, c,* and *v* pulse waveforms are a function of uninterrupted return of venous blood to the right atrium, right atrial contraction and right atrial size and compliance, intrathoracic pressure, and mechanical properties of the tricuspid valve and right ventricle. The normal CVP is 6 to 10 mm Hg and is measured at end exhalation. A decrease in CVP suggests hypovolemia or vasodilation. An increased CVP with normal cardiac function occurs with hypervolemia, vasoconstriction, and increased intrathoracic pressure. CVP is increased by positive-pressure ventilation and positive end-expiratory pressure. Systemic hypotension accompanied by an increased CVP suggests cardiac dysfunction. The most common cause of venous hypertension is left-sided heart failure, although acute left ventricular dysfunction may cause an increase in left atrial and pulmonary artery occlusion pressure without significant change in CVP.

Pulmonary artery catheters are inserted via the central venous circulation through the right side of the heart with the catheter tip positioned just downstream of the pulmonic valve. The pulmonary artery catheter measures pulmonary artery pressure, pulmonary artery occlusion pressure, cardiac output, and mixed venous oxygen saturation and permits calculation of the derived values of systemic and pulmonary vascular resistance. The pulmonary artery occlusion pressure is an index of left ventricular preload in the absence of mitral stenosis. However, the use of a pressure measurement to estimate preload is limited because of variability in left ventricular size and compliance. The hemodynamic parameters derived from the pulmonary artery catheter may be used to detect myocardial ischemia if ischemia produces ventricular dysfunction that is associated with a decrease in

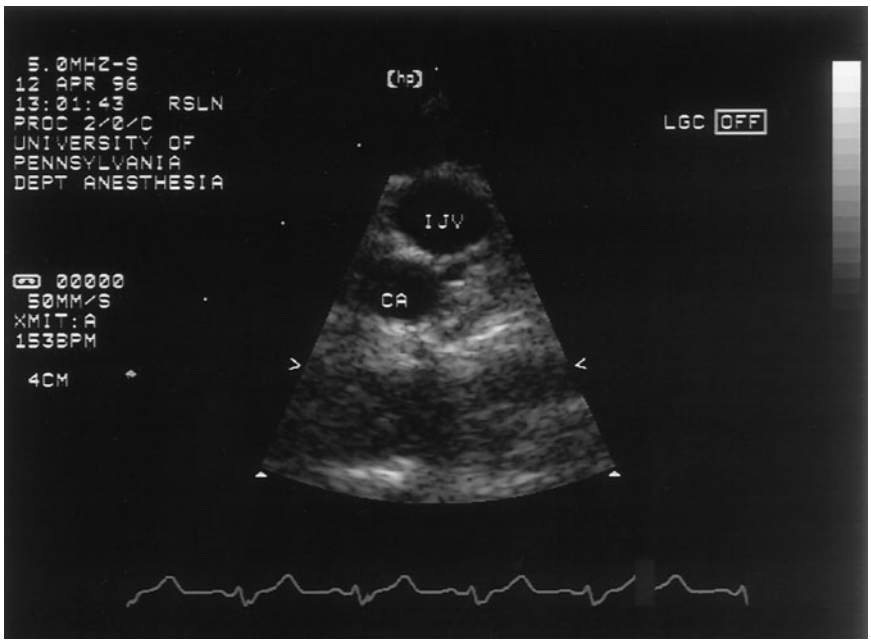

Figure 10-6. A two-dimensional short-axis image of the internal jugular vein (IJV) and carotid artery (CA) using a handheld ultrasound transducer.

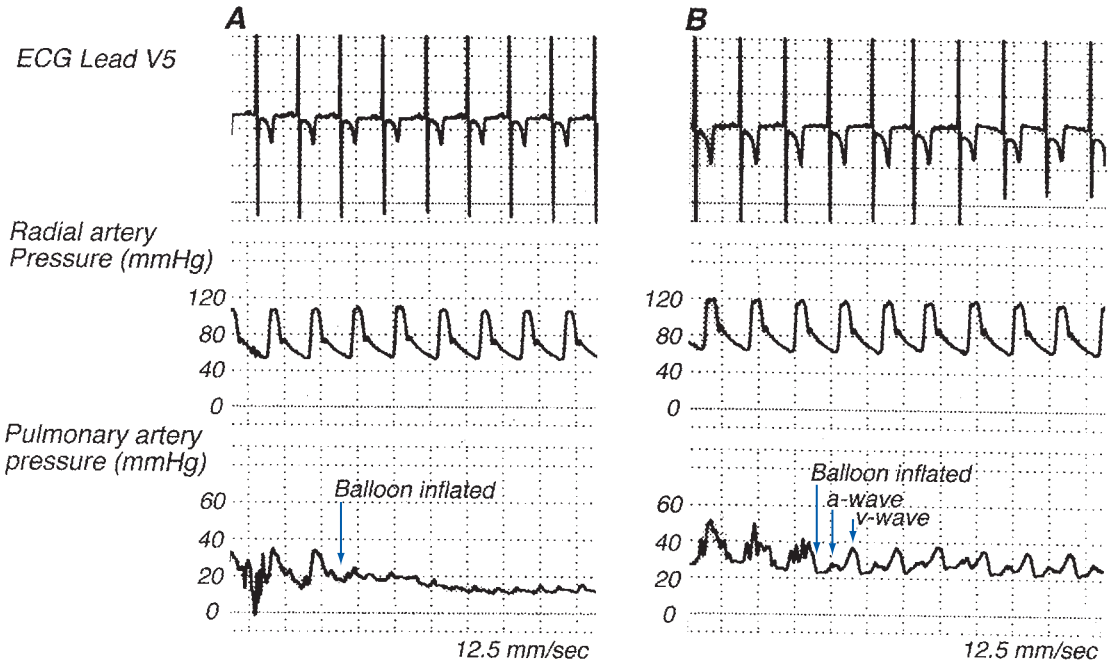

Figure 10-7. Pulmonary artery occlusion pressure tracing at two time points. The acute onset of myocardial ischemia (*B*) was associated with ST-segment depression in ECG lead V_5, increased pulmonary artery pressures, and a prominent *v* wave.

cardiac output, increase in left ventricular end-diastolic pressure, or pulmonary hypertension (Fig. 10-7). However, hemodynamic parameters derived from the pulmonary artery catheter are not as sensitive or as specific for detecting myocardial ischemia as the ECG.[31] Pulmonary artery occlusion pressure is affected by volume status, myocardial compliance, mode of ventilation, and ventricular afterload.

Complications associated with insertion of a pulmonary artery catheter include infections, dislodgment of pacemaker wires or right atrial or ventricular clot or tumor, atrial and ventricular arrhythmias, pulmonary infarction, pulmonary artery rupture, catheter entrapment, and heart block. The incidence of right bundle-branch block (RBBB) is approximately 3% and may cause complete heart block in patients with a preexisting left bundle-branch block (LBBB).[32] A mechanism to treat complete heart block (e.g., external pacer) should be available for these patients. Passage of the pulmonary artery catheter can be delayed for most patients until after sternotomy, when heart block can be treated with epicardial pacing wires. Chronic indwelling pulmonary artery catheters are associated with a progressive thrombocytopenia.[33] Heparin-bonded catheters decrease the incidence of thrombus formation,[34] but high-dose aprotinin may increase the risk of early thrombus formation.[35]

Multiport pulmonary artery catheters equipped with a tip thermistor permit the measurement of pulmonary blood flow or cardiac output by thermodilution. Thermodilution cardiac output is an indicator-dilution technique. The indicator, a known volume of cold saline, is injected rapidly into the right atrium. Cardiac output (CO) is calculated from the rate of change in blood temperature in the pulmonary artery over time using the Stewart-Hamilton equation[36,37]:

$$CO = \frac{V(T_B - T_1)K_1K_2}{\int_0^\infty \Delta T_B(t)\,dt}$$

where CO is cardiac output, V is the volume of the injectate, T_B is the blood temperature at time 0, T_I is the injectate temperature at time 0, $\Delta T_B(t)$ is the change in blood temperature at time t, K_1 is the density factor, and K_2 is the computation factor.

Thermodilution measures the degree of mixing that occurs between the cold injectate and blood. More mixing implies increased flow. Complete mixing of 10 mL of cold injectate with a circulating blood volume produces a small decrease in temperature at the catheter tip. Poor mixing, suggestive of slow, sluggish flow, produces a large decrease in temperature as the injectate bolus passes the thermistor. The derived value for cardiac output is inversely proportional to the area under the thermodilution curve. Rapid infusion of cold intravenous fluids at the time of measurement may falsely increase the derived cardiac output. Thermodilution measures right-sided cardiac output, which does not equal left-sided cardiac output in patients with intracardiac shunts. There are no outcome data to support the routine use of a pulmonary artery catheter in cardiac surgery.

Cardiac output may be monitored continuously using a specialized pulmonary artery catheter. The continuous cardiac output catheter intermittently heats blood adjacent to a proximal portion of the catheter and senses changes in blood

temperature at the catheter tip using a fast-response thermistor. The method requires no manual injections, and values are acquired, averaged, and updated automatically every several minutes. Disadvantages include increased cost and a cardiac output display that is not instantaneous but is an average value over the prior 2 to 10 minutes. Other methods of measuring cardiac output that do not depend on an indwelling pulmonary artery catheter include transthoracic bioimpedance, echocardiography, and analysis of the aortic pressure pulse contour. These have proven cumbersome, impractical, or unreliable for routine use.[38]

Mixed venous oxygen saturation ($S\bar{v}O_2$) can be measured intermittently by manual blood sampling from the pulmonary artery or continuously using a modified pulmonary artery catheter equipped with an oximeter. The $S\bar{v}O_2$ provides a continuous monitor of cardiovascular well-being. Assuming normal oxygen consumption, a normal $S\bar{v}O_2$ generally denotes adequate oxygen delivery but does not provide information about the adequacy of perfusion to specific organs. A normal $S\bar{v}O_2$ may not reflect adequate tissue perfusion in patients with intracardiac shunts, sepsis, or liver failure. A decrease in $S\bar{v}O_2$ is rarely caused by an increase in oxygen consumption during cardiac surgery but is more likely a sign of decreasing oxygen delivery owing to decreased cardiac output, anemia, or hypoxia.

$S\bar{v}O_2$ provides an alternative method to calculate cardiac output if oxygen consumption is assumed to be constant. By the Fick equation, cardiac output is equal to the rate of systemic oxygen consumption divided by the arterial-venous oxygen content difference:

$$O_2 \text{ delivery} = CO \times CaO_2$$
$$O_2 \text{ delivery} = \dot{V}O_2 + (CO \times C\bar{v}O_2)$$
$$CO \times CaO_2 = \dot{V}O_2 + (CO \times C\bar{v}O_2)$$
$$CO(CaO_2 - C\bar{v}O_2) = \dot{V}O_2$$
$$CO = \frac{\dot{V}O_2}{CaO_2 - C\bar{v}O_2}$$

where $\dot{V}O_2$ is oxygen consumption, CO is cardiac output, CaO_2 is the oxygen content in arterial blood, and $C\bar{v}O_2$ is the oxygen content in mixed venous blood.

Although routine use of a pulmonary artery catheter for monitoring patients during cardiac operation is debated, it does provide clinical information that is used to direct therapy in high-risk patients (Fig. 10-8). Hypotension associated with increased cardiac output with a normal pulmonary artery occlusion pressure likely is caused by vasodilation and is treated effectively with a vasoconstrictor such as phenylephrine, vasopressin, or norepinephrine. Hypotension associated with a low cardiac output and a low pulmonary artery occlusion pressure indicates hypovolemia and is treated with volume expansion (Fig. 10-9). Hypotension associated with a low cardiac output and increased pulmonary artery and pulmonary artery occlusion pressure indicates cardiac dysfunction and may require treatment with an inotropic or anti-ischemic medication. Increasing evidence suggests that pulmonary artery catheter–guided therapy is not necessary for management of acute respiratory distress syndrome, congestive heart failure, and some types of surgery.[39] The pulmonary artery catheter appears to demonstrate continued utility in the care of pulmonary hypertension and right ventricular dysfunction.[40]

An insidious decrease in $S\bar{v}O_2$ may be an early warning of impending circulatory insufficiency owing to a decrease in arterial oxygen tension, ventricular dysfunction, bleeding, or tamponade. $S\bar{v}O_2$ pulmonary artery catheters serve as diagnostic tools and vigilance monitors, especially in the intensive-care unit, where early deterioration in cardiac function can be detected and treated before an adverse event occurs.

Anesthetic Gas Monitors

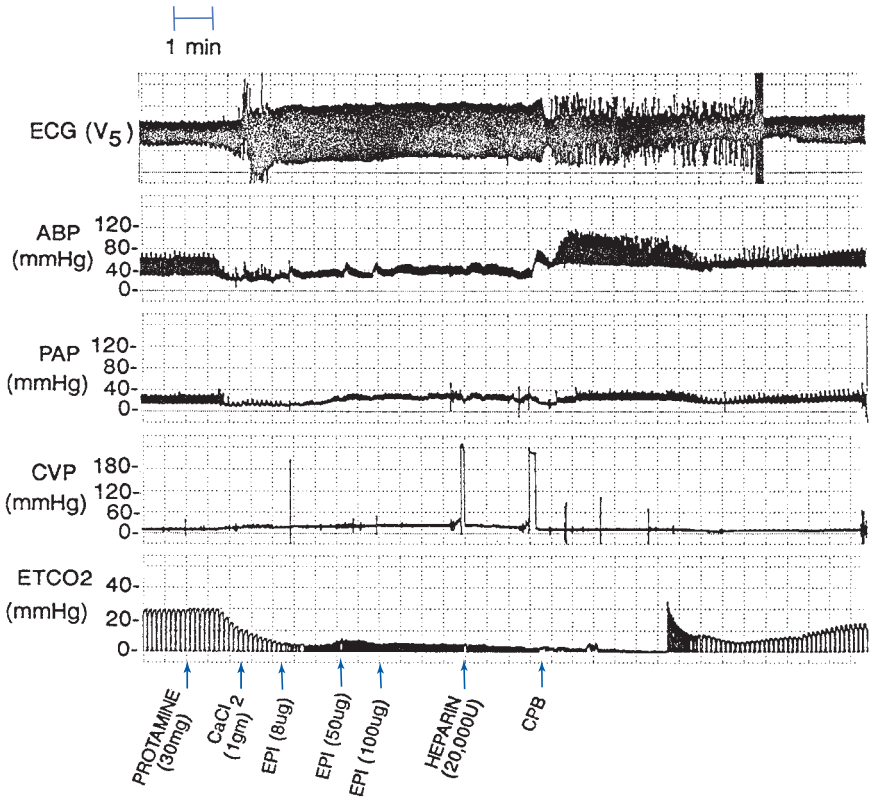
Inhaled volatile anesthetics are different from other parenteral medications. The dose of the drug administered is dictated by its concentration in the blood rather than by a set standard. The concentration of an anesthetic in the exhaled gas at end exhalation reflects the alveolar gas concentration that is in direct equilibrium with the blood. Monitoring the concentration of anesthetic in the end-tidal gas mixture adds precision to the administration of inhaled anesthetics and guards against inadvertent overdose.

The concentration of anesthetic gases is measured clinically by mass spectroscopy. A gas sample retrieved from the breathing circuit is analyzed offline by measuring the dispersion of the ionized sample as it is accelerated and deflected by a magnetic field. The site of impact on a collecting plate is specific for a gas species, and the number of impacts represents the relative concentration of the gas species in the sample. The end-tidal concentration is determined by gating the measure of the anesthetic gas to the carbon dioxide expirogram (capnogram). Other methods of measuring anesthetic and respiratory gases include infrared spectroscopy, Raman spectroscopy, electrochemical and polarographic sensors, and piezoelectric absorption.[41]

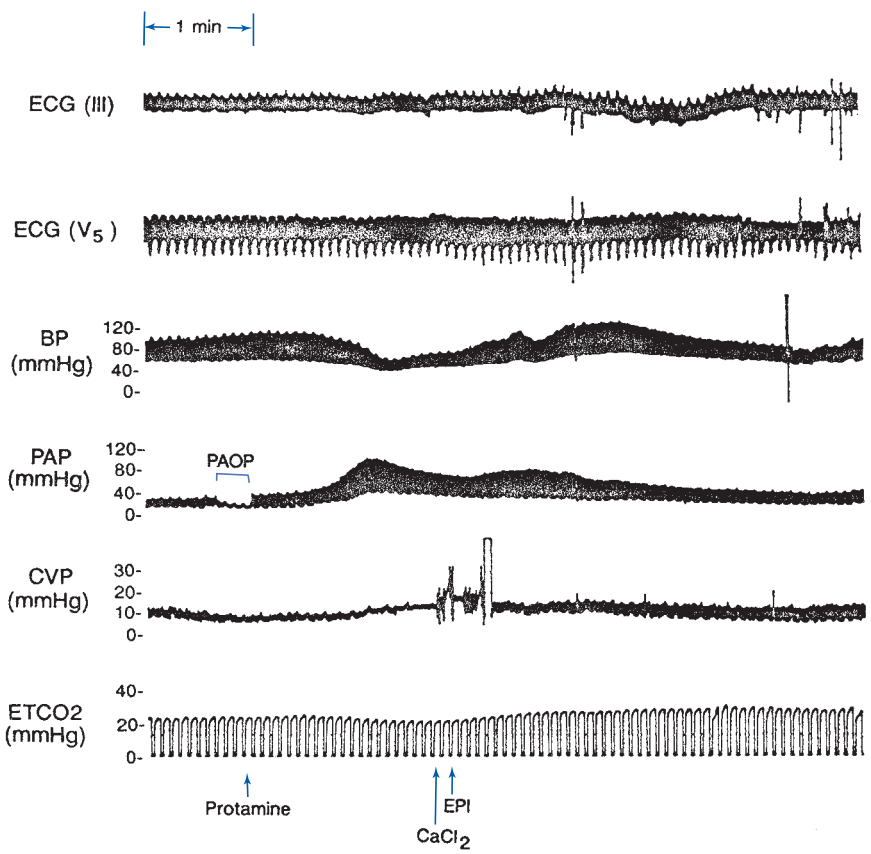
Measurement of Electrolyte Concentration

Electrolyte abnormalities occur commonly during and after cardiopulmonary bypass and are monitored intermittently using routine laboratory tests that are reported promptly to the operating room.[42] Reliable online measurements of electrolytes are not yet available. The capability to detect and correct electrolyte disturbances is an important aspect of intraoperative care.

Abnormalities in sodium and water homeostasis are caused primarily by hemodilution with solutions used to prime the cardiopulmonary bypass circuit. Nonosmotic secretion of arginine vasopressin provoked by surgical stress, pain, hypotension, or nonpulsatile perfusion contributes to the development of hyponatremia by stimulating renal retention of free water. A 2 to 5 mEq/L decrease in the plasma sodium concentration is expected after beginning cardiopulmonary bypass and does not normally require treatment. Hyperglycemia or excessive mannitol administration causes



A



B

Figure 10-8. Intraoperative hemodynamic recordings showing the time sequence of systemic severe vasodilation (*A*) and catastrophic pulmonary vasoconstriction–type (*B*) protamine reactions during the reversal of heparin anticoagulation in patients undergoing heart operation. Arterial blood pressure (ABP) and pulmonary artery pressure (PAP) decrease in parallel during systemic vasodilation. In contrast, an increase in PAP and central venous pressure (CVP) precedes the decrease in ABP during the pulmonary vasoconstriction–type reaction. The decreases in end-tidal carbon dioxide concentration ($ETCO_2$) during the protamine reactions reflect the decrease in blood flow through the lungs.

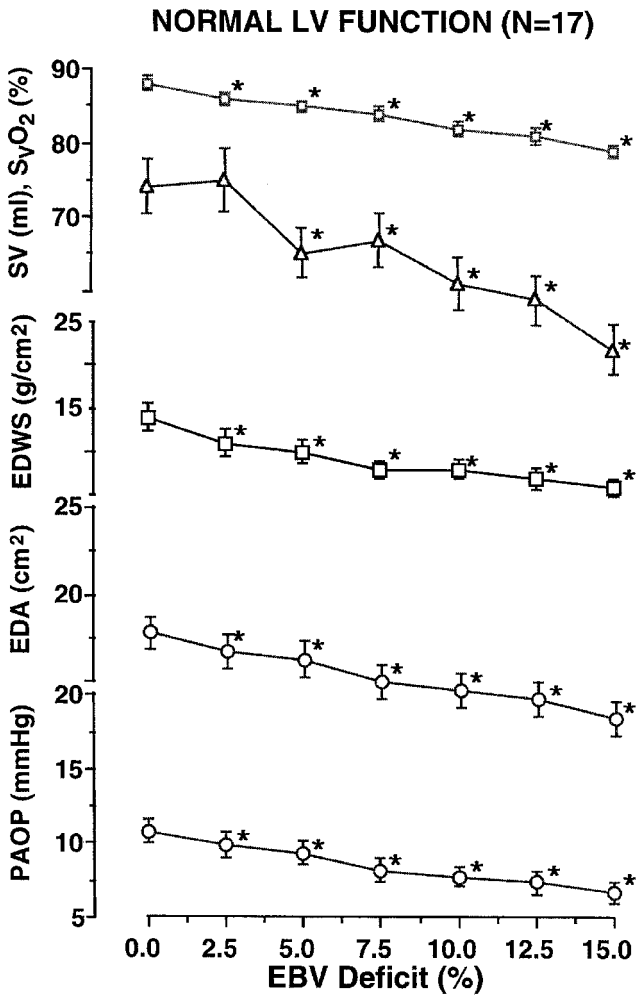


Figure 10-9. Decreased left ventricular preload produced by graded estimated blood volume deficits (EBVs) was associated with a serial decreases in the mixed venous oxygen saturation ($S\bar{v}O_2$), cardiac stroke volume (SV), left ventricular end-diastolic meridional wall stress (EDWS), left ventricular end-diastolic cavity cross-sectional area (EDA), and pulmonary artery occlusion pressure (PAOP). Patients with dilated cardiomyopathy displayed less change in SV and $S\bar{v}O_2$ in response to equivalent EBV deficits. *$p < .05$ versus baseline value (ANOVA for repeated measures). (*Modified with permission from Cheung AT, Weiss SJ, Savino JS: Protamine-induced right-to-left intracardiac shunting. Anesthesiology 1991; 75:904.*)

pseudohyponatremia by decreasing the plasma sodium concentration. Hypernatremia usually is caused by excessive diuresis without free-water repletion or by the administration of hypertonic sodium bicarbonate solutions. Hyperkalemia is common because high-potassium cardioplegic solutions are distributed into the systemic circulation. Hyperkalemia during cardiac surgery also may be caused by hemolysis, acidosis, massive depolarization of muscle, and tissue cell death. Increasing serum potassium concentration is manifested by peaked T waves, a widened QRS complex, disappearance of the P wave, heart block, and conduction abnormalities that may be life-threatening. Very high concentrations of potassium used to provide cardioplegia inhibit spontaneous depolarization and produce asystole. Patients with diabetes mellitus are at increased risk for hyperkalemia because cellular uptake of potassium is mediated by insulin. Impaired renal excretion of potassium enhances hyperkalemia in patients with renal insufficiency. The initial treatment of hyperkalemia is aimed at redistributing extracellular potassium into cells, but the elimination of potassium from the body requires excretion by the kidneys or gastrointestinal tract. Insulin and glucose administration rapidly decrease extracellular potassium by redistributing the ion into cells. Alkalosis, hyperventilation, and beta-adrenergic agonists also favor redistribution of potassium into cells, but the response is less predictable. Calcium carbonate and calcium chloride antagonize the effects of hyperkalemia at the cell membrane. A typical intravenous dose of glucose and insulin for the acute treatment of hyperkalemia is 1 g/kg of glucose and 1 unit of regular insulin per 4 g of glucose administered.

Hypokalemia is also common during cardiac surgery and may be caused by hemodilution with nonpotassium priming solutions, diuresis, or increased sympathetic tone during nonpulsatile perfusion. Intraoperative hypokalemia is exacerbated by preoperative potassium depletion owing to chronic diuretic therapy. Beta$_2$-adrenergic agonists acutely decrease the plasma potassium concentration by directly stimulating cellular uptake of potassium. Hypokalemia predisposes to atrial arrhythmias, ventricular ectopy, digitalis toxicity, and prolonged response to neuromuscular blocking drugs. Hypokalemia is treated by slow administration of KCl in increments of 10 mEq, with potassium concentrations measured between doses.

Hypocalcemia decreases myocardial contractility and peripheral vascular tone and is associated with tachycardia.[43,44] Hypocalcemia produces prolongation of the QT interval and T-wave inversions, but significant arrhythmias owing to disturbances in ionized calcium concentration are not common. Hypocalcemia occurs soon after the onset of cardiopulmonary bypass but may resolve without treatment. Increasing serum concentrations of parathyroid hormone during cardiopulmonary bypass may explain, in part, the gradual increase in ionized calcium concentration to pre–cardiopulmonary bypass levels.[45] The etiology of cardiopulmonary bypass–induced hypocalcemia probably is multifactorial, but hemodilution and decreased metabolism of citrate after rapid blood transfusion are contributing factors. The routine administration of calcium salts without prior measurement of ionized calcium concentration poses the risk of hypercalcemia. Excessive calcium administration may increase the risk of postoperative pancreatitis and myocardial reperfusion injury.[46]

Magnesium deficiency is common in cardiac surgical patients, and acute magnesium supplementation decreases the incidence of postoperative cardiac dysrhythmias and overall morbidity after cardiac operations.[47,48] However, measuring total plasma magnesium concentration has questionable clinical significance because the value primarily

reflects the concentration of protein-bound magnesium and not physiologically active, ionized magnesium.[49]

Perioperative glucose control affects outcome after heart surgery. Hyperglycemia increases the risk after myocardial infarction, stroke, and cardiac surgery.[50–52] Aggressive protocols aimed at maintaining normoglycemia with the use of insulin infusions during cardiac surgery and into the early postoperative period lead to a decrease in morbidity (e.g., sternal wound infection) and possibly mortality.[49,53] However, aggressive control of blood glucose in diabetic patients increases the incidence of hypoglycemia, which can have severe consequences if not detected early and treated.[54]

Monitoring the Nervous System

Anesthetics produce characteristic changes in the electrical activity of the brain. The cellular mechanism of general anesthetics is controversial. Unconsciousness and general anesthesia are not achieved by producing energy failure in the brain. The central nervous system cellular concentrations of ATP, ADP, phosphocreatine, glucose, and glycogen are increased and lactate concentrations are decreased during general anesthesia. Most general anesthetics, and especially the extensively studied barbiturates, decrease cerebral metabolic rate and oxygen consumption.

A myriad of neurologic complications may be associated with cardiac surgery,[55] including stroke, paralysis, cognitive dysfunction, blindness, and peripheral nerve injury.

Stroke

Stroke associated with cardiac surgery occurs in 3 to 8%[56,57] of patients, but the incidence alarmingly may approach 35 to 70% in those with multiple risk factors such as previous stroke, carotid disease, advanced age, hypertension, and diabetes mellitus.[56] The majority of strokes are not identified immediately after cardiac surgery but occur in the first several days postoperatively. The cause of these strokes and their causal relationship to cardiopulmonary bypass remain unclear.

Strokes may be related to micro- or macroemboli but also may be secondary to regional hypoperfusion. The combination of preexisting regional hypoperfusion and embolic phenomenon may be particularly deleterious.[58] The existence of a heavily calcified aorta increases the risk of stroke secondary to macroemboli.[59] Efforts to reduce the incidence of stroke in this patient group include the use of off-pump coronary artery bypass grafting, epiaortic ultrasound to identify "safe" areas for cannulation, and single clamping techniques for proximal anastamoses.[60] Previous work in animal models has demonstrated that in regions of the brain with compromised blood flow, acute anemia may not be well tolerated.[61] Acute anemia in individuals at risk for cerebrovascular disease may be exacerbated by an imbalance in oxygen supply and demand.[62]

The possibility exists to intervene to alter the course of perioperative stroke in individuals at high risk. For example, the application of intra-arterial thrombolytics in a highly selective fashion to the affected cerebral arteries can be done with acceptable morbidity even early after cardiac surgery.[63,64]

Paralysis

Paralysis, a devastating complication, is associated with dissection of the thoracic aorta, with repair of descending thoracic and thoracoabdominal aneurysm, and most recently after placement of endovascular stents.[65] The incidence in repair of a descending thoracic or thoracoabdominal aneurysm is 5 to 10%[66,67] and may exceed 25% in certain high-risk groups.[68] The likely cause is hypoperfusion of the spinal cord during aortic cross-clamping and ligation of intercostal and lumbar arteries.[69] Risk factors for paralysis include extent of the aneurysm and acuteness of disease. Patients without demonstrated flow in intercostals within the aneurysm may be at lower risk for paralysis after resection,[70] presumably because collateral blood supply to the cord in the involved region has been allowed to occur slowly, whereas subjects experiencing acute dissection, which does not permit time for collateralization, may experience a high rate of paralysis.

Intraoperative monitoring, including motor evoked potentials and somatosensory potentials, may be of some benefit to detect early spinal cord ischemia[71,72] yet may lack the sensitivity and specificity necessary to reliably guide intervention.[73] Preemptive measures to limit the degree of spinal cord ischemia have included identification and reimplantation of the artery of Adamkiewicz as well as intercostal vessels,[74,75] placement of cerebrospinal fluid (CSF) drainage catheters to increase the mean arterial pressure to CSF pressure gradient, epidural cooling of the spinal cord,[76,77] and distal perfusion techniques such as left atrial–femoral artery (LA-FA) bypass to enhance cord perfusion from below the inferior clamp site.[78,79] All these techniques have met with potentially important but limited success, and controlled studies demonstrating a difference in outcome do not exist.[80] Spinal cord ischemia is managed in a similar fashion to the management of cerebral ischemia.[81] A continuum of injury exists from infarcted to ischemic tissue. Signs of spinal cord ischemia may improve or deteriorate with time, and there may be, at the very least, an opportunity to ameliorate the extent of the injury through early intervention, such as increasing perfusion pressure and decreasing CSF pressure through drainage.[82] Most treatments are fraught with risk (e.g., the placement of CSF drainage catheters).[83]

Cognitive dysfunction

Postoperative alterations in cognitive function include disturbances of memory, attention, and intellectual function. Cognitive dysfunction occurs after cardiac operations at a rate estimated to be as high as 80% in the acute phase after surgery and may persist in 20 to 40% of patients depending on length of follow-up.[84] More than any other factor, advanced age has been identified consistently as the greatest risk factor for cognitive dysfunction after cardiac surgery

with cardiopulmonary bypass. Early and late mortality may be markedly increased, quality of life is diminished, and costs of care are increased in the short and long run.[85,86]

Etiology has focused on a myriad of potential causes[71] that predominantly include the effects of cardiopulmonary bypass such as hypotension,[87] microemboli,[88] open versus closed cardiac procedures,[89] acute anemia,[90] changes in brain water content,[91] hypoxemia, rewarming strategies,[92] cold versus warm cardiopulmonary bypass,[93] pH management strategy (alpha-stat versus pH-stat),[94] pulsatile versus nonpulsatile perfusion,[95] bypass duration,[96] flow rates,[97] hypo- and hyperglycemia,[98] presence of the apolipoprotein E ϵ-4 allele,[99] and immunologic mechanisms.[100] Lastly, although cognitive dysfunction in the general population has been associated with chronic hypotension[101] and congestive heart failure,[102] the role of left ventricular function in cognition surrounding cardiac surgery is not known.

Research outside the arena of cardiac surgery into neurologic injury in cerebrovascular disease has focused on the immune system as the generator of mediators and modulators of the cerebral endothelium[103,104] and of blood-brain barrier permeability.[105] One theory of immunologic-mediated neuronal injury postulates a cascade of events initiated by complement- and neutrophil-mediated vascular endothelial damage and disruption of the blood-brain barrier, thus allowing neutrophil access to the parenchyma with resulting neural destruction.[103,105]

Neurologic sequelae in noncardiac surgery

It would be irresponsible not to mention that stroke and cognitive dysfunction occur in patients after noncardiac surgery at a rate that is significantly less than that seen in the cardiac surgery group, yet the incidence is not negligible[106–108] and also may be associated with prolonged deficits.[109,110] There may be similar risk factors and similar pathophysiologic mechanisms in this group of patients, especially in the origins of delayed stroke in the perioperative period. Investigations ultimately even may implicate the anesthetic agents themselves,[111] irrespective of issues of intraoperative hemodynamic management.

Neurophysiologic monitoring techniques permit assessment of nervous system function during and early after operation because clinical evaluation is not possible. Techniques to monitor neurophysiologic function during general anesthesia include electroencephalography (EEG) and somatosensory evoked potentials (SSEPs). The EEG is a recording of the spontaneous electrical activity of the cerebral cortex and is defined by frequency, amplitude, and spatial distribution.[112] The amplitude of electrical activity decreases by more than 80% when the recording electrode is displaced only 2 cm from the site of maximum amplitude. This necessitates multiple electrodes and channel recordings to obtain a spatial representation of the EEG rhythm.[113] A change in EEG amplitude or frequency may be produced by cerebral ischemia, anesthetics, or hypothermia. Barbiturates produce a flat EEG, whereas enflurane may cause seizurelike activity. EEG burst suppression is not uncommon after induction of general anesthesia but does not exclude an impending neurologic catastrophe if induced by changes in cerebral blood flow. While continuous EEG monitoring may detect cerebral ischemia during carotid operations, its application during cardiac operations is problematic because the decrease in EEG frequency and amplitude owing to anesthesia and hypothermia during operation cannot be distinguished from changes caused by cerebral ischemia.[114,115] Electrical artifacts from the heart-lung machine also interfere with the ability to monitor the EEG continuously during operation. Intraoperative monitoring of SSEPs to detect cerebral ischemia overcomes some of the problems inherent in EEG monitoring because the temperature dependency of SSEPs is well established.[116] Embolic stroke and brachial plexus injury can be detected using intraoperative SSEP monitoring, but the utility, sensitivity, and specificity of this technique for detecting, preventing, and guiding the treatment of neurologic complications remain to be established[117,118] (Fig. 10-10).

Alternatively, intraoperative transesophageal echocardiography (TEE) and transcranial Doppler (TCD) may be used to detect arterial embolic events (Fig. 10-11). The embolic burden to the cerebral circulation measured by quantitative TCD correlates with the incidence of intraoperative surgical manipulation and postoperative neurologic deficits.[119] Intraoperative TEE can be applied to detect right-to-left intracardiac shunting through an atrial septal defect,[120,121] intracardiac masses,[122,123] or residual air within the cardiac chambers.[124] Routine epiaortic ultrasonography to assess the degree of aortic atherosclerosis and guide the insertion of the aortic cannula and application of the aortic cross-clamp may decrease the risk of embolic stroke, but outcome data to suggest efficacy are sparse.[125]

ANESTHESIA

Anesthetic techniques presently employed for patients undergoing cardiac operations have been selected after extensive testing and clinical experience. Current clinical practice techniques have minimal organ toxicity, predictable cardiovascular and physiologic effects, well-established pharmacokinetic behavior, and excellent safety profiles. No benchmark anesthetic technique has been defined for all patients undergoing cardiac operations.[126–129] Combining drugs that selectively provide hypnosis, amnesia, analgesia, and muscle relaxation permits control of the anesthetic state and minimizes side effects of a single anesthetic drug used in high concentrations. Achieving the desired anesthetic state while preserving or improving vital organ function during operation requires an understanding of the physiologic actions of anesthetics, individually and in combination, in patients with a wide range of medical conditions.

Anesthesia drug management is dictated, in part, by the underlying cardiovascular disorder. Coronary artery disease renders the ventricle susceptible to myocardial ischemia, and management is designed to support coronary perfusion

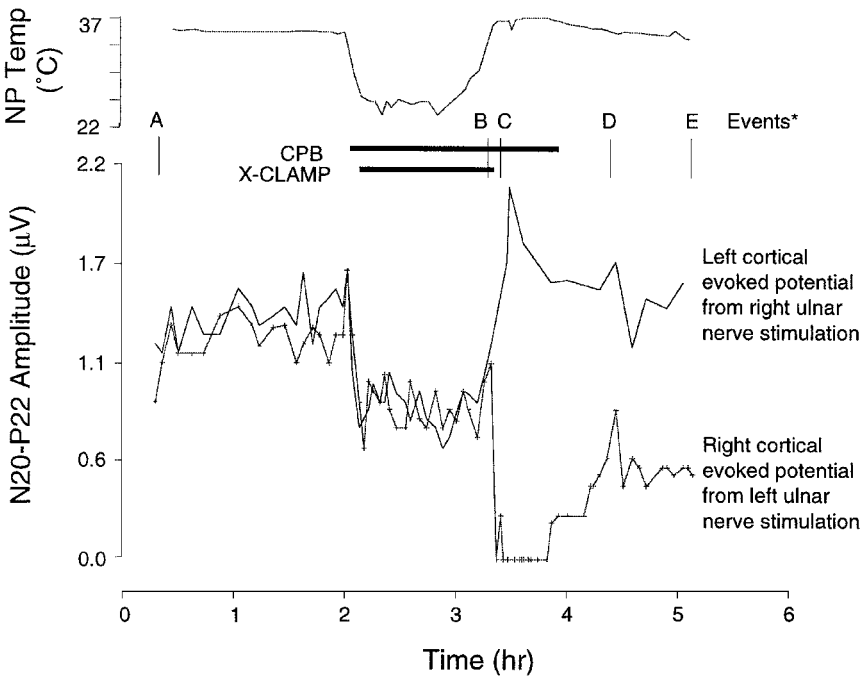

Figure 10-10. Intraoperative monitoring of somatosensory evoked potentials (SSEPs) was used for the acute detection of embolic stroke during mitral valve replacement. The symmetric changes in the peak-to-peak amplitudes of N20-P22 SSEPs before removal of the aortic cross-clamp were caused by the decrease in body temperature during deliberate hypothermia. The asymmetric decrease in the right cortical SSEPs after removal of the aortic cross-clamp was associated with an acute embolic stroke to the right thalamus or right somatosensory cortex. CPB = cardiopulmonary bypass; NP = nasopharyngeal temperature; X-clamp = ascending aorta cross-clamp. (*Reproduced with permission from Cheung AT, Savino JS, Weiss SJ, et al: Detection of acute embolic stroke during mitral valve replacement using somatosensory evoked potential monitoring. Anesthesiology 1995; 83:201.*)

pressure while decreasing myocardial oxygen demands. Tachycardia, hypertension, and increased inotropic state caused by nociception during operation are prevented by anticipating the inciting events and providing effective anesthesia. In contrast, patients with heart failure owing to valvular disease, dilated cardiomyopathy, or cardiac tamponade may depend on underlying sympathetic tone to support the circulation. In these patients, the anesthetist must be prepared to replace endogenous catecholamines pharmacologically while the patient is anesthetized.

Anesthetic-induced hemodynamic perturbations must be considered when assessing valve function intraoperatively using TEE (Fig. 10-12). Patients with regurgitant valve lesions frequently exhibit acute hemodynamic improvement during anesthesia because systemic oxygen demand and ventricular afterload decrease with anesthetic agents. Potent volatile anesthetics produce varying degrees of dose-dependent vasodilation and afterload reduction: isoflurane > enflurane > halothane. Assessment of mitral regurgitant grade during general anesthesia is not necessarily predictive of regurgitant grade in the awake state and may lead to mismanagement.[130,131] Provocative pharmacologic testing may be required to mimic circulatory conditions in the awake, exercising patient. Stress-testing the mitral valve may be achieved with incremental doses of phenylephrine to increase the transmitral systolic pressure gradient; however, the determinants of regurgitant volume are many, and it is unlikely that phenylephrine reliably reproduces the cardiovascular conditions that occur when a patient is exercising.

Maintenance of cardiovascular stability during general anesthesia for patients with aortic stenosis is based on avoiding systemic vasodilation and tachycardia and preserving sinus rhythm. Systemic vasodilation provides no significant decrease in left ventricular afterload because of the stenotic aortic valve. Tachycardia is poorly tolerated owing to shortened diastole and decreased filling of the noncompliant left ventricle. Nonsynchronous atrial contraction, a common occurrence during induction of general anesthesia, may produce significant hypotension and rapid deterioration in stroke volume. Narcotic-based anesthetics possess many desired hemodynamic attributes for patients with aortic stenosis. Synthetic narcotics are potent vagotonic drugs that decrease heart rate with minimal vasodilating effects and provide profound analgesia.

Anesthetics and Neuromuscular Blockers

Inhaled anesthetics

Inhaled anesthetics alone produce all the conditions necessary for operation.[132] All inhaled anesthetics cause circulatory depression at concentrations necessary to produce general anesthesia. When ventilation is controlled, circulatory actions of the inhaled anesthetics usually limit the anesthetic dose that can be tolerated, especially in patients with cardiovascular disease. For this reason, lower doses of inhaled anesthetics usually are combined with other anesthetics to produce general anesthesia for cardiac operations.

The decrease in blood pressure caused by volatile anesthetics is a direct result of vasodilation and depression of myocardial contractility and an indirect result of attenuation of sympathetic nervous system activity. The decrease in blood pressure is so predictable that it is often used as a sign for assessing the depth of anesthesia. Overdose with inhaled anesthetics is manifested by hypotension, arrhythmias, and bradycardia that, if unrecognized, may lead to circulatory shock.

The inhaled anesthetics decrease myocardial contractility based on both experimental and clinical studies[133–135]

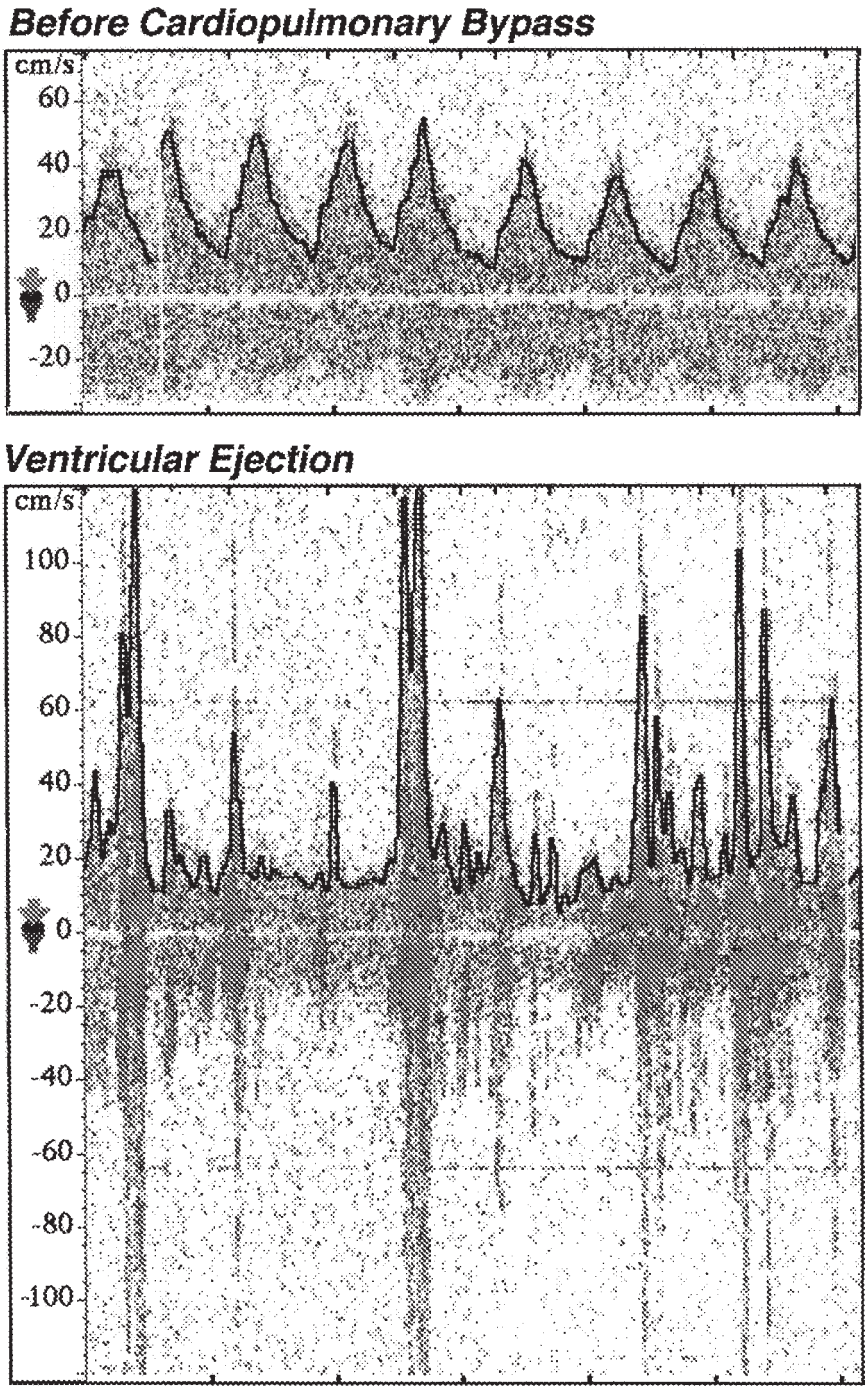

Figure 10-11. Middle cerebral artery blood flow velocity measured intraoperatively using a 2-MHz transcranial Doppler ultrasound transducer. The phasic velocity profile in the top panel was recorded before cardiopulmonary bypass. The irregular high-velocity, high-amplitude signals recorded in the lower panel indicate microemboli traveling through the middle cerebral artery immediately after ventricular ejection.

(Fig. 10-13). Inhalation anesthetics produce a dose-dependent decrease in mean maximal velocity of circumferential shortening, mean maximal developed force, and dP/dt.[136–138] The effects of each individual inhaled anesthetic on cardiovascular function depend on selective dose-dependent effects of the drug on myocyte contraction and relaxation, vascular smooth muscle tone, and sympathetic nervous system reflexes, as well as the underlying disease state, intravascular volume status, surgical stimulation, temperature, mode of ventilation, and acid-base status. The decrease in blood pressure in response to 1.0 minimum alveolar concentration (MAC) of halothane is primarily the result of decreased cardiac output caused by direct myocardial depression. Despite a decrease in myocardial contractility, cardiac output generally is unchanged at 1.0 MAC of isoflurane because of direct arterial vasodilation and preservation of baroceptor reflexes, with a resulting decrease in ventricular afterload and increase in heart rate and stroke volume[139] (Fig. 10-14). Halothane, enflurane, isoflurane, desflurane, and sevoflurane decrease global left ventricular systolic function at any given left ventricular loading condition or at any given degree of underlying sympathetic tone (Fig. 10-15).

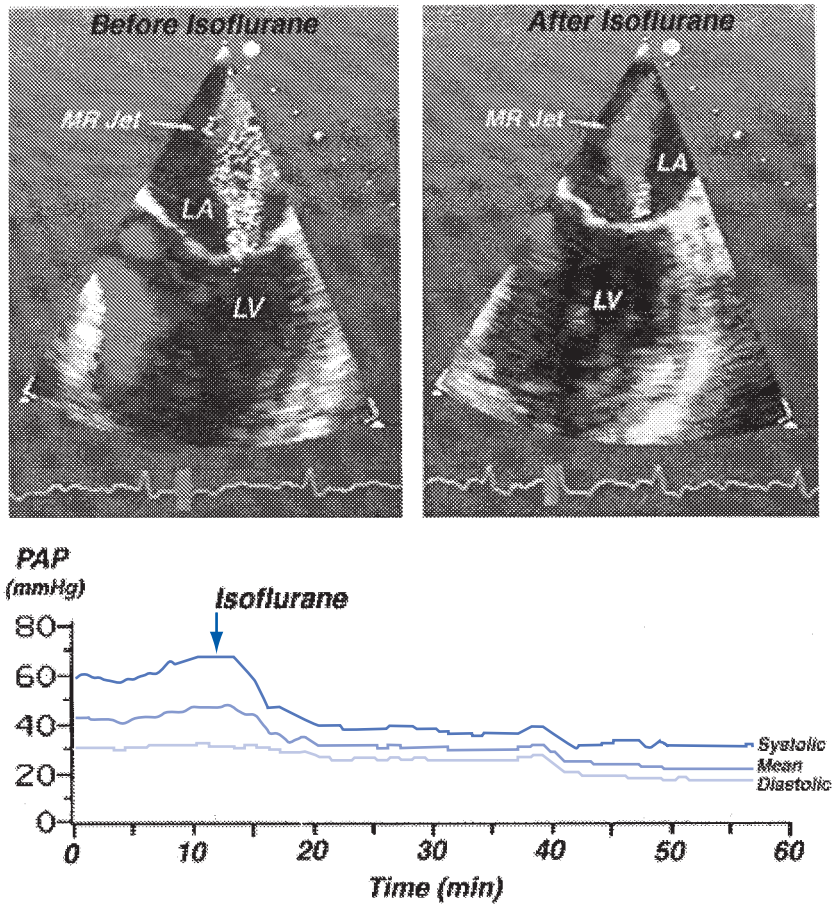

Figure 10-12. The relationship of increasing doses of isoflurane to the magnitude of mitral regurgitation and pulmonary artery pressures. The systemic unloading effects of isoflurane decreased mitral regurgitation from moderate to mild and decreased pulmonary artery pressures almost to normal.

Experimental studies suggest these agents cause minimal changes in left ventricular diastolic compliance but impair left ventricular diastolic relaxation in a dose-dependent manner.[140] These agents have minimal direct effects on left ventricular preload. Left and right ventricular end-diastolic pressures may increase during anesthesia because of impaired diastolic filling and decreased cardiac output. Halothane and enflurane are the most potent direct myocardial depressants, followed by isoflurane, desflurane, and sevoflurane.

Patients in shock or with profound ventricular dysfunction may not tolerate the cardiovascular depressant effects of inhaled anesthetics given in concentrations that are needed to produce anesthesia. Volatile anesthetics have a proportionally greater negative inotropic effect on diseased myocardium than on normal myocardium. In contrast, sympathetic nervous system activation owing to nociception may mask clinical signs of circulatory depression caused by inhaled anesthetics. Cardiodepressants and adrenergic antagonists potentiate the cardiovascular depressant actions of inhaled anesthetics.

The administration of inhaled anesthetics in patients with preexisting cardiovascular diseases has potential advantages. The myocardial depressant and arterial vasodilating actions of anesthetics benefit patients with coronary insufficiency if perfusion pressure is maintained. The negative inotropic properties of inhalation anesthetics decrease myocardial oxygen demand and may create a more favorable myocardial oxygen balance. The vasodilating and antihypertensive actions of anesthetics effectively control an increase in blood pressure in response to surgical pain, but anesthetic-induced hypotension may reduce coronary perfusion pressure and coronary blood flow.

Enflurane is a mild coronary vasodilator, whereas halothane has little effect on coronary vascular tone. Regional wall motion abnormalities and ECG evidence of myocardial ischemia associated with enflurane or halothane are due to decreases in coronary perfusion pressure rather than to a redistribution of myocardial blood flow.[140–142] Isoflurane causes endothelium-dependent inhibition of the contractile response of canine coronary arteries.[143] The direct coronary artery vasodilating action of isoflurane may increase coronary blood flow but also may increase the risk of myocardial ischemia in patients with steal-prone coronary anatomy by attenuating autoregulation of coronary blood flow. Coronary anatomy associated with isoflurane-induced coronary steal is a total occlusion of a major coronary branch and a hemodynamically significant (>50%) stenosis in the artery that supplies the collateral-dependent myocardium. The proposed mechanism is vasodilation and a decrease in coronary perfusion pressure downstream of the stenosis that decreases blood flow through the high-resistance, less-

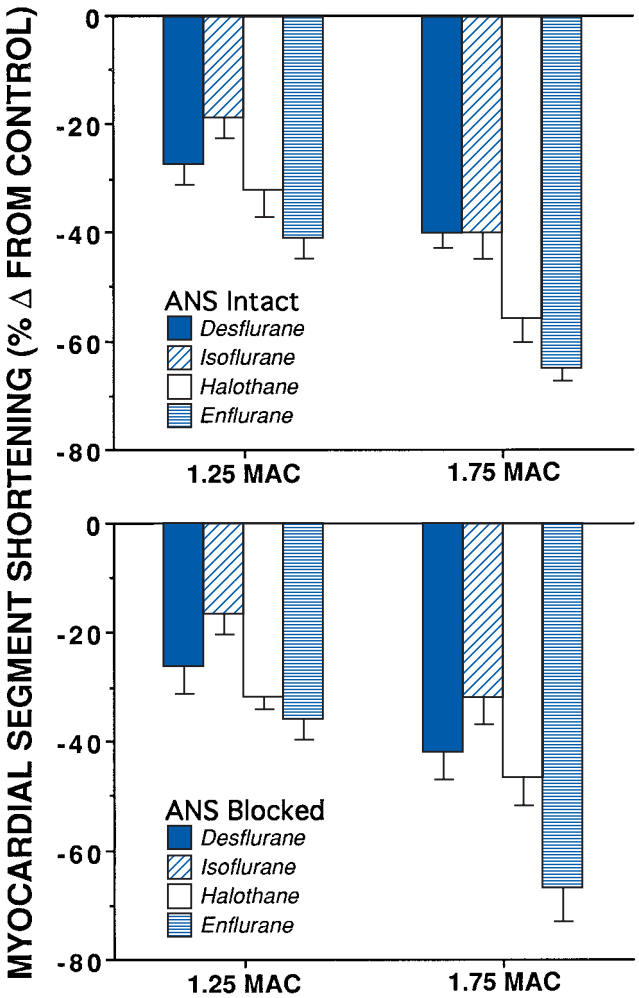

Figure 10-13. The actions of inhaled anesthetics on left ventricular myocardial segment shortening as measured in chronically instrumented dogs with an intact and blocked autonomic nervous system (ANS). All inhaled anesthetics caused a significant decrease in segment shortening at both 1.25 and 1.75 MAC in comparison with awake animals. (*Reproduced with permission from Pagel PS, Kampine JP, Schmeling WT, Warltier DC: Comparison of the systemic and coronary hemodynamic actions of desflurane, isoflurane, and enflurane in the chronically instrumented dog. Anesthesiology 1991; 74:539.*)

responsive collateral network.[144] However, there is no convincing clinical evidence that isoflurane should be avoided in patients with coronary artery disease any more than other nonselective coronary vasodilators (e.g., nitroprusside).[145] The increase in heart rate and sympathetic tone associated with isoflurane and desflurane increases oxygen demand by producing tachycardia and may cause myocardial ischemia in susceptible patients. This is more important than the theoretical risk of coronary steal.[146–148]

Volatile anesthetics have anti-ischemic preconditioning properties resulting in cardioprotection against myocardial infarction via K_{ATP} channels.[149] Isoflurane, desflurane, and sevoflurane have cardioprotective properties independent of anesthetic improvement of myocardial oxygen supply-demand balance.[150] However, there are no clinical outcome data to suggest that anesthetized patients with coronary artery disease fare better with the use of volatile anesthetics than with intravenous agents.

Halothane sensitizes the myocardium to epinephrine-induced ventricular dysrhythmias and may be problematic in patients at risk for ventricular tachycardia, especially if sympathomimetics are given concurrently. The subcutaneous dose of epinephrine required to cause ventricular premature contractions during anesthesia with isoflurane, enflurane, or desflurane is approximately fourfold greater than the dose required during halothane anesthesia.[151,152] The susceptibility to catecholamine-induced dysrhythmias is exacerbated by hypercarbia.

Junctional rhythms are observed often with all inhaled anesthetics but most commonly with enflurane. The loss of atrial augmentation of ventricular preload with a junctional rhythm contributes to a decrease in blood pressure during inhalation anesthesia. Junctional rhythms are frequently problematic in patients with aortic stenosis and left ventricular hypertrophy who have poor ventricular diastolic compliance. Junctional rhythms can be treated with transesophageal, transvenous, or direct atrial pacing; decreasing the dose of inhalation anesthetic; or administering an anticholinergic drug such as glycopyrrolate or atropine.

Regional blood flow to other vital organs may be modified by inhaled anesthetics because of their effects on metabolic demands and autoregulation. The normal circulatory response to hypotension and low cardiac output is redistribution of blood flow to vital organs (i.e., brain, heart, and kidneys) and a decrease in blood flow to skin, muscle, and the gastrointestinal system. Volatile inhalation anesthetics impair this protective response and compromise vital organ perfusion if administered in high doses during periods of circulatory shock.

Nitrous oxide (N_2O) is also an inhaled anesthetic, but it is not potent enough to be used alone for general anesthesia. It is often used with other anesthetics because it decreases the MAC of halothane and isoflurane. N_2O is used rarely during cardiac operations because it diffuses into and expands the volume of gas-containing cavities and may increase the size of arterial gas emboli.

