There is no effective medical therapy for aortic valve stenosis. Diuretics and digitalis may improve the symptoms of CHF. ACE inhibitors are relatively contraindicated in patients with AS. Afterload reduction therapy is contraindicated in patients with AS because it can reduce coronary perfusion pressure. Prophylactic antibiotics are recommended prior to any dental or surgical procedures as a prevention strategy for endocarditis. Percutaneous balloon aortic valvotomy is indicated mainly in the treatment of children with AS and as a temporary maneuver in some symptomatic adults who are poor surgical candidates. Aortic valve repair for aortic valve stenosis has yielded poor results compared with aortic valve repair.[55] Aortic valve replacement is indicated in patients with symptomatic AS. Patients who present with angina, syncope, or symptoms of heart failure should undergo AVR.

Percutaneous AVR represents a novel, less invasive approach to the treatment of AS. This approach has been applied successfully in high-risk patients with severe symptomatic AS who were not deemed to be candidates for conventional surgery.

Asymptomatic patients

Aortic valve replacement in asymptomatic patients is currently controversial. The decision to operate on asymptomatic patients with severe AS remains difficult.[57,58] Considering the high rate of cardiac events and sudden death in previous reports, early elective surgery could be indicated in a high-risk subset of patients, such as those with an AVA of <0.75 cm^2, an abnormal exercise test, or an increase in transaortic gradient during exercise. Other patients with a poor prognosis are those with moderate or severe valvular calcification and a rapid increase in aortic jet velocity between two echocardiographic studies.[58] Asymptomatic patients with an AVA of <0.8 cm^2 or a peak aortic gradient of 40 mm Hg may benefit from AVR. Moreover, any evidence of impaired LVF as demonstrated by depressed ejection fraction (EF), left ventricular dilatation, or significantly elevated left ventricular diastolic pressure (LVDP) at rest or during exercise is an indication for AVR. Patients with CAD and AS with a mean transvalvular gradient of more than 40 mm Hg undergoing coronary artery revascularization should undergo coronary artery bypass with concomitant AVR. Combined coronary artery bypass grafting (CABG) and AVR generally is indicated in patients with CAD and at least moderate AS, higher transvalvular gradients, and calcified valves.[59] In patients with low EF and a small transvalvular gradient, AVR results in improvement in only 50% of patients, the other 50% being complicated by perioperative death or CHF.[60] Controversy currently exists as to whether asymptomatic patients with mild AS also should undergo AVR at the time of CABG.

AORTIC REGURGITATION

Aortic regurgitation (AR) is a diastolic reflux of blood from the aorta into the left ventricle owing to failure of coaptation of the valve leaflets during diastole. The presentation varies depending on the acuity of onset, severity of regurgitation, compliance of the ventricle and aorta, and hemodynamic conditions prevalent at the time. Whereas chronic AR is well tolerated for years, acute AR can be debilitating and life-threatening if not treated emergently.

Prevalence and Etiology

AR has numerous causes, which can be grouped according to the structural components of the valve affected. The valve leaflets may be distorted, thereby preventing proper valve coaptation. Calcific aortic disease, idiopathic degenerative disease, active or chronic aortic valve endocarditis, rheumatic disease, a biscuspid aortic valve, and myxomatous proliferation of aortic valve tissue all prevent the valve cusps from closing properly.[62,63] More recently, anorectic medications, such as fenfluramine and phentermine, have been found to cause aortic valve distortion from accelerated degeneration of valve leaflets, leading to regurgitation similar to that seen in carcinoid syndrome. Aortic annular dilatation will prevent the aortic cusps from closing properly, as well as leading to valve insufficiency. Aortic dissection; trauma; chronic systemic hypertension; aortitis from syphilis, viral syndromes, or other systemic arteritides (e.g., giant cell and Takayasu); and connective tissue disorders such as Marfan syndrome, Reiter disease, Ehlers-Danlos syndrome, osteogenesis imperfecta, and rheumatoid arthritis all lead to annular dilatation and valvular insufficiency.[61,64–69] Pure AR is rare and is seen commonly only in aortic dissection or in pathophysiologic processes causing annular dilatation. Most commonly, aortic valvular insufficiency is seen in combination with AS, as is often seen in aortic disease, rheumatic valvular disease, or myxomatous degenerative disease.

Pathophysiology

The pathophysiology of AR varies according to the onset and duration of the disease process.

Acute aortic regurgitation

By definition, acute AR is a hemodynamically significant aortic incompetence of sudden onset across a previously competent aortic valve into a left ventricle not previously subjected to volume overload. The inability to adapt is worse for concentrically thickened hypertrophic myocardium typically seen in those with chronic hypertension.

Disease states that typically present in this acute fashion include endocarditis, trauma, and aortic dissection. Even small regurgitant volumes result in a dramatic increase in left ventricular end-diastolic pressures. The mitral valve may close earlier in late diastole to reduce the amount of left atrial blood entering the ventricle, thereby preventing backflow into the left atrium and pulmonary veins. Pulmonary wedge pressure increases with resulting pulmonary edema. The normally widened pulse pressure of chronic AR is attenuated or nonexistent in the acute AR owing to the rapid rise in diastolic pressure.[70] Effective cardiac output is less than that of the chronic state because compensatory dilatation has not occurred, and, hence, left ventricular end-diastolic volume (LVEDV) remains larger than normal but small in comparison with effective stroke volume. Compensatory changes in heart rate occur, higher than those of chronic AR, to augment cardiac output. Overall, the hemodyamic effects of acute aortic insufficiency produce a low effective cardiac output with an elevated LVDP and heart rate, which are maintained in a precarious balance leading to the onset of early CHF with any perturbation in diastolic filling or heart rate.

Patients with acute AR and decreased cardiac output often present with chest pain that is a result of decreased coronary blood flow from changes is diastolic perfusion

pressures and an increase in myocardial oxygen consumption. In acute AR, coronary blood flow occurs in systole.

Chronic aortic regurgitation

In contrast, chronic AR is a slow and insidious process, which sets in motion numerous compensatory mechanisms. The left ventricle accommodates increased volume and pressure caused by the regurgitant flow by eccentric ventricular hypertrophy, with a consecutive increase in LVEDVs. Left ventricular end-diastolic pressure does not approach aortic diastolic pressure, as can occur in acute insufficiency, leading to a widened pulse pressure, which is an associated physical sign of this disease. Cardiac output is maintained with the aid of the autonomic nervous system. This increase in stroke volume (SV) is responsible for the wide pulse pressure and hypertension seen in AR.

AR also impairs early diastolic function because eccentric hypertrophy leads to impaired left ventricular relaxation during later stages of the disease process.[71] Unlike acute aortic insufficiency, premature closure of the mitral valve does not occur. However, flutter of the anterior leaflet of the mitral valve may occur owing to a Bernoulli effect. AR leads to changes in diastolic perfusion pressure, and coronary blood flow may be reduced, leading to chest pain in patients. Myocardial oxygen demands are high in hearts with aortic insufficiency due to large end-diastolic volumes and pressures, which lead to increased ventricular wall tension according to Laplace's law. With only a moderate reduction in aortic diastolic perfusion pressure, myocardial blood flow usually is adequate to meet the metabolic demands of the myocardium. However, with a severe reduction in diastolic pressure, a decrease in diastolic coronary perfusion occurs that is compensated only partially by increased coronary arterial flow during systole. With decreased diastolic pressure, coronary perfusion is now unable to meet the oxygen demands of the overloaded ventricular myocardium. In experimental models, diastolic aortic pressures of 40 mm Hg or less dramatically reduce coronary artery blood flow and increase myocardial ischemia, as measured by lactate production.[72] Severe regurgitant flow even may lead to a reversal of diastolic coronary arterial flow. This is seen more often in degenerative and bicuspid valve disease because the various valve shapes allow for more regurgitant flow than for valves made incompetent by rheumatic disease.[73] Left ventricular hypertrophy not only increases myocardial oxygen demand but also reduces coronary artery vascular reserve in proportion to the degree of hypertrophy likely by compression of capillary blood flow.[74] Superimposed CAD only exacerbates the effect of decreased diastolic coronary perfusion pressure and myocardial hypertrophy.

As seen from the hemodynamic effects of aortic insufficiency, effective forward cardiac output is enhanced by any physiologic changes that decrease afterload or increase heart rate, which in and of itself increases cardiac output and decreases diastolic filling time and hence regurgitant flow time. The peripheral vasodilatation and increased heart rate that accompany exercise increase effective cardiac output in this manner.[75] This is the physiologic basis for vasodilator therapy for the treatment of acute and chronic aortic insufficiency. It also becomes clear why bradycardia and negative inotropic and chronotropic agents are to be used carefully or avoided in AR because increased filling times lead to increased regurgitative flow and pulmonary congestion.

As aortic insufficiency progresses, the preload reserve of the left ventricle is reached eventually. Thereafter, any further increase in afterload creates afterload mismatch. In general, patients with aortic insufficiency have slightly depressed ventricular function when compared with normal subjects if ventricular function is evaluated in terms of end-systolic pressure-volume relationships (ESPVRs). A depressed ejection fraction with a near-normal ESPVR indicates afterload mismatch.[76] Hence, EF may not be a good indicator of ventricular function.[77] However, a depressed EF with a depressed ESPVR indicates intrinsic myocardial disease, especially in patients with large end-systolic and end-diastolic volumes. At this stage, prolonged aortic insufficiency has led to further increases in wall stress without compensatory hypertrophy, leading to eventual myofibrillar slippage. Subsequent molecular events lead to fibrosis and irreversible changes in ventricular function.

It is at this point in the natural history of aortic insufficiency that AVR will not improve cardiac function. Identifying these patients is somewhat difficult at the clinical level. Ejection fraction alone is a poor indicator of postoperative functional recovery because it depends on preload and afterload. Irreversible changes decrease both the EF and the ability to develop peak systolic stress in relation to chamber size. Attempts to identify these patients include studies illustrating that patients with left ventricular end-systolic volumes (LVESVs) exceeding 60 mL/m^2 remain in New York Heart Association (NYHA) functional class IV postoperatively. Other studies have suggested that when the ratio of chamber volume to wall thickness exceeds 3.8, postoperative recovery may be compromised.[78] This ratio is indicative of progressive dilatation with myofibrillar slippage. Some echocardiographic studies have found that an end-systolic left ventricular dimension of $>$55 mm and a fractional shortening of $<$25% are associated with decreased ventricular recovery postoperatively and increased mortality.[79] This is based on the belief that LVESV is an indicator of LVF. Other studies have refuted this finding, but current guidelines recommend AVR in asymptomatic patients when LVESV is $>$55 mL/m.[46]

Signs and symptoms

Physical examination findings of AR vary with the chronicity of the disease process. The widened pulse pressure seen in chronic AR results from the augmentation of total cardiac output that leads to the distention of the peripheral arterial system followed by a quick collapse from regurgitant flow. This leads to many classic physical findings such as a "water-hammer" pulse (Corrigan pulse), head bobbing with each heart beat (DeMusset sign), and capillary pulsations at the lips and fingers (Quincke pulses). Other findings are associated

with CHF if present (e.g., rales, S_3, etc).[80] Many of the classic signs and symptoms of chronic aortic insufficiency are absent in the acute manifestation of this valvular disorder. In acute insufficiency, as discussed earlier, pulse pressure is not widened, and, hence, the signs associated with this pathologic physiology are absent. Instead, the signs of acute CHF predominate.

Patients with compensated AR remain asymptomatic for prolonged periods of time. However, with ventricular decompensation occurring with large regurgitant volumes, patients may experience palpitations; an awareness of each heartbeat, especially at the ventricular apex; or atypical chest pain syndromes.[80] Chest pain is rare in aortic insufficiency, unlike AS. The eccentric hypertrophic myocardium of compensated aortic insufficiency is by no means as thick as that of AS, leading to lower degrees of increased oxygen requirement and a maximally dilated coronary circulation. However, turbulent flow patterns and diminished diastolic perfusion pressure at some point may lead to insufficient coronary and myocardial perfusion. Most symptoms of aortic insufficiency occur from underlying heart failure and pulmonary congestion as the ventricle decompensates.

Diagnostic Evaluation

Often the signs and symptoms of aortic insufficiency are all that are needed to make the diagnosis. However, if the diagnosis is unclear or the desire is to quantify the severity of disease, other diagnostic tests can be employed, including an electrocardiogram (ECG), echocardiography (ECHO), cardiac catheterization, and MRI, which are discussed below.

ECG

Chronic AR results in left axis deviation. Q waves in leads I, V_1, and V_3 to V_6 are indicative of diastolic volume overload.[81] Left ventricular conduction defects usually are associated with left ventricular dysfunction. The QRS complex amplitude is linearly correlated with left ventricular mass. The finding of a strain pattern in relation to a reduction in the QRS complex amplitude is indicative of severe depression of EF and contractility.[82] Overall, the ECG is not an accurate predictor of the severity of AR.

Echo

Echocardiography is the most useful diagnostic modality in both the initial diagnosis and continued monitoring of patients with AR. Transthoracic echocardiography (TTE) is the most commonly used imaging tool. Transesophageal echocardiography is invasive and used only when patient body habitus does not allow for adequate assessment of valvular function or when evaluation of the aortic valve and ascending aorta is needed in a patient with suspected aortic dissection (Fig. 32-8). Transthoracic echocardiography is indispensable in the diagnosis of the presence and degree of aortic insufficiency, its etiology, valve morphology and presence of vegetations and calcification, quantification of pulmonary hypertension, and determination of ventricular function. Most important, though, it allows for the noninvasive monitoring of valvular disease and LVF in asymptomatic patients. This is critically important in determining the timing of surgery in asymptomatic patients prior to the onset of permanent ventricular decompensation.

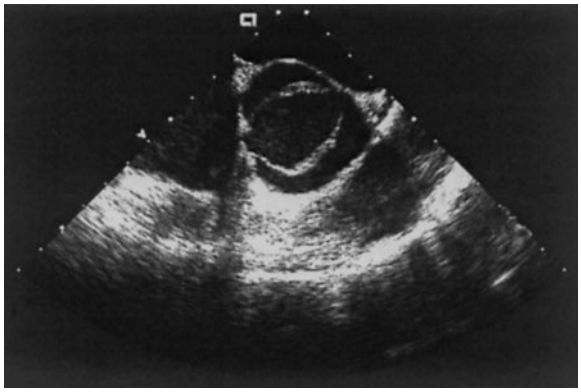

Figure 32-8. Transesophageal echocardiographic image of bicuspid aortic valve. Noncoronary cusp (at the tip of the viewing triangle) is freestanding, Left and right coronary cusps are fused.

The etiology of aortic insufficiency is defined by failure of leaflets to coapt versus stiffness of fibrotic or calcified leaflets. The quality of the regurgitant murmur is evaluated by color-flow techniques. Measurements of end-systolic and end-diastolic volumes, as well as measurement of wall thickness, can be obtained. These measurements are useful for determining irreversible changes in LVF. Two-dimensional (2D) echocardiography, along with Doppler color-flow mapping, has been used routinely to diagnose and assess the severity of AR.[83–85] The color-flow jets typically are composed of three segments: (1) proximal flow convergence zone (area of acceleration into the orifice), (2) vena contracta (the narrowest and highest-velocity region of the jet), and (2) the jet itself distal to the orifice in the left ventricular cavity. The severity of AR can be defined by the ratio of the proximal jet width to LVOT width, with a ratio of less than 25% consistent with mild AR and a ratio of greater than 65% diagnostic of severe AR.

Quantitative Doppler flow measurements use the total stroke volume (i.e., flow at the aortic valve level) and the forward stroke volume (i.e., flow at the mitral valve level) to calculate the AR volume and fraction.[86] The effective regurgitant orifice (ERO) area can be calculated by dividing the regurgitant volume by the velocity time integral of the AR jet calculated by continuous-wave Doppler.[87]

Premature closure of the mitral valve, as seen in acute AR, can be recognized. Fluttering of the anterior mitral leaflet from regurgitant flow also may occur during diastole and can be appreciated. This is a sensitive indicator of both acute and chronic AR. Although fluttering of the open mitral valve is seen classically during diastole, fluttering also may occur with the mitral valve closed. Fluttering of the posterior mitral valve leaflet is also described.[88] Measurement of left ventricular dimension and function by echocardiography

is essential and plays a significant role in management decisions.

Catheterization

Cardiac catheterization is important to estimate the severity of aortic insufficiency if echocardiographic studies are equivocal or if there is concomitant CAD. The amount of regurgitant flow can be determined by calculating the angiographic stroke volume minus a measured fixed stroke volume. The difference between these two measured volumes divided by the angiographic stroke volume determines the regurgitant fraction. In general, a regurgitant fraction of less than 20% is 1+ aortic insufficiency. An increase in regurgitant fraction to 60% corresponds to 4+ insufficiency.[92] Left ventricular end-diastolic pressure is measured directly, and EF is estimated roughly. Radionucleotide imaging with ventriculography can be substituted for angiography if there is a contradiction to cardiac catheterization or serial follow-up of patients is required.[54] This imaging modality, like echocardiography, allows for noninvasive monitoring of aortic insufficiency and ventricular function, although it does not visualize the valvular apparatus directly.

MRI

With current improvements in MRI technology, MRI cineangiography is able to provide some of the same information provided by TTE and TEE. MRI in some aspects provides superior resolution of the valves and better quantification of regurgitant flow and LVF. The regurgitant volume can be calculated by quantitative assessment, wherein aortic flow is subtracted from the ventricular stroke volume measured by volumetric technique. It also can be assessed using flow mapping downstream from the aortic valve by measuring the retrograde volume flow after valve closure. This method is more reproducible and is used more frequently for follow-up studies. However, MRI is costly, and expertise is not available in most centers. Future improvements in technology may reduce costs and increase its availability, thereby making it a standard imaging modality along with or in substitution for echocardiography.[90–92]

Indications for Surgery

Acute AR is treated by early valve replacement. With inadequate time for the left ventricle to compensate by myocardial hypertrophy, progressive CHF, tachycardia, and diminished cardiac output occur rapidly.

Compensated chronic AR is well tolerated by most patients.[93–94] Aortic valve replacement is currently not recommended for patients who are asymptomatic, even with severe chronic AR. These patients, however, must have normal ventricular function and good exercise tolerance. In asymptomatic patients, AVR is indicated for deteriorating ventricular function.[46,95] An EF of less than 55% with a diastolic diameter approaching 75 mm or an end-systolic diameter approaching 55 mm is an indication for operation.[46,82,96–99]

Predictive indicators of impending symptoms in asymptomatic patients are not available. One potential indicator is measurement of left ventricular wall stress at rest and after exercise. Some studies have shown that patients with increased wall stress during exercise develop decompensated left ventricular failure within 5 years.[100] Aortic valve replacement is indicated if patients develop symptoms of CHF or decreased exercise tolerance. However, decreased EF during exercise is not a good measure to indicate the need for valve replacement in asymptomatic patients with normal systolic function at rest. The lack of correlation between exercise EF and the need for operation lies in that exercise EF depends on multiple factors, and no studies have shown conclusive proof linking exercise EF with mortality preoperatively or to be of prognostic value postoperatively.

Ideally, AVR should be performed before irreversible myocardial damage from myocyte apoptosis with resulting fibrosis occurs. Although patients with impaired ventricular function are at an increased perioperative risk, survival is prolonged when compared with patients undergoing medical management. Nonoperative management of patients with severe AR and abnormal LVF is associated with a 50% mortality in 1 year.[101] Risk factors for postoperative mortality include a radius-to-wall-thickness ratio of 3.8 or greater.[80–102] However, despite AVR, impaired LVF may continue in some patients. These patients are difficult to identify preoperatively, and their hearts, as expected, show increased interstitial fibrosis.

In patients in whom ventricular remodeling occurs after AVR, the regression of left ventricular dimension and cross-sectional area can take as long as 3 years. The best predictor for persistent postoperative left ventricular enlargement is preoperative enlargement of the end-diastolic dimension, but this predictor is not always predictive of outcome. Duration of symptoms of left ventricular dysfunction preoperatively is also an indicator for poor reversibility of ventricular function postoperatively.[103]

Early postoperative studies of left ventricular size and function reveal that end-diastolic volumes decrease significantly with valve replacement. With the decrease in preload, subsequent EF decreases; however, if the operation is timed correctly, EF eventually recovers to near-normal values in selected patients.[104] Further recovery includes regression of myocardial hypertrophy, reduction in left ventricular size, normalization of the mass:volume ratio, and increased diastolic coronary flow.[105,106] If improvement is going to occur after AVR, it occurs within the first 6 months as the ventricular end-diastolic dimension decreases. A decrease in the peak systolic wall stress and an increase in EF also occur within the first 6 months.[107–109]

CHAPTER 33

Aortic Valve Replacement with a Mechanical Cardiac Valve Prosthesis

Robert W. Emery • Ann M. Emery • Amy Knutsen • Goya V. Raikar

In 1931, Paul Dudley White stated "There is no treatment for aortic stenosis." Even today the medical therapy of aortic stenosis has not significantly advanced (Fig. 33-1).[1] Conversely, patients may tolerate aortic insufficiency for many years, but as the ventricle starts to dilate, a progressive downhill course begins and early operation is warranted.[2] Definitive therapy for aortic valve disease was unavailable until the advent of cardiopulmonary bypass. Innovative cardiovascular surgeons then began to develop cardiac valve prostheses. Over the subsequent 50 years,[3] the variety of prostheses that have become available for use have expanded greatly. Available aortic valve substitutes include: mechanical valve prostheses, stented biologic valve prostheses, stentless biologic valve prostheses, human homograft tissue (both as isolated valve replacement and aortic root replacement), and a combination of a biologic valve utilizing a pulmonary autograft and pulmonary outflow tract replacement with heterograft prostheses (Ross procedure). This chapter will focus on the use of mechanical valve replacement in the aortic position.

HISTORY

In 1952, Hufnagel used an aortic valve ball and cage prosthesis heterotopically in the descending thoracic aorta to treat aortic insufficiency.[4] After the advent of cardiopulmonary bypass, initial attempts at aortic valve replacement (AVR) consisted of replacement of the individual aortic cusps with Ivalon gussets sewn to the annulus. When successful, these prostheses often calcified and results were short-lived. Shortly thereafter, surgical pioneers Starr, Braunwald, and Harkin began replacement of the aortic valve in the orthotopic position. First-generation aortic valve prostheses, the ball and cage, became the standard for AVR for over a decade (Fig. 33-2). Many of these prostheses have remained durable for up to 40 years.[5,6] Multiple modifications ensued including: changing the material of the ball from Silastic to Stellite, changes in the shape of the cage, depression of the ball occluder, the addition of cloth coating to the sewing ring and the cage, and changes in the sewing ring itself. These valves, however, required intense anticoagulation.[7] Hemodynamic performance was compromised, as there were three areas of potential outflow obstruction: the annular size of the sewing ring (the effective orifice area of the valve), the distance between the cage and the walls of the ascending aorta (particularly in the small aortic root), and obstruction to outflow by the ball itself distal to the tissue annulus. Flow patterns were also abnormal (Fig. 33-3). These problems led to the development of the next generation of aortic valve prostheses: the tilting disc valve. Innovators such as Bjork, Hall, Kastor, and Lillehei developed three models of tilting disc prostheses that became the second generation of commonly implanted aortic valve replacement devices between 1968 and 1980. The low-profile configuration simplified surgical implantation (Fig. 33-4). Problems with the tilting disc valve included stasis and eddy current formation at the minor flow orifice (see Fig. 33-3), and sticking or embolization of the leaflet, the latter leading to discontinuation of the Bjork prosthesis in spite of otherwise good long-term results.[8] The Lillehei-Kastor prosthesis has evolved into the Omniscience valve. The Medtronic Hall valve, the third tilting disc prosthesis, continues to be used globally (Fig. 33-5).

Kalke and Lillehei developed the first rigid bileaflet valve, but it had very limited clinical use. In 1977, the St. Jude Medical (SJM) prosthesis was developed and implanted by Nicoloff and associates (Fig. 33-6).[3,9] Over the following decades, the dramatic step of a bileaflet prosthesis nearly obviated the use of all other kinds of mechanical prosthetic valves in the United States and to a large extent elsewhere. The SJM valve demonstrated low aortic gradients, minimal aortic insufficiency, and low rates of thromboembolism (TE) (Fig. 33-7).[9–11] Anticoagulation continued to be necessary but to a lesser extent than with previous design models.[12] Because of the low-profile design and lesser need for

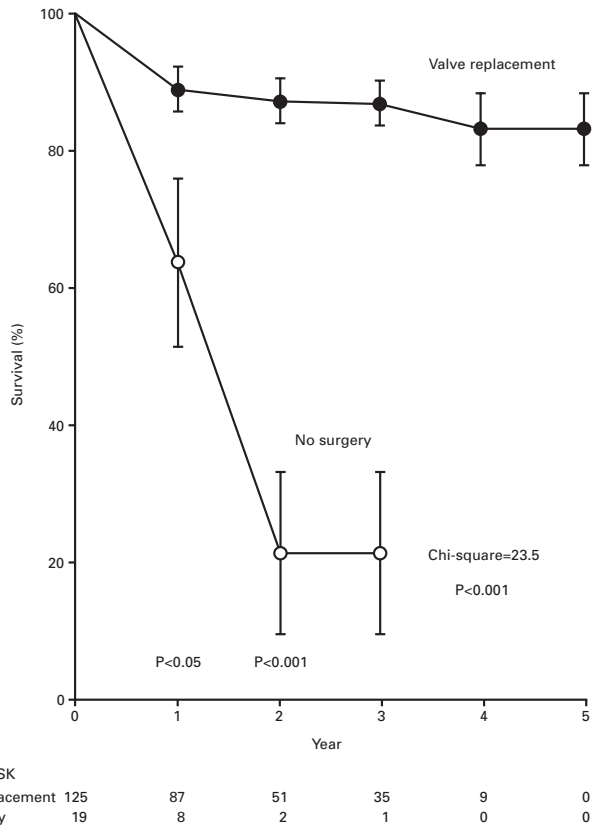

Figure 33-1. Survival of patients having aortic valve replacement compared to those not having valve replacement. (*Reproduced with permission from Carabello.*[1])

orientation, surgical implant was further simplified. Following the introduction of the SJM valve, several other third-generation models of bileaflet prostheses were introduced, including the Sulzer CarboMedics valve (Fig. 33-8), the ATS Medical prosthesis (Fig. 33-9), and the On-X prosthesis (Fig. 33-10). Since the introduction of the bileaflet valve, over 2 million implants on a global basis have been accomplished and extensive literature has developed. Surgeons have become more confident in earlier aortic valve replacement and guidelines for anticoagulation necessary for all mechanical valves have been developed for each generation of prosthesis at progressively decreasing target levels.[12]

Figure 33-2. Prototype model of a ball and cage valve, an early Starr-Edwards model.