Rare cases of acute postoperative hepatic necrosis have been attributed to halothane administration.[153] Although the epidemiologic evidence implicating halothane as the cause of this syndrome remains controversial, the incidence of this idiosyncratic reaction is estimated to be in the range of 1 in 10,000 to 1 in 35,000 halothane anesthetics. Repeated exposures to halothane, reduced splanchnic blood flow, obesity, hypoxemia, enhanced reductive metabolism of the drug, and increased levels of hepatic enzymes induced by chronic drug use, malnutrition, and underlying liver disease appear to be risk factors for postoperative hepatitis. The perceived risk of halothane-induced hepatitis has favored increased use of newer anesthetic agents such as enflurane, isoflurane, and desflurane. Sevoflurane, a newer-generation ether volatile agent, offers lack of airway reactivity, nonpungent odor, low

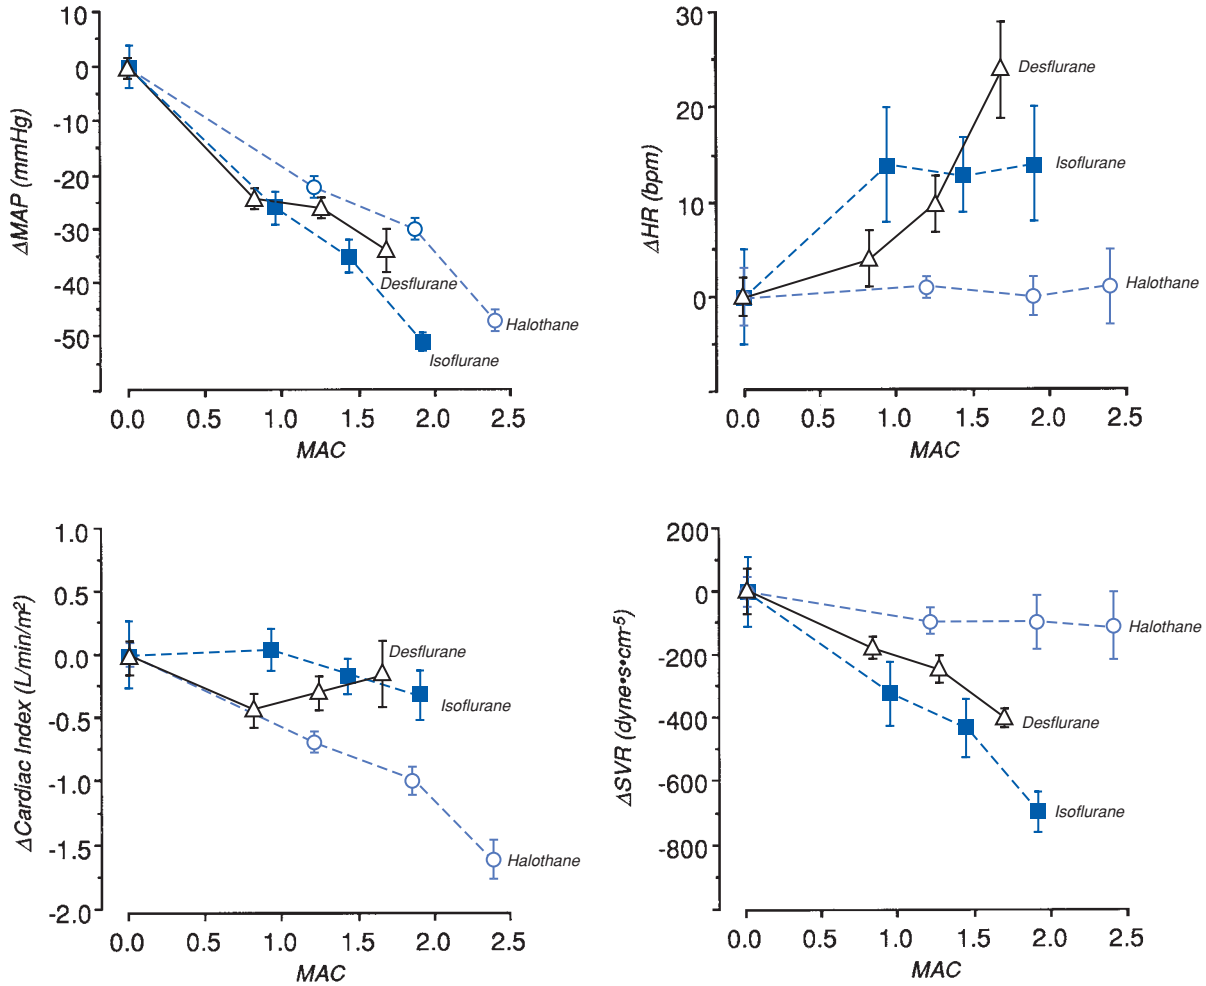

Figure 10-14. Dose-dependent changes in mean arterial pressure, heart rate, cardiac index, and systemic vascular resistance produced by halothane, isoflurane, and desflurane in normocarbic adults. Despite the myocardial depressant effects of isoflurane and desflurane, cardiac output is maintained during anesthesia with these agents in part because of a decrease in left ventricular afterload and increase in heart rate. (*Data from Weiskopf RB, Cahalan MK, Eger EI 2nd, et al: Cardiovascular actions of desflurane in normocarbic volunteers. Anesth Analg 1991; 73:143. Used with permission.*)

flammability, rapid induction and emergence, and minimal cardiovascular and respiratory side effects.[154,155] The accumulation of compound A, a potential renal toxin and by-product of sevoflurane use, has been associated only with low fresh gas flow (<1 L/min). These newer agents undergo minimal hepatic metabolism, do not decrease hepatic blood flow, and have not been implicated in anesthetic-induced liver dysfunction.

In general, carefully conducted clinical trials suggest that almost any inhaled anesthetic can be administered safely to patients with cardiovascular disease if the hemodynamic condition of the patient is controlled closely.[128,152]

Sedative-hypnotics

Sedative-hypnotics are a broad class of anesthetic drugs that includes barbiturates, benzodiazepines, etomidate, propofol, and ketamine. They are used for preoperative sedation, produce immediate loss of consciousness during intravenous induction of general anesthesia, supplement the actions of the inhaled anesthetics, and provide sedation in the immediate postoperative period. The circulatory effects of individual agents are an important consideration for patients with cardiovascular disease. The sedative-hypnotics have direct effects on cardiac contractility and vascular tone, in addition to indirect effects on autonomic tone.

The barbiturates, such as thiopental or methohexital, are negative inotropic agents. They produce dose-dependent decreases in ventricular *dP/dt* and the force-velocity relationship of ventricular muscle.[156] Induction of general anesthesia with a barbiturate is associated with a decrease in blood pressure and cardiac output. In comparison with barbiturates, propofol appears to cause less myocardial depression.[157,158] The decrease in arterial pressure after propofol administration is attributed primarily to arterial and venous dilatation.[159,160] Propofol is well suited for continuous intravenous infusion for sedation because it has a short duration

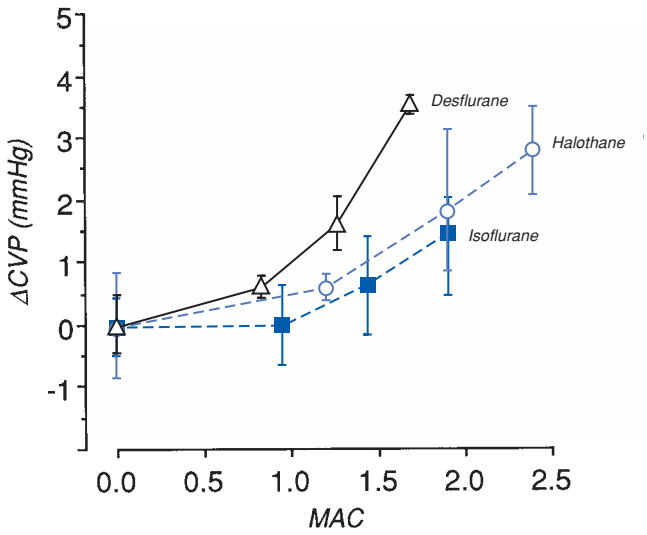

Figure 10-15. Dose-dependent changes in central venous pressure produced by halothane, isoflurane, and desflurane in normocarbic adults. (*Data from Weiskopf RB, Cahalan MK, Eger EI 2nd, et al: Cardiovascular actions of desflurane in normocarbic volunteers. Anesth Analg 1991; 73:143. Used with permission.*)

of action and can be titrated to effect. Propofol given intravenously for sedation in an nonintubated patient requires the presence of an anesthesiologist because respiratory depression is common. Etomidate and ketamine are administrated for rapid induction of general anesthesia in patients with preexisting hemodynamic compromise because they generally cause little or no change in circulatory parameters.[161] These agents are useful for unstable patients undergoing emergency operation, reexploration for bleeding, or cardioversion. Etomidate has virtually no effect on myocardial contractility even in diseased ventricular muscle.[162,163] However, etomidate inhibits adrenal synthesis of cortisol by blocking beta-hydroxylase and therefore is limited to short-term use as an intravenous anesthetic induction agent. Ketamine often increases heart rate and blood pressure after anesthetic induction because it maintains sympathetic tone.[164] The direct negative inotropic and vasodilating effects of ketamine can be unmasked when it is administered to critically ill patients with catecholamine depletion.[165] Ketamine is not used routinely because it may cause postoperative delirium, especially if it is administered in the absence of other sedative-hypnotics.

Centrally acting alpha$_2$-adrenergic agonists such as clonidine possess sedative and analgesic actions but do not produce anesthesia. Preoperative administration of clonidine to cardiac surgical patients decreases narcotic requirements and improves hemodynamic stability during operation.[166] Alpha$_2$ agonists are potent sympatholytic agents and also may be effective at attenuating sympathetically mediated myocardial ischemia.[167] Dexmedetomidine is a highly selective intravenous alpha$_2$-adrenergic agonist with sedative actions.[168] Dexmedetomidine administered at a rate of 0.2 to 0.7 μg/kg per hour intravenously provides effective postoperative sedation for intubated cardiac surgical patients and decreases the need for narcotic analgesics by approximately 50%. Because alpha$_2$-adrenergic agonists have little or no respiratory depressant actions, weaning from mechanical ventilatory support and tracheal extubation can be accomplished without interruption of the dexmedetomidine infusion. The most common adverse effects of dexmedetomidine are hypotension and bradycardia. At dexmedetomidine doses greater than 1.0 μg/kg per hour, arterial pressure may increase owing to direct activation of the alpha$_{2B}$ receptor subtype, which produces peripheral vasoconstriction. Dexmedetomine-induced vasoconstriction causes an increase in systemic vascular resistance, an increase in pulmonary vascular resistance, and a decrease in cardiac output.

Narcotic anesthetics

Narcotics remain an important adjunct for cardiac anesthesia. Analgesic actions are mediated by direct activation of opioid receptors in the central nervous system, spinal cord, and periphery. The three types of opioid receptors most studied are the mu, delta, and kappa receptors. Mu receptors are densely concentrated in the neocortex, brain stem, and regions of the central nervous system associated with nociception and sensorimotor integration.[169] Two different mu receptor subtypes produce analgesia and respiratory depression, leading to the possible development of selective agonist or antagonist compounds.

Narcotic-based anesthetics offer the advantages of profound analgesia, attenuation of sympathetically mediated cardiovascular reflexes in response to pain, and virtually no direct effects on myocardial contractility or vasomotor tone. Narcotics may be administered intravenously, intrathecally, or into the lumbar or thoracic epidural space. Even though narcotics have little direct action on the cardiovascular system, they may cause profound hemodynamic changes indirectly by attenuating sympathetic tone. Narcotics decrease serum catecholamine levels and produce cardiovascular depression indirectly, especially in a patient who is critically ill and dependent on endogenous catecholamines (e.g., those with hypovolemia or cardiac tamponade). Morphine sulfate may decrease blood pressure by provoking the release of histamine.

Problems encountered with narcotic-based anesthetics include difficulty estimating the dose required because of patient variability, predicting the duration of postoperative narcotic-induced respiratory depression, and ensuring hypnosis during operation. Rapid administration of narcotics is associated with muscle rigidity that may impede the ability to ventilate the patient immediately after the induction of general anesthesia.[170] The rigidity usually affects the thoracic and abdominal musculature and is observed commonly with doses of narcotic used in cardiac anesthesia. Myoclonic activity often associated with muscle rigidity easily can be mistaken for grand mal seizures. There is no evidence that opioids induce seizures when there is adequate oxygenation and

ventilation.[171] Opioid-induced muscle rigidity is reversed immediately by the administration of neuromuscular blockers.

The nonselective opioid antagonist naloxone reverses narcotic-induced respiratory depression. Narcotic antagonists must be titrated carefully to effect. Sudden reversal of opioid-mediated analgesia may produce systemic and pulmonary hypertension and tachycardia and is potentially life-threatening for patients with coronary artery disease.[172] The reversing effect of naloxone on narcotic-induced respiratory depression is significantly shorter than the respiratory depressant effects of most opioids, except for ultra-short-acting synthetic narcotics (e.g., alfentanil and remifentanil). A patient who receives a single intravenous dose of naloxone is susceptible to renarcotization after initial reversal of respiratory depression. For this reason, the initial bolus dose of naloxone typically is followed by an intramuscular injection or intravenous infusion, and patients are monitored closely. Longer-acting opioid antagonists include nalmefene, which has an elimination half-life ($t_{1/2B}$) of 8.5 hours, in contrast with the $t_{1/2B}$ of 1.5 hours for naloxone.[173] Mixed opioid agonists-antagonists (e.g., nalbuphine) may decrease the risk of hypertension, tachycardia, and dysrhythmias but do not reverse respiratory depression as reliably as naloxone.[174]

Opioid tolerance is a decrease in response (both analgesia and respiratory depression) to a narcotic owing to prior exposure. Tachyphylaxis is the rapid development of drug tolerance. Drug dependence is a patient condition or disorder that occurs as a consequence of sustained exposure to a drug such that withdrawal or antagonism of the drug prohibits normal function.[175] Perioperative exposure to morphine and synthetic narcotics is unlikely to produce the downregulation and desensitization of opioid receptors believed necessary for narcotic dependence.[176] Acute tolerance to fentanyl in humans is likely to occur only after prolonged infusion and to a lesser extent in the perioperative period. Cardiac surgical patients receiving narcotic infusions in the intensive-care unit develop tolerance and require increasing doses to sustain the desired effect.[177]

The synthetic narcotics such as fentanyl, sufentanil, and alfentanil overcome some of the problems of morphine-based anesthetics because of increased lipid solubility, more rapid onset of action, increased anesthetic potency, absence of histamine release, and independence of renal function for drug clearance. Development of short-acting narcotic anesthetics also may improve the ability to control anesthetic depth without prolonging recovery time. Ultra-short-acting narcotics (e.g., remifentanil) may have a unique niche in cardiac anesthesia because their effect is terminated almost immediately on stopping the drug infusion owing to rapid in vivo ester hydrolysis.[178] Other side effects of narcotics include pruritus, nausea, constipation, and urinary retention.

Neuromuscular blocking drugs

Neuromuscular blocking drugs are administered to facilitate intubation of the trachea, prevent patient movement during operation, improve surgical exposure of the operating field, and attenuate metabolic demands caused by shivering during hypothermia. Except for succinylcholine, the neuromuscular blocking drugs used in clinical practice are typically nondepolarizing competitive antagonists of acetylcholine at the nicotinic acetylcholine receptor at the motor end plate. Succinylcholine is an acetycholine agonist that produces rapid, short-acting muscle paralysis by depolarizing the motor end plate.

Muscle relaxants are chosen based on the desired speed of onset, duration of action, route of elimination, spectrum of cardiovascular side effects, and cost (Table 10-3). The newer neuromuscular blocking drugs such as vecuronium, *cis*-atracurium, doxacurium, and rocuronium have virtually no cardiovascular side effects and do not depend on renal function for elimination. Metocurine and gallamine are completely dependent on renal function for elimination and are used infrequently in clinical practice. Succinylcholine has the most rapid onset of action (90 seconds) but produces unpredictable changes in heart rate; increases serum potassium concentration by approximately 0.5 mEq/L; may cause life-threatening hyperkalemia in patients with denervation, burn, or compression injuries; and can trigger malignant hyperthermia in susceptible individuals. Pancuronium increases blood pressure and heart rate by blocking muscarinic acetylcholine receptors in the sinoatrial node, increases sympathetic activity via antimuscarinic actions, and inhibits reuptake of catecholamines. The neuromuscular blockers D-tubocurarine, metocurine, mivacurium, and atracurium may decrease blood pressure and increase heart rate indirectly by mediating release of histamine. The cardiovascular effects of these neuromuscular blockers may be attenuated by pretreatment with H_1- and H_2-receptor antagonists. Long-term administration of vecuronium is associated with development of myopathy in patients on glucocorticoid therapy.[179]

Discontinuing general anesthesia or sedation before complete recovery from neuromuscular blockade is very distressing for a patient because the awake, alert, and paralyzed patient has no means to communicate discomfort. Discontinuing mechanical ventilatory support in patients with residual neuromuscular blockade may cause acute or delayed respiratory failure. Even mild residual neuromuscular blockade contributes to pulmonary insufficiency by compromising mechanics of breathing and decreasing negative inspiratory force, vital capacity, tidal volume, and the ability to generate an effective cough. Muscle fatigue may produce airway obstruction by decreasing muscle tone in the oropharynx. Recovery from nondepolarizing neuromuscular blockade may be hastened by administering an acetylcholine -esterase inhibitor such as neostigmine or edrophonium that decreases degradation of acetylcholine at the neuromuscular junction and thereby increases the concentration of the neurotransmitter at the motor end plate. The undesirable systemic effects of acetylcholine-esterase inhibitors are bronchospasm, bradycardia, and hypersalivation, which can be minimized by simultaneous administration of anticholinergic

Table 10–3.

Neuromuscular Blocking Drugs

Drug	ED_{95} (mg/kg)	Dose (mg/kg)	Onset (min)	Duration (min)	Effects of drug on: HR	BP	CO	Histamine release	Renal elimination
Succinylcholine	0.25	1.5	1–1.5	12–15	(+)	(+)	(0)	(+)	0%
D-Tubocurarine	0.51	0.6	3–5	180–240	(+)	(−)	(−)	(+++)	60%
Pancuronium	0.07	0.1	3–5	180–240	(++)	(+)	(+)	(0)	70%
Metocurine	0.28	0.4	3–5	240	(+)	(−)	(0)	(++)	90%
Gallamine	3.0	3.5	3–5	180	(+++)	(++)	(++)	(0)	100%
Vecuronium	0.06	0.1	2–3	75–120	(0)	(0)	(0)	(0)	15%
Atracurium	0.25	0.5	2–3	60–90	(0)	(−)	(0)	(+)	<5%
Doxicurium	0.04	0.06	3–5	180–240	(0)	(0)	(0)	(0)	75%
Rocuronium	0.3	0.6	1–2	45–90	(0)	(0)	(0)	(0)	0%
Mivacurium	0.1	0.2	2–3	40–60	(0)	(0)	(0)	(+)	<5%

ED_{95} = dose required to produce 95% suppression of muscle twitch in response to nerve stimulation; dose = initial dose required for intubation of the trachea; onset = time required to achieve conditions required for tracheal intubation; duration = time after injection required for recovery to 95% of baseline function; (+) = increase; (−) = decrease; (0) = no effect; HR = heart rate; BP = arterial pressure; CO = cardiac output; histamine release = drug-induced histamine release; renal elimination = percentage of injected dose that is dependent on renal function for excretion

agents such as atropine or glycopyrrolate. Severe bradycardia has been described in heart transplant patients after reversal of neuromuscular blockade, possibly owing to the nonantagonized parasympathetic activity associated with acetylcholinesterase inhibitors in the denervated heart.[180] Reliable reversal of neuromuscular blockade with cholinesterase inhibitors usually is achieved only after muscle strength has recovered spontaneously to approximately 25% of baseline levels. Recovery of neuromuscular function is measured by a train-of-four twitch monitor applied to the ulnar nerve.

Local anesthetics

Local anesthetic drugs block the propagation of action potentials in electrically excitable tissue. Local anesthetics can be delivered by topical application to mucosa, infiltration into tissues, injection into the region of a peripheral nerve, infusion into the epidural space, or injection intrathecally into cerebrospinal fluid. Regional nerve blocks can be used to supplement a general anesthetic or to provide postoperative analgesia. Epinephrine often is added to local anesthetic solutions to prolong the anesthetic duration but may cause tachycardia or cardiac arrhythmias when absorbed into the systemic circulation. Inadvertent intravascular injection of a local anesthetic may cause seizures, myocardial depression, hypotension, bradycardia, ventricular arrhythmias, or even cardiac arrest. Among the local anesthetics, bupivacaine has the greatest potential for cardiac toxicity. Ropivacaine is less cardiotoxic than bupivacaine.[181,182]

Special Anesthetic Techniques

Emergency airway management

Establishing a patent and secure airway is essential for the conduct of general anesthesia and is the first step in emergency life support for cardiovascular resuscitation. Tracheal intubation for airway protection and mechanical ventilation can be challenging in a patient with cardiovascular disease. Anesthesia is often necessary to facilitate tracheal intubation; however, the effects of general anesthetics on respiratory and circulatory function typically produce respiratory depression and may cause apnea, instability of the patient's airway, aspiration pneumonitis, hypoxia, hypercarbia, and cardiovascular collapse. Inadequate anesthesia during tracheal intubation may provoke myocardial ischemia or tachyarrhythmias in susceptible patients. The American Society of Anesthesiologists has established practice guidelines for the emergency management of the difficult airway.[183] The difficult airway (e.g., Mallampati class 4) often can be

intubated with the patient in a sedated state using fiberoptic bronchoscopy. This technique requires time and special equipment. The risk of hypertension, tachycardia, and discomfort during tracheal intubation in an awake patient can be offset partially by topical anesthesia. Other techniques include mask ventilation, laryngeal mask ventilation, esophageal-tracheal combitube ventilation, blind oral or nasal intubation, direct laryngoscopy, rigid ventilating bronchoscopy, light wand intubation, retrograde intubation, transtracheal jet ventilation, cricothyroidotomy, and tracheostomy.

Single-lung ventilation

Single-lung ventilation, or the ability to collapse one lung and selectively ventilate the contralateral lung, is necessary for operative exposure when the heart or great vessels are approached through a lateral thoracotomy incision. Selective lung ventilation is integral in the intraoperative management of patients undergoing minimally invasive direct coronary artery bypass (MIDCAB) procedures. Adequate surgical exposure with minithoracotomy for coronary revascularization without cardiopulmonary bypass requires deflation of the left lung. Single-lung ventilation is also used in patients undergoing thoracoscopic procedures, lung transplantation, thoracic aortic operations, mitral valve surgery through a right thoracotomy, closure of large bronchopleural fistulas, intrathoracic robotic surgery, or life-threatening hemoptysis. Single-lung ventilation may be achieved using double-lumen endobronchial tubes (Fig. 10-16) or bronchial blockers (Fig. 10-17).

Wire-guided bronchial blocker kits often contain an adapter for a standard endotracheal tube with ports for the bronchial blocker and fiberoptic bronchoscope. A central lumen for the blocker contains a monofilament loop that passes out the end of the catheter. Placement of the loop over a fiberoptic bronchoscope permits the bronchial blocker to be guided directly into position using the bronchoscope. Removal of the monofilament loop from the central lumen

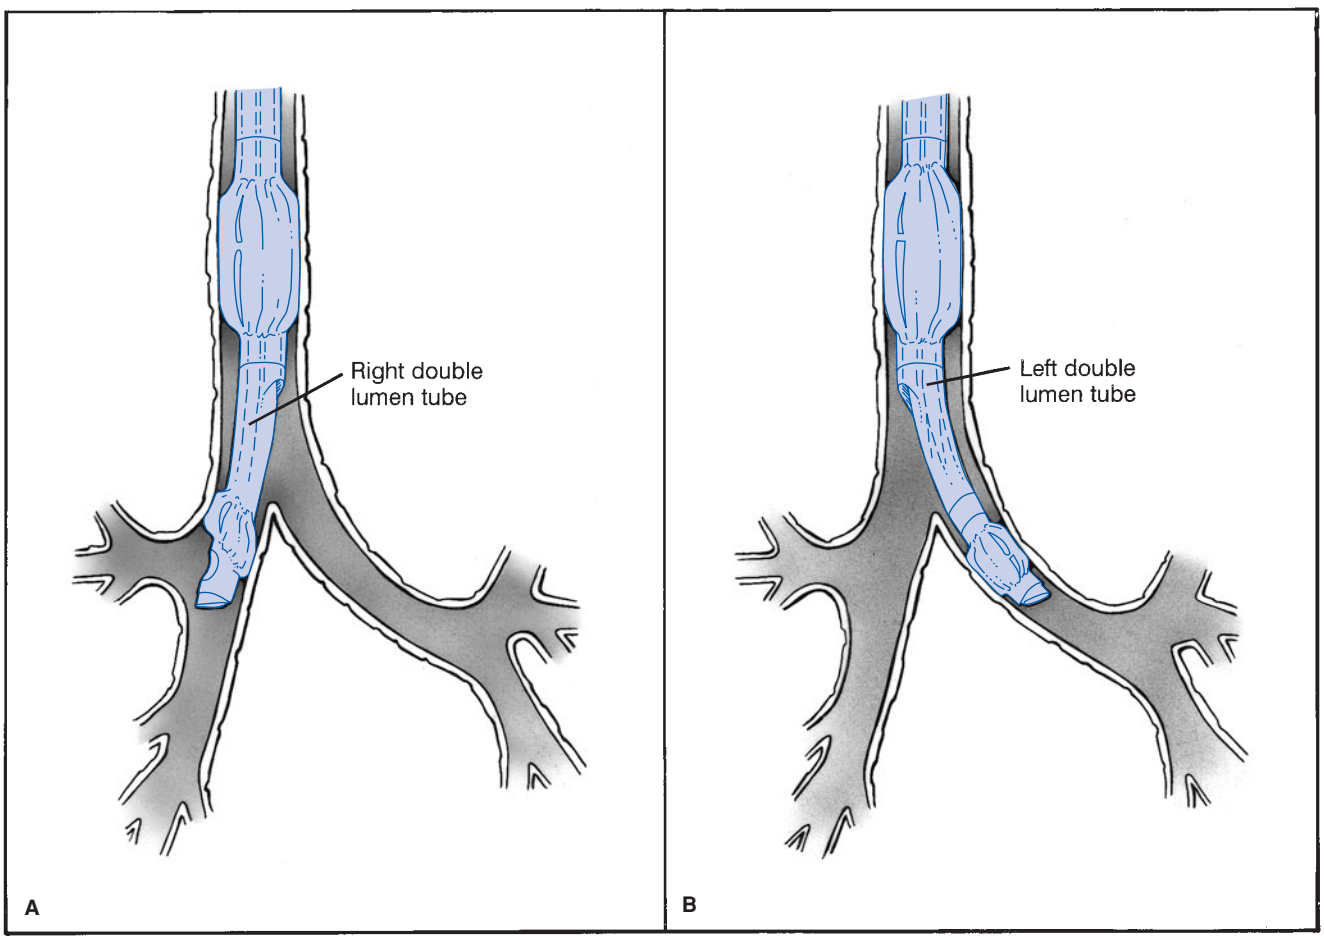

Figure 10-16. (*A*) Right-sided double-lumen endobronchial tube positioned such that Murphy's eye is aligned with the orifice of the right upper lobe bronchus. Indications for a right-sided tube are surgery involving the left main stem bronchus; patients with a prior left pneumonectomy, stenosis, compression, or mass in the left main stem bronchus; and circumstances in which the trachea needs to be protected from soilage from contents in the right lung (e.g., abscess). (*B*) Left-sided double-lumen endobronchial tube.

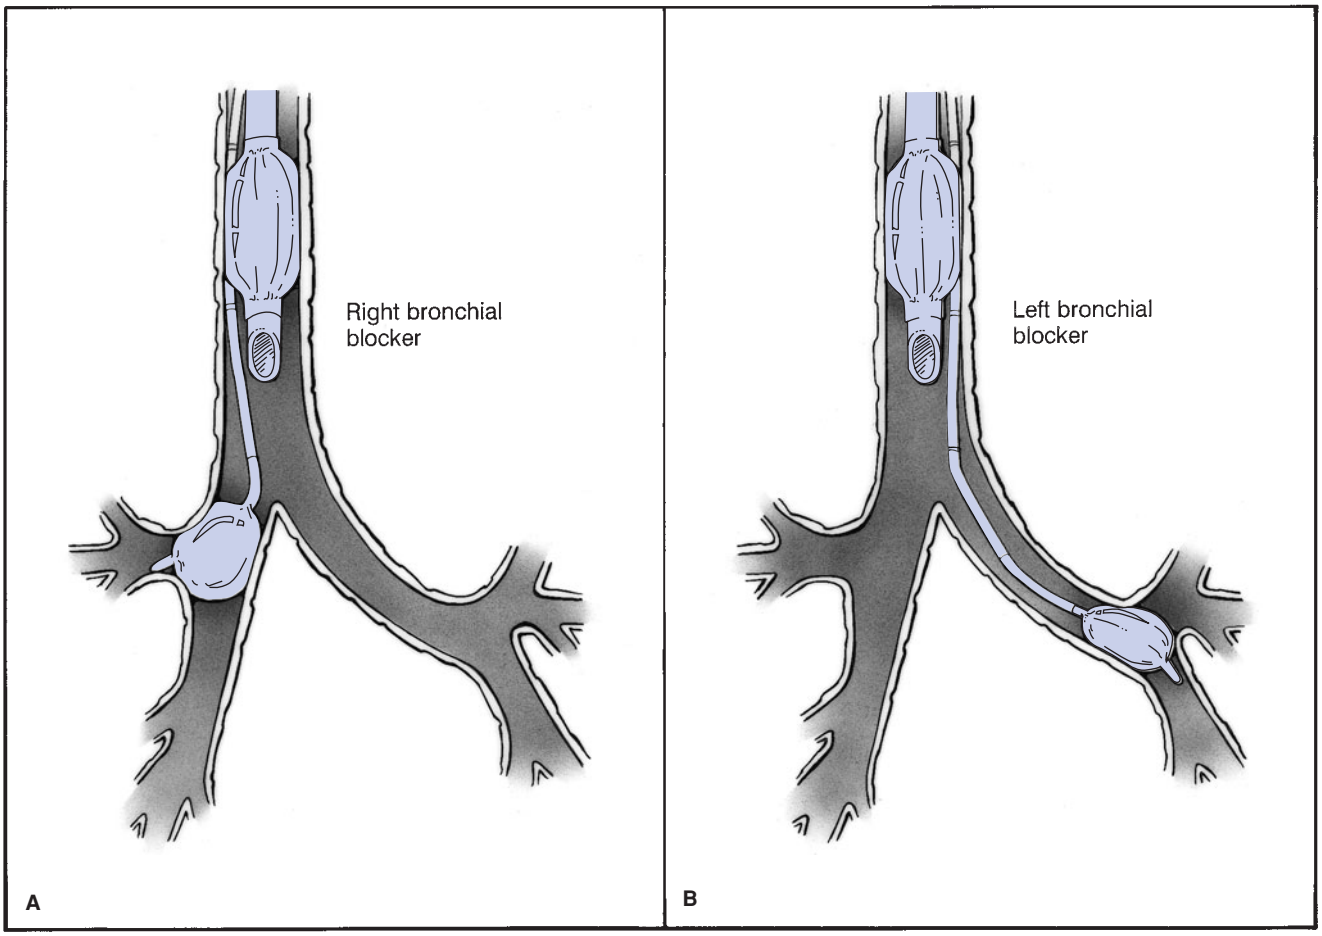

Figure 10-17. Bronchial blockers permit single-lung ventilation but do not permit suctioning or rapid deflation of the nonventilated lung. Position of the bronchial blocker is less stable compared with a double-lumen endobronchial tube.

provides a port for venting the nonventilated lung. Bronchial blockers for lung isolation are preferred when the larynx is too small to accommodate a double-lumen endobronchial tube (rare in the adult patient), when it is difficult or dangerous to change an existing endotracheal tube, or when the tracheal or main stem bronchus is distorted by a mediastinal mass or aortic aneurysm.

The routine use of fiberoptic bronchoscopy has decreased the complication rates and eliminated uncertainty regarding positioning of these devices in the airway. Hypoxemia caused by transpulmonary shunt through the nonventilated lung during single-lung ventilation often requires modification of the anesthetic technique to preserve hypoxic pulmonary vasoconstriction.

Regional anesthesia and analgesia

Epidural or intrathecal administration of local anesthetics and narcotics can provide profound postoperative analgesia after thoracic and major abdominal operations with less sedation or respiratory depression than parenteral narcotic analgesia.[184–186] However, the risk of hematoma in the spinal canal during or after cardiopulmonary bypass and heparinization has limited the use of epidurals for cardiac surgery. Patient-controlled epidural analgesia using infusion pumps can be triggered by patient demand with a predetermined maximum lockout dose to prevent overdose. Patient-controlled epidural analgesia is an effective method to titrate the dose of epidural local anesthetic and narcotic based on clinical need. The potential clinical advantages of epidural or intrathecal analgesia are less postoperative pain, decreased duration of postoperative ventilatory support, attenuation of the surgical stress responses, and improved pulmonary function.[187]

The epidural catheter most often is inserted prior to operation before systemic anticoagulation. Instrumentation of the epidural space for insertion of the catheter or removal of the epidural catheter is contraindicated in anticoagulated patients and in patients with coagulopathy because of the risk of epidural hematoma formation.[188,189] Epidural analgesia is provided by administering a continuous infusion of dilute solution of local anesthetic or narcotic, or a combination of the two, into the epidural catheter (e.g., bupivacaine 0.05% and fentanyl 2μg/mL at a rate of 4 to 8 mL/h).

The most common side effect of epidural analgesia is hypotension caused by local anesthetic blockade of the pre-

ganglionic vasomotor efferents of the sympathetic nervous system and loss of compensatory vasoconstriction. This side effect can be decreased by decreasing the concentration of the local anesthetic relative to the narcotic analgesic used in the epidural infusion. Respiratory depression also can occur with systemic absorption of the narcotic. The onset of respiratory depression sometimes is delayed or unpredictable. Nausea and pruritus are also common side effects of epidural or intrathecal narcotics. Epidural hematoma formation causing spinal cord compression is a rare but potentially catastrophic complication of epidural and intrathecal analgesia, with an estimated frequency of 1 in 150,000 patients.[190] Insufficient evidence to characterize the risks and benefits of epidural anesthesia compared with more conventional analgesic techniques has precluded the widespread acceptance of epidurals in cardiac surgery.[191]

Thoracic epidural anesthesia has been employed successfully for treatment of refractory angina.[192,193] Selective anesthesia of T_1 to T_5 thoracic dermatomes with epidural local anesthetic inhibits sympathetic innervation of the heart and regional vasculature. Thoracic epidural anesthesia decreases left ventricular contractility and heart rate while prolonging phase IV of the cardiac action potential.[194] The decrease in myocardial oxygen consumption, reduced arrhythmogenicity, and increase in diameter of the stenotic coronary arteries are the proposed mechanisms for the abolition of chest pain in unstable angina patients who receive thoracic epidural local anesthetic.[195–199] With exercise testing, these patients have a smaller ischemic burden (less ST-segment depression) for a given workload with epidural anesthesia compared with control exercise without epidural anesthesia. Treatment of myocardial ischemia with an infusion of local anesthetics or opioids into the epidural space is not without risk in patients who are likely to receive anticoagulants and/or thrombolytics and who may have significant preexisting left ventricular dysfunction.

Controlling lumbar cerebrospinal fluid pressure

Spinal fluid drainage may improve neurologic outcome from spinal cord ischemia during thoracoabdominal aortic (TAA) operations.[200–202] Lumbar CSF drainage is part of a multimodal approach to prevent paraplegia after thoracoabdominal aortic surgery.[203,204] Although the clinical efficacy of lumbar CSF drainage remains controversial, the technique is routine at some institutions.[205,206] CSF drainage and a decrease in the lumbar CSF pressure can be achieved by aseptically inserting a subarachnoid catheter through a Tuohy needle positioned in a lower lumbar vertebral interspace. The insertion of a CSF drain prior to a patient undergoing extracorporeal circulation with anticoagulation appears safe.[207,208] The catheter typically is inserted 1 to 2 hours before systemic anticoagulation with the patient in a lateral decubitus position. CSF is drained passively to reduce lumbar CSF pressure to approximately 10 to 12 mm Hg during operation. Reducing CSF pressure further may cause an abducens nerve palsy and postoperative diplopia. The catheter is secured, and CSF drainage is continued typically for 24 hours after operation. In the absence of spinal cord ischemia, the catheter is capped at 24 hours after operation and removed at 48 hours after operation. Arterial blood pressure augmentation is an important adjunct to treatment of spinal cord ischemia after TAA surgery or stent placement.[209] Emergent implementation of lumbar CSF drainage to a target lumbar CSF pressure of 10 mm Hg, combined with augmentation of the mean arterial pressure to 100 mm Hg, has been reported to successfully reverse delayed-onset paraplegia or paraparesis in some patients after thoracic aortic reconstruction.[210,208] Complications associated with lumbar CSF catheters include meningitis, persistent CSF leak, breakage and retention of catheter fragments, and epidural hematoma. The risk of epidural hematoma is increased when the CSF catheter is inserted or removed in anticoagulated patients.

THE CONDUCT OF ANESTHESIA, SURGERY, NURSING, AND PERFUSION

Cardiac surgery is conducted in an interdisciplinary environment among surgeon, anesthesiologist, perfusionist, and nursing staff. The operating room requires a minimum of 800 ft^2 to comfortably accommodate the patient, health care providers, standard operating room equipment, intraoperative cell salvage machine, heart-lung machine, and assist devices, if needed.[211] The required square footage may be greater for the higher-technology procedures such as robotic surgery.

The anesthetic begins before the patient arrives in the operating room. Patients are premedicated with a sedative-hypnotic (e.g., scopolamine or benzodiazepine) and an analgesic (e.g., morphine) unless the associated mild degree of respiratory depression is unwarranted. The patient's identification and scheduled procedure are verified immediately on arrival in the operating room. The patient is escorted into the operating room and placed onto the operating table, and routine noninvasive monitors are applied. The physical condition of the patient is assessed clinically, and medical events that occurred over the previous 12 to 24 hours are reviewed. For elective surgery, the patient should have fasted for a minimum of 6 hours prior to induction of general anesthesia. Prophylactic antibiotics are administered after insertion of an intravenous catheter. A catheter is inserted in the radial artery. A blood sample is acquired for laboratory analysis, and a blood type and crossmatch are requested, if not done already. A central venous catheter is always indicated, although in many patients it can be inserted after the induction of general anesthesia. A pulmonary artery catheter is used commonly to provide measures of cardiac output and estimates of ventricular filling pressures.[212] Large-bore intravenous catheters are inserted for patients who are undergoing reoperation because of the possibility of rapid blood loss during sternotomy. The immediate availability of typed and crossmatched blood is verified before skin incision. Patients undergoing reoperation

are more likely to have a positive antibody screen that delays the availability of blood products. External defibrillation pads are always applied to patients undergoing reoperation or in procedures in which access to the heart with internal paddles is not readily available.

Anesthesia care begins in the preinduction period, documents significant events of surgery, and becomes part of the patient's medical record. Prior to induction of general anesthesia, a baseline set of hemodynamic measurements is obtained and recorded. These measures often guide the choice of anesthetic drugs and technique, provide a baseline for comparison later, and confirm hemodynamic data acquired during cardiac catheterization. Automated record keepers eventually may relieve the anesthetist of recording these data.

Induction of general anesthesia is achieved by inhalation of volatile potent anesthetics, intravenous administration of sedative-hypnotics, or both. Inhalation inductions permit maintenance of spontaneous ventilation and a controlled titration of anesthetic dose but prolong the excitatory phase of anesthesia when the patient is prone to cough, move, develop laryngospasm, or vomit and aspirate. Inhalation inductions are not used commonly in adults. Intravenous induction produces rapid apnea that requires immediate ventilatory support. Administration of neuromuscular blocking drugs produces profound muscle paralysis and facilitates laryngoscopy and tracheal intubation. Vasoactive drugs are titrated, if necessary, to counteract the cardiovascular effects of anesthetics. Laryngoscopy is extremely stimulating (painful) and, if the patient is inadequately anesthetized, causes severe hypertension and tachycardia and stimulates vasovagal reflexes. The inability to ventilate or intubate the trachea in a patient after the induction of general anesthesia is a medical crisis and may require transtracheal jet ventilation, cricothyroidotomy, or tracheostomy. Patients with a history of a technically difficult tracheal intubation, poor dentition, large tongue, limited mouth opening, inability to sublux the mandible, or a recessed chin are at increased risk of airway complications, and it may be prudent to secure the airway while they are still awake. Successful intubation of the trachea is verified by the appearance of a carbon dioxide expirogram. Most adult patients can be intubated with an 8.0-mm internal-diameter polyvinyl chloride endotracheal tube that accommodates an adult flexible bronchoscope. The tip of the tracheal tube is secured above the carina by documenting breath sounds bilaterally. The patient is positioned prior to surgical preparation and draping. Regions susceptible to pressure injuries are protected and padded. Arm abduction is limited to less than 90 degrees. The patient is positioned to decrease pressure on the postcondylar groove of the humerus.[213] ECG wires, tubes, and lines are not run under the arm. The incorporation of a simple examination of extremity nerve function during the postoperative visit provides a means to detect peripheral nerve injury.

Maintenance of general anesthesia is achieved by continuous or intermittent administration of anesthetic drugs titrated to effect while monitoring the conduct of the operation and vital physiologic functions. Short-acting vasoactive agents with rapid onset of action usually are preferred for controlling the circulation because conditions change constantly. The cardiovascular actions of inhaled anesthetics are used often for short-term blood pressure control because effective concentrations can be reached quickly and monitored in real time by expired gases. Direct-acting vasodilators may be required for blood pressure control if the patient cannot tolerate the myocardial depressant effects of an inhaled anesthetic. Vasopressors and inotropic agents sometimes are required to support the circulation in response to anesthetic-induced vasodilation and cardiac depression. Using nitroglycerin to modify venous capacitance permits buffering acute changes in intravascular volume. Heart rate can be controlled by short-acting cardioselective beta-adrenergic agonists and antagonists, vagolytic agents, or chronotropic drugs or, alternatively, by direct cardiac pacing. The urgency to control hemodynamic parameters with pharmacologic therapy must be tempered by recognizing the risk of drug overdose from overzealous treatment. Intraoperative events associated with acute increases in anesthetic requirements are sternotomy, chest wall retraction, manipulations and cannulation of the aorta, rewarming during cardiopulmonary bypass, and sternal wiring. Intraoperative awareness from insufficient anesthesia may occur during cardiac surgery, especially if the anesthetist places a greater emphasis on avoiding cardiovascular actions of anesthetic agents than on providing sufficient anesthesia.

Initiation of cardiopulmonary bypass acutely changes circulating drug concentrations. The addition of 2 L of pump prime has a negligible effect on plasma concentrations of lipophilic drugs with a large volume of distribution but significantly decreases the concentration of drugs distributed primarily in the intravascular space. Despite measurable decreases in blood anesthetic concentrations during cardiopulmonary bypass, the anesthetic level may not change because systemic hypothermia decreases anesthetic requirements, potentiates the effects of neuromuscular blocking drugs, and increases the solubility of volatile anesthetics in blood. Rewarming returns anesthetic requirements to baseline levels and predisposes to inadequate anesthesia if therapeutic drug concentrations are not maintained. The judicious use of sedative-hypnotics, analgesics, and amnestic agents during rewarming decreases the incidence of recall but does not guarantee unconsciousness. Volatile inhalation anesthetics can be given during cardiopulmonary bypass by adding them to the oxygen-rich gas mixture ventilating the pump oxygenator. This use of volatile anesthetics requires an effective scavenging system to prevent accumulation of anesthetic gases in ambient air.

Separation from cardiopulmonary bypass requires effective communication among members of the intraoperative team. Similar to an airline pilot preparing to land, the cardiac anesthesiologist has a checklist that ensures that all systems are in working order (Table 10-4).

Table 10–4.

Checklist for Preparation to Separate from Cardiopulmonary bypass

1. Stable rhythm preferably with a synchronized atrial contraction
2. Pacemaker and cables available
3. Positive inotropes available (e.g., epinephrine, dopamine)
4. Vasodilators available (e.g., nitroglycerine, nitroprusside)
5. Vasopressors available (e.g., phenylephrine, norepinephrine)
6. Adequate levels of anesthesia and paralysis
7. Normothermia: nasopharyngeal temperature = 37°C, rectal or bladder temperature = 35°C
8. Normal serum electrolyte concentrations: K^+, Ca^{+2}
9. Normal serum glucose
10. Normal blood acid-base status
11. No systemic oxygen debt: oxygen saturation in cardiopulmonary bypass venous inflow >70%
12. Acceptable O_2-carrying capacity: hemoglobin concentration
13. Normal systemic vascular resistance
14. Recalibration of pressure transducers
15. ECG in diagnostic mode
16. Clearance of air by TEE
17. Hemothorax evacuated
18. Ventilation with 100% oxygen and atelectatic lungs reexpanded

ANESTHESIA IN THE IMMEDIATE POSTOPERATIVE PERIOD

Continuous monitoring of physiologic functions during transport to the postoperative intensive-care unit is paramount because of the possibility of hemodynamic instability. Cardiac output, blood pressure, and vascular tone decrease acutely in the immediate postoperative period because surgical stimulation no longer increases sympathetic tone. Vasodilation also occurs from increases in cutaneous blood flow during active rewarming. Reducing positive-pressure ventilatory support during weaning from mechanical ventilation may alter hemodynamic function by increasing venous return and decreasing pulmonary vascular resistance. Sedative-hypnotic or analgesic drugs administered in the immediate postoperative period contribute to changes in the circulatory state.

Anesthesia is required in the early postoperative period because of mechanical ventilatory support, hypothermia, and the possibility of hypertension and tachycardia from pain and tracheal intubation if abrupt emergence occurs. Several hours may be needed to achieve criteria for tracheal extubation (e.g., minimal bleeding, cardiovascular stability, and systemic rewarming). Arrival in the intensive-care unit triggers a battery of laboratory tests designed to assess rapid changes in vital organ function and prompt corrective therapy. These tests include a chest radiograph, complete blood and platelet count, chemistry battery with blood urea nitrogen and serum creatinine determinations, a serum glucose determination, ECG, prothrombin time and partial thromboplastin time, and arterial blood gas determination.

Preemptive patient management during operation and in the early postoperative period can decrease intensive-care-unit and hospital length of stay after cardiac surgery.[214] Traditionally, high-dose narcotic anesthesia provided profound analgesia, sympathetic blockade, and a gradual emergence that was managed over a time course of 8 to 12 hours. With high-dose narcotic anesthesia, patient recovery often was determined by the duration of action of the anesthetic given in the operating room. The time required for recovery from general anesthesia may be decreased by short-acting sedative-hypnotics (e.g., propofol) or analgesics administered by infusion that continues into the postoperative period and permits recovery according to the patient's condition rather than the anesthetic. Implementation of protocol-based care plans designed to expedite patient recovery after cardiac operations requires a coordinated effort and mutual understanding between the anesthesiologist, surgeon, and critical care team.

Hemodynamic management of cardiac surgical patients is integrated with anesthetic management. The ability to establish a diagnosis and circulation rapidly during anesthesia is essential for safe conduct of cardiac operations. The challenge to maintain control of the cardiovascular system during the course of a typical operation is complicated by actions of the anesthetic drugs on the circulation, autonomic nervous system reflexes, variability in individual responses to vasoactive drug therapy, continuous fluctuations in the intensity of painful stimuli, rapid intravascular volume shifts, the patient's underlying medical condition, and the urgency of operation.

CHAPTER 11

Principles and Practice of Echocardiography in Cardiac Surgery

Maurice Enriquez-Sarano · Vuyisile T. Nkomo · Hector Michelena

Echocardiography is an imaging modality that, in the past 25 years, has developed to be the major imaging and diagnostic modality of cardiac disease, so all cardiac specialists, clinicians, invasive cardiologists, and surgeons need to understand the basic principles, approaches, indications, physiologic determinants, pitfalls, and expected results of echocardiography to make an appropriate interpretation. Beyond physical principles affecting the imaging results, Doppler echocardiography is, like all complex testing modalities, subject to operator-dependent factors and Bayesian interpretation of results. Hence it is essential that quality of imaging and integration of reported results be challenged critically by the clinician "consumers." The goal of this chapter is to provide basic to advanced knowledge of the echocardiographic aspects of major cardiac conditions (mostly acquired) to ensure proper functioning of the team echocardiographer/cardiac surgeon.

PRINCIPLES OF ECHOCARDIOGRAPHY FOR THE CARDIAC SURGEON: A PRIMER

Echocardiography uses high-frequency ultrasound (2.0 to 7.5 MHz) to generate images of the heart and measure blood flow velocity. It is important to understand some principles of ultrasound for proper interpretation. Images are produced by reflection of ultrasound (produced by crystals contained in the transducer) off cardiac walls. To achieve reflection, ultrasound first must penetrate body tissues. Water (blood) allows excellent penetration of ultrasonic energy, and penetration is less through fat and is minimal through air; bones are such strong reflectors that no energy is left to progress into the cardiac tissue. Therefore, echocardiographers use "windows" (between the ribs, sternum, and lungs) such as the parasternal, apical, subcostal, suprasternal, transesophageal, and intracardiac windows to ensure good penetration of ultrasound into the heart and thus good images. Ultrasonic imaging is not photography, and images of the cardiac structures (e.g., aortic walls) are generated by a scan converter that counts the time between emission of ultrasound and the return of the reflected wave to the same crystal and calculates the distance from transducer to reflective structure, assuming a constant speed of progression of ultrasound energy in blood. This mostly true assumption ensures excellent measurement of depth, but lateral resolution is less precise because strong reflectors tend to diffract the ultrasound energy, which rebounds not only toward the original crystal but also toward adjoining crystals. Thus a point is well defined in depth but appears fattened laterally (lateral lobes). Clinically, this lateral "thickening" of echoes tends to minimize the apparent size of cavities. Strong reflectors (e.g., calcified walls) also reflect so much ultrasound energy back to the transducer, the wall again, and the transducer again that artifact at double depth may be generated. Single-crystal imaging is time-motion echocardiography, whereas most usually two-dimensional (2-D) echocardiograms are produced by a series of crystals. 2-D echocardiography is a tomograph slicing the heart and requires comprehensive imaging to reconstruct the heart. Newly developed three-dimensional (3-D) imaging produces an ultrasonic cone that reflects the true 3-D structure of the heart, but diffraction of ultrasound waves and computational issues degrade image definition. Hopefully, future development will provide high-resolution and 3-D imaging.

Intracardiac velocity is measured based on the Doppler effect; i.e., a moving target changes the wavelength of the reflected sound. The magnitude of frequency change (the Doppler shift) is proportional to the velocity of the moving target and the direction of the frequency change, indicating the direction of the moving target (toward or away from the transducer). Velocity measurement is very precise if the ultrasound beam and moving target directions are identical (Fig. 11-1). With angulation of these directions, measured velocity decreases with the cosine of the angle (cosine 90° = 0,

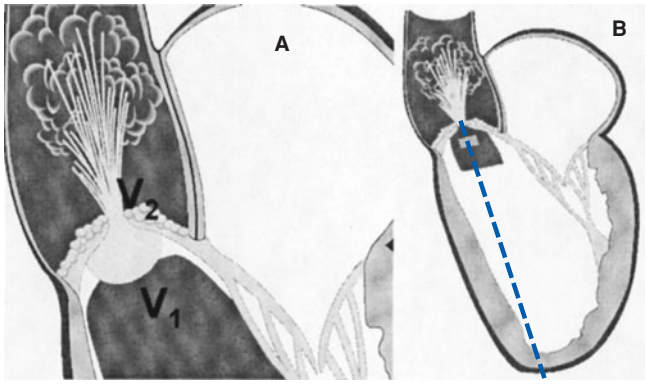

Figure 11-1. Flow through a restrictive orifice and Doppler measures. *A.* A restrictive orifice creates a pattern of flow convergence proximal to the orifice with acceleration of flow through the narrowest portion of the orifice (vena contracta) and expansion with deceleration beyond the orifice. *B.* The necessary alignment of the ultrasound beam and flow is shown to measure velocity accurately. The small box proximal to the jet represents a sample volume of pulsed-wave Doppler. (*Cortesy of Dr. F. A. Miller.*)

no signal). Thus, to measure blood velocity, appropriate alignment is required. Since alignment is uncertain, a multiwindow search of the peak measured velocity (indicating alignment) is indispensable. Blood and tissue velocities can be measured with the use of filters. Two types of Doppler ultrasound can be used: pulsed Doppler (velocity is measured through a small gate), precisely locating the measure but limited in peak velocity measurement, and continuous-wave Doppler, which does not discriminate location of the ultrasonic beam but allows measurement of high velocity, i.e., of gradients. Indeed, a small orifice (stenosis) forces blood (incompressible fluid) to accelerate (constant flow through a smaller orifice means higher velocity). Velocity (V) allows calculation of gradients usually with the simplified Bernoulli equation (gradient $= 4V^2$), which ignores some components (e.g., viscosity and inertia) but generally is accurate for clinical purposes. It should be noted that compared with catheterization, a gradient may be underestimated owing to angulation but also can be slightly overestimated owing to pressure recovery.[1] This phenomenon is due to energy conservation (constant through a stenotic orifice) such that when kinetic energy (velocity) is maximum at the stenotic orifice, potential energy (pressure) is lowest. However, after the orifice, when blood decelerates, potential energy (pressure) increases. Thus, slightly downstream from the orifice, where catheters usually are placed, pressure is higher and the gradient is lower than at the valve orifice itself. This phenomenon is usually minimal but can be clinically significant with some prostheses and with small aortas. Color-flow imaging is based on velocity measurement by Doppler and is coded yellow for flows toward the transducer and blue for flows away. It is important to remember that color-flow imaging does not measure volumetric flow but indicates displacement of red blood cells and that it is Doppler, so flows at a 90-degree angle are not seen and appear black, and high velocities are shown as "aliasing," whereby when the maximum blue color is reached, the color switches to yellow for higher velocity (and so on), giving high-velocity jets their mosaic appearance.

Jet imaging is a major application of color-flow Doppler. Jet extent is influenced by technical, physiologic, and physical factors. For example, a lower scale of color will allow detection of lower velocities and increase the jet area artificially. Physiologically, jet extent is determined by jet momentum, i.e., the product of flow and velocity. This means that very small jets have very low flow, but larger jets can be due to higher jet velocity (e.g., development of hypertension enlarges the jet of mitral regurgitation with unchanged flow). Physically, jets are constrained by cavity size, so larger cavities contain larger jets. In addition, jets directed on a wall are constrained irrespective of their flow. Thus interpretation of jet extent should be made with an awareness of these pitfalls.

MODALITIES OF DOPPLER ECHOCARDIOGRAPHY

Echocardiography provides essential information about most adult cardiovascular diseases requiring cardiac surgery, including detailed information on cardiac structure, function, and hemodynamics. Thus it is essential in indicating and planning surgery and anesthesia, in managing patients intraoperatively, and in monitoring patients postoperatively to ensure the best possible clinical outcome. However, there are multiple echocardiographic modalities that respond to different clinical questions, and it is important that these modalities and their indications be clearly understood by the managing team for optimal use.

Transthoracic Echocardiography

Transthoracic echocardiography (TTE) is completely noninvasive and safe. It is crucial that all windows and views be used with multiple tomographic slices to obtain high-resolution assessment of anatomy and function of the heart and great vessels.[2] There are several submodalities that should be selected carefully:

Standard TTE. This includes 2-D morphologic assessment and 2-D derived M-mode imaging measurement of cardiac dimensions with pulsed and continuous-wave Doppler.[3] Color-flow imaging verifies normalcy of valve function and intracardiac flows. Visual assessment of ejection fraction is often appropriate and can be combined with M-mode measurements.[4,5] Using continuous-wave Doppler (CWD), tricuspid regurgitation allows estimation of right ventricular systolic pressure.[6]

TTE with advanced hemodynamics. This is indicated for most patients with valve disease or poor hemodynamics. Doppler echocardiography calculates stroke volume, cardiac output, and cardiac index. Flow across an orifice is the product of cross-sectional area (CSA, often

assumed circular, where area = πr^2) and flow velocity, and stroke volume (SV) sums flow over the cardiac cycle [product of CSA and summed velocities, called the *time-velocity integral* (SV = CSA × TVI)]. Cardiac output is SV multiplied by hear rate and cardiac index, the ratio of output to body surface area.[7] These principles are simple, but pitfalls have to be recognized: The only valve orifice where SV is consistently measurable is the aortic valve because it is circular, and the flow profile is usually flat (meaning that velocities are identical throughout the orifice). SV measurement is more difficult on the mitral valve and virtually impossible on the tricuspid valve. Even aortic SV can be underestimated if the diameter (squared in calculation of CSA) is underestimated. CVD measures velocity and pressure gradients for stenotic valves with the simplified but accurate Bernoulli equation (gradient = $4V^2$).[8–10] Note that catheterization peak-to-peak gradient (not recommended as an adequate measure) is not the peak gradient but is closer to the mean gradient. Mean gradient obtained by Doppler correlates extremely well with that obtained by catheterization. Velocity decay through a diastolic orifice (mitral stenosis or aortic regurgitation) is faster through a larger orifice and allows assessment of the severity of disease.[11]

Another important principle in advanced Doppler hemodynamics is the conservation of mass.[12] Blood is incompressible, and when it passes through a stenotic orifice, flow remains constant through an increase in velocity (smaller area means higher velocity). This principle, also the basis of Gorlin's formulas, is the basis of stenotic[13] and regurgitant[14] effective area measurement by Doppler, whereby orifice area equals flow/velocity. The flow measurement can be deduced from stroke volumes or, for regurgitant valves, can be measured by the proximal isovelocity surface area (PISA) method.[15] In this method, the flow convergence proximal to a regurgitant orifice (i.e., blood converging toward the orifice) is analyzed by color-flow imaging, which provides the speed of blood and the size of the flow convergence, allowing calculation of flow (flow = $2\pi r^2\ V_r$, where r is the radius of the flow convergence, and V_r is the blood velocity indicated by the machine as aliasing velocity) and regurgitant volume. Thus comprehensive hemodynamic assessment should provide cardiac index, pulmonary pressures, valve lesion severity (orifice area regurgitant or stenotic), and overload severity (gradient or regurgitant volume).[16]

TTE with advanced cardiac size and function assessment. This involves ventricular and atrial characterization. Left ventricular (LV) size usually is characterized as end-diastolic and end-systolic diameters. These dimensions are useful but have important limitations in that they poorly estimate LV dilatation and are biased in terms of women, who, with smaller body size, have smaller LV dimensions. Measurement of LV volumes has been codified by the American Society of Echocardiography.[17,18] One limitation of LV volume measurement is underestimation of true volumes owing to LV trabeculations and echolateral lobes, which can be addressed by using contrast agents that pass into the left side of the heart. These agents allow visualization of the entire left ventricle and accurate measurement of LV volume and stroke volume with minimal inter- and intraobserver variability, and their use should be generalized for patients with LV overload or enlargement.[19] LV diastolic function is critical information to obtain in many diseases. While the reference standard is LV filling pressure obtained by high-fidelity catheters, routine LV diastolic function can be obtained by Doppler echocardiography by compounding Doppler signals of mitral inflow, LV myocardial velocity, and pulmonary venous inflow.[20] Assessment of right ventricular size and function is mostly qualitative, and much progress remains to be made.