Over the past 25 years, design and configurational changes have been made in bileaflet prostheses. The ATS Medical valve changed the "rabbit ears" pivot style of other bileaflet prostheses, incorporating a convex or open-pivot design allowing more complete washing of the moving parts

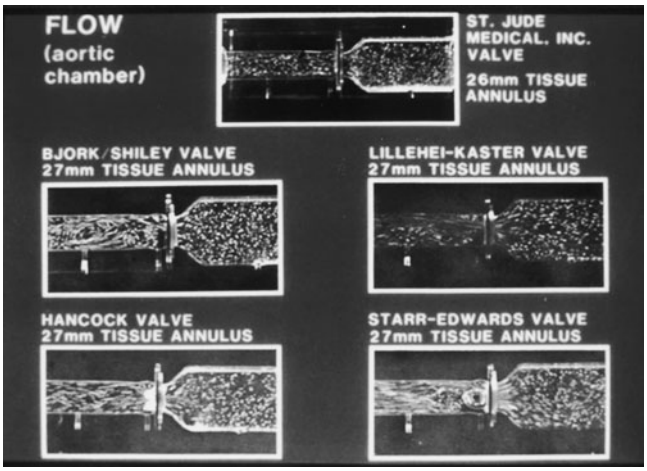

Figure 33-3. Prosthetic valve flow patterns utilizing the Weiting CBA-77-03 pulse duplicator with high-speed photography and resin particles. Note the laminar flow with the bileaflet aortic valve as opposed to other clinically available prostheses and the flow similarity between the bileaflet valve and the tissue valve in the lower left corner. Tilting disk valves show directional flow, stasis at the minor flow orifice, and eddy current formation distally. The ball valve demonstrates stasis beyond the ball and eddy current formation around the ball itself. Note that the ball is obstructive to outflow, as is the proximity of the ball cage to the walls of the outflow chamber. (*Reproduced with permission from Emery et al.*[10])

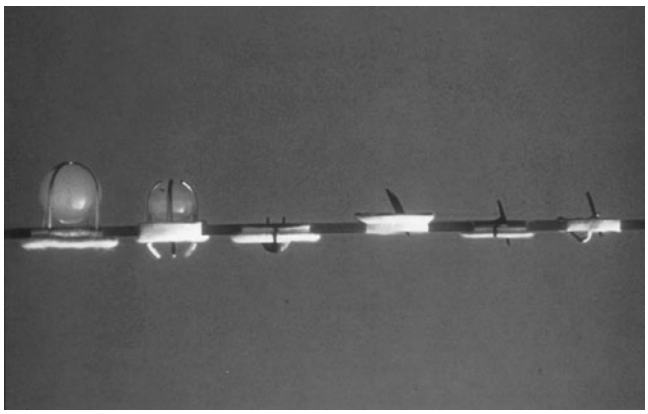

Figure 33-4. Low-profile prostheses simplify the surgical implant. The lowest profile is that of the bileaflet valve, and orientation of the leaflets is most commonly not necessary, as compared to tilting disc prostheses, for which the major flow orifice should be directed along the greater curvature of the aorta.

of the valve and possibly a quieter valve closing.[13,14] The sewing ring of the SJM valve has changed (SJM HP) to allow a larger valve size implantation for any given tissue annulus, as has ATS Medical with its AP design. The sewing ring of the Sulzer CarboMedics valve has been modified such that this valve is implanted in a supravalvular position (top hat model). The On-X valve incorporates advanced pyrolytic carbon technology using a purer, more flexible coating to allow flanging of the inflow portion of the valve housing, mimicking the normal flow pattern.

The most recent development in bileaflet valve design was the introduction of the SJM Regent valve (Fig. 33-11). This valve model not only modified the sewing ring, but also redefined the external profile in a nonintrinsic structural portion of the valve, increasing the effective flow orifice area.

Figure 33-5. The Medtronic Hall valve.

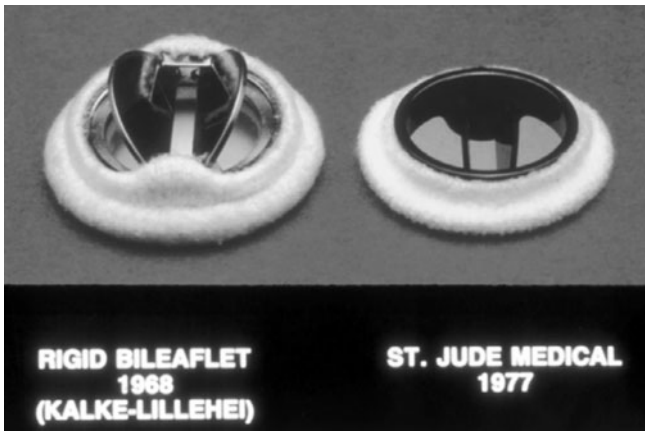

Figure 33-6. The original Kalke-Lillehei bileaflet valve as compared to the St. Jude Medical valve introduced nearly a decade later.

Thus, a larger prosthesis could be implanted for any given tissue annulus diameter. This was the first mechanical prosthesis to demonstrate left ventricular mass regression across all valve sizes.[15,16] The Regent valve is seated supra-annular with only the pivot guards protruding into the aortic annulus.[17]

PATIENT SELECTION

As with any medical therapy, AVR with a mechanical prosthesis is not indicated for all patients. Several prospective randomized studies have shown no difference in survival in patients having biologic or mechanical valve prostheses or among mechanical prostheses per se.[18–22] However, follow-up was limited. Conversely, in other nonrandomized studies of patients followed over longer time frames, freedom from all valve-related events and from reoperation were improved in patients with mechanical valve prostheses as compared to patients with biologic prostheses.[8,23]

While the advantages of large effective flow orifice and durability with a mechanical valve are paramount, the

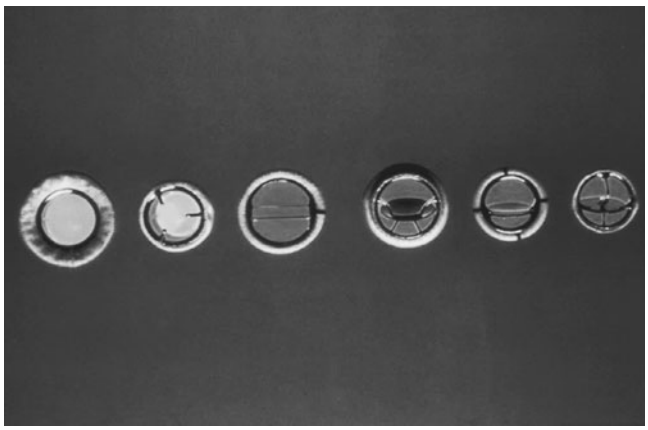

Figure 33-7. The increased flow orifice of the bileaflet valve is clearly shown as compared to ball valves and tilting disc valves available at the time of introduction of the bileaflet bioprosthesis.

Figure 33-8. CarboMedics Top Hat valve.

confounding effects resulting from the necessity for anticoagulation continue. Patients that are transient, noncompliant, or incapable of managing medications are not good candidates for long-term chronic anticoagulation, nor are those with dangerous lifestyles or hobbies.[24] Patients with higher levels of education, and those from geographic areas with a sophisticated medical infrastructure and a static population have better compliance with necessary medication and anticoagulant monitoring.[25]

A mechanical valve prosthesis is recommended to patients having second valve reoperations regardless of the nature of the first procedure, as re-reoperative risks are substantial.[26,27] Some studies report low mortality for reoperation of patients with failed biologic valves, but failures can occur abruptly, creating more risk.[28] Reoperative risk is also higher in those patients having combined procedures[26,29] or after prior coronary bypass.

Many surgeons have opted for an age of >70 years as the indication for bioprosthetic AVR, based on data by Akins.[26] In patients younger than 60 years of age, most would opt for a mechanical prosthesis based on prosthesis durability.[30]

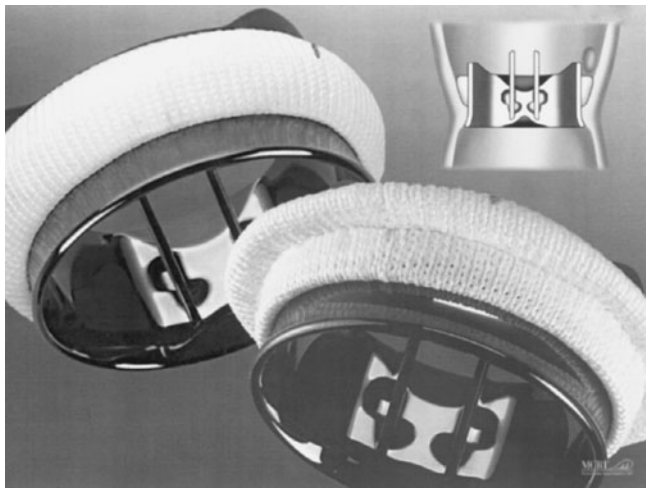

Figure 33-10. On-X valve. Note the flange of the inflow portion of the valve housing which seats in the left ventricular outflow tract.

In the decade between 60 and 70 years of age, other factors have to be taken into account.[31,32]

SURGICAL TECHNIQUES

Implantation of mechanical valve prostheses has been previously described and is straightforward.[11] Historically, high-profile aortic valve prostheses can be difficult to implant, particularly in small aortic roots. In such cases, a hockey-stick aortotomy is used to "unroll" the aorta and expose the annulus. While the implantation of low-profile bileaflet prostheses is simpler, problems can still arise in the small aortic root. If a tilting disc prosthesis is utilized, orienting the major flow orifice toward the greater curve of the aorta is necessary. Because bileaflet prostheses are the most commonly utilized, the surgical technique for implantation of these devices is described: A midline incision and sternotomy

Figure 33-9. ATS Medical valve. Note the open pivot design maintaining leaflet insertion.

Figure 33-11. St. Jude Medical Regent valve.

Figure 33-12. A transverse aortotomy has been made above the level of the sinotubular ridge. The diseased valve can readily be visualized and excised in toto.

is made and a pericardial well created. Alternatively, a right anterior thoracotomy approach with femoral cannulation has been reported. A partial sternotomy is also an alternative in thin patients, creating a sternal "T" at the fourth interspace. This alternative technique is particularly amenable to the implantation of low-profile aortic valve prostheses. The patient is cannulated via the aorta and a single atrial venous cannula. Most commonly, retrograde cardioplegic solution is utilized and a left ventricular vent is placed via the right superior pulmonary vein to maintain a dry operative field. After cross-clamping of the aorta, a transverse aortotomy is made approximately 1 cm above the take off of the right coronary artery, slightly above the level of the sinotubular ridge (Fig. 33-12). The incision is extended three-quarters of the way around the aorta, leaving the posterior one-quarter of the aorta intact allowing excellent visualization of the

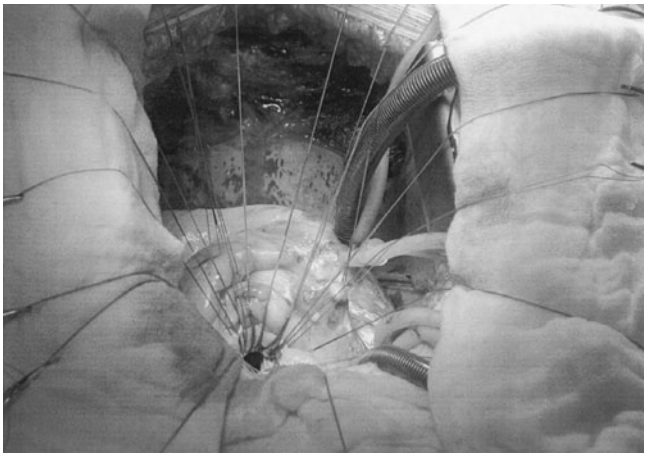

Figure 33-13. The annulus has been encircled with multiple interrupted pledgeted mattress sutures of 2-0 braided suture. The annulus can be readily visualized and all calcification has been extensively débrided.

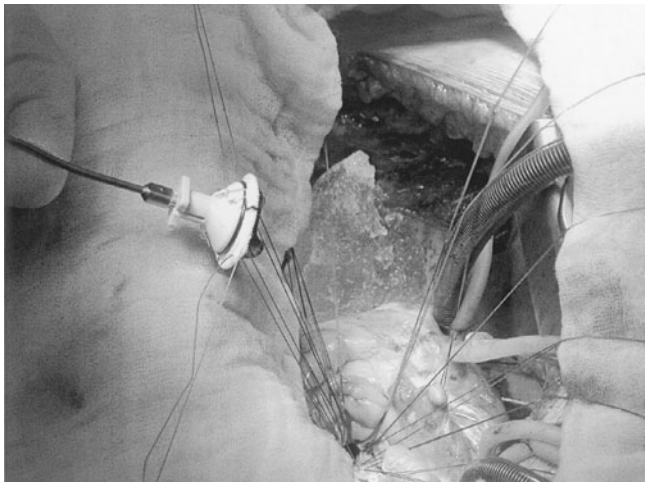

Figure 33-14. The pivot guard sutures have been placed aligning the pivot guards with the right and the left coronary artery.

native aortic valve and annulus. The leaflets of the aortic valve are excised to the level of the annulus and the annulus is thoroughly débrided of any calcium. Extensive de-calcification will minimize the risk of paravalvular leak, particularly in newer-generation prostheses with thinner sewing rings, and allows for better seating of the valve prosthesis. Braided 2-0 sutures with pledgets are utilized. Beginning at the noncoronary commissure, the annulus is encircled with interrupted mattress sutures (Fig. 33-13) extending from the aortic to the ventricular surface (everting). Alternatively, multiple single interrupted sutures may be placed. After placement, the suture bundles are divided into two equal portions and two individual sutures placed into the sewing ring at the level of the pivot guards, orienting the pivot guard toward the ostia of the left and right coronary artery (Fig. 33-14). Next, each half of the suture bundles are implanted in the sewing ring and the prosthesis seated (Figs. 33-15 and 33-16).

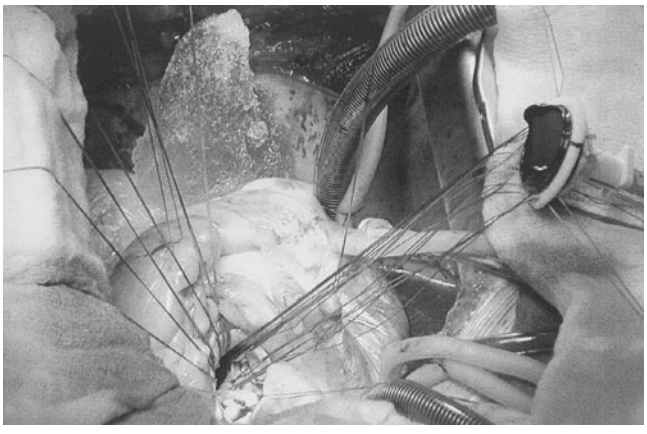

Figure 33-15. The first half of the remaining suture bundles has been passed through the sewing ring of the valve. The valve has been moved to the opposite side of the patient and the remaining suture bundle is to be placed.

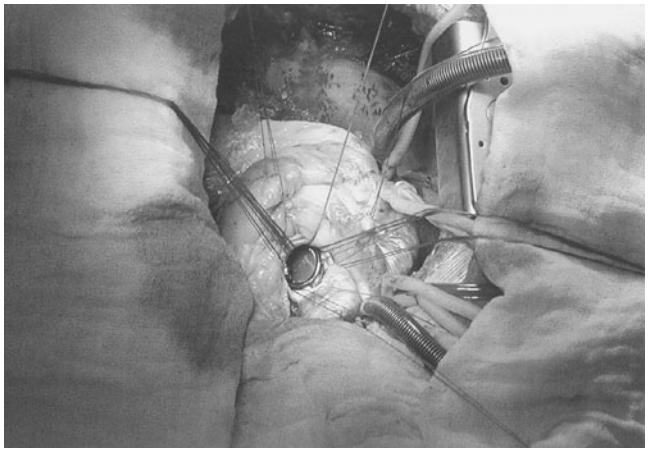

Figure 33-16. All sutures have been passed through the sewing ring and the valve is lowered to the aortic annulus and seated appropriately by placing gentle leverage on the valve sewing ring and traction on the suture bundles.

The pivot guard sutures are tied first followed by the sutures beginning at the left coronary cusp extending to the mid-portion of the right coronary cusp. Lastly, the sutures of the noncoronary cusp are secured, seating the valve appropriately. In a small aortic root, should a valve not be able to be seated, paravalvular leak can be prevented if the unseated area of the valve is in the noncoronary cusp. External aortic sutures can be placed from outside the aorta to the valve sewing ring, securing the prosthesis and preventing regurgitation. Because of the low-profile nature of the leaflets, opening and closing can still occur unimpeded. Leaflet motion should always be checked and the surgeon must be assured that the coronary arteries are not obstructed. The aortotomy is closed with a double layer of polypropylene suture consisting of an underlying mattress suture and a more superficial over-and-over suture. The patient is placed in the Trendelenburg position and the heart filled with blood and cardioplegic solution, vented, and the cross-clamp removed. After resuscitation and de-airing of the heart, the procedure is completed and the patient transferred to the intensive care unit. On the first postoperative day the chest tubes are removed if output is less than 125 mL in the previous 8 hours. Following the removal of the chest tube, the patient is begun on subcutaneous heparin (5000 U every 8 hours) or low-molecular-weight heparin (1 mg per kg twice a day), and warfarin therapy started. Valve implantation can usually be accomplished in under 40 minutes of aortic cross-clamping and with cardiopulmonary bypass times of approximately 1 hour, allowing limited coagulopathic and homeopathic alterations.

When coronary bypass grafting is indicated, the order of the operation changes. The diseased valve is excised, distal vein or free arterial grafts constructed, the valve is replaced, and the aortotomy closed. Proximal anastomoses are then completed, with one left untied for de-airing. The distal anastomoses of pedicled grafts (internal maxillary artery, IMA) are then completed. De-airing is accomplished through the untied proximal anastomosis.

ANTICOAGULATION

The durability and function of mechanical valve prostheses, particularly those of the modern generation, is unquestioned.[23,30,33–36] It is the process of anticoagulation that is key and drives long-term success. International Normalized Ratio (INR) is the standard to which anticoagulation levels should be targeted.[24,37] Anticoagulation is begun slowly following removal of the chest tubes, as the danger of overshooting target INR to dangerous levels is common.[38] Current data on anticoagulant regimens indicate that a one-size-fits-all recipe is inadequate to obtain excellent long-term results.[25] Horstkotte noted that complications occur during fluctuations in the INR, and less often during steady-state levels, be they high or low.[39] When levels of INR increase, bleeding episodes become more common, and when levels of INR decrease, thromboembolic episodes become more common, both on the slope of the change. These events are opposite ends of the continuum of anticoagulation-related complications. The presence of a mechanical valve prosthesis is also not the only risk factor for TE.[25,40] Traditional risk factors for TE listed in Table 33-1 predispose patients to thromboembolic episodes, and as such higher therapeutic INRs are warranted. Similarly, as shown in Table 33-2, nontraditional risk factors for thromboembolism will also predispose patients to embolic events.[25,40] Butchart has noted that the more of these risk factors patients have, the greater the incidence of events and the greater the need for a higher target INR (Fig. 33-17).[25] Thus, it is imperative in the modern era that patient risk factors be taken into account and the INR individualized for a given patient. Recommendations for INR target levels in our practice are shown in Table 33-3. These levels are more liberal than those offered by the American College of Cardiology/American Heart Association (ACC/AHA) and the American College of Chest Physicians (ACCP) guidelines, but more conservative than those recommended by the European self-anticoagulation trials.[41–43] These later reports are especially

Table 33–1.

Traditional Risk Factors for Thromboembolism

• Atrial fibrillation
• Increased left ventricular cavity size
• Regional wall motion abnormality
• Depressed ejection fraction
• Hypercoagulability
• Increased age

Table 33–2.

Nontraditional Risk Factors for Thromboembolism

• Cancer
• Systemic infection
• Diabetes
• Prior event
• IgA against Chlamydia pneumoniae (CP)
• Eosinophilia
• Hypertension

relevant, because they demonstrate that a lower INR is consistent with a lower incidence of TE if patients are maintained in the therapeutic target range.[41,44] Patients with home testing were maintained in the therapeutic range a substantially greater percentage of the time than those whose status was monitored at anticoagulation clinics.[41,44] Starting self-management early after mechanical valve replacement further reduced valve-related events.[38] In the United States, home testing has not become commonplace or popular. However, home testing could certainly be expected to lower the incidence of valve-related thromboembolic and bleeding events. It has recently been approved for reimbursement for weekly testing in patients with a mechanical valve prosthesis or atrial fibrillation.

A recent report of patients followed over 25 years noted that approximately 40% of the bleeding episodes occurred in the first year following surgery. It is thus important during this initial postoperative time frame when the patient's anticoagulant levels are more likely to fluctuate that INR be measured more frequently.[30] In the early postoperative period, INR can occasionally jump to supratherapeutic levels and result in significant bleeding events. This is an

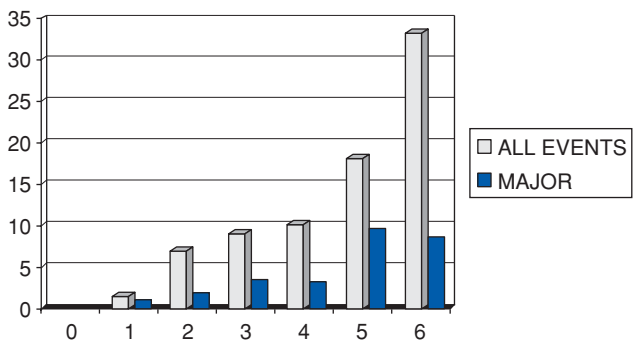

Figure 33-17. The correlation of number of risk factors to thromboembolic events. (*Reproduced with permission from Butchart et al.*[25])

Table 33–3.

Target INR Recommendations

1. Normal ejection fraction and cavity size, NSR: INR 1.82.0, ASA
2. Any single factor: INR 2.0–2.5, ASA
3. Multiple factors or atrial fibrillation: INR 2.5–3.5
4. ? Antiplatelet only

ASA = aspirin; INR = International Normalized Ratio; NSR = normal sinus rhythm.

independent risk factor for mortality at 60 days.[45] Furthermore, the most important independent predictor of reduced survival is anticoagulant variability.[24] We and others therefore recommend in the early postoperative period that one proceed slowly to bring the INR to target levels while the patient is under the protection of subcutaneous enoxaparin (100 IU/kg twice a day) or heparin (5000 U every 8 hours) until the INR is therapeutic.[12,30,46,47]

The addition of aspirin to a warfarin regimen can be expected to result in a lower incidence of TE at any given therapeutic INR with a low probability for bleeding events and so is recommended.[48,49]

An educational program to teach patients how to manage their anticoagulation is an important part of the overall operative process. Patients should be instructed on the influence of alcohol and diet on anticoagulant levels, the need for regular dosing, and the potential impact of travel and gastrointestinal illnesses on fluctuations in anticoagulant levels. Warfarin is well known to be high-risk, as is insulin, yet both drugs can be managed with proper compliance and education so that the impact on lifestyle and quality of life is minimal.[7,50] Patient age does not appear to be a risk factor for anticoagulation[50–53] as long as there are no specific contraindications to anticoagulation. The presence of a mechanical valve is not a risk factor for long-term neurocognitive dysfunction.[54] The importance of regular testing cannot be overstated.

Newer antithrombin agents may obviate several of the issues discussed above. These agents are showing promise in the treatment of atrial fibrillation, with a lower incidence of embolism and bleeding complications. The drugs are expensive, require multiple administrations per day, and may cause hepatic dysfunction, yet they do not require blood testing or physician visits to maintain the therapeutic effect.[55] Their application to mechanical valve prostheses is as yet unknown.

RESULTS

Outcomes from aortic valve replacement with mechanical valve prostheses vary among reports depending on the patient population. Patients with higher risk factors for TE and those

with risk factors for anticoagulation will have a higher incidence of valve-related events, making meta-analyses less meaningful.[56] Older patients are at higher risk for valve-related events, particularly thromboembolic episodes, because of the greater number of risk factors that accumulate with aging.[25] The incidence of valve-related events is also determined by the intensity with which the investigators follow their patients. A higher incidence of early hemorrhagic events may also be diluted over the longer periods of follow-up.[57] Compliance is key to good long-term outcomes. Traditional and nontraditional risk factors for embolism and risk factors for anticoagulation and valve-related events must be considered.[25,40] Several trials have indicated no significant differences in events among various mechanical prostheses, but follow-up was short.[19,21,23,58] There are, however, certain standards within which one should expect a mechanical valve to perform, and within which the medical decisions for anticoagulation must be made. The majority of valve-related morbidity is related to TE and anticoagulation-related hemorrhage.[36] The sections below deal with specific valve-related complications and acceptable current incidence.

Valve Type

Freedom from all valve-related events over the long term is shown in Fig. 33-18. In the early follow-up period, anticoagulation-related hemorrhage is the most common untoward event for mechanical valve prostheses. Thus, over the first 10 years of follow-up there is a higher incidence of valve-related events in patients with mechanical prostheses as opposed to those with biologic valves.[23] However, over the subsequent period of 10 to 20 years, the incidence of biologic valve failure changes this ratio such that the valve-related complications of biologic prostheses become more common than those with mechanical valve prostheses. In a series of aortic reoperations, Potter has noted that the time to biologic valve failure was only 7.6 years.[28] This failure rate will increase over time.[23,59] Overall, freedom from valve-related events is more strongly influenced by pre-existing comorbidities than the presence of a mechanical prosthesis per se.[23,25,30,36]

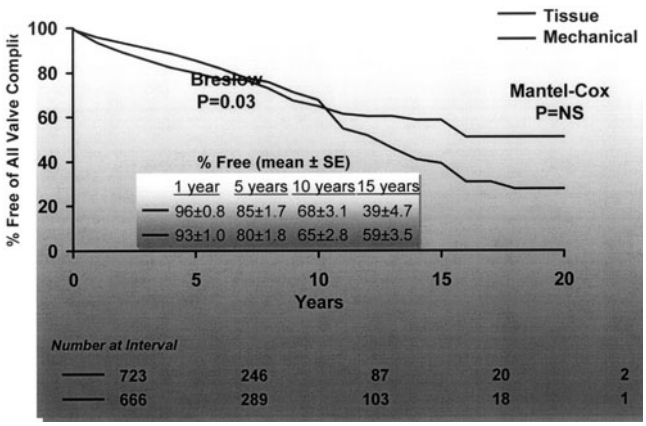

Figure 33-18. Freedom from all valve-related complications over 20 years. Note that in the first 10-year period of follow-up, complications related to mechanical valves exceeded those of tissue valves. The lines cross at approximately 10 years, and over the following period, complications from tissue valves were more frequent than those from mechanical valves. (*Reproduced with permission from Khan et al.*[23])

Anticoagulant-Related Hemorrhage

Anticoagulation -related hemorrhage (ARH) is the most common valve-related event. The more intense the anticoagulation regimen, the higher the incidence of valve-related hemorrhage. Most commonly ARH will occur during fluctuations in INR values commonly related to changes in warfarin dosing or medical or drug interactions.[39] The most common site for ARH is the gastrointestinal tract, the second being the central nervous system.[30] ARH also accounts for the highest incidence of patient mortality for valve-related events. Acceptable ARH rates range from 1.0 to 2.5% per patient-year in long-term reports.[8,23,30,33–36] These long-term reports dilute the short-term impact, as ARH risks are higher early after valve replacement.[30,36,57] With individualized and home monitored anticoagulant regimens, both related events TE and ARH are diminished.[41] Freedom from anticoagulation at 10 and 20 years are 75 to 80% and 65 to 70%, respectively. Importantly, one long-term study noted that nearly 40% of all ARH that occurred over a 25-year follow-up period occurred during the first 6 months of anticoagulation (Fig. 33-19), indicating that a slow increase to therapeutic levels, coupled with close follow-up during this early period is warranted.[30,45,46] Results of the European self-anticoagulation study indicate that a lower INR target is appropriate if home testing is initiated, as a greater time is spent in the therapeutic range.[41] Mortality more commonly occurs in relation to bleeding events than in relation to thromboembolic events.[30]

Thromboembolism

Thromboembolic episodes are the second most common valve-related event and are the reason that chronic anticoagulation is warranted. Khan and associates reported in a large series of patients that the incidence of thromboembolic events between bioprostheses and mechanical prostheses are the same (Fig. 33-20), but the mechanical valve patients are on warfarin.[23] Acceptable thromboembolic rates range between 0.8 and 2.3% per patient-year.[8,23,30,33–36,60] Approximately one-half of these events are neurologic events, 40% are transient, and 10% peripheral.[30] Freedom from thromboembolic events at 10 and 20 years is approximately 80 to 85% and 65 to 70%, respectively.

Thromboembolism is a continuous risk factor that is present throughout the life of the mechanical valve prosthesis. As patients age, risk factors for TE increase, so one must be on guard to maintain therapeutic anticoagulant levels. Changes in the target INR may be necessary as individual risks increase.

Valve Thrombosis

Valve thrombosis in the aortic position is an unusual event that occurs late after valve replacement and is most commonly due to inadequate anticoagulation or noncompliance.[61,62] In bileaflet valves, thrombus formation impinging valve function occurs at the pivot guards and in the crevices of the valve. Only one bileaflet design does not have convexities into which the leaflets fit.[63] In tilting disc valves, thrombus is most common at the minor flow orifice. The incidence of thrombosis is approximately <.3% per patient-year and freedom from valve thrombosis at 20 years is >97%.[8,23,30,33–36]

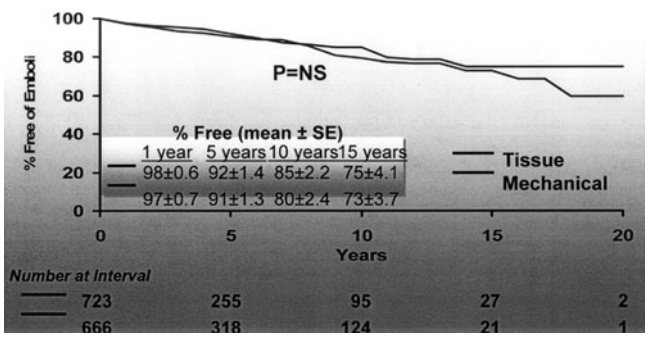

Figure 33-20. Freedom from thromboembolism in patients followed for 20 years. Note that there is no difference in the incidence of thromboembolic events between mechanical and tissue valves. (*Reproduced with permission from Khan et al.*[23])

Prosthetic Valve Endocarditis

Prosthetic valve endocarditis is also a rare event in the modern era with prophylactic antibiotics. Approximately 60% of events occur early and are associated with staphylococci. The mortality for this event is high. The remainder appear late (>60 days). Prosthetic valve endocarditis is also a continuous variable, and patients must be cautioned to take prophylactic antibiotics for any invasive procedure. Freedom from endocarditis with mechanical valve prostheses is 97 to 98% at 20 to 25 years.[30,36]

Paravalvular Leak

Paravalvular leak is an operative complication and is related to operative technique and to endocarditis. With annular decalcification and closely placed sutures, these events can be minimized. The Silzone experience showed an increased incidence of paravalvular leak wherein the silver impregnated in the sewing ring not only impeded bacterial growth, but also healing of the annular ring, doubling the accepted rate of this complication.[64] The Silzone coated sewing ring was removed from the market. There may be an anatomic predisposition to paravalvular leak in the area of the annulus extending from the right and noncoronary commissure, one-third the distance along the right coronary cusp, and two-thirds the distance to the noncoronary cusp, due to intrinsic weakness in this area of the annulus.[65] The acceptable range of paravalvular leak is approximately <.1% per patient-year, with early postoperative occurrence predominating.

Structural Failure

Structural failure of bileaflet aortic prostheses due to wear has not been observed or reported in long-term studies totaling more than 50,000 patient-years of follow-up. This indicates the high structural integrity of these modern aortic devices.[23,30,36] In a single study totaling 21,742 patient-years with 94% complete follow-up, there was no structural failure.[46]

Freedom from Reoperation

The long-term durability of modern mechanical valve prostheses is excellent, and a valve replacement rate of less than 2% over 25 years (Fig. 33-21) can be expected, and re-reoperation after AVR replacement is even more rare.[27] Subvalvular pannus formation is rare with bileaflet valves.[30,36] The most common reasons for prosthetic valve reimplantation are pre- and postoperative endocarditis, paravalvular leak, and valve thrombosis.

SPECIAL CIRCUMSTANCES

Technical Considerations

While the technique of implanting a mechanical valve prosthesis is very straightforward, special circumstances arise. Because of the large size of the valve housing of the St. Jude Medical Regent valve compared to the tissue annulus, entry into the aorta can sometimes be difficult. Occasionally, patients have the smallest diameter of their aortic root at the sinotubular ridge. While the sizer will pass readily through the aortic annulus, seating the Regent valve itself into the annulus can sometimes be difficult and frustrating. It is important to gently rock the valve back and forth through the sinotubular ridge, tilting the valve circumferentially through the narrowest part. Once the valve is below the level of the sinotubular ridge, it will seat readily in the annulus if sizing has been correct. When tying the valve into the annulus, sutures in the pivot guards and the left and right coronary cusps should be first completed. The last sutures ligated are those of the noncoronary cusp for two reasons. It may seem like the Regent valve will not seat because of the large-sized valve housing; however, with gentle persistence seating can be completed as long as sizing has been correct. The Regent valve sits supra-annular and only the pivot guards lie inside the annulus (Fig. 33-22). Therefore one should leave the last sutures to be tied in the mid-part of the noncoronary cusp with the valve oriented so the leaflets are parallel to the ventricular septum.[66] With proper annular decalcification and flexibility of the annulus, we have not seen a Regent valve that has not been able to be seated properly.

Figure 33-21. Freedom from reoperations in patients having mechanical valve replacement followed over 25 years. Note that the rate of reoperation in patients with aortic valve replacement is less than 2% in over 21,000 patient-years of follow-up. (*Reproduced with permission from Emery et al.*[30])

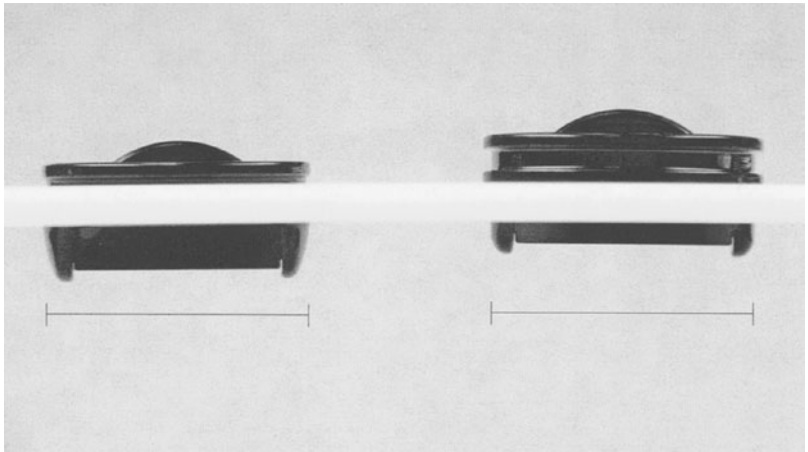

Figure 33-22. The St. Jude Medical Regent valve on the right as compared to the St. Jude Medical HP valve on the left. With the Regent valve only the pivot guards insert into the annulus, allowing a larger valve housing for any given tissue annulus diameter. (*Reproduced with permission from Emery et al.*[30])

Similarly, when using the On-X valve one has to be sure that the flare of the valve inflow is seated properly in the left ventricular outflow tract. Gentle manipulation and patience may be necessary. Walther and colleagues note that exact sizing requires some experience.[20]

If an oversized bileaflet valve has been implanted purposefully in a small aortic root, the valve can be tilted and will still function without coronary obstruction as long as the highest portion of the valve is in the noncoronary cusp. Pledgeted sutures placed from outside the aorta through the sewing ring of the valve can prevent paravalvular leak, and opening and closing can still occur due to the low-profile nature of the prosthetic valve. In our review of nearly 3000 bileaflet aortic valve replacements, no annular enlarging procedures were completed.[46]

Patient-Prosthesis Mismatch

Patient-prosthesis mismatch (PPM) is a concept first described by Rahimtoola and popularized by Pibarot and Dumesnil.[67,68] Unfortunately, views are varied on the importance of PPM.[69–72] This is due to the fact that virtually all contributions to the literature study mixtures of mechanical and biologic prostheses and varying types of each. In a 25-year follow-up of patients with a single model mechanical valve prosthesis, no difference was found in overall valve-related mortality for patients who had severe PPM, moderate PPM, or insignificant PPM according the criteria described by Blais and associates.[71] This similarity in long-term survival was sustained whether the effective area was measured by in vitro (internal geometric valve area) or in vivo criteria (echo-calculated valve area) as shown in Figs. 33-23 and 33-24. This study also found no difference in valve-related events, including operative mortality, long-term cumulative mortality, anticoagulant-related hemorrhage, TE, valve thrombosis, paravalvular leak, or diagnosis of congestive heart failure. Follow-up in this study was 94% complete and extended over 13,000 patient-years.[73] Therefore, with bileaflet mechanical valve prostheses, PPM does not appear to be an issue. This study was limited in that it did not address patient age (i.e., younger versus older), patient activity, or ventricular function. Thus, it is likely that PPM is important in patients with small biologic prostheses, because as the valve leaflets stiffen, clinical aortic stenosis becomes prominent early in the postoperative follow-up period, affecting symptoms and survival. If one is, however, concerned about PPM, the indexed effective orifice area can be calculated for any given prosthetic valve and a determination made whether an annular enlarging procedure or a different model prosthesis with a larger effective orifice area is warranted.[74] PPM has been minimized by the new-generation Regent valve and is very rare with this prosthesis.[16,46]

Off Anticoagulation

Anticoagulation is recommended in all patients with mechanical valve prostheses. Limited trials have been undertaken with low-risk patients, but only after a several-month course of systemic anticoagulation. An increased incidence of valve thrombosis but with little increase in the incidence of TE has been reported in patients not taking chronic anticoagulation if antiplatelet agents are utilized.[61,75,76] One study found no significant differences in valve-related events in patients on warfarin as compared to antiplatelet therapy alone, but follow-up was limited.[77] One prospective study is currently ongoing consisting of a randomized trial of antiplatelet therapy versus warfarin after 3 months of formal anticoagulation, but the results are not yet available.[78] Certainly one can expect that highly selected patients with mechanical valve prostheses will do well off warfarin on antiplatelet agents, but this is unproven.[17,79]

When anticoagulation requires reversal electively, as for scheduled surgery, the INR is allowed to slowly drift toward normal over 5 days and the patient is admitted for intravenous heparin therapy 24 hours prior to the procedure. Anticoagulation is restarted after the procedure with antiplatelet therapy, and subcutaneous heparin with

There is no difference in the survival curves after implant of a bileaflet prosthesis. The numbers at the bottom of the graph represent patients available for follow-up.

warfarin is restarted on postoperative day one. Abrupt reversal of INR in patients who have bleeding episodes may be warranted, but carries increased risk of TE. Fresh frozen plasma will gently reverse INR when necessary, but it is best to avoid the use of vitamin K. Frequent INR checks are warranted.

Following ARH episodes, when feasible, because of the high incidence of recurrent bleeding, anticoagulant therapy is withheld up to 2 weeks or until the source of the bleeding has been identified and definitively treated, using antiplatelet agents only.[76] For those patients in whom anticoagulant therapy cannot be restarted, antiplatelet therapy is warranted, but the patient should be informed of an increased incidence of thromboembolism to approximately 4% per patient-year and that of valve thrombosis to 2% per patient-year with bileaflet valves.[61,75,76,80]

Mechanical Valve Replacement in the Younger Patient

A major deterrent to mechanical valve replacement in the younger patient is the impact of long-term anticoagulation. Mechanical valves are, however, more ideal for younger patients due to their excellent durability characteristics. Most importantly, younger patients (i.e., patients under the age of 50 years) are a low-risk subset for valve-related events. These individuals have very few risk factors for TE, and thus anticoagulation can be run at the lower end of the therapeutic target range, decreasing the incidence of anticoagulant-related hemorrhage without altering the incidence of TE. In fact, many infants and children have been managed with only aspirin with quite good long-term results.[81] While this is not recommended in patients older than infancy, it is a feasible alternative. A recent study in patients under 50 years of age followed 254 patients for up to 20 years and found an exceedingly low rate of valve-related events (Table 33-4), an exceptional long-term overall survival of nearly 88%, and event-free survival probability of 92% at 19 years.[82]

The longest surviving patient in a series of bileaflet valve replacement patients is currently over 27 years from his procedure, which was completed in his early forties and has been without complication.[30] The low incidence of valve-related complications in younger patients should drive a discussion of the alternative prostheses available for such individuals, especially with new aggressive antiplatelet drugs. Operative mortality increases with each succeeding procedure; therefore discussion of durability with patients becomes mandatory.[26–28]

Follow-Up

With the use of any valve prosthesis, long-term follow-up is a key factor. Ten years is certainly not long enough to ascertain the true durability of a prosthesis. Grunkemeier reviewed several types of biologic prostheses and found that the 10-year durability was excellent, but between 12 and 18 years durability fell off and prosthetic replacement was necessary.[59] These data were echoed by Khan and colleagues.[23] Valve-related failure of all biologic alternatives including stented prosthetic replacements, stentless prostheses, and homograft and autograft replacements have all shown long-term durability to be less than that of modern mechanical valve prostheses.

Even with some mechanical valve prostheses, durability after 10 years has not been adequate. In recommending mechanical valve replacement, one should be assured to have clinically available data on the prostheses that extend beyond 15 years.

In conclusion, with proper selection of patients for mechanical valve replacement, one can expect excellent long-term results, long-term survival, and a low incidence of valve-related complications. Current indications for recommending aortic valve replacement with mechanical prostheses are shown in Table 33-5.

Table 33–4.

Valve-Related Events with the St. Jude Medical Prosthetic Valve

Event	No. of events	Percent per patient-year	No. deaths
Endocarditis	3	0.15	0
Paravalvular leak	6	0.30	2
Embolism	6	0.30	0
Valve thrombosis	23	0.10	0
Bleeding	6	0.10	2
Structural failure	0	0	0

Source: Data from Emery et al.[82]

Table 33–5.

Indications for Mechanical Valve Replacement

- High probability for anticoagulant use
- Need for chronic anticoagulation (any age)
- Preferences of patient
- Surgical risk for reoperation
- Age <60 years
- Age 60–70 years with patient discussion
- Reoperations
- Good medical infrastructure

CHAPTER 34

Bioprosthetic Aortic Valve Replacement: Stented Pericardial and Porcine Valves

Nimesh D. Desai • George T. Christakis

This chapter provides an overview of aortic valve replacement (AVR) with stented bioprostheses. The indications for aortic valve surgery are reviewed with an emphasis on current evidence-based guidelines and currently available stented aortic bioprostheses are described. Clinical and physiologic outcomes of aortic valve surgery are critically examined to create a rational basis for prosthesis selection.

NATURAL HISTORY AND INDICATIONS FOR OPERATION

Aortic Stenosis

Natural history

Aortic stenosis (AS) may be caused by degenerative calcification, congenital malformations, or rheumatic fever. It may also be found in association with systemic diseases such as Paget's disease of bone and end-stage renal disease. Congenital malformations include unicommisural, and more commonly, bicuspid valves. Detailed descriptions of these pathologies are presented elsewhere in this volume. Degenerative calcification is common in the elderly population and although limited calcific deposits often do not have any clinical significance, severe degenerative calcification is the most common pathology among patients undergoing AVR. Regardless of the initial pathology, there is a progressive reduction of orifice cross-sectional area caused by calcification of the cusps that resembles atherosclerotic processes that include inflammation and lipid accumulation.[1,2] Commissural fusion is typically seen in rheumatic AS but not in degenerative calcification of tricuspid or bicuspid valves. The normal human aortic valve has an area between 3.0 and 4.0 cm^2. Mild, moderate, and severe AS are defined as aortic valve areas (AVAs) greater than 1.5 cm^2, 1.0 to 1.5 cm^2, and less than 1.0 cm^2, respectively.[3] This corresponds to a mean gradient of 25 mm Hg and peak jet velocity of less than 3.0 m/s in mild cases, a mean gradient of 25 to 40 mm Hg and peak jet velocity of 3.0 to 4.0 m/s in moderate cases, or a mean gradient of greater than 40 mm Hg and peak jet velocity of greater than 4.0 m/s in severe cases. In the presence of normal cardiac output, transvalvular gradient is usually greater than 50 mm Hg when the AVA is less than 1.0 cm^2.[4] There is a rapid increase in transvalvular gradient when the AVA is less than 0.8 to 1.0 cm^2.

Exposure to elevated intracavitary pressures causes increased wall stress leading to parallel replication of sarcomeres and concentric hypertrophy.[5,6] These mechanisms compensate for the obstruction to flow created by the reduced orifice area of the aortic valve in order to maintain normal cardiac output. With progressive hypertrophy, the compliance of the ventricle decreases and end-diastolic pressure rises.[7,8] In this situation, the contribution of atrial contraction to preload becomes more significant and loss of sinus rhythm may lead to rapid progression of symptoms.[6]

Symptomatic patients

Hemodynamically significant AS is initially counteracted by left ventricular hypertrophy (LVH). Progression of outflow obstruction and ventricular hypertrophy lead to the cardinal symptoms of AS: angina, syncope, and congestive heart failure (CHF). The average AVA is 0.6 to 0.8 cm^2 at the onset of symptoms.[6] Classic natural history studies have shown that the average life expectancy in patients with hemodynamically significant AS is 4 years if anginal symptoms are present, 3 years if they have experienced syncope, and 2 years with the onset of CHF.[9] Symptomatic patients should therefore undergo AVR in a timely fashion.[10] Excessive waiting periods for AVR in symptomatic patients are associated with increased mortality and the rate of sudden death is >10% per year in these symptomatic patients. Once a patient is symptomatic, average

survival is less than 3 years.[11–14] The typical modes of death in untreated severe AS are sudden death from ventricular arrhythmia or CHF.

Asymptomatic patients

Managing asymptomatic patients with hemodynamically significant AS can be a challenging problem, as there is often a prolonged latent period before symptoms emerge. During the latent period, there is a progression of concentric LVH as the ventricle adapts to elevated chamber pressures. Studies by Otto and colleagues have shown that up to 7% of asymptomatic patients experience death or aortic valve surgery 1 year after diagnosis.[15] After 5 years, the incidence of death or aortic valve surgery increases to 38%. The average decrease in AVA is 0.12 cm^2 per year, while the average increase in transvalvular pressure is often 10 to 15 mm Hg per year.[16] Sudden death is quite uncommon in the asymptomatic patient and occurs at a rate of 0.4% per year. The vast majority of patients who experience sudden death will become symptomatic in the months immediately prior to the fatal event.[17,18]

There is considerable variation in the rate of disease progression and many patients do not experience any change in gradient for several years. To provide improved guidance on which asymptomatic patients need closer follow-up or early operation, a study by Rosenhek and colleagues identified that asymptomatic patients with an increase in peak velocity jet greater than 0.45 m/s per year on serial echocardiography were substantially more likely to need operation than patients with lesser changes in jet velocity.[19]

Low-gradient severe aortic stenosis

The significance of AS is often unclear in patients with very poor ventricular function (ejection fraction <20%) who have severely stenotic valves but small (<30 mm Hg) transvalvular gradients. The compromised left ventricular function (LVF) in these patients may be caused by afterload mismatch created by the stenotic valve or by intrinsic cardiomyopathy, particularly in the setting of chronic ischemia from diffuse coronary disease. In these patients, measurement of transvalvular gradient and valve area at rest and with positive inotropy (i.e., dobutamine infusion) may distinguish whether cardiomyopathy or true valvular stenosis is the most responsible lesion. Although some patients with a preponderance of cardiomyopathy do not experience significant benefit from valve replacement,[20] a recent study by Pereira and colleagues suggests that in a balanced, propensity matched comparison, patients with poor LVF and severe AS experience a significant survival benefit from valve replacement[21] (Fig. 34-1). Hwang and colleagues, using a multivariate analysis to determine factors that predict poor LVF after AVR for AS, identified that poor preoperative LVF was the most significant predictor, indicating suboptimal outcome in the low-gradient group of patients.[22]

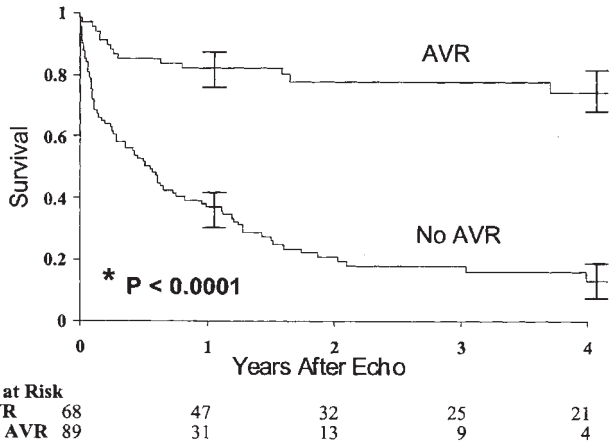

Figure 34-1. Impact of aortic valve replacement on survival in patients with low-gradient aortic stenosis. Survival by Kaplan-Meier analysis among all propensity-matched patients in the aortic valve replacement (AVR) and control (No AVR) groups (p <0.0001). The number of patients at risk during follow-up is shown on the x axis. (*Reproduced with permission from Pereira et al.*[21])

Medical therapy

No known medical therapy has been shown to alter the natural history of AS. Although several small nonrandomized studies have shown a reduction in disease progression with antilipid therapy,[23–25] a recent prospective randomized clinical trial of aggressive antilipid therapy with atorvastatin did not demonstrate decreased rates of disease progression as determined by changes in aortic jet velocity or valve calcification score[26] (Fig. 34-2).

Indications for operation

In 1998, a joint task force of the American College of Cardiology (ACC) and the American Heart Association(AHA) developed evidence-based consensus guidelines for management of valvular heart disease.[27] These were updated in 2006.[28] Their recommendations for AVR in the setting of AS are summarized in Table 34-1. A class I recommendation indicates there is good evidence and general agreement that the treatment is beneficial, useful, and effective. Class IIA recommendation indicates there may be disagreement but the weight of evidence supports the usefulness/efficacy of the treatment in that setting, Class IIB recommendation indicates that the usefulness/efficacy of the treatment is less well established, and class III recommendation indicates that the treatment is either not useful/effective or potentially harmful.