Left atrial (LA) dimension from parasternal views is a useful measure of LA enlargement but usually underestimates LA posterior development. The American Society of Echocardiography preferred measure of LA size is the LA volume by the area-length method from two orthogonal views. This measure is simple and reproducible, and LA volume indexed to body surface area of 40 cm/m^2 or greater is considered marked LA enlargement. Information on right atrial size is limited, and volume measurements are possible.[18]

TTE with respirometer study. This is used when pericardial versus restrictive myocardial disease is suspected.[21] It allows characterization of the excessive flow changes with respiration observed in pericardial diseases with cardiac compression (e.g., tamponade or constriction). Pericardial effusion is readily visible by echocardiography, but 2-D signs of tamponade are insensitive. Pericardial thickening is difficult to measure by echocardiography. Observation of excess LV septal displacement with respiration, mitral inflow increase with expiration and reduction with inspiration, and the opposite changes of tricuspid inflow is helpful in diagnosing pericardial compression.

Stress with TTE. This is used much more than with transesophageal echocardiography and mostly in myocardial diseases.[22–24] Several goals can be achieved. First, diagnosis of ischemia is based on maximum stress with either exercise (preferred) or dobutamine administration in patients who have a noncardiac impairment to exercise.[25] Rarely, other stressors have been used. Second, myocardial viability can be assessed in patients with reduced LV function by low-dose dobutamine administration, which stimulates function of viable myocardium, and a biphasic response (improved contraction at low doses and then ischemia with reduced contraction at high doses) is suggestive of viability. Third, hemodynamic stress usually is performed on a recumbent bike with continuous imaging.[26] It is particularly useful in mitral stenosis to characterize the exertional increase in gradient and pulmonary pressure. It also has been used in patients with mitral regurgitation to measure a dynamic increase in regurgitation with stress.[26]

TTE with three-dimensional (3-D) imaging. This was added to our armamentarium recently. While the ability to display the 3-D structure is certainly interesting, the current tradeoff is a loss of resolution that results in increased apparent thickness of tissue and increased complexity of lesion definition.[27]

Interventional echocardiography: Echo-guided interventions. Echocardiography plays an essential role in guiding interventions. The most direct is guidance of pericardiocentesis by TTE, which ensures safe access to the pericardium for drainage of compressive (including postoperative) effusions.[28] Echocardiographic guidance by TTE is also essential in mitral balloon valvuloplasty success[29] and is likely to have a growing role in the promises of percutaneous and perapical insertion of sutureless prostheses or percutaneous mitral repair procedures.[30] The role of transesophageal echocardiography versus TTE remains uncertain.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) provides superior quality in imaging the heart and great vessels owing to excellent ultrasound penetration from the esophagus, which allows use of higher ultrasonic frequencies and provides higher resolution.[31] TEE allows multiplane 2-D imaging (Fig. 11-2) with color, pulsed, and continuous-wave Doppler

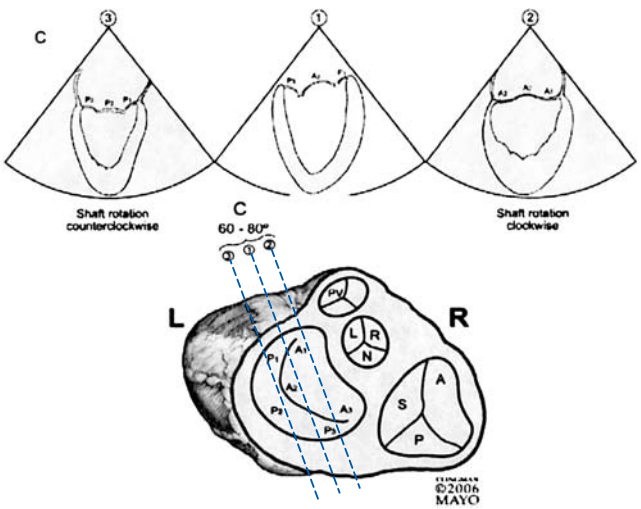

Figure 11-2. Imaging of the mitral valve by transesophageal echocardiography. This schematic description shows the four-chamber cut (*C*) and the segment of the mitral valve observed by clockwise and counterclockwise rotation of the probe (shaft). The heart is see from a posterior view, with the planes of imaging in the lower part (numbered 1, 2, and 3), represented as two-dimensional views above. L = left; R = right; A, S, P = anterior, septal, and posterior leaflets of the tricuspid valve; L, R, N = left, right, and noncoronary cusps of the aortic valve; PV = pulmonary valve; A_1, A_2, A_3 = segments of anterior mitral leaflet; P_1, P_2, P_3 = scallops of the posterior leaflet.

and is the test of choice with difficult or nonfeasible (such as during surgery) TTE images or for detection with superior sensitivity of vegetations, abscesses, mitral ruptured chords, intra-atrial (particularly appendage) thrombi, pulmonary venous abnormalities, interatrial shunt, aortic dissection, and severe atherosclerosis.[32]

The risks attached to TEE are extremely low but not absent. In a multicenter survey of 15 European institutions, among 10,218 successful TEEs, 1 patient with previous esophageal pathology died (mortality = 0.01%).[33] Overall complications are approximately 0.2%,[33,34] and odynophagia occurs in 0.1%.[35,36] There is no known esophageal damage owing to thermal or barometric injury with TEE,[37,38] but poor perfusion, descending thoracic aortic aneurysms, previous prolonged use of steroids, previous thoracic irradiation, large left atria, and advanced age[39,40] predispose to esophageal injury. Carefully ruling out esophageal disease is essential prior to TEE, and continuous cardiopulmonary monitoring of blood pressure, heart rate, respiration, and oxygen saturation is necessary. Esophageal perforation should be suspected in the presence of pneumothorax, pleural effusion, sepsis, and/or respiratory distress in the early postoperative period[39] and should lead to a prompt contrast swallow study with Gastrografin.

Drawbacks and limitations of TEE are related to (1) the hemodynamic effect of conscious sedation or anesthesia on the evaluation of cardiac diseases, particularly valve regurgitations, (2) the limited ability to modify the position of the transducer (thus hemodynamic assessment by TEE usually is limited), and (3) the loss of image quality in the distant field so that LV apical abnormalities most often are better defined by TTE. Multiplane TEE transducers are now the rule, and rotation of 180 degrees allows recording of most imaging planes.[32] Standard views place the transducer in the midesophagus (about 25 to 30 cm from incisors), distal esophagus (about 30 to 35 cm from incisors), and stomach fundus (about 35 to 40 cm from incisors) and allow for complete cardiac morphologic and functional assessment.

Intraoperative (IO) echocardiography detects unexpected findings, confirms morphologic findings, and monitors LV performance[41,42] and surgical results.[43,44] Unsuspected findings were reported in 12 to 15% of patients.[45–47] These unexpected findings lead to alteration of the surgical plan in 8 to 14% of patients. Post–cardiopulmonary bypass findings of significance are noted in 5 to 6% of patients and may lead to second pump runs,[47,48] the indications for which are closely related to the original surgical indication and hemodynamic instability.[46,49,50] Thus IO TEE is a cost-effective procedure that avoids later reoperations.[51–53] IO TEE also allows detection of residual air in cardiac cavities after cardiopulmonary bypass, which suggests the need for more thorough deairing maneuvers.[54] Aortic atheroma can be detected by TEE and may contribute to postoperative embolisms and strokes.[55,56] The suggestion that altered handling of the aorta may reduce strokes[57] should be further evaluated. Postoperatively, IO TEE may be helpful in the assessment of patients with poor hemodynamics. Observation

of markedly reduced LV function or of regional wall motion abnormalities may reveal ischemia, particularly owing to bypass graft dysfunction or air embolism. Signs of dysfunction of the implanted device or repaired valve or vessel also should be sought carefully to support a revision. Unexpected complications such as aortic dissection or hematoma may require urgent correction. Finally, in patients in whom an intra-aortic balloon pump is required, examination of the aorta may reveal atheroma with floating debris that may lead to thromboembolic complications. Overall, IO TEE has been shown to be an essential addition to intraoperative monitoring.[46,47,58–60]

Use of Echocardiography in Cardiac Surgery

Echocardiography is used before, during, and after cardiac surgery to ensure appropriate indications for surgery, to verify the progress of the intervention, to diagnose complications, and to assess the long-term results of surgery. Preoperatively, echocardiography defines the morphology of cardiac lesions and thus often defines the etiology and mechanism of disease but also provides hemodynamic information, characterizes disease severity, and often defines markers of poor outcome. This role usually is the province of TTE, which records patient status under routine hemodynamic conditions reflective of daily-living circumstances. Intraoperative assessment is performed mostly by TEE to detect unexpected findings, verify preoperative assessment, and assess the postoperative result when hemodynamic conditions are restored (and the possible use of second bypass runs). Postoperatively, echocardiography, usually TTE, detects early complications and defines the early and long-term quality of operative result and LV function.

ECHOCARDIOGRAPHY IN SPECIFIC CARDIAC DISEASES TREATED BY CARDIAC SURGERY

The diagnostic value of echocardiography pre-, intra-, and postoperatively depends on the type of cardiac disease.

Valve Diseases

Native valve disease

Preoperatively, it is essential that echocardiography sequentially reports valvular disease etiology, specific mechanism, and valve dysfunction type and severity (e.g., rheumatic disease with valvular retraction, mixed mitral valve disease with severe mitral regurgitation and mild mitral stenosis), as well as the associated ventricular and atrial alterations that may affect treatment.

MITRAL VALVE DISEASES: Mitral valve diseases are now dominated by mitral regurgitation owing to degenerative diseases and by functional regurgitation owing to primary LV disease, which are approached quite differently clinically.

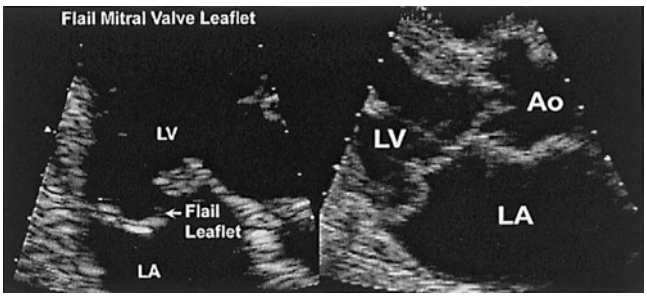

Figure 11-3. Examples of morphologic examination of organic mitral regurgitation in transthoracic echocardiography. (*Left*) The patient has a flail segment of the posterior leaflet with marked gap between the anterior and posterior leaflets during systole and the tip of the posterior leaflet in the left atrium. (*Right*) Simple mitral valve prolapse (or billowing mitral valve) shows posterior movement of the leaflet in the left atrium but no gap between the leaflets, and the tip of the posterior leaflet remains in the left ventricle in systole. Ao = aorta; LV = left ventricle; LA = left atrium; MVP = mitral valve prolapse.

ORGANIC MITRAL REGURGITATION

PREOPERATIVE ASSESSMENT: ETIOLOGY AND MECHANISM: Organic mitral regurgitation results from diseases affecting the valve leaflets or supporting structures resulting in improper coaptation of the valve. Etiology and mechanism are important to define because these determine reparability, which is an essential determinant of improved outcome.[61] TTE usually can determine organic mitral regurgitation etiology (Fig. 11-3), the most frequent of which is degenerative myxomatous mitral valve disease with prolapse (with oe without flail segment) or fibroelastic degeneration of the mitral leaflets generally associated with primary flail leaflet or annular (with or without valvular) calcification.[62,63] The distinction between the diffusely myxomatous valve and fibroelastic degeneration is not accepted by all investigators, but the echocardiographic presentation usually is strikingly different with diffuse valve thickening and excess tissue (hooding) in the former, whereas the latter is characterized by a normal-appearing leaflet apart from in the flail segment. Rheumatic valves are characterized echocardiographically by thickening (with distal predominance) and valve retraction leading to shortened (sometimes absent) coaptation and limited mobility of leaflets (particularly the posterior leaflet). These rheumatic lesions are difficult to distinguish from those due to lupus, anticardiolipin syndrome, radiation, or drugs (diet pills or ergot).[64] Endocarditis creates destructive lesions with, in addition to vegetations, ruptured chordae or perforations. Cleft anterior leaflets are rare and easily recognized in short-axis views, but smaller posterior leaflet clefts may be missed. In analyzing mitral regurgitation mechanisms, Carpentier's classification[65] simplified description into three basic types based on leaflet motion—type 1: normal; type 2: excessive; and type 3: restricted motion—and on anatomic localization (two commissures and three segments by leaflet starting with A1 and P1 for the anterior and posterior leaflets close to the external commissure). Beyond these important and useful

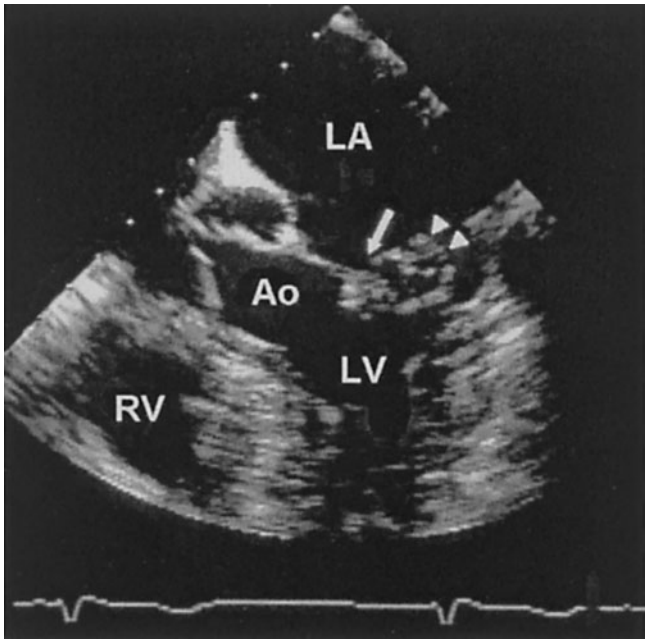

Figure 11-4. Morphologic examination of organic mitral regurgitation in transesophageal echocardiography. The patients presents with a flail posterior leaflet imaged in a long-axis view. The long arrow shows the ruptured chorda of the posterior leaflet. The arrowheads show the flail segment of P_2. Ao = aorta; LV = left ventricle; LA = left atrium; RV = right ventricle.

classifications, a detailed description should be provided by echocardiography (e.g., for an endocarditic etiology, mechanisms can be type 1, perforation, located on A2, for example, versus type 2, ruptured chordae, located on P3). Complete etiology and mechanism description usually is obtained by TTE (85 to 90% in our institution) and is supported by the direction of jets,[66] but it may require TEE (Fig. 11-4). In operated patients, TEE currently is used widely (pre- or intraoperatively) so that the correspondence of echocardiographic view with anatomic presentation is important to memorize. In the midesophageal position, the electronic dial can draw a 180-degree inspection arc and can render a complete anatomic mitral valve examination.[67–69] Evaluation of the mitral valve with the transgastric short-axis approach is difficult but may confirm the location of defects.[70] Color-flow imaging, by showing where the flow convergence is located and by showing the initial direction of the jet, is useful to confirm mitral regurgitation mechanism.[66] This complete etiologic and mechanistic analysis is particularly important for each surgeon to define the probability of valve repair in view of the lesions. Degenerative lesions, unless extensive annular calcification is present, are particularly susceptible to repair, which provides the best postoperative outcome.[62,63]

PREOPERATIVE ASSESSMENT: VALVE DYSFUNCTION SEVERITY: Color-flow Doppler alerts to the presence of mitral regurgitation[71] (Figs. 11-5 and 11-6), but estimation of the severity of mitral regurgitation should rely on comprehensive assessment (Fig. 11-7) based on American Society of Echocardiography criteria[16] and not just on jet extent in the left atrium because jet constraints by the LA wall make this measurement unreliable.[72,73] The signs of severe mitral regurgitation are classified as specific (e.g, flail, large flow convergence, large vena contracta, and pulmonary flow reversal), supportive (e.g., dense jet, high E velocity, and enlarged left ventricle and left atrium), and quantitative (e.g., regurgitant volume ≥ 60 mL and effective regurgitant orifice ≥ 40 mm^2). It is important to note that pulmonary venous

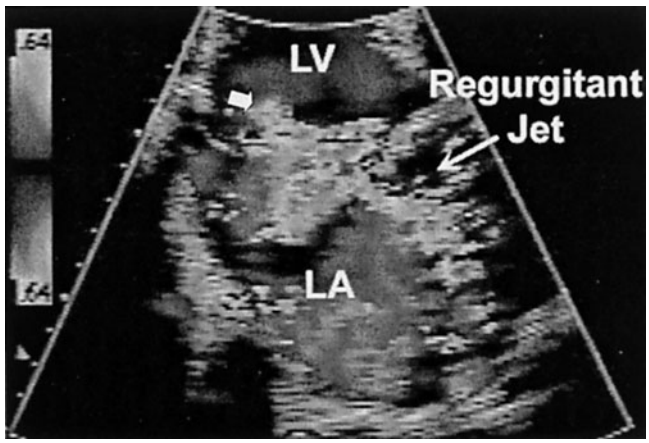

Figure 11-5. Eccentric jet of mitral regurgitation (MR) seen as a thin layer of color, with aliasing appearing as a mosaic color in the left atrium (LA). MR severity is often underestimated with this type of jet, but visualization of a large flow convergence (*large arrow*) in the left ventricle (LV) suggests severe MR.

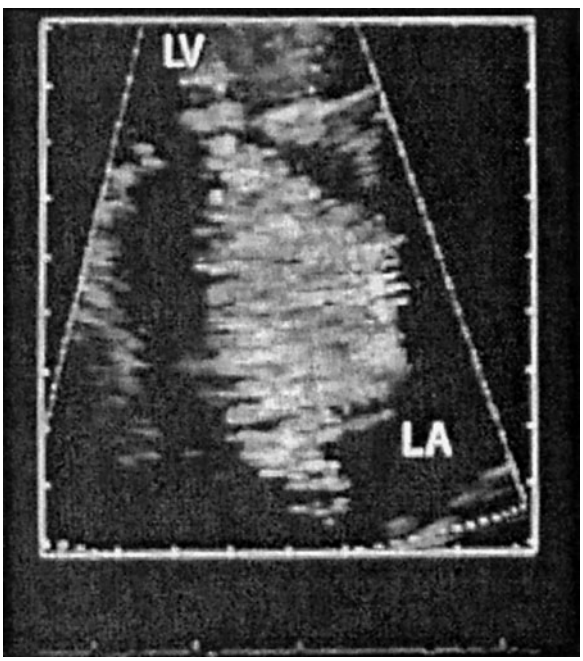

Figure 11-6. Central jet of mitral regurgitation (MR) seen as a large area of mosaic flow in the left atrium (LA). MR severity often is overestimated with this type of jet. LV = left ventricle.

Table 11–1.

Qualitative Signs of Severe Valve Regurgitation

	AR	MR	TR
Specific signs	• Central jets of width ≥65% of LVOT • Vena contracta >0.6 cm	• Vena contracta ≥0.7 cm with large central jet or swirling eccentric jet • Large flow convergence • Systolic reversal in pulmonary veins • Flail leaflet or ruptured papillary muscle	• Flail, incomplete coaptation • Central jet with area ≥10 cm^2 • Vena contracta >0.7 cm • Systolic reversal in hepatic veins
Supportive signs	• PHT <200 msec • Holodiastolic aortic reversal • ≥moderate LV enlargement	• Dense triangular jet by CWD • E-wave dominant • Enlarged LV and LA	• Dense triangular jet by CWD • Large flow convergence • EnlargedRV

CWD, continuous wave Doppler; LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract; PHT, pressure half time; RV, Right ventricle

flow systolic blunting is not interchangeable with reversal; blunting can be seen in all grades of mitral regurgitation and has a very low predictive value for the severity of mitral regurgitation.[74,75] The suboptimal sensitivity of pulmonary vein flow reversal is another reason that highlights the importance of quantifying mitral regurgitation[75] (Fig. 11-8).

Quantitative methods derived from PISA, quantitative Doppler (Fig. 11-9), and quantitative 2-D echocardiography (LV volumes) have been validated extensively in mitral regurgitation.[14,15,76–79] Although surgery is mostly reserved for patients with severe mitral regurgitation, the severity of the regurgitation is a continuum better quantified than categorized.[80] Mitral regurgitation severity tends to progress by 5 to 7 mL per beat of regurgitant volume per year,[81] so patients who are not operated on immediately should be monitored regularly. As indicated in the guidelines, acquiring proficiency in quantification of the degree of mitral regurgitation in an important step in developing advanced valve centers.

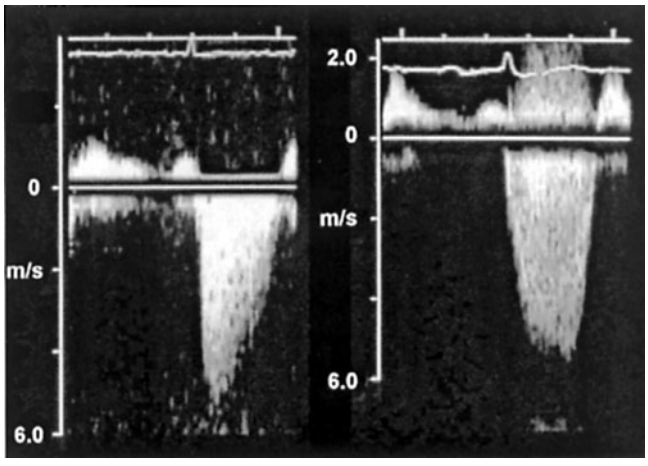

Figure 11-7. Continuous-wave Doppler of mitral regurgitant (MR) jets. (*Left*) The jet is holosystolic, but the peak velocity is reached during the first half of systole, suggesting the existence of a large *v* wave on the left atrial pressure, which leads to rapid equalization of pressure between ventricle and atrium. This type of jet is seen often in acute MR. (*Right*) The jet is also holosystolic, but the peak velocity is reached in middle to late systole without late effacement of velocity. This type of jet is seen often in patients with chronic MR without a large *v* wave.

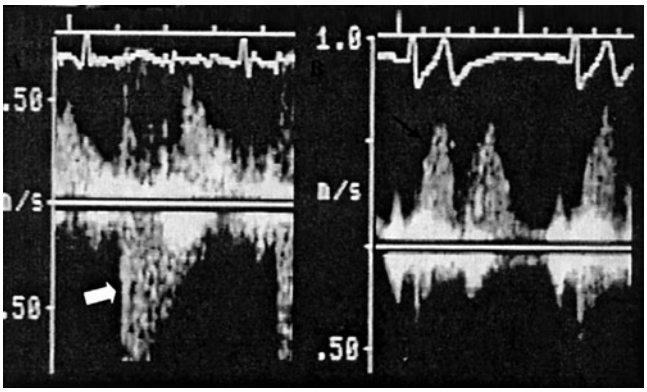

Figure 11-8. Pulsed-wave Doppler of pulmonary venous flow in two cases of mitral regurgitation. (*Left*) There a systolic flow reversal (negative flow in systole, *large arrow*) consistent with severe mitral regurgitation (MR) and a large *v* wave on the left atrial pressure. (*Right*) There is a normal forward flow (positive flow in systole, *thin arrow*) suggestive of the absence of a *v* wave. The systolic pulmonary venous flow reversal is a specific sign with high positive predictive value but of low sensitivity for severe MR.

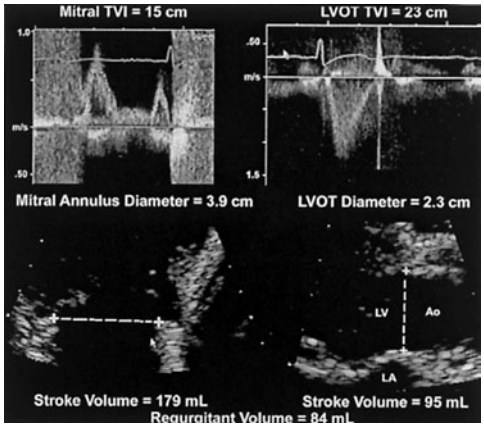

Figure 11-9. Quantitative Doppler assessment of mitral regurgitation (MR) based on stroke volume measurement using the annular diameter to calculate the annular area and its product with the pulsed-wave Doppler as the stroke volume traversing the specific annular area. The left part of the figure measures the mitral stroke volume (179 mL/beat), whereas the right side measures the aortic stroke volume (95 mL/beat). Thus the regurgitant volume is calculated as the difference between mitral and aortic stroke volumes, or 84 mL/beat.

PREOPERATIVE ASSESSMENT: PROGNOSTIC INDICATORS: Assessment of the left ventricule usually is performed by measuring LV diameters and ejection fraction.[82] End-systolic diameter of 40 to 45 mm or more[83–85] and ejection fraction of less than 60%[86,87] are markers of poor outcome. These characteristics are considered class I indications for surgery, but the postoperative outcome when these characteristics are observed[86] is not optimal, so these markers should be considered as advanced signs indicating rescue surgery. LA diameter of 50 mm or more is associated with high risk of subsequent atrial fibrillation under medical management[88] but also after successful surgery.[89] Therefore, LA dilatation should alert the clinician early for the need for surgery. Pulmonary hypertension is considered a marker of poorly tolerated mitral regurgitation, although its association with subsequent prognosis is uncertain.[82] Mitral regurgitation severity assessment is essential for prognosis.[90] Although assessment of mitral regurgitation may be qualitative, quantitation provides stronger prognostic information.[91] In asymptomatic patients with organic, holosystolic mitral regurgitation,[91] the risk of death under medical management increased by 18% for each 10 mm^2 of effective regurgitant orifice (ERO). ERO was the strongest echocardiographic predictor of outcome. With an ERO of 40 mm^2 or more, the risk of death is multiplied by 5 and that of cardiac events by 8 compared with mild mitral regurgitation, and excess mortality is observed as compared with the general population. Importantly, surgery restores life expectancy in these asymptomatic patients. Therefore, echocardiographic data participate importantly to the indication for surgery.

INTRA-OPERATIVE ASSESSMENT: Before cardiopulmonary bypass, TEE confirms the mitral lesions[62,66,92,93] but also identifies associated conditions that may benefit from surgical therapy (e.g., patent foramen ovale and appendage or LA thrombus). Whether the valve is amenable to repair should be resolved preoperatively,[62,63] but rarely, there are surprises regarding the extent or type of lesion that may lead to a change in strategy.[94,95] After cardiopulmonary bypass, intraoperative TEE assesses the result of mitral valve repair[96] and the need for a second pump run based on the presence of residual mitral regurgitation. The timing of evaluation is essential. Postbypass TEE performed too early with inappropriate loading conditions will result in faulty assessment of residual mitral regurgitation. Insufficient preload and low ventricular pressure result in a decline of regurgitant orifices and underestimation of residual mitral regurgitation. When performed adequately, excellent correlation between post-bypass TEE and pre-discharge assessment of residual mitral regurgitation is observed.[97] It is essential not to tolerate mitral regurgitation after bypass, unless very trivial, because more patients with or without residual mitral regurgitation require reoperation during follow-up.[98] Thus post–cardiopulmonary bypass IO TEE serves as a tool in deciding which patient should return to cardiopulmonary bypass for a second repair or replacement. Over time, surgical management of anterior leaflet pathology and bileaflet prolapse has evolved,[99–102] and new techniques have emerged that provide better results. IO TEE still plays a pivotal role in adequate identification of mechanisms and anatomic location of disease as well as post–cardiopulmonary bypass evaluation of results.

After mitral valve repair, major repair failures are threefold: insufficient correction of the mitral lesion with residual mitral regurgitation (e.g., residual prolapse) and LV outflow tract obstruction by systolic anterior motion of the mitral apparatus owing to inadequate repair or stenotic repair. Severe residual mitral regurgitation obviously is rare but requires immediate correction. Observation of milder residual mitral regurgitation by IO TEE immediately after repair[103] with "less than echo-perfect"[104] result leads to higher long-term reoperation risk for mitral regurgitation.[98] It is essential to define by IO TEE the mechanisms and anatomic location of the defect causing residual mitral regurgitation to establish the best correction strategy and the possibility of re-repair. LV outflow tract obstruction is due to systolic anterior motion of the mitral valve with contact with the LV septum, to which contribute excess or deformed mitral tissue, small LV size, and hyperdynamic LV function.[105] LV outflow tract obstruction occurs in 1 to 4% of mitral valve repairs[106–108] and is diagnosed by visualization of the systolic motion combined with increased velocity through the LV outflow tract. LV outflow tract obstruction results generally in notable residual mitral regurgitation owing to the deformation of the mitral valve in systole, and it is essential in patients with residual mitral regurgitation to rule out LV outflow tract obstruction before recommending a second pump run.[96] Usually, increasing LV filling, reducing or discontinuing inotropic drug administration, and in some cases adding beta blockers result in elimination of LV

obstruction.[96] If the obstruction persists, consideration should be given to a second cardiopulmonary bypass run for sliding valvuloplasty, although the systolic anterior motion tends to improve over time,[106] and most patients can be managed medically. Prevention of LV outflow tract obstruction is based on careful examination of excess tissue on prebypass IO TEE[109,110] to select the patients who may benefit from specific repair techniques such as sliding annuloplasty.[108,111,112] Markedly restrictive repairs with stenosis result from the combination of anatomic alterations such as diseased, rigid leaflets (e.g., rheumatic), commissural fusion, or markedly protruding calcification of the mitral annulus, with excessive repairs involving rings too small and/or large edge-to-edge sutures. Diagnosis is based on high transvalvular gradients of 8 to 10 mm Hg or more by Doppler. Normal postrepair gradients (3 to 6 mm Hg) may be exacerbated by high output and tachycardia reducing the diastolic filling period. It is thus prudent before a second pump run to reassess the mitral gradient after cardiac output has stabilized and administration of beta blockers to control tachycardia.

The most common immediate complications after mitral valve replacement are periprosthetic leaks and mechanical dysfunction of the prosthesis owing to interaction of tissue remnants with the mobile elements of the prosthesis.[113,114] In contrast to TTE, TEE has no shadowing from the mitral prosthesis,[115] so periprosthetic mitral regurgitation should be sought carefully after bypass, and that which is clinically relevant should be distinguished from the minor paravalvular[116] or intravalvular[117,118] leaks often noted. Diagnosis is quite accurate and should lead to prompt consideration of a second pump run,[115,119] particularly if the paravalvular leak persists after protamine administration.[120] The location and severity assessment of the leak are critical information to evaluate in multiple planes to enhance the probability of a simple repair of the leak avoiding dismounting the prosthesis. The mobile prosthetic element or leaflet can be impinged on by suture or valve material, leading to obstruction or most often regurgitation, which sometimes can vary from beat to beat owing to a variable interaction. Thus it is important to examine the mobile element in 2-D and color-flow images for a sufficient time to ensure consistent and appropriate function.

POSTOPERATIVE ASSESSMENT: VALVULAR RESULT: Postoperative assessment is performed consistently at predischarge and yearly and often in our practice 3 to 6 months postoperatively. While the IO TEE is quite accurate in the assessment of residual valve dysfunction, changes in loading conditions and remodeling may reveal changes in valvular function. The rate of recurrence of mitral regurgitation after valve repair is 5 to 10% at 10 years[98,99] and is due in two-thirds of patients to new valve lesions (e.g., new ruptured chordae), whereas in one-third it is due to defective repair (e.g., insufficiently corrected prolapse of the anterior leaflet in bileaflet prolapse).[121] TTE provides the mechanism and location of the mitral regurgitation and allows discussion of the possibility of re-repair. It also allows assessment of mitral regurgitation severity. Qualitative assessment of mitral regurgitation is even more difficult after than before repair, and quantitative techniques (particularly the PISA method) are of particular importance. We rarely refer patients with moderate regurgitant volumes (30 to 60 mL/beat) for reoperation. Development of stenotic repair is rare and is observed mostly with rheumatic or rigid leaflets, sometimes after edge-to-edge repair. Standard repair represents a mild stenosis but, in combination with an enlarged left atrium, may lead to new atrial fibrillation[89] and thrombus formation with possible stroke, for which TEE allows thorough examination of the LA appendage. New dysfunction of a mitral prosthesis often requires TEE examination, particularly for detection of prosthetic thrombosis or tissue degeneration.

LEFT VENTRICULAR ASSESSMENT: After surgical correction of mitral regurgitation, preload is decreased with decline of end-diastolic volume, but end-systolic indices are little changed, so ejection fraction falls by an average of 10%.[85,122] However, there is a large individual variation, and changes in LV function with changes in LV reverse remodeling may be quite different between patients. There are no definite predictors of the changes in LV end-systolic indices, which need to be monitored closely during the first postoperative year.[84] The value of medical therapies shown to result in reverse remodeling in patients with primary LV dysfunction (e.g., beta blockers and angiotensin-converting enzyme inhibitors) is not established, but early diagnosis may lead to early intervention. Irrespective, residual postoperative LV ejection fraction is an important predictor of postoperative survival and should be monitored. The result seen early after surgery usually is stable unless marked LV dilatation results in further dysfunction or coronary artery disease leads to intrinsic myocardial deterioration.[123]

FUNCTIONAL MITRAL VALVE REGURGITATION: Functional mitral regurgitation is the regurgitation occurring on structurally normal valves owing to primary LV alteration, such as those due to coronary artery disease, cardiomyopathy, myocarditis, or transient LV dysfunction.[124] Although the disease is primarily myocardial, functional mitral regurgitation diagnosed by angiography[125] or echocardiography[126–129] exerts an important influence on outcome, but major controversy persists regarding the role of mitral surgery in these patients.[130,131]

PREOPERATIVE ASSESSMENT: The diagnosis of functional mitral regurgitation is based on the presence of LV dysfunction (generalized most often but sometimes localized, requiring a thorough regional assessment) and on a structurally "normal" mitral valve with normal tissue or at most minor degenerative calcifications (Fig. 11-10). It is also important to demonstrate the deformation of the mitral valve leading to functional mitral regurgitation. There is apical and posterior displacement of the papillary muscles with traction through the inextensible chordae on both leaflets, which

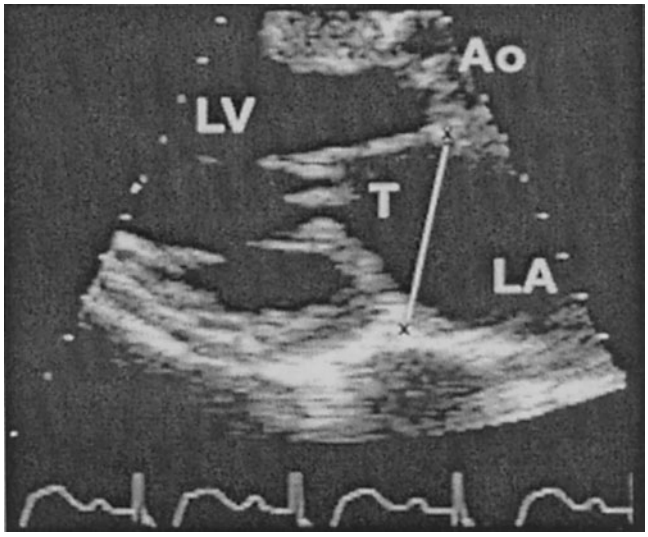

Figure 11-10. Two-dimensional echocardiography showing the parasternal long-axis view of a patient with functional mitral regurgitation (MR). Note the protrusion of the mitral leaflets toward the left ventricle (LV), resulting in a large tenting area (T) between the leaflets and the annulus (white line with x marking the mitral annulus) and an insufficient coaptation surface available on each leaflet to prevent MR. LA = left atrium; Ao = aorta. (*Reproduced with permission of the American Heart Association.*)

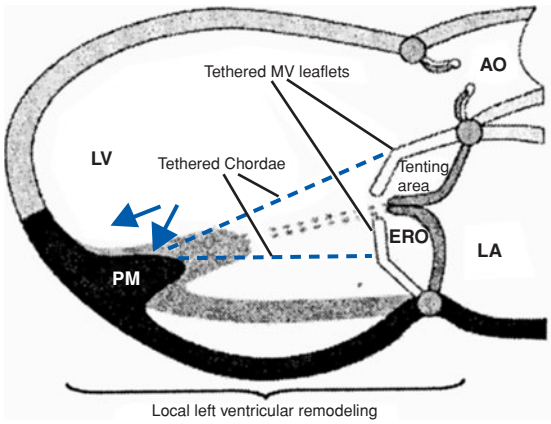

Figure 11-11. Schematic representation of the mechanism of functional mitral regurgitation (MR). In light gray is represented the normal position of the papillary muscle (PM) chordae (*dashed lines*) and mitral leaflets shown with adequate coaptation surface. With local left ventricular (LV) remodeling, the papillary muscle is repositioned apically and posteriorly (*dark gray*) and exerts traction through the nondistensible chordae on the leaflets. Traction on the strut chords (inserted on the midportion of each leaflet) is most manifest, leading to deformation of the mitral leaflet, tenting, reduced coaptation, and creation of an effective regurgitant orifice (ERO). LA = left atrium; Ao = aorta.

results in apical displacement of the leaflet body leading to absent or reduced coaptation to the leaflet tipS.[132,133] This deformation of normal leaflets, called *tenting,* is the direct determinant of the functional severity of the mitral regurgitation. The mechanism of mitral regurgitation usually is a central gap in coaptation, usually worse during isovolumic contraction and relaxation, when the left ventricle exerts a low pressure on the leaflets.[134] With ischemic LV dysfunction, the mitral regurgitation may originate from the medial commissure, where the traction may be predominant,[135] but apart from scars from myocardial infarction, there are no specific sign of ischemic versus myopathic mitral regurgitation. The traction of the chords on the leaflets may be inhomogeneous and predominate on one leaflet.[136] In such cases, an "overshoot" of the other, less tethered leaflet behind the tethered leaflet is observed, should not be mistaken for a prolapse, and may lead to unusual eccentric jets.[137] Therefore, the mechanism of functional mitral regurgitation is not just the frequent annular dilatation but is more complex, involving a combination of annular and leaflet tethering alterations (Fig. 11-11). Mitral regurgitation severity assessment is particularly crucial in view of the notable surgical risk (Table 11-2). Mitral regurgitation jets that are central tend to be overestimated, and diastolic function alterations may mimic the tall E wave, low systolic venous flow, usually suggestive of severe mitral regurgitation. Thus it is essential to quantify the mitral regurgitation, but two essential issues need to be examined. First, functional mitral regurgitation is prominent during isovolumic contraction and relaxation,[134] but since these phases involve little regurgitant driving force, their contribution to the regurgitant volume is small, and it is essential with the PISA method to quantify mitral regurgitation in midsystole. Second, the grading of mitral regurgitation has been established in organic mitral regurgitation, but recent data[26,127,138] suggest that thresholds of effective regurgitant orifice (ERO) associated with poor outcome are lower in functional than in organic mitral regurgitation. Thus, pending further

Table 11–2.

Quantitative Thresholds for Severe Regurgitation

	AR	Organic MR	Functional MR	TR
ERO	≥0.30 cm^2	≥0.40 cm^2	≥0.20 cm^2	≥0.40 cm^2
RVol	≥60 mL	≥60 mL	≥30 mL	≥45 mL

confirmation, patients with functional mitral regurgitation and an ERO of 20 mm^2 or greater should be considered as having severe mitral regurgitation, and this prognostic effect comes in addition to ejection fraction and left atrial volume.[139] Also, functional mitral regurgitation is dynamic, and ERO often increases during exercise, which may have important functional[140] and outcome[26] implications, but decreases during dobutamine echocardiography,[141] making this test useless for the assessment of functional mitral regurgitation. While the role of imaging during exercise in defining the surgical indications needs further evaluation, a dynamic ERO also may decrease with interventions such as vasodilatation[142] or beta blockade.[143,144] Not surprisingly, sedation or anesthesia necessary for TEE may result in regression of mitral regurgitation and underestimation of the degree of mitral regurgitation[145] compared with habitual life conditions. Preoperative assessment of functional mitral regurgitation should assess not only the mitral regurgitation but also other components of the disease, namely, LV remodeling, systolic dysfunction, and diastolic dysfunction, because severe LV remodeling may be a marker for poor response to valve repair.[146]

INTRAOPERATIVE ASSESSMENT: Before bypass, it is essential to confirm the structural normality of the mitral leaflet and to avoid the pitfall in the assessment of mitral regurgitation of reduced loading owing to anesthesia. Thus, if the degree of mitral regurgitation is in doubt, assessment with increasing loading conditions similar to those of outpatient evaluation should be performed by a loading challenge,[147] but this does not replace an appropriate outpatient evaluation. Postbypass IO TEE evaluates residual mitral regurgitation. After repair, reduced loading conditions may lead to major underestimation of residual functional mitral regurgitation, emphasizing the importance of adjusting pre- and afterload. Functional mitral regurgitation is particularly prone to recurring after surgical correction owing to continued LV remodeling, continued displacement of papillary muscles, and mitral valve tenting[148,149] despite a repair judged as adequate intraoperatively. Thus postbypass assessment is difficult and may be overly optimistic, and a careful judgment of residual tenting and valve deformation is essential. Contrary to organic mitral regurgitation, the most advanced subsets of patients benefit as much from bioprosthetic replacement as they do from repair.[150] Thus doubts on repair quality should be pursued aggressively to decide if a new pump run and valve replacement should be recommended.

POST-OPERATIVE ASSESSMENT: Postoperative assessment focuses on potential recurrence of mitral regurgitation, which has been reported as rare[151] or frequent in various clinical series, and on its mechanism, if present (increased tenting versus insufficient annular restriction).[130,148] Postoperative mitral regurgitation also should be quantified if more than mild. Beyond mitral regurgitation, echocardiography focuses on the assessment of LV dysfunction, its systolic and diastolic components, and its consequences on LA and pulmonary pressures. Active prevention of further LV remodeling is recommended and should be monitored by echocardiography.[143,144]

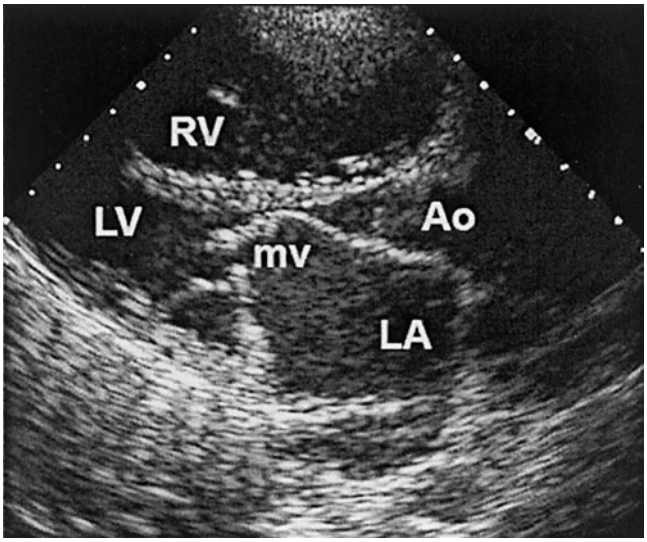

Figure 11-12. Parasternal long-axis view of a patient with mitral stenosis. Note the thickening and hockey-stick deformation of the anterior leaflet of the mitral valve (mv) and the protrusion of the posterior leaflet. Note also the normal left ventricle (LV) contrasting with the enlarged left atrium (LA) and right ventricle (RV). Ao = aorta.

MITRAL VALVE STENOSIS: Mitral stenosis is currently treated preferentially by balloon valvuloplasty,[152] so the role of surgery is relatively limited at present. However, there are patients who benefit from surgery rather than balloon valvuloplasty, so the role of echocardiography in defining these subsets should be examined carefully.

PREOPERATIVE EVALUATION: Classic mitral stenosis (MS) is invariably due to rheumatic valve disease, and its features are characteristic (e.g., immobile posterior leaflet, fused commissures with reduced orifice area, and hockey-stick deformation of the anterior leaflet in diastole)(Fig. 11-12). Other causes of stenosis are lupus and anticardiolipin heart diseases (producing very similar lesions), ergot heart disease,[153] and other iatrogenic valve diseases that thicken leaflets without fusing commissures and produce protruding annular calcifications that restrict the orifice without commissural fusion.[154] Anatomic analysis is essential because balloon valvuloplasty is the most widely used procedure to treat MS and produces a commissurotomy identical to closed commissurotomy (hemicommissurotomy in most cases). Therefore, balloon valvuloplasty is not indicated in (1) mitral valve obstructions without commissural fusion, (2) heavily calcified mitral valves, (3) MS with nodular calcification involving both commissures (high risk of splitting the leaflet and not the commissures),[155] and (4) MS associated with more than mild mitral regurgitation. In such cases, the best treatment is surgical valve replacement. Thus an essential component of the

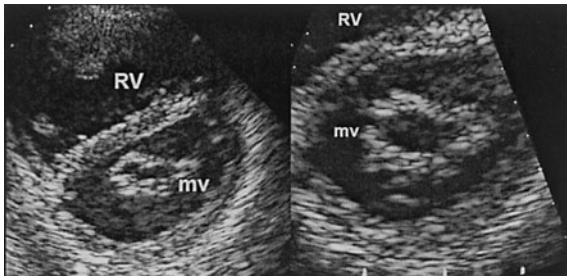

Figure 11-13. Mitral valve (mv) area of a patient with mitral stenosis (MS) before (*left*) and after (*right*) commissurotomy. Note in the panel on the right the narrow orifice and in the panel on the left the large orifice with wide opening of the medial commissure. Note also in the panel on the left the right ventricular (RV) enlargement with signs of pulmonary hypertension manifested by a flat septum and D-shaped left ventricle. In the panel on the right, the position of the septum and the shape of the left ventricle have normalized.

echocardiographic assessment of MS is the short-axis view to ascertain the presence of commissural fusion and the severity and location of leaflet calcifications.[155] Another important component of decision making is alteration of the subvalvular apparatus.[29,156] Very short chordae or direct insertion of papillary muscle on the leaflets may lead to poor results with balloon valvuloplasty but may allow good surgical splitting of the commissures and the papillary muscles. MS severity is assessed using two variables: the transvalvular gradient, representing the pressure overload to the LA and pulmonary circulation, and the mitral valve area (MVA) (Fig. 11-13). The gradient measured is the mean gradient (Fig. 11-14) and not only is affected by the severity of the stenosis but also is increased by tachycardia and increased transvalvular flow (e.g., anemia, pregnancy, hyperthyroidism, and

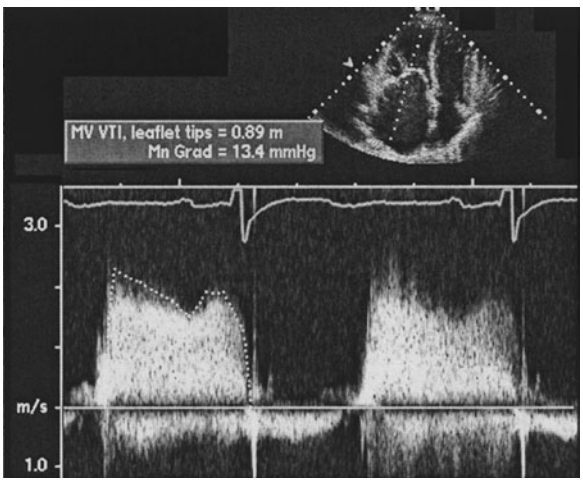

Figure 11-14. Continuous-wave Doppler recording of the mitral gradient in a patient with severe mitral stenosis (MS). Note the high velocity (≥2 m/s) with a mean gradient of more than 13 mm Hg. Note also the flat slope of deceleration of the early diastolic velocity consistent with severe MS.

associated mitral regurgitation) and decreased by bradycardia and low cardiac output. Mild MS is associated with a resting mean diastolic Doppler gradient (measured by continuous-wave Doppler) of 5 mm Hg or less; moderate, with a gradient of 5 to 10 mm Hg; and severe, with a gradient of 10 mm Hg or greater. The normal MVA is 4 to 6 cm^2, and guidelines for MS severity suggest thresholds of 2.0 cm^2 for mild MS, 1.5 cm^2 for moderate MS, and 1.0 cm^2 for severe MS. However, most patients undergoing interventions for MS are in the range of 1 to 1.2 cm^2 and symptomatic, so in our institution, an MVA of less than 1.5 cm^2 is considered severe MS. MS severity assessment also involves LA enlargement and elevation of pulmonary pressure and in time also may involve right-sided heart enlargement and failure and tricuspid regurgitation, whereas the levt ventricle remains of normal size but may show reduced ejection fraction. MVA measurement can be obtained by several methods that are combined because all methods have limitations, and averaging reduces the risk of error. The pressure half-time (PHT) method is the simplest, where the PHT is measured from the Doppler mitral signal using the deceleration from the peak early velocity and calculates MVA using the empirical formula 220/PHT.[157] However, this method may not be accurate in the presence of changes in LV or LA compliance and has a wide range of error with short diastole.[158] Other methods of MVA measurement are (1) direct planimetry of the orifice in short-axis view (technically demanding), (2) a continuity equation in which MVA is calculated as the ratio of flow measured on the aortic valve to mitral velocity (false if mitral regurgitation or atrial regurgitation is present), and (3) the PISA method, imaging of mitral inflow with color using baseline shift (requires an angle correction for the funnel shape of the mitral valve with potential for error).[159,160] Important issues in MS severity assessment are (1) the essential combination of methods of MVA assessment to minimize the potential for error and (2) the need for exercise hemodynamic assessment (with bike allowing continuous hemodynamic monitoring) in patients who present with a low gradient and doubt on MS severity. Thus TTE should provide definite assessment of MS severity and in most cases is the procedure most suited for treatment.[161] Outpatient TEE is systematic in patients considered for balloon valvuloplasty to assess the presence of LA thrombus and mitral regurgitation. If surgery is definitely indicated, TEE can be performed intraoperatively.

INTRAOPERATIVE ASSESSMENT: Intraoperative assessment in patients with MS is most often that of mitral replacement, but in patients suited for open commissurotomy, it provides anatomic and mitral regurgitation reassessment before bypass and repair assessment postoperatively. A high gradient or moderate mitral regurgitation may lead to consideration of a second pump run after mitral valve repair. Mobile element dysfunction or periprosthetic regurgitation suggest consideration of further correction after valve replacement. Although decisions with regard to repair of tricuspid regurgitation should be made preoperatively, IO TEE allows

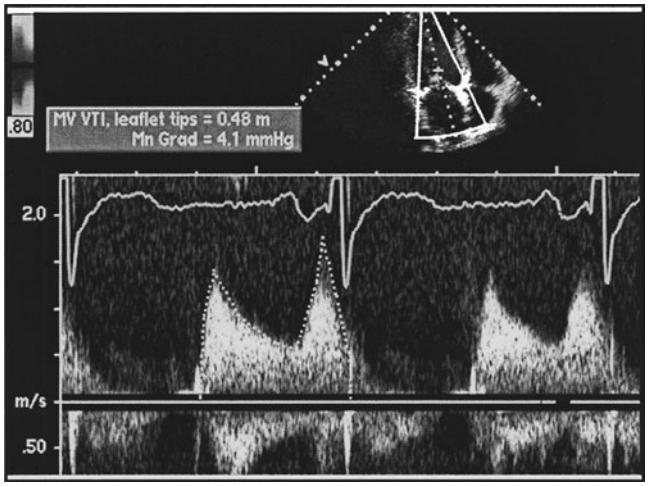

Figure 11-15. Continuous-wave Doppler in the same patient as in Fig. 11-13 after commissurotomy. The mean gradient is now low, with rapid deceleration of early diastolic velocity consistent with mild MS.

reassessment, rarely discovery of organic tricuspid lesions, and consideration of repair of associated moderate or severe regurgitation.

POST-PROCEDURE ASSESSMENT: Postprocedure assessment follows the usual postoperative and 1-year assessments (Fig. 11-15). MS remains a progressive lesion even after valve repair, and there is the potential for recurrence of severe MS and also for progressive scarring and retraction of the mitral valve, leading to progression of mitral regurgitation.[162] Depending on the severity of the mitral lesions, age, and mitral regurgitation, a notable proportion of patients will need reoperation between 5 and 10 years after the original intervention (balloon valvuloplasty or valve repair). Patients should be monitored carefully to avoid progressive heart failure and pulmonary hypertension. After surgery, pulmonary hypertension owing to MS regresses almost uniformly unless chronic pulmonary disease has developed, LV dysfunction usually normalizes with normalization of preload unless coronary artery disease is present, but LA enlargement persists, and patients with atrial fibrillation remain at substantial risk for stroke.

MIXED MITRAL VALVE DISEASE: Mixed mitral valve diseases are those with substantial components of stenosis and regurgitation, and most are due to rheumatic disease. Therefore, this type of situation is rare in Western countries but continues to be prevalent in developing countries.

PREOPERATIVE ASSESSMENT: Preoperative assessment recognizes the rheumatic valve lesions and the combination of stenosis and regurgitation precluding the possibility of valve repair. The major challenge is to evaluate the severity of the mitral valve disease. Often the stenosis and regurgitation are both moderate, and criteria for severe valve diseases are difficult to establish. A transvalvular gradient higher than expected on the basis of MVA alone reflects the severity of the combined disease.

INTRAOPERATIVE ASSESSMENT: Intraoperative assessment confirms the rheumatic features and analyzes the absence of postoperative complications after valve replacement. Tricuspid regurgitation is frequent in mixed valve disease and often requires associated repair.

POST-OPERATIVE ASSESSMENT: This is important not only to monitor the mitral prosthesis but also to assess LV function. LV dysfunction is a frequent complication of the mitral regurgitation of mixed mitral valve diseases, so aggressive detection and treatment of this complication are essential to obtain the best outcome.

AORTIC VALVE DISEASES: These are now dominated by aortic stenosis. The aortic valve normally is formed by three cusps and is bicuspid in 1 to 2% of the population, but the physiology of the aortic valve is poorly understood irrespective of the number of cusps.

AORTIC STENOSIS

PREOPERATIVE ASSESSMENT: Preoperative assessment focuses on the etiology and mechanism, although assessment usually is simplified as compared with assessment of the mitral valve. Most aortic stenoses are due to degenerative disease irrespective of the number of cusp. Indeed, recent data have shown the association of aortic stenosis (AS) with atherosclerosis and the importance of cholesterol deposition with lipid oxidization as the initial step in aortic sclerosis and stenosis, but bicuspid valves tend to calcify more frequently than tricuspid valves for unknown reasons. Rheumatic AS is now rare and is characterized by commissural fusion, whereas commissures are open in degenerative diseases. However, clinically, the various etiologies of AS in the adult are difficult to recognize because with advanced AS, valves are uniformly calcified. Therefore, morphologically, 2-D echocardiography recognizes the valvular calcification associated with AS in the adult (Fig. 11-16). Absence of aortic valve calcification makes AS unlikely and makes a systolic gradient most likely to originate from the sub- or supravalvular region. In children, calcification is inconsistent and not indispensable to a diagnosis of AS. The degree of valvular calcification is difficult to analyze by echocardiography[163] and is measured more precisely with high-resolution computed tomography.[164] The volume or score of calcification is linked to AS severity in a nonlinear manner, so both measures are complementary in assessing AS.[164] The fact that most aortic stenoses are due to valve rigidity caused by calcification and not to commissural fusion explains the lack of efficacy of balloon valvuloplasty in AS.[3] The left ventricle responds to the pressure overload by increasing wall thickness and LV mass.[165] The hypertrophic response is variable, and its absence does not rule out severe AS. LV hypertrophy regresses after aortic valve replacement,[166–168] which is the only effective treatment of AS currently available. [82,166,169] Recent attempts at percutaneous

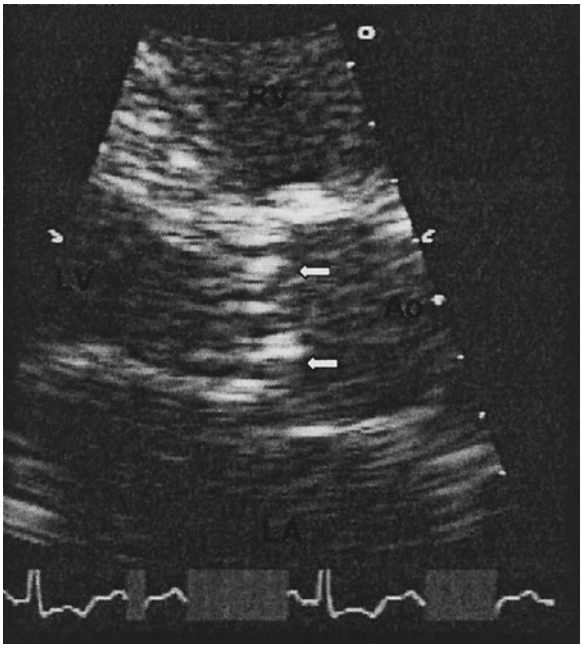

Figure 11-16. Two-dimensional echocardiography of a patient with aortic stenosis (AS). The aortic valve (*arrows*) is heavily calcified (dense nodules). LV = left ventricle; LA = left atrium; Ao = aorta, RV = right ventricle.

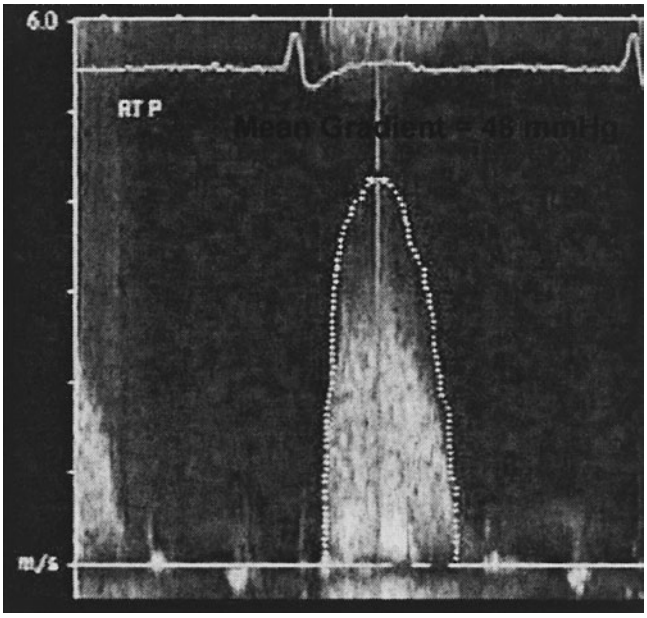

Figure 11-17. Continuous-wave Doppler obtained from the right parasternal window (RT P) in a patient with severe aortic stenosis (AS). The paek velocity is more than 4 m/s, and the mean gradient is 48 mm Hg.

aortic valve replacement have been reported, but the safety of this approach remains to be determined. Moreover, morphologic criteria to indicate such an approach have not yet been developed.[170] Another morphologic component of AS is poststenotic aortic dilatation, which rarely requires repair.