Aortic valve replacement is indicated in all symptomatic patients with severe AS or patients with severe asymptomatic AS who require concomitant coronary bypass, aortic surgery, or other valve replacement. It is our practice to perform AVR on patients with moderate AS requiring concomitant cardiac surgery. We do not routinely perform AVR in patients with mild AS undergoing concomitant cardiac

Available at: http://www.americanheart.org.

surgery unless the aortic valve is heavily calcified and the stenosis likely to rapidly progress. Aortic valve replacement is commonly performed in otherwise asymptomatic patients with severe AS and severe left ventricular dysfunction (LVD), exercise-induced symptoms, significant hypertrophy, or ventricular arrhythmia. Asymptomatic patients with very high transvalvular gradients (>60 mm Hg) or highly stenotic valves (valve area <0.6 cm^2) are at higher risk for progression to symptoms and should have valve replacement prior to significant ventricular decompensation or sudden death.

Aortic Regurgitation

Acute aortic regurgitation

Acute aortic regurgitation (AR) may be caused by acute dilatation of the aortic annulus preventing adequate cusp coaptation or by disruption of the valve cusps themselves. This typically occurs in the setting of acute aortic dissection, infective endocarditis, trauma, active connective tissue disease, aortic cusp prolapse associated with ventricular septal defects (VSDs), aortitis (syphilitic or giant cell), Marfan syndrome, Ehlers-Danlos syndrome, or iatrogenically after aortic balloon valvotomy.[6] The heart cannot readily tolerate acute AR, as the normal left ventricle is unable to compensate for the sudden increase in end-diastolic volume caused by the large regurgitant volume load, thereby overwhelming the Frank-Starling mechanism.[29] A dramatic reduction in forward stroke volume then occurs. If there is poor left ventricular compliance from hypertrophy prior to the onset of acute AR, hemodynamic decompensation is significantly more dramatic.

To compensate for the acute decline in forward stroke volume, tachycardia ensues. Volume overload causes the left ventricular diastolic pressure to acutely rise above left atrial pressure resulting in early closure of the mitral valve.[30] Although early mitral valve closure protects the pulmonary venous circulation from high end-diastolic pressures, rapid progression of pulmonary edema and cardiogenic shock are often unavoidable.

Death is the common endpoint of all etiologies of acute AR. Progressive cardiogenic shock and malignant ventricular arrhythmias are common causes of death. Urgent surgical treatment is warranted for all causes of hemodynamically significant acute AR.

Chronic aortic regurgitation

Chronic AR is caused by either slow enlargement of the aortic root or dysfunction of the valve cusps. Common etiologies include congenital abnormalities, calcific cusp degeneration, rheumatic fever, endocarditis, degenerative aortic dilatation as seen in the elderly, Marfan syndrome, Ehlers-Danlos syndrome, myxomatous proliferation, osteogenesis imperfecta, ankylosing spondylitis, Behçet syndrome, Reiter syndrome, psoriatic arthritis, severe systemic hypertension, and idiopathic aortic root dilatation.[6] The anorectic drugs fenfluramine and dexfenfluramine have been implicated in left- and right-sided valvular disease, including AR.[31,32] Bicuspid aortic valve is the most common congenital abnormality but unicommissural, quadricuspid, and fenestrated valves may also occur.[33]

Chronic AR causes a chronic volume overload of the left ventricle. The volume load leads to progressive chamber enlargement without increasing end-diastolic pressure during the asymptomatic phase of the disease.[34] Progressive chamber enlargement is accompanied by eccentric hypertrophy, with sarcomere replication and elongation of myocytes. The combination of chamber dilatation and hypertrophy leads to a massive increase in left ventricular mass. Initially, the ratio of wall thickness to chamber diameter, ejection fraction (EF), and fractional shortening are all maintained.[35] However, this degenerates into a repetitive cycle of enlarging chamber radius with continually increasing wall stress. This wall stress is compensated by ventricular hypertrophy. Interstitial fibrosis limits the ability of the ventricle to further dilate and this cycle becomes overwhelmed, leading to elevated end-diastolic pressure, left ventricular systolic dysfunction, and CHF.[36] Vasodilator therapy may delay progression of ventricular dysfunction by decreasing afterload and decreasing regurgitant flow. Vasodilator therapy is currently indicated in asymptomatic patients with hypertension; asymptomatic patients with severe AR, ventricular dilatation, and preserved systolic function; and for short-term hemodynamic tailoring prior to operation.[37] This therapy is not recommended in patients with severe AR and LVD, as it does not improve survival but may be used in these patients if they are not considered operable.[38]

Symptomatic chronic aortic regurgitation

The time course from diagnosis of AR to the development of symptoms is highly variable. Since symptoms, such as angina and dyspnea, develop only after significant ventricular decompensation has occurred, surgery is advocated prior to the symptomatic phase of the disease. Symptomatic patients experience >10% mortality per year without surgical management.[38,39]

Asymptomatic chronic aortic regurgitation

Natural history studies of asymptomatic AR show that symptoms, LVD, or both develop in <6% of patients per year.[40] Progression to LVD without symptoms occurs in <4% of patients per year. Sudden death occurs in <0.2% per year.[41] Age, left ventricular end-systolic dimension, rate of change in end-systolic dimension, and rest EF are all independent predictors of progression to symptoms, LVD, or death in asymptomatic patients.[42] Asymptomatic patients with left ventricular systolic dysfunction experience onset of symptoms at a rate exceeding 25% per year.[43]

Indications for operation

In cases of isolated AR, timing of surgery on the asymptomatic patient is predicated on the identification of subtle changes in myocardial function before they become irreversible and negatively affect the patient's long-term prognosis. Unfortunately, such changes are often recognized by current

imaging modalities only after irreversible damage and fibrosis has occurred. Patients with more severe LVD have decreased perioperative and late survival due to irreversible changes to the ventricle including hypertrophy and interstitial fibrosis.[43–45] The decision to operate on such patients is dependent on individual variables since the outcomes are poor with surgery or medical therapy. Advances in imaging such as cardiac magnetic resonance imaging (MRI) may allow identification of candidates for AVR prior to the onset of LVD.[46]

A summary of the revised ACC/AHA Task Force guidelines for AVR for chronic AR is presented in Table 34-2.[28] Aortic valve replacement is indicated in all symptomatic patients with severe AR, regardless of LVF, and in all asymptomatic patients with severe AR with left ventricular ejection fraction (LVEF) <50%. Aortic valve replacement is also recommended in asymptomatic patients with normal LVF but significant left ventricular dilatation (end-diastolic diameter >75 mm or end-systolic diameter >55 mm). Aortic valve replacement is recommended in patients with moderate to severe AR who require concomitant coronary artery bypass surgery (CABS) or ascending aortic surgery.

Asymptomatic patients with severe AR and an enlarged left ventricle with end-systolic diameter <50 mm, and those with end-diastolic dimension >70 mm should have AVR if there is evidence of serial deterioration of ventricular function or exercise intolerance.

CORONARY ANGIOGRAPHY AND AORTIC VALVE REPLACEMENT

Many patients requiring AVR have coexistent coronary artery disease (CAD). In North America, more than one-third of AVR procedures are accompanied with coronary bypass

Table 34–2.

ACC/AHA Recommendations for Aortic Valve Replacement (AVR) in Chronic Severe Aortic Regurgitation (AR)

Indication	Class
1. AVR is indicated for symptomatic patients with severe AR irrespective of left ventricular systolic function	I
2. AVR is indicated for asymptomatic patients with chronic severe AR and left ventricular systolic dysfunction (ejection fraction ≤0.50) at rest	I
3. AVR is indicated for patients with chronic severe AR while undergoing coronary artery bypass graft or surgery on the aorta or other heart valves	I
4. AVR is reasonable for asymptomatic patients with severe AR with normal left ventricular systolic function (ejection fraction >0.50) but with severe left ventricular dilatation (end-diastolic dimension >75 mm or end-systolic dimension >55 mm)*	IIA
5. AVR may be considered in patients with moderate AR while undergoing surgery on the ascending aorta	IIB
6. AVR may be considered in patients with moderate AR while undergoing coronary artery bypass graft surgery	IIB
7. AVR may be considered for asymptomatic patients with severe AR and normal left ventricular systolic function at rest (ejection fraction >0.50) when the degree of left ventricular dilatation exceeds an end-diastolic dimension of 70 mm or end-systolic dimension of 50 mm, when there is evidence of progressive left ventricular dilatation, declining exercise tolerance, or abnormal hemodynamic responses to exercise.*	IIB
8. AVR is not indicated for asymptomatic patients with mild, moderate, or severe AR and normal left ventricular systolic function at rest (ejection fraction >0.50) when the degree of dilatation is not moderate or severe (end-diastolic dimension <70 mm, and those with end-diastolic dimension >70 mm should have aortic valve replacement if there is evidence of serial deterioration of ventricular function or exercise intolerance.).*	III

**Consider lower threshold values for patients of small stature of either gender.*

Available at: http://www.americanheart.org.

graft surgery. This proportion may increase as the surgical population continues to age. Risk assessment for ischemic heart disease is complicated in patients with aortic valve disease since angina may be related to true ischemia from hemodynamically significant coronary lesions, or other causes such as left ventricular wall stress with subendocardial ischemia or chamber enlargement in the setting of reduced coronary flow reserve. Since traditional coronary risk stratification is unreliable in aortic valve patients, it is our practice to routinely perform diagnostic coronary angiography on all patients over the age of 35. ACC/AHA Task Force guidelines for preoperative angiography are presented in Table 34-3.[28]

Technique of Operation

Myocardial protection and cardiopulmonary bypass

Isolated AVR is performed using a single two-stage venous cannula inserted into the right atrium for venous return and a standard arterial cannula into the ascending aorta for systemic perfusion of oxygenated blood. A retrograde cardioplegia cannula may be placed into the coronary sinus via the right atrium. A left ventricular vent cannula is placed through a purse-string suture in the right superior pulmonary vein and advanced into the left ventricle to ensure a bloodless field and to prevent ventricular distention if there is aortic insufficiency. Once cardiopulmonary bypass (CPB) is initiated, the aorta and pulmonary artery are dissected to expose the anterior aortic root to the left coronary artery. Careful dissection of the pulmonary artery from the aorta ensures that the cross-clamp will be fully occlusive on the aorta and prevents inadvertent opening of the pulmonary artery with the aortotomy incision. Pulmonary artery injuries may be difficult to repair, as this tissue is substantially more friable than the aorta.

After the cross-clamp is applied, myocardial protection is initially delivered as a single dose of high potassium blood through the ascending aorta.[47–49] This will achieve

Table 34–3.

ACC/AHA Task Force Guidelines on Coronary Angiography in Patients with Valvular Heart Disease

Indication	Class
1. Before valve surgery (including infective endocarditis) or mitral balloon commissurotomy in patients with: a. Chest pain b. Other objective evidence of ischemia c. Decreased left ventricular systolic function d. History of coronary artery disease e. Coronary risk factors (including advanced age)	I
2. Patients with apparently mild to moderate valvular heart disease but with: a. Progressive (class II or greater) angina b. Objective evidence of ischemia c. Decreased left ventricular systolic function d. Overt congestive heart failure	I
3. Before valve surgery in men aged 35 and older, premenopausal women aged 35 years or older who have coronary risk factors, and postmenopausal women	I
4. Surgery without coronary angiography is reasonable for patients having emergency valve surgery for acute valve regurgitation, aortic root disease, or infective endocarditis	IIA
5. Patients undergoing catheterization to confirm the severity of valve lesions before valve surgery without pre-existing evidence of coronary artery disease, multiple coronary risk factors, or advanced age	IIB
6. Coronary angiography is not indicated in young patients undergoing nonemergent valve surgery when no further hemodynamic assessment by catheterization is deemed necessary and no coronary risk factors, no history of coronary artery disease, and no evidence of ischemia are present	III
7. Patients should not undergo coronary angiography before valve surgery if they are severely hemodynamically unstable	III

Source: Adapted with permission from Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients with Valvular Heart Disease). Available at: http://www.americanheart.org.

prompt diastolic arrest unless there is moderate to severe AR. Myocardial protection is maintained by continuous infusion of cold or tepid oxygenated blood cardioplegia delivered via direct cannulation of both coronary ostia after the aorta has been opened.[50] Many surgeons do not routinely use retrograde cardioplegia for aortic valve cases, but this strategy is helpful in patients with significant AR or severe concomitant coronary disease.[51] In cases in whom the retrograde cannula cannot be placed into the coronary sinus, conversion to bicaval cannulation and opening the right atrium to directly place the cannula into the coronary sinus is possible. If retrograde perfusion is employed, this is also used in a continuous manner. Right ventricular myocardial protection may be inadequate with only retrograde cardioplegia and can lead to significant right ventricular dysfunction after CPB is discontinued. This may be avoided by ensuring that the retrograde cannula is not placed beyond the origin of the right coronary vein ostium in the coronary sinus.[52–55] The patient's systemic body temperature is allowed to drift downward, but active cooling for noncirculatory arrest cases is unnecessary.

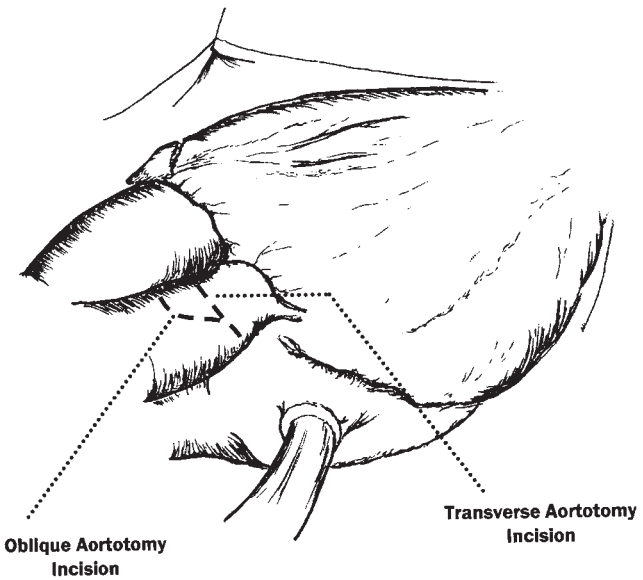

Figure 34-3. Exposure and aortotomy incision. A two-stage venous cannula is in place in the right atrial appendage. The aortotomy (dashed line) may be made in the transverse or oblique direction.

Aortotomy, valve excision and débridement

After the cross-clamp has been applied and cardioplegic arrest has been achieved, the aorta is opened either with a transverse or oblique aortotomy. The low transverse aortotomy is a common approach to the aortic valve when using stented bioprostheses or mechanical valves. The aortotomy is started approximately 10 to 15 millimeters above the origin of the right coronary artery (RCA) and extended anteriorly and posteriorly. The initial transverse incision over the RCA may also be extended obliquely in the posterior direction into the noncoronary sinus or the commissure between the left and noncoronary cusps (Fig. 34-3). The oblique incision is often used in patients with small aortic roots, in whom root enlargement procedures may be required (see below) and may also be used to tailor a larger ascending aorta.

Morphology of the valve is then inspected (Fig. 34-4). Excision of the valve cusps starts with scissors to incise into the right cusp between the right coronary ostium and the commissure between the right coronary and noncoronary cusps (Fig. 34-5). Mayo scissors or special right-angled valve scissors are usually used at this stage and the calcific deposits are squeezed away from the aortic wall. One to two millimeters of tissue is left behind to provide a sewing surface. Right cusp excision is carried first toward the left coronary cusp and then toward the noncoronary cusp and the cusp is removed as a single piece if possible. Excision is then carried toward the left and noncoronary commissure along the noncoronary cusp and then the left coronary cusp. A moistened radiopaque sponge is placed into the outflow area to catch debris, and the surgeon must ensure that this is removed before placing the valve sutures. Thorough decalcification is then performed with a scalpel or rongeur.

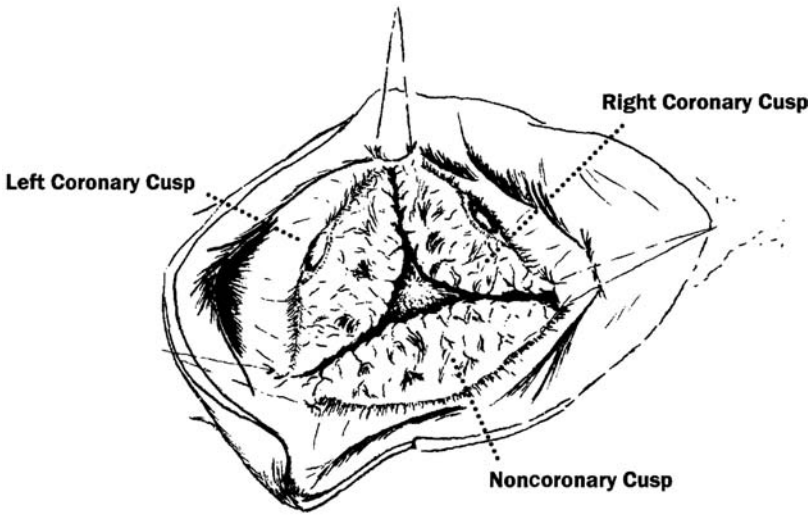

Figure 34-4. The exposed aortic valve.

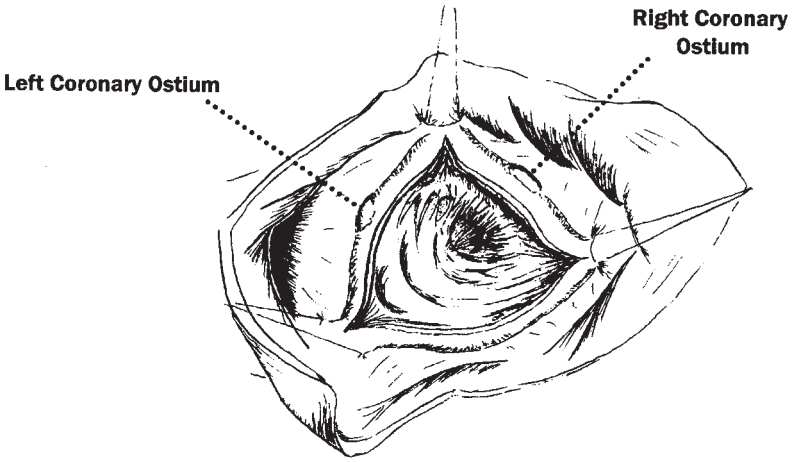

Figure 34-5. The aortic valve after leaflet excision.

Débridement of all calcium deposits back to soft tissue improves seating of the prosthesis and decreases the incidence of paravalvular leak and dehiscence.

Care must be taken to prevent aortic perforation while calcific deposits are débrided from the aortic wall, particularly at the commissure between the left and noncoronary cusps, where perforation is most likely. Several anatomic relationships must be respected during valve excision (Fig. 34-6). The bundle of His (conduction system) is located below the junction of the right and noncoronary cusps in the membranous septum. Deep débridement in this area can result in permanent heart block. The anterior leaflet of the mitral valve is in direct continuity with the left aortic valve cusp. If it is damaged during decalcification, an autologous pericardial patch is used to repair the defect.

Once débridement is completed, the aortic root is copiously flushed with saline while the left ventricular vent is stopped. To prevent pushing debris into the left ventricle, saline in a bulb syringe is flushed through the left ventricular vent and out the aortic valve in an antegrade manner instead of retrograde through the valve. The irrigation solution is suctioned with the external wall suction and not into the cardiotomy suction.

Valve implantation

After the native valve has been excised, the annulus is sized with a valve-sizer designed exactly for the selected prosthetic device. The valve is secured to the annulus using 12 to 16 double-needled interrupted 2-0 synthetic braided pledgeted sutures that are alternating in color. The pledgets can be left on the inflow/ventricular side or the outflow/aortic side of the aortic annulus (Figs. 34-7 and 34-8). Placing the pledgets on the inside of the annulus allows supra-annular placement of the valve and generally will allow implantation of a

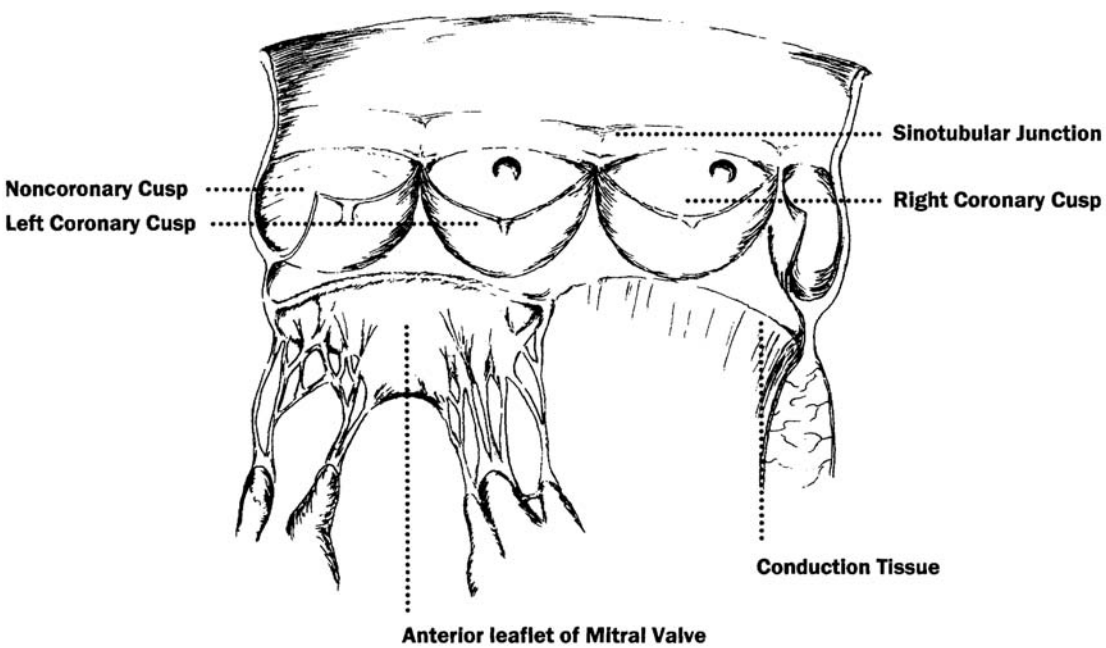

Figure 34-6. Anatomic relationships of the aortic valve.

slightly larger prosthesis. In cases in whom the coronary ostia are close to the annulus, supra-annular placement may only be possible along the noncoronary cusp. Mattress sutures are first placed in the three commissures and retracted to assist visualization. Some surgeons will place the commissural suture between the right and noncoronary cusps from the outside of the aorta (i.e., the pledget is left on the outside of the aorta) to prevent injury to the conduction system. Pledgeted mattress sutures are then placed in a clockwise fashion typically starting in the noncoronary cusp. Sutures may be placed into the sewing ring of the prosthetic valve with each annular suture or after all annular sutures are placed. The sutures for each of the three cusps are held separately with three hemostats and retracted while the prosthesis is slid into the annulus. Sutures are then tied down in a balanced fashion alternating among the three cusps.

Aortic closure and de-airing

The aorta is closed with a double row of synthetic 4-0 polypropylene sutures. The first suture line is started on the right side at the posterior end of the aortotomy and the double-needled suture is secured slightly beyond the incision to ensure there is no leak in this region. One end of the suture is run as a horizontal mattress anteriorly to the midpoint of the aortotomy, and then the second end of the suture is run anteriorly, slightly superficial to the horizontal mattress suture, in an over-and-over manner. On the left side, a similar technique is performed, the aorta is de-aired (described below), and the two sutures are tied to themselves and to each other at the aortotomy midpoint.

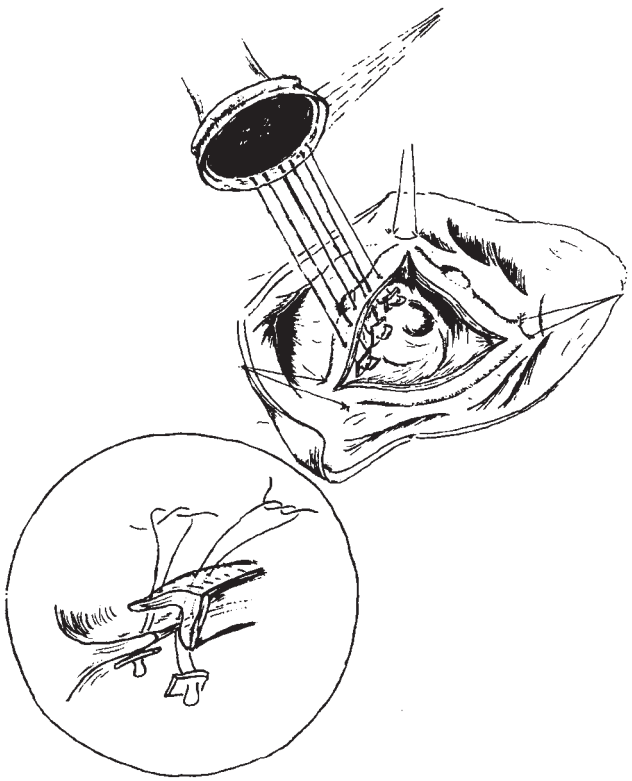

Figure 34-7. Placement of sutures with pledgets below the annulus.