Assessment of AS severity is the major goal of TTE. Opening of even just one aortic leaflet to the aortic wall is usually a marker for nonsevere AS, but AS severity should be assessed quantitatively by measuring mean systolic gradient[8] as a marker of pressure overload and aortic valve area (AVA) to assess lesion severity.[12,13] Normal aortic valve opening area is 2.5 to 4.5 cm^2 . AS is considered present with an AVA of 2 cm^2 or less and a pressure gradient developing across the aortic valve, and AS is considered severe (Fig. 11-17) with an AVA of 1.0 cm^2 or less (using the continuity equation) and a mean gradient of 40 mm Hg or greater (using the Doppler velocity).[82] Other criteria of AS are peak velocity of 4 m/s or more[171,172] and velocity ratio (LV outflow tract to jet) of 0.25 or less.[13] Indeed, in patients with LV outflow tract obstruction, the AVA may not be measurable, and velocity may be the only available criterion to diagnose severe AS (Fig. 11-18). AS is progressive because of progressive calcium deposition, with gradient progression by 5 to 7 mm Hg per year and AVA decline by 0.1 cm^2 per year.[173–175] The major pitfall of gradient measurement is underestimation owing to excessive flow ultrasonic beam angle, so systematic multiwindow Doppler is the key to appropriate assessment of AS severity. Another pitfall is underestimation of the LV outflow tract diameter, which is necessary to the measurement of stroke volume and valve area. Such underestimation leads to underestimation of valve area. Thus the triad of normal LV function, low gradient, and low AVA is not physiologically consistent, is suggestive of inadequate echocardiographic measurements, and should lead to comprehensive reassessment in a reference laboratory. Conversely, coexistence of low gradient and low valve area is possible physiologically in patients with reduced LV function.[176–178] This combination may be due to severe AS and low gradient owing to low output secondary to poor LV function,[179] but the AVA also simply may be measured low owing to insufficiently forceful ejection to overcome a mildly stenotic valve inertia. Diagnosis of severe

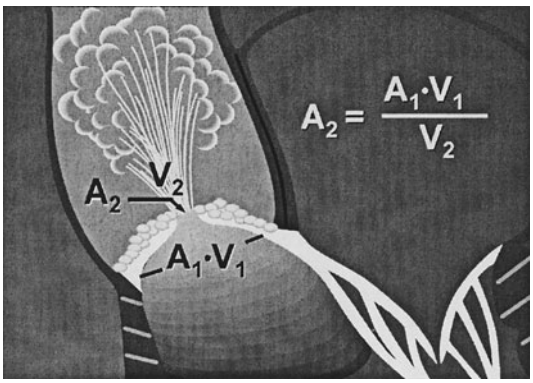

Figure 11-18. Schematics of the measurement of aortic valve area in aortic stenosis (AS). Because blood is incompressible, flow is constant through the left ventricular outflow tract (area A_1) through the aortic orifice (area A_2). Thus the aortic stenosis manifests itself by increased velocity ($V_2 > V_1$). Because flow is equal to area multiplied by velocity, aortic valve area $A_2 = (A_1^* \times V_1)/V_2$. (*Courtesy of Dr. F. A. Miller.*)

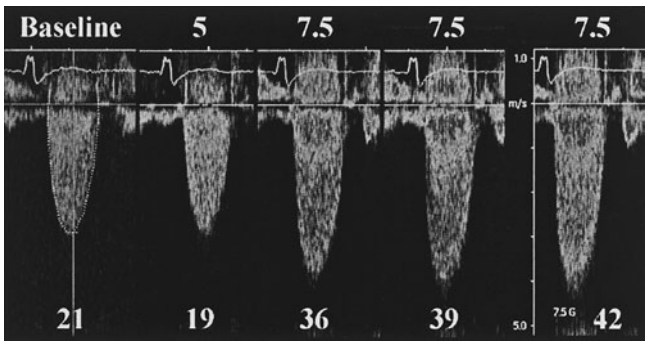

Figure 11-19. Measurement of aortic velocity by continuous wave Doppler in a patient with severe Aortic stenosis, low ejection fraction, low output and low gradient. The baseline (*left*) mean gradient was 21 mm Hg and increased (*bottom line*) with increasing doses of dobutamine (*top line*). The peak dose was 7.5 μg/min, and the mean gradient was 42 mm Hg (*Courtesy of Dr. Messika-Zeitoun.*)

AS in such patients requires additional testing with high-resolution computed tomography to measure a high calcium load[164] and with dobutamine echocardiography to increase myocardial contraction and aortic flow.[180] The classic response is an increased gradient with severe AS (Fig. 11-19) and an increased AVA with cardiomyopathy and mild AS.[176,178] However, this test may not be conclusive in patients lacking contractile response.[177]

While classically asymptomatic severe AS was considered well tolerated, recent data demonstrated excess mortality during follow-up and noted that a large proportion of patients were never offered surgery.[171] Therefore, surgery in asymptomatic patients based on echocardiographic criteria is debated. Asymptomatic patients with rapid decline in AVA and a large calcification load display poor clinical outcome under medical management[163,164] and may be considered for surgery, whereas those with reduced LV function are definitely at high risk and should be offered prompt surgery if the AS is severe.[181]

INTRAOPERATIVE ASSESSMENT: This examines the valve morphology, confirms the large calcification load, and can measure the orifice area by direct planimetry before institution of bypass.[182,183] AVA measurement by 2-D echocardiography is difficult because one has to ascertain measurement at the leaflet tip and cannot replace an appropriate Doppler hemodynamic measurement before surgery.[184] Determination of aortic annulus size may be helpful for early surgical sizing of allografts destined for the aortic position[185] or homografts[186] and may play a role in preventing patient-prosthesis mismatch, which is a cause of postoperative mortality and morbidity[187,188] and may be prevented by sizing taking into account the patient's body surface area.[189] Another important goal of IO TEE is examination of the ascending aorta and, for patients with aneurysmal dilatation, consideration of ascending aortic repair. IO TEE in patients undergoing aortic valve replacement for severe AS may alter the planned surgical procedure in approximately 10% of patients[190] for unexpected severe mitral regurgitation, patent foramen ovale, mass, or thrombus. After bypass, specific issues examined are lack of signs of dysfunction of the prosthesis and potential changes in LV function and functional mitral regurgitation. In patients with prominent LV hypertrophy, LV outflow tract obstruction may occur after aortic valve replacement and should be detected by color imaging or Doppler and verified by simultaneous intraventricular pressure measurement. Myectomy associated with valve replacement may prevent or treat the LV outflow obstruction. Attempts at measuring prosthetic gradient using a transgastric approach are of uncertain reliability, and lack of patient-prosthesis mismatch cannot be ascertained by intraoperative Doppler echocardiography currently.

POSTOPERATIVE ASSESSMENT: Postoperative assessment focuses on prosthetic, LV, and aortic evaluation. Prosthetic function is not entirely predictable on the basis of patient and prosthesis size, and the postoperative Doppler echocardiogram is essential in detecting obstruction, particularly thrombosis,[191] and in following mismatch. Reoperation, considered in limited cases for mismatch,[187] is the mainstay of treatment for prosthetic thrombosis or panus formation, all manifested by prosthetic obstruction.[192] In the diagnosis of prosthetic obstruction, it is important to consider the role of pressure recovery, which may lead to (usually slight) gradient overestimation by Doppler. The 2-D examination rarely discriminates between causes of obstruction for which the context of occurrence is more specific. Degeneration of bioprostheses is rarely observed in elderly patients currently affected by AS but is part of the yearly prosthetic monitoring. LV function usually is maintained after valve replacement for AS. Changes are observed in two circumstances. First, patients with LV dysfunction owing to critical AS generally display improvement in ejection fraction and sometimes normalization after aortic valve repair.[179] Even small improvements have important beneficial impact on outcome, but persistence of LV dysfunction requires active medical therapy. Second, patients with associated coronary artery disease may display a postoperative decline in LV function owing to the coronary artery disease despite successful aortic valve surgery. Such patients also need active echocardiographic follow-up to ensure appropriate medical treatment.[193] Ascending aortic dilatation generally stabilizes postoperatively, but the rare possibility of continued enlargement and need for repair also requires regular echocardiographic follow-up. A particularly difficult group of patients for follow-up is those with postradiation heart disease,[194] in whom cardiac disease is only part of postradiation lesions that affect the lungs with frequent persistence of postoperative symptoms. The valve disease is only part of the cardiac disease, often involving coronary lesions, conduction abnormalities, pericardial constriction, and myocardial fibrosis. These complex lesions lead to an often complex follow-up.

AORTIC REGURGITATION

PREOPERATIVE ASSESSMENT: This focuses on the etiology and mechanism in that it determines the possibility of repair.[195]

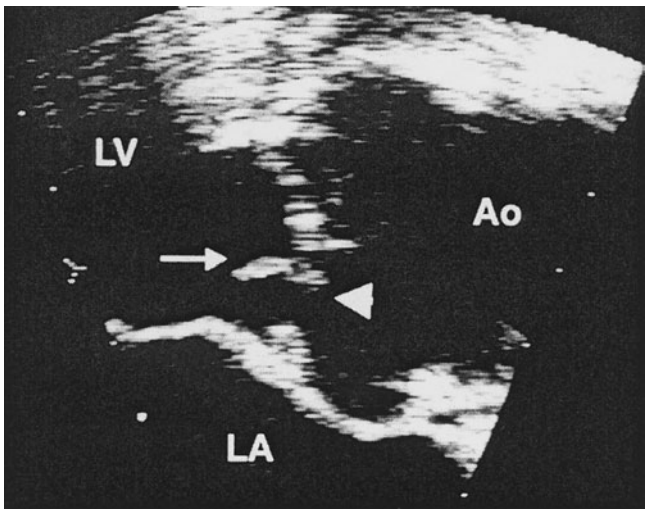

Figure 11-20. Imaging of the aortic valve in a patient with endocarditic aortic regurgitation (AR). The long arrow denotes a vegetation, whereas the arrowhead denotes a perforation of the noncoronary cusp. LA = left atrium; LV = left ventricle; Ao = aorta.

Most frequently, aortic regurgitation in Western countries is due to degenerative disease.[196,197] Minor calcifications may be noted but rarely with thickened myxomatous tissue. The aortic regurgitation is due to annular enlargement and sometimes to valve prolapse. Bicuspid aortic valve is the second cause of aortic regurgitation and leads to regurgitation by malcoaptation and sometimes prolapse of the largest cusp. Aortic root disease more often involves annuloaortic ectasia than Marfan syndrome or aortitis (such as syphilis). Rheumatic aortic regurgitation is recognized by retraction of the leaflet, leaving a central regurgitant orifice, and is rarely repairable. Endocarditis is recognized by echocardiography when vegetations are present and may require TEE (Fig. 11-20). Repair is predictable with detection of a perforation but is not possible with a calcified or retracted leaflet. Repair is also particularly feasible with a prolapsed leaflet, especially if the valve is bicuspid, or with dystrophic leaflets and moderate aortic regurgitation, where resuspension of commissures may be sufficient. Therefore, morphologic assessment should be focused on clearly defining the mechanism of aortic regurgitation.[198]

Aortic regurgitation results in both volume and pressure overload of the left ventricle, which adapts by both concentric and eccentric remodeling until a point of afterload mismatch when LV systolic function fails.[199] Assessment of LV size and systolic function by echocardiography is essential. The recommended approach is M-mode 2-D guided, but with increasing frequency, LV volumes are calculated particularly with use of contrast material injection.[200] Moderate LV dysfunction (defined as an ejection fraction of 50%) and severe LV dysfunction (ejection fraction of 35% or less) justify rescue surgery but result in decreased postoperative survival.[197] No lower limit of ejection fraction firmly contraindicates surgery. Even patients with ejection fractions of 35% or less may benefit from valve replacement. An ejection fraction of less than 55% is associated with reduced survival under medical treatment and should be strong indication for surgery before LV dysfunction affects postoperative survival. Marked LV enlargement is another indication for surgery and is uncovered by LV dimensions of 75 mm or more (end-diastolic) or 55 mm or more (end-systolic)[201] or, better, 25 mm/m^2 or more (end-systolic adjusted to body surface area)[196] because women with smaller body sizes almost never reach absolute LV sizes comparable with those of men.[202] These LV size differences lead to worse postoperative outcomes in women, emphasizing the importance of adjusting LV measures to body size.[202] Exercise changes in LV function may be helpful, but monitoring of complex variables such as wall stress limits applicability.[203]

Assessment of aortic regurgitation severity is key to the surgical indication and should be based on comprehensive integration of all signs.[16] Among qualitative approaches, color Doppler (Fig. 11-21) detects the presence of aortic regurgitation and provides simple measures of severity[204] (Fig 11-22). Vena contracta of 0.6 cm or more and a ratio of jet width to left ventricular outflow tract width of 65% or greater in parasternal long-axis view suggest severe aortic regurgitation (Fig. 11-23), but jet length does not correlate with aortic regurgitation severity.[205,206] Color Doppler has many limitations when assessing aortic regurgitation severity and is used as a gross estimation. Eccentric jet direction leads to underestimation of aortic regurgitation, and jets arising from the entire coaptation line of bicuspid valves may be overestimated. Holodiastolic flow reversal in the abdominal or descending thoracic aorta is consistent with severe aortic regurgitation[207] (Fig. 11-24). Maximum aortic regurgitation velocity (measured by continuous-wave Doppler) deceleration suggest severe aortic regurgitation with fast

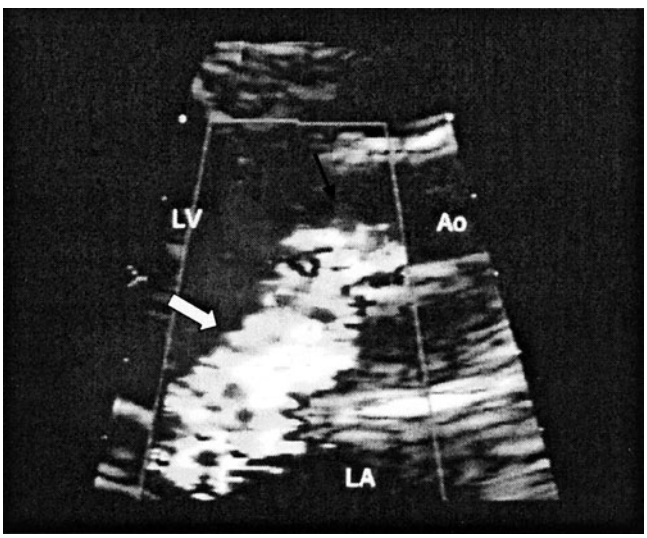

Figure 11-21. Parasternal view of aortic regurgitation (AR) using color-flow imaging. The flow convergence (*thin arrow*) and jet (*thick arrow*) are well seen. Note the limited expansion of the jet owing to its eccentricity.

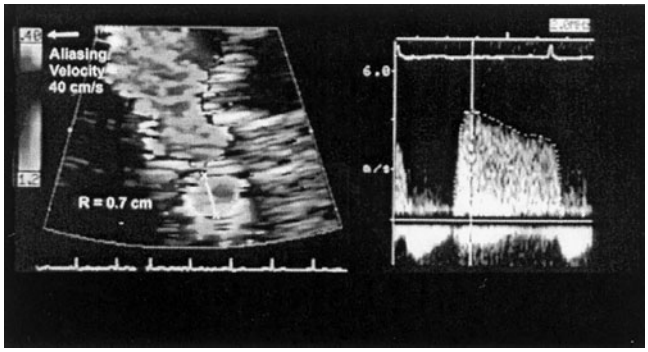

Figure 11-22. Quantitation of aortic regurgitation (AR) using the proximal isovelocity surface area (PISA) method. Note that the color baseline is shifted upward. (*Left*) Analysis of the flow convergence allows measurement of the regurgitant flow. (*Right*) AR velocity is measured using continuous-wave Doppler to calculate the regurgitant volume (RVol) as flow multiplied by the ratio of regurgitant time velocity integral (RTVI) to regurgitant velocity (RVel).

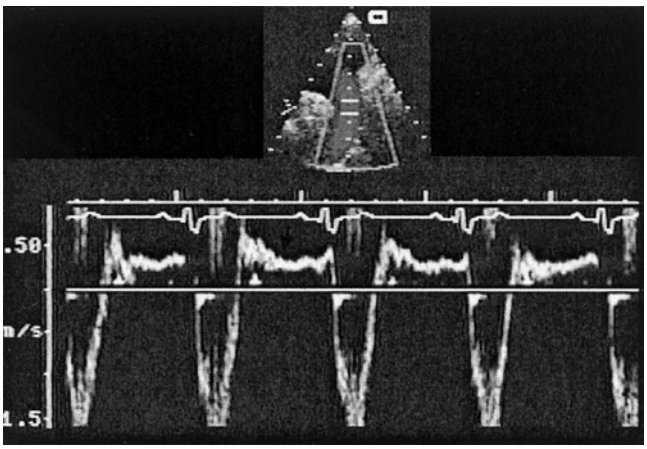

Figure 11-24. Recording of pulsed-wave Doppler in the high descending aorta in a patient with severe aortic regurgitation. Note during diastole the holodiastolic reversal of flow with high velocity (*arrow*).

pressure half-time (<200 ms) (Fig. 11-25). However, aortic regurgitation velocity deceleration is also influenced by LV compliance and reflects elevated LV end-diastolic pressure. Quantitative aortic regurgitation assessment is essential for patients with moderate or severe aortic regurgitation.[16] Regurgitant volume and ERO can be calculated by PISA,[208] quantitative Doppler (mitral and aortic stroke volumes), or the LV volumetric method.[79] While a regurgitant volume of 60 mL/beat, similarly to mitral regurgitation, is consistent with severe regurgitation, a smaller ERO ($\geq$30 mm^2) than in mitral regurgitation is consistent with severe aortic regurgitation[209] because the longer diastolic than systolic time allows larger volume overload for a smaller orifice size.[16]

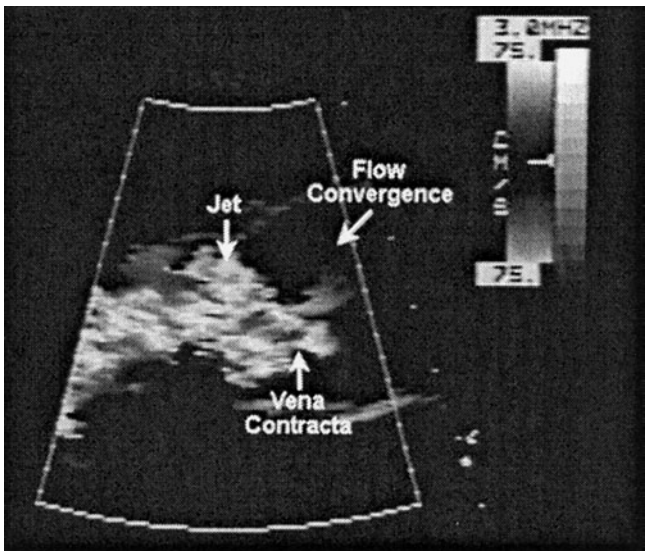

Figure 11-23. Parasternal view of aortic regurgitant flow used to delineate and measure the vena contracta (narrow neck) of the aortic regurgitation.

Quantitative methods are not as consistently applicable in aortic regurgitation than in mitral regurgitation but have relatively few limitations and should be used in clinical practice, similarly to in aortic regurgitation.[208]

INTRAOPERATIVE ASSESSMENT: Before bypass, IO TEE verifies the aortic valve lesions and the extent of aortic aneurysmal dilatation. Aortic valve repair is a safe alternative to valve replacement in selected patients with aortic regurgitation and requires detailed assessment of the mechanism of aortic

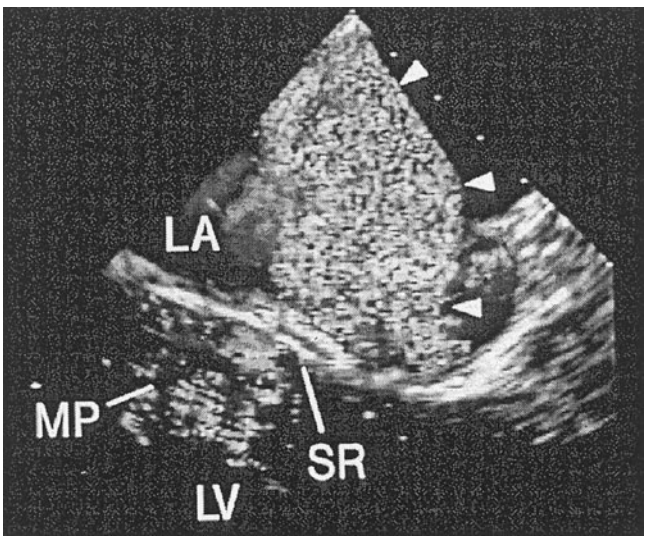

Figure 11-25. Continuous-wave Doppler recording in a patient with endocarditic aortic regurgitation (AR). The rapid deceleration of AR velocity in diastole is quite different from that noted in Fig. 11-22 and is consistent with acute and severe AR revealing a low end-diastolic gradient between the low aortic diastolic pressure and the high left ventricular end-diastolic pressure. The pressure half-time of 154 ms is shorter than the 200-ms threshold for severe AR.

regurgitation.[195,210] Assessment of the mechanism of aortic regurgitation by IO TEE is accurate and reliable compared with surgical findings.[198] Rarely, IO TEE notes aortic dissection or wall hematoma not previously diagnosed, and IO TEE can assist in identifying patients likely to benefit from aortic valve repair.[211] Quantitation of aortic regurgitation is challenging by TEE, and although deep transgastric views may show the flow convergence of aortic regurgitation,[209] imaging usually is poor using this view. A broad jet width on color-flow imaging in central aortic regurgitation is suggestive of severe regurgitation, but a simple, more reliable method by TEE is measurement of the vena contracta width,[206] a surrogate measure of the ERO.[212] Vena contracta assessment by TEE is feasible and has been validated for aortic regurgitation.[206]

After bypass, IO TEE verifies the functional result, anatomically, and for residual aortic regurgitation. This early assessment is important because aortic valve repair is a technique in progress, and results that appear mediocre should lead to consideration of a second pump run. After valve replacement for aortic regurgitation, mismatch is unusual because the annulus is in general dilated with aortic regurgitation and often allows insertion of a sufficiently sized prosthesis. Residual periprosthetic regurgitation is a notable problem in patients with endocarditis, particularly recent, and should be actively evaluated with appropriate loading conditions.

POST-OPERATIVE ASSESSMENT: This focuses on prosthetic or repair function. In patients with allograft replacement of the aortic valve and homograft replacement of the pulmonary valve, calcification of the pulmonary homograft may develop and requires a systematic examination of the pulmonary outflow tract. Failure of valve repair most often involves recurrent prolapse, and timely diagnosis requires regular echocardiographic follow-up.[195,210] Patients with aortic regurgitation are younger than those with AS, and bioprosthetic or homograft aortic valve replacement is associated with notable rates of primary failure depending on age. In patients with dystrophic aortic valves, late aortic dissection may develop and requires careful examination of the aorta, and progressive aortic dilatation should lead to consideration of TEE or computed tomography. LV function is of particular concern if patients were operated with an ejection of less than 50%.[197] In general, given the high preoperative wall stress, aortic valve replacement is associated with improvement in LV function, but the effect is usually modest, and the need for vasoactive treatment aimed at improving LV function and clinical outcome should be assessed postoperatively.

MIXED AORTIC VALVE DISEASE: Mixed aortic valve disease is often rheumatic or associated with aortic valve calcifications, precluding valve repair.[213] The essential step in preoperative evaluation is severity assessment of the valve disease. A composite of moderate AS (with valve area $> 1.0\ cm^2$) and moderate aortic regurgitation (with regurgitant volume $< 60\ mL$) may represent severe valve disease and is diagnosed by a higher mean gradient than the AS severity would justify. IO TEE and postoperative monitoring are similar to those of AS and aortic regurgitation.

TRICUSPID VALVE DISEASES: These are dominated by functional tricuspid regurgitation, but salient issues are the numerous etiologies that may result in notable tricuspid disease and the frequency with which these lesions may be ignored.

TRICUSPID VALVE STENOSIS: This is mostly rheumatic, associated with mitral stenosis and rarely pure. It is difficult to diagnose because there are no absolute morphologic criteria. The essential diagnostic step is to perform a continuous-wave Doppler examination of the tricuspid valve when the morphology is unusual. Mean gradients of 5 mm Hg or more are significant for the tricuspid valve, and the degree of inferior vena cava dilatation reflects the hemodynamic consequences of the stenosis. IO TEE also can examine obstruction of the tricuspid valve if the preoperative hemodynamic assessment was insufficient. Tricuspid valve replacement usually is required, and postoperative echocardiography focuses of the appropriate function of the prosthesis. Other causes of organic tricuspid valve disease such as carcinoid heart disease produce in general mixed tricuspid valve disease with dominant regurgitation.

TRICUSPID VALVE REGURGITATION

PREOPERATIVE ASSESSMENT: Tricuspid regurgitation (TR) is called functional when the valve is structurally normal and regurgitation ensues from incomplete coaptation. Functional TR is the usual consequence of right ventricular dilatation owing to pulmonary hypertension of left-sided heart disease or pulmonary disease but also can be due to primary right ventricular dysfunction or primary atrial and annular dilatation seen in chronic atrial fibrillation. Organic causes of TR include myxomatous valve degeneration with or without ruptured chordae.[214] TR owing to excessive valve movement also can be caused by endocarditis with destructive lesions, blunt chest trauma with chordal or papillary muscle rupture, and iatrogenic trauma after myocardial biopsy. Echocardiography establishes the mechanism more definitely than the etiology of these types of TR and thus is essential in planning valve repair, which is often highly successful.[214] Organic TR with restricted valve motion includes serotoninergic lesions such as carcinoid heart disease, diet-drug valve diseases, ergot valve disease, postradiation valve disease rarely, or more frequently, leaflet impingement (or perforation) by pacemaker or defibrillator leads.[215] The degree of valve thickening or rigidity is an essential guide to predicting repair versus replacement. Congenital causes such as Ebstein anomaly are uncommonly diagnosed in adulthood but may cause severe TR and may be missed easily by a cursory echocardiogram.

There is growing appreciation of tricuspid valve regurgitation as an independent predictor of long-term outcome irrespective of the original cause of this heterogeneous valve disease.[214,216,217] The important consequence of this recognition is that surgery for isolated TR is more common, that in

left-sided valve disease the coexistence of TR should not be ignored because simultaneous correction often is required, and that high-quality echocardiographic assessment of TR severity is warranted because the clinical signs of TR are often ignored. Assessment of TR severity uses mainly (1) the size of the jet in the right atrium (larger is more severe) but with the usual limitation of jets (underestimated with eccentricity and overestimated with high ventricular pressure), (2) vena contracta width of 7 mm or more as a sign of severe TR[218] (useful but limited by lateral resolution issues), (3) the presence of systolic flow reversal in hepatic veins (specific for severe TR but not sensitive), and (4) quantitation of TR by the PISA method.[219,220] For TR quantitation, since the right- versus the left-sided circulatory system is a lower-pressure system, thresholds for severe TR compared with MR are similar for ERO ($\geq$0.40 cm^2) but lower for regurgitant volume ($\geq$45 mL/beat).[220] Severe TR can lead to right-sided volume overload with right ventricular and right atrial enlargement and right ventricular systolic dysfunction.[214] There are no quantitative criteria to assess these changes yet, but qualitative assessment provides useful information. With right ventricular volume overload, the septum may display paradoxical motion and affect LV function and ultimately exercise capacity. With advanced cases, inferior vena cava and hepatic vein dilatation reflects elevated right atrial pressure.

INTRAOPERATIVE ASSESSMENT: TR is often overlooked at left-sided valve surgery,[221] so it is essential that TR assessment be performed without sedation in the outpatient setting.[222] IO TEE before initiation of bypass requires restoration of preload conditions to assess TR. Quantitative assessment of TR by TEE has limitations and cannot replace preoperative assessment. Annular enlargement is important to assess because it is associated with recurrence of TR[221,223] or even development of severe TR in patients with no or mild TR preoperatively.[223] Annulus diameter of more than 70 mm has been considered as markedly enlarged,[223] but there is no consensus on specific annular diameters (absolute or adjusted for body size) that should indicate tricuspid repair.[221] After bypass, it is importance to assess residual TR, although its absence is not invariably synonymous with operative success. Persistent right ventricular enlargement and dysfunction tend to improve later. IO TEE in patients in whom tricuspid surgery is considered results in alteration of the surgical plan in approximately 10% of patients.[224] Rarely is surgery converted to tricuspid replacement because it is considered a predictor of worse survival.

POSTOPERATIVE ASSESSMENT: This focuses mostly on recurrent TR, which, unfortunately, is not uncommon.[221] TR recurrence depends on the surgical techniques used, such as lack of ring annuloplasty[224,225] on lesions (leaflet tethering or thickening),[226] on severe TR at baseline,[225–227] on IO residual TR,[227] and on persistence of pulmonary hypertension of left-sided disease. Right ventricular enlargement and dysfunction improve but often incompletely, particularly if pressure or volume overload persists.

PULMONARY VALVE DISEASES: These are mostly congenital but also can be acquired owing to carcinoid heart disease (now exceptionally rheumatic heart disease) and endocarditis.

PREOPERATIVE ASSESSMENT: This requires proactive examination of the pulmonary valve because the usual examination tends to record few views of the valve, and TEE may be particularly helpful. Knowledge of a disease likely to affect the pulmonary valve is essential in focusing attention to this valve.[228] The valve morphology is difficult to analyze and requires unusual views, elongating the subvalvular, valvular, and supravalvular regions. Thickening can be observed and, more rarely, prolapse, retraction, or vegetation. Morphologically, the pulmonary annulus can be constricted in carcinoid disease in association to intrinsic valve thickening.[229,230] Dilatation of pulmonary artery is important to assess and may require TEE. Hemodynamic assessment is somewhat simpler. Continuous-wave Doppler assesses pulmonary stenosis appropriately. Mild pulmonary regurgitation is frequent in normal individuals. Severe pulmonary regurgitation is rare, detected by color-flow Doppler, but ascertaining severe regurgitation is difficult because the jet may be of limited extent and duration owing to equalization of pulmonary and right ventricular pressures. In such cases, rapid deceleration of the regurgitant jet is suggestive of severe regurgitation.

IO ASSESSMENT: Since pulmonary stenosis is usually treated by balloon valvuloplasty, operative treatment is reserved for regurgitant or mixed lesions. Measurement of the pulmonary annulus and assessment of sub- or supravalvular stenosis are important to operative management. Postoperative assessment of pulmonary regurgitation intends to avoid more than moderate residual regurgitation but is more difficult than outpatient evaluation because restoration of the normal hemodynamic condition is inconsistent. Careful examination of color-flow and continuous-wave Doppler is important in this regard.

POSTOPERATIVE ASSESSMENT: This focuses on assessing function of the native repaired or prosthetic pulmonary valve. Degeneration, stenosis, and regurgitation may develop over time and should be diagnosed early with a combination of color-flow and continuous-wave Doppler. Right ventricular dilatation and dysfunction may persist after surgery or recur with dysfunction of the treated pulmonary valve.[231]

Bacterial endocarditis

Bacterial endocarditis has remained of unchanged incidence despite the decline in rheumatic valve disease and, despite effective antibiotics, continues to carry considerable mortality and morbidity. Since the risk associated with endocarditis drops precipitously with therapy, prompt diagnosis and treatment are essential to improve diagnosis.

PREOPERATIVE ASSESSMENT: This is centered on diagnosis and assessment of complications. Echocardiography aids in the rapid diagnosis of endocarditis and provides one of two

major Duke diagnostic criteria by demonstrating the presence of typical vegetations.[232] Less typical but suspicious lesions represent a minor diagnostic criterion. Vegetations vary in size or shape and are mobile masses attached to endocardium or are implanted material and frequently showing high-frequency oscillations.[233] Vegetations are made of fibrin and are of low density when recent, but there are no definitive criteria to differentiate them from thrombi, particularly on foreign material, or from Lambl's excrescences when small.[234–236] Therefore, diagnosis of vegetation implies contextual interpretation. TEE is superior to TTE in detecting vegetations (sensitivity 95% versus 65 to 80%, respectively), especially in prosthetic valve endocarditis, where TTE may miss vegetations because of shadowing.[237,238] Right-sided vegetations are usually bigger than those on the left, and TEE does not improve diagnostic accuracy.[239]

Apart from diagnosis, TTE and TEE evaluate the presence and severity of endocarditic lesions. Endocarditis is destructive to valves and cardiac tissue and may lead to abscess formation. Valve lesions are perforations or rupture of supportive structures. Perforations are voids, often difficult to visualize directly by TTE or TEE, but observation by the color of the regurgitating flow with flow convergence in the center of a valve leaflet is strongly supportive of a perforation.[105] Ruptures of chordae have nonspecific features unless a vegetation is attached to their tip. Aortic valve prolapse may result from destruction of the central coaptation zone or of the supporting commissural area. Abscesses may involve any region of the myocardium but often involve the fibrosa between the mitral and aortic annuli. Expansion of annular abscesses may lead to conduction abnormalities and to cavity (aneurysm) formation when the abscess ruptures in a cardiac cavity, most often the LV, with sometimes secondary rupture and fistula formation. These complex lesions are better identified by TEE than by TTE. Of note, abscess cavities are seen rarely around the mitral and tricuspid annuli, and abscesses are more prone to be present in patients with prosthetic valve endocarditis. Nevertheless, in all cases of endocarditis, comprehensive assessment of all possible abscesses and fistulous tracts is indispensable. Assessment of the severity of valve lesions is particularly difficult because regurgitations owing to the destructive valve lesions form and progress acutely as sudden tissue loss. Thus clinical signs of regurgitation, particularly murmur intensity, and, similarly, color-flow jets may not be impressive owing to rapid equalization of pressure (e.g., in acute endocarditic aortic regurgitation, LV diastolic pressure is markedly elevated and early in diastole equalizes the aortic pressure so that the murmur and jet are brief and of low energy). This acuteness makes quantitation of regurgitation, particularly measures of effective regurgitant orifice, essential in assessing regurgitation severity.[16] Also, heart failure owing to valve regurgitation may progress rapidly, particularly in patients with acute endocarditic aortic regurgitation, and surgery may be indicated urgently. In patients with mitral or tricuspid regurgitation, heart failure may be controllable with medical treatment, and this may offer some opportunity for sufficient antibiotic therapy.[241,242] Nevertheless, even in clinically stable patients with endocarditis, monitoring of lesions and valvular regurgitation severity by regular echocardiography is essential. Vegetations can be complicated rarely by accumulation and valvular obstruction and more frequently by embolism. Characteristics of vegetations, size (>10 mm), and marked mobility are predictors of the risk of embolism,[243] which led to controversy regarding intervention for ablation of vegetations. While this controversy is unresolved, the precipitous decline in vegetation size with antibiotic treatment and the risk of embolism associated with surgery should be taken into account in this discussion.[235,243] Over time, endocarditic lesions become chronic, and vegetations heal, leaving fibrotic lesions that offer more solid suturing possibilities.

INTRAOPERATIVE ASSESSMENT: This confirms the lesions, assesses the possibility of silent progression and unexpected abscess cavity or fistulous tract, and reassess regurgitations that may have appeared moderate on preoperative assessment. Of particular importance is careful examination of moderate lesions that may require interventional treatment simultaneously with that of severe lesions.

After bypass, it is essential to examine the surgical correction of complex abscesses and fistulous tracts. Also, since recently infected valvular and annular tissue may not offer a solid basis for suturing, examination of all reparative procedures and of the seating of prosthetic valves is particularly important.

POSTOPERATIVE ASSESSMENT: This usually demonstrates that acute LV dysfunction is reversible. With appropriate antibiotic treatment, recurrence of endocarditis is rare, and development of echocardiographic signs may be delayed in contrast to fever and positive blood cultures. A possible complication is the occurrence of aseptic perivalvular regurgitation developing with some delay after the intervention. Low intensity of murmurs may contrast with symptoms, and early detection by systematic TTE and, if necessary, TEE is paramount to appropriate care. Repeated prosthetic dehiscence owing to tissue friability is not uncommon and makes such situations difficult to manage.

Prosthetic valves

Prosthetic valves require specific approaches, and comparison with early postoperative assessment is essential to detect dysfunction.

ECHOCARDIOGRAPHY OF PROSTHETIC VALVES: Although valve repair generally is preferred, valve replacement remains the leading way to correct severe valvular disease. Echocardiography currently is the best approach to evaluate prosthetic valves, but it has limitations that must be recognized for appropriate interpretation. All prostheses are responsible for acoustic shadowing behind them, so examination of all aspects of a prosthesis often requires both TTE and TEE. Morphologically, mechanical prostheses also have specific characteristics that influence their imaging.[189] For example,

in a ball-cage prosthesis, the ball transmits ultrasound slower than blood, so its distal limit appears beyond the prosthetic seating. In bileaflet prostheses, leaflets may be placed in an angle to the thoracic wall, preventing their visualization. Struts of bioprostheses may prevent imaging of leaflets. With Doppler, the presence of a restrictive orifice may create pressure recovery, so gradients may be somewhat overestimated, particularly with small aortas. In prostheses that have no clinical signs of dysfunction, it is important to obtain early and serial hemodynamic assessments that serve as reference points if the clinical issue of dysfunction arises. Each prosthesis is characterized by its gradient, effective orifice area, and physiologic regurgitation. The gradient is measured by continuous-wave Doppler, from apical views for mitral and tricuspid prostheses and from multiple views for aortic prostheses. Mean and peak gradients are measured using the same $4V^2$ formula used in native valves. Each type and size of prosthesis has a range of expected gradients that should be used as a guide to assessment of normal function. Effective orifice area (EOA) is measurable for aortic prostheses, similar to the valve area of AS, as the ratio of stroke volume (LV outflow tract) to time-velocity integral of prosthetic jet velocity. For mitral and tricuspid prostheses, measuring orifice area relies on aortic stroke volume, which is not adequate if aortic regurgitation or prosthetic regurgitation is present. Lack of mitral or tricuspid prosthetic stenosis beyond the normal range is defined by a rapidly declining velocity (and gradient) in early diastole. Physiologic regurgitation of prostheses is common and constant in appearance in mechanical prostheses but rare in bioprostheses. Readily visible for aortic prostheses, it is more difficult to detect with TTE for mitral or tricuspid prostheses owing to prosthetic shadowing and may be observable only by color with TEE. However, physiologic regurgitation is detectable by continuous-wave Doppler and is usually brief, faint, and central. In normally functioning prostheses clinically and as visualized by TTE, TEE is not necessary unless other lesions (e.g., aortic dilatation or aneurysm) are suspected.

MECHANICAL PROSTHESIS DYSFUNCTION: There is no primary failure of mechanical prostheses components because ball variance of Starr-Edwards prostheses and strut ruptures of Bjork-Shiley prostheses have been eliminated. The mechanism of failure of mechanical prostheses is either by tissue interposition rarely[244] or more frequently by obstruction owing to thrombosis or its chronic equivalent, panus formation, or by periprosthetic regurgitation.[245] Tissue interposition usually is detected early and is characterized mostly by regurgitation owing to lack of closure of the mobile element, but it can have a component of stenosis.[113] Incomplete movement of the mobile element can be detected by TTE, TEE, and fluoroscopy with angle-of-movement measurement. Hemodynamic dysfunction is detected by Doppler. Increased flow velocities beyond the normal range (and beyond previous measurements) suggest increased pressure gradients and prosthetic obstruction. However, with increased flow (e.g., from pregnancy, anemia, hyperthyroidism, and sepsis), gradients may increase, so stenosis should be characterized, if possible, by measuring effective orifice area using continuity equations.[246] A ratio of valvular to subvalvular velocity of 3 or more suggests aortic prosthesis stenosis, whereas a slow decline in diastolic velocity suggest stenosis of mitral or tricuspid prostheses.[247] A stenotic prosthesis should lead the clinician to rule out patient-prosthesis mismatch by comparison of prosthesis size and previous measurements.[188] Sudden obstruction suggests acute thrombosis,[191] whereas progressive obstruction suggests panus formation. However, the mechanism of obstruction is rarely defined directly by echocardiography, although a thrombus may be seen by TEE in acute thrombosis.[248] Thrombus size affects the potential efficacy of thrombolysis.[249,250] If thrombolysis is elected as treatment because the prosthesis is in a tricuspid location or because reoperation presents a high risk, monitoring of the prolonged thrombolysis administration requires daily echocardiography with subsequent frequent measurements because recurrence is common, affecting around half the successfully treated patients.[251] Panus obstruction is organized and not affected by thrombolysis.[192] Postoperatively, recurrence of prosthetic thrombosis should be monitored by Doppler. Periprosthetic regurgitation is, if large enough, usually associated with hemolysis and heart failure or progression of symptoms but inconsistently with a murmur. TTE easily detects the regurgitant jet on aortic prostheses, and determination of jet origin requires complete prosthesis scanning to observe periannular flow (Fig. 11-26). For mitral and tricuspid prostheses, shadowing often prevents TTE from recording the color jet, but detection of periprosthetic regurgitation is possible by continuous-wave Doppler, leading to TEE for assessing the severity of regurgitation.

BIOLOGIC PROSTHESIS DYSFUNCTION: Although thrombus (exceedingly rare) and periprosthetic regurgitation (rare) may occur on bioprostheses, primary tissue failure is the most frequent failure mode.[252] The specific mechanism can be early, owing to tears often close to struts, or late, owing to

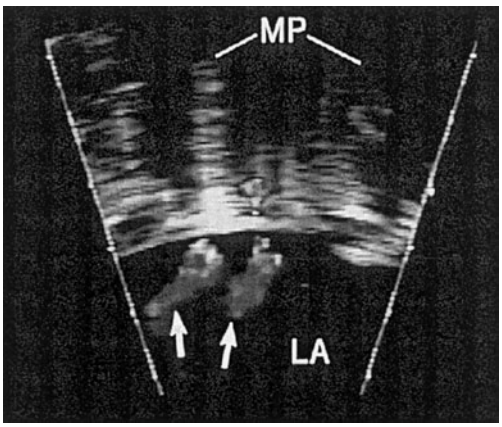

Figure 11-26. Transesophageal imaging of a severe periprosthetic regurgitation (*arrowheads*) around the sewing ring (SR) of a mitral prosthesis (MP). LA = left atrium; LV = left ventricle.

calcification or rupture of cusps. The diagnosis of valve stenosis owing to calcification is based on standard Doppler criteria of excessive gradient, decreased effective orifice area, persistence of end-diastolic high velocity in mitral and tricuspid prostheses, and direct visualization of calcifications by TTE or TEE, if necessary. The diagnosis of tissue failure with regurgitation is suspected by murmur and confirmed by color imaging, but severity often is difficult to confirm because of eccentric jets (even by TEE). In this circumstance, observations of a severe lesion such as a torn cusp and of a large flow convergence proximal to the intraprosthetic regurgitant orifice are important clues to severe regurgitation. With primary tissue failure, it is important to exclude prosthetic endocarditis by blood cultures and by searching for vegetations by TEE.

Coronary Artery Diseases

Coronary artery disease is the most frequent indication for cardiac surgery. Echocardiography does not allow direct observation of coronary artery lesions unless intravascular ultrasound is used for proximal coronary artery segments but reveals the consequences of coronary artery disease. Echocardiography is pivotal to lay the suspicion of coronary artery disease on the basis of stress-induced ischemia, to assess myocardial viability, and to diagnose myocardial infarction and its complications requiring surgical intervention.[22]

Diagnosis of coronary artery diseases

Echocardiography allows visualization of multiple tomographic planes to assess regional wall motion.[22] The American Society of Echocardiography recommends 16-segment analysis of the left ventricle for regional wall motion evaluation.[253] A wall thickness increase in systole of 40% or more characterizes normal LV contractility, whereas less than 30% characterizes reduced contractility (hypokinetic) and less than 10% indicates absent contractility (akinetic). Myocardial segment outward motion during systole (dyskinesis) usually is associated with thinning, whereas an aneurysm is a permanent outwardly bulging wall with or without dyskinesis. LV segments are scored from 1 to 5, with 1 being normal, 2 being hypokinetic, 3 being akinetic, 4 being dyskinetic, and 5 being aneurysmal, and the wall motion score index is the sum of scores divided by the number of segments visualized.[22] A wall motion score index of 1 is normal, and 2 or greater is associated with poor outcome following myocardial infarction. Resting scar (i.e., wall akinetic, dyskinetic, or aneurysmal and dense with thinning) is a resting abnormality diagnostic of myocardial infarction and coronary artery disease (wall motion abnormalities without scar are seen in cardiomyopathies). Stress echocardiography can identify coronary artery disease by inducing new regional wall motion abnormalities.[23] There are many stress modalities, including exercise treadmill or bicycle; pharmacologic with dobutamine, adenosine, or dipyridamole; and rarely TEE atrial pacing.[25] Pharmacologic or pacing stress testing is reserved for patients who are unable to exercise enough to reach maximum effort.[254] With stress, normal LV response is hyperdynamic with increased ejection fraction and decreased LV end-systolic dimension. Resting regional wall motion abnormalities unchanged with stress are consistent with coronary artery disease (previous myocardial infarction) but without ischemia. Increased LV end-systolic dimension or decreased ejection fraction with stress suggest severe coronary artery disease. The diagnostic value of stress echocardiography for coronary artery disease is imperfect, with acceptable sensitivity but mediocre specificity, not notably different from other stress modalities.[255] Once angiography referral bias is accounted for, the sensitivity of stress testing is less impressive.[256] The indications of stress echocardiography for diagnosing coronary artery disease should be weighed according to the pretest probability of disease and are most contributive in the intermediate probability range. The prognostic value of stress echocardiography is considerable in patients presenting with chest pain, justifying its widespread use.[24,257,258]

In evaluating chest pain, echocardiography may reveal resting regional wall motion abnormalities consistent with acute coronary syndrome, but if the findings are normal, this is usually associated with a good prognosis.[259] Stress echocardiography is safe in patients with no sign of myocardial infarction or ischemia and a normal baseline echocardiogram. In overt acute coronary syndromes, a wall motion score index 1.7 or greater suggests a large area at risk.[260]

Postoperatively, stress echocardiography is most useful when chest pain is moderate or atypical to weigh the indication for repeat coronary angiogram. The localizing value of regional wall motion abnormalities for a specific coronary artery bed is mediocre and cannot imply that a specific graft may be dysfunctioning.

Myocardial viability

Myocardial contraction declines when 20% or more of the myocardial wall is ischemic or infracted.[261] Thus, resting hypokinesis or akinesis does not rule out viability (myocardial hibernation) and may improve with revascularization. Dobutamine stress echocardiography is the preferred stress method to assess viability in patients with LV dysfunction (with or without regional wall motion abnormalities).[262] With increasing infusion rates of dobutamine, initially improved contractility of an akinetic segment at low dose suggests viability, and worsening with higher doses (biphasic response) suggests ischemia.[263] This biphasic pattern is typical of viable myocardium that will improve with revascularization.[264] Sustained improvement with increasing dobutamine (monophasic response) often predicts functional recovery after revascularization. Scarred or unresponsive myocardium tends not to improve with revascularization.[265] Strain-rate imaging with low-dose dobutamine may increase the ability to detect viability.[266]

Complications of coronary artery diseases

Heart failure with cardiogenic shock complicating acute myocardial infarction is the leading cause of hospital death

in patients hospitalized for myocardial infarction and may result from various causes that demand specific interventions.[267] Echocardiography can identify the mechanism of circulatory failure and in patients with LV dysfunction identify those at higher risk based on markedly reduced LV ejection fraction and moderate to greater mitral regurgitation.[268]

FREE WALL RUPTURE: This is an important cause of death.[269] There are no predictive echocardiographic features that define a high risk of rupture, but echocardiography provides early and rapid diagnosis in patients with this fatal complication. In patients who are hemodynamically unstable, free wall rupture should be suspected with pericardial effusion, particularly gelatinous-appearing pericardial clot, and with thin-walled myocardium.[270] An incomplete free wall rupture results in a "subepicardial aneurysm" contained by the epicardial layer.[271] The pericardial effusion, even if compressive and with signs of tamponade, should not be tapped for evacuation because this may precipitate catastrophic rupture, but a minimal echocardiography-guided tap to confirm the presence of blood may help in surgical decision making. Rarely, color-flow Doppler detects flow in the pericardial cavity, but the absence of such flow does not rule out rupture. Intramyocardial hematoma is consistent with impending rupture. A pseudoaneurysm is a contained rupture bordered by organized clot and is diagnosed on the basis of a narrow neck with to-and-fro flow and carries a considerable risk of delayed rupture. Detection of early free wall rupture allows surgical repair. Postoperatively, since the infarct often is limited in size, excellent long-term result can be obtained.

VENTRICULAR SEPTAL RUPTURE: Ventricular septal rupture complicating myocardial infarction occurs in the first weeks after infarction. Echocardiography shows the ventricular septal defect, but it is important to use multiple views to identify it because those associated with inferior infarction may be elusive. The defect borders are ragged, different from those of a congenital defect, and fall of myocardial eschars tends to increase the defect size progressively.[272] Color-flow Doppler is critical to diagnosis by demonstrating directly a left-to-right shunt at the ventricular level, and TEE is rarely needed. Surgery is preferable before hemodynamic compromise is intractable, but a shunt may recur postoperatively owing to progressive septal necrosis, which should be monitored. Closure with an endovascular device is possible but entails the possibility of recurrent shunt after the procedure.

PAPILLARY MUSCLE RUPTURE: Mitral regurgitation associated with acute myocardial infarction may be functional or organic owing to papillary muscle rupture, but both frequently are silent, so mitral regurgitation revealed by echocardiography ofter is indicated by hemodynamic compromise or pulmonary edema. Papillary muscle rupture may be incomplete (i.e., one head partially separated but remaining attached to papillary muscle) or complete (i.e., head detachment from the papillary muscle resulting in a flail leaflet). The morphologic abnormality is diagnosed by TTE, but TEE may be necessary.[273] Color-flow imaging detects mitral regurgitation but may underestimate it because of rapid and severe increase in LA pressure. Confirmation by echocardiography of papillary muscle rupture leads to prompt surgical correction. Repair often is feasible with IO TEE monitoring, and rarely, mitral regurgitation recurs postoperatively.[274]

RIGHT VENTRICULAR MYOCARDIAL INFARCTION: Right ventricular myocardial infarction typically is associated with an inferior infarct but rarely is isolated.[275] Patients present with elevated jugular venous pressure contrasting with clear lungs or may present with hypotension or shock. TTE provides rapid diagnosis, showing an enlarged and hypokinetic right ventricle, commonly associated with LV inferior wall motion abnormalities. Color-flow Doppler reveals tricuspid regurgitation with normal pulmonary pressure and low peak velocity. High right atrial pressure may lead to right-to-left shunting via a patent foramen ovale, manifested clinically as hypoxemia and diagnosed by agitated saline contrast material injection showing the shunt as contrast material passing from the right to the left atrium. TEE is useful for diagnosing shunt and supporting closure of a patent foramen ovale percutaneously, which results in marked clinical improvement. Right ventricular function almost universally improves over time, but residual tricuspid regurgitation may be observed and may require surgical correction.[276]

Pericardial, Endocardial, and Myocardial Diseases

Pericardial effusion was the first clinical application of echocardiography and remains, with other pericardial diseases, one of the most important indications for the test.

Pericardial effusion

Pericardial effusion is diagnosed as an echo-free space around the heart. This fluid collection follows the anatomic landmarks of the pericardium, covering both ventricles and most of the right atrium, whereas a small portion of the LA wall is surrounded by pericardium.[277] Pericardial effusion should be differentiated from left pleural effusion, an echo-free space that extends posterior to the descending aorta, and from increased pericardial fat content, of typical granular appearance, that does not deserve medical attention. Pericardial effusion is more often compressive if large (with a swinging heart within the effusion), but tamponade may occur in small acute effusions. Diagnosis of tamponade relies on inferior vena cava dilatation, invagination of right atrial wall in diastole, expiratory collapse of the right ventricle, and marked Doppler and respirometer variability (of opposite timing) of mitral and tricuspid inflows.[277,278] While classically large effusions required surgical drainage, an echocardiography-directed pericardial tap with prolonged catheter drainage is now the mainstay of treatment and is particularly useful in postoperative effusions. Approaches most are often para-apical and rarely subcostal. Effusions of aortic dissection or myocardial infarction should not be drained

percutaneously because full rupture may ensue. The other indications for surgical drainage are purulent effusions, pericardial thrombi, and loculated effusions that cannot be reached safely.[279] Postoperatively, echocardiography monitors the recurrence of effusions and the possible occurrence of constriction.[280]

Pericardial constriction

Pericardial constriction can occur while fluid remains in the pericardium but is mostly due to thickened, rigid pericardium.[281] The classic tuberculous pericarditis is now rare, and most constrictive pericardites are idiopathic, postoperative, and rarely, due to hemopericardium, purulent pericarditis, radiation, or inflammatory disease of the pericardium.[282] Diagnosis should be suspected when heart failure with dilatation of the inferior vena cava is associated with normal LV function. Doppler signs that are specific for pericardial constriction are increased pericardial thickness (difficult to measure),[283] ventricular interaction indicating fixed intrapericardial space diagnosed by leftward septal shift, decreased mitral inflow and pulmonary venous flow and increased tricuspid inflow during inspiration, atrial interaction with diastolic hepatic venous flow reversal with expiration,[284] and isolation from thoracic pressure changes with stable superior vena caval flow with respiration.[285] Pericardial constriction should be differentiated from restrictive cardiomyopathy, which is not associated with ventricular interaction and is associated with reduced myocardial velocity by tissue Doppler, whereas it is normal in pericardial constriction. Pericardial constriction and chronic obstructive pulmonary disease share the respiratory variation of flow, but subtle differences allow diagnosis.[285] Thus Doppler is the mainstay of the preoperative diagnosis of constriction. IO TEE shows the thickened pericardium and monitors the sudden hemodynamic changes after pericardectomy. Postoperatively, echocardiography monitors the persistence of constrictive signs that may be due to a severe epicarditis or insufficient pericardectomy.

Endomyocardial fibrosis

Endomyocardial fibrosis starts as an endomyocarditis with thrombosis that becomes organized and fibrotic, resulting in elevated filling pressures. Imaging shows early the apical obliterative thrombosis that invades the region below the posterior mitral leaflet and encases it. Eosinophilia is observed generally. The fibrosis also can be observed later and results in mitral and tricuspid regurgitation. IO TEE allows monitoring of potential aggravation of valve regurgitations during endomyocardectomy. Postoperatively, persistence of signs of elevated pressures is common.

Cardiomyopathies

Cardiomyopathies usually are diagnosed easily when presenting with congestion owing to LV dysfunction. Regional wall motion abnormalities may be present and are not synonymous with coronary artery diseases. It is not possible to rule out myocarditis by echocardiography. IO TEE during cardiac transplantation excludes dysfunction of the donor heart and monitors tolerance of frequent residual pulmonary hypertension. Posttransplantation assessment notes atrial enlargement, a feature of the atrial connection, with dual atrial activity. Myocardial biopsy may result over time in severing of tricuspid chordae and flail tricuspid valve that require tricuspid repair. Restrictive cardiomyopathy is exemplified by amyloidosis, which characteristically displays wall thickening of the levt and right ventricles, mild valvular regurgitation, pericardial effusion, and restrictive LV filling. Occurrence of LV systolic dysfunction or irreversible diastolic dysfunction is associated with a poor prognosis. Rarely, these patients undergo cardiac transplantation. Hypertrophic cardiomyopathy may be mostly basal and obstructive. LV outflow tract obstruction results from the characteristic septal bulge with systolic anterior motion of the mitral valve and is diagnosed by typical late peaking systolic acceleration by Doppler. These patients benefit from myectomy guided by measures of depth and thickness of the septal bulge to be removed by IO TEE.[286] Elimination of the obstruction and mitral regurgitation are the IO measures of success, as well as absence of iatrogenic ventricular septal defect. Midventricular and apical hypertrophic cardiomyopathy can be missed easily and have complex intracardiac flows but rarely require surgery.

Diseases of the Aorta

The entire thoracic aorta can be visualized by combined TTE and TEE,[31,287,288] but TEE provides complete and detailed imaging of the aorta and should be preferred if a disease of the aorta is suspected.

Aortic dissection

TEE allows rapid visualization of the entire thoracic aorta and proximal abdominal aorta and diagnosis of aortic dissection, whereas TTE provides a more limited view but one that is sometimes sufficient to direct patients to the operating room, where TEE is performed. TTE has limited sensitivity (79%) compared with TEE (99%) in diagnosing aortic dissection,[289] and a negative TTE should be followed by a TEE study is patients in whom aortic dissection is suspected.[289–292] Aortic dissection is seen as an undulating intimal flap and should be distinguished from artifacts often seen in the aorta, using particularly color-flow imaging. The proximally extent of the dissection, dislocation of the intima of the sinus of Valsalva, prolapsed or aortic cusp, and presence and severity of aortic regurgitation should be defined but should not delay access to the operating room if the ascending aorta is involved, where these issues can be examined further. Involvement of the origins of the coronary arteries (particularly the right) may cause myocardial infarction but is not easily visualized, even by TEE. The presence of a pericardial effusion that may cause tamponade is particularly of concern for imminent aortic rupture and should lead to prompt surgery. IO TEE helps to define the presence and

extent of residual dissection involving the aortic arch and descending aorta and of pleural effusion. Postoperatively, TEE evaluates residual aortic regurgitation if the aortic valve has been preserved and LV function if myocardial infarction is suspected, as well as the progression of residual aortic dissection.