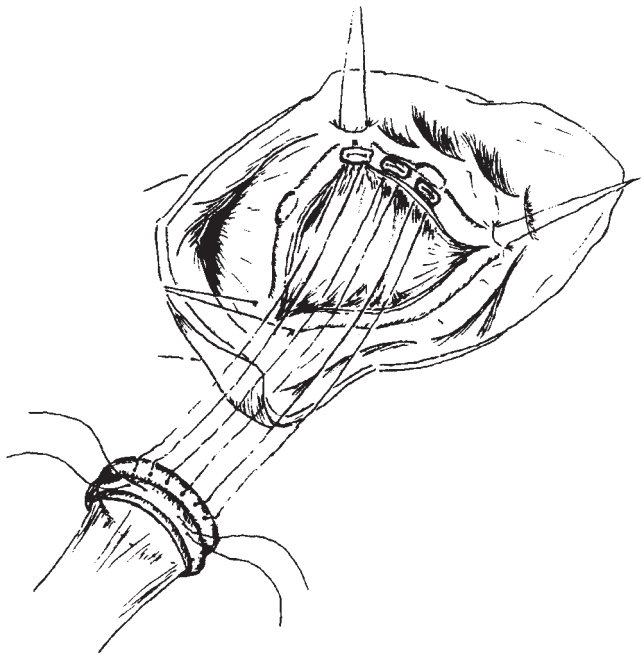

Figure 34-8. Placement of sutures with pledgets above the annulus.

During AVR, air is entrained into the left atrium and ventricle, and aorta. This must be removed to prevent catastrophic air embolization. Immediately prior to tying the suture of the aortotomy, the heart is allowed to fill, the vent in the superior pulmonary vein is stopped, the lungs are inflated, and the cross-clamp is briefly partially opened. The subsequent influx of blood should expel most air from these cavities out of the partially open aortotomy. Closure of the aortotomy is then completed and the cross-clamp is fully removed. The cardioplegia cannula in the ascending aorta and the left ventricular vent are then placed on suction to remove any residual air as the heart begins electrical activity. A small needle (21-gauge) is used to aspirate the apex of the left ventricle and the dome of the left atrium. To prevent air entrainment, the left ventricular vent must be removed while the pericardium is filled with saline irrigation. De-airing maneuvers are verified with transesophageal echocardiographic visualization to verify that all air has been removed from the left side of the heart. Vigorous shaking and careful manual compression of the heart while suctioning through the aortic vent (i.e., cardioplegia tack) is helpful to remove air trapped within trabeculations. Once de-airing is complete, the aortic vent is removed. The patient is then weaned from CPB and decannulated in the standard fashion.

Concomitant coronary artery bypass grafting

Operative technique is modified when there is concomitant CAD to optimize myocardial protection. Distal anastomoses are performed prior to AVR so that antegrade cardioplegia

may be administered through these grafts during the operation. The left internal thoracic artery should be used for revascularization of the left anterior descending artery, as this may improve long-term survival in aortic valve patients.[56] This anastomosis is performed after the aortotomy is closed to ensure that the coronary circulation is not exposed to systemic circulation during cardioplegic arrest and to prevent trauma to the anastomosis during manipulation of the heart.

Concomitant ascending aortic replacement

In general, the ascending aorta is replaced electively when maximal diameter exceeds 5.5 to 6.0 cm in patients without Marfan syndrome, and 4.5 to 5.0 cm in patients with Marfan syndrome. In the setting of concomitant aortic valve replacement, aortic replacement is advised if the ascending aortic diameter is >5.0 cm. Recent data suggest that patients with bicuspid aortic valves have an underlying aortopathy that leads to significant risk of late ascending aortic complications, and these patients should have replacement of their ascending aorta if its diameter exceeds 4.5 cm at the time of AVR[57] (Fig. 34-9).

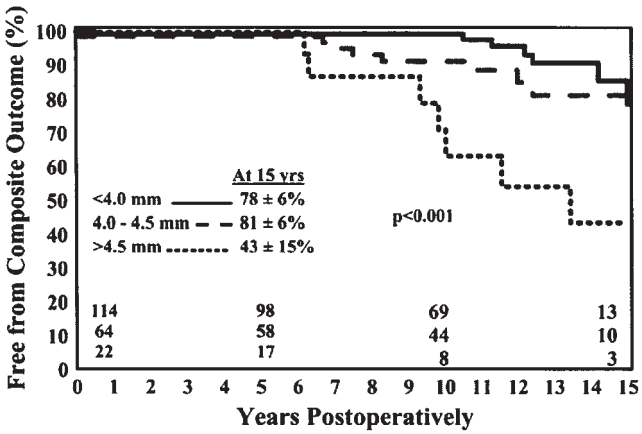

Figure 34-9. Freedom from ascending aortic complications for patients with a bicuspid aortic valve with an ascending aortic diameter of <4 cm, 4.0 to 4.5 cm, and 4.5 to 4.9 cm at the time of aortic valve replacement. (*Reproduced with permission from Borger MA, et al: Should the ascending aorta be replaced more frequently in patients with bicuspid aortic valve disease? J Thorac Cardiovasc Surg 2004; 128:677.*)

Aortic root enlargement procedures

Detailed descriptions of aortic root enlargement procedures are presented in a later chapter. Either an anterior or posterior annular enlargement procedure may be performed in a patient with a small aortic root to allow for implantation of a larger valve. The posterior approach is the most commonly used aortic root enlargement procedure in adults and can increase the annular diameter by 2 to 4 mm. Nicks and colleagues in 1970 described a technique of root enlargement in which the aortotomy is extended downward through the noncoronary cusp, through the aortic annulus to the anterior mitral leaflet.[58] In 1979 Manouguian and Seybold-Epting described a procedure extending the aortotomy incision in a downward direction through the commissure between the left and noncoronary cusps into the interleaflet triangle and into the anterior leaflet of the mitral valve.[59,60] The anterior approach is generally used in the pediatric population. Described by Konno and colleagues in 1975, this technique, which is also known as aortoventriculoplasty, is used when more than 4 mm of annular enlargement is required.[61] Instead of a transverse incision, a longitudinal incision is made in the anterior aorta and extended to the right coronary sinus of Valsalva and then through the anterior wall of the right ventricle to open the right ventricular outflow tract. The ventricular septum is incised, allowing significant expansion of the aortic annulus and left ventricular outflow tract.

Reoperative aortic valve surgery

Repeat sternotomy after AVR may be performed for valve-related complications, progressive ascending aortic disease, or CAD. Valve-related causes include structural valve deterioration, prosthetic endocarditis, prosthesis thrombosis, or paravalvular leak. Chest re-entry is the most hazardous portion of any repeat cardiac procedure. It is our routine practice to obtain an adequate lateral chest x-ray and computed tomography (CT) scan to determine the proximity of cardiac structures to the posterior sternum. Cardiopulmonary bypass is instituted through the femoral vessels when there is concern about chest re-entry. An oscillating saw is used to open the sternum and the dissection is kept as limited as possible. Extreme caution must be employed during dissection when there are patent bypass grafts. When only the aortic valve needs reoperation, advanced port-access technologies such as percutaneous coronary sinus cannulation and pulmonary artery venting can allow the operation to proceed with only a limited upper sternotomy.

Once cardioplegic arrest is established, the old prosthesis is excised with sharp dissection. Care must be taken to remove all sutures and pledgets from the annulus. Annular injuries caused while excising the prosthesis are repaired with pledgeted interrupted sutures. Removal of stentless prostheses may be particularly difficult in this regard. In the setting of endocarditis, aggressive débridement of infected tissue must be performed with appropriate annular reconstruction with pericardium when root abscesses are present.[62,63] All foreign graft material, including Dacron aortic grafts, must be excised in the presence of active endocarditis.[64]

In the presence of a Dacron prosthesis in the ascending aorta, chest re-entry may be extremely hazardous since exsanguination will occur if the graft is accidentally opened during dissection. To limit the systemic consequences of exsanguination at normothermia, the patient should be placed on femoro-femoral CPB and cooled to 20°C prior to chest reentry.[65] If the Dacron graft is accidentally opened, local control of the bleeding is established and CPB is stopped. Under circulatory arrest, atrial venous cannulation

is instituted and the graft is controlled distal to the tear. Cardiopulmonary bypass may then be restarted. In all repeat aortic procedures, rigorous myocardial protection must be applied since these procedures often have very long ischemic times. Antegrade cold blood cardioplegia is usually employed in a continuous fashion throughout the case by selective cannulation of the coronary ostia. Retrograde cardioplegia may have benefit in the setting of patent old saphenous vein grafts.[66]

Aortic balloon valvotomy

Aortic balloon valvotomy may be performed percutaneously via a femoral artery puncture in the interventional angiography suite to treat AS.[67] Inflation of the balloon within the valve orifice can stretch the annular tissue and fracture calcified areas or open fused commissures. There is no role for valvotomy in the patient with significant AR, as this will become significantly worse after the procedure.[68–70] Balloon valvotomy is rarely successful if significant calcification is present and carries a prohibitive risk of stroke from calcific emboli.[71,70] The long-term outcomes of this procedure in adult patients are dismal, with restenosis usually occurring within 1 year.[70,72,73] Patients with severe symptomatic AS who are too hemodynamically unstable to tolerate operation or have comorbid illnesses, such as advanced malignancy, which contraindicate operation, may benefit from palliative balloon valvotomy.[74–77] More recently, techniques have developed in implant prosthetic valves using transcatheter approaches. These procedures are discussed later in this chapter.

POSTOPERATIVE MANAGEMENT

Special consideration must be given to the underlying pathologic changes to the ventricle during the immediate postoperative period. The severely hypertrophied, noncompliant left ventricle found in AS is highly dependent on sufficient preload for adequate filling. Filling pressures should be carefully titrated between 15 and 18 mm Hg with intravenous volume infusion. Maintenance of sinus rhythm is also essential since up to one-third of cardiac output is derived from atrial contraction in a noncompliant ventricle. Up to 10% of patients will experience low cardiac output syndrome in the immediate postoperative period.[78] If pacing is required postoperatively, synchronous atrioventricular pacing is beneficial in preventing low cardiac output syndrome. If patients are pacemaker-dependent when weaned from CPB in the operating room, it is recommended to insert atrial pacing wires to allow for synchronous atrioventricular pacing.

In cases of severe hypertrophy, subvalvular left ventricular outflow obstruction with systolic anterior wall motion of the mitral valve may occur. Intravenous beta-adrenergic blockade may relieve this obstruction by decreasing inotropy. In extreme cases reoperation and surgical myectomy may be required.[79]

Profound peripheral vasodilation, often seen in patients with aortic insufficiency, is treated with vasoconstrictors including alpha-adrenergic agonists or vasopressin. Adequate filling of the dilated left ventricle may also require volume infusion.

Complete heart block occurs in 3 to 5% of AVR patients. This complication may be due to suture placement or injury from débridement near the conduction system. Transient complete heart block caused by perioperative edema usually resolves in 4 to 6 days. After this time, insertion of a permanent pacemaker is recommended if there is no resolution. Echocardiographic evaluation of valve function should be performed in the operating room with transesophageal echocardiography (TEE) and then at discharge, at 3 months, and yearly with transthoracic echocardiography (TTE).

STENTED BIOPROSTHETIC AORTIC VALVE REPLACEMENT DEVICES

Stented biologic prostheses may be constructed of porcine aortic valves or bovine pericardium. Over the past 40 years, advances in tissue fixation methodology and chemical treatments to prevent calcification have yielded improvements in the longevity of bioprostheses. All heterograft valves are preserved with glutaraldehyde, which cross-links collagen fibers and reduces the antigenicity of the tissue. Glutaraldehyde also reduces the rate of in vivo enzymatic degradation and causes the loss of cell viability, thereby preventing normal turnover and remodeling of extracellular matrix tissues.[80,81] Calcification occurs when nonviable glutaraldehyde-fixed cells cannot maintain low intracellular calcium.[81] Calcium phosphate crystals form at the phospholipid-rich membranes and their remnants, and the collagen matrix also calcifies.[82]

Glutaraldehyde fixation of porcine valves can be performed at high pressure (60 to 80 mm Hg), low pressure (0.1 to 2 mm Hg), or zero-pressure (0 mm Hg). Pericardial prostheses are fixed in low- or zero-pressure conditions. Porcine prostheses fixed at zero pressure retain the collagen architecture of the relaxed aortic valve cusp.[83] Higher fixation pressures cause tissue flattening and compression with loss of transverse cuspal ridges and collagen crimp, which may lead to earlier calcification.[84,85]

Multiple chemical treatments have been proposed to decrease the calcification process that invariably leads to material failure and valvular dysfunction. These include sodium dodecyl sulfate, polysorbate-80, Triton X-100, N-lauryl sarcosine, amino-oleic acid, aminopropane-hydroxydiphosphonate, toluidine blue, controlled-release diphosphonates, ferric chloride, aluminum chloride, and phosphocitrate.[86–100]

When comparing various bioprostheses, it is important to be aware of lack of standardization in methodologies for labeling valve sizes by the different manufacturers. In general, label sizes refer to either the internal or external

diameter of the stent, not the external diameter of the sewing cuff or the maximal opening diameter of the valve leaflets. Thus, the same aortic annulus will likely fit different sized valves from different manufacturers, depending on the convention they use and the size of their sewing cuff. Figure 34-10 compares internal and external sizes for a variety of prostheses.

First-Generation Prostheses

First-generation bioprostheses were preserved with high-pressure fixation and were placed in the annular position. They include the Medtronic Hancock Standard and Modified Orifice (Medtronic, Minneapolis, MN), and Carpentier-Edwards Standard porcine prostheses (Edwards Life Sciences, Irvine, CA).

Second-Generation Prostheses

Second-generation prostheses are treated with low- or zero-pressure fixation. Several second-generation prostheses may also be placed in the supra-annular position, which allows placement of a slightly larger prosthesis. Porcine second-generation prostheses include the Medtronic Hancock II valve (Medtronic, Minneapolis, MN), the Medtronic Intact porcine valve (Medtronic, Minneapolis, MN), and the Carpentier-Edwards Supraannular valve (SAV) (Edwards Life Sciences, Irvine, CA). Second-generation pericardial prostheses include the Carpentier-Edwards Perimount (Edwards Life Sciences, Irvine, CA), and the Pericarbon (Sorin Biomedica, Saluggia, Italy) prostheses.

Third-Generation Prostheses

Newer-generation prostheses incorporate zero- or low-pressure fixation with anti-mineralization processes that are designed to reduce material fatigue and calcification. Stents have become progressively thinner, have a lower profile, and are more flexible, and sewing rings have become scalloped for supra-annular placement. The Medtronic Mosaic porcine valve (Medtronic, Minneapolis,

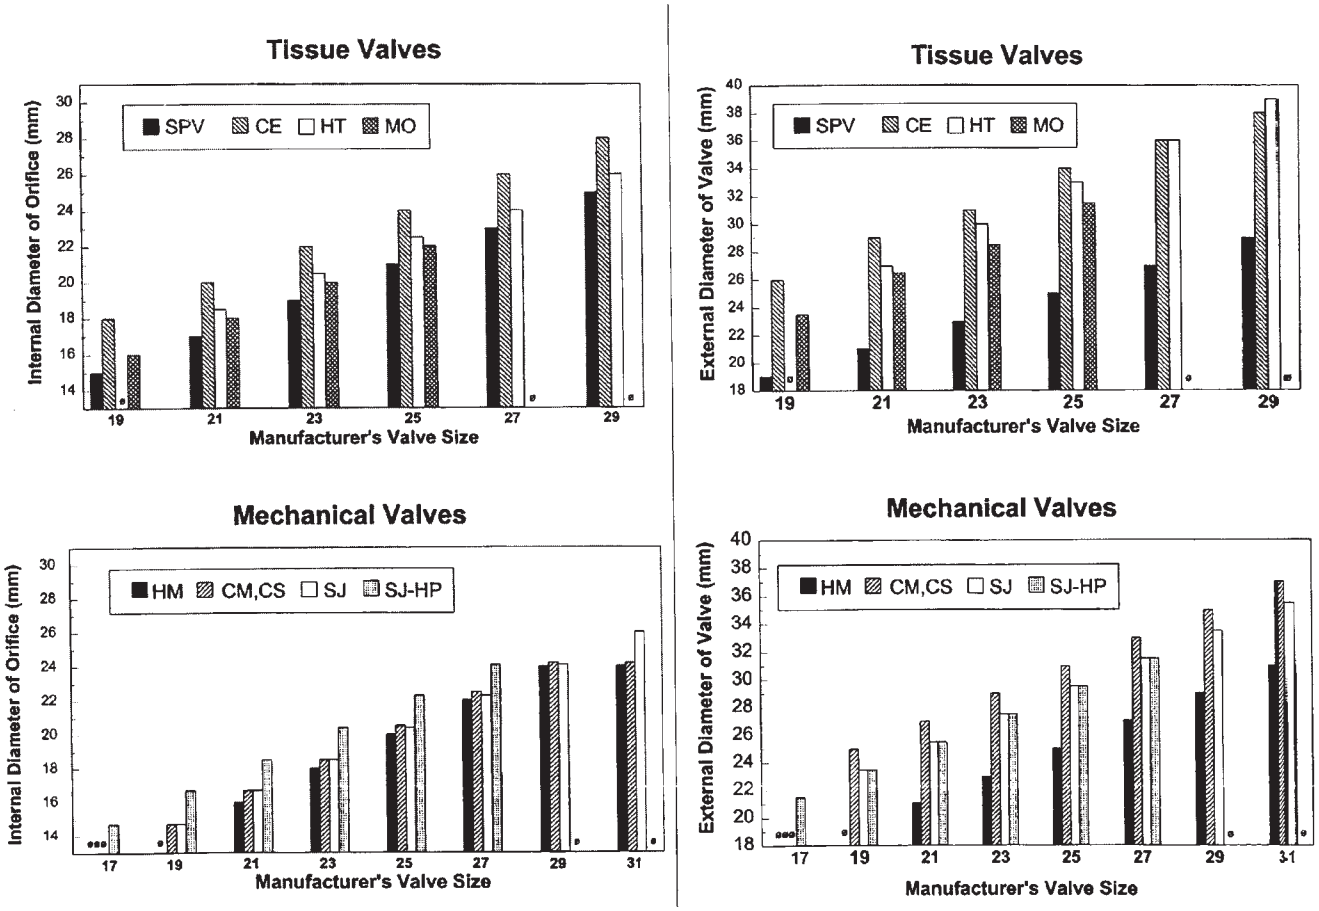

Figure 34-10. Comparison of the internal and external diameter of prosthetic aortic valves to the manufacturers' labeled size of each valve. No two manufacturers' valves have the same internal diameter for a given labeled size. (CE = Carpentier-Edwards Pericardial valve; CM = Carbomedics Standard valve; CS = Carbomedics Supra-annular valve; HM = Medtronic Hall valve; HT = Hancock II Bioprosthesis; MO = Hancock Modified Orifice Bioprosthesis; SJ = St. Jude Standard valve; SJ-HP = St. Jude Hemodynamic Plus valve; SPV= stentless porcine valve.) (*Reproduced with permission from Christakis GT, et al: Inaccurate and misleading valve sizing: a proposed standard for valve size nomenclature. Ann Thorac Surg 1998; 66:1198.*)

MN) is fixed in a "physiologic" environment with equal pressure (40 mm Hg) applied to the ventricular and aortic sides of the leaflets, resulting in net zero pressure on the leaflets themselves (Figs. 34-11 and 34-12). By pressurizing the root without placing pressure on the leaflets, this process stabilizes the root to maintain its anatomic shape. Alpha-amino oleic acid, which permanently covalently binds to free aldehyde groups, is used as the anticalcification treatment.

The St. Jude Medical Epic valve (St. Jude Medical Inc., Minneapolis, MN) is a porcine valve with a very low stent post and base profile to minimize protrusion into the aortic wall and facilitate coronary clearance (Fig. 34-13). The valve is composed of three separate porcine leaflets matched to size and low-pressure fixed in glutaraldehyde. A proprietary anticalcification treatment is used on the leaflet tissue. The outflow edge of the stent is covered with pericardium to prevent leaflet contact with the fabric of the sewing cuff.

The Carpentier-Edwards Magna valve (Edwards Life Sciences, Irvine, CA) is the evolution of the Perimount pericardial valve, with a narrower sewing cuff and scalloped

design for supra-annular placement (Fig. 34-14). The bovine pericardial leaflets are fixed at low pressure and treated with proprietary treatments to eliminate phospholipids and unstable and residual glutaraldehyde molecules, which are calcium-binding sites.

The Mitroflow Pericardial aortic prosthesis (Carbomedics, Austin, TX) is a pericardial valve that is unique in that the pericardium is placed around the exterior of the stent, presumably allowing for a larger opening diameter (Fig. 34-15). Although the current version does not have anticalcification treatment, this is being developed for future iterations.

Transcatheter Stented Bioprostheses

Transcatheter valve replacement technologies are evolving and have recently become a clinical reality, applied to high-risk patients who are not operative candidates. Valves comprised of equine pericardium have been mounted onto stents which can be delivered by three different techniques (Fig. 34-16). The antegrade approach involves femoral venous access, transseptal puncture, dilation of the atrial septum, guiding a flotation balloon through the mitral valve, antegrade cannulation of the aortic valve, snaring of a guidewire from opposite the femoral artery with exteriorization of an arteriovenous wire loop, balloon dilatation, and device delivery.[101] Initial results of this technique were associated with many mechanical and arrhythmic complications and a high periprocedural mortality, leading to virtual abandonment of this technique.[102–105] The retrograde femoral approach involves percutaneous femoral artery access, retrograde cannulation of the aortic valve, balloon dilatation, and device delivery. This technique has been applied with acceptable early results in elderly and high-risk patients, and represents an emerging option for nonoperative candidates.[106]

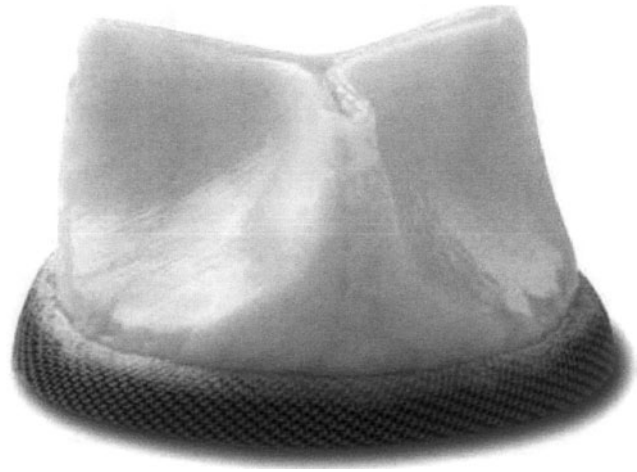

Figure 34-15. The Mitroflow Pericardial aortic prosthesis (*Figure courtesy of Carbomedics Inc., Austin, TX.*)

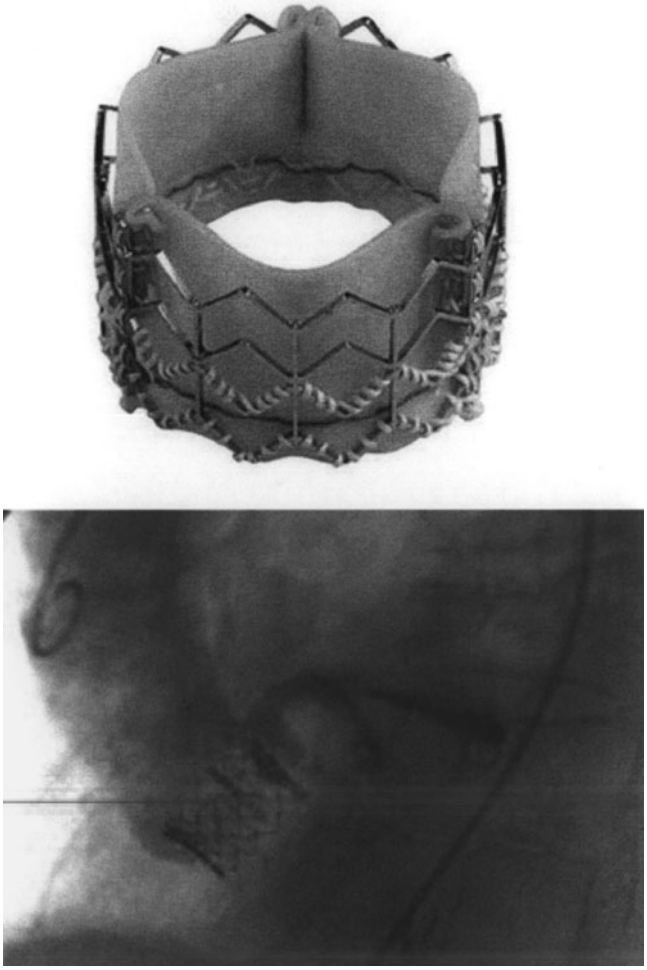

Figure 34-16. The Cribier-Edwards aortic percutaneous heart valve (upper panel) and fluoroscopic view of this prosthesis deployed in the aortic root (lower panel). (*Figure courtesy of Edwards Life Sciences, Irvine, CA.*)

The third approach is transapical transcatheter valve delivery. Performed in the operating room under general anesthesia, this technique involves creating a small thoracotomy, direct cannulation of the left ventricular apex, and passing of a wire under fluoroscopic guidance through the aortic valve.[107] The stent-mounted valve is then deployed with fluoroscopic and echocardiographic guidance. This technique avoids CPB and may be particularly beneficial for previous prosthetic valve failure, since the sternotomy incision may be avoided and the new prosthesis is placed inside the failed prosthesis. All three techniques require rapid ventricular pacing to ensure there is no cardiac output during device deployment.

The ultimate role of these catheter-based techniques of AVR has yet to be determined. Questions regarding prosthesis durability, periprocedural stroke, coronary artery injury, and hemodynamic performance remain unanswered, and will continue to evolve with successive iterations of the technology. At present, these techniques are enabling very high-risk patients to experience some relief of

their symptoms without undergoing a complex operation. Given the excellent current results of open operative AVR, the use of these procedures in lower-risk patients is not currently warranted.