Aortic hematoma and rupture

Intramural hematoma precedes aortic dissection in 15 to 20% of patients who present with aortic dissection.[287,293] It results from blood collection between the intima and adventitia and appears as increased echocardiographic density along the aortic wall visible by TEE but usually not by TTE. Aortic perforation can be caused by aortic ulcers complicating atherosclerosis. Its diagnosis is raised in older patients with upper chest pain, but such a diagnosis is difficult even using TEE. Aortic rupture complicates deceleration injury and can be diagnosed by multiplane TEE.[294] Despite the trauma, TEE is feasible in the vast majority of patients and is rarely complicated. TEE is sensitive to detect isthmic rupture. Pseudoaneurysm resulting from containment of rupture by surrounding tissue can be differentiated from true aneurysm by the sharply demarcated rupture site and the narrow communication between the aorta and the pseudoaneurysm.

Aortic aneurysm

Aortic dilatation and aneurysms are visualized and measurable by TTE and TEE, but the extent of the entire aneurysm is better determined by TEE (Fig. 11-27). Rupture rates increase with aneurysm size, and the risk is considerable if the aneurysm is 6 cm or larger but also is notable if the aneurysm is between 5.5 and 6 cm in size. Smaller aneurysms can be followed serially with echocardiography. Patients with Marfan syndrome and those with bicuspid aortic valve are at risk for aortic dilatation and potentially dissection. Prophylactic beta blockers are helpful in delaying progressive aorta dilatation detected by echocardiography and possibly dissection.[295] Sinus of Valsalva aneurysm is best assessed from parasternal long- and short-axis views. Sinus of Valsalva aneurysm may cause compression of adjacent structures or rupture into the cardiac chambers, most commonly the right atrium or right ventricle.[296,297]

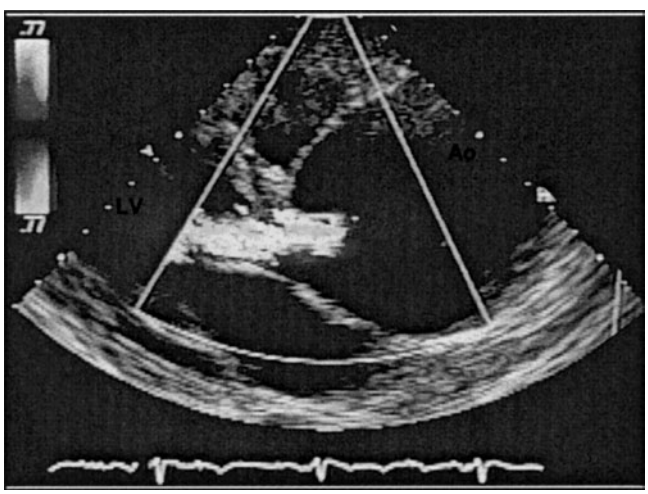

Figure 11-27. Annuloaortic ectasia associated with aortic regurgitation diagnosed by transthoracic echocardiography. Ao = aorta; LV = left ventricle.

Aortic artherosclerosis

Aortic atherosclerosis causes plaques and debris within the aorta, particularly in the elderly. Plaques of higher thickness, irregular surface (ulceration), and with mobile components have higher embolic potential[298–301] Intraoperatively, the presence of severe aortic plaques is of particular importance when an intra-aortic balloon pump is considered. The role of cholesterol embolism in postoperative strokes and decline of renal function is uncertain.

Aortic coarctation

Coarctation of the aorta can be diagnosed by TTE with suprasternal imaging, and Doppler gradient can be measured at rest and with exercise. TEE shows the narrowing of the descending thoracic aorta. TTE and TEE also show the frequently associated bicuspid aortic valve. Postoperatively, echocardiography follows the residual stenosis and the progression of aortic valve dysfunction and ascending aortic enlargement.

CHAPTER 12

Extracorporeal Circulation

John W. Hammon

Cardiac surgery is unique in that a special perfusion system is required for open cardiac surgery and many other examples of closed surgery. It is remarkable that in this new millennium, only 50 years after the first use of extracorporeal circulation, hundreds of thousands of patients a year undergo successful surgery augmented by extracorporeal circulation at a very low risk and with superb clinical outcomes. These occur despite the fact that blood exposed to nonendothelial cell surfaces is collected and continuously recirculated throughout the entire body. This contact with synthetic surfaces in the perfusion circuit and multiple tissues within the wound triggers a defense reaction that involves at least five plasma protein systems and five blood cells. This reaction—the inflammatory response to cardiopulmonary bypass—initiates a powerful thrombotic stimulus and the production, release, and circulation of vasoactive and cytotoxic substances that affect every organ and tissue within the body. Cardiopulmonary bypass and open heart surgery are simply not possible without heparin; thus the inflammatory response to cardiopulmonary bypass describes the consequences of exposing heparinized blood to nonendothelial cell–covered surfaces.

Much has been learned about the inflammatory response since early pioneers first described hemolysis, thrombocytopenia, and production of emboli during and after open heart surgery. Still, much remains to be learned and the goal of a truly nonthrombogenic synthetic surface remains beyond the horizon. This chapter summarizes applications of extracorporeal circulation as used in adult cardiac surgery. The presentation is divided into three sections. Section 12A describes the components and operation of perfusion systems and related special topics. The humoral response to cardiopulmonary bypass, including the reaction of blood elements and the inflammatory response, are presented in section 12B. The consequences of extracorporeal perfusion in terms of organ damage are summarized in section 12C.

Perfusion System

COMPONENTS

During cardiopulmonary bypass (CPB) for clinical cardiac surgery, blood is typically drained by gravity into the venous reservoir of the heart-lung machine via cannulas placed in the superior and inferior venae cavae or a single cannula placed in the right atrium. Blood from this reservoir is pumped through a membrane oxygenator into the systemic arterial system, usually through a cannula placed in the distal ascending aorta (Fig. 12-1). This basic extracorporeal perfusion system can be adapted to provide partial or total circulatory and respiratory support or partial support for the left or right heart or for the lungs separately.

The complete heart-lung machine includes many additional components (Fig. 12-2).[1] Most manufacturers consolidate a *membrane oxygenator, venous reservoir,* and *heat exchanger* into one unit. A *microfilter-bubble trap* is added to the arterial outflow. Depending on the operation, various suction systems are used to return blood from the surgical field, cardiac chambers, and/or the aorta. Aspirated blood passes through a *cardiotomy reservoir* and *microfilter* before returning to the venous reservoir. Optionally, but increasingly recommended, field blood is washed in a *cell saver system* and returned to the perfusate as packed red cells. In addition to adjusting pump flow, partial and occluding *clamps* on venous and arterial lines are used to direct and

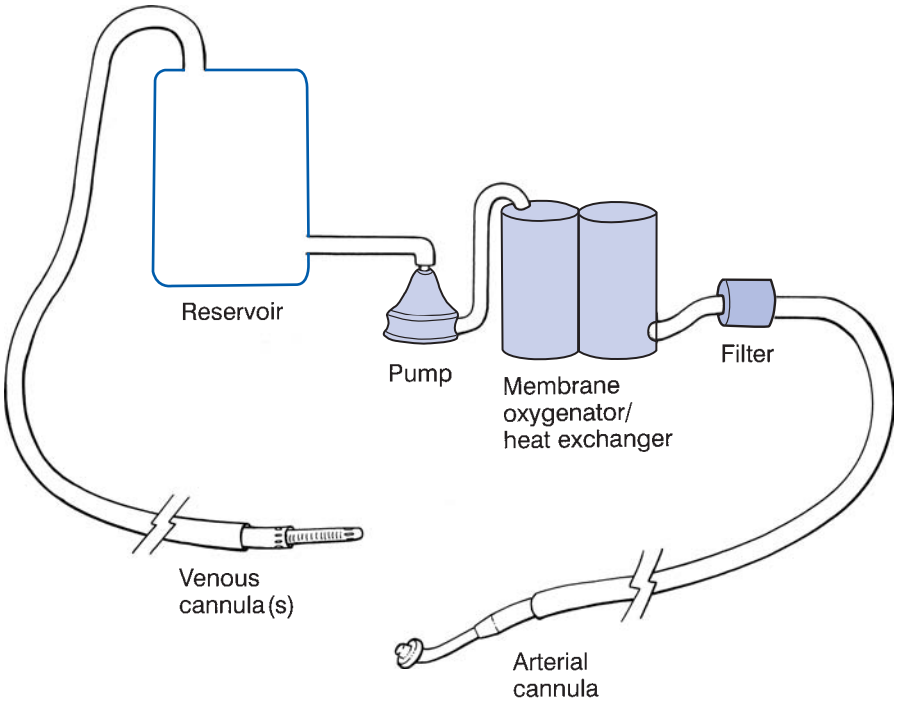

Figure 12-1. Basic cardiopulmonary bypass circuit with membrane oxygenator and centrifugal pump.

regulate flow. *Sites* for obtaining blood samples and *sensors* for monitoring pressures, temperatures, oxygen saturation, blood gases, and pH are included, as are various safety devices.

A separate circuit for administering *cardioplegic* solutions at controlled composition, rate, and temperature is usually included in the system. Often a *hemoconcentrator* (for removal of water and small molecules) is added to the primary circuit.

Venous Cannulation and Drainage

Principles of venous drainage

Venous blood usually enters the circuit by gravity or siphonage into a venous reservoir placed 40 to 70 cm below the level of the heart. The amount of drainage is determined by central venous pressure; the height differential; resistance in cannulas, tubing, and connectors; and absence of air within the system. Central venous pressure is determined by intravascular volume and venous compliance, which is influenced by medications, sympathetic tone, and anesthesia. Inadequate blood volume or excessive siphon pressure may cause compliant venous or atrial walls to collapse against cannular intake openings to produce "chattering" or "fluttering." This phenomenon is corrected by adding volume to the patient.

Venous cannulas and cannulation

Venous cannulas are usually made out of flexible plastic, which may be stiffened against kinking by wire reinforcement. Tips are straight or angled and often are constructed of thin, rigid plastic or metal. Size is determined by patient size, anticipated flow rate, and an index of catheter flow characteristics and resistance (provided by the manufacturer). For an average adult with 60-cm negative siphon pressure, a 30F cannula in the superior vena cava (SVC) and 34F in the inferior vena cava (IVC) or a single 42F cavoatrial catheter suffices. Catheters are typically inserted through purse-string guarded incisions in the right atrial appendage, lateral atrial wall, or directly in the SVC and IVC.

Three basic approaches for central venous cannulation are used: bicaval, single atrial, or cavoatrial ("two stage") (Fig. 12-3). *Bicaval cannulation* and caval tourniquets are necessary to prevent bleeding and air entry into the system when the right heart is entered during CPB. Because of coronary sinus return, caval tourniquets should not be tightened without decompressing the right atrium. Bicaval cannulation without caval tapes is often preferred to facilitate venous return during exposure of the left atrium and mitral valve.

Single venous cannulation is adequate for most aortic valve and coronary artery surgery; however, usually a cavoatrial cannula ("two-stage") is employed (see Fig. 12-3B). This catheter is typically introduced via the right atrial appendage. Its narrowed distal end is threaded into the IVC while the wider proximal portion has side holes designed to rest within the right atrium. It tends to be more stable and provide better drainage than a single cannula, but proper positioning is critical.[2] With single cannulas, elevation of the heart may kink the junction of the SVC with the atrium and partially obstruct venous drainage and more importantly, block venous outflow from the cerebral circulation.

At times, venous cannulation is accomplished via the femoral or iliac vein. This either open or percutaneous

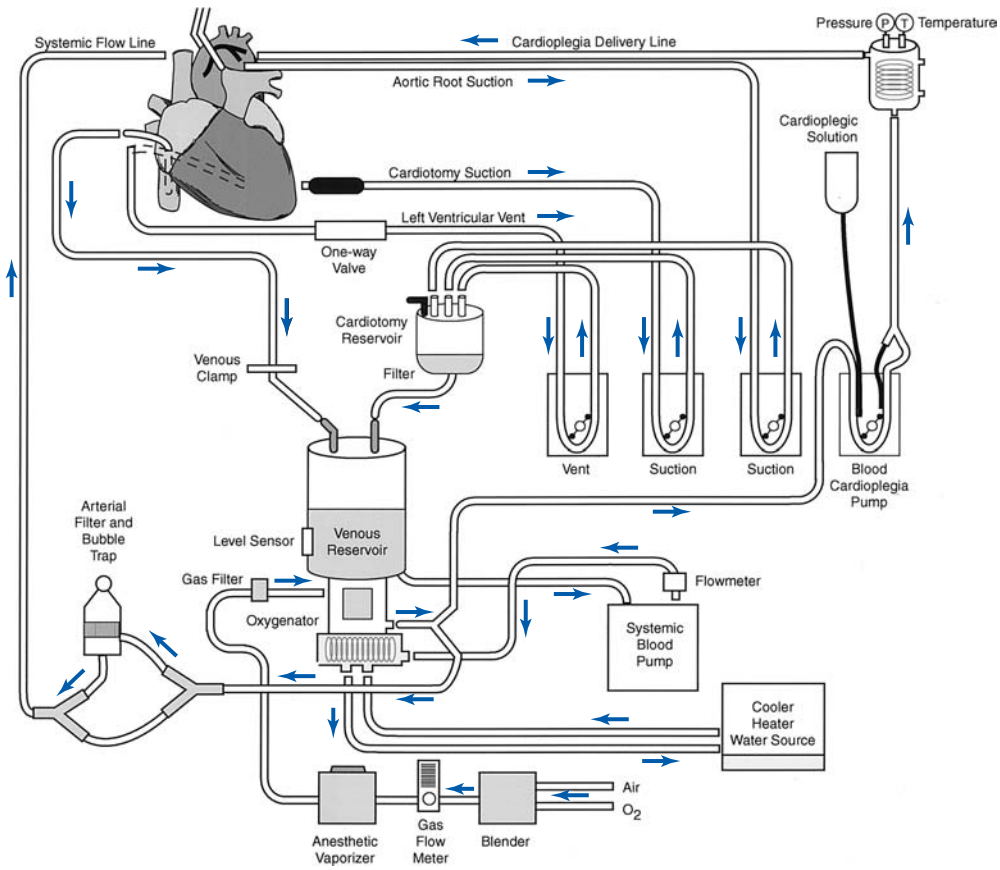

Figure 12-2. Diagram of a typical cardiopulmonary bypass circuit with vent, field suction, aortic root suction, and cardioplegic system. Blood is drained from a single "two-stage" catheter into the venous reservoir, which is part of the membrane oxygenator/heat exchanger unit. Venous blood exits the unit and is pumped through the heat exchanger and then the oxygenator. Arterialized blood exits the oxygenator and passes through a filter/bubble trap to the aortic cannula, which is usually placed in the ascending aorta. Blood aspirated from vents and suction systems enters a separate cardiotomy reservoir, which contains a microfilter, before entering the venous reservoir. The cardioplegic system is fed by a spur from the arterial line to which the cardioplegic solution is added and is pumped through a separate heat exchanger into the antegrade or retrograde catheters. Oxygenator gases and water for the heat exchanger are supplied by independent sources.

cannulation is used for emergency closed cardiopulmonary assist, for support of particularly ill patients before induction of anesthesia, for prevention or management of bleeding complications during sternotomy, for reoperations,[3] for certain types of aortic and thoracic surgery, and for applications of CPB that do not require thoracotomy. Adequate flow rates require using a cannula that is as large as possible and advancing the catheter into the right atrium guided by transesophageal echocardiography (TEE). Specially designed commercially manufactured long, ultra-thin, wire-reinforced catheters are available for this purpose.

Persistent left superior vena cava

A persistent left superior vena cava (PLSVC) is present in 0.3 to 0.5% of the general population and usually drains into the coronary sinus; however, in about 10% of cases it drains into the left atrium.[4–6] The presence of a PLSVC should be suspected when the (left) innominate vein is small or absent, and when a large coronary sinus or the PLSVC itself is seen on baseline TEE.[7,8]

A PLSVC may complicate retrograde cardioplegia or entry into the right heart.[9] If an adequate sized innominate vein is present (30% of patients), the PLSVC can simply be occluded during CPB, if the ostium of the coronary sinus is present.[10] If the right SVC is not present (approximately 20% of patients with PLSVC), the left cava cannot be occluded. If the innominate vein is absent (40% of patients) or small (about 33% of patients), occlusion of the PLSVC may cause venous hypertension and possible cerebral injury. In these patients a cannula is passed retrograde into the PLSVC through the coronary sinus ostium and secured. Alternatively, a cuffed endotracheal tube may be used as a cannula.[11]

Augmented or assisted venous return

Negative pressure is sometimes applied to the venous lines to provide assisted venous drainage using a roller pump or

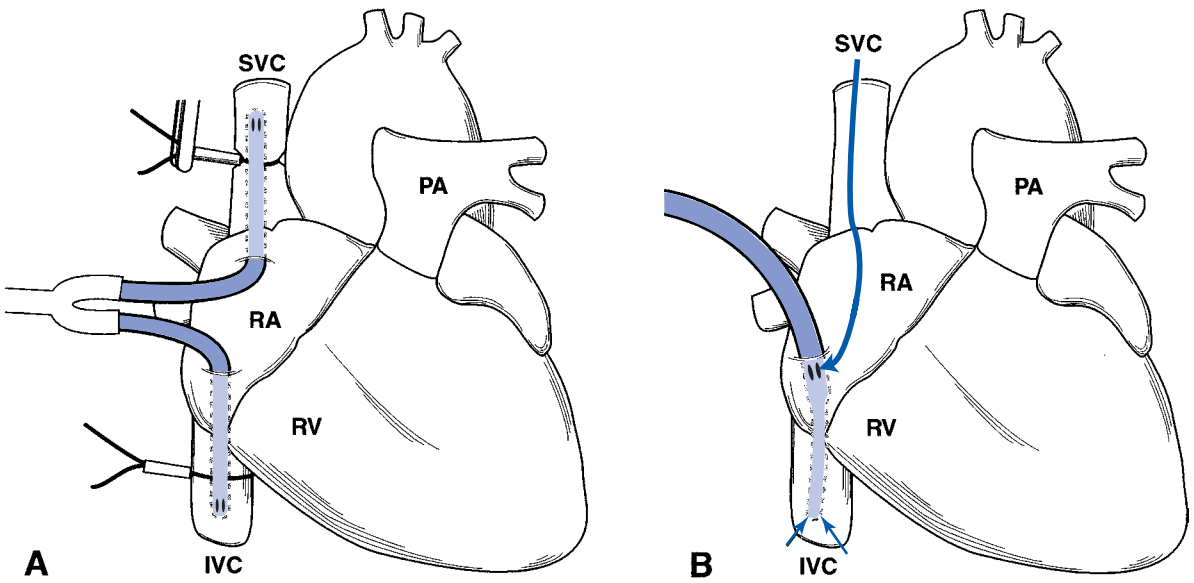

Figure 12-3. Placement of venous cannulas. (A) Cannulation of both cavae from incisions in the right atrium. (B) Cannulation using the "two-stage cannula." Blood in the right atrium is captured by vents in the expanded shoulder several inches from the narrower IVC catheter tip. IVC = inferior vena cava; PA = pulmonary artery; RA = right atrium; RV = right ventricle; SVC = superior vena cava.

centrifugal pump,[12] or by applying a regulated vacuum to a closed hard-shell venous reservoir (vacuum-assisted venous drainage).[13] This may permit use of smaller diameter catheters,[14] and may be helpful when long peripheral catheters are used. Augmented negative pressure in the venous line increases the risk of aspirating gross or microscopic air and causing cerebral injury,[15–18] hemolysis, or aspiration of air into the blood compartment of membrane oxygenators. Positive pressure in the venous reservoir can cause air to enter the venous lines and right heart.[19] These potential complications require special safety monitors and devices and adherence to detailed protocols.[19,20]

Complications associated with venous cannulation and drainage

These include atrial arrhythmias, atrial or caval tears and bleeding, air embolization, injury or obstruction due to catheter malposition, reversing arterial and venous lines, and unexpected decannulation. Placing tapes around the cavae may lacerate branches, nearby vessels (e.g., the right pulmonary artery), or the cava itself. Before or after CPB, catheters may compromise venous return to the right atrium from the body. Venous catheters and/or caval tapes may displace or compromise central venous or pulmonary arterial monitoring catheters; conversely, monitoring catheters may compromise the function of caval tapes.

Any intracardiac catheter may be trapped by sutures, which may impede removal before or after the wound is closed. Any connection between the atmosphere and cannula intake ports may entrain air to produce an air lock or gaseous microembolism. Assisted venous drainage increases the risk of air entrainment.[21,22] Finally, improperly placed purse-string sutures may obstruct a cava when tied.[23]

Causes of low venous return

Low venous pressure, hypovolemia, drug- or anesthetic-induced venous dilatation, inadequate differential height between heart and reservoir, too small cannula size, cannula obstruction from any cause, air locks, or excessive flow resistance in the drainage system are possible causes of reduced venous return. Partial obstruction of the venous line may distend the right ventricle and impair later contractility.

Arterial Cannulation

Arterial cannulas

The tip of the arterial cannula is usually the narrowest part of the perfusion system and at required flows small aortic and arterial catheters produce high pressure differentials, jets, turbulence, and cavitation. Most arterial catheters are rated by a performance index, which relates external diameter, flow, and pressure differential.[24] High-velocity jets may damage the aortic wall, dislodge atheroemboli, produce dissections, disturb flow to nearby vessels, and cause cavitation and hemolysis. Pressure differences that exceed 100 mm Hg cause excessive hemolysis and protein denaturation.[25] Weinstein[26] attributed a predominance of left-sided stroke following cardiac surgery to the sand-blasting effect of end-hole aortic cannulas directing debris into the left carotid artery. Aortic catheters with only side ports[27] are designed to minimize jet effects and better distribute arch vessel perfusion and pressure[28] and may be associated with fewer strokes.[26]

Recently a dual-stream aortic perfusion catheter has been developed that features an inflatable horizontal streaming baffle that is designed to protect the arch vessels from atherosclerotic and other emboli and permits selective cerebral

hypothermia.[29,30] Another novel aortic cannula features a side port that deploys a 120-μm mesh filter to remove particulate emboli beyond the ascending aorta.[31] Although this catheter increased the pressure gradient by 50%,[32] it removed an average of 8 emboli in 99% of 243 patients and cerebral injuries were less than expected.[33]

Connection to the patient

Anatomic sites available for arterial inflow include the proximal aorta, innominate artery and distal arch, and femoral, external iliac, axillary, and subclavian arteries. The choice is influenced by the planned operation[34] and distribution of atherosclerotic disease.[35]

Atherosclerosis of the ascending aorta

Dislodgment of atheromatous debris from the aortic wall from manipulation,[36] cross-clamping, or the sand-blasting effect of the cannula jet is a major cause of perioperative stroke[37,38] and a risk factor for aortic dissection[39] and postoperative renal dysfunction.[40] Simple palpation during transient hypotension or TEE is less sensitive and accurate for detecting severe atherosclerosis than epiaortic ultrasonic scanning.[36,41,42] TEE views of the middle and distal ascending aorta are often inadequate,[41–44] but some recommend this method for screening.[44,45] Epiaortic scanning is preferred for all patients who have a history of transient ischemic attack, stroke, severe peripheral vascular disease, palpable calcification in the ascending aorta, calcified aortic knob on chest radiograph, age older than 50 to 60 years, or TEE findings of moderate aortic atherosclerosis.[36] Calcified aorta ("porcelain aorta"), which occurs in 1.2 to 4.3% of patients,[46,47] is another indication for changing the location of the aortic cannula.[48,49] Alternative sites include the distal aortic arch[46,50] and innominate, axillary-subclavian, or femoral arteries.

Ascending aortic cannulation

The distal ascending aorta is the preferred cannulation site because of ease and fewest complications. Most surgeons place two sutures, full- or partial-thickness, through the aortic wall, followed by a 4- to 5-mm, full-thickness stab wound, and insert the cannula under a finger while the mean arterial pressure is approximately 60 to 80 mm Hg. Usually the cannula is inserted 1 to 2 cm with a whiff of back bleeding, rotated to ensure that the tip is completely within the lumen, and positioned to direct flow to the mid-transverse aorta. A few surgeons prefer a long catheter with the tip placed beyond the left subclavian artery.[51] Proper cannula placement is critical[28] and is confirmed by noting pulsatile pressure in the aortic line monitor and equivalent pressure in the radial artery. Once inserted the cannula must be adequately secured in place.

COMPLICATIONS OF ASCENDING AORTA CANNULATION: Complications include difficult insertion; bleeding; tear in the aortic wall; intramural or malposition of the cannula tip (in or against the aortic wall, toward the valve, or in an arch vessel)[52]; atheromatous emboli; failure to remove all air from the arterial line after connection; injury to the aortic back wall; high line pressure indicating obstruction to flow; inadequate or excessive cerebral perfusion[53]; inadvertent decannulation; and aortic dissection.[54,55] It is essential to monitor aortic line and radial artery pressures and to carefully observe the aorta for possible cannula-related complications during onset of CPB and during placement of aortic clamps. Asymmetric cooling of the face or neck may suggest a problem with cerebral perfusion. Late bleeding and infected or noninfected false aneurysms are delayed complications of aortic cannulation.

Aortic dissection occurs in 0.01 to 0.09% of aortic cannulations[39,55–58] and is more common in patients with aortic root disease. The first clues may be discoloration beneath the adventia near the cannula site, an increase in arterial line pressure, or a sharp reduction in return to the venous reservoir. TEE may be helpful in confirming the diagnosis,[59] but prompt action is necessary to limit the dissection and maintain perfusion. The cannula must be promptly transferred to a peripheral artery or uninvolved distal aorta. Blood pressure should be controlled pharmacologically and perfusion cooling to temperatures less than 20°C initiated. During hypothermic circulatory arrest, the aorta is opened at the original site of cannulation and repaired by direct suture, patch, or circumferential graft.[57,58] When recognized early, survival rates range from 66 to 85%, but when discovered after operation, survival is approximately 50%.

Cannulation of the femoral or iliac artery

These vessels are usually the first alternative to aortic cannulation, but are also indicated for initiating CPB quickly for severe bleeding, cardiac arrest, acute intraoperative dissection or severe shock, limited access cardiac surgery, and selected reoperative patients.[3] Femoral or iliac cannulation limits cannula size, but the retrograde distribution of blood flow is similar to antegrade flow.[60]

Femoral cannulation is associated with many complications[3,61] that include tears, dissection, late stenosis or thrombosis, bleeding, lymph fistula, infection in the groin, or cerebral and coronary atheroembolism. In patients with prior aortic dissections femoral perfusion may cause malperfusion; thus some surgeons recommend alternative cannulation sites for these patients.[62,63] Ischemic complications of the distal leg may occur during prolonged (3 to 6 hours) retrograde perfusions[64,65] unless perfusion is provided to the distal vessel. This may be provided by a small Y catheter in the distal vessel[65] or a side graft sutured to the artery.[66]

Retrograde arterial dissection is the most serious complication of femoral or iliac arterial cannulation and may extend to the aortic root and/or cause retroperitoneal hemorrhage. The incidence is between 0.2 and 1.3%[67–70] and is associated with a mortality of about 50%. This complication is more likely in diseased arteries and in patients over 40 years old. The diagnosis is similar for an aortic cannula dissection and may be confirmed by TEE of the descending thoracic aorta.[59] Antegrade perfusion in the true lumen must be immediately resumed by either the heart itself or by cannulation in

the distal aorta or axillary-subclavian artery. It is not always necessary to repair the dissected ascending aorta unless it affects the aortic root.[67–69]

Other sites for arterial cannulation

The axillary-subclavian artery is increasingly used for cannulation.[71–75] Advantages include freedom from atherosclerosis, antegrade flow into the arch vessels, and protection of the arm and hand by collateral flow. Because of these advantages and the dangers of retrograde perfusion in patients with aortic dissection, some surgeons prefer this cannulation site for these patients.[63,75,76] Brachial plexus injury and axillary artery thrombosis are reported complications.[71] The axillary artery is approached through a subclavicular incision; the intrathoracic subclavian artery may be cannulated through a thoracotomy.[77]

Occasionally the innominate artery may be cannulated through a purse-string suture without obstructing flow around a 7F to 8F cannula to the right carotid artery.[34,49] The ascending aorta can also be cannulated by passing a cannula through the aortic valve from the left ventricular apex.[78,79] Coselli and Crawford[80] also describe retrograde perfusion through a graft sewn to the abdominal aorta.

Venous Reservoir

The venous reservoir serves as volume reservoir and is placed immediately before the arterial pump when a membrane oxygenator is used (see Fig. 12-1). This reservoir serves as a high-capacitance (i.e., low-pressure) receiving chamber for venous return; facilitates gravity drainage; is a venous bubble trap; provides a convenient place to add drugs, fluids, or blood; and adds storage capacity for the perfusion system. As much as 1 to 3 L of blood may be translocated from patient to circuit when full CPB is initiated. The venous reservoir also provides several seconds of reaction time if venous return is suddenly decreased or stopped during perfusion.

Reservoirs may be rigid (hard) plastic canisters ("open" types) or soft, collapsible plastic bags ("closed" types). The rigid canisters facilitate volume measurements and management of venous air, often have larger capacity, are easier to prime, permit suction for vacuum-assisted venous drainage, and may be less expensive. Some hard-shell venous reservoirs incorporate macrofilters and microfilters and can serve as cardiotomy reservoirs and to receive vented blood.

Disadvantages include the use of silicon antifoam compounds, which may produce microemboli,[81,82] risk of microembolism, and increased activation of blood elements.[83] Soft bag reservoirs eliminate the blood-gas interface and by collapsing reduce the risk of pumping massive air emboli.

Oxygenators

Membrane oxygenators imitate the natural lung by interspersing a thin membrane of either microporous polypropylene (0.3- to 0.8-μm pores) or silicone rubber between the gas and blood phases. Compared to bubble oxygenators, membrane oxygenators are safer, produce less particulate and gaseous microemboli,[84,85] are less reactive to blood elements, and allow superior control of blood gases.[86,87] With microporous membranes, plasma-filled pores prevent gas from entering blood, but facilitate transfer of both oxygen and carbon dioxide. Because oxygen is poorly diffusible in plasma, blood must be spread as a thin film (approximately 100 μm) over a large area with high differential gas pressures between compartments to achieve oxygenation. Areas of turbulence and secondary flow enhance diffusion of oxygen within blood and thereby improve oxyhemoglobin saturation.[88] Carbon dioxide is highly diffusible in plasma and easily exits the blood compartment despite small differential pressures across the membrane.

The most popular design uses sheaves of hollow fibers (120 to 200 μm) connected to inlet and outlet manifolds within a hard-shell jacket (Fig. 12-4). The most efficient configuration creates turbulence by passing blood between fibers and oxygen within fibers. Arterial partial carbon dioxide pressure ($PaCO_2$) is controlled by gas flow, and arterial partial oxygen pressure (PaO_2) is controlled by the fraction of inspired oxygen (FIO_2) produced by an air-oxygen blender. Modern membrane oxygenators add up to 470 mL of O_2 and remove up to 350 mL CO_2 per minute at 1 to 7 L of flow with priming volumes of 220 to 560 mL and resistances of 12 to 15 mm Hg per liter blood flow. Most units combine a venous reservoir, heat exchanger, and hollow fiber membrane oxygenator into one compact unit.

Oxygen and CO_2 diffuse across thin silicone membranes, which are made into envelopes and wound around a spool to produce a spiral coil oxygenator. Gas passes through the envelope and blood passes between the coil windings. Because of protein leakage, which degrades membrane function, these spiral coil oxygenators are preferred over hollow fiber microporous oxygenators for the prolonged perfusions (days) used in respiratory support.

A new membrane oxygenator features a very thin (0.05 μm), solid membrane on the blood side of a highly porous support matrix. This membrane reduces the risk of gas emboli and plasma leakage during prolonged CPB, but may impair transfer of volatile anesthetics.[89]

Flow regulators, flow meters, gas blender, oxygen analyzer, gas filter, and moisture trap are parts of the oxygenator gas supply system used to control the ventilating gases within membrane oxygenators. Often an anesthetic vaporizer is added, but care must be taken to prevent volatile anesthetic liquids from destroying plastic components of the perfusion circuit.

Bubble oxygenators are obsolete in the United States, but are used elsewhere for short-term CPB because of cost and efficiency. Because each bubble presents a new foreign surface to which blood elements react, bubble oxygenators cause progressive injury to blood elements and entrain more gaseous microemboli.[90,91] In bubble oxygenators, venous blood drains directly into a chamber into which oxygen is infused through a diffusion plate (sparger). The sparger

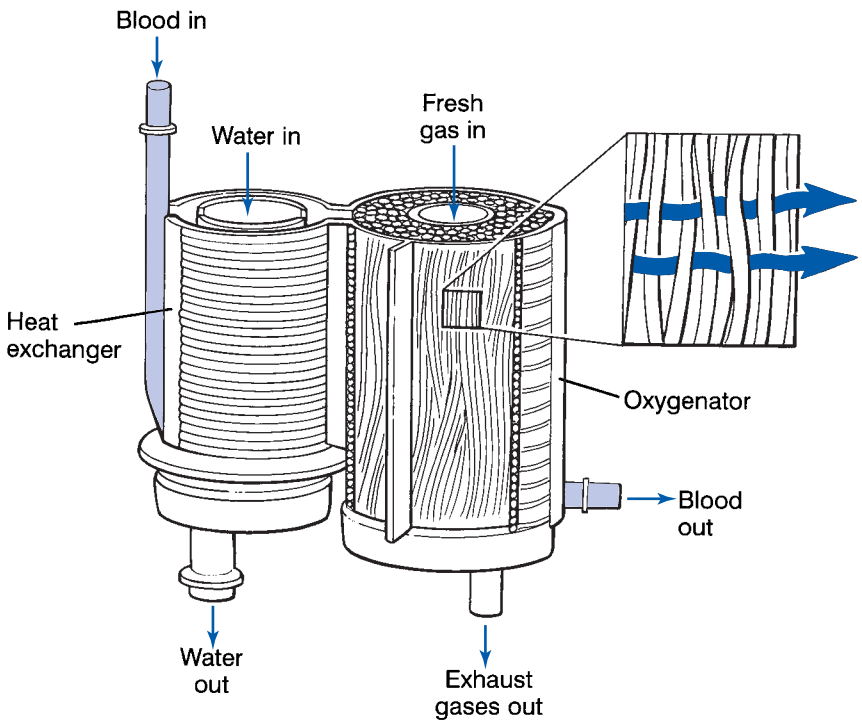

Figure 12-4. Diagram of a hollow fiber membrane oxygenator and heat exchanger unit. Blood enters the heat exchanger first and flows over water-cooled or -warmed coils and then enters the oxygenator to pass between woven strands of hollow fibers. Oxygen enters one end of the bundles of hollow fibers and exits at the opposite end. The hollow fiber bundles are potted at each end to separate the blood and gas compartments. Oxygen and carbon dioxide diffuse in opposite directions across the aggregate large surface of the hollow fibers.

produces thousands of small (approximately 36 μm) oxygen bubbles within the blood. Gas exchange occurs across a thin film at the blood-gas interface around each bubble. Carbon dioxide diffuses into the bubble and oxygen diffuses outward into blood. Small bubbles improve oxygen exchange by effectively increasing the surface area of the gas-blood interface,[92] but are difficult to remove. Large bubbles facilitate CO_2 removal. Bubbles and blood are separated by settling, filtration, and defoaming surfactants in a reservoir. Bubble oxygenators add 350 to 400 mL of oxygen to blood and remove 300 to 330 mL of CO_2 per minute at flow rates from 1 to 7 L/min.[86,93] Priming volumes are less than 500 mL. Commercial bubble oxygenators incorporate a reservoir and heat exchanger within the same unit and are placed upstream to the arterial pump.

Oxygenator malfunction requiring change during CPB occurs in 0.02 to 0.26% of cases,[94–96] but the incidence varies between membrane oxygenator designs.[97] Development of abnormal resistant areas in the blood path is the most common cause,[96] but other problems include leaks, loss of gas supply, rupture of connections, failure of the blender, and deteriorating gas exchange. Blood gases need to be monitored to ensure adequate CO_2 removal and oxygenation. Heparin coating may reduce development of abnormally high resistance areas.[95]

Heat Exchangers

Heat exchangers control body temperature by heating or cooling blood passing through the perfusion circuit. Hypothermia is frequently used during cardiac surgery to reduce oxygen demand or to facilitate operative exposure by temporary circulatory arrest. Gases are more soluble in cold than in warm blood; therefore, rapid rewarming of cold blood in the circuit or body may cause formation of bubble emboli.[98] Most membrane oxygenator units incorporate a heat exchanger upstream to the oxygenator to minimize bubble emboli. Blood is not heated above 40°C to prevent denaturation of plasma proteins, and temperature differences within the body and perfusion circuit are limited to 5 to 10°C to prevent bubble emboli. The heat exchanger may be supplied by hot and cold tap water, but separate heater/cooler units with convenient temperature-regulating controls are preferred. Leakage of water into the blood path can cause hemolysis and malfunction of heater/cooler units may occur.[94]

Separate heat exchangers are needed for cardioplegia. The simplest system is to use bags of precooled cardioplegia solution. More often cardioplegia fluid is circulated through a dedicated heat exchanger or tubing coils placed in an ice- or warm-water bath.

Pumps

Most heart-lung machines use two types of pumps, although roller pumps can be used exclusively (Table 12-1). Centrifugal pumps are usually used for the primary perfusion circuit for safety reasons and for a possible reduction in injury to blood elements. However, this latter reason remains highly controversial and unproven.[99–104]

Centrifugal pumps (Fig. 12-5) consist of a vaned impeller or nested, smooth plastic cones, which when rotated rapidly, propel blood by centrifugal force.[105] An arterial flowmeter is required to determine forward blood flow, which varies with the speed of rotation and the afterload of the arterial line. Unless a check valve is used,[106] the

Table 12–1.

Roller Versus Centrifugal Pump

	Roller pump	Centrifugal pump
Description	Nearly occlusive Afterload independent	Nonocclusive Afterload sensitive
Advantages	Low prime volume Low cost No potential for backflow Shallow sine-wave pulse	Portable, position insensitive Safe positive and negative pressure Adapts to venous return Superior for right or left heart bypass Preferred for long-term bypass Protects against massive air embolism
Disadvantages	Excessive positive and negative pressure Spallation Tubing rupture Potential for massive air embolism Necessary occlusion adjustments Requires close supervision	Large priming volume Requires flowmeter Potential passive backward flow Higher cost

arterial line must be clamped to prevent backward flow when the pump is off. Centrifugal blood pumps generate up to 900 mm Hg of forward pressure, but only 400 to 500 mm Hg of negative pressure, and therefore less cavitation and fewer gaseous microemboli. They can pump small amounts of air, but become "deprimed" if more than 30 to 50 mL of air enters the blood chamber. Centrifugal pumps are probably superior for temporary extracorporeal assist devices and left heart bypass, and for generating pump-augmented venous return.

Roller pumps consist of a length of $^{1}/_{4}$- to $^{5}/_{8}$-inch (internal diameter) polyvinyl, silicone, or latex tubing, which is compressed by two rollers 180° apart inside a curved raceway. Forward flow is generated by roller compression and flow rate depends on the diameter of the tubing, rate of rotation, the length of the compression raceway, and completeness of compression. Compression is adjusted before use to be barely nonocclusive against a standing column of fluid that produces 45 to 75 mm Hg back pressure.[107–110] Hemolysis and tubing wear are minimal at this degree of compression.[107] Flow rate is determined from calibration curves for each pump for different tubing sizes and rates of rotation. Roller pumps are inexpensive, reliable, safe, insensitive to afterload, and have small priming volumes, but can produce high negative pressures and microparticles shed from compressed tubing (spallation).[111] Roller pumps are vulnerable to careless operation that results in propelling air, inaccurate flow calibration, backflow when not in use if rollers are not sufficiently occlusive, excessive pressure with rupture of connections if arterial inflow is obstructed, tears in tubing, and changing roller compression settings during operation. Roller pumps, but not centrifugal pumps, are used for sucker systems and for delivering cardioplegic solutions.

Centrifugal pumps produce pulseless blood flow and standard roller pumps produce a sine wave pulse around 5 mm Hg. The arterial cannula dampens the pulse of pulsatile pumps, and it is difficult to generate pulse pressures above 20 mm Hg within the body during full CPB.[112,113] To date no one has conclusively demonstrated the need for pulsatile perfusion during short-term or long-term CPB or circulatory assistance.[114–117]

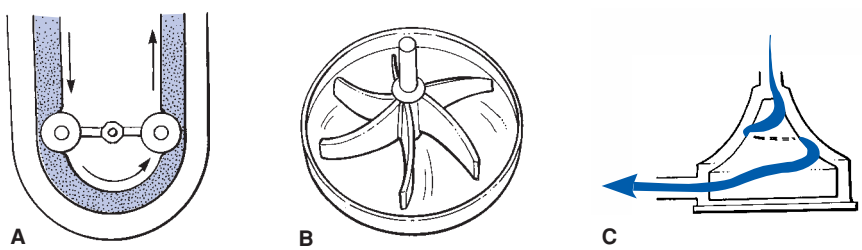

Figure 12-5. Diagrams of blood pumps. (A) Roller pump with two rollers, 180° apart. The compression of the rollers against the raceway is adjustable and is set to be barely nonocclusive. Blood is propelled in the direction of rotation. (B) The impeller pump uses vanes mounted on a rotating central shaft. (C) The centrifugal pump uses three rapidly rotated, concentric cones to propel blood forward by centrifugal force.

Complications that may occur during operation of either type of pump include loss of electricity, loss of the ability to control pump speed, which produces "runaway pump" or "pump creep" when turned off, loss of the flow meter or RPM indicator, rupture of tubing in the roller pump raceway, and reversal of flow by improper tubing in the raceway. A means to manually provide pumping in case of electrical failure should always be available.

Filters and Bubble Traps

Microemboli

During clinical cardiac surgery with CPB the wound and the perfusion circuit generate gaseous and biologic and nonbiologic particulate microemboli (<500 μm diameter).[31,118–123] Microemboli produce much of the morbidity associated with cardiac operations using CPB (see section 12C). Gaseous emboli contain oxygen or nitrogen and may enter the perfusate from multiple sources and pass through other components of the system.[18,21] Potential sources of gas entry include stopcocks, sampling and injection sites,[122] priming solutions, priming procedures, intravenous fluids, vents, the cardiotomy reservoir, tears or breaks in the perfusion circuit, loose purse-string sutures (especially during augmented venous return),[18] rapid warming of cold blood,[98] cavitation, oxygenators, venous reservoirs with low perfusate levels,[21,82] and the heart and great vessels. Bubble oxygenators produce many gaseous emboli; membrane oxygenators produce very few.[84–86] Aside from mistakes (open stopcocks, empty venous reservoir, or air in the heart) the cardiotomy reservoir is the largest source of gaseous emboli in membrane oxygenator perfusion systems.

Blood produces a large number of particulate emboli related to thrombus formation (clots), fibrin, platelet and platelet-leukocyte aggregation, hemolyzed red cells, cellular debris, and generation of chylomicrons, fat particles, and denatured proteins.[124] Stored donor blood is also an important source of blood-generated particles.[125] Other biologic emboli include atherosclerotic debris and cholesterol crystals and calcium particles dislodged by cannulation, manipulation for exposure, or the surgery itself. Both biologic and nonbiologic particulate emboli are aspirated from the wound. Bits of muscle, bone, and fat are mixed with suture material, talc, glue, and dust and aspirated into the cardiotomy reservoir.[125,126] Materials used in manufacture, spallated material, and dust may also enter the perfusate from the perfusion circuit[125] if it is not first rinsed by recirculating saline through a prebypass microfilter, which is discarded.

In vivo microemboli larger than 100 μm are detected by transcranial Doppler ultrasound,[127] fluorescein angiography,[84] TEE, and retinal inspection. In the circuit, microemboli are monitored by arterial line ultrasound[128] or monitoring screen filtration pressure. Microfilter weights and examination, histology of autopsy tissues, and electron particle size counters of blood samples[125] verify microemboli beyond the circuit.

PREVENTION AND CONTROL OF MICROEMBOLI: Table 12-2 outlines methods to reduce microembolism. Major methods include using a membrane oxygenator and cardiotomy reservoir filter, minimizing and washing blood aspirated from the field,[129] and preventing air entry into the circuit and using left ventricular vents when the heart is opened.[130,131]

The brain receives 14% of the cardiac output and is the organ most sensitive to microembolic injury.[132] Strategies to selectively reduce microembolism to the brain include reducing Pa_{CO_2} to cause cerebral vasoconstriction,[133] hypothermia,[134] placing aortic cannulas downstream to the cerebral vessels,[50,51,122] and using special aortic cannulas with[29–31,33] or without[26] special baffles or screens designed to prevent cannula-produced cerebral atherosclerotic emboli.

Two types of blood microfilters are available for use within the perfusion circuit: depth and screen.[135–137] Depth filters consist of packed fibers or porous foam; have no defined pore size; present a large, tortuous, wetted surface; and remove microemboli by impaction and absorption. Screen filters are usually made of woven polyester or nylon

Table 12–2.

Minimizing Microemboli

Membrane oxygenator, centrifugal arterial pump
Cardiotomy reservoir filter (≤40 μm)
Arterial line filter/bubble trap (≤40 μm)
Keep temperature differentials <8–10°C
Prime with carbon dioxide flush; recirculate with saline and filter (5 μm)
Prevent air entry into the circuit Snug purse-string sutures Three-way stopcocks on all sampling ports Meticulous syringe management Adequate cardiotomy reservoir volume (for debubbling) Avoid excessive suction on vents One-way valved purge lines for bubble traps Use transesophageal echocardiography to locate trapped intracardiac air; de-air thoroughly
Wash blood aspirated from the surgical field
Prevent thrombus formation with adequate anticoagulation
Assess inflow cannulation site by epiaortic ultrasound imaging
Cannulate distal aorta or axillary artery
Consider use of special aortic cannulas

thread, have a defined pore size, and filter by interception. Screen filters vary in pore size and configuration and block most air emboli; however, as pore size decreases, resistance increases. As compared to no filter, studies indicate that all commercial filters effectively remove gaseous and particulate emboli.[138–141] Most investigations find that the Dacron wool depth filter is most effective, particularly in removing micro- and macroscopic air. Pressure differences across filters vary between 24 and 36 mm Hg at 5 L/min flow. Filters cause slight hemolysis and tend to trap some platelets; nylon filters may activate complement.[135,136]

The need for microfilters in the cardiotomy suction reservoir is universally accepted,[126] and most commercial units contain an integrated micropore filter. The need for a filter in the cardioplegia delivery system, however, is questionable,[142] and while almost always used, the need for an arterial line filter is unsettled.[137] In vitro studies demonstrate that an arterial filter reduces circulating microemboli[139–141] and clinical studies are confirmatory.[140,141] However, these filters do not remove all microemboli generated by the extracorporeal circuit.[18,122,126,143] When bubble oxygenators are used, studies show equivocal or modest reductions in microemboli[84,144–146] and neurologic outcome markers.[146–150] In contrast, membrane oxygenators produce far fewer microemboli, and when used without an arterial filter, the numbers of microemboli are similar to those found with bubble oxygenators plus arterial line filters.[85,137]

Although efficacy of arterial line microfilters remains unsettled, use is almost universal.[151] Filters are effective bubble traps, but increase costs, occasionally obstruct during use, are difficult to de-air during priming, and should be used with a bypass line and valved purge line to remove air.

Other sources of biologic microemboli may be more important. Cerebral microemboli are most numerous during aortic cannulation,[152–154] application and release of aortic clamps,[153,154] and at the beginning of cardiac ejection after open heart procedures.[155] Furthermore, as compared to perfusion microemboli, surgically induced emboli are more likely to cause postoperative neurologic deficits.[156]

Leukocyte-depleting filters

Leukocyte-depleting filters are discussed in section 12B and have been recently reviewed.[157–160] These filters reduce circulating leukocyte counts in most studies,[161–163] but fail to produce convincing evidence of clinical benefit.[164–166]

Tubing and Connectors

The various components of the heart-lung machine are connected by polyvinyl tubing and fluted polycarbonate connectors. Medical grade polyvinyl chloride tubing is universally used because it is flexible, compatible with blood, inert, nontoxic, smooth, nonwettable, tough, transparent, resistant to kinking and collapse, and can be heat sterilized. To reduce priming volume, tubing connections should be short; to reduce turbulence, cavitation, and stagnant areas, the flow path should be smooth and uniform without areas of constriction or expansion. Wide tubing improves flow rheology, but also increases priming volume. In practice $^{1}/_{2}$- to $^{5}/_{8}$-inch (internal diameter) tubing is used for most adults, but until a compact, integrated, complete heart-lung machine can be designed and produced as a unit, the flow path produces some turbulence. Careless tubing connections are sources of air intake or blood leakage and all connections must be secure. For convenience and safety, most tubing and connectors are prepackaged and disposable.

Heparin-Coated Circuits

Heparin can be attached to blood surfaces of all components of the extracorporeal circuit by ionic or covalent bonds. The Duraflo II heparin coating ionically attaches heparin to a quaternary ammonium carrier (alkylbenzyl dimethyl-ammonium chloride), which binds to plastic surfaces (Edwards Lifesciences, Irvine, Calif). Covalent attachment is produced by first depositing a polyethylenimine polymer spacer onto the plastic surface, to which heparin fragments bind (Carmeda Bioactive Surface, Medtronic Inc., Minneapolis, Minn). Ionic-bound heparin slowly leaches, but this is irrelevant in clinical cardiac surgery. The use of heparin-coated circuits during CPB has spawned an enormous literature[167–172] and remains controversial largely because studies are contaminated by patient selection, reduced doses of systemic heparin, and washing or discarding field-aspirated blood.[172] There is no credible evidence that heparin-coated perfusion circuits reduce the need for systemic heparin or reduce bleeding or thrombotic problems associated with CPB (see section 12B). Although the majority of studies indicate that heparin coatings reduce concentrations of C3a and C5b-9,[173] the inflammatory response to CPB is not reduced (see section 12B), and the evidence for clinical benefit is not convincing.[174,175]

Other surface modifications and coatings in development[168] include a phosphorylcholine coating,[176] surface-modifying additives,[179] a trillium biopassive surface,[177,178] and a synthetic protein coating[180] (see also section 12B).

Cardiotomy Reservoir and Field Suction

Blood aspirated from the surgical wound may be directed to the cardiotomy reservoir for defoaming, filtration, and storage before it is added directly to the perfusate. A sponge impregnated with a surfactant removes bubbles by reducing surface tension at the blood interface and macrofilters, microfilters, or combined filters remove particulate emboli. Negative pressure is generated by either a roller pump or by a vacuum applied to the rigid outer shell of the reservoir. The degree of negative pressure and blood level must be monitored to avoid excessive suction or introducing air into the perfusate.

The cardiotomy suction and reservoir are major sources of hemolysis, particulate and gaseous microemboli, fat globules, cellular aggregates, platelet injury and loss, thrombin generation, and fibrinolysis.[82,118,126,181,182] Air aspirated with wound blood contributes to blood activation and destruction and is difficult to remove because of the high proportion of nitrogen, which is poorly soluble in blood. High suction volumes and admixture of air are particularly destructive of platelets and red cells.[181,183] Commercial reservoirs are designed to minimize air entrainment and excessive injury to blood elements. Air and microemboli removal are also facilitated by allowing aspirated blood to settle within the reservoir before it is added to the perfusate.

An alternative method for recovering field-aspirated blood is to dilute the blood with saline and then remove the saline to return only packed red cells to the perfusate. Two types of centrifugal cell washers automate the process. Intermittent centrifugation (e.g., Haemonetics Cell Saver, Haemonetics Corp., Braintree, Mass) removes air, thrombin, and many biologic and nonbiologic microemboli from the aspirate at the cost of discarding plasma. Continuous centrifugation (e.g., Fresenius Continuous AutoTransfusion System, distributed in the U.S. by Terumo Corp., Ann Arbor, Mich) in addition removes fat and activated leukocytes.[184] A third alternative is to discard all field-aspirated blood, although most surgeons would find this practice unacceptable if it increased allogeneic blood transfusion. Increasingly, field-aspirated blood is recognized as a major contributor to the thrombotic, bleeding, and inflammatory complications of CPB (see section 12B).

Venting the Heart

If the heart is unable to contract, distention of either ventricle is detrimental to subsequent contractility.[185] Right ventricular distention during cardiac arrest or ventricular fibrillation is rarely a problem, but left ventricular distention can be insidious in that blood can enter the flaccid, thick-walled chamber from multiple sources during this period. During CPB blood escaping atrial or venous cannulas and from the coronary sinus and thebesian veins may pass through the unopened right heart into the pulmonary circulation. This blood plus bronchial arterial and venous blood, blood regurgitating through the aortic valve, and blood from undiagnosed abnormal sources (e.g., patent foramen ovale or patent ductus) may distend the left ventricle unless a vent catheter is used (Fig. 12-6). During CPB bronchial blood and noncoronary collateral flow average approximately 140 ± 182 and 48 ± 74 mL/min, respectively.[186]

There are several methods for venting the left heart during cardiac arrest. Few surgeons vent the left ventricular apex directly because of inconvenience and myocardial injury. Most often a multihole, soft-tip catheter (8F to 10F) is inserted into the junction of the right superior pulmonary vein and left atrium (see Fig. 12-6B) or left atrial appendage and may or may not be passed into the left ventricle. Others prefer to place a small suction catheter into the pulmonary artery.[187] The ventricle can also be vented by passing a catheter retrograde across the aortic valve when working on the mitral valve. Vent catheters are drained to the cardiotomy reservoir by a roller pump, vacuum source, or gravity drainage,[188,189] but must be carefully monitored for malfunction. If connected to a roller pump, the system should be carefully tested before use to ensure proper operation. Although inspection and palpation may detect ventricular distention, TEE monitoring or direct measurements of left atrial or pulmonary arterial pressures are more reliable. The heart is no longer vented for most myocardial revascularization operations, but the ventricle must be protected from distention.[190–192] If the heart cannot remain decompressed during distal anastomoses, a vent should be inserted. Often the cardioplegia line inserted into the aortic root is used for venting when not used for cardioplegia.[193]

The most common and serious complication of left heart venting is residual air when the heart is filled and begins to contract. De-airing maneuvers and TEE are important methods for ensuring removal of all residual air. In addition, many surgeons aspirate the ascending aorta via a small metal or plastic cannula to detect and remove any escaping air as the heart begins to eject.[194,195] Bleeding

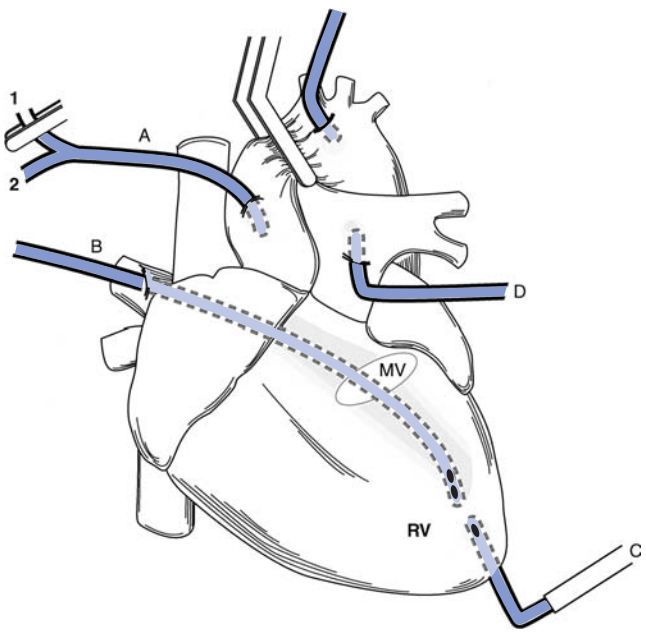

Figure 12-6. Diagram shows locations used to vent (decompress the heart). (A) Aortic root vent, which can also be used to administer cardioplegic solution after the ascending aorta is clamped. (B) A catheter placed in the right superior pulmonary vein/left atrial junction can be passed through the mitral valve into the left ventricle. (C) Direct venting of the left ventricle at the apex. (D) Venting the main pulmonary artery, which decompresses the left atrium because pulmonary veins lack valves.

problems or direct injury to the myocardium are other complications associated with left ventricular vents.

Cardioplegia Delivery Systems

Cardioplegic solutions contain 8 to 20 mEq/L potassium, magnesium, and often other components and are infused into the aortic root proximal to the aortic cross-clamp or retrograde into the coronary sinus to arrest the heart in diastole. The carrier may be crystalloid or preferably blood and is infused at temperatures around 4°C or 37°C, depending upon surgeon preference. Normothermic cardioplegia must be delivered almost continuously to keep the heart arrested; cold cardioplegia is infused intermittently. Cardioplegic solutions are delivered through a separate perfusion system that includes a reservoir, heat exchanger, roller pump, bubble trap, and perhaps microfilter (see Fig. 12-2). Temperature and infusion pressure are monitored. The system may be completely independent of the main perfusion circuit or branch from the arterial line. The system also may be configured to vent the aortic root when between infusions.

Antegrade cardioplegia is delivered through a small cannula in the aortic root or via cannulas directly into the coronary ostia when the aortic valve is exposed. Retrograde cardioplegia is delivered through a cuffed catheter inserted blindly into the coronary sinus.[196] Proper placement of the retrograde catheter is critical, but not difficult, and is verified by palpation, TEE, color of the aspirated blood, or pressure waveform of a catheter pressure sensor.[197] Complications of retrograde cardioplegia include rupture or perforation of the sinus, hematoma, and rupture of the catheter cuff.[198,199]

Hemoconcentrators (Hemofiltration/Ultrafiltration)

Hemoconcentrators, like oxygenators, contain one of several available semipermeable membranes (typically hollow fibers) that transfer water, electrolytes (e.g., potassium), and molecules up to 20 kD in size out of the blood compartment.[200] Hemoconcentrators may be connected to either venous or arterial lines or a reservoir in the main perfusion circuit, but require high pressure in the blood compartment to effect fluid removal. Thus a roller pump is needed unless connected to the arterial line. Suction may or may not be applied to the air side of the membrane to facilitate filtration. Up to 180 mL/min of fluid can be removed at flows of 500 mL/min.[201] Hemoconcentrators conserve platelets and most plasma proteins as compared to centrifugal cell washers, and may allow greater control of potassium concentrations than diuretics.[202] Aside from cost, disadvantages are few and adverse effects are rare.[201]

Perfusion Monitors and Safety Devices

Table 12-3 lists monitors and safety devices that are commonly used during CPB. Pressure in the arterial line between

Table 12–3.

Safety Devices and Procedures

Device or procedure	Usage (%)*
Low venous blood level alarm	60–100
With pump cut-off	34–80
High arterial line pressure alarm	84–94
With pump cut-off	35–75
Macrobubble detector	42–88
With pump cut-off	62–63
Arterial line filter	44–99
Pre-bypass recirculation/filtration	75–81
Oxygen supply filter	81–95
In-line venous oxygen saturation	75–76
In-line arterial oxygen saturation	12–13
Oxygenator gas supply oxygen analyzer	43–53
One-way valved intracardiac vent lines	18–73
Batteries in heart-lung machine	29–85
Alternate dedicated power supply	36
Electrical generator	28
Back-up arterial pump head	80
Back-up heater-cooler	97
Back-up oxygen supply	88–91
Emergency lighting	62–91
Pre-bypass activated clotting time	74–99
Activated clotting time during cardiopulmonary bypass	83
Pre-bypass check list	74–95
Written protocols	49–75
Log of perfusion incidents	46
Log of device failures	52

**Usage data represent ranges from various surveys, in references 94, 151, 354, 363, and 364.*

pump and arterial line filter is monitored continuously to instantly detect any increased resistance to arterial inflow into the patient. This pressure should be higher than radial arterial pressure because of resistance of the filter (if used) and cannula. The arterial pressure monitor may be connected to an audible alarm or the pump switch to alert the perfusionist of abrupt increases.

An *arterial line flowmeter* is essential for centrifugal pumps and may be desirable to confirm flow calculations with roller pumps.

Flow-through devices are available to continuously measure *blood gases, hemoglobin/hematocrit, and some electrolytes.*[203] These devices in the venous line permit rapid assessment of oxygen supply and demand.[204–206] In the arterial line the devices offer better control of blood gases.[207] The need for these devices is unproven and because reliability is still uncertain, use may distract operative personnel and spawn unnecessary laboratory measurements.[208–211] The use of automated analyzers by the perfusion team in the operating room is an alternative if frequent measurement of blood gases, hematocrit, and electrolytes is desirable.[203]

The *flow and concentration of oxygen* entering the oxygenator should be monitored.[212] Some teams also monitor exit gases to indirectly estimate metabolic activity and depth of anesthesia.[212] Some manufacturers recommend monitoring the *pressure gradient across membrane oxygenators,* which may be an early indication of oxygenator failure.[95–97]

Temperatures of the water entering heat exchangers must be monitored and carefully controlled to prevent blood protein denaturation and gaseous microemboli.[98] During operations using deep hypothermia, changes in venous line temperatures reflect rates of temperature change in the patient, and arterial line temperatures help protect against brain hyperthermia during rewarming.

A *low-level sensor* with alarms on the venous reservoir and a bubble detector on the arterial line are desirable safety devices. A *one-way valve* is recommended in the purge line between an arterial filter/bubble trap and cardiotomy reservoir to prevent air embolism. Ultrasound transducers embedded in the arterial perfusion tubing distal to the filter are now available to monitor low-level air entry into the circulation. Valves in the venous and vent lines protect against retrograde air entry into the circulation or in the arterial line to prevent inadvertent exsanguination.[106]

Automatic data collection systems are available for preoperative calculations and to process and store data during CPB.[213,214] Computer systems for operating CPB are in development.[215]

CONDUCT OF CARDIOPULMONARY BYPASS

The Perfusion Team

Although the surgeon is directly responsible to the patient for the outcome of the operation, he or she needs a close working relationship with the anesthesiologist and perfusionist. These three principals must communicate freely, often, and candidly. Their overlapping and independent responsibilities relevant to CPB are best defined by written policies that include protocols for various types of operations and emergencies and by periodic multidisciplinary conferences. This teamwork is not unlike the communication advocated for the cockpit crew of commercial and military aircraft.

The surgeon determines the planned operation, target perfusion temperatures, methods of cardioplegia, cannulations, and anticipated special procedures. During operation the surgeon communicates the procedural steps involved in connecting and disconnecting the patient to CPB and interacts with the other principals to coordinate perfusion management with surgical exposure and working conditions. The perfusionist is responsible for setting up and priming the heart-lung machine, performing safety checks, operating the heart-lung machine, monitoring the conduct of bypass, monitoring anticoagulation, adding prescribed drugs, and maintaining a written perfusion record.

The anesthesiologist monitors the operative field, anesthetic state and ventilation of the patient, the patient's physiology, and conduct of perfusion. A vigilant anesthesiologist is the safety officer and often "troubleshooter" of these complex procedures and along with the surgeon is in the best position to anticipate, detect, and correct deviations from desired conditions. In addition the anesthesiologist provides TEE observations before, during, and immediately after bypass.

Assembly of the Heart-Lung Machine

The perfusionist is responsible for setting up and preparing the heart-lung machine and all components necessary for the proposed operation. Most perfusionists use commercial, sterile, pre-packaged customized tubing packs that are connected to the various components that constitute the heart-lung machine. This dry assembly takes about 10 to 15 minutes, and the system can be kept in standby for up to 7 days. Once the system is primed with fluid, which takes about 15 minutes, it should be used within 8 hours. After assembly the perfusionist conducts a safety inspection and completes a written pre-bypass checklist.

Priming

Adult extracorporeal perfusion circuits require 1.5 to 2.0 L of balanced electrolyte solution (lactated Ringer solution, Normosol-A, or Plasma-Lyte). Before connections are made to the patient, the prime is recirculated through a micropore filter to remove particulate matter and air. The priming volume represents approximately 30 to 35% of the patient's blood volume and reduces the hematocrit to about two-thirds of the preoperative value. The addition of crystalloid cardioplegia causes further dilution. Thus sometimes a unit of banked blood is added to raise the

perfusate hematocrit to a predetermined minimum (e.g., 25% or more). Porcine heparin (2000 units) is added to each unit of banked whole blood to ensure anticoagulation. There is no consensus regarding the optimal hematocrit during CPB; most perfusates have hematocrits between 20 and 25% when used with moderate hypothermia (25 to 32°C). Dilution reduces perfusate viscosity, which is not a problem during clinical CPB, but also reduces oxygen-carrying capacity; mixed venous oxygen saturations below 60% usually prompt either transfusion or increased pump flow.[204,205] Sometimes 12.5 to 50 g of mannitol is added to stimulate diuresis and possibly minimize postoperative renal dysfunction.

Efforts to avoid the use of autologous blood include reducing the priming requirement of the machine by using smaller-diameter and shorter tubing lengths and operating the machine with minimal perfusate in the venous and cardiotomy reservoirs. This latter practice increases the risk of air embolism, the risk of which can be reduced by using collapsible reservoirs and reservoir level sensors that stop the pump. Autologous blood prime is another method, which displaces and then removes crystalloid prime by bleeding the patient into the circuit just before beginning CPB.[216,217] This method reduces perfusate volume, but phenylephrine may be required to maintain stable hemodynamics.[216,217] The method reduces transfusions and does not affect clinical outcome.

The use of colloids (albumin, gelatins, dextrans, and hetastarches) in the priming volume is controversial.[218] Colloids reduce the fall in colloid osmotic pressure[219,220] and may reduce the amount of fluid entering the extracellular space. The question is whether or not clinical outcome is improved. Prospective clinical studies have failed to document significant clinical benefits with albumin,[219–224] which is expensive and may have adverse effects.[225,226] Hetastarch may contribute to postoperative bleeding.[227] McKnight and colleagues found no influence of prime composition on postoperative nitrogen balance.[228] Because of possible adverse effects, including neurologic deficits, the addition of glucose and/or lactate to the prime is avoided.[229,230]

Anticoagulation and Reversal

Porcine heparin (300 to 400 U/kg IV) is given before arterial or venous cannulas are inserted. CPB is not started until anticoagulation is confirmed by either an activated clotting time (ACT) or the Hepcon test. Although widely used, bovine heparin is more antigenic in inducing antiplatelet IgG antibodies than is porcine heparin.[231] The anticoagulation effect is measured about 3 minutes after heparin administration. However, groups differ in the minimum ACT that is considered safe for CPB. The minimum ACT is 400 seconds; many groups recommend 480 seconds[232] because heparin only partially inhibits thrombin formation during CPB (see section 12B). In patients who have received aprotinin, ACT should be measured using kaolin as opposed to celite, because celite artifactually and erroneously increases ACT. Failure to achieve a satisfactory ACT may be due to inadequate heparin or to low concentrations of antithrombin. If a total of 500 U/kg of heparin fails to adequately prolong ACT, fresh frozen plasma (or recombinant antithrombin when available[233]) is needed to increase antithrombin concentrations to overcome "heparin resistance." Antithrombin is a necessary cofactor that binds circulating thrombin; heparin accelerates this reaction a thousandfold. See section 12B for management of patients with suspected or proven heparin-induced antiplatelet IgG antibodies and alternative anticoagulants to heparin.

During CPB, ACT or the Hepcon test is measured every 30 minutes. If ACT goes below the target level, more heparin is given. Usually one-third of the initial heparin bolus is given every hour even when the ACT is within the normal range. The Hepcon test titrates the heparin concentration and is more reproducible than ACT, but ACT provides satisfactory monitoring of anticoagulation. Although excessively high concentrations of heparin (ACT >1000 s) may cause remote bleeding away from operative sites, low concentrations increase circulating thrombin concentrations and risk clotting within the extracorporeal perfusion circuit.

One milligram of protamine (not to exceed 3 mg/kg) is given for each 100 units of heparin injected in the initial bolus dose. The heparin-protamine complex activates complement and often causes acute hypotension, which may be attenuated by adding calcium (2 mg/1 mg protamine). After a third of the planned protamine dose, blood must not be returned to the cardiotomy reservoir from the surgical field. Rarely, protamine may cause an anaphylactic reaction in patients with antibodies to protamine insulin.[234] Neutralization of heparin is usually confirmed by an ACT or Hepcon test and more protamine (50 mg) is given if either test remains prolonged and bleeding is a problem. Heparin rebound is the term used to describe a delayed heparin effect due to release of tissue heparin after protamine is cleared from the circulation. Although protamine is a mild anticoagulant, one or two supplemental 25- to 50-mg doses can be given empirically if heparin rebound is suspected. In most instances the heart-lung machine should be available for immediate use until the patient leaves the operating room.

Starting Cardiopulmonary Bypass

CPB is started at the surgeon's request with concurrence of the anesthesiologist and perfusionist. As venous return enters the machine, the perfusionist progressively increases arterial flow while monitoring the patient's blood pressure and volume levels in all reservoirs. Six observations are critical:

1. Is venous drainage adequate for the desired flow?
2. Is pressure in the arterial line acceptable?
3. Is arterial blood adequately oxygenated?

4. Is systemic arterial pressure acceptable?
5. Is systemic venous pressure acceptable?
6. Is the heart adequately decompressed?

Once full stable cardiopulmonary bypass is established for at least 2 minutes, lung ventilation is discontinued, perfusion cooling may begin, and the aorta may be clamped for arresting the heart.

Cardioplegia

Antegrade blood or crystalloid cardioplegia is administered directly into the aortic root at 60 to 100 mm Hg pressure proximal to the aortic cross-clamp by a dedicated cardioplegia roller pump (see Fig. 12-2). Blood entering the coronary sinus is captured by the right atrial or unsnared caval catheters; right ventricular distention is prevented. Usually the heart is cooled to a prespecified myocardial temperature range. The heart usually arrests within 30 to 60 seconds; delay indicates problems with delivery of the solution or unrecognized aortic regurgitation. Some surgeons monitor myocardial temperature or pH via direct needle sensors.[235]

The usual flow of retrograde cardioplegia is 200 to 400 mL/min at coronary sinus pressures between 30 and 50 mm Hg.[236] Higher pressures may injure the coronary venous system;[198] low pressures usually indicate inadequate delivery due to malposition of the catheter or leakage around the catheter cuff, but may indicate a tear in the coronary sinus.[199] Induction of electrical arrest is slower (2 to 4 minutes) than with antegrade, and retrograde cardioplegia may provide incomplete protection of the right ventricle.[196,237]

Key Determinants of Safe Perfusion

The following offers rational guidelines for management of CPB, which uses manipulation of temperature, hematocrit, pressure, and flow rate to adequately support cellular metabolism during nonphysiologic conditions.

Blood flow rate

Normally, basal cardiac output is determined by oxygen consumption, which is approximately 250 mL/min. It is impractical to measure oxygen consumption during cardiac surgery; therefore, the generally accepted flow rate at 35 to 37°C and hematocrit of 25% is approximately 2.4 L/min/m^2 in deeply anesthetized and muscle-relaxed patients. Hemodilution reduces blood oxygen content from approximately 20 mL/dL to 10 to 12 mL/dL; consequently flow rate must increase over resting normal cardiac output or oxygen demand must decrease. The resistance of venous catheters, turbulence, and loss of physiologic controls of the vasculature are reasons venous return and maximum pump flows are limited.

Hypothermia reduces oxygen consumption by a factor of 0.5 for every 10°C decrease in temperature. However, at both normothermia and hypothermia maximal oxygen consumption falls with decreasing flow as described in the following equation:

$$V_{O_2} = 0.44\,(Q - 62.7) + 71.6$$

This relationship at various temperatures is depicted in Fig. 12-7. For this reason Kirklin and Barrett-Boyes[238] recommend that flows be reduced only to levels that permit at least 85% of maximal oxygen consumption. At 30°C this

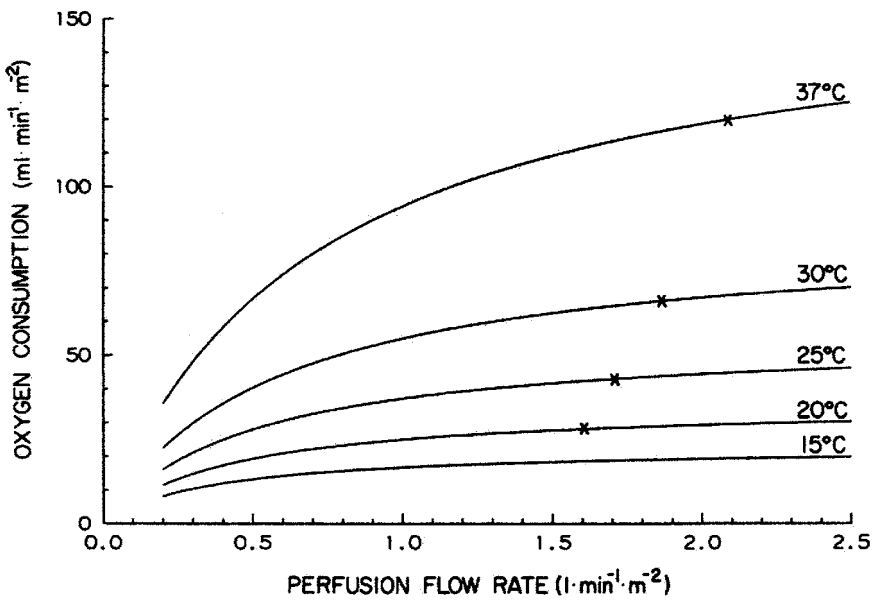

Figure 12-7. Nomogram relating oxygen consumption to perfusion flow rate and temperature. The small x's indicate clinical flow rates used by Kirklin and Barrett-Boyes. (*Reproduced with permission from Kirklin JW, Barrett-Boyes BG: Hypothermia, circulatory arrest, and cardiopulmonary bypass, in Kirklin JW, Barrett-Boyes BG [eds]: Cardiac Surgery, 2nd ed. New York, Churchill Livingstone, 1993; p 91.*)

flow rate is approximately 1.8 L/min/m^2; at 25°C, 1.6 L/min/m^2; and at 18°C, 1.0 L/min/m^2.

As long as mean arterial pressure remains above 50 to 60 mm Hg (i.e., above the autoregulatory range), cerebral blood flow is preserved even if systemic flow is less than normal. However, there is a hierarchical reduction of flow to other organs as total systemic flow is progressively reduced. First skeletal muscle flow falls, then abdominal viscera and bowel, and finally kidneys.

Pulsatile flow

Theoretical benefits of pulsatile blood flow include transmission of more energy to the microcirculation, which reduces critical capillary closing pressure, augments lymph flow, and improves tissue perfusion and cellular metabolism. Pulsatile flow theoretically also reduces vasocontrictive reflexes and neuroendocrine responses and may increase oxygen consumption, reduce acidosis, and improve organ perfusion. However, despite extensive investigation no one has convincingly demonstrated a benefit of pulsatile blood flow over nonpulsatile blood flow for short- or long-term CPB.[112,115,116,239–243] Two studies reported the association of pulsatile flow with lower rates of mortality, myocardial infarction, and low cardiac output syndrome,[244,245] but others failed to detect clinical benefits.[246–251]

Pulsatile CPB, which actually reproduces the normal pulse pressure within the body, is expensive, complicated, and requires a large-diameter aortic cannula. Higher nozzle velocities increase trauma to blood elements,[252] and pulsations may damage micromembrane oxygenators.[253] Thus for clinical CPB, nonpulsatile blood flow is an acceptable, nonphysiologic compromise with few disadvantages.

Arterial pressure

Systemic arterial blood pressure is a function of flow rate, blood viscosity (hematocrit), and vascular tone. Perfusion of the brain is normally protected by autoregulation, but autoregulation appears to be lost somewhere between 55 and 60 mm Hg during CPB at moderate hypothermia and a hematocrit of 24%.[133,254–256] Cerebral blood flow may still be adequate at lower arterial pressures,[257,258] but the only prospective randomized study found a lower combined major morbidity/mortality rate when mean arterial pressure was maintained near 70 mm Hg (average 69 $\pm$ 7) rather than below 60 (average 52 mm Hg).[259] In older patients, who may have vascular disease[260] and/or hypertension, mean arterial blood pressure is generally maintained between 70 and 80 mm Hg at 37°C. Higher pressures are undesirable because collateral blood flow to the heart and lungs increases blood in the operative field.

Hypotension during CPB may be due to low pump flow, aortic dissection, measurement error, or vasodilatation. Phenylephrine is most often used to elevate blood pressure, but arginine vasopressin (0.05 to 0.1 U/min) has recently been introduced. If anesthesia is adequate, hypertension can be treated with nitroprusside, an arterial dilator, or nitroglycerin, which predominately dilates veins and pulmonary vessels.

Hematocrit

The ideal hematocrit during CPB remains controversial because of competing advantages and disadvantages. Low hematocrits reduce blood viscosity and hemolysis, reduce oxygen-carrying capacity, and reduce the need for autologous blood transfusion. In general, viscosity remains stable when percent hematocrit and blood temperature (in degrees centigrade) are equal (i.e., viscosity is constant at hematocrit 37%, temperature 37°C, or at hematocrit 20%, temperature 20°C). Hypothermia reduces oxygen consumption and permits perfusion at 26 to 28°C with hematocrits between 18 and 22%, but at higher temperatures limits on pump flow may not satisfy oxygen demand.[261–263] Hill[264] and associates found that hematocrit during CPB did not affect either hospital mortality or neurologic outcome, but DeFoe and colleagues observed[265] increasing hospital mortality with hematocrits below 23% during CPB; thus the issue remains unresolved.[266] However, higher hematocrits (25 to 30%) during CPB appear justified[263] in view of the increasing safety of autologous blood transfusion, improved neurologic outcomes with higher hematocrits in infant cardiac surgery,[267] and more frequent operations near normothermia in older sicker patients.

Temperature

The ideal temperature for uncomplicated adult cardiac surgery is also an unsettled question.[263] Until recently nearly all operations reduced body temperature to 25 to 30°C during CPB to protect the brain, support hypothermic cardioplegia, permit perfusion at lower flows and hematocrits, and increase the safe duration of circulatory arrest in case of emergency. Hypothermia, however, interferes with enzyme and organ function, aggravates bleeding, increases systemic vascular resistance, delays cardiac recovery, lengthens duration of bypass, increases the risk of cerebral hyperthermia, and is associated with higher levels of depression and anxiety postoperatively.[268] Since the embolic risk of cerebral injury often is greater than perfusion risk, perfusion at higher temperatures (33 to 35°C), or "tepid" CPB, is recommended, in part because detrimental high blood temperatures are avoided during rewarming.[269] Increasingly, efforts are made to avoid cerebral hyperthermia during and after operation, and one study suggests improved neuropsychometric outcomes if patients are rewarmed to only 34°C.[270]

pH/P_{CO_2} management

There are two strategies for managing pH/P_{CO_2} during hypothermia: pH stat and alpha stat. During deep hypothermia and circulatory arrest (see below) there is increasing evidence that pH-stat management may produce better neurologic outcomes during pediatric cardiac surgery.[267] Alpha stat may be better in adults.[248,271,272] pH stat maintains temperature-corrected pH 7.40 at all temperatures and requires the addition of CO_2 as the patient is cooled. Alpha stat allows the pH to increase during cooling so that blood becomes alkalotic. Cerebral blood flow is higher, and pressure is passive and uncoupled from cerebral oxygen demand with pH

stat. With alpha stat, cerebral blood flow is lower, autoregulated, and coupled to cerebral oxygen demand.[273]

Arterial pao_2

Pao_2 should probably be kept above 150 mm Hg to assure complete arterial saturation. Whether or not high levels (i.e., >200 mm Hg) are detrimental has not been determined.

Glucose

Although Hill and associates[264] found no relationship between blood glucose concentrations during CPB and adverse neurologic outcome, others are concerned that hyperglycemia (>180 mg/dL) aggravates neurologic injury[230] and other morbidity/mortality.[274]

Patient Monitors

Systemic arterial pressure is typically monitored by radial, brachial, or femoral arterial catheter; central venous pressure is routinely monitored by a jugular venous catheter. Routine use of a Swan-Ganz pulmonary arterial catheter is controversial and not necessary for uncomplicated operations in low-risk patients.[275] During CPB the pulmonary artery catheter should be withdrawn into the main pulmonary artery to prevent lung perforation and suture ensnarement.

Transesophageal echocardiography

A comprehensive transesophageal echocardiography (TEE) examination[276] is an important monitor during most applications of CPB[277] to assess catheter and vent insertion and location;[196,278,279] severity of regional atherosclerosis;[43,44] myocardial injury, infarction, dilatation, contractility, thrombi, and residual air; undiagnosed anatomic abnormalities;[276] valve function after repair or replacement; diagnosis of dissection;[59,280] and adequacy of de-airing at the end of CPB.[281]

Temperature

Bladder or rectal temperature is usually used to estimate temperature of the main body mass, but does not reflect brain temperature.[282] Esophageal and pulmonary artery temperatures may be affected by local cooling associated with cardioplegia. The jugular venous bulb temperature is considered the best surrogate for brain temperature, but is difficult to obtain.[283] Nasopharyngeal or tympanic membrane temperatures are more commonly used, but tend to underestimate jugular venous bulb temperature during rewarming by 3 to 5°C.[284] During rewarming, arterial line temperature correlates best with jugular venous bulb temperature.[285]

Neurophysiologic monitoring

The efficacy of neurophysiologic monitoring during CPB is under investigation and not yet established as necessary. Techniques being investigated include jugular venous bulb temperature and saturation, transcranial Doppler ultrasound, near-infrared transcranial reflectance spectroscopy, and the raw or processed electroencephalogram.[286,287]

Adequacy of perfusion

During CPB oxygen consumption (Vo_2) equals pump flow rate times the difference in arterial (Cao_2) and venous oxygen content (Cvo_2). For a given temperature, maintaining Vo_2 at 85% predicted maximum during CPB assures adequate oxygen delivery (see Fig. 12-7).[238] Oxygen delivery (Do_2) equals pump flow times Cao_2 and should be above 250 mL/min/m^2 during normothermic perfusion.[261] Mixed venous oxygen saturation (Svo_2) assesses the relationship between Do_2 and Vo_2; values below 60% indicate inadequate oxygen delivery. Because of differences in regional vascular tone, higher Svo_2 does not assure adequate oxygen delivery to all vascular beds.[210,288] Metabolic acidosis (base deficit) or elevated lactic acid levels also indicate inadequate perfusion.

Urine output

Urine output is usually monitored but varies with renal perfusion, temperature, composition of the pump prime, diuretics, absent pulsatility, and hemoconcentration. Urine production is reassuring during CPB and oliguria requires investigation.

Gastric tonometry and mucosal flow

These Doppler and laser measurements gauge splanchnic perfusion but are rarely used clinically.

Stopping Cardiopulmonary Bypass

Prior to stopping CPB the patient is rewarmed to 34 to 36°C, the heart is defibrillated, and the lungs are re-expanded (40 cm H_2O pressure) and ventilated. Cardiac rhythm is monitored, and hematocrit, blood gases, acid-base status, and plasma electrolytes are reviewed. If the heart has been opened, TEE is recommended for detection and removal of trapped air before ejection begins. Caval catheters are adjusted to ensure unobstructed venous return to the heart. If inotropic drugs are anticipated, these are started at low flow rates. Vent catheters are removed, although sometimes an aortic root vent is placed on gentle suction to remove undiscovered air.

Once preparations are completed, the surgeon, anesthesiologist, and perfusionist begin to wean the patient off CPB. The perfusionist gradually occludes the venous line and simultaneously reduces pump input as cardiac rate and rhythm, arterial pressure and pulse, and central venous pressure are monitored and adjusted. Initially blood volume within the pump is kept constant, but as pump flow approaches zero, volume is added or removed from the patient to produce arterial and venous pressures within the physiologic ranges. During weaning, cardiac filling and contractility is often monitored by TEE, and intracardiac repairs and regional myocardial contractility are assessed. Pulse oximetry saturation near 100%, end-tidal CO_2 greater than 25 mm Hg, and mixed venous oxygen saturation higher than 65% confirm satisfactory ventilation and circulation. When cardiac performance is satisfactory and stable, all

catheters and cannulas are removed, protamine is given to reverse heparin, and blood return from the surgical field is discontinued.

Once the patient is hemodynamically stable, as determined by surgeon and anesthesiologist, and after starting wound closure, the perfusate may be returned to the patient in several ways. The entire perfusate may be washed and returned as packed cells. Excess fluid may be removed by a hemoconcentrator. More often the perfusate, which still contains heparin, is gradually pumped into the patient for hemoconcentration by the kidneys. Occasionally some of the perfusate must be bagged and given later. The heart-lung machine should not be completely disassembled until the chest is closed and the patient is ready for transfer.

SPECIAL TOPICS

Special Applications of Extracorporeal Perfusion

Reoperations, surgery of the descending thoracic aorta, and minimally invasive procedures may be facilitated by surgical incisions other than midline sternotomy. These alternative incisions often require alternative methods for connecting the patient to the heart-lung machine. Some alternative applications of CPB are presented below.

Right thoracotomy

Anterolateral incisions through the fourth or fifth interspaces provide easy access to the cavae and right atrium, adequate access to the ascending aorta, and no direct access to the left ventricle. Adequate exposure of the ascending aorta is available for cross-clamping, aortotomy, and administration of cardioplegia by retracting the right atrial appendage. De-airing the left ventricle (e.g., after mitral valve repair) is more difficult. External pads facilitate defibrillation.

Left thoracotomy

Lateral or posterolateral incisions in the left chest are used for a variety of operations. Venous return may be captured by cannulating the pulmonary artery via a stab wound in the right ventricle, or by retrograde cannulation of the left pulmonary artery or cannulation of the left iliac or femoral vein. With iliac or femoral cannulation, venous return is augmented by threading the cannula into the right atrium using TEE guidance.[289] The descending thoracic aorta or left subclavian, iliac, or femoral arteries are accessible for arterial cannulation.

Left heart bypass

Left heart bypass utilizes the beating right heart to pump blood through the lungs to provide gas exchange.[290] An oxygenator is not used and intake cannulation sites are exposed through a left thoracotomy. The left superior pulmonary vein–left atrial junction is an excellent cannulation site for capturing blood. The left atrial appendage can also be used, but is more friable and difficult. The apex of the left ventricle is infrequently used because of myocardial injury. The tip of the intake catheter must be free in the left atrium and careful technique is required to avoid air entry during cannulation and perfusion. The extracorporeal circuit typically consists only of tubing and a centrifugal pump and does not include a reservoir, heat exchanger, or bubble trap. This reduces the thrombin burden (see section 12B) and may permit reduced or no heparin, if anticoagulation poses an additional risk (e.g., in acute head injury). Otherwise, full heparin doses are recommended. The reduced perfusion circuit precludes the ability to add or sequester fluid, adjust temperature, or intercept systemic air emboli. Intravenous volume expanders may be needed to maintain adequate flows; temperature can usually be maintained without a heat exchanger.[291]

Full left heart bypass may be employed for left-sided coronary artery surgery by draining all of the pulmonary venous return out of the left atrium and leaving no blood for left ventricular ejection. If the heart fibrillates, blood can still passively pass through the right heart and lungs, but often an elevated central venous pressure is required.[292]

Partial left heart bypass is identical in configuration and cannulation to full left heart bypass and is used to facilitate surgery on the descending thoracic aorta. The patient's left ventricle supplies blood to the aorta proximal to aortic clamps, and the circuit supplies blood to the distal body. Typically about two-thirds normal basal cardiac output (i.e., 1.6 L/min/m^2) is pumped to the lower body. Arterial pressure is monitored proximal (radial or brachial) and distal (right femoral or pedal) to the aortic clamps. Blood volume in the body and circuit is assessed by central venous pressure and TEE monitoring of chamber dimensions. Management is more complicated because of the single venous circulation and separated arterial circulations.[290,293]

Partial cardiopulmonary bypass

Partial CPB with an oxygenator is also used to facilitate surgery of the descending thoracic aorta. After left thoracotomy, systemic venous and arterial cannulas are placed as described above. The perfusion circuit includes a reservoir, pump, oxygenator, heat exchanger, and bubble trap. The beating left ventricle supplies the upper body and heart, so lungs must be ventilated and upper body oxygen saturation should be independently monitored. Blood flow to the separate upper and lower circulations must be balanced as described for partial left heart bypass above.

Full cardiopulmonary bypass

Full CPB with peripheral cannulation is used when access to the chest is dangerous because of proximity of the heart, vital vessels (e.g., mammary arterial graft), or pathologic condition (e.g., ascending aortic mycotic aneurysm) abutting the anterior chest wall.[3] The patient is supine and a complete extracorporeal perfusion circuit is prepared and primed. Venous cannulas may be inserted into the right atrium via the iliac or femoral vessels and/or the right jugular vein. The iliac, femoral, or axillary-subclavian arteries may be used for arterial

cannulation. Initiation of CPB decompresses the heart, but cooling is usually deferred to keep the heart beating and decompressed until the surgeon can insert a vent catheter.

Femoral vein to femoral artery bypass

Femoral vein to femoral artery bypass with full CPB is used to initiate bypass outside the operating room for emergency circulatory assistance,[3] supportive angioplasty,[294] and intentional (aneurysm repair) or accidental hypothermia. Femoral vessel cannulation is occasionally used during other operations to facilitate control of bleeding (e.g., cranial aneurysm, tumor invading the inferior vena cava) or ensure oxygenation (e.g., lung transplantation or upper airway reconstruction).

Cannulation for minimally invasive (limited access) surgery

Off-pump coronary artery bypass describes construction of coronary arterial bypass grafts on the beating heart without CPB. Minimally invasive direct coronary artery bypass refers to coronary arterial bypass grafting with or without CPB through small, strategically placed incisions. Peripheral cannulation sites, described above, may be used, but often central cannulation of the aorta, atrium, or central veins is accomplished using specially designed or smaller cannulas placed through the operative incision or through separate small incisions in the chest wall.[295,296] Venous return may be augmented by applying negative pressure (see discussion of venous cannulation above); often soft-tipped arterial catheters are used to minimize arterial wall trauma.[27]

The Port-Access System provides a means for full CPB, cardioplegia administration, and aortic cross-clamping without exposing the heart and can be used for both valvular and coronary arterial operations.[70,279] Through the right internal jugular vein separate transcutaneous catheters are inserted into the coronary sinus for retrograde cardioplegia and the pulmonary artery for left heart venting. A multilumen catheter is inserted through the femoral artery and using TEE and/or fluoroscopy is positioned in the ascending aorta for arterial pump inflow, for balloon occlusion of the ascending aorta, and for administration of antegrade cardioplegia into the aortic root. Venous return is captured by a femoral venous catheter advanced into the right atrium. The system allows placement of small skin incisions directly over the parts of the heart that require surgical attention.

Minimally invasive surgery using CPB is associated with potential complications that include perforation of vessels or cardiac chambers, aortic dissection, incomplete de-airing, systemic air embolism, and failure of the balloon aortic clamp. Because CO_2 is heavier than air and more soluble in blood, the surgical field is sometimes flooded with CO_2 at 5- to 10-L/min flow to displace air when the heart is open. The balloon aortic clamp can leak, prolapse through the aortic valve, or move distally to occlude arch vessels. For safety the position of the occluding balloon is closely monitored by TEE, bilateral radial arterial pressures, and one of the following: transcranial Doppler ultrasound, cerebral near-infrared spectroscopy, or electroencephalogram.[296a]

Deep Hypothermic Circulatory Arrest

Deep hypothermic circulatory arrest (DHCA) is used for operations involving the aortic arch, porcelain aorta, thoracoabdominal aneurysms, pulmonary thromboendarterectomy, selected uncommon cardiovascular and neurologic procedures,[297,298] and certain complex congenital heart procedures. The technology involves reducing body temperature to less than 20°C, arresting the circulation for a short period, and then rewarming to 37°C. Deep hypothermia reduces cerebral oxygen consumption (Fig. 12-8), and attenuates release of toxic neurotransmitters and reactive oxidants during ischemia and reperfusion.[299]

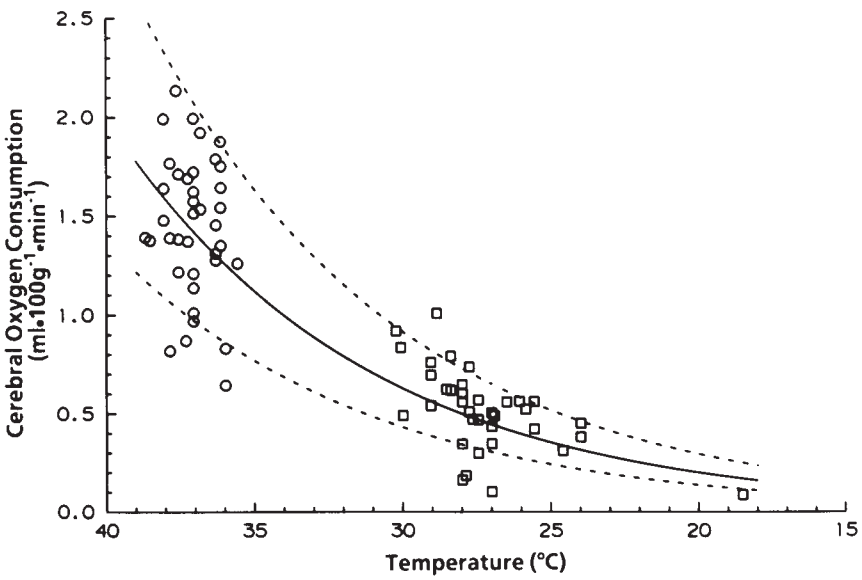

Figure 12-8. Relation between cerebral oxygen consumption and nasopharyngeal temperature during CPB at 2 L/min/m^2. (*Reproduced with permission from Kirklin JW, Barrett-Boyes BG: Hypothermia, circulatory arrest, and cardiopulmonary bypass, in Kirklin JW, Barrett-Boyes BG [eds]: Cardiac Surgery, 2d ed. New York, Churchill Livingstone, 1993; p 91.*)

Because perfusion cooling produces differential temperatures within both the body and brain,[282] more than one temperature is customarily monitored. Bladder, pulmonary artery, esophageal, or rectal temperatures are used to estimate body temperature. Nasopharyngeal and tympanic membrane temperatures are imperfect surrogates for mean brain temperature. Most surgical teams cool to either electroencephalographic silence, jugular venous saturation above 95%, or for at least 30 minutes before stopping circulation at nasopharyngeal or tympanic membrane temperatures below 20°C. Caloric exchange is proportional to body mass, rate of perfusion, and temperature differences between patient and perfusate; however, rates of perfusion cooling and rewarming are restricted (see the section on heat exchangers above). Perfusion cooling is usually supplemented by surface cooling using hypothermia blankets and/or packing the head in ice. Hyperthermia is avoided by keeping arterial inflow temperature below 37°C during rewarming.

Changes in temperature affect acid-base balance, which must be monitored and managed during deep hypothermia. The pH-stat protocol (CO_2 is added to maintain temperature-corrected blood pH at 7.4) may be preferred over the alpha-stat protocol, which allows cold blood to become alkalotic. Compared to alpha stat, pH stat increases the rate and uniformity of brain cooling,[300,301] slows the rate of brain oxygen consumption by 30 to 40% at 17°C,[301–303] and improves neurologic outcomes in animal models[267,304,305] and perhaps in infants,[306–308] but not necessarily in adults.[309] Hyperglycemia appears to increase brain injury and is avoided during deep hypothermia.[310] The value of high-dose corticosteroids or barbiturates remains unproven.

The safe duration of circulatory arrest during deep hypothermia is unknown. In adults arrest times as short as 25 minutes are associated with poor performance on neuropsychologic tests of fine motor function and memory.[311] Ergin and coworkers[312] found duration of arrest was a predictor of temporary neurologic dysfunction, which correlated with long-term neuropsychologic deficits.[313] At 18°C, cerebral metabolism and oxygen consumption are 17 to 40% of normothermia[314–316] and abnormal encephalographic patterns and cerebrovascular responses can be detected after 30 minutes of circulatory arrest.[314,317] Most investigators,[318–322] but not all[323] report increased mortality and adverse neurologic outcomes after 40 to 65 minutes of circulatory arrest. Most surgeons try to keep the period of arrest at less than 45 minutes, and if the operation allows, many perfuse for 10 to 15 minutes between serial arrest periods of 10 to 20 minutes.

Antegrade and Retrograde Cerebral Perfusion

Antegrade cerebral perfusion is used in lieu of DHCA or as a supplement. The cerebral vessels can be cannulated separately and perfused together by a single pump[324] or perfused collectively after a graft with a side branch is sewn to the top of the aortic arch from which the innominate, left carotid, and left subclavian arteries originate. Separate perfusion of separately cannulated vessels is rarely done. Perfusion is usually provided by a separate roller pump that receives blood from the arterial line. Line pressure is monitored and a microfilter may or may not be used. The cerebral vessels are collectively perfused with cold blood between 10 and 18°C and at approximate flows of 10 mL/kg/min; perfusion pressures are restricted to 30 to 70 mm Hg. At the present time each individual surgeon seems to have a preferred protocol between these broad ranges.[325–332] The adequacy of cerebral perfusion can be assessed by monitoring jugular venous saturation or near-infrared spectroscopy. Selective antegrade cerebral perfusion risks dislodging atheromatous emboli or causing air embolism, cerebral edema, or injury from excessive perfusion pressure.

Retrograde cerebral perfusion (RCP) was introduced in 1980 as emergency treatment for massive air embolism.[333] Ueda and associates introduced continuous RCP for cerebral protection as an adjunct to deep hypothermic circulatory arrest during aortic surgery.[334] During RCP and DHCA the superior vena cava is perfused at blood pressures usually between 25 and 40 mm Hg, temperatures between 8 and 18°C, and flows between 250 and 400 mL/min from a spur off the arterial line, which is clamped downstream to the spur. Some surgeons advocate much higher pressures and flows to compensate for runoff and have not shown detrimental effects.[335] A snare is usually placed around the superior caval catheter cephalad to the azygos vein to reduce runoff. The IVC may or may not be occluded.[322,336–339]

Retrograde cerebral perfusion has been widely and safely used,[321,335,339–347] but its effectiveness in protecting the brain is not clear.[322,328,348] The method can wash out some particulate emboli entering from arteries, which is a major cause of brain injury after aortic surgery.[337,349] However, it is not clear how adequately and completely all regions of the brain are perfused.[322,339,348,350] Lin and colleagues[342] found cortical flows to be only 10% of control values. RCP slows but does not arrest the decrease in cerebral oxygen saturation[324,335] and the decay in amplitude of somatosensory evoked potentials.[351] Others from clinical comparisons and animal studies believe RCP provides some cerebral protection over DHCA alone.[321,335,339,341,342,344,345,347,352] A few studies report that antegrade cerebral perfusion provides better protection than retrograde.[324,338,353]

Complications and Risk Management

Life-threatening incidents occur in 0.4 to 2.7% of operations with CPB and the incidence of serious injury or death is between 0.06 and 0.08% (Table 12-4).[94,151,354] Massive air embolism, aortic dissection, dislodgment of cannulas, and clotting within the circuit during perfusion are the principal causes of serious injury or death. Malfunctions of the heater-cooler, oxygenator, pumps, and electrical supply are the most common threatening incidents related to equipment. Other threatening incidents include premature takedown or clotting within the perfusion circuit. Complications related to

Table 12–4.

Adverse Incidents Involving Cardiopulmonary Bypass

	Incidence (events/1000)	Death or serious injury (%)*
Protamine reaction	1.3	10.5
Thrombosis during cardiopulmonary bypass	0.3–0.4	2.6–5.2
Aortic dissection	0.4–0.8	14.3–33.1
Dislodgment of cannula	0.2–1.6	4.2–7.1
Rupture of arterial connection	0.2–0.6	0–3.1
Gas embolism	0.2–1.3	0.2–8.7
Massive systemic gas embolism	0.03–0.07	50–52
Electrical power failure	0.2–1.8	0–0.6
Pump failure	0.4–0.9	0–3.5
Heater-cooler problems	0.5–3	0
Replace oxygenator during cardiopulmonary bypass	0.2–1.3	0–0.7
Other oxygenator problems	0.2–0.9	0
Urgent re-setup after takedown	2.9	13
Early unplanned cessation of cardiopulmonary bypass	0.2	0–0.7

**Percentage of incidents that resulted in death or serious injury. Data derived from references 94 and 151.*

connections to and from the heart-lung machine and perfusion during operation are described above with descriptions of the various components of the perfusion circuit.

Massive Air Embolism

The incidence of massive air embolism is between 0.003 and 0.007% with 50% of outcomes adverse.[94,151] Air can enter any component of the perfusion circuit at any time during operation if the integrity of the circuit is broken.[355] Stopcocks, connections, vent catheters, empty reservoirs, purse-string sutures, cardioplegia infusion catheters, and unremoved air in opened cardiac chambers are the most common sources of air emboli. Uncommon sources include oxygenator membrane leaks; residual air in the circuit after priming; reversal of flow in venous, vent, or arterial lines; and unexpected inspiration by the patient during cannula removal.

Massive air embolism during perfusion is a catastrophe and management guidelines are evolving.[20,333,355–358] Perfusion should stop immediately and clamps should be placed on both venous and arterial lines. Air in the circuit should be rapidly removed by recirculation and entrapment of all air in a reservoir or bubble trap. The patient should be immediately placed in steep Trendelenburg position and blood and air at the site of entry should be aspirated until no air is retrieved. TEE should be rapidly employed to search for air, but perfusion must resume promptly depending on body temperature to prevent ischemic brain damage. Cooling to deep hypothermia should be considered to protect the brain and other organs while air is located and removed. As soon as possible, retrograde perfusion of the brain should be undertaken while the aortic arch is simultaneously aspirated with the patient in steep Trendelenburg position. Corticosteroids and/or barbiturates may be considered. Depending upon circumstances and availability, hyperbaric oxygen therapy may be helpful if patients can be treated within 5 hours of operation.[357,359]

Risk management

Minimizing risks of extracorporeal perfusion requires strict attention to personnel training, preparation and training for emergencies, equipment function, and recordkeeping.[20] All members of the operative team must be trained, certified, and recertified in their respective roles and participate in continuing education programs. A policy manual for the perfusion team and written protocols should be developed

and continuously updated for various types of operations and emergencies. Emergency kits are prepared for out-of-operating-room crises. Adequate supplies are stocked in designated locations with sufficient inventory to support any operation or emergency for a specified period. An inventory of supplies is taken and recorded at regular intervals. Checklists are prepared and used for setting up the perfusion system and connecting to the patient. Equipment is inspected at regular intervals; worn, loose, or outdated parts are replaced; and preventive maintenance is provided and documented. New equipment is thoroughly checked before use and instructions are thoroughly digested by all user personnel. Safety alarms are optional; none replace the vigilance and attention of all OR personnel during an operation. Complete, signed written records are required for every perfusion; adverse events are recorded in a separate log and reviewed by the entire OR team. A continuous quality assurance program is desirable.[360]

During the procedure communication must be open between the surgeon, anesthetist, and perfusionist to coordinate activities. Statements are verbally acknowledged. Distractive conversations are discouraged. The entire OR team is committed to a zero-error policy, which can only be achieved by discipline and attention to details.[354,361,362]

The Response of Humoral and Cellular Elements of Blood to Extracorporeal Circulation

Within the body the endothelial cell, the only surface in contact with circulating blood, simultaneously maintains the fluidity of blood and the integrity of the vascular system. This remarkable cell maintains a dynamic equilibrium by producing anticoagulants to maintain blood in a fluid state and by generating procoagulant substances to enhance gel formation when perturbed. Blood proteins circulate as inert zymogens, which convert to active enzymes when stimulated. Likewise, blood cells remain quiescent until activated to express surface receptors and release proteins and enzymes involved in coagulation and inflammation. The continuous exposure of heparinized blood to the perfusion circuit and to cell tissues and fluid constituents of the wound during clinical cardiac surgery produces an intense thrombotic stimulus that involves both the tissue factor pathway (extrinsic coagulation pathway) in the wound and the contact and intrinsic coagulation pathways in the perfusion circuit. Thrombin is continuously generated and circulated despite massive doses of heparin in all applications of extracorporeal perfusion.[365–369] This powerful enzyme along with tissue factor from the wound and many other cytokines also activate an inflammatory reaction which can damage tissues and ultimately produce cell death by necrosis or apoptosis.

THROMBOSIS AND BLEEDING

Initial Reactions in the Perfusion Circuit

When heparinized blood contacts any biomaterial, plasma proteins are instantly adsorbed (<1 s) onto the surface to form a *monolayer* of selected proteins.[370–372] For each protein the amount adsorbed depends on its bulk concentration in plasma and the *intrinsic surface activity* of the biomaterial. Different biomaterials have different intrinsic surface activities for each plasma protein. The physical and chemical composition of the *biomaterial surface* determine the intrinsic surface activity of the biomaterial, but intrinsic surface activity is not predictable from knowledge of chemical and physical characteristics. Thus intrinsic surface activity differs among biomaterial surfaces, among plasma proteins, and among different bulk concentrations of plasma proteins. Concentrations of plasma proteins on a given biomaterial differ from concentrations in bulk plasma. Similarly, concentrations of surface-adsorbed proteins from the same plasma differ on different biomaterials. The composition of the protein monolayer is specific for the biomaterial and for various concentrations of proteins in the plasma, but the topography of the adsorbed protein layer may not be uniform across the surface of the biomaterial.[373] Thus it is not possible to predict the "thrombogenicity" of any biomaterial except by trial and error.

On most biomaterial surfaces fibrinogen is selectively adsorbed, but the adsorbed concentration of fibrinogen and other proteins may change over time.[372] Surface-adsorbed proteins "compete" for space on the biomaterial surface, but are tightly packed, irreversibly bound, and immobile. The density of surface-adsorbed proteins is 100 to 1000 times greater than the density of proteins in bulk plasma.[373] The complexity of blood-biomaterial interactions is further compounded by the fact that adsorbed proteins often undergo limited conformational changes[374,375] that may expose "receptor" amino acid sequences that are recognized by specific blood cells or bulk plasma proteins. Conformational changes of adsorbed

Figure 12-9. Electron micrograph of a rabbit endothelial cell (E), the only known nonthrombogenic surface. Note the overlapping junctions with neighboring endothelial cells. Endothelial cells rest on the internal elastic lamina (I), which abut medial smooth muscle cells. The vessel lumen is at the top. (*Reproduced with permission from Stemerman MB: Anatomy of the blood vessel wall, in Colman RW, Hirsh J, Marder VJ, Salzman E [eds]: Hemostasis and Thrombosis: Basic Principles and Clinical Practice, 2nd ed. Philadelphia, JB Lippincott, 1987; p 775.*)

factor XII and fibrinogen initiate activation of the contact pathway and platelet surface adhesion, respectively; similar changes in complement protein 3 participate in activation of the complement system.[375] For a given adsorbed protein these conformational changes may vary between biomaterial surfaces and in turn vary the reactivity of the adsorbed protein with cells and blood proteins in the bulk phase.

Thus heparinized blood does not directly contact biomaterial surfaces in extracorporeal perfusion circuits, but contacts monolayers of densely packed, immobile plasma proteins arranged in undefined mosaics that differ between locations and possibly across time. All biomaterial surfaces, including heparin-coated surfaces, are *procoagulant*;[367,376] only the endothelial cell is truly nonthrombogenic (Fig. 12-9).

ANTICOAGULATION

Extracorporeal perfusion and CPB are not possible without anticoagulation; the large procoagulant surface quickly overwhelms natural circulating anticoagulants—antithrombin, proteins C and S, tissue factor pathway inhibitor, and plasmin—to produce thrombin and thrombosis within the circuit. Thrombin is produced in extracorporeal perfusion systems with small surface areas and high-velocity flow,[368,377,378] but thrombosis may not be apparent if other procoagulants (e.g., addition of blood from wounds) are absent. Generation of thrombin varies widely between applications of extracorporeal technology (see below), but this powerful and potentially dangerous enzyme is produced whenever blood contacts a nonendothelial cell surface (Fig. 12-10).

During CPB and open heart surgery high concentrations of heparin (3 to 4 mg/kg, initial dose) are needed to maintain the fluidity of blood. Heparin has both advantages and disadvantages; the most notable advantages are parenteral use, immediate onset of action, and rapid reversal by protamine or recombinant platelet factor 4.[379] Heparin does not directly inhibit coagulation, but acts by accelerating the actions of the natural protease, antithrombin.[380] Heparin-catalyzed antithrombin, however, does not inhibit thrombin bound to fibrin[381] or factor Xa bound to platelets within clots;[382] thus heparin only partially inhibits thrombin in vivo. Antithrombin primarily binds thrombin; its action on factors Xa and IXa is much slower. Heparin inhibits coagulation at the end of the cascade after nearly all other coagulation proteins have been converted to active enzymes. In addition, heparin to varying degrees activates several blood constituents: platelets,[383–385] factor XII,[386] complement, neutrophils, and monocytes.[387–389] Heparin increases the sensitivity of platelets to soluble agonists,[385] inhibits binding to

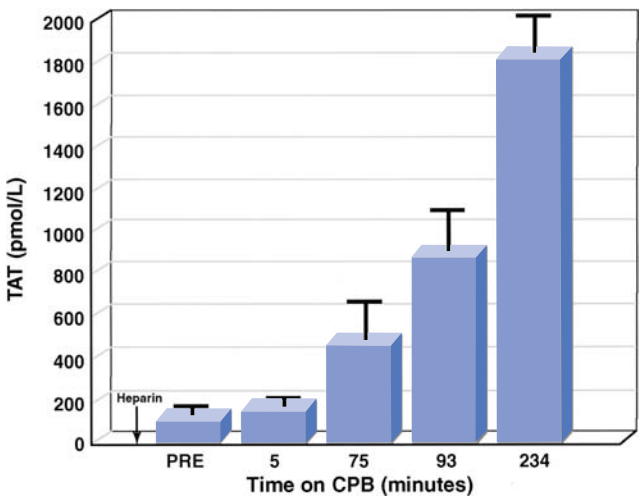

Figure 12-10. Plasma thrombin-antithrombin (TAT) measurements of thrombin generation during CPB and clinical cardiac surgery of varying duration. (*Data from Brister et al.*[366])

von Willebrand factor,[390] and modestly increases template bleeding times.[384] Thrombin concentrations cannot be measured in real time and only insensitive, indirect methods are available to regulate heparin anticoagulation in the operating room.[391–393]

Heparin is also associated with some clinical idiosyncrasies. In some patients recent, prolonged parenteral heparin may reduce antithrombin concentrations and produce *heparin resistance.*[380,394,395] Insufficient antithrombin may also occur due to insufficient synthesis or increased consumption in some cyanotic infants, premature babies, cachectic patients, and patients with advanced liver or renal disease. The deficiency in antithrombin prevents heparin from prolonging activated clotting times to therapeutic levels. In these patients fresh frozen plasma is needed to increase plasma antithrombin concentrations to inhibit thrombin. *Heparin rebound* is a delayed anticoagulant effect after protamine neutralization due to the rapid metabolism of protamine and delayed seepage of heparin into the circulation from lymphatic tissues and other deposits. Heparin is also associated with an allergic response in some patients that produces heparin-induced thrombocytopenia (HIT) with or without thrombosis (see below). Lastly, heparin only partially suppresses thrombin formation during CPB and all applications of extracorporeal perfusion and mechanical circulatory and respiratory assistance despite doses two to three times those used for other indications (see Fig. 12-10).[365–368] Thus heparin is far from an ideal anticoagulant.

Potential alternatives for heparin during extracorporeal perfusion (ECP) include low-molecular-weight heparin, danaparoid (Organan), recombinant hirudin (Lepirudin), and the organic chemical argatroban (Texas Biotechnology Corp., Houston, Texas). All have important drawbacks and are approved for use in HIT and in patients with circulating IgG anti-heparin-PF4 complex antibodies (see below). Low-molecular-weight heparins have long half-lives in plasma (4 to 8 hours), require antithrombin as a cofactor, primarily inhibit factor Xa, and are not reversible by protamine.[396,397] Although less antigenic than standard heparin, low-molecular-weight heparins can stimulate production of IgG anti-heparin-PF4 complex antibodies.[397] Danaparoid is a mixture of heparin sulfate, dermatan sulfate, and chrondroitin sulfate that catalyzes antithrombin to inhibit thrombin and factor Xa. To a lesser extent, danaparoid also catalyzes inhibition of thrombin by heparin cofactor II. The anticoagulant effect is long lasting (plasma half-life 4.3 hours)[398] and is not reversed by protamine.

Recombinant hirudin (Lepirudin) is a direct inhibitor of thrombin, is effective rapidly, does not have an effective antidote, is monitored by the partial thromboplastin time, is cleared by the kidney, and has a relatively short half-life in plasma (40 minutes).[399] This drug has been successfully used during CPB and open heart surgery, but in many instances bleeding after bypass has been troublesome and substantial. A newer drug is a semisynthetic bivalent thrombin inhibitor composed of 12 amino acids from hirudin, which binds to exosite 1 of thrombin linked to an active site-directed moiety, D Phe Pro Arg Pro, by four glycines.[400] This drug, bivalirudin (Angiomax), has a shorter half-life than hirudin and therefore may be safer. In addition, only a small amount is excreted by the kidney. In coronary angioplasty, bivalirudin was as effective as heparin but there was less bleeding. Argatroban is also a direct thrombin inhibitor[401] with rapid onset of action and short plasma half-life (40 to 50 minutes).[402] Argatroban is metabolized in the liver and is without an antidote, but can be monitored with partial thromboplastin times or activated clotting times. At present there is little clinical experience with argatroban or bivalirudin in cardiac surgical patients.

HEPARIN-ASSOCIATED THROMBOCYTOPENIA, HEPARIN-INDUCED THROMBOCYTOPENIA, AND HEPARIN-INDUCED THROMBOCYTOPENIA AND THROMBOSIS

Heparin-associated thrombocytopenia is a benign, nonimmune, 5 to 15% decrease in platelet count that occurs within a few hours to 3 days after heparin exposure. The etiology is due to mild platelet stimulation from multifactorial causes; bleeding does not occur; and the condition is clinically inconsequential.[403]

Heparin-induced thrombocytopenia (HIT) and heparin-induced thrombocytopenia and thrombosis (HITT) are different manifestations of the same immune disease. Heparin binds to platelets in the absence of an antibody and releases small amounts of platelet factor 4 (as occurs in heparin-associated thrombocytopenia). PF4 avidly binds heparin to form a heparin-PF4 (H-PF4) complex, which is antigenic in some people. In these individuals IgG antibodies to the H-PF4 complex are produced within 5 to 15 days after exposure to heparin and continue to circulate in the absence of more heparin for approximately 3 to 6 months.[404] IgG-anti-H-PF4 antibodies plus H-PF4 complexes form *HIT complexes,* which unite IgG Fc terminals to platelet Fc receptors (Fig. 12-11). This binding strongly stimulates platelets to release more PF4.[405] A self-perpetuating, accelerating cascade of platelet activation, release, and aggregation ensues. Since platelet granules contain several procoagulatory proteins (e.g., thrombin, fibronectin, factor V, fibrinogen, and von Willebrand factor), release also activates coagulation proteins to generate thrombin.