OUTCOMES OF AORTIC VALVE REPLACEMENT

Operative Mortality

Operative mortality is defined as all-cause mortality within 30 days of operation or during the same hospital admission.[108] Contemporary series describe a very low operative mortality for isolated AVR. The mortality from AVR varies between 1 and 8%, depending on the patient population, the presence of coronary disease, and the era of study.[109–120] A publication from the Society of Thoracic Surgeons' (STS) database reviewing the results of 86,580 valve procedures found an overall mortality of 4.3% for isolated AVR, and 8.0% for AVR with CABS.[121] Aortic valve replacement with ascending aortic aneurysm repair had an operative mortality of 9.7%.[121] The results of this study are summarized in Table 34-4. It is important to note that information in this database is voluntarily submitted and includes both low-volume and high-volume centers.

Advanced patient age, poor preoperative LVF, New York Heart Association (NYHA) class IV symptoms, concomitant CAD, severe preoperative renal dysfunction, active endocarditis, female gender, emergent or salvage operation, and previous AVR have been associated with increased operative mortality in several series.[121–130] In the absence of major comorbidities and preserved LVF, isolated AVR can be performed with an expected mortality of less than 2%.[131] Kouchoukos and colleagues have shown that operative mortality is not further increased if simple resection of an ascending aortic aneurysm is performed concurrently at an experienced center.[132] Concomitant CABS is associated with approximately double the operative mortality of isolated AVR.[131–137] Table 34-5 presents the preoperative risk factors of operative mortality derived from the Society of Thoracic Surgeons database. Most early deaths are attributable to postoperative low cardiac output syndrome, neurologic injury, or infection. In Table 34-6, mortality data from a recent update of the Society of Thoracic Surgeons' database are presented describing the operative risk of isolated and combined valve procedures.[138] Isolated AVR was the valve procedure associated with the lowest perioperative mortality.

Long-Term Survival

Longitudinal analysis shows that there is no difference in survival between patients receiving mechanical and bioprosthetic valves when they are implanted in similar age cohorts over 10 years of follow-up.[139] However, at 15 years' follow-up, structural valve deterioration in bioprosthetic valves leads to a survival benefit for patients with mechanical valves. In a prospective trial by Hammermeister and colleagues, 11-year mortality was 62 and 57% for bioprosthetic and mechanical valves,

Table 34–4.

Operative Mortality Rates for Aortic Valve Replacement (AVR) Procedures from the Society of Thoracic Surgeons' Database

Operative category	Number	Operative mortality (%)
AVR (isolated)	26,317	4.3
Multiple valve replacement	3840	9.6
AVR + coronary artery bypass	22,713	8.0
Multiple valve replacement + coronary artery bypass	1424	18.8
AVR + any valve repair	938	7.4
Aortic valve repair	597	5.9
AVR + aortic aneurysm repair	1723	9.7
AVR + other*	356	8.4

**Other includes left ventricular aneurysm, ventricular septal defect, atrial septal defect, congenital defect, cardiac trauma, cardiac transplant, permanent pacemaker, automatic implanted cardioverter-defibrillator, aortic aneurysm, or carotid endarterectomy. Isolated aortic valve replacement and aortic aneurysm are not included in aortic valve replacement + other.*

respectively.[140] At 15 years, mortality in the bioprosthetic group rose to 79% while mortality in the mechanical valve group rose to 66%.[140] There were substantially more bleeding events in patients with mechanical valves. It is important to note that the effect of bioprosthetic structural deterioration on mortality in this series was influenced by the actual prosthesis used in the study (Medtronic Hancock porcine). This is a first-generation prosthesis and is more prone to structural failure than newer devices.[141,142]

In most published series, the expected survival after AVR is approximately 80 to 85% at 5 years, 65 to 75% at 10 years, and 45 to 55% at 15 years.[143–146] The outcomes of AVR are highly dependent on the functional status, comorbidities, and age of each individual patient.[146,147] The effect of age at the time of surgery on late mortality for a variety of prostheses is depicted in Fig. 34-17. Cohen and colleagues studied the impact of age, concomitant CAD, LVD, and poor functional status on middle to late survival after bioprosthetic AVR. Their results, presented in Table 34-7, show an additive risk for each of these comorbid factors.[148] Other studies have shown that concomitant renal disease, female gender, concomitant cardiac or vascular procedure, and atrial fibrillation are also risk factors for late mortality.[149–154] Studies of mechanical valves often show superior long-term survival, as these patients are significantly younger at the time of operation. No prospective series of comparable patients has

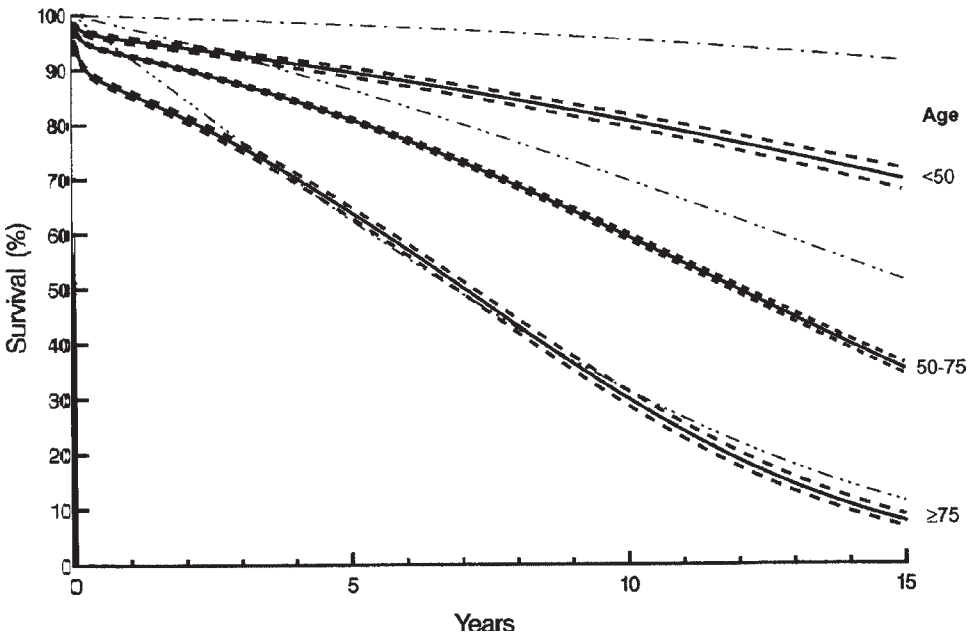

Figure 34-17. Projected long-term survival after aortic valve replacement stratified by age at time of surgery. For each age group the age-, race-, and ethnicity-matched population life table curve is shown as a dot-dashed line. Note that younger patients show more marked departure from normal life expectancy. shown any survival benefit comparing pericardial to porcine valves in similar eras.

Valve-Related Mortality

Long-term survival data distinguish between valve-related mortality, non–valve-related cardiac mortality, and mortality from other causes. A revised consensus document from the STS and the American Association of Thoracic Surgeons (AATS) was published in 1996 outlining a standardized method to report valve-related complications in prosthetic and repaired heart valves.[155] This panel defined valve-related mortality as all deaths caused by structural valve deterioration, nonstructural valve dysfunction, valve thrombosis, embolism, bleeding event, operated valvular endocarditis, or death related to reoperation of an operated valve. Sudden, unexplained, unexpected deaths of patients with an operated valve are included as valve-related mortality. Deaths caused by progressive heart failure in patients with satisfactorily functioning cardiac valves are not included. In the Hammermeister series, valve-related deaths accounted for 37% of all deaths in patients with mechanical valves and 41% of all deaths in patients with bioprostheses at 15 years.[156] Nonvalvular cardiac deaths accounted for 17 and 21% of deaths at 15 years in patients with mechanical and bioprostheses, respectively.[156] There are no well designed prospective randomized series comparing the long-term outcomes of specific pericardial or porcine prostheses to each other.

Nonfatal Valve Events

The joint STS/AATS panel defined specific guidelines for reporting outcomes on structural and nonstructural valve deterioration, valve thrombosis, embolic events, bleeding events, and prosthetic endocarditis.[157] These definitions are summarized below.

1. Structural valve deterioration: Any change in function of an operated valve resulting from an intrinsic abnormality of the valve that causes stenosis or regurgitation, such as wear, leaflet tears, or suture line disruption of components.
2. Nonstructural dysfunction: Any abnormality of an operated valve resulting in stenosis or regurgitation that is caused by factors not intrinsic to the valve itself, such as pannus overgrowth, inappropriate sizing, or paravalvular leak.
3. Valve thrombosis: Any thrombus attached near an operated valve that interferes with valve function in the absence of infection.
4. Embolism: Any embolic event that occurs after the immediate postoperative period when perioperative anesthesia has been completely reversed. Emboli may be peripheral (noncerebral) or cerebral. Myocardial infarction is excluded unless the event occurs after the perioperative period and coronary artery embolus is unequivocally documented.
   Cerebral embolic events are subclassified into:
   a. Transient ischemic attacks: Fully reversible neurologic events lasting less than 24 hours.
   b. Reversible ischemic neurologic deficit: Fully reversible neurologic events lasting more than 24 hours and less than 3 weeks.
   c. Stroke: Permanent neurologic deficit lasting longer than 3 weeks or causing death.
5. Bleeding event: Any episode of major internal or external bleeding that causes death, hospitalization, or permanent injury, or requires transfusion,

Table 34–7.

Survival Probability Calculated from an Accelerated Time Failure Model for Combinations of Risk Factors*

CAD	Age >65	NYHA class IV	Left ventricular grade III or IV	Predicted 5-year survival (%)	Predicted 10-year survival (%)
				89.1 (73, 100)	83.9 (73, 95)
X				83.4 (70, 97)	76.2 (67, 85)
	X			84.5 (71, 98)	77.7 (69, 86)
		X		83.6 (70, 97)	76.6 (68, 85)
			X	82.3 (69, 96)	74.8 (66, 84)
X	X			77.1 (66, 88)	68.2 (61, 75)
X		X		75.9 (65, 87)	66.8 (60, 74)
X			X	74.1 (63, 85)	64.6 (58, 72)
	X	X		77.4 (66, 88)	68.6 (62, 76)
	X		X	75.7 (65, 86)	66.5 (59, 74)
		X	X	74.5 (64, 85)	65.1 (58, 72)
X	X	X		67.8 (59, 77)	57.4 (52, 63)
X	X		X	65.7 (57, 75)	55.0 (49, 61)
	X	X	X	66.2 (57, 75)	55.5 (50, 61)
X	X	X	X	54.6 (47, 62)	43.5 (39, 48)

**Each of these four risk factors was entered into the model as a dichotomous variable (i.e., NYHA IV versus NYHA I, II, or III; left ventricular grades 3 or 4 versus left ventricular grades 1 or 2). The "X" indicates that the risk factor is present. These four risk factors are not present for the first row of estimates. The upper and lower 95% confidence interval for the predicted survival probabilities are given in parentheses.*

regardless of the patient's anticoagulation status. This does not include embolic stroke followed by hemorrhagic transformation and intracranial bleed.

6. Operated valvular endocarditis: Any infection involving an operated valve; any structural or nonstructural valvular dysfunction, thrombosis, or embolic event associated with operated valvular endocarditis is included only in this category.

Time-related analysis of nonfatal complications is often expressed by the Kaplan-Meier actuarial method, or by the recently described cumulative incidence method proposed by Grunkemeier and Wu.[158] Cumulative incidence (or actuarial) reporting provides additional information, as it removes the impact of mortality on nonfatal outcomes. This is most relevant in higher-risk groups such as elderly patients, a group in which many patients will die from other causes prior to the occurrence of nonfatal events. Kaplan-Meier actuarial methods tend to overestimate nonfatal events by continuing to assume that patients who have died are still at risk for these nonfatal events.

Structural Valve Deterioration

Mechanical prostheses

Currently available mechanical prostheses are extremely resistant to material fatigue or structural valve deterioration (SVD). Very long-term follow-up of the Starr-Edwards caged-ball prosthesis, the Medtronic Hall tilting disc prosthesis, and the St. Jude bileaflet mechanical prosthesis show

that these valves are exceedingly resistant to structural failure. Some discontinued mechanical prostheses, such as the Bjork-Shiley convexo-concave valve, had high rates of structural failure due to fracture of the outlet strut.[159]

Stented bioprostheses

There are several large series describing long-term follow-up of first- and second-generation stented bioprostheses. These series are not comparable to each other since they took place in different patient populations or in different eras. Structural valve deterioration is the most common nonfatal valve-related complication in bioprosthetic aortic valves. Table 34-8 summarizes the long-term SVD outcomes of commonly used first- and second-generation stented bioprostheses. Long-term follow-up of currently available second-generation stented bioprostheses, including the Medtronic Hancock II porcine and Carpentier-Edwards pericardial valves, shows that these prostheses have a freedom from structural valve deterioration <90% at 12-year follow-up.[160–162] However, beyond 15-year follow-up, freedom from SVD falls rapidly.[163] There is no good evidence to suggest that comparable, well-established second-generation pericardial or porcine prostheses differ in longevity, and decisions to choose a specific prosthesis should be made based on surgeon comfort and familiarity with the prosthesis and its sizing and holding mechanisms. While newer third-generation prostheses with advanced tissue treatments may eventually be shown to have superior longevity, data about these prostheses are currently limited to 5- to 6-year outcomes, which appear comparable to those of the second-generation prostheses.[164]

Table 34–8.

Bioprosthetic Valve Failure 10 years After Valve Replacement According to the Patient's Age at the Time of Implantation

Patient's age (y)	Percentage with valve failure after 10 years
<40	42
40–49	30
50–59	21
60–69	15
>70	10

Source: Adapted from Vongpatanasin et al[166] based on data from Grunkemeier et al.[167]

There is an important predisposition for premature bioprosthetic structural valve deterioration in younger patients, particularly those under the age of 40 years.[165,166] Table 34-9 summarizes the effect of patient age on SVD. Structural valve deterioration may be less common in elderly patients due to decreased hemodynamic stress placed on the valve. The freedom from SVD may be underestimated in the literature since most series report SVD by the actuarial method instead of the actual or cumulative incidence

Table 34–9.

Structural Deterioration of Stented Bioprosthetic Valves in the Aortic Position: Long-term Follow-up Over 12–15 years

Study	Prosthesis	Number of patients	Mean age (years)	Mean follow-up (months)	Time of SVD estimate (years)	Actuarial freedom from SVD	Actuarial freedom from reoperation

CE = Carpentier-Edwards; MO = modified orifice; SA = supra-annular; SVD = structural valve deterioration

method.[167] Actuarial statistical analysis overestimates SVD in older patients since it assumes that patients who have died of other causes will continue to be at risk for SVD.[168]

Stentless bioprostheses

Longevity of stentless bioprostheses appears to be significantly dependent on the native valve pathology and implantation technique. Retrospective studies have shown that such valves are prone to early structural deterioration when used in the subcoronary position in patients with AR or bicuspid pathology as the primary indication for operation. In these patients, progressive root dilatation due to aortic pathology often leads to poor leaflet coaptation, leaflet tears, and recurrent AR.[169–171] Such modes of failure have not been observed when stentless valves are used as root replacements, which appear to have similar mid-term durability to the stented prostheses.[172,173]

Freedom from Reoperation

Freedom from reoperation for currently available mechanical valves is >95% at 10 years and >90% at 15 years.[174–180] Bioprostheses have a significantly higher rate of reoperation due to structural valve dysfunction. In large series, freedom from reoperation is >95% at 5 years, >90% at 10 years, but <70% at 15 years.[181–200] The long-term freedom from reoperation for several commonly available valves is presented in Table 34-9.

Optimal Antithrombotic Therapy

Mechanical valves

All mechanical valves require formal anticoagulation with warfarin for the lifetime of the patient since these valves are inherently thrombogenic. The overall linearized risk of thromboembolism in patients on warfarin therapy is 1 to 2% per year in most published series.[201–219] A meta-analysis of over 13,000 patients showed that the incidence of major embolism in mechanical valves without antithrombotic therapy was 4 per 100 patient-years.[220] With antiplatelet therapy this risk was 2.2 per 100 patient-years, and with warfarin therapy it was reduced to 1 per 100 patient-years. The incidence of thromboembolism was slightly higher in caged-ball prostheses than other mechanical prostheses.[221]

The embolic risk is highest in the first few months, before the exposed cloth sewing ring and valve components have fully endothelialized.[222] Antithrombotic therapy is initiated on the second postoperative day with oral warfarin. In the presence of complicating factors such as gastrointestinal or mediastinal bleeding or perioperative neurologic injury, anticoagulation may be held initially. If the target level of anticoagulation is not achieved by the fourth postoperative day, intravenous heparin is instituted to achieve a partial thromboplastin time between 60 and 90 seconds. If the patient is at high risk for thromboembolism, heparin is started concurrently with warfarin on the second postoperative day. High-risk patients include those with atrial fibrillation, intracardiac thrombus, left atrial enlargement, severe LVD, and history of systemic emboli or hypercoagulable state.[223]

The target level of anticoagulation for each individual patient is dependent on their thrombotic risk profile and the type of valve employed. It is our practice to establish an International Normalized Ratio (INR) of 3.0 (acceptable range 2.5 to 3.5) for high-risk patients with mechanical valves and additionally institute low-dose aspirin therapy (80 to 100 mg once daily). For lower-risk patients, the target INR is 2.5 (acceptable range 2.0 to 3.0) and low-dose aspirin is started on an individual basis.

Several articles suggest that caged-ball valves in the aortic position require a higher level of anticoagulation than tilting monoleaflet or bileaflet prostheses.[224,225] These valves should be anticoagulated to an INR of 3.5 to 4.5. Although older tilting monoleaftlet prostheses were associated with an increased rate of thromboembolism, currently available prostheses such as the Medtronic Hall valve do not appear to have an increased thromboembolism risk versus bileaflet prostheses and should have the same target INR.[226–228]

Aspirin, an antiplatelet agent, is routinely used at a low dose to minimize the risk of thromboembolic events. Randomized trials have shown that low-dose aspirin significantly reduces fatal cardiovascular and embolic events for all patients with mechanical valves, particularly in patients with concomitant coronary or vascular disease.[229–232] There are increased bleeding events when higher doses of aspirin are used in patients formally anticoagulated with warfarin.[233,234] The linearized risk of a bleeding event is 0.1 to 3.5% per year, depending on how these events are defined, the range of anticoagulation used, and how often coagulation parameters are measured.[235–238]

The On-X valve (Medical Carbon Research Institute, Austin, TX) is purported to have lower thrombogenicity due to use of a purer form of carbon and enhanced contours over the pivot guides. This device is currently being investigated in a Food and Drug Administration–approved clinical trial for reduced anticoagulation with only clopidogrel and aspirin versus standard warfarin.

Bioprosthetic valves

Bioprosthetic valves are less thrombogenic than mechanical prostheses and do not require long-term anticoagulation with warfarin unless the patient is at high risk for thromboembolism or has had a thromboembolic event with their prosthesis.[252] Stented bioprostheses have a linearized risk for thromboembolism between 0.5 and 1% per year.[240–246] This risk appears to be lower in patients with stentless heterograft, allograft, or autograft valves.[247–252] Anticoagulant management of bioprostheses during the first 3 months after implantation remains variable between institutions. There is an increased hazard function for thromboembolism before the exposed surfaces of stented bioprostheses endothelialize.[253] The current ACC/AHA guidelines recommend anticoagulation with warfarin to an INR between 2.0 and 3.0 for the first

3 months for bioprosthetic valves as a class IIB recommendation.[28] This is discontinued at the end of the third month unless the patient is at high risk for thromboembolism. Low-dose aspirin is continued as monotherapy in low-risk patients, and in conjunction with warfarin in high-risk patients for the lifetime of the patient. Combined aspirin and warfarin have a survival benefit over warfarin alone in high-risk patients with bioprosthetic heart valves.[236] Aspirin significantly decreases the risk of thromboembolism in low-risk patients with bioprostheses versus no antiplatelet therapy.[254–257] If a patient has identified high-risk factors for thrombosis preoperatively, a mechanical prosthesis should be implanted unless the risk factor is amenable to correction since formal anticoagulation with warfarin will still be necessary. With aspirin, bioprosthetic valves have approximately the same risk of thromboembolism as fully anticoagulated mechanical valves, with fewer bleeding complications.[236]

Prosthesis Thrombosis

Prosthesis thrombosis is a rare but potentially devastating outcome after AVR. The incidence of prosthesis thrombosis is <0.2% per year and it occurs more often in mechanical prostheses.[258–260] Thrombolytic therapy may be used in some patients but it is often ineffective. Thrombolysis is recommended in patients with left-sided thrombosis who are experiencing significant heart failure (NYHA class III or higher) and are considered too high risk for surgery.[261,262] Cerebral or peripheral thromboembolism occurs in 12% of patients after thrombolytic therapy.[261] Surgical treatment includes replacement of the valve or open thrombectomy, and mortality from either procedure is similar at approximately 10 to 15%.[261] Recurrent thrombosis after de-clotting occurs in up to 40% of patients and we recommend valve replacement in virtually all patients who are managed operatively.

Prosthetic Valve Endocarditis

Prosthetic valve endocarditis (PVE) is separated into two time frames: early (<60 days postimplantation) and late (>60 days postimplantation). Early PVE is usually a sequela of perioperative bacterial seeding of the valve, either during implantation or postoperatively from wound or intravascular catheter infections.[263] *Staphylococcus aureus*, *S. epidermidis*, gram-negative bacteria, and fungal infections are common in this period.[264–285] Although most cases of late PVE are caused by septicemia from noncardiac sources, a small proportion of late cases in the first year are attributable to less virulent organisms introduced in the perioperative period, particularly *S. epidermidis*.[269] Organisms responsible for late PVE include *Streptococcus* and *Staphylococcus* species and other organisms commonly found in native valve infectious endocarditis. All unexplained fevers should be meticulously investigated for PVE with serial blood cultures and TE and TTE. Transesophageal echocardiography provides more detailed anatomic information such as the presence of vegetations, abscesses, and fistulas, but often does not provide adequate views of the anterior portion of the valve.[270] Transthoracic views may be helpful in these cases. Mechanical valves are particularly difficult to visualize by echocardiography due to shadowing created by valve components.

The annual risk of PVE in the aortic position is 0.6 to 0.9% per patient year.[215,242,271–283] The 5-year freedom from PVE reported in many major series is >97%.[284–287] Mechanical valves may have a slightly higher early hazard for PVE than stented bioprostheses.[287] However, there is no difference in risk between patients with mechanical and stented bioprosthetic prostheses after the early phase. Stentless porcine heterografts and allografts are less likely to develop PVE since they have less prosthetic material that may serve as a nidus of infection.[288–295] These valves may be particularly helpful in valve rereplacement for PVE.

Outcome for patients with PVE is very poor. Invasive paravalvular infection occurs in up to 40% of cases of PVE.[296] Early PVE is associated with 30 to 80% mortality, while late PVE is associated with 20 to 40% mortality.[297,298]

Surgery is indicated for PVE in the following circumstances:

1. All cases of early (<60 days) of PVE.
2. Concomitant heart failure and valvular dysfunction.
3. Paravalvular leak or partial dehiscence, even in a stable patient, requires operative management, particularly if more than 40% of the valve's annular circumference is involved.
4. The presence of a new conduction defect, abscess, aneurysm, or fistula mandates operative management. All fungal, and most virulent strains of *Staphylococcus aureus*, *Serratia marcescens*, and *Pseudomonas aeruginosa* also require operation, as these organisms are highly invasive and antibiotic therapy is generally ineffective.
5. Any case of persistent bacteremia despite a maximum of 5 days of appropriate antibiotic therapy and no other source of infection.
6. Vegetations >10 mm are not penetrated well by antibiotics and usually need operative management.
7. Multiple systemic emboli.

Paravalvular Leak and Hemolysis

Paravalvular leak is uncommon outside of the setting of infective endocarditis when pledgeted sutures are routinely used. Technical errors may result in inappropriately large gaps between sutures, leaving a small portion of the prosthesis unattached to the annulus. If paravalvular leak is sufficient to cause significant hemolysis, surgical correction may be performed with a few interrupted pledgeted sutures. Hemolysis is uncommon with the currently available mechanical or stented bioprosthetic valves if they are functioning well. Pannus overgrowth and prosthetic structural degeneration interfering with normal valve opening and closure may cause hemolysis severe enough to warrant reoperation. Milder cases of hemolysis may be managed conservatively by dietary supplementation with iron and folic acid, and routine

measurement of hemoglobin, serum haptoglobin, and lactate dehydrogenase.

HEMODYNAMIC PERFORMANCE AND VENTRICULAR REMODELING

Left Ventricular Mass Regression

Pressure and volume overloading caused by aortic valve disease leads to increased intracavitary left ventricular pressures and compensatory LVH. In severe AS, concentric ventricular hypertrophy occurs without increasing end-diastolic dimension until late in the disease process, thus maintaining the ventricular wall thickness:cavity radius ratio. Severe AR causes volume overload with an increase in left ventricular end-diastolic volume and eccentric hypertrophy, but may not change the ratio of ventricular wall thickness to cavity radius.

Both pathologies result in an increase in left ventricular mass (LVM). Studies from the hypertension literature indicate that increased LVM has a strong negative prognostic effect. Several reports, including the Framingham Heart Study, indicate that increased LVM was a predictor of all cardiac events, including sudden cardiac death.[299–301] The overall goal of AVR is to alleviate the pressure and volume overload on the left ventricle, allowing myocardial remodeling and regression of left ventricular mass.

The clinical impact of LVM regression is not as well understood, despite its widespread acceptance as a measure of outcome after aortic valve surgery. Smaller studies have shown that in hypertensive patients undergoing medical treatment, patients with a reduction of left ventricular mass had fewer cardiac events than those whose left ventricular mass did not change or increased.[302] The prognostic implications of LVM regression after aortic valve surgery have not been rigorously studied, but logic would suggest that lack of LVM regression is associated with poor clinical outcome. There are no studies showing that there is incremental clinical benefit with greater degrees of ventricular mass regression.