The intensity of the immune reaction varies between patients, but also varies by the indications for heparin use. Both heparin and PF4 must be available to form the antigenic H-PF4 complex. Patients who do not have conditions that activate platelets have a low incidence of HIT following administration of heparin, because few PF4 molecules are available to form H-PF4 complexes. In medical patients the incidence of thrombocytopenia after heparin is about 0.5%, the incidence of HITT is approximately 0.25%, and only 3% have IgG anti-H-PF4 antibodies by enzyme immunoassay.[406] Large doses of heparin are given and huge numbers of

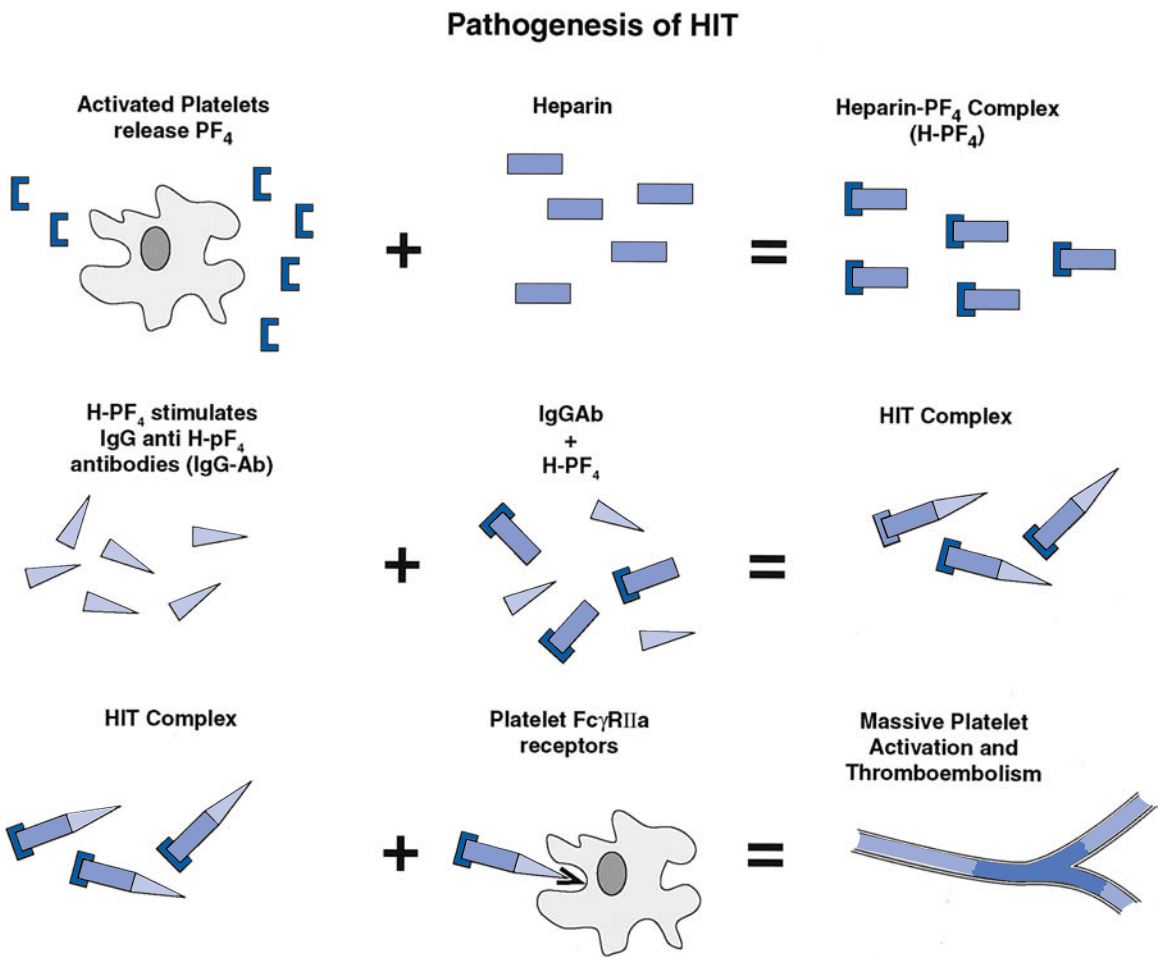

Figure 12-11. The generation of HIT complexes. Read each horizontal group of three left to right beginning at top left. See text for full explanation.

platelets are activated during CPB. Thus after CPB, 50% of patients have IgG anti-H-PF4 antibodies, 2% have immune heparin-induced thrombocytopenia, and approximately 1% develop HITT.[406] A combination of three ingredients is necessary to produce HIT or HITT: heparin, platelet factor 4, and IgG anti-H-PF4 antibodies. Since IgG antibodies are transient, a second heparin exposure 6 months after HIT is not likely to produce HIT or HITT,[404] but will stimulate production of new IgG antibodies to the H-PF4 complex. The danger is a second heparin exposure when IgG anti-H-PF4 antibodies are still circulating.

IgG anti-H-PF4 antibodies are detected in two ways. The serotonin release test detects the release of radioactive serotonin from normal platelets washed by the patient's serum.[407] An enzyme immunoassay measures IgG anti-H-PF4 antibodies directly. Both assays are equally sensitive in patients with clinical HIT, but the enzyme immunoassay is more sensitive in detecting IgG anti-H-PF4 antibodies in patients without other evidence of the disease.[407]

The clinical presentation of HIT may be insidious. If the platelet count was originally normal, the earliest sign is an abrupt decrease of at least 50% in platelet count (to less than 150,000/μL) in a patient who has had exposure to heparin within the past 5 to 15 days.[404] This event is a preoperative stop sign for elective cardiac operations. After CPB, platelet counts below 80,000/μL should trigger an order to stop all heparin, including heparin flushes, and to obtain daily platelet counts. The patient should be thoroughly examined for deep vein thrombosis, extremity ischemia, stroke, myocardial infarction, or any evidence of intravascular thrombosis using ultrasound and appropriate radiographic technology. Any evidence of vascular thrombosis should prompt a plasma sample for IgG anti-H-PF4 antibodies. A positive antibody test confirms the diagnosis of HIT in patients with thrombocytopenia and HITT in those with either venous or arterial thrombosis or both. It is important to stress that HIT or HITT is a clinical diagnosis and that a positive antibody test is not required before stopping heparin.

Once the diagnosis of HIT or HITT is suspected, management must focus on prevention of further intravascular thrombosis. Bleeding is rarely the problem; intravascular

thrombosis is. Neither heparin nor platelet transfusions should be given; platelet transfusions only add more PF4 if heparin and IgG anti-H-PF4 antibodies are still circulating. If heparin is proven absent from the circulation, platelet transfusions may be used very cautiously if the patient has significant nonsurgical bleeding. Surgical measures to reopen thrombosed large arteries are usually futile because the platelet-rich thrombus (white clot) often extends into small arteries and arterioles. An inferior vena cava filter is recommended if pulmonary embolism is likely or has occurred.

Modern management also includes full anticoagulation with recombinant hirudin (Lepirudin), argatroban, or possibly bivalirudin to prevent further extension of thrombosis or development of clinical intravascular thrombosis. This may occur in 40 to 50% of patients with HIT who are treated only with heparin cessation.[408] At present there is little experience with argatroban in cardiac surgical patients with HITT, but the drug is a direct thrombin inhibitor, has attractive pharmacokinetics, and is approved for patients with HITT. Full anticoagulation with hirudin in fresh postoperative cardiac surgical patients is recommended, but the safety zone between bleeding and thrombosis is narrow. The patient must be carefully monitored for pericardial tamponade and signs of hidden bleeding. Hirudin is monitored by activated partial thromboplastin time and the range used is similar to that with intravenous heparin. The effective blood concentration of hirudin for thrombin inhibition is 0.5 to 1.5 μg/mL.[409] To achieve this, 0.2-mg/kg/h infusions are recommended.[409] Dose must be reduced in patients with renal failure because the kidney clears the drug. Argatroban is sometimes a better choice, but it should be remembered that it is difficult to manage in the presence of liver disease since it is metabolized in that organ. In most patients oral anticoagulation with warfarin is started at the same time as intravenous hirudin, but warfarin should not be started prior to hirudin.

Emergency or urgent open heart surgery with CPB using hirudin is possible in patients with circulating IgG anti-HPF4 antibodies. The therapeutic level of drug should be between 3.5 and 4.5 μg/mL during CPB.[409] Greinacher recommends bolus doses of 0.25 mg/kg IV and 0.2 mg/kg in the priming volume followed by an infusion of 0.5 mg/min until 15 minutes before stopping CPB.[409] At that time 5 mg of hirudin is added to the perfusate to prevent clotting within the heart-lung machine.

Patients who require elective cardiac surgery are best deferred until circulating IgG anti-H-PF4 antibodies are absent by enzyme immunoassay. Patients with a history of HIT who require elective cardiac surgery with CPB should have IgG anti-H-PF4 antibodies measured in their serum before surgery is scheduled. If antibodies are absent, elective surgery can be safely carried out using heparin anticoagulation, *if the first re-exposure to heparin is the bolus dose given just before starting CPB.* Since HIT requires the presence of the H-PF4 complex plus IgG anti-H-PF4 antibodies to form the HIT complex, and since it takes about 5 days to produce these antibodies, HIT or HITT will not occur if no further heparin is given after operation.

COAGULATION AND EXTRACORPOREAL PERFUSION THROMBIN GENERATION

Generation of thrombin during cardiopulmonary bypass and other applications of extracorporeal circulatory technology is the cause of the thrombotic and bleeding complications associated with ECP. Theoretically, if thrombin formation could be completely inhibited during ECP, the consumptive coagulopathy, which consumes coagulation proteins and platelets and causes bleeding complications, would not occur.

Thrombin generation and the fibrinolytic response primarily involve the extrinsic and intrinsic coagulation pathways, the contact and fibrinolytic plasma protein systems, and platelets, monocytes, and endothelial cells.

Contact System

The contact system includes four primary plasma proteins—factor XII, prekallikrein, high-molecular-weight kininogen, and C-1 inhibitor[410]—and is activated during CPB and clinical cardiac surgery.[411] This system is involved in complement and neutrophil activation and the inflammatory response to ECP, but is not involved in thrombin formation in vivo. However, when blood contacts a negatively charged surface (protein surfaces contain both positive and negative charges) in ECP, small amounts of factor XII are adsorbed and undergo a conformational change to factor XIIa.[373,412] Factor XIIa in the presence of high-molecular-weight kininogen activates factor XI and initiates the intrinsic coagulation pathway (Fig. 12-12). Thrombin also activates factor XI, and is the predominating agonist in vivo in pathologic states.[413]

Intrinsic Coagulation Pathway

The intrinsic coagulation pathway probably does not generate thrombin in vivo, but does initiate thrombin formation when blood contacts nonendothelial cell surfaces such as perfusion circuits.[414,415] Factor XIa, produced by activation of the contact system and subsequently thrombin generation, activates factor IX, which forms part of the intrinsic tenase complex.[416,417] Factor XI is primarily activated by thrombin (see Fig. 12-12).

Extrinsic (Tissue Factor) Coagulation Pathway

The extrinsic coagulation pathway is the major coagulation pathway in vivo and is a major source of thrombin generation during CPB and clinical cardiac surgery.[418,419] Exposure of blood to tissue factor by direct contact in the wound or by wound blood aspirated into the ECP circuit

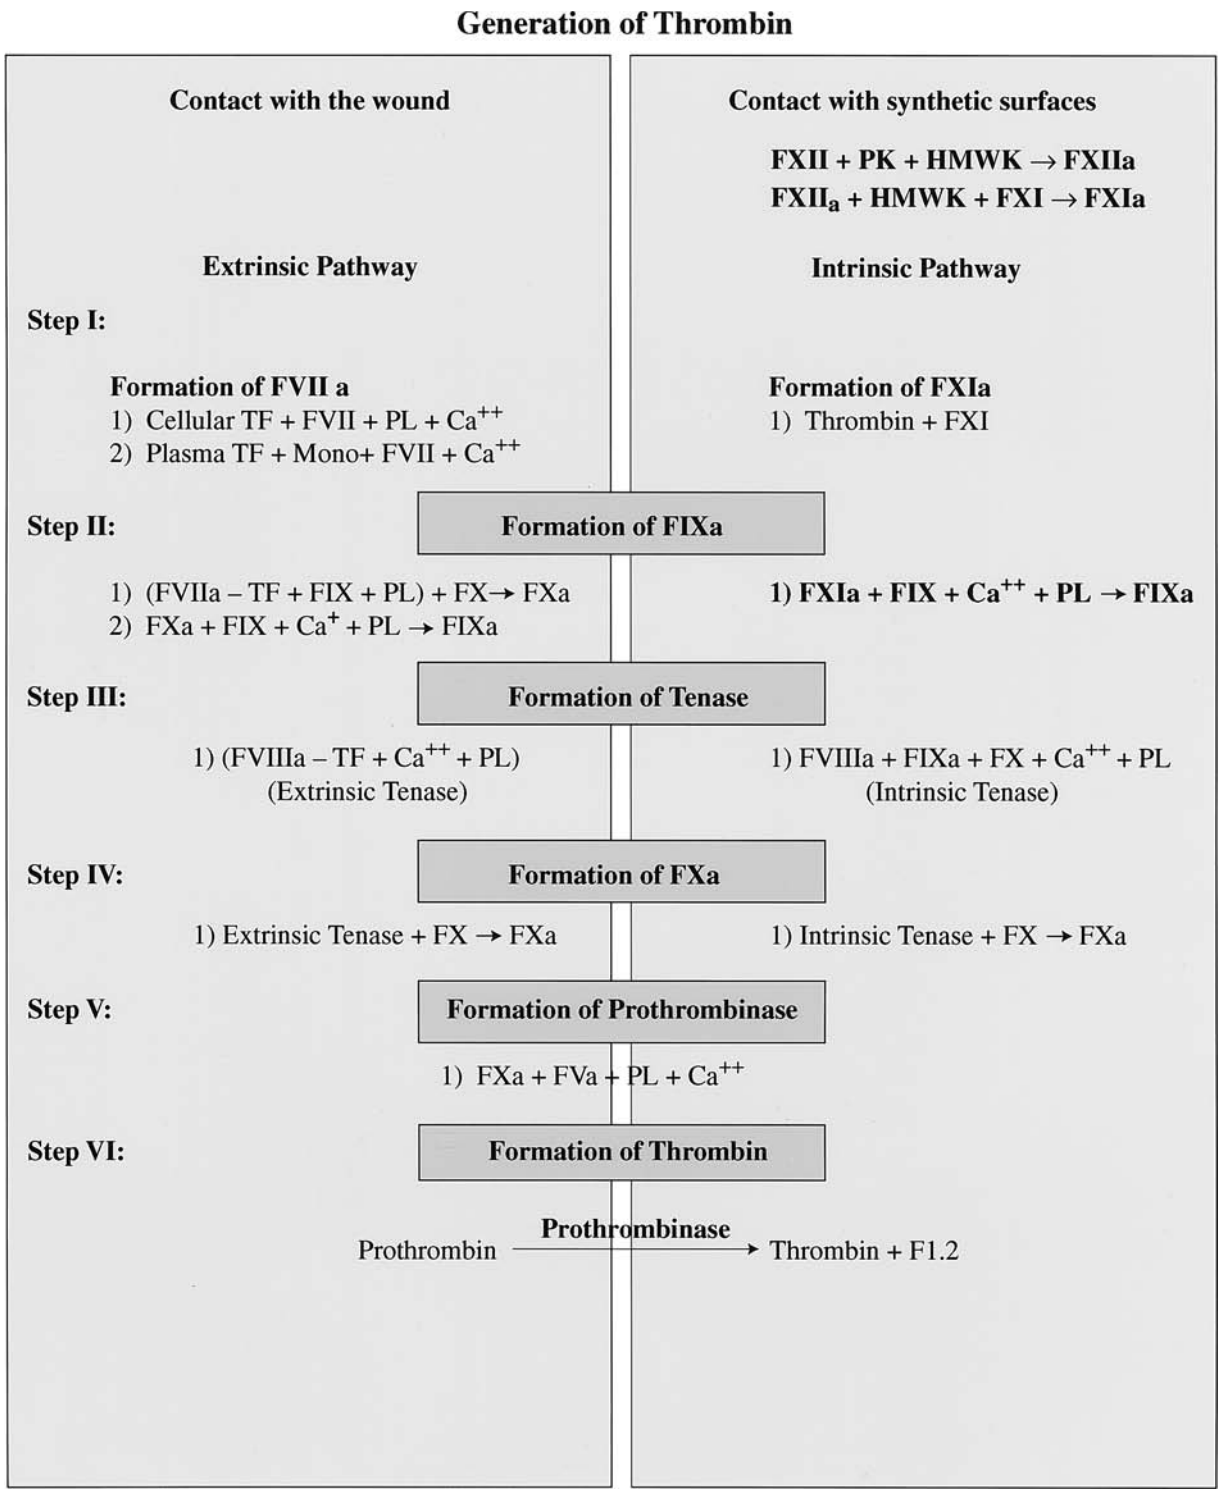

Figure 12-12. Steps in the generation of thrombin in the wound and in the perfusion circuit via the extrinsic, intrinsic, and common coagulation pathways. Ca^{++} = calcium ion; HMWK = high-molecular-weight kininogen; mono = monocyte; PK = prekallikrein; PL = cellular phospholipid surface; TF = tissue factor. Activated coagulation proteins are indicated by the suffix "a."

initiates the extrinsic coagulation pathway.[417] Tissue factor (TF) is a cell-bound glycoprotein that is constitutively expressed on the cellular surfaces of fat, muscle, bone, epicardium, adventitia, injured endothelial cells, and many other cells except pericardium.[419–421] Plasma TF associated with wound monocytes is a second source of TF and may be an important source during CPB and clinical cardiac surgery.[422] Tissue factor is the cofactor for the activation of factor VII to factor VIIa, which is part of extrinsic tenase (see Fig. 12-12).

Tenase Complexes

Intrinsic and extrinsic tenase catalyze the activation of factor X to factor Xa (see Fig. 12-12). Extrinsic tenase is formed by the combination of tissue factor, factor VIIa, calcium, and a phospholipid surface to cleave a small peptide from factor X to form factor Xa.[417] Extrinsic tenase also generates small amounts of factor IXa,[423] which greatly accelerates formation of intrinsic tenase and is the major pathway for the formation of factor Xa. Intrinsic tenase is produced by the combination of factor IXa, factor VIIIa, and calcium on the surface of an activated platelet,[424] and catalyzes production of factor Xa 50 times faster than extrinsic tenase.[417] Factor Xa activates factors V and VII in feedback loops.

Common Coagulation Pathway

Factor Xa is the gateway protein of the common coagulation pathway. Factor Xa slowly cleaves prothrombin to alpha-thrombin, the active enzyme, and a fragment, F1.2, but the reaction is 300,000 times faster if catalyzed by the *prothrombinase complex.*[417] The prothrombinase complex is produced when factor Xa, in the presence of Ca^{2+}, is anchored by factor Va onto a phospholipid surface provided by platelets, monocytes, or endothelial cells.[417] Either factor Xa or thrombin activates factor V to factor Va. The prothrombinase complex cleaves prothrombin to alpha-thrombin and a fragment, F1.2, and is the major pathway producing thrombin.[417] F1.2 is a useful marker of the reaction.

Thrombin

Thrombin is a powerful enzyme that accelerates its own formation by several feedback loops.[425] Thrombin is the major activator of factor XI and the exclusive activator of factor VIII in the intrinsic pathway. Thrombin is a secondary activator of factor VII, but once formed may be the most important activator in the wound. Lastly, thrombin is the primary activator of factor V in the formation of the prothrombinase complex (see Fig. 12-12).

Thrombin has both procoagulant and anticoagulant properties.[425] Thrombin is the enzyme that cleaves fibrinogen to fibrin and in the process creates two fragments, fibrinopeptides A and B. Thrombin activates platelets via the platelet thrombin receptor and thus may be the major agonist for platelets both in the wound and in the perfusion circuit. Thrombin also activates factor XIII to cross-link fibrin to an insoluble form and to attenuate fibrinolysis. Lastly, thrombin activates thrombin-activated fibrinolysis inhibitor, which alters fibrin to reduce lysis.[425]

Thrombin also stimulates the production of anticoagulants. Surface glycosaminoglycans, such as heparan sulfate, inhibit thrombin and coagulation via antithrombin. Thrombin stimulates endothelial cells to produce tissue plasminogen activator (t-PA), which is the major enzyme that cleaves plasminogen to plasmin. Thrombin also stimulates the production of nitric oxide and prostaglandin by endothelial cells. Thrombin in the presence of thrombomodulin activates protein C, which in the presence of protein S destroys activated factor V and VIII.

Thrombin Generation during Extracorporeal Perfusion

All applications of extracorporeal perfusion and exposure of blood to nonendothelial cell surfaces generate thrombin.[365–367] F1.2 is a protein fragment that is formed when prothrombin is cleaved to thrombin; thus F1.2 is a measure of thrombin generation but not of thrombin activity. F1.2 and thrombin-antithrombin complex increase progressively during clinical cardiac surgery with CPB, during applications of circulatory assist devices,[368,379] and during extracorporeal life support (see Fig. 12-10). The amount of thrombin produced seems to vary with the intensity of the stimuli for thrombin production and may vary with age, comorbid disease, and clinical health of the patient. The cytokines interleukin-1-beta (IL-1-beta) and tumor necrosis factor-alpha (TNF-alpha) are procoagulant and inhibit the thrombomodulin/protein C anticoagulant pathway and stimulate production of type I plasminogen activator inhibitor.[426] Complex cardiac surgery that requires several hours of CPB produces more F1.2[366] than short procedures with minimal exposure of circulating blood to the wound.[427] Thrombin generation varies with the amount and type of anticoagulant used; surface area of the blood-biomaterial interface; duration of exposure to the surface; turbulence, stagnation, and cavitation within perfusion circuits; and to a lesser degree temperature and the "thromboresistant" characteristics of biomaterial surfaces.[428] Very high concentrations of heparin, sufficient to increase spontaneous bleeding, reduce F1.2 production, probably by interfering with thrombin-activated feedback loops,[429] since heparin does not directly inhibit thrombin formation.

For many years blood contact with the biomaterials of the perfusion circuit was thought to be the major stimulus to thrombin formation during CPB and open heart surgery. Increasing evidence indicates that the wound is the major source of thrombin generation during CPB and clinical cardiac surgery.[430–431] This understanding has encouraged development of strategies to reduce the amounts of circulating thrombin during clinical cardiac surgery by either discarding wound blood[432] or by exclusively salvaging red cells by centrifugation and washing in a cell saver. The reduced thrombin formation in the perfusion circuit has also supported misguided strategies for reducing the systemic heparin dose during first-time coronary revascularization procedures using heparin-bonded circuits.[427] While there is no good evidence that heparin-bonded circuits reduce thrombin generation,[367] there is strong evidence that discarding wound plasma or limiting exposure of circulating blood to the wound (e.g., less bleeding in the wound) does reduce the circulating thrombin burden.[376,432]

CELLULAR PROCOAGULANTS AND ANTICOAGULANTS

Platelets

Platelets are activated by thrombin, contact with the surface of nonendothelial cells, heparin, and platelet-activating factor produced by a variety of cells during all applications of extracorporeal perfusion and/or recirculation of anticoagulated blood that has been exposed to a wound. Circulating thrombin and platelet contact with surface-adsorbed fibrinogen in the perfusion circuit are probably the earliest and strongest agonists. Circulating thrombin, although rapidly inhibited by antithrombin, is a powerful agonist and binds avidly to two specific thrombin receptors on platelets: PAR-1 and GPIb-alpha.[433] As CPB continues, C5a, C5b-9,[434,435] plasmin,[436] hypothermia,[437] platelet-activating factor (PAF), interleukin-6,[438] cathepsin G, serotonin, epinephrine, eicosanoids, and other agonists also activate platelets and contribute to their loss and dysfunction.

The initial platelet reaction to agonists is shape change. Circulating discoid platelets extend pseudopods, centralize granules, express glycoprotein Ib (GPIb) and GPIIb/IIIa receptors,[439] and secrete soluble and bound P selectin receptors from alpha granules.[440] GPIIb/IIIa ($alpha_{IIb}beta3$) receptors almost instantaneously bind platelets to exposed binding sites on the alpha- and gamma-chains on surface-adsorbed fibrinogen (Fig. 12-13).[441] The number of adherent platelets is proportional to the amount of surface-adsorbed fibrinogen recognized by fibrinogen antibody,[442] but the density of adherent platelets also varies with the chemical and physical composition of the surface biomaterial.[443,444] Rough surfaces accumulate more platelets than smooth surfaces.[445] Fewer platelets adhere to polyurethane, cuprophane, and PMEA (poly-2-methoxyethylacrylate) than to silicone rubber.[374,428] Platelet adhesion and aggregate formation reduce the circulating platelet count, which is already reduced by dilution with pump priming solutions.

Plasma fibrinogen forms bridges between platelets expressing GPIIb/IIIa receptors to produce circulating platelet aggregates. Platelet bound P-selectin binds platelets to monocytes and neutrophils to form aggregates.[446] During ECP some adherent platelets detach, leaving membrane fragments behind,[447] to produce platelet microparticles and partially fragmented platelets.[448,449] Some of these platelet membrane fragments also detach and circulate.[448,449]

A small percentage of activated platelets synthesize and release a variety of chemicals and proteins from granules that include thromboxane A_2,[450] platelet factor 4, beta-thromboglobulin,[451] P-selectin, and serotonin. Platelet lysosomes release neutral proteases and acid hydrolases.[452]

During ECP the circulating platelet pool is reduced by dilution, adhesion, aggregation, destruction, and consumption. The platelet mass consists of a reduced number of morphologically normal platelets, platelets with pseudopod formation, new and larger platelets released from megakaryocytes,[453] partially and completely degranulated platelets, platelet membrane fragments, platelet microparticles, and resealed platelets that have lost some of their membrane receptors.[446,447,452,453] Most of the circulating platelets appear structurally normal,[453] but bleeding times increase and remain prolonged for several hours after protamine.[454] The functional state of the circulating intact platelet during and early after CPB is reduced, but it is not clear whether this functional defect is intrinsic or extrinsic to the platelet. Flow cytometry studies of circulating intact platelets show little change in platelet membrane receptors.[455] In prolonged applications of ECP, platelets are consumed and may or may not be adequately replaced by new platelets from the bone marrow.[456]

Monocytes

During CPB and clinical cardiac surgery the concentration of plasma tissue factor, which normally is 0.26 to 1.1 pM,[422,457] doubles to 2.0 pM.[432] During cardiac surgery wound plasma contains 6 to 11 pM.[432] In the wound with calcium present, monocytes associate with plasma tissue factor to rapidly accelerate the conversion of factor VII to factor VIIa.[458] This association is specific for monocytes—the reaction is essentially nil for platelets, neutrophils, and

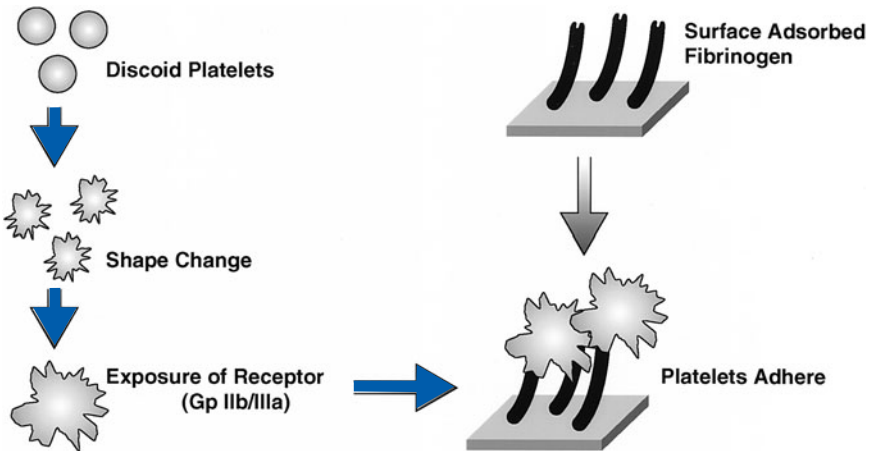

Figure 12-13. Adhesion of activated platelets binding to surface-adsorbed fibrinogen via GPIIb/IIIa ($\alpha_{IIb}\beta3$) receptors. The same receptors bind plasma fibrinogen molecules to form platelet aggregates.

lymphocytes—and does not occur if monocytes, plasma tissue factor, or factor VII is not present. Monocytes also synthesize and express tissue factor, but this process, which peaks 3 to 4 hours after monocytes are activated,[458] is not a major source of tissue factor during CPB and clinical heart surgery but does occur during prolonged perfusions.[459] Plasma microparticles, also present in wound plasma, are procoagulant[460] and monocytes may express the procoagulant CD 11b receptor,[461] but the clinical importance of these pathways in thrombin generation is not clear and probably minor. The major sources of tissue factor in the wound are the combination of monocytes, plasma tissue factor, and cell-bound tissue factor.

Agonists for activating monocytes during CPB and clinical cardiac surgery include C5a,[462] endotoxin, IL-6, IL-1-beta, TNF-alpha, and monocyte chemotactic protein-1 (MCP-1). Monocytes and macrophages produce MCP-1, IL-1-beta, IL-6, and TNF-alpha;[463,464] express tissue factor,[458] Mac-1,[461] L-selectin, and MCP-1;[465] and form aggregates with platelets.[440] For the most part, monocyte reactions are slow and peak concentrations of cytokines occur several hours after CPB ends.[466–468]

Endothelial Cells

Endothelial cells, charged with maintaining the fluidity of circulating blood and the integrity of the vascular system, are activated during CPB and clinical cardiac surgery by thrombin, C5a,[469] IL-1, and TNF-alpha.[470] Endothelial cells produce both procoagulants and anticoagulants. Procoagulant activities of endothelial cells include expression of tissue factor and production of a host of procoagulant proteins, including collagen, elastin, microfibillar protein, laminin, fibronectin, thrombospondin, von Willebrand factor, factor V, platelet-activating factor, and plasminogen activator inhibitor-1, and the vasoconstrictors endothelin-1 and renin. Endothelial cells also bind von Willebrand factor, vibronectin, and factors IXa and Xa. Anticoagulant activities of endothelial cells include the production of t-PA, heparin sulfate, dermatan sulfate, protein S (which accelerates the activation of protein C), tissue factor inhibitor protein, thrombomodulin and protease nexin 1 (which both bind thrombin), prostacyclin,[471] nitric oxide, and adenosine. Prostacyclin concentrations increase rapidly at the beginning of CPB and then begin to decrease.[472] During clinical cardiac surgery endothelin-1 peaks several hours after CPB ends.[473]

Except for expression of tissue factor and expression of CD11b/CD18 (Mac-1), which is weakly procoagulant, endothelial cell receptors do not participate heavily in thrombin generation during ECP.

Neutrophils

During ECP neutrophils express Mac-1 receptors,[474] which bind factor X and fibrinogen and weakly facilitate thrombin formation. Neutrophils secrete elastase, which can destroy protease inhibitors such as antithrombin and coagulation factors such as factor V and may contribute significantly to the equilibrium between the fluid and gel forms of blood.

FIBRINOLYSIS

Circulating thrombin activates endothelial cells to produce t-PA, which binds avidly to fibrin.[475–477] Endothelial cells are the principal source of t-PA.[476] The combination of t-PA, fibrin, and plasminogen cleaves plasminogen to plasmin; plasmin cleaves fibrin.[476] This reaction produces the protein fragment D-dimer, which is a useful marker of fibrinolysis, and a marker of thrombin activity because fibrin is cleaved from fibrinogen by thrombin. Kallikrein produced by the contact system cleaves pro-urokinase to urokinase; however, this enzyme is less important in fibrinolysis than t-PA because urokinase binds poorly to fibrin.[477] F1.2, D-dimer, and fibrinopeptide A (produced by the conversion of fibrinogen to fibrin) increase during extracorporeal perfusion, indicating ongoing thrombin production, fibrin formation, and fibrinolysis.[366,367,478,479] D-dimer and other fibrin degradation products are themselves anticoagulants inhibiting fibrin polymerization.[476]

Fibrinolysis is controlled by native protease inhibitors, $alpha_2$-antiplasmin, $alpha_2$-macroglobulin, and plasminogen activator inhibitor-1.[477] Plasminogen activator inhibitor-1, produced by endothelial cells, directly inhibits t-PA and urokinase, but little is produced during CPB and open cardiac surgery.[480] $Alpha_2$-antiplasmin rapidly inhibits unbound plasmin, preventing the enzyme from circulating, but poorly inhibits plasmin bound to fibrin. $Alpha_2$-Macroglobulin is a slow inhibitor of plasmin.

Plasmin is both a stimulator and inhibitor of platelets, depending on concentration and temperature.[481] High concentrations of plasmin at normothermia and low concentrations during hypothermia cause conformational changes in platelets, centralization of platelet granules, and internalization of platelet GPIb receptors but not GPIIb/IIIa receptors.[482]

CONSUMPTIVE COAGULOPATHY

Simultaneous and ongoing thrombin formation and fibrinolysis is by definition a consumptive coagulopathy[483] and is present in all applications of ECP. In the normal state the fluidity of blood and the integrity of the vascular system are established and maintained by an equilibrium between procoagulants favoring clot and anticoagulants favoring liquidity (Fig. 12-14A). Blood contact with ECP systems and the wound disrupts this equilibrium to produce a massive procoagulant stimulus that overwhelms natural anticoagulants; therefore an exogenous anticoagulant, heparin, is required for nearly all applications of ECP (Fig. 12-14B). Exceptions are only possible in applications that produce a relatively weak procoagulant stimulus and a minimal thrombin burden that can be contained by natural anticoagulants. Surgeons

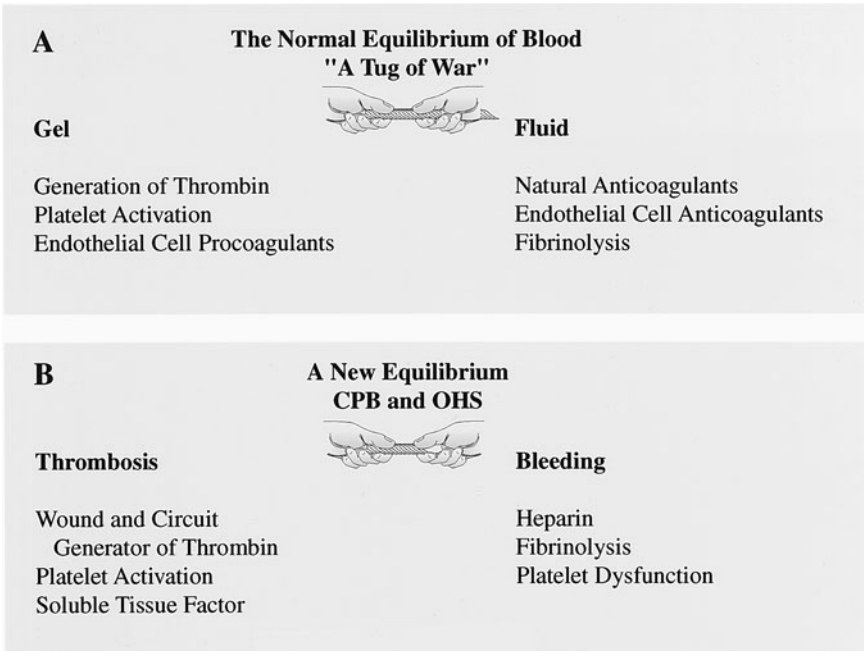

Figure 12-14. (A) The balance between procoagulant and anticoagulant forces that produces an equilibrium that allows blood to circulate. (B). During CPB and OHS (open heart surgery) the normal equilibrium is disturbed by changes in both procoagulants and anticoagulants. Imbalance of procoagulants risks thrombosis; an imbalance of anticoagulants risks bleeding.

must realize that any blood exposure to nonendothelial cell surfaces, including prosthetic heart valves, produces a procoagulant stimulus whether or not clot is produced. Except for the healthy endothelial cell, no nonthrombogenic surface exists.

This concept of an equilibrium between procoagulants and anticoagulants is helpful in managing the thrombotic and bleeding complications associated with all applications of ECP. During ECP procoagulant stimuli, manifested by thrombin formation that is not measurable in real time, must be balanced by either increased anticoagulation or a reduction in the thrombin burden to maintain equilibrium. After ECP, anticoagulants must be inhibited to avoid excessive bleeding. During consumptive coagulopathy, coagulation proteins and platelets are consumed and may become too deficient to generate thrombin and fibrin-platelet clots. In cardiac surgical patients many additional variables affect the coagulation equilibrium and impact the availability of coagulation proteins and functional platelets. These variables include the quantity of blood in contact with the wound, surface area of the perfusion system, duration of perfusion, circulating anticoagulants, and to lesser degrees temperature and the rheology and biomaterials of the perfusion system. Patient factors also affect the coagulation equilibrium; these include age, infection, history or presence of cardiogenic shock, massive blood losses and transfusions, platelet coagulation deficiencies, fibrinolysis, liver disease, cachexia, reoperation, and hypothermia.

MANAGEMENT OF BLEEDING

The cornerstone of bleeding management is meticulous surgical hemostasis during all phases of an operation. The surgical techniques, topical agents, and customary drugs used do not need reiteration for trained surgeons. Most cardiac surgical operations involving CPB are accompanied by net blood losses between 200 and 600 mL. Reoperations, complex procedures, prolonged (>3 hours) cardiopulmonary bypass, and patient factors listed above may be associated with excessive and ongoing blood losses. Most surgeons use an antifibrinolytic, such as aprotinin or epsilon-aminocaproic acid, to reduce fibrinolysis in prolonged or complex operations. Problem patients who bleed excessively after heparin neutralization require an attempt to rebalance pro- and anticoagulants to near normal pre-CPB concentrations.

The most useful tests in the operating room are an activated clotting time or a protamine titration test to assess the presence of heparin, prothrombin time to uncover deficiency in the extrinsic coagulation pathway, and platelet count. If heparin is neutralized, the partial thromboplastin time may be measured to assess possible deficiency of coagulation proteins. Other tests such as measurements of fibrinogen, template bleeding time, and the thromboelastography are controversial and/or difficult to obtain. Platelet counts below 80,000 to 100,000/μL require platelet transfusions in bleeding patients, except those with IgG anti-H-PF4 antibodies, to add functioning platelets to the mass of partially dysfunctional platelets.

Measurements of F1.2 and D-dimer are two tests that can be very helpful and probably should be made available on an emergency basis in hospitals that perform complex procedures and offer mechanical circulatory and respiratory assistance. F1.2 measures thrombin formation by factor Xa, and if absent or low, there may be a deficiency in the concentrations of coagulation proteins; fresh frozen plasma is needed. If F1.2 and D-dimer (a measurement of fibrinolytic activity) are both elevated, thrombin is being formed and an

antifibrinolytic (aprotinin or epsilon-aminocaproic acid) is needed to neutralize plasmin. If both markers or F1.2 remain elevated after the antifibrinolytic drug, this indicates continuing thrombin generation and the cause (e.g., usually infection) should be aggressively treated with antibiotics. Some thrombin is needed to stop bleeding, but excessive thrombin production feeds the consumptive coagulopathy. As with disseminated intravascular coagulopathy,[483] no guaranteed therapeutic recipe is known; success requires patience, persistence, and judicious use of platelets, antifibrinolytics, specific clotting factors, and replacement transfusions to rebalance the coagulation equilibrium at near normal concentrations of the constituents.

THE INFLAMMATORY RESPONSE

The inflammatory response to CPB is initiated by contact between heparinized blood and nonendothelial cell surfaces.[484–486] Blood contact with nonendothelial cell surfaces in the wound and in the perfusion circuit activates plasma zymogens and cellular blood elements that constitute part of the body's defense reaction to all noxious substances including infectious agents, toxins, foreign antigens, allergens, and also injuries. All surgery, like accidental trauma, triggers an acute inflammatory response, but the continuous exposure of heparinized blood to nonendothelial cell surfaces followed by reinfusion of wound blood and recirculation within the body greatly magnifies this response in operations in which CPB is used. Although far from fully described and understood, this primary "blood injury" produces a unique response, which is different in detail from that caused by other threats to homeostasis.

The principal blood elements involved in this acute defense reaction are contact and complement plasma protein systems, neutrophils, monocytes, endothelial cells, and to a lesser extent platelets. Lymphocytes are also altered by CPB,[487,488] but are more involved in the immune response to foreign proteins and acute rejection and do not materially contribute to the acute response to CPB. Likewise, eosinophils and basophil/mast cells are primarily activated by IL-5 and IgE antibodies, respectively, and have prominent roles in allergy, parasitic diseases, and histamine production. When activated during CPB, the principal blood elements release vasoactive and cytotoxic substances, produce cell signaling inflammatory and inhibitory cytokines, express complementary cellular receptors that interact with specific cell signaling substances and other cells, and generate a host of vasoactive and cytotoxic substances that circulate.[489] Normally these reactive blood elements mediate and regulate the defense reaction,[490–492] but during CPB an orderly, targeted response is overwhelmed by the massive activation and circulation of these reactive blood elements.

Admittedly there is considerable overlap between the plasma and blood cellular responses involved in bleeding and thrombosis, ischemia/reperfusion,[493] acute rejection, and acute and chronic inflammation, but these responses are separated in this book in the interest of simplification. This section offers a simplified overview of the acute inflammatory response to cardiopulmonary bypass; the detailed interactions of the body's defense system against hurtful stimuli are under active and intense investigation and are far beyond the author's expertise.

PRIMARY BLOOD CONSTITUENTS

Complement

The complement system constitutes a group of more than 30 plasma proteins that interact to produce powerful vasoactive anaphylatoxins, C3a, C4a, and C5a, and the terminal complement cytotoxic complex, C5b-9.[494] Complement is activated by three pathways, but only the classical and alternative pathways are involved in cardiopulmonary bypass,[495,496] although a role for the mannose-lectin pathway has not been excluded. Direct contact between heparinized blood and the synthetic surfaces of the extracorporeal perfusion circuit activates the contact plasma proteins and the classical complement pathway.[495] Activation of C1, possibly by activated factor XIIa, sequentially activates C2 and C4 to form C4b2a (classical C3 convertase) that cleaves C3 to form C3a and C3b (Fig. 12-15).[494]

Generation of C3b activates the alternative pathway, which involves factors B and D in the formation of C3bBb, which is the alternative pathway C3 convertase that cleaves C3 to form C3a and C3b (see Fig. 12-15). Whereas the classical pathway proceeds in sequential steps, the alternative pathway contains a feedback loop that greatly amplifies cleavage of C3 by membrane-bound C3 convertase to membrane-bound C3b and C3a. During CPB complement is largely activated by the alternative pathway.[496–498]

The complement system is activated at three different times during CPB and cardiac surgery: during blood contact with nonendothelial cell surfaces[495,499] and wound exudate containing tissue factor;[485] after protamine administration and formation of the protamine-heparin complex;[495,500] and after reperfusion of the ischemic, arrested heart.[493] CPB and myocardial reperfusion activate complement by both the classical and alternative pathways; the heparin-protamine complex activates complement by the classical pathway.[495] Other agonists that activate the classical pathway during CPB include endotoxin,[496] apoptotic cells, and C-reactive protein.[494]

The two C3 convertases effectively merge the two complement pathways by producing C3b, which activates C5 to C5a and C5b (see Fig. 12-15). C3a and C5a are potent vasoactive anaphylatoxins. C5a, which avidly binds to neutrophils and therefore is difficult to detect in plasma, is the major agonist. C3b acts as an opsonin, which binds target cell hydroxyl groups and renders them susceptible to phagocytic cells expressing specific receptors for C3b.[494,497] C5b is the first component of the terminal pathway that ultimately leads to formation of the membrane attack complex, C5b-9.

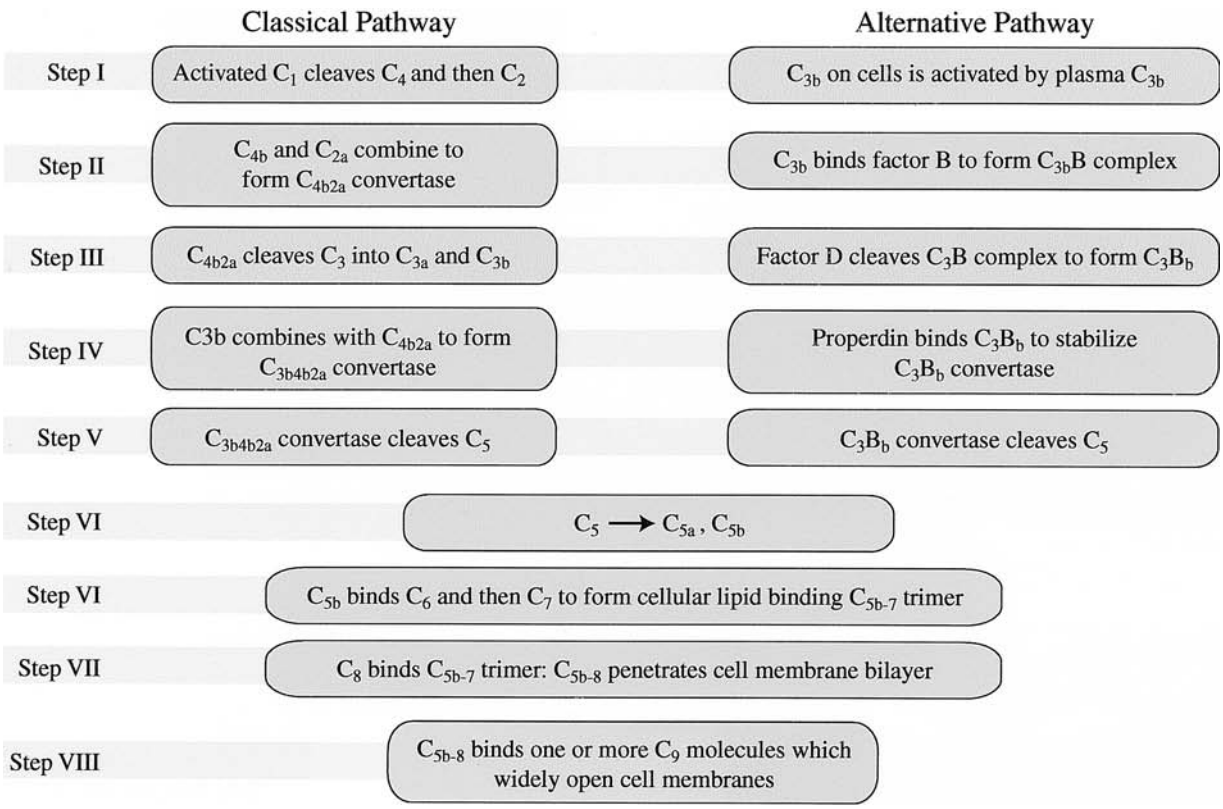

Figure 12-15. Steps in activation of the classical and alternative complement pathways and formation of the membrane attack complex, C5b-9. (*Adapted with permission from Walport*[494] *and Plumb and Sadetz.*[684])

In prokaryotic cells like erythrocytes, C5b-9 creates transmembrane pores, which cause death by intracellular swelling following loss of the intracellular/interstitial osmotic gradient. In eukaryotic cells, deposits of C5b-9 may not be immediately lethal but may eventually cause injury mediated by release of arachidonic acid metabolites (thromboxane A_2 and leukotrienes) and oxygen free radicals by macrophages and neutrophils, respectively.[497]

Together, C5a and C5b-9 play major roles in promoting neutrophil–endothelial cell interactions through upregulation of specific adhesion molecules (see below). Importantly, C5b-9 may also activate platelets and promote platelet-monocyte aggregates.[501] As such, these complement proteins contribute to neutrophil loss from the circulation by adhesion to surface-bound platelets,[501] but more importantly to endothelial cells. The interaction between complement proteins and neutrophils contributes to postoperative organ damage in both adults[502] and in children.[503]

Normally, several regulatory proteins modulate the inflammatory actions of C5a and C5b-9 by inactivating convertases, which cleave C3 and C5,[504] but these inhibitors are usually overwhelmed during CPB. Two proteins, factors H and I, are soluble; three others, complement receptor 1 (CD35), decay accelerating factor, and membrane cofactor protein (CD46), are membrane bound.[494] Factor I cleaves C3 into inactive iC3b, which cannot form C3 convertase, but can be an opsonin.[505] Factor H is the dominant complement regulatory protein and competes with factor B in binding to C3.[494] CD59 and homologous restriction factor are direct inhibitors of the membrane attack complex.[497,506]

Neutrophils

Leukocyte counts decrease in response to hemodilution during CPB and increase moderately after operation.[486,507] Only a few neutrophils attach to synthetic surfaces, to each other, or to platelets and monocytes.[507,508] Nevertheless, neutrophils are strongly activated during CPB (Fig. 12-16).[486,509] The principal agonists are kallikrein[510] and C5a[511,512] produced by the contact and complement systems, respectively.[511,513,514] C5a, generated early during CPB and clinical cardiac surgery, is a particularly potent chemotactic protein that induces neutrophil chemotaxis, degranulation, and superoxide generation.[515] Other agonists involved during CPB include IL-1-beta,[516] TNF-alpha,[492,517] IL-8,[518] C5b-9,[512] factor XIIa,[519] heparin, histamine, hypochlorous acids, and products of arachidonate metabolism (leukotriene B_4),[492] platelet activating factor (PAF), and thromboxane A_2.[515] Lastly, CPB, perhaps mediated by IL-6 and IL-8,[520] partially inhibits neutrophil apoptosis and prolongs the period of neutrophil activity.[521]

Neutrophils are recruited to localized areas of injury or inflammation by chemokines, complement proteins (C5a),

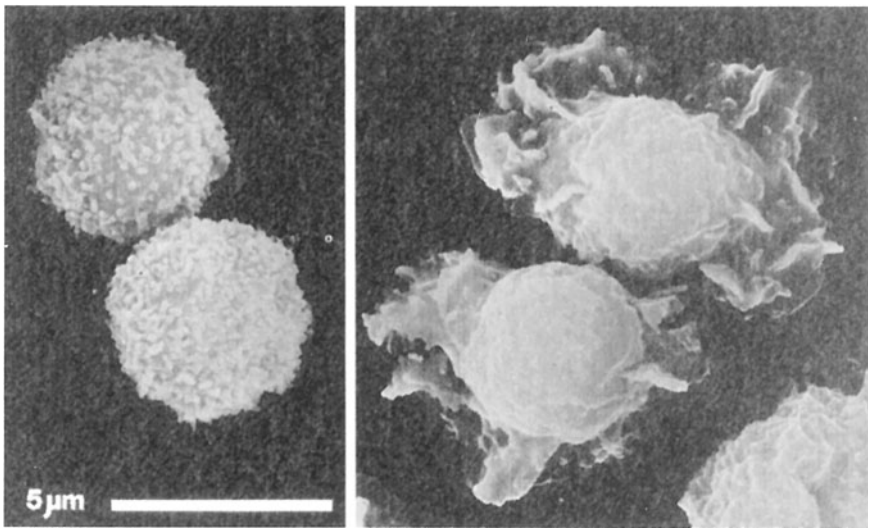

Figure 12-16. Scanning electron micrographs of resting neutrophils (left) and 5 seconds after exposure to a chemoattractant (right). (*Reproduced with permission from Baggiolini M: Chemokines and leukocyte traffic. Nature 1998; 392:565.*)

IL-1-beta, TNF-alpha, and adhesion molecules. Neutrophils respond to the CXC (alpha) family of chemokines that includes IL-8, platelet factor 4 (PF4), neutrophil activating factor-2, and granulocyte chemotactic protein 2.[522–524] During CPB thrombin stimulates endothelial cell production of PAF.[492] Thrombin and PAF cause rapid expression of P-selectin by endothelial cells[490] and circulating IL-1-beta and TNF-alpha stimulate endothelial cells to synthesize and express E-selectin.[490,525] Regional vasoconstriction reduces blood flow rates within local vascular beds to allow neutrophils to marginate near endothelial cell surfaces. L-selectins are constitutively expressed by all types of activated leukocytes and lightly bind to endothelial cell mucin-like glycoproteins before being shed with the onset of transmigration.[490] P-selectin weakly binds to P-selectin glycoprotein-1 on neutrophils;[526] E-selectin binds to a different sialyl Lewis antigen (CD62E). Selectin binding causes the slowly passing neutrophils to roll and eventually stop (Fig. 12-17).[527] Stronger adherence is produced by intracellular adhesion molecule-1 (ICAM-1) expressed on endothelial cells, which binds beta-2 neutrophil integrins, principally CD11b/CD18 (Mac-1) and to some extent CD11a/CD18.[490,528] These adhesion molecules from the immunoglobulin superfamily completely stop neutrophils[529] and the process of transmigration begins in response to chemoattractants and cytotoxins produced in the extravascular space.[530,531] Platelet-endothelial cell adhesion molecule-1 expressed on leukocytes and endothelial cells mediates transmigration of leukocytes.[532] This trafficking is strongly regulated by IL-8 produced by neutrophils, macrophages, and other cells. During CPB neutrophils express the Mac-1 (CD11b/CD18) receptor[533,534] and CD11c/CD18, which binds to fibrinogen and a complement fragment,[528] and VLA-4 (alpha1beta4) receptors that are involved in cellular adhesion.[528] Neutrophil receptor CXCR1 is not affected by CPB, but CXCR2 is downregulated.[535]

Using pseudopods and following the scent of complement proteins (C5a, C3b, and iC3b),[536] IL-8,[492,518,537,538] hypochlorous acids, leukotriene B_4,[539] and locally produced IL-1 and TNF-alpha,[492,537] neutrophils arrive at the scene of inflammation to begin the process of phagocytosis and release of cytotoxins. Organs and tissues experience periods of ischemia followed by reperfusion (lung, heart, and brain) during CPB, and as a result express adhesion receptors[540] and reactive oxidants,[541] and are sources of neutrophil chemoattractants.[520,542]

Neutrophils vary considerably among individuals in expression of adhesive receptors[543] and responsiveness to chemoattractants during CPB. There also is substantial variation in measurements of soluble and cellular adhesion receptors.[534] The presence of diabetes,[544] oxidative stress,[545] and perhaps genetic factors (see below) influences expression of cellular and soluble adhesive receptors and cytokines, which affect neutrophil adhesion and release of granule contents. It is difficult to show a correlation between markers of neutrophil activation and measurements of organ dysfunction.[546]

Neutrophils contain a potent arsenal of proteolytic and cytotoxic substances. Azurophilic granules contain lysozyme, myeloperoxidase, cationic proteins, elastase, collagenases, proteinase 3, acid hydrolases, defensins, and phospholipase.[547] Specific granules contain beta-2 integrins, lactoferrin, lysozyme, type IV collagenase, histaminase, heparanase, complement activator, alkaline phosphatase, and membrane-associated NADPH (nicotinamide adenine dinucleotide phosphate, reduced form) oxidase.[515] Activated neutrophils, in a "respiratory burst," also produce cytotoxic reactive oxygen and nitrogen intermediates including superoxide anion, hydrogen peroxide, hydroxyl radicals, singlet oxygen molecules, N-chloramines, hypochlorous acids, and peroxynitrite.[490,548] Finally, neutrophils produce arachidonate metabolites, prostaglandins, leukotrienes, and platelet-activating factor. During CPB these vasoactive and cytotoxic substances are produced and released into the extracellular environment and circulation.[486,489] Circulation of these substances mediates many of the manifestations of the "whole

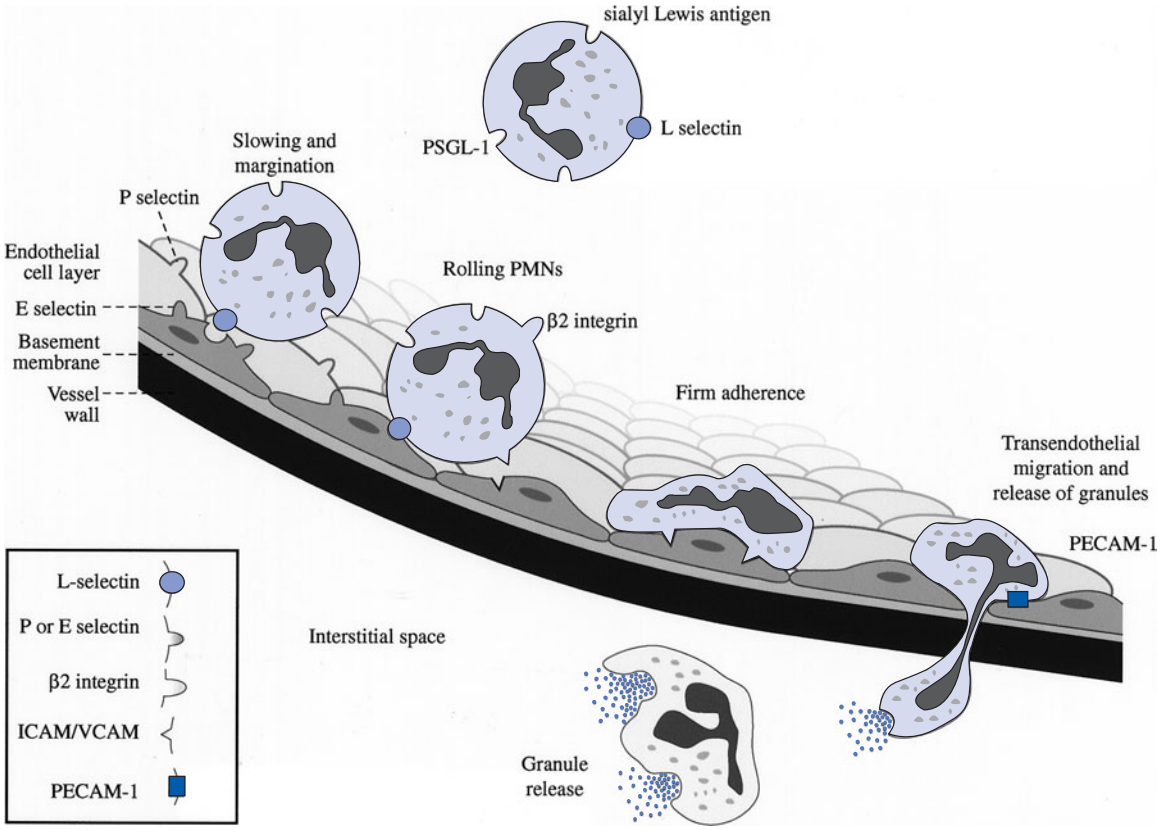

Figure 12-17. Mechanism of arrest and transmigration of neutrophils into the interstitial space. Neutrophils constitutively express L-selectin, which binds to endothelial cell glycoprotein ligands. Simultaneously, early response cytokines stimulate endothelial cells to rapidly express P-selectin and later E-selectin receptors, which weakly bind neutrophil P-selectin glycoprotein-1 (PSGL-1) ligands. Marginated neutrophils, which are slowed by local vasoconstriction and reduced blood flow, lightly adhere to endothelial cells via selectin expression and begin to roll. Neutrophils activated by C5a, kallikrein, and early response cytokines express β-2 CD11b and c receptors, which bind firmly to cytokine-activated endothelial cell integrins, intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). Once arrested, L-selectins are shed and platelet-endothelial cell adhesion molecule (PECAM) receptors on endothelial cell surfaces mediate neutrophil transmigration through endothelial cell junctions, led by chemoattractants into the interstitial space. PMN = polymorphonuclear leukocyte; PSGL-1 = P-selectin glycoprotein ligand-1.

body inflammatory response" or "systemic inflammatory response syndrome" associated with CPB and clinical cardiac surgery.[549]

Monocytes

Monocytes and macrophages (tissue monocytes) are relatively large, long-lived cells that are involved in both acute and chronic inflammation. Monocytes respond to chemical signals, are mobile, phagocytize microorganisms and cell fragments, produce and secrete chemical mediators, participate in the immune response, and generate cytotoxins.[550] Monocytes are activated during CPB[551] and have a major role in thrombin formation.[552] Monocytes also produce and release many inflammatory mediators during acute inflammation including proinflammatory cytokines (principally TNF-alpha, IL-1-beta, IL-6, IL-8, and MCP-1), reactive oxygen and nitrogen intermediates, and prostaglandins.[524]

The mechanism by which monocytes are initially activated during CPB is not known, but the most likely candidates are C5a,[550] thrombin,[553] platelet factor 4, and bradykinin,[554] which are four potent agonists rapidly generated from blood contact with nonendothelial cell surfaces. Monocytes possess a huge list of surface receptors,[550] but those apt to be involved in the inflammatory response to CPB are C5a and three other complement proteins (IL-1, CD11b/CD18, and CD 11c/CD18), leukotriene B_4, and the C-C family of chemokine receptors.[550] Monocytes also possess C-reactive protein receptors, which when activated, strongly upgrade proinflammatory cytokine production.[491]

Monocytes are the major source of the early response cytokines IL-1-beta and TNF-alpha,[491,554] which play an important role in directing both neutrophils and monocytes to local sites of inflammation. Monocytes are also the major producer of IL-8,[491] which also is produced by neutrophils[492] and induces neutrophil chemotaxis.[490] Other cytokines

produced by monocytes include IL-1-alpha, IL-6, and IL-10.[491] Monocytes also produce important growth factors, matrix proteins, interferons, and a variety of enzymes, including elastase, collagenases, acid hydrolases, prostaglandins, and lipooxygenase products,[524] and contain myeloperoxidase, which converts hydrogen peroxide into more powerful oxidants.

Endothelial Cells

Endothelial cells are activated during CPB and open heart surgery by a variety of agonists. The principal agonists for endothelial cell activation during CPB are thrombin, C5a,[555] and the cytokines IL-1-beta and TNF-alpha.[537,556] Other agonists, such as endotoxin, histamine, and interferon-gamma (from lymphocytes), are less important during CPB, and endothelial cells are largely unresponsive to chemokines.[525]

IL-1-beta and TNF-alpha induce the early expression of P-selectin and the later synthesis and expression of E-selectin, which are involved in the initial stages of neutrophil and monocyte adhesion.[490] The two cytokines also induce expression of ICAM-1 and vascular cell adhesion molecule-1, which firmly bind neutrophils and monocytes to the endothelium and initiate leukocyte trafficking to the extravascular space (see Fig. 12-17).[492,525,537] Experimentally ICAM-1 is upregulated during CPB in pulmonary vessels[557] and there is evidence that P- and E-selectins are upregulated during CPB and in myocardial ischemia-reperfusion sequences. IL-1-beta and TNF-alpha induce endothelial cell production of the chemotactic proteins IL-8 and MCP-1, and induce production of prostaglandin I_2 (prostacyclin) by the cyclooxygenase pathway[532,558] and nitric oxide by nitric oxide synthase.[532,559] These two vasodilators reduce shear stress and increase vascular permeability and therefore enhance leukocyte adhesion and transmigration. Lastly, IL-1-beta and TNF-alpha stimulate endothelial cell production of proinflammatory cytokines, IL-1, IL-6, IL-8, MCP-1, and PAF.[525]

In addition to nitric oxide and prostacyclin, endothelial cells produce the vasoconstrictor endothelin-1[489,560] and inactivate other vasoactive mediators, including histamine, norepinephrine, and bradykinin.[561] Prostacyclin concentrations increase rapidly at the beginning of CPB and then begin to decrease.[562] Endothelin-1 peaks several hours after CPB ends.[563]

Platelets

Platelets are probably initially activated during CPB by thrombin, which is the most potent platelet agonist, but plasma epinephrine, PAF, vasopressin,[564] cathepsin G[565] from other cells, serotonin, and adenosine diphosphate (ADP) secreted by platelets, and internally generated thromboxane A_2[566] contribute to activation as CPB continues.[489] Platelets possess several protease-activated receptors[564] to most of these agonists and to collagen, which has an important role in adhesion and thrombus formation. Collagen binding causes release of thromboxane A_2 and ADP, which help recruit platelets.[564] Platelets contribute to the inflammatory response by synthesis and release of eicosanoids;[566] serotonin from dense granules; IL-1-beta;[567] CXC chemokines, PF4, neutrophil-activating protein-2, IL-8, and endothelial cell neutrophil attractant-78; and C-C chemokines, macrophage inflammatory protein-1a, MCP-3, and RANTES[568] from alpha granules. Platelets also produce and release acid hydrolases from membrane-bound lysozymes. Platelet-secreted cytokines, neutrophil-activating protein-2, RANTES, PF4, IL-1-beta, IL-8, and endothelial cell neutrophil attractant-78 may be particularly involved in the inflammatory response to CPB because of strong activation of platelets in both the wound and perfusion circuit.

Circulating monocytes and neutrophils constitutively express P-selectin glycoprotein-1, which interacts with aggregated platelets via P-selectin expressed on activated platelets.[526] Platelets aggregrate using platelet GPIIb/IIIa (alpha2beta3) receptors attached to symmetric fibrinogen molecules to form bridges between platelets. During CPB platelets aggregate with each other and also to monocytes and neutrophils.[507,561]

OTHER MEDIATORS OF INFLAMMATION

Anaphylatoxins

The anaphylatoxins C3a, C4a, and C5a are bioactive protein fragments released by cleavage of complement proteins C3, C4, and C5. These fragments have potent proinflammatory and immunoregulatory functions and contract smooth muscle cells, increase vascular permeability, serve as chemoattractants, and in the case of C5a, activate neutrophils and monocytes.[514] Anaphylatoxins contribute to increased pulmonary vascular resistance, edema, and neutrophil sequestration and an increase in extravascular water during CPB. The duration of postoperative ventilation directly correlates with plasma C3a concentrations.[569–570] C3a and C5a are important mediators in ischemia/reperfusion injuries.

Cytokines

Cytokines are small, cell-signaling peptides produced and released into blood or the extravascular environment by both blood and tissue cells. Cytokines stimulate specific receptors on other cells to initiate a response in that cell. All blood leukocytes and endothelium produce cytokines, but many tissue cells including fibroblasts, smooth muscle cells, cardiac myocytes, keratinocytes, chrondrocytes, hepatocytes, microglial cells, astrocytes, endometrial cells, and epithelial cells also produce cytokines.[537,554,571] IL-1-beta and TNF-alpha are early response cytokines that are promptly produced at the site of injury by resident macrophages.[537] These cytokines stimulate surrounding stromal and parenchymal cells to produce more IL-1-beta and TNF-alpha and chemokines, particularly IL-8 and MCP-1, which are powerful chemoattractants for neutrophils and macrophages, respectively. Together with IL-6, the cytokine that regulates

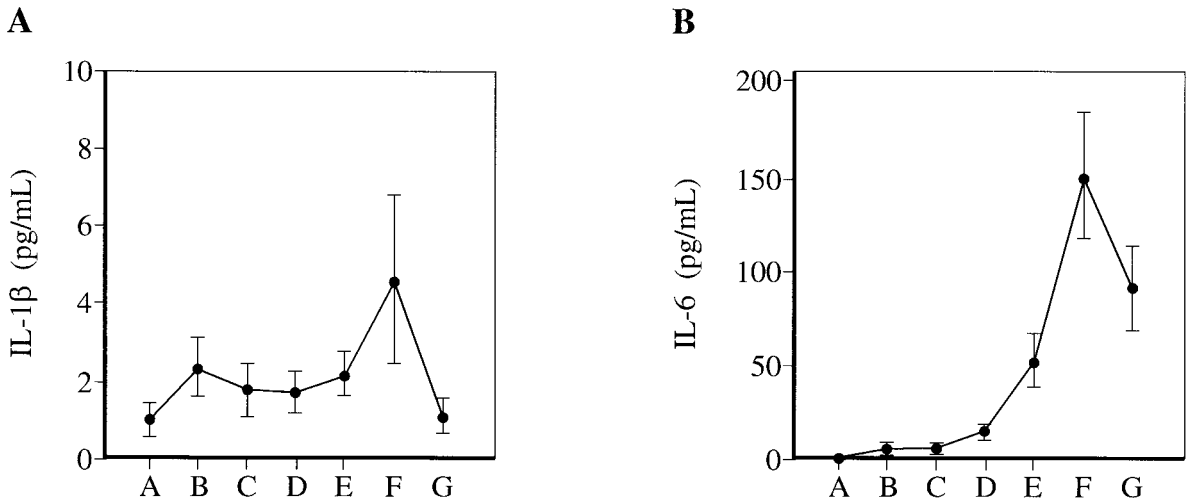

Figure 12-18. Changes in IL-1-β (A) and IL-6 (B) in 30 patients who had elective first-time myocardial revascularization. Letters on the *x* axis represent the following events: A, induction of anesthesia; B, 5 minutes after heparin; C, 10 minutes after starting CPB; D, end of CPB; E, 20 minutes after protamine; F, 3 hours after CPB; G, 24 hours after CPB. (*Redrawn from Steinberg et al.*[466])

production of acute-phase proteins (e.g., C-reactive protein and alpha$_2$-macroglobulin) by the liver,[572] these five cytokines are the major proinflammatory cytokines involved in the acute inflammatory response to CPB.

The major anti-inflammatory cytokine involved during CPB is IL-10.[573] IL-10 inhibits synthesis of proinflammatory cytokines by monocytes and macrophages[574] and induces production of IL-1 receptor antagonist (IL-1ra), which downgrades the response to IL-1.[554,575] IL-13 downregulates production of IL-1, IL-8, and IL-10 and reduces monocyte production of reactive oxidants;[576] its role during CPB is undetermined.

Proinflammatory cytokines increase during and after clinical cardiac surgery using CPB, but peak concentrations usually occur 12 to 24 hours after CPB ends (Fig. 12-18).[570,577–581] Measured amounts differ greatly in timing and within and between studies, probably because of differences in the duration of CPB, perfusion temperatures,[582] perfusion equipment, and aortic cross-clamp times; differences in methods of myocardial protection; possibly variable concentrations of inhibitory cytokines;[583–585] and perhaps exogenous factors such as priming solutions, anesthesia, and intravascular drugs.[570,577–581] Some of the variation in measurements between studies also may be due to patient factors such as age, left ventricular function, and genetic factors.[586] The presence of the APOE4 allele (one of the common human polymorphisms of the gene encoding apolipoprotein E) is associated with increased TNF-alpha and IL-8.[586] Patients who are homozygous for TNF-beta-2 have elevated levels of TNF-alpha and IL-8 during both on- and off-pump cardiac surgery.[587] Carriers of APOE4 have reduced concentrations of IL-1ra, the inhibitory peptide of IL-1.[588] Additional hints of a genetic role in the acute inflammatory response are the association between postoperative serum creatinine and different APO-epsilon alleles[589] and the association between length of stay after coronary artery surgery and 174GG polymorphism of the IL-6 gene.[590]

Reactive Oxidants

Neutrophils, monocytes, and macrophages produce reactive oxidants, which are cytotoxic inside the phagosome, but act as cytotoxic mediators of acute inflammation outside. Four enzymes generate a large menu of reactive oxidants: NADPH (nicotinamide adenine dinucleotide phosphate, reduced form) oxidase, superoxide dismutase, nitric oxide synthase, and myeloperoxidase.[548] The enzyme NADPH oxidase adds a free electron to molecular oxygen to create superoxide (O_2^-) and two hydrogen ions, H^+. Superoxide dismutase catalyzes the conversion of superoxide to hydrogen peroxide, H_2O_2, and molecular oxygen. Nitric oxide synthase produces nitric oxide (NO) from NADPH, arginine, and oxygen, and myeloperoxidase uses H_2O_2 to oxidize halide ions to hypochlorous acids.[591–592] The four products produced by these enzymes, O_2^-, H_2O_2, NO, and hypochlorous acids, generate all reactive oxidants from nonenzymatic reactions with other molecules or ions.[548]

Free radicals have one or more unpaired electrons and are highly reactive in scavenging hydrogen ions from other molecules. $OH^\cdot$ is produced from H_2O_2 by low-valence iron or copper ions, which are reduced to the original low valence after the reaction by various reducing agents, such as ascorbic acid. Secondary free radicals, containing carbon, oxygen, nitrogen, or sulfur, are formed when a free radical reacts with molecules that lack unpaired electrons;[548] this self-perpetuating sequence produces a chain reaction of highly cytotoxic substances.

Endotoxins

Endotoxins, including lipopolysaccharides, are fragments of bacteria that are powerful agonists for complement,[593] neutrophils, monocytes, and other leukocytes. Endotoxins have been detected during CPB[593–596] and after aortic cross-clamping using a very sensitive bioassay.[597,598] Sources include contaminants in sterilized infusion solutions, the bypass circuit, and possibly the gastrointestinal tract due to changes in microvascular intestinal perfusion, which may translocate bacteria.[599] Intestinal microvascular blood flow is sensitive to both flow rate and duration of CPB. In some instances leakage of endotoxin into the systemic circulation occurs if clearance by the hepatic Kupffer cells fails. The quantitative significance of the role of endotoxins in the acute inflammatory response to CPB is unknown.

Metalloproteinases

CPB induces the synthesis and release of matrix metalloproteinases,[600] which are one of the four major classes of mammalian proteinases. These proteolytic enzymes have a major role in degradation of collagens and proteins in the extracellular matrix and vascular basement membrane and in the pathogenesis of atherosclerosis and postinfarction left ventricular remodeling. The significance and possible injury produced by activation of these interstitial degradation enzymes over the long term remain to be determined.

Angry Blood

Blood circulating during clinical cardiac surgery with cardiopulmonary bypass can be a stew of vasoactive and cytotoxic substances, activated blood cells, and microemboli. Shear stress, turbulence, cavitation, and other rheologic forces and C5b-9 cause hemolysis of some red cells. Complement anaphylatoxins,[514] bradykinin formed by activation of the contact proteins,[490,513] and proinflammatory cytokines stimulate endothelial cells to contract, allowing extravasation of intravascular fluid into the extravascular space.[601] Numerous circulating vasoactive substances cause vasoconstriction or vasodilatation of heterogeneous regional vascular networks.[489] As neutrophils and monocytes migrate across the endothelial cell barrier, stromal and parenchymal cells are exposed to a cytotoxic environment mediated by neutral proteases, collagenases and gelatinases, reactive oxidants, lipid peroxides, C5b-9, and other cytotoxins.[486,545,602,603] This injury is magnified by microemboli produced from platelet-leukocyte aggregates, lipids, and other blood elements and emboli from other sources (see section 12C). The manifestations of the inflammatory response include systemic symptoms such as malaise, fever, increased heart rate, mild hypotension,[582] interstitial fluid accumulation,[604] and temporary organ dysfunction, particularly of the brain, heart, lungs, and kidneys.

The magnitude of this defense reaction during and after CPB is influenced by many exogenous factors that include the surface area of the perfusion circuit, the duration of blood contact with extravascular surfaces, the amount of unwashed cardiotomy suction blood returned to the patient, general health and preoperative organ function of the patient, blood loss and replacement, organ ischemia and reperfusion injury, sepsis, different degrees of hypothermia, periods of circulatory arrest, genetic profiles, corticosteroids, and other pharmacologic agents. When well managed, these factors result in a postoperative patient with few, if any, overt manifestations of inflammation.

CONTROL OF THE ACUTE INFLAMMATORY RESPONSE TO CARDIOPULMONARY BYPASS

Off-Pump Cardiac Surgery

Myocardial revascularization without either CPB or cardioplegia reduces the acute inflammatory response but does not prevent it.[605–607] The response to surgical trauma, manipulation of the heart, pericardial suction, heparin, protamine, other drugs, and anesthesia activates the extrinsic clotting system and produces an increase in the markers of acute inflammation, C3a, C5b-9, proinflammatory cytokines (TNF-alpha, IL-6, and IL-8), neutrophil elastase, and reactive oxidants,[545] but the magnitude of the response is significantly less than that observed with CPB.[606–608] Although it has not been shown that the attenuated acute inflammatory response directly reduces organ dysfunction,[605,608] elderly patients and those with reduced renal and pulmonary function often tolerate off-pump surgery with less morbidity and mortality than patients treated with CPB.[608–611]

Perfusion Temperature

Release of mediators of inflammation is temperature sensitive. Normothermic CPB increases the release of cytokines and other cellular and soluble mediators of inflammation,[582] whereas hypothermia reduces production and release of these mediators until rewarming begins.[612] Perfusion at tepid temperatures between 32 and 34°C is a reasonable compromise for many operations requiring 1 to 2 hours of CPB.[580,602]

Perfusion Circuit Coatings

Ionic- or covalent-bonded heparin perfusion circuits are the most widely used surface coatings and are often combined with reduced doses of systemic heparin in first-time myocardial revascularization patients.[613] It is well established that heparin is an agonist for platelets, complement, factor XII, and leukocytes, but there is no reproducible evidence that heparin coating either produces a nonthrombogenic surface or reduces activation of the clotting cascade.[614–615] A review of a large portion of this literature concluded that heparin-bonded circuits reduced concentrations of the terminal complement complex, C5b-9 (Fig. 12-19),[616] but for nearly every study showing a beneficial anti-inflammatory or antithrombotic effect, another study shows no effect.[617] Clinical trials that have combined heparin-coated circuits with

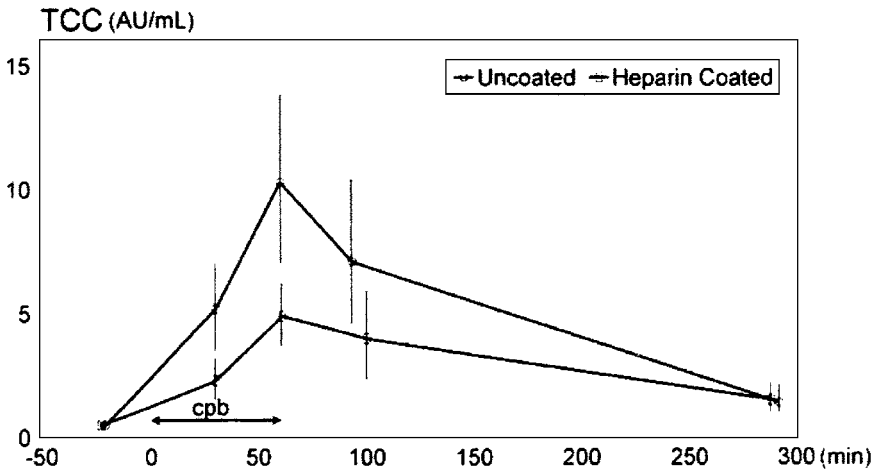

Figure 12-19. Changes in C5b-9 (TCC) terminal complement complex in heparin-coated (n = 15) and uncoated (n = 14) perfusion circuits during myocardial revascularization. The two curves are significantly different by ANOVA ($p = .004$). (*Reproduced with permission from Videm et al.*[173])

reduced systemic heparin and exclusion of field-aspirated blood from the perfusion circuit have demonstrated modest clinical benefits.[618] However, most trials, including a large European trial of 805 patients, have not observed clinical benefits except in certain subsets of patients that are not the same between studies[617,619–624] and which report sporadic differences that barely reach statistical significance.[624,625] Excluding unwashed field blood from the perfusion circuit reduces admixture of high concentrations of thrombin,[552] fibrinolysins,[626] cytokines, activated complement,[422] and leukocytes to the perfusate. Exclusion of these inflammatory mediators may be more important in reducing the amounts of vasoactive and cytotoxic substances circulating within the body than the heparin surface coating.

New surface coatings are being developed or undergoing clinical trials.[627] Surface-modifiying additives are chemicals used in low concentrations to reduce interfacial energy and modify the mosaic of adsorbed surface plasma proteins. One commercially available surface-modifiying additive uses a triblock copolymer containing polar and nonpolar chains of polycaprolactone-polydimethylsiloxane-polycaprolactone.[628] In clinical trials this surface significantly reduced platelet loss and granule release, and reduced markers of thrombin generation.[629–630] PMEA (poly-2-methylethylacrylate) is another manufactured surface coating designed to reduce surface adsorption of plasma proteins. Laboratory studies show reduced surface adsorption of fibrinogen and reduced bradykinin and thrombin generation in pigs.[631] Early clinical studies show significant reductions in C3a, C4D, and neutrophil elastase, but ambivalent effects on IL-6 and platelets.[632–633]

Modified Ultrafiltration

Although effective in pediatric cardiac surgery,[634–635] ultrafiltration to remove intravascular (and extravascular) water and inflammatory substances has produced mixed results in adults.[636] Dialysis during CPB in adults may be beneficial in removing water, potassium, and protein wastes in patients with renal insufficiency.

Leukocyte Filtration

The role of neutrophils in the acute inflammatory response has led to development of leukocyte-depleting filters for the CPB circuit. Multiple groups have investigated these filters in clinical trials, but consistent efficacy in reducing markers of neutrophil activation and improvement in respiratory or renal function are lacking. Most clinical studies fail to document significant leukocyte depletion or clinical benefits.[637–640] Washing cardiotomy suction blood and using leukodepleted allogeneic red cell and platelet transfusions has reduced the interest in leukocyte filtration. Active sequestration of leukocytes and platelets using a separate cell separator during CPB may have beneficial clinical effects,[644,645] but requires a separate inflow cannula and separator system.

Complement Inhibitors

The central role of complement in the acute inflammatory response to CPB provides ample rationale for inhibition. The anaphylatoxins and C5b-9 are direct mediators of the inflammatory response, and C5a is the principal agonist for activating neutrophils and is a potent chemoattractant for neutrophils, monocytes, macrophages, eosinophils, basophils, and microglial cells.[514] C1-inhibitor is a natural inhibitor of complement C1 components C1s and C1r, factor XIIa, kallikrein, and factor XIa.[504] Factor H and C4BP inhibit C3 and C5 convertase subunits, but are poor inhibitors of induced activation of the complement system.[504] None of these inhibitors are attractive candidates for inhibiting complement activation during CPB.

The sequential activation cascade with convergence of the classical and alternative pathways at C3 offers many opportunities for inhibition by recombinant proteins.[641] Using a humanized, recombinant antibody to C5 (h5G1.1-scFv), Fitch and associates demonstrated that generation of C5b-9 was completely blocked in a dose-response manner (Fig. 12-20) and that neutrophil and monocyte CD11b/CD18 expression was attenuated in patients during and for several hours after clinical cardiac surgery using CPB.[642] Large scale clinical trials

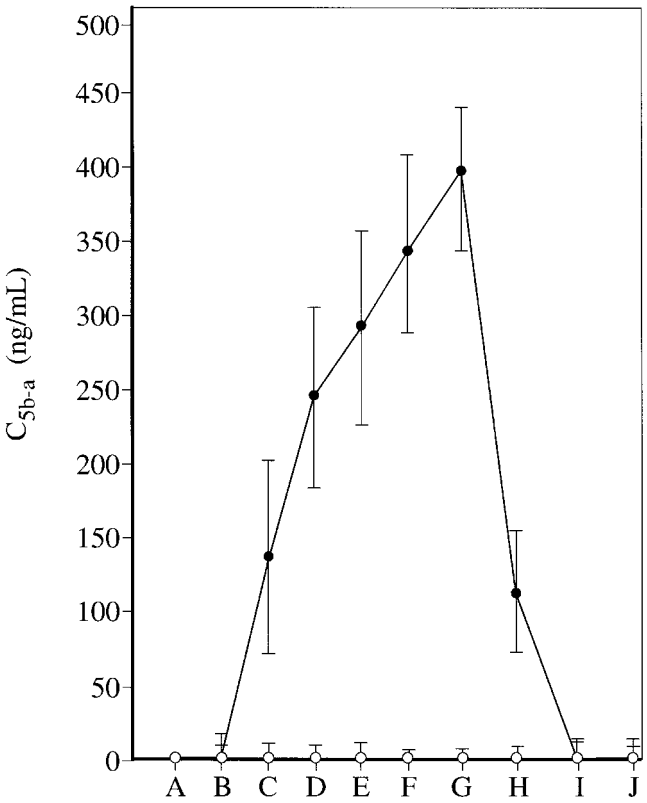

Figure 12-20. Inhibition of C5b-9, complement terminal attack complex, with placebo (solid circles) and 2 μg/kg of h5G1.1-scFv (open circles) during clinical cardiac surgery with CPB. Letters on the *x* axis represent the following events: A, before heparin; B, 5 minutes after drug; C, 5 minutes after cooling to 28°C; D, after beginning rewarming; E, 5 minutes after reaching 32°C; F, 5 minutes after reaching 37°C; G, 5 minutes after CPB; H, 2 hours after CPB; I, 12 hours after CPB; J, 24 hours after CPB. h5G1.1-scFv completely inhibited formation of the C5b-9 terminal attack complex. (*Data redrawn from Fitch et al.*[643])

that have followed but are not yet published have shown modest improvements in morbidity and mortality.

Fung and associates[496] used an anti–factor D monoclonal antibody to inhibit production of complement proteins, Bb, C3a, sC5b-9, and C5a, via the alternate pathway, and to attenuate upregulation of neutrophil and platelet adhesive receptors during CPB in vitro.[496] Undar and coworkers confirmed these results during CPB in baboons and additionally found inhibition of complement C4d, attenuation of IL-6 concentrations, and reduced markers of cardiac injury.[643] Compstatin, a very small (1593-Da) synthetic peptide, binds C3 and therefore inhibits both the classical and alternative pathways.[494] This peptide inhibits generation of C3a and sC5b-9 and neutrophil binding during in vitro CPB.[644] In baboons, after activation of complement by the heparin-protamine complex, compstatin completely inhibits C3 cleavage without causing any change in hemodynamic measurements or side effects.[645]

Other complement recombinant protein inhibitors have been developed and are under active investigation and in clinical trials because of the importance of this plasma protein system in CPB, ischemia/reperfusion, and injuries that summon the acute inflammatory response.[504,646–648] Although any effective and safe inhibitor is welcome, C3 may be a better target for inhibition because both activation pathways are blocked at the point of convergence and because C3 concentrations in plasma are 15 times greater than those of C5.[504,649–651]

Glucocorticoids

Many investigators have used glucocorticoids to suppress the acute inflammatory response to CPB and clinical cardiac surgery, but beneficial effects in adult patients have been inconsistent.[652–654] Steroids reduce release of rapid-response cytokines, TNF-alpha, and IL-1-beta from macrophages,[655] enhance release of IL-10,[656–657] and suppress expression of endothelial cell selectins and neutrophil integrins.[658] Clinically, glucocorticoids decrease endotoxin release,[659] shift the cytokine balance towards the anti-inflammatory side,[659–661] and decrease expression of neutrophil integrins.[652] Clinical results from a few randomized trials are conflicting: one study observed earlier extubation and reduced shivering,[662] but another found increased blood glucose levels and delayed extubation.[663,664] Differences in specific steroids, dosing, and timing may explain some of these discrepancies.

Recent observations regarding the inhibitory effect of glucocorticoids on transcription factor nuclear factor-κB (NF-κB) may provide a rationale for using glucocorticoids to suppress the acute inflammatory response to CPB.[665] This inducible transcription factor controls the expression of genes encoding a wide array of proinflammatory mediators, including cytokines, inducible NO synthase, and adhesion molecules, and is activated by IL-1-beta, TNF-alpha, reactive oxidants, and other noxious stimuli.[654,666–668] Given the multiplicity and redundancy of pathways involved in the inflammatory response to bypass, inhibition of a common "upstream" control point in transcriptional regulation of inflammatory genes is an attractive strategy.

Protease Inhibitors

Aprotinin is a natural serine protease inhibitor in the kinin superfamily that strongly inhibits plasmin and weakly inhibits kallikrein.[669] Plasma concentrations of 4 to 10 KIU (kallikrein inhibitory units) of aprotinin completely inhibit plasmin, but 250 to 400 KIU are required to fully inhibit kallikrein.[669] Clinical doses of aprotinin totally inhibit plasmin, but are not sufficient to completely inhibit kallikrein.[670] The antifibrinolytic and platelet-sparing effects of the drug are well known and significantly reduce blood losses during and after complex cardiac surgery.[671–672] The anti-inflammatory effects of aprotinin are more difficult to quantitate and may reflect multiple mechanisms including partial kallikrein inhibition, direct effects, and inhibition of NF-κB.[673]

In vitro aprotinin inhibits kallikrein formation, and attenuates complement activation and release of platelet beta thromboglobulin and neutrophil elastase.[674] Aprotinin also

reduces neutrophil transmigration and expression of ICAM-1 and vascular cell adhesion molecule-1 by endothelial cells.[675–676] Clinically, aprotinin reduces circulating TNF-alpha, IL-6, IL-8, and neutrophil CD11b expression,[653,677–678] and synergistically increases IL-10 synthesis.[657,678] The drug may also attenuate neutrophil activation and myocardial damage during aortic cross-clamping[679] and reduce overall mortality.[672] Nevertheless, low- or high-dose aprotinin used in large, randomized controlled clinical trials fails to show a reduction in proinflammatory cytokines, activated complement, neutrophil elastase, and myeloperoxidase.[680] Thus the efficacy of aprotinin as an anti-inflammatory agent remains unresolved.

Nafamostat mesilate is a trypsin-like protease inhibitor that inhibits platelet aggregation and release, formation of kallikrein, and factor XIIa and neutrophil elastase release during in vitro extracorporeal recirculation.[681] Early clinical trials show that nafamostat mesilate inhibits fibrinolysis, preserves platelet numbers and function, reduces blood loss, and attenuates the acute inflammatory response by suppressing IL-6, IL-8, and malondialdehyde formation and neutrophil integrin expression.[682–683]

Comment

As described above, CPB and clinical cardiac surgery can produce a broad and acute inflammatory response that varies in degree among patients. The cause is the continuous recirculation of blood that is sequentially in contact with the wound, perfusion circuit, and intravascular compartment, to which is added the washout of reperfused ischemic organs and tissues. The acute inflammatory response together with microembolization is responsible for most of the morbidity of CPB and clinical cardiac surgery. Given the magnitude and diversity of the acute inflammatory response, it appears unlikely that drug cocktails or indirect measures directed against specific mediators of this response will prove more than mildly effective. Efforts to temporarily inhibit the more important mediators, specifically complement[684] and neutrophils, during the perioperative period are more attractive and achievable targets that could produce more immediate clinical benefits. Because our patients are vulnerable to infection and other forms of injury during and immediately after operation, and because the acute inflammatory response is an important first step in healing, the clinician must remember that temporary, reversible inhibitors are probably safer than permanent inhibitors.

Organ Damage

Cardiopulmonary bypass can preempt normal reflex and chemoreceptor control of the circulation, initiate coagulation, activate blood cells, release circulating cell-signaling proteins, generate vasoactive and cytotoxic substances, and produce a variety of microemboli. Venous pressure can be elevated, plasma colloid osmotic pressure is reduced, flow is nonpulsatile, and temperature is manipulated. Tissues and organs may suffer from regional malperfusion that is independent of physiologic controls, and is caused by microemboli, increased interstitial water, and perfusion with a variable amount of cytotoxic substances. Reversible and irreversible cell injury may occur, but damage is diffusely distributed throughout the entire body as individual cells or small groups of cells are affected. Ischemia-reperfusion injury augments damage to the heart and on occasion to other organs. Amazingly, the body is able to withstand and for the most part repair the cellular damage, although some abnormalities may appear later. This section summarizes the reversible and permanent organ damage produced by cardiopulmonary bypass (CPB) and complements the preceding two sections of this chapter.

MECHANISMS

Cardiac output during CPB is carefully monitored and synchronized with temperature and hemoglobin concentration to ensure that the entire body is adequately supplied with oxygen (see earlier section on extracorporeal perfusion systems). Excessive hemodilution reduces oxygen delivery,[685] and hemoglobin concentrations significantly below 8 g/L cause organ dysfunction at temperatures above 30°C.[686] However, regional hypoperfusion is not monitored,[687] is independent of reflex and chemoreceptor controls, and is influenced by the inflammatory response, which produces circulating vasoactive substances.[688–689] Regional perfusion is also influenced by acid-base relationships during cooling and may affect postoperative organ function.[690–691] Alpha-stat management (pH increases during cooling) decreases cerebral perfusion during hypothermia; pH stat (pH 7.40 is maintained by adding CO_2) improves organ perfusion but may increase embolic injury.[692] Temperature differences within the body and within organs produce regional temperature-perfusion mismatch,[693] which can precipitate regional hypoperfusion and acidosis due to inadequate oxygen delivery.

The inflammatory response produces the cytotoxic compounds and activated neutrophils and monocytes that can and do destroy organ and tissue cells (see section 12B). These agents directly access the specialized cells of every organ by passing between endothelial cell junctions to reach the interstitial compartment. Reduced plasma colloid osmotic pressure, elevated venous pressure, and widened endothelial cell junctions[694] increase the volume of the interstitial space during CPB in proportion to the duration of bypass, magnitude of the dissection, transfusions, and other factors. In prolonged complicated perfusions the interstitial

Table 12–5.

Major Sources of Microemboli

Gas	Foreign	Blood
Bubble oxygenators	Atherosclerotic debris	Fibrin
Air entry into the circuit	Fat, fat droplets	Free fat
Residual air in the heart	Fibrin clot	Aggregated chylomicrons
Loose purse-string sutures	Cholesterol crystals	Denatured proteins
Cardiotomy reservoir	Calcium particles	Platelet aggregates
Rapid rewarming	Muscle fragments	Platelet-leukocyte aggregates
Cavitation	Tubing debris, dust	Hemolyzed red cells
	Bone wax, talc	Transfused blood
	Silicone antifoam	
	Glue, Surgicel	
	Cotton sponge fiber	

compartment may increase 18 to 33%,[695] but intracellular water does not increase during CPB.

Microemboli are defined as particles less than 500 microns in diameter. They enter the circulation during CPB from a variety of sources.[696] Table 12-5 summarizes sources of gas, foreign, and blood-generated microemboli, which are more fully discussed in section 12A. Air entry into the perfusion circuit produces the most dangerous gas emboli because nitrogen is poorly soluble in blood and is not a metabolite. Carbon dioxide is rapidly soluble in blood and is sometimes used to flood the surgical field to displace air.[697] Foreign emboli, largely generated in the surgical wound, reach the circulation from the surgical field via the cardiotomy reservoir. The cardiotomy reservoir is the primary source of foreign emboli and the major source of blood-generated emboli, particularly fat emboli.[698] Extensive activation and physical damage to blood elements produce a wide variety of emboli, which tend to increase with the duration of perfusion.[692,699]

STRATEGIES FOR REDUCING MICROEMBOLI

Although discussed in earlier sections, the principal methods for reducing circulating microemboli deserve emphasis and include the following: adequate anticoagulation; membrane oxygenator; washing blood aspirated from the surgical wound;[700] filtering the cardiotomy reservoir; secure purse-string sutures around cannulas; strict control of all air entry sites within the perfusion circuit; removal of residual air from the heart and great vessels; avoidance of atherosclerotic emboli; and selective filtration of cerebral vessels.[701–702]

Many intraoperative strategies are available to reduce cerebral atherosclerotic embolization. These include routine epicardial echocardiography of the ascending aorta to detect both anterior and posterior atherosclerotic plaques and to find sites free of atherosclerosis for placing the aortic cannula.[703] Recently, special catheters with or without baffles or screens have been developed to reduce the number of atherosclerotic emboli that reach the cerebral circulation.[701,704] In patients with moderate or severe ascending aortic atherosclerosis a single application of the aortic clamp, as opposed to partial or multiple applications, is strongly recommended and has been shown to reduce postoperative neuronal and neurocognitive deficits in a large clinical series.[705] Retrograde cardioplegia is preferred over antegrade cardioplegia in these patients to avoid a sandblasting effect of the cardioplegic solution.[706] No aortic clamp may be safe or even possible in some patients with severe atherosclerosis or porcelain aorta. If intracardiac surgery is required in these patients, deep hypothermia may be used with or without graft replacement of the ascending aorta. If only revascularization is needed, pedicled single or sequential arterial grafts,[707] T or Y grafts from a pedicled mammary artery,[708] or vein grafts anastomosed to arch vessels can be used.

In-depth or screen filters (see section 12A) are essential for cardiotomy reservoirs and are usually used in arterial lines. The efficacy of arterial line filters is controversial since

screen filters with a pore size less than 20 microns cannot be used because of flow resistance across the filter. However, air and fat emboli can pass through filters, although 20-micron screen filters more effectively trap microemboli than larger sizes.[709]

CARDIAC INJURY

It is difficult to separate postoperative cardiac dysfunction from injury due to CPB, ischemia/reperfusion, direct surgical trauma, the disease being treated, and maladjustment of preload and afterload to myocardial contractile function. The heart, like all organs and tissues, is subject to microemboli, protease and chemical cytotoxins, activated neutrophils and monocytes, and regional hypoperfusion during CPB before and after cardioplegia or fibrillatory arrest. However, the heart is protected from CPB for at least one-half of the case when the aorta is cross-clamped. Some degree of myocardial "stunning" during the period coronary blood flow is interrupted is inevitable,[710] as is some degree of reperfusion injury after ischemia. Both myocardial edema and distention of the flaccid cardioplegic heart during aortic cross-clamping[711] reduce myocardial contractility. Lastly, if myocardial contractility is weak, excessive preload or high afterload during weaning from CPB increases ventricular end-diastolic volume, myocardial wall stress, and oxygen consumption. Thus postoperative performance of the heart depends on many variables and not just the injuries produced by CPB.

NEUROLOGIC INJURY

Because the brain controls all body activity, even small injuries may produce symptomatic, functional losses that are not detectable or important in other organs. Regional hypoperfusion, edema, microemboli, and circulating cytotoxins may cause subtle losses in cognitive function, behavioral patterns, and physiologic and physical function that can pass unnoticed, be accepted and dismissed, or profoundly compromise the patient's quality of life. Thus the brain is the most sensitive organ exposed to damage by CPB and also the organ that with the heart is most important to protect.

Assessment

Routine assessment of neurologic injury due to CPB is not done for most patients because of the priority of the cardiac lesion and because of costs in time and money. General neurologic examinations by untrained individuals or by members of the surgical team are not adequate to rule out subtle neurologic injuries, and this is the principal reason that the incidence of post-CPB nonstroke neurologic injury varies widely in the surgical literature.[712–714]

For studies designed to assess or reduce neurologic injury caused by CPB, nonroutine preoperative and postoperative tests are required. These special tests include a complete neurologic examination by a trained neurologist. To improve accuracy, a single neurologist should conduct all serial examinations. A standardized protocol of examination should be followed, with uniform reporting of results. The basic, structured examination includes a mental state examination; cranial nerve, motor, sensory, and cerebellar examinations; and examination of gait, station, deep tendon, and primitive reflexes.

The most obvious neuropsychologic abnormalities are coma, delirium, and confusion, but transitory episodes of delirium and confusion are often dismissed as due to anesthesia or medications. More subtle losses are determined by comparison of preoperative and postoperative performances using a standard battery of neuropsychologic tests prepared by a group of neuropsychologists.[715] A 20% decline in two or more of these tests suggests a neuropsychologic deficit that should be followed until resolved or not resolved.[716]

Computed axial tomograms or magnetic resonance imaging (MRI) scans are essential for the definitive diagnosis of stroke, delirium, or coma. Preoperative imaging is usually not necessary when new techniques such as diffusion-weighted MRI imaging, MRI spectroscopy, or MRI angiography are used to assess possible new lesions after operation.[717–719]

Biochemical markers of neurologic injury after cardiac surgery are relatively nonspecific and inconclusive. Neuron-specific enolase (NSE) is an intracellular enzyme found in neurons, normal neuroendocrine cells, platelets, and erythrocytes.[720] S-100 is an acidic calcium-binding protein found in the brain.[721–722] The beta dimer resides in glial and Schwann cells. Both S-100 and NSE increase in spinal fluid with neuronal death[721–722] and may correlate with neurologic injury after CPB.[723] However, plasma levels are contaminated by aspiration of wound blood into the pump and hemolysis, and are often elevated following prolonged CPB in patients without otherwise detectable neurologic injury.[724]

Populations at Risk

Advancing age increases the risk of stroke or cognitive impairment in the general population, and surgery, regardless of type, increases the risk still higher.[725] A European study compared 321 elderly patients without surgery to 1218 patients who had noncardiac surgery and found a 26% incidence of cognitive dysfunction 1 week after operation and a 10% incidence at 3 months.[726] Between 1974 and 1990 the number of patients undergoing cardiac surgery over age 60 and over age 70 increased twofold and sevenfold, respectively.[727] Figure 12-21 illustrates the relationship between age and cognitive dysfunction after coronary artery bypass graft and demonstrates a steep increase after the age of 60. Genetic factors also influence the incidence of cognitive dysfunction following cardiac surgery.[728] The incidence of cognitive dysfunction at 1 week following cardiac surgery is approximately double that of noncardiac surgery.

As the age of cardiac surgical patients increases, the number with multiple risk factors for neurologic injury also

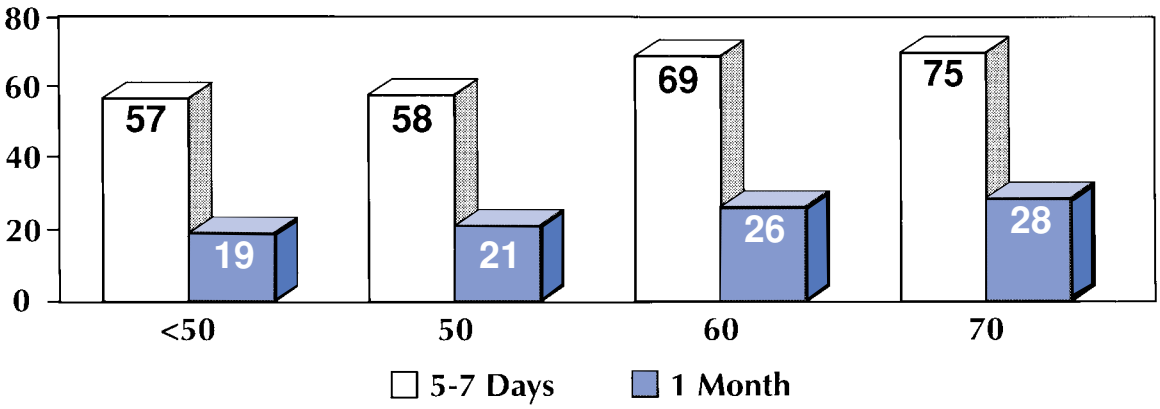

Figure 12-21. Effect of age by decade on neuropsychologic outcome after coronary artery bypass graft surgery. Abnormal neuropsychologic outcomes at 1 week and 1 month postoperatively are more common with advancing age. Percentages of patients with deficits on two or more tests are shown (n = 374). increases. Risk factors for adverse cerebral outcomes are listed in Table 12-6.[729] These factors are divided into stroke with a permanent fixed neurologic deficit (type I) and coma or delirium (type II). Hypertension and diabetes occur in approximately 55% and 25% of cardiac surgical patients, respectively.[730] Fifteen percent have carotid stenosis of 50% or greater, and up to 13% have had a transient ischemic attack or prior stroke. The total number of atherosclerotic stenoses in the brachiocephalic vessels adds to the risk of stroke or cognitive dysfunction,[731] as does the severity of atherosclerosis in the ascending aorta as detected by epiaortic ultrasound scanning.[732] Palpable ascending aortic athero-

Table 12–6.

Adjusted Odds Ratios for Type I and Type II Cerebral Outcomes Associated with Selected Risk Factors

Factor	Model for type I cerebral outcome	Model for type II cerebral outcome
Significant factors, $p < .05$		
Proximal aortic atherosclerosis	4.52	
History of neurologic disease	3.19	
Use of intra-aortic balloon pump	2.60	
Diabetes mellitus	2.59	
History of hypertension	2.31	
History of pulmonary disease	2.09	2.37
History of unstable angina	1.83	
Age (per additional decade)	1.75	2.20
Systolic blood pressure >180 mm Hg at admission		3.47
History of excessive alcohol consumption		2.64
History of coronary artery bypass graft		2.18
Dysrhythmia on the day of surgery		1.97
Antihypertensive therapy		1.78
Other factors (p not significant)		
Perioperative hypotension	1.92	1.88
Ventricular venting	1.83	
Congestive heart failure on the day of surgery		2.46
History of peripheral vascular disease		1.64

sclerotic plaques markedly increase the risk of right carotid arterial emboli as detected by Doppler ultrasound.[733] The incidence of severe aortic atherosclerosis is 1% in cardiac surgical patients less than 50 years old and is 10% in those aged 75 to 80.[734]

Mechanisms of Injury

The two major causes of organ dysfunction and injury during CPB are microemboli and hypoperfusion, which are to some extent mutually exclusive. Microemboli are distributed in proportion to blood flow;[735] thus reduced cerebral blood flow reduces microembolic injury but increases the risk of hypoperfusion.[736] During CPB both alpha-stat acid-base management and phenylephrine reduce cerebral injury in adults, probably by causing cerebral vessel vasoconstriction and reducing the number of microemboli.[736–737] Air,[738] atherosclerotic debris,[739] and fat are the major types of microemboli causing brain injury in clinical practice, and all cause neuronal necrosis by blocking small cerebral vessels.[692] Massive air embolism causes a large ischemic injury, but gaseous cerebral microemboli may directly damage endothelium in addition to blocking blood flow.[740] The recent identification of unique small capillary arteriolar dilatations in the brain associated with fat emboli (Fig. 12-22)[741] raises the possibility that these emboli not only block small vessels, but also release cytotoxic free radicals, which may significantly increase the damage to lipid-rich neurons.

Anemia and elevated cerebral temperature increase cerebral blood flow but may cause inadequate oxygen delivery to the brain;[742] however, these conditions are easily avoided during clinical cardiac surgery. Although some investigators speculate that normothermic and/or hyperthermic CPB cause cerebral hypoperfusion,[743] experimental studies indicate that cerebral blood flow increases with temperature.[744] Brain injuries associated with this practice are more likely due to increased cerebral microemboli, which produce larger lesions at higher cerebral temperatures.[735] Reduced brain temperature is protective against neural cell injury and remains an important neuroprotective strategy.

Additional Neuroprotective Strategies

Primary strategies for avoiding air, atherosclerotic particulates, and blood-generated microembolism are presented above and in section 12A. Recommended conditions for protecting the brain during CPB include mild hypothermia (32 to 34°C) and hematocrit above 25%.[744] Temporary increases in cerebral venous pressure caused by superior vena cava obstruction and excessive rewarming above blood temperatures of 37°C should be avoided.[745–746] A randomized study in which patients were mildly rewarmed to 35°C core temperature demonstrated improved neurocognitive outcomes over patients rewarmed to 37°C.[746] Either jugular venous bulb oxygen saturation or near-infrared cerebral oximetry are recommended for monitoring cerebral perfusion in patients who may be at high risk for cerebral injury.[747]

Barbiturates reduce cerebral metabolism by decreasing spontaneous synaptic activity[748] and provide a definite neuroprotective effect during clinical cardiac surgery using CPB.[749] Unfortunately, these agents delay emergence from anesthesia and prolong intensive care unit stays. A recent study of high-risk patients randomized to aprotinin or placebo found a powerful protective effect against stroke for full-dose aprotinin in coronary artery bypass graft patients.[750] A larger randomized multi-institutional study is planned. N-methyl-D-aspartate antagonists, which are effective in animals, provide mild protection compared to control

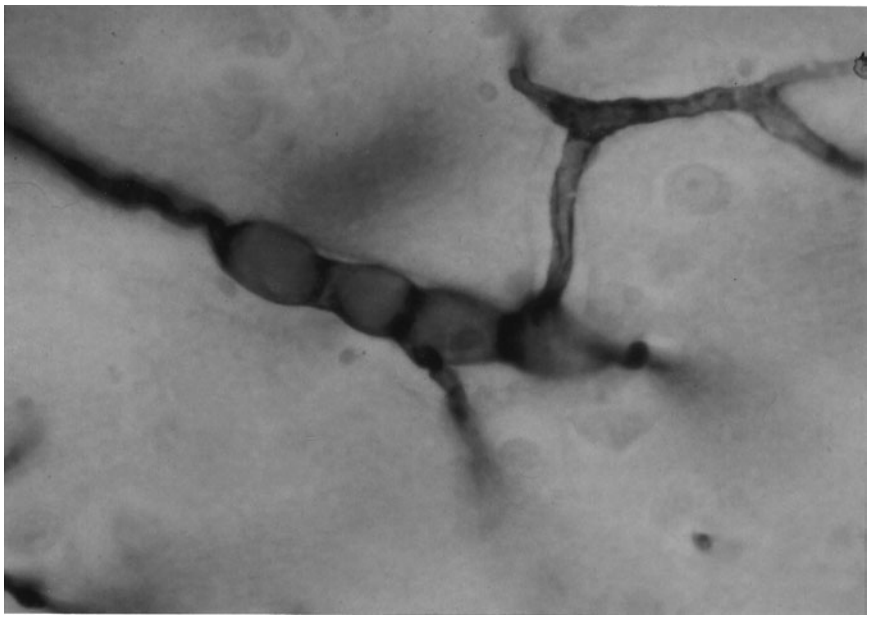

Figure 12-22. Small capillary and arterial dilatations in cerebral vessels in a patient who expired 48 hours after coronary artery bypass graft surgery using cardiopulmonary bypass. Alkaline phosphatase-stained celloidin section, 100 μm thick 100×.

patients, but have a high incidence of neurologic side effects.[751] A small study demonstrated a neuroprotective effect of lidocaine.[752] Currently no pharmacologic agent is recommended for protection of the central nervous system during CPB.

Off-pump myocardial revascularization theoretically avoids many of the causes of cerebral injury due to CPB, but as noted above, many causes of neuronal injury are independent of CPB and related to atherosclerosis and air entry sites into the circulation. Nonrandomized measurements of carotid emboli by Doppler ultrasound indicate fewer emboli and slightly improved neurocognitive outcomes in high-risk patients who have off-pump surgery.[753] A randomized trial of off-pump versus on-pump patients failed to show a significant difference in neurologic outcome between methods.[754]

Prognosis

Neuropsychologic deficits that are present after 3 months are almost always permanent.[755] Assessments after that time are confounded by development of new deficits, particularly in aged patients.[756]

LUNG INJURY

Patient factors and the separate effects of operation and CPB combine to compromise lung function early after operation. Chronic smoking and emphysema are the most common patient factors, but muscular weakness, chronic bronchitis, occult pneumonia, preoperative pulmonary edema, and unrelated respiratory disease are other contributors to postoperative pulmonary dysfunction. Incisional pain, lack of movement, shallow respiratory sighs, increased work of breathing, reduced pulmonary compliance, weak cough, increased pulmonary arterial-venous shunting, and interstitial edema, to some degree are consequences of anesthesia and any operation. CPB significantly adds to this injury.

During CPB the lungs are supplied by the bronchial arteries and pulmonary arterial blood flow may be absent or minimal. Whether or not alveolar cells suffer ischemic/reperfusion injury is unclear, but the lungs are subject to many insults that combine to increase pulmonary capillary permeability and interstitial lung water. Hemodilution, reduced plasma oncotic pressure, and temporary elevation of left atrial or pulmonary venous pressure during CPB or during weaning from CPB increase extravascular lung water.[757,758] Microemboli[759] and circulating cellular, vasoactive, and cytotoxic mediators of the inflammatory response[760–764] reach the lung via bronchial arteries during CPB and with resumption of the pulmonary circulation during weaning. These agents increase pulmonary capillary permeability, perivascular edema, and bronchial secretions, and perhaps cause observed changes in alveolar surfactant.[765] The combination of increased interstitial lung water and bronchial secretions, altered surfactant, patient factors, and the consequences of operation reduces pulmonary compliance and functional residual capacity and increases the work of breathing.[766] All of these changes combine to enhance regional atelectasis, increase susceptibility to infection, and increase the physiologic arterial-venous shunt, which reduces systemic arterial Pa_{O_2}.

Postoperative respiratory care is based upon restoring normal pulmonary capillary permeability and interstitial lung volume; preventing atelectasis; reinflating atelectatic segments; maintaining normal arterial blood gases; and preventing infection and facilitating removal of bronchial mucus. Improved postoperative respiratory care, an understanding of the mechanisms of lung injury during CPB, and efforts to prevent or control the causes of injury[767,768] have markedly reduced the incidence of pulmonary complications in recent years[769] (see Chapter 16 for a more detailed discussion of postoperative care).

Acute respiratory distress syndrome is a rare complication of lung injury during cardiopulmonary bypass and is usually caused by intrabronchial bleeding from traumatic injury by the endotracheal tube or pulmonary artery catheter,[766] or to extravasation of blood into alveoli from acute increases in pulmonary venous pressure or severe pulmonary capillary toxic injury.

RENAL INJURY

As with other organs, the preoperative health of the kidneys is a major factor in the ability of that organ to withstand the microembolic, cellular,[770] and regional malperfusion injuries caused by CPB. Risk factors for postoperative renal dysfunction include age over 70 years, diabetes mellitus, previous cardiac surgery, congestive heart failure, and a complex, prolonged operation.[771] The incidence of acute renal failure requiring dialysis after CPB is remarkably low, averaging 1%; however, the incidence increases to 5% with complex operations.[772]

Some degree of renal injury is inevitable during CPB[773] and postperfusion proteinuria occurs in all patients.[774] Increased expression of neutrophil CD11b receptors and elevated neutrophil count are significantly related to postoperative acute renal failure, defined as a 150% increase in plasma creatinine over baseline.[775] Renal blood and plasma flow, creatinine clearance, free water clearance, and urine volume decrease without hemodilution.[776] Hemodilution attenuates most of these functional changes and also reduces the risk of hemoglobin precipitation in renal tubules if plasma-binding proteins become saturated with free hemoglobin during extracorporeal perfusion. Hemoglobin is toxic to renal tubules and precipitation can block both blood and urine flow to the tubules.[777] Hemodilution dilutes plasma hemoglobin; improves flow to the outer renal cortex; improves total renal blood flow; increases creatinine, electrolyte, and water clearance; and increases glomerular filtration and urine volume.[775]

Perioperative periods of low cardiac output and/or hypotension added to the microembolic, cellular, and cytotoxic injuries of CPB, and to any preoperative renal disease are the major causes of postoperative renal failure.[770,777] Low cardiac output reduces renal perfusion pressure and causes angiotensin II production and renin release, which further decrease renal blood flow. Kidneys, already compromised by preoperative disease and the CPB injury, are particularly sensitive to ischemic injury secondary to low cardiac output and hypotension. Thus perioperative management includes efforts to maximize cardiac output using dopamine or dobutamine if necessary,[778] avoiding renal arterial vasoconstrictive drugs, providing adequate crystalloid infusions to maintain urine volume, and alkalinizing urine to minimize precipitation of tubular hemoglobin if excessive hemolysis has occurred. Preliminary studies with a natriuretic peptide found in human urine, urodilantin, indicate the possibility of attenuating postoperative oliguria.[779]

If perioperative low cardiac output and hypotension do not occur,[780] the normal kidney has sufficient functional reserve to provide adequate renal function during and after operation. The appearance of oliguric renal failure is ominous and usually requires dialysis, which is generally permanent if required for more than 2 weeks.[780] Oliguric renal failure markedly increases morbidity and mortality by approximately eightfold.[781]

INJURY TO THE LIVER AND GASTROINTESTINAL ORGANS

Although subjected to microemboli, cytotoxins, and regional malperfusion during CPB, the enormous functional reserve and reparative processes of the normal liver nearly always overcome the injury without consequences. Often liver enzymes are mildly elevated,[782] and 10 to 20% of patients are mildly jaundiced.[783] Extensive red cell hemolysis increases the likelihood of mild jaundice. Persistent and rising bilirubin two or more days after CPB may precede development of liver failure and is associated with increased morbidity and mortality.[784] Catastrophic liver failure, however, occurs in patients with overwhelming sepsis, oliguric renal failure, anesthetic or drug toxicity, or after a prolonged period of low cardiac output or an episode of hemorrhagic shock and multiple blood transfusions and is uniformly fatal.[785] The liver usually is involved in patients who develop multiorgan failure and is often presaged by sudden hypoglycemia.

PANCREATIC INJURY

Less than 1% of patients develop clinical pancreatitis after CPB, but approximately 30% develop a transitory, asymptomatic increase in plasma amylase and/or lipase.[786–788] Autopsy studies of the pancreas soon after CPB indicate occasional evidence of histologic pancreatitis.[789] A history of recurrent pancreatitis, perioperative circulatory shock or hypotension, excessively prolonged CPB, and continuous high doses of inotropic agents are risk factors for developing postoperative pancreatitis.[790] Experimentally and clinically, high doses of calcium increase intracellular trypsinogen activation and histologic evidence of pancreatitis.[791–793] Fulminant pancreatitis is very rare, but is often fatal.[794]

STOMACH AND GUT INJURY

CPB at adequate flow rates does not decrease splanchnic blood flow.[795] Risk factors for gastrointestinal complications include advanced age, emergency surgery, prolonged CPB, postoperative low cardiac output or shock, prolonged vasopressor therapy, and elevated preoperative systemic venous pressure.[796]

CPB decreases gastric pH, which declines further after operation.[797] Prior to the advent of histamine blockers and regular use of antacids, duodenal and/or gastric erosion, ulcer, and bleeding were frequent complications following clinical cardiac surgery[798] and were associated with mortality that approached 33 to 50%.[799] These complications are now uncommon.

Several days to 1 week after operation very elderly patients rarely may develop mesenteric vasculitis or severe mesenteric vasoconstriction that proceeds to small bowel ischemia and/or infarction in response to vasopressors. New-onset abdominal pain with a silent, rigid abdomen and abrupt rise in white blood cell count may be the only signs of this catastrophic complication, which is frequently fatal. If suspected before infarction, infusion of papaverine or alternative vasodilators directly into the mesenteric arteries may prevent or limit subsequent infarction.[800] The role of CPB in the etiology of this complication is not known.