Generally, LVM regresses significantly over the first 18 months and returns to within normal limits in many patients after AVR for isolated AS.[303–308] Ventricular mass regression may continue for up to 5 years after valve replacement.[309] However, some patients do not experience adequate ventricular mass regression and may experience poorer prognoses. Several authors have identified a situation, referred to as patient-prosthesis mismatch, in which the poor hemodynamic performance of a prosthesis results in poor regression of LVH and poor patient outcome.

Prosthesis-Patient Mismatch

Definitions

The term prosthesis-patient mismatch has been applied to several different clinical situations. It has been used to describe absolute small valve size (i.e., <21 mm), small valve size in a patient with a large body surface area, excessive transvalvular gradient postimplantation, increased transvalvular gradient with exercise, indexed effective orifice area, and various combinations of these variables.

Rahimtoola defined prosthesis-patient mismatch as a condition that occurs when the valve area of a prosthetic valve is less than the area of that patient's normal valve.[310] He described a clinical condition in which the patient experienced either no relief or worsening of symptoms due to the obstructive nature of the prosthesis, which creates a residual stenosis resulting in an elevated transvalvular gradient. To varying degrees, all mechanical and stented tissue prostheses and stentless tissue prostheses used in the subcoronary or inclusion root position are inherently stenotic.[311] The presence of rigid sewing rings, and in the case of stented bioprostheses, struts to hold the valve commissures, cause obstruction to outflow and will therefore cause a residual gradient despite normal prosthesis function. This was more true of first-generation prostheses used during the 1970s, when this condition was first described. The problem is exacerbated by annular fibrosis, annular calcification, and LVH, as seen in AS, that cause contraction of the native annulus, leading to the implantation of a smaller prosthesis. Two distinct terms are commonly used to describe the size of prosthetic valves: effective orifice area and geometric orifice area.

Effective orifice area

The most commonly cited definition of prosthesis-patient mismatch is a low indexed effective orifice area (IEOA). The IEOA is calculated by dividing the echocardiographically determined effective orifice area (EOA) by the body surface area. Effective orifice area is calculated by a reconfiguration of the continuity equation:

$$EOA = (CSA_{LVOT} \times TVI_{LVOT})/TVI_{AO}$$

where EOA is the effective orifice area in square centimeters, CSA_{LVOT} is the cross-sectional area of the left ventricular outflow tract(LVOT) in square centimeters as determined by two-dimensional measurement of the LVOT diameter, TVI_{LVOT} is the velocity time integral of forward blood flow in centimeters as derived from pulse-wave Doppler in the LVOT, and TVI_{AO} is the velocity time integral of forward blood flow in centimeters as derived from software integration of transvalvular continuous wave Doppler.[312] The EOA and mean systolic gradient of several commonly available bioprostheses are shown in Table 34-10.

Several authors suggest that prosthesis-patient mismatch occurs at an IEOA of <0.85 cm^2/m^2.[313,314] Dumesnil and Pibarot have redefined prosthesis-patient mismatch as follows, "prosthesis-patient mismatch occurs when the EOA of the prosthesis is too small in relation to the patient's body size, resulting in abnormally high postoperative gradients."[314] This definition is based on the assumption that transvalvular gradients begin to rise substantially at IEOAs below this value, and these elevated gradients potentially

cause increased left ventricular work that prevents adequate regression of LVH.[315]

EOA is an in vivo, functional estimate of the minimal cross-sectional area of the transvalvular flow jet downstream of a valve (Fig. 34-18). The EOA is dependent on several factors including the geometric area of the prosthesis, the shape and size of the LVOT and ascending aorta, blood pressure, and cardiac output. Mechanistic studies have shown that Doppler-derived EOA correlates best with catheter-derived EOA(as determined by the Gorlin formula) when the ascending aortic diameter is 4 cm, and tends to underestimate EOA in patients with smaller aortic diameters.[316] The EOA cannot be known for a specific valve in a specific patient until the valve has actually been implanted. Studies examining the effect of low IEOA on clinical outcomes have typically used published tables of EOA derived from historical controls instead of actually measuring true in vivo postoperative EOA. Moreover, these tables have been derived from relatively small numbers of valves in each size for each manufacturer with wide variability between studies. EOA has been shown to correlate with postoperative valve gradients.[317] Gradients and EOA are, in

Table 34–10.

The Effective Orifice Area (EOA) and Mean Systolic Gradient (MSG) of Commonly Available Bioprostheses

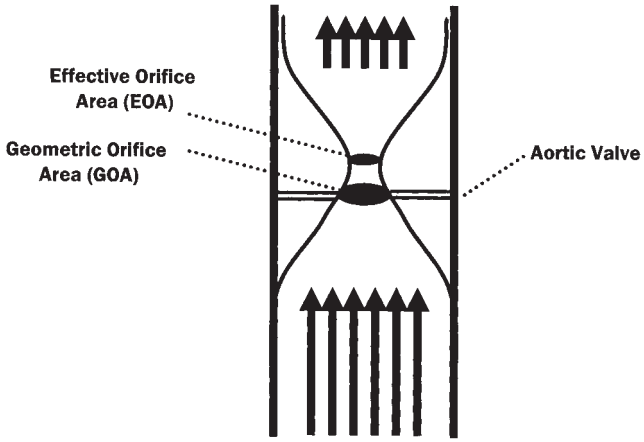

Figure 34-18. Diagrammatic representation of effective orifice area and geometric orifice area in relation to the left ventricular outflow tract and aortic root.

fact, mathematically related. Echocardiographic mean and peak gradients are calculated according to the Bernoulli equation:

$$\text{Peak gradient (mm Hg)} = 4 \times (V_{AVmax}{}^2 - V_{LVOTmax}{}^2)$$

$$\text{Mean gradient (mm Hg)} = 4 \times (V_{AVmean}{}^2 - V_{LVOTmean}{}^2)$$

Geometric orifice area

The geometric orifice area (GOA) (also known as the internal geometric area) of the valve is the maximal cross-sectional area of the valve opening that does not vary significantly between same-sized valves from the same manufacturer. It is a static measure that is known preoperatively for any given prosthesis based on manufacturer specifications or by measurement with calipers. As seen in Fig. 34-18, the GOA is always larger than the EOA for any given prosthesis.

Clinical significance

The significance of prosthesis-patient mismatch is controversial since there is conflicting evidence that lower IEOA causes diminished short or long-term clinical results.

Pibarot and Dumesnil studied 1266 patients undergoing AVR at a single institution. They defined moderate prosthesis-patient mismatch as IEOA <0.85 cm^2/m^2 and severe prosthesis-patient mismatch as IEOA <0.65 cm^2/m^2. They found that moderate or severe prosthesis-patient mismatch was present in 38% of patients. Multivariate analysis showed that moderate prosthesis-patient mismatch was associated with a doubling of perioperative mortality, and severe prosthesis-patient mismatch was associated with an 11-fold increase of perioperative mortality. Of note, the poor outcomes in the severe mismatch group were based on only 27 patients with 7 perioperative mortalities. These patients also had substantially longer intraoperative cardiopulmonary bypass times and concurrent coronary surgery. Rao and colleagues retrospectively studied prosthesis-patient mismatch in patients undergoing AVR at two large centers.[318] A total of 2154 patients were reviewed including 227 patients with prosthesis-patient mismatch, and 1927 patients without prosthesis-patient mismatch. Overall mortality was similar in both groups, but valve-related mortality was higher in the prosthesis-patient mismatch group at 10 years. Many valve-related mortalities included mechanisms of death that were unrelated to prosthesis-patient mismatch (embolic stroke, valve failure, endocarditis, bleeding, and reoperation) and supportive echocardiographic data were not provided. Effective orifice area was obtained from in vitro data supplied by the manufacturers according to the valve size implanted.

Ruel and colleagues performed a single-center analysis of 1563 mechanical and tissue aortic prostheses and found that IEOA <0.8 cm^2/m^2 was associated with increased prevalence of heart failure symptoms at a mean follow-up time of 4.3 years.[314] This relationship was not seen when prosthesis-patient mismatch was defined as IEOA <0.85 cm^2/m^2. Prosthesis-patient mismatch was not associated with early or late mortality in this series. Ruel and colleagues in a subsequent analysis showed that the effect of prosthesis-patient mismatch was confined to patients with preoperative LVD.[320] Using multivariate methods, they determined that overall survival and LVM regression was poorer in patients with prosthesis-patient mismatch and LVD than those who had LVD without prosthesis-patient mismatch. A confounding factor in this study was that patients with prosthesis-patient mismatch and LVD were 12 years older and had more significant comorbidities including concomitant coronary disease, which are independently associated with poorer survival and LVM regression.

Mohty-Echahidi and colleagues examined prosthesis-patient mismatch in patients receiving 19 mm and 21 mm mechanical valves and found that severe mismatch, defined as IEOA <0.60 cm^2/m^2, was associated with increased late mortality (hazard ratio 2.18) and increased CHF symptoms (hazard ratio 3.1) versus patients without mismatch. In a series of 1400 patients, Moon and colleagues reported that prosthesis-patient mismatch affected long-term survival in patients less than 60 years old but not in older patients.[321]

Several studies have also shown that prosthesis-patient mismatch does not influence clinical outcomes. Medalion and colleagues studied 892 AVRs and demonstrated that although 25% of patients received valves with an indexed internal orifice area less than two standard deviations below predicted normal aortic valve size, there were no differences in 15-year survival between patients with or without patient-prosthesis mismatch.[322]

Hanayama and colleagues recently reported a single institutional experience with patient-prosthesis mismatch in 1129 patients who were followed over a 10-year period.[323] They defined patient-prosthesis mismatch using two definitions: (1) IEOA less than the 90th percentile in the study population; and (2) valve gradient in the highest 90th percentile of the study population. The cut-off value for IEOA to define patient-prosthesis mismatch was 0.6 cm^2/m^2, which would be considered very severe by most groups. The cut-off

values for peak gradient and mean gradient were 38 mm Hg and 21 mm Hg. In this study, the average labeled size of valve in the low-IEOA and high-gradient groups were 22.4 mm and 23 mm, respectively. There were no differences in left ventricular mass index (LVMI) or survival at midterm follow-up between patients with normal and abnormal gradients. The only multivariate predictor of elevated postoperative gradient was valve size. Thus, although valve size is a predictor of abnormal postoperative gradient, no clinical significance could be correlated with this finding. Figure 34-19 shows that there were no differences in LVMI or survival at midterm follow-up between patients with or without patient-prosthesis mismatch defined as IEOA <0.6 cm^2/m^2.

More recently, Blackstone and colleagues have compiled the largest and most statistically sound examination of the role of prosthesis-patient mismatch in short- and long-term outcomes.[324] In a multi-institutional study of over 13,000 aortic prostheses, presence of an indexed GOA in the lowest 10th percentile was associated with a 1 to 2% increase in perioperative (30-day) mortality and had no effect on medium- or long-term survival (Fig. 34-20). An important finding in this study was that virtually no stented bioprostheses were in the group of patients in the lowest 10th percentile of indexed GOA, who predominantly received mechanical prostheses. In a subsequent study from the same group, Koch and colleagues prospectively examined functional status using the Duke Activity Status Index in 1108 patients undergoing AVR and found no relationship between indexed GOA and functional status at a mean follow-up of 8.3 months. Predictors of postoperative functional status are presented in Table 34-11.

Small aortic root

Many surgeons have expressed concern about postoperative outcomes in patients with small aortic roots in whom only very small (19 mm or smaller) valves can be implanted. Adams and colleagues reported significantly elevated perioperative, but not late, mortality among men, but not women, receiving 19 mm prostheses.[325] Conversely, Sawant and colleagues demonstrated that in patients with small aortic roots, body surface area and valve size were not determinants of long-term survival.[326] Studies by DePaulis and colleagues have shown that there was no difference in LVM regression between patients receiving 19 mm and 21 mm mechanical valves versus those with 23 mm or 25 mm valves.[327] Foster and colleagues showed that in patients with 17 mm and 19 mm prostheses who had resting transvalvular gradients >30 mm Hg, 93% were in NYHA class I at late follow-up.[328] Kratz and associates also reported that small valve size was not predictive of CHF or late death.[329] Khan and colleagues studied 19 mm to 23 mm Carpentier-Edwards pericardial valves and found that significant LVM regression occurred with each valve size, including 19 mm valves.[330]

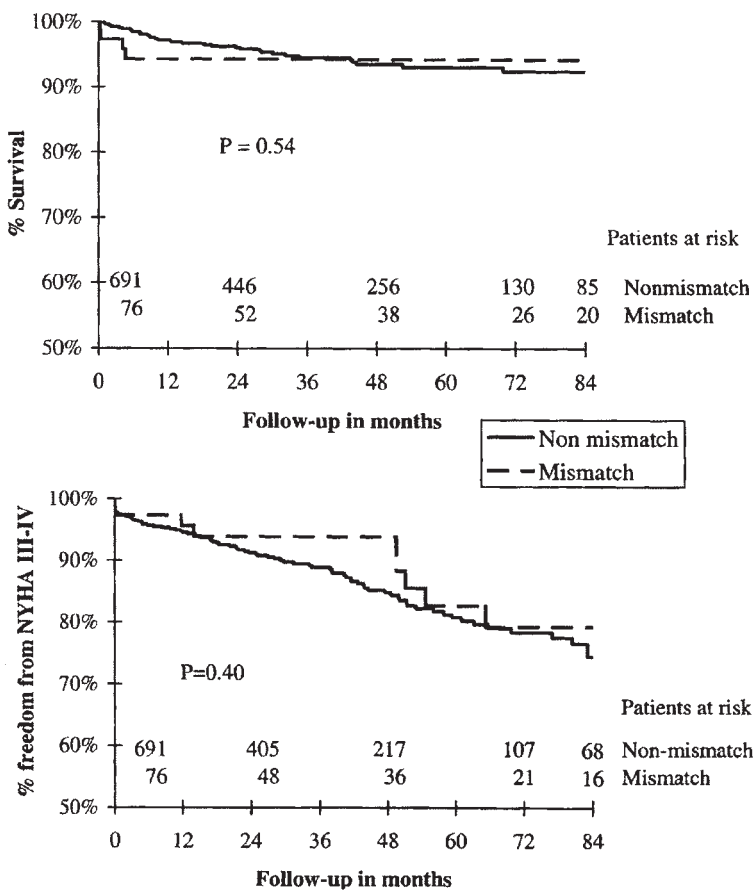

Figure 34-19. Actuarial survival and freedom from NYHA class III or IV in patients with and without prosthesis-patient mismatch. There were no significant differences in the two groups. (*Reproduced with permission from Hanayama et al.*[324])

Data synthesis

While the literature regarding the clinical significance of prosthesis-patient mismatch remains divided, proponents of the concept advocate use of mechanical prostheses, which are presumably less obstructive than stented bioprostheses, aortic root enlargement, and stentless valves used in the subcoronary position and as full root replacement to achieve improved hemodynamics. Mechanical prostheses are not likely to alleviate prosthesis-patient mismatch versus the current generation of tissue valves. Mechanical valves may even be more often associated with prosthesis-patient mismatch.[331] Aortic root enlargement procedures require significant experience operating on the aortic root and may carry excessive mortality. Sommers and David reported a doubling of perioperative mortality among patients receiving annular enlargement procedures with AVR.[332] However, Castro and colleagues reported no increase in perioperative mortality among patients receiving annular enlargement procedures, implying that there is wide variability in surgical outcomes even among highly experienced centers.[333]

Use of a stentless prosthesis in the subcoronary position requires additional technical skill and cross-clamp time. Rao and colleagues compared hemodynamic data between stented Carpentier-Edwards pericardial valves and Toronto stentless porcine valves of equivalent diameter and found no hemodynamic differences in peak or mean gradient.[334] Additionally, concerns about durability discussed previously for patients with bicuspid pathology make subcoronary stentless bioprostheses a less viable option.

Aortic root replacement in patients without ascending aortic pathology, solely to diminish the potential long-term effects of prosthesis-patient mismatch is a potentially high-risk strategy. Recent data from the Society of Thoracic Surgeons' database on over 200,000 patients suggests that mortality for aortic root replacement for this indication was 9.5 versus 5.7% for isolated AVR.[138,335] This report strongly discouraged the use of aortic root replacement for this indication.

Table 34–11.

Multivariate Predictors of Functional Recovery After Aortic Valve Replacement

Follow-up DASI	Factor	Estimate ± standard error	Estimated odds ratio (95% upper and lower confidence intervals)	*p*	Reliability (%)
	Standardized orifice size (*z* score)	0.0040 ± 0.074	1.00 (0.87, 1.16)	0.96	1
	Balancing score	0.11 ± 0.11	1.11 (0.90, 1.37)	0.3	
Worse	Female sex	−0.50 ± 0.14	0.61 (0.46, 0.80)	<0.001	79
Worse	Age*	−0.39 ± 0.075	0.68 (0.58, 0.78)	<0.001	81
Better	Preoperative DASI	0.018 ± 0.0041	1.02 (1.01, 1.03)	<0.001	94
Worse	Preoperative creatinine (mg/dL)	−0.37 ± 0.094	0.69 (0.58, 0.83)	<0.001	41
Worse	Central venous pressure in the intensive care unit (mm Hg)	−0.037 ± 0.014	0.96 (0.94, 0.99)	0.01	46
Worse	Red blood cells transfused (units)	−0.45 ± 0.14	0.64 (0.49, 0.83)	0.001	82

When faced with potential prosthesis-patient mismatch in the operating room, the decision to perform a more complex, higher-risk procedure must be balanced carefully with the potential benefits of implanting a larger prosthesis. Some reports have shown that transvalvular gradients in patients with lower IEOA often rise substantially with exercise.[336,337] Although the majority of patients undergoing AVR are elderly and unlikely to experience functional limitations from this situation, in younger, highly-active patients either root enlargement or stentless prostheses may provide better functional outcome with lower transvalvular gradients. In the rare circumstance of anticipated extreme mismatch (i.e., IEOA <0.6 cm^2/m^2) root enlargement is an acceptable approach in the hands of an experienced surgeon. Except in these circumstances, given the paucity of long-term data to support more complex procedures and well-documented increased risk, routine AVR with modern standard prostheses is acceptable and preferable.

PROSTHESIS SELECTION

An ideal aortic prosthesis would be simple to implant, widely available, possess long-term durability, would have no intrinsic thrombogenicity, would not have a predilection for endocarditis, and would have no residual transvalvular pressure gradient. Such a valve does not currently exist. Currently available options include mechanical valves, stented biologic heterograft valves, stentless biologic heterograft valves, allograft valves, and pulmonary autograft valves. Among these options pulmonary autograft valves and allograft valves are the most physiologic prostheses. They are less prone to thrombosis or endocarditis and have excellent hemodynamic characteristics.[338–346] The longevity of such valves is dependent on patient factors, the preparation of the valve, and the technical skill of the operating surgeon. Despite their potential benefits, these prostheses are not readily available and can be very technically demanding to implant compared to standard mechanical or stented bioprostheses. They are most beneficial in children and younger adults. Allograft valves may also improve the results of AVR in active endocarditis.[347] A further discussion of these valves is presented in subsequent chapters. As their use has remained confined to a few centers that perform such operations regularly, the remainder of this discussion will focus on issues regarding selection of mechanical or bioprosthetic valves.

Mechanical versus Biologic Valves

When selecting between mechanical and biologic heart valves, the surgeon and patient must balance the risks and

benefits of each choice. Mechanical valves are much less likely to undergo structural deterioration than bioprosthetic valves, and reoperation for structural valve deterioration is more common in patients with bioprosthetic valves. Mechanical valves are more thrombogenic than bioprosthetic valves and require formal anticoagulation with oral warfarin. Anticoagulated patients have a significantly increased risk of bleeding complications. Patients with mechanical valves and adequate anticoagulation do not have significantly greater risk of thromboembolic events than do those with bioprosthetic valves.[348] There is no difference in actuarial freedom from bacterial endocarditis between mechanical and bioprosthetic valves. In recent years a significant trend toward increasing use of bioprostheses has occurred in North America.

As stated earlier, the two randomized comparisons of mechanical and bioprosthetic aortic valves performed in the 1970s showed equivalent survival between valve types at 12 years of follow-up.[349,350] Long-term survival beyond 15 years was superior in the mechanical valve groups due to the risks of reoperation and structural failures of bioprostheses became more common.[351]

In these studies, the bleeding risk was significantly higher than the current standard in the anticoagulated group due to monitoring of the prothrombin time instead of the INR. Also, the rate of structural valve deterioration was higher than currently expected, since first-generation prostheses were used in these studies. It would not be practical or ethical to conduct a similar randomized study today with current prostheses. Analyses based on mathematical modeling of historic data currently suggest that at approximately 60 years of age, patients derive improved life expectancy and event-free life expectancy regardless of the need for concomitant coronary surgery.[352–354]

Special patient groups

Patients with an absolute requirement for long-term anticoagulation such as atrial fibrillation, previous thromboembolic events, hypercoagulable state, severe LVD, another mechanical heart valve in place, or intracardiac thrombus, should receive a mechanical valve regardless of age.

Patients in whom anticoagulation with warfarin is contraindicated, such as women of child-bearing age wishing to become pregnant, patients with other bleeding disorders, or those who refuse anticoagulation should receive a bioprosthesis. There is growing interest in using mechanical prostheses in women of child-bearing age and providing anticoagulation with subcutaneous low-molecular weight heparin injections.

Patients with end-stage renal failure were previously believed to have significantly elevated risk for early bioprosthetic structural valve deterioration. However, increased anticoagulation-related complications are also more likely in this group, and the current ACC/AHA guidelines do not recommend routine use of mechanical prostheses in these patients.

Age considerations

Currently available bioprostheses, such as the Medtronic Hancock II porcine and Carpentier-Edwards pericardial valve, have >90% freedom from structural valve dysfunction and >90% freedom from reoperation at 12-year follow-up.[355–357] The rate of structural deterioration is lower in patients over 65 to 70 years.

Hence, patients over 65 years at the time of surgery should receive a biologic valve. Patients under the age of 60 should have a mechanical prosthesis to minimize the risk of structural failure requiring repeat AVR in an octogenarian. Patients between 60 and 65 represent the group in whom there is still considerable debate regarding prosthesis selection. Those patients who have comorbidities such as severe CAD may be less likely to outlive their prosthesis and should receive a biologic valve. A detailed discussion of these risks and benefits of prosthesis selection should occur with all patients and their families prior to entering the operating room.

Stented versus Stentless Biologic Valves

Stentless porcine valves have gained popularity in cardiac surgery due to pioneering work by Dr. Tirone David at the Toronto General Hospital in 1988.[358] Since they lack obstructive stents and strut posts, stentless valves provide residual gradients that are similar to those of freehand allografts. Stentless valves, however, are more difficult to implant and require a longer cross-clamp time such that the risks of a more complex operation must be matched to a specific benefit the patient may receive with a stentless valve. Cohen and colleagues randomized patients to receive Carpentier-Edwards pericardial valves and Toronto stentless porcine valves and compared clinical outcomes.[359] There were no differences in the measured size of the aortic root between the two groups. Postoperative echocardiography showed that there was no difference in indexed EOA or LVM regression between groups (Fig. 34-21). They also found no difference in functional outcome between valves at 1-year follow-up (Fig. 34-22). These findings challenge the notion that stentless

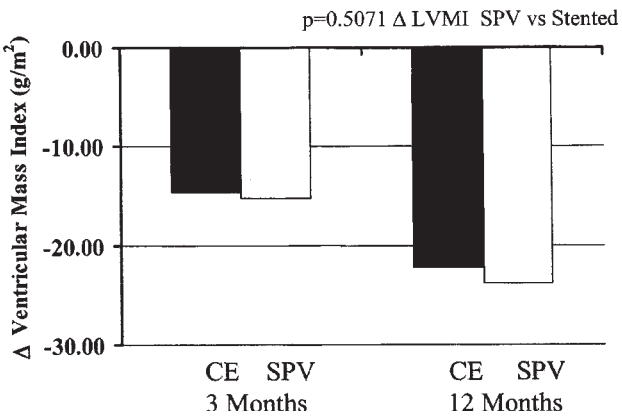

Figure 34-21. Indexed ventricular mass regression in stentless and stented valve patients over time. There were no significant differences in the two groups. Figure 34-22. Change in Duke Activity Status Index (D.A.S.I.) scores in stentless and stented valve patients over time. There were no significant differences in the two groups. CE = Carpentier-Edwards stented valve; SPV = Toronto stentless porcine valve; Preop = preoperative. (*Reproduced with permission from Cohen et al.*[359])

porcine valves provide increased IEOA or hemodynamic or clinically significant benefit. In a randomized trial comparing Sr. Jude Toronto stentless porcine valves to Carpentier-Edwards pericardial valves, Chambers and colleagues found no difference in hemodynamic function including gradients or IEOA, LVM regression, or mortality between groups. Arenaza and colleagues also performed a multicenter randomized trial comparing the Medtronic Freestyle valve to the Medtonic Mosaic valve and found increased IEOA in the stentless group, but no differences in LVM regression or clinical outcomes at 1-year.

Walther and colleagues performed a small randomized trial comparing the ability of stented porcine and stentless porcine valves to cause regression of LVH.[360] They showed that despite equivalent annular dimensions in the stented and stentless groups, larger valves (by labeled size) were implanted in the stentless group. The patients receiving stentless valves had a slightly higher degree of LVM regression than those receiving stented valves. No clinical follow-up was provided. Borger and colleagues showed modestly lower mean gradients in stentless prostheses versus stented prostheses (9 mm Hg versus 15 mm Hg) and LVMI (100 g/m^2 versus 107 g/m^2) in their nonrandomized study.[361] However, there was no difference in risk-adjusted midterm survival between groups.

Hence, there is conflicting evidence that the use of stentless valves results in improved LVM regression or clinical outcomes over stented bioprostheses. Several studies have shown adequate LVM regression in patients receiving even small stented bioprostheses. There is also little evidence that incremental improvements in LVM provide additional clinical benefit. Thus, the routine use of stentless bioprostheses cannot be recommended for most patients with small aortic roots based on currently available data. At this time, stentless porcine valves are most useful in a relatively younger patient with a small aortic root who is active and likely to be limited by the elevated residual gradient a small stented bioprosthesis may create. There are reports of decreased thromboembolic events in stentless valves.[362]

CHAPTER 35

Stentless Aortic Valve Replacement: Autograft/Homograft

Craig R. Hampton • Edward D. Verrier

The number of heart valve procedures performed annually in the United States continues to increase and surpassed 93,000 in 2003. Despite this increasing experience, the search for an ideal replacement for a diseased aortic valve continues. Currently, there are essentially five choices for replacement of the aortic valve including a mechanical valve prosthesis (e.g., St. Jude bileaflet), a stented bioprosthetic valve (e.g., xenograft), a stentless bioprosthetic valve (e.g., Medtronic Freestyle), an aortic homograft, and a pulmonary autograft (i.e., the Ross procedure). Since there is not an ideal valve choice, the selection of a suitable valve for aortic valve replacement (AVR) must be individualized through consideration of the relative advantages and disadvantages of these five options. To this end, we believe there are seven valve-related issues to be considered when selecting a valve replacement option. These include durability, flow characteristics, risk of thromboembolism and need for anticoagulation, technical ease of insertion, infectibility, availability, and valve-related noise. Consideration of these issues in the context of an individual patient will allow prudent selection of a suitable valve, all having their relative advantages and disadvantages. This chapter will provide an overview of aortic allografts and pulmonary autografts, and provide a basis for their consideration, relative to other AVR choices currently available. See Table 35-1 for a listing of the advantages and disadvantages of currently available valves.

HISTORICAL PERSPECTIVE

Gordon Murray was the first to utilize an aortic homograft for treatment of aortic valvular disease.[1] After successful attempts in the animal laboratory, Murray placed valve-bearing aortic homograft segments in the descending aorta for treatment of severe aortic insufficiency (AI) with good results up to 4 years postoperatively.[2] Subsequently, the hemodynamic benefits of heterotopic placement of an aortic homograft in the descending aorta for AI were confirmed by Beall and associates, also in the animal laboratory.[3] Kerwin and colleagues of Toronto extended the clinical experience of heterotopic homograft to nine patients, with good results in six patients up to 6 years postoperatively.[4] At nearly the same time, Bigelow and coworkers of Toronto reported placing an aortic homograft in the orthotopic position, but the patient died of a coronary thrombosis within a day.[5] Successful orthotopic placement of an aortic homograft was soon performed independently and nearly simultaneously[6] by Donald Ross of Guy's Hospital in London,[7] Barratt-Boyes of Green Lane Hospital in Auckland,[8] followed a few months later by Paneth and O'Brien of The Brompton Hospital. In 1964, Barratt-Boyes reported his early experience with aortic homografts in 44 patients, with good to fair results in all but three patients.[8]

Since these initial efforts to utilize homografts in the aortic position, the procurement and preservation of these biologic valves have changed significantly. Initially, aortic valves were implanted shortly after collection.[9] This technique fell out of favor and was rapidly supplanted by techniques to sterilize and preserve the valve for later use—a fundamental strategy of contemporary tissue banking. Valves were collected cleanly or sterilely and then were sterilized with beta-propiolactone[8,10] or 0.02% chlorhexidine,[11] followed by ethylene oxide[11] or radiation exposure.[12] After chemical sterilization, valves were placed in Hanks balanced salt solution at 4°C for up to 4 weeks, followed by freeze-drying.[8,13] Recognizing that the incidence of valve rupture was high in chemically treated valves, Barratt-Boyes introduced antibiotic sterilization of homografts in 1968.[14] Cryopreservation of allografts was introduced in 1975 by O'Brien in an attempt to increase the cell viability of preserved allografts.[15] Cryopreservation continues to be the most commonly used method for aortic allografts.

Table 35–1.

Advantages and Disadvantages of Different Types of Aortic Valve Replacements

	Durability	Hemodynamics	Thromboembolic risk	Difficulty of insertion	Availability	Infectibility	Noise
Mechanical	Excellent	Good	Low with anticoagulation	Easy	Yes	?Increased	Increased
Stented bioprosthetic	Limited	Good	Low	Moderate	Yes	?Increased	Minimal
Stentless bioprosthetic	Limited	Excellent	Low	Moderate-difficult	Yes	?Lower	Minimal
Allograft	Limited	Excellent	Low	Moderate-difficult	Limited	?Lower	Minimal
Autograft	Limited	Excellent	Low	Moderate-difficult	Yes	?Lower	Minimal

Recognizing that homografts may incite alloreactivity, it was suggested that autologous biologic valves would diminish this risk while maintaining the superior hemodynamic profile. In accord, use of the pulmonic valve to replace another valve was first reported in 1961 when Lower and colleagues of Stanford transposed the pulmonic valve to the mitral position in dogs.[16] Shortly thereafter, Pillsbury and Shumway, also of Stanford, experimentally transposed the autologous pulmonic valve to replace a diseased aortic valve.[17] Donald Ross extended this work to humans, reporting in 1967 a series of 14 patients in whom he replaced a diseased aortic valve (AV) with an autologous pulmonic valve.[18] Since that time, this procedure has come to bear his name—the Ross procedure—also described as a pulmonary autograft. Widespread early fervor about this procedure was quickly tempered when surgeons appreciated its technical demands as well as considering it to be a "double valve" replacement for a "single valve" problem. While there was a surge of renewed interest in the Ross procedure in the 1990s, this has diminished in recent years. Currently, over 240 surgeons worldwide have performed the Ross procedure, as reported in The Ross Procedure International Registry, which was established in the early 1990s to catalogue these procedures and follow the outcomes.

ALLOGRAFTS

Procurement and Preservation

In the United States, the majority of allograft valves are obtained from heart-beating organ donors whose hearts are not suitable for transplantation. Allografts obtained from fresh cadavers less than 24 hours old comprise the second main source of valves. The processing of cadaveric tissue is increasingly performed by regional tissue centers that specialize in the procurement and preservation of human tissues for ultimate allotransplantation. The increasing prevalence of cardiac allotransplantation has allowed the use of fresh "homovital" allografts,[19] which may have enhanced preservation of cellular viability. Ideally, fresh valves would be implanted within 24 hours, but even at centers with significant experience, the interval between harvesting and implantation is up to 60 days, with an average interval of 3.9 days.[19] Accordingly, cryopreservation is the most common technique used, which optimizes cellular viability[15] and prolongs shelf life, which is an obvious advantage given the shortage of organ donors.

For cryopreservation, the heart is procured under sterile (multi-organ donor) or clean (cadaveric donor) conditions and gently rinsed with cold isotonic salt solution (e.g., Ringer lactate) to remove the blood and its elements from the cardiac chambers. The heart is then placed in a bag containing ice-slush solution and kept cold until further processing. Warm ischemia time does not exceed 12 hours, unless the donor is in an environment with temperature $\leq$8°C within 6 hours of death, which can extend the "warm" ischemia time to 24 hours. Donor blood is obtained for culture and serologic testing for common infectious agents (e.g., hepatitis B and C, human immunodeficiency virus, human T-cell lymphoma virus, and *Treponema pallidum*). The following details are based on procedural protocols of The Northwest Tissue Center, Seattle, WA,[20] and are similar to those of other institutions.[21] Once at the tissue center, an aortic block is dissected in a controlled environment (a class 100 clean room environment). Donor tissue and the transport solution are cultured for aerobic and anaerobic organisms, fungi, and acid-fast bacilli. Proximally the dissection includes the aortic ring and the anterior leaflet of the mitral valve with a variable amount of ventricular muscle, and extends distally to the left subclavian

Figure 35-1. Aortic valve allograft after harvesting from the donor. The block includes a variable amount of ventricular muscle and the anterior leaflet of the mitral valve. Additional trimming for replacement is performed at the time of implantation. (*Reproduced with permission from The Northwest Tissue Center, Puget Sound Blood Center.*)

artery, including the branches of the thoracic aorta. The coronary ostia are ligated, allowing a subsequent interposition "free-root" allograft if needed. The base of the graft contains a variable amount of ventricular muscle that may be trimmed at the time of graft implantation. The valve is inspected for leaflet fenestrations, atheroma, or damage that may make it unsuitable for implantation. Of these, leaflet atheroma absolutely contraindicates use of the allograft, while fenestrations or other damage are relative contraindications, and depend on their severity and magnitude. Obturators are then used to size both the valve and the aorta (Fig. 35-1).

After harvesting, the allograft block undergoes a series of rinses and is then placed in a nutrient medium (e.g., RPMI-1640) with low levels of antibiotics (polymyxin B sulfate 250,000 units, cefoxitin sodium 60 mg, vancomycin HCl 12.5 mg, and lincomycin HCl 30 mg)[22] for sterilization. Although this regimen originally included amphotericin B, it is often omitted to optimize cellular viability.[23] The allograft can then either be used as a fresh homovital allograft, or prepared for cryopreservation. Throughout this process, cultures are serially obtained to rule out contamination that may preclude use of the graft.

The sine qua non of cryopreservation is controlled rate freezing, as introduced by O'Brien and colleagues in 1975.[15] Prior to packaging, the air in the packaging room is sampled for viable particles, as are the gloves of the technologist, and three designated locations in the sterile packaging field. The allograft is transferred from the antibiotics to a sterile storage pouch containing culture medium (e.g., RPMI-1640), 10% fetal calf serum, and 7.5% dimethyl sulfoxide DMSO (a cryoprotectant). These substrates are designed to provide nutritive support to the allograft and minimize crystal formation and tissue damage during the freezing process. A final sample is taken of the packaging solution for aerobic and anaerobic organisms. Within 2 hours of exposure to DMSO, the allograft is frozen at −1°C per minute down to −40°C and then placed in vapor-phase liquid nitrogen storage (about −195°C) until it is used. After tissue cultures and serology results are available (about 4 to 6 weeks) and negative, the valve may be used for implantation; if there are any positive culture or serology results, the valve is discarded.

After release of the allograft from the tissue center, it is shipped in a container validated to maintain temperatures below −100°C for 10 days. Two temperature-sensitive indicators, which turn red if temperatures exceed −100°C, are included with each shipment to ensure maintenance of shipping temperatures. Upon arrival at the institution where it will be used, the storage pouch is removed from the liquid nitrogen and placed in warm saline (37° to 42°). The allograft size and

number are confirmed. After removal from the storage pouch, the allograft then undergoes a series of gentle rinses and thawing, in solutions that have increasingly dilute DMSO, followed by a final rinse in pure nutrient media prior to use. The allograft is then ready for final trimming and implantation.

Cellular and Immunologic Aspects of Allografts

Normal valves are ultrastructurally comprised of viable cellular components, including endothelium, fibroblasts, and smooth muscle cells, and an amorphous and fibrillar extracellular matrix, derived primarily from fibroblasts and smooth muscle cells.[24] In nonpathologic states, there is a steady state between destruction of these elements and remodeling, which underlies an overall structure and function. In accordance with the paradigm that structural integrity, and thus function, depends on cellular viability of an allograft, preservation techniques have attempted to optimize the preservation of viable cellular elements to improve function and durability.

As mentioned, earlier methods of chemical sterilization and irradiation had a prohibitive incidence of cusp rupture[14] and histologic analysis of these allograft valves reveals nonviable cellular elements.[25] Antibiotic sterilization of allografts and storage in a balanced salt solution or nutrient medium at 4°C does not maintain cellular viability beyond a few days.[26,27] The durability of these valves is improved over chemically sterilized valves with a freedom from reoperation for valve degeneration at 10 years of 89%.[15] Gentle procurement and cryopreservation of allografts has been shown to maintain donor fibroblast viability up to $9^{1}/_{2}$ years after implantation in one patient, and viable fibroblasts have been consistently demonstrated in a small number of other patients.[15] More recently, persistence of viable, functional donor fibroblasts in allografts harvested up to 70 months earlier has been reported.[29] Also, using in situ hybridization technology, the viable fibroblasts in the explanted allografts were demonstrated to be of both recipient and donor origin. Other investigators have demonstrated no cellular viability of allograft valves after antibiotic treatment[26] or after explantation.[28] Of note, however, the methods of valvular preservation in the latter investigation[28] were not reported, and these valves were explanted primarily for deterioration, contributing to significant selection bias. In the end, the extent to which viable cellular elements persist in allografts after cryopreservation is not clear. Given the occasional findings of viable cells, particularly fibroblasts, up to 9 years after implantation,[15] it is likely that some viable cells persist in allografts, at least some of the time. Moreover, when viable cells are present, they are likely to be of both donor and recipient origin.[15,29] The discrepant findings with respect to the persistence of viable cells in the allograft may relate to warm ischemia times or differences in procurement and preservation techniques. More importantly, when present, the extent to which these viable fibroblasts remain functional and contribute to the structural integrity of the allograft components is not known.

While modifications of valve preservation have attempted to maintain cellular viability of the allograft[15] to improve long-term structural integrity and function,[30] the presence of viable donor cells may be detrimental by inciting an allograft rejection reaction.[31] Multiple studies have demonstrated the generation of donor-specific alloantibodies directed against human leukocyte antigens (HLA) class I (A and B antigens) and II (DR antigens) in allograft valve recipients.[32,33] The development of panel reactive antibodies seems to increase with time,[33] approximating 82% at 6 years postgraft implantation,[34] occurs in both adults and children, and is irrespective of the method of cryopreservation.[35] Despite consistent evidence of antibody formation directed against the HLA antigens of the allograft, the clinical significance is not clear.

Dignan and associates reported a significant association between HLA class II antigen mismatch and postoperative fever and homograft dysfunction in recipients of cryopreserved allografts.[36] In recipients of homovital allografts, Smith and colleagues reported no significant association between HLA class I or II antigens and long-term (6 years) valve function,[34] although there was an increased prevalence of valve degeneration in those patients with HLA antibodies: in HLA antibody–negative patients the actuarial freedom from valve degeneration at 1, 5, and 10 years was 100%. In patients with panel reactive antibodies <50% freedom from valve degeneration at 1, 5, and 10 years was 100, 97, and 92%, and 98, 94, and 88% in those patients who were highly sensitized.[34] Taken together, these data suggest that antibody-mediated alloreactivity may play a causal role in allograft valve dysfunction over time, but larger studies are certainly needed with adequate power to detect small (i.e., 5% at 10 years) differences between allograft recipients who are HLA matched and mismatched. In the meantime, until such data are available, it has been suggested that prospective matching of HLA antigens may be warranted.[34] Recognizing that investigation of allografts in humans is limited to preimplanation analysis (i.e., during procurement or preservation) or valves that require explantation due to valve failure, heart transplantation of the recipient, or recipient death, investigators have developed alternative models for this inquiry.

Accordingly, to better understand the immunologic aspects of allograft valve dysfunction, numerous investigators have used animal models of allograft implantation. Multiple studies of allograft implantation across major histocompatibility complex barriers in rats demonstrate significant cellular infiltration into thickened valve leaflets over the first 28 days, which is temporally followed by valve degeneration and failure.[37–40] The cellular infiltration may be phasic, characterized by early monocyte infiltration,[37] followed by progressive monocyte/macrophage and T-lymphocyte infiltration, which is maximal by 7 days postimplantation.[37,40] There is a coincidental decline in allograft donor cell viability over this time that is paralleled by declining valve structure and function.[37] Importantly, in T-cell–deficient rats, these cellular events do not occur and allograft function is preserved, providing additional support for immune-mediated valvular destruction.[38] Moreover, immune modulation with cyclosporine and antiadhesion molecule (anti-α4/β2 integrin) therapy attenuates leaflet cellular

infiltration and prevents allograft structural failure.[41] Taken together, these data strongly support a donor-specific, cell-mediated (primarily T lymphocytes) immune reaction directed against the donor alloantigens that is followed by structural valve failure—a cellular cascade typical of solid organ rejection.

In summary, despite intensive investigation over the past three decades, the relative contribution of the immune response, preservation techniques, and warm ischemia time to ultimate valve degeneration (i.e., sclerosis or calcification) is not clear. More importantly, after consideration of the structural benefits and the immune-reaction risks, the net advantage of maintaining cellular (particularly fibroblasts) viability in the allograft is not well defined.[31] Future investigations should endeavor to further clarify the relative contributions of these factors to allograft valve antigenicity, immunogenicity, and durability. Furthermore, the impact of immune modulation on long-term allograft function warrants further study.

Indications

Aortic valve replacement with an allograft has a number of advantages including excellent hemodynamic profile with low transvalvular gradients and possibly enhanced regression of left ventricular mass (LVM),[42] low risk of thromboembolism without the need for systemic anticoagulation, and low risk of prosthetic valve infection. Allograft durability is limited, however, with a freedom from reoperation at 20 years of 38 to 50% and a freedom from structural valve failure at 20 years of 18 to 32%.[43,44] The incidence of structural failure is dependent on the ages of the recipient and the donor. Allograft failure increases with decreasing recipient age, and durability is improved in older recipients. Also, allograft failure increases as the donor age increases. Considering these data underscoring poor allograft durability, we believe the current indications for an aortic allograft are limited. The primary indication in adults is for treatment of active AV endocarditis. However, we are not aware of any data indicating the superiority of allografts compared to other valve options in this setting, and the ideal valve choice for replacement of an infected AV has not been defined. Aortic allografts can also be considered for patients requiring composite valve/root aortic replacement who cannot be anticoagulated.

Preoperative Evaluation

Preoperative preparation for placement of an aortic allograft is similar to that for other AV operations. Transthoracic echocardiography (TTE) is an invaluable diagnostic tool for evaluation of the AV and associated anatomic structures, including the leaflets, the annulus, the sinuses, the sinotubular junction, the subvalvular left ventricular outflow tract (LVOT), and the ascending aorta. In this regard, the preoperative TTE can accurately predict aortic annulus diameter within a few millimeters, and thus the size of the homograft required.[45–47] Transesophageal echocardiography (TEE) should routinely be used for intraoperative confirmation of the anatomy and to assist with sizing of the homograft, and to assess postrepair function. The accuracy of TEE in assessing annular dimensions has been demonstrated.[48,49] While TTE and TEE can accurately approximate the annular dimensions and homograft size, direct surgical measurement is imperative.

Operative Technique

General preparation

A full median sternotomy is used with standard techniques of cardiopulmonary bypass (CPB). Aortic cannulation is obtained as far distally as possible, near the innominate artery, and a two-stage cannula is placed into the right atrial appendage. A ventricular vent can be placed into the right superior pulmonary vein. Both antegrade and retrograde blood cardioplegia are delivered. The aortotomy incision can be transverse or an obliquely oriented reverse "lazy-S" that begins above the right coronary ostia (Fig. 35-2). After

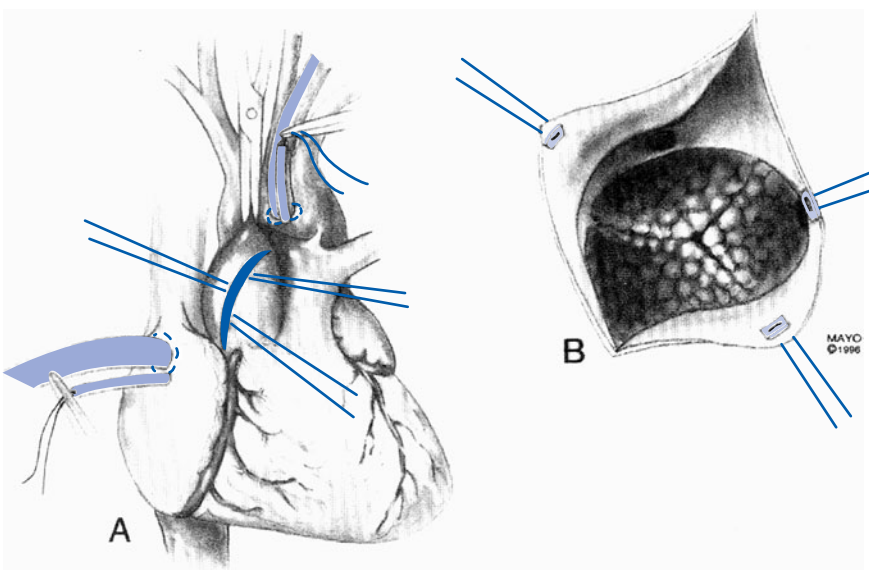

Figure 35-2. Standard cardiopulmonary bypass is performed. A "lazy-S" or oblique aortotomy is performed beginning above the right coronary cusp with the transverse portion just cephalad to the noncoronary cusp. This incision provides excellent exposure for all techniques when replacing the aortic valve and root. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

retraction of the aorta, facilitated with silk stay sutures, the valve is excised. The aortic root and annulus are then closely examined for geometric morphology and symmetry, indicating feasibility of a good result with a homograft. Next, the aortic ring is sized with standardized obturators or Hagar dilators. Since this represents an external diameter of the recipient, and allografts are sized based on internal diameters, an allograft 2 to 4 mm smaller than the recipient measurement is obtained. The appropriately sized allograft can then be thawed. If the allograft was selected based on accurate TTE or TEE measurements, it should already have been thawed. The allograft is then trimmed.

Because the allograft block contains a variable amount of ventricular muscle, mitral leaflet, and the arch, the goal of trimming is to remove excess tissue and tailor the allograft for placement depending on the planned insertion technique. To this end, the mitral leaflet is shaved and trimmed, and the ventricular septum is debulked. A straight lower margin, which will contain the lower suture line, is created 2 to 3 mm below the nadir of each aortic cusp. If the freehand scalloped techniques (i.e., scalloped or intact noncoronary sinus) are to be used, the sinuses are removed from the ascending aorta, leaving three pillars of aorta supporting each commissure of the cusps. For the intact noncoronary sinus technique, the noncoronary sinus is spared (Fig. 35-3). Finally, in cases of active endocarditis with annular abscess, the excess allograft tissue may be used to reconstruct the annulus following adequate débridement.

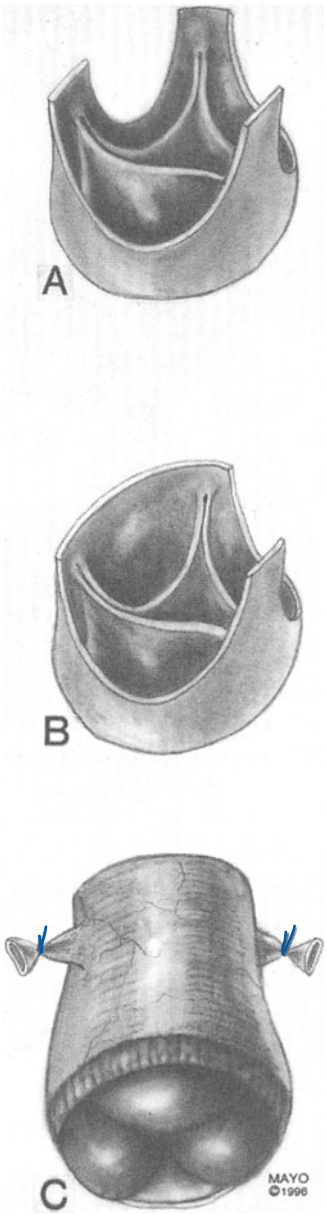

Figure 35-3. Preparation of an aortic homograft from the aortic block. The ventricular muscle and mitral leaflet are removed. (A) The freehand subcoronary insertion technique involves removal of sinus aorta within 5 mm of the cusp attachments down to within 3 mm of the cusp bases, thus removing all three sinuses. (B) The intact noncoronary sinus technique involves preservation of the noncoronary sinus. (C) For aortic root replacement, the entire aortic wall can be retained, and then be implanted as an "inclusion cylinder" or "mini-root" insertion. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

Techniques of allograft placement

There are multiple techniques for placing the allograft in the aortic position, and the strategies have continued to evolve over time. Ross[7] and Barratt-Boyes[50] originally described the 120° rotation scalloped freehand technique. Numerous groups later modified this technique, whereby the right and left coronary sinuses were scalloped, but the noncoronary sinus was left intact—the intact noncoronary sinus technique. Later this technique was further altered to preserve all the sinuses on the donor and insert the allograft as a cylinder within the recipient aortic root, with reimplantation of the coronary ostia as needed. More recently, the allograft has been implanted as a mini-root interposition graft when the severely diseased aortic root must be excised. Thus, there are essentially four techniques for placing an aortic allograft: (1) 120° rotation scalloped implant, (2) intact noncoronary sinus scalloped technique, (3) aortic root inclusion cylinder technique, with reimplantation of the coronary ostia as needed, and (4) aortic mini-root replacement with interposition allograft.

SCALLOPED 120° ROTATION FREEHAND TECHNIQUE: For the scalloped 120° freehand rotation technique, the sinus aorta is trimmed within 5 mm of the cusp attachments down to within 3 mm of the cusp bases, effectively removing all three sinuses.[50] The valve is then rotated 120° in the counterclockwise direction, so that the donor right sinus lies below the recipient left coronary sinus (Fig. 35-4). This critical maneuver brings the weaker muscular portion of the allograft posteriorly adjacent to the fibrous trigone and anterior leaflet of the mitral valve.[50,51] Two suture lines are required for this technique. The lower suture line can either be a continuous running suture or simple interrupted sutures can be used, usually of 4-0 or 5-0 polypropylene (Figs. 35-5 through 35-7). For the running suture, the homograft can be turned

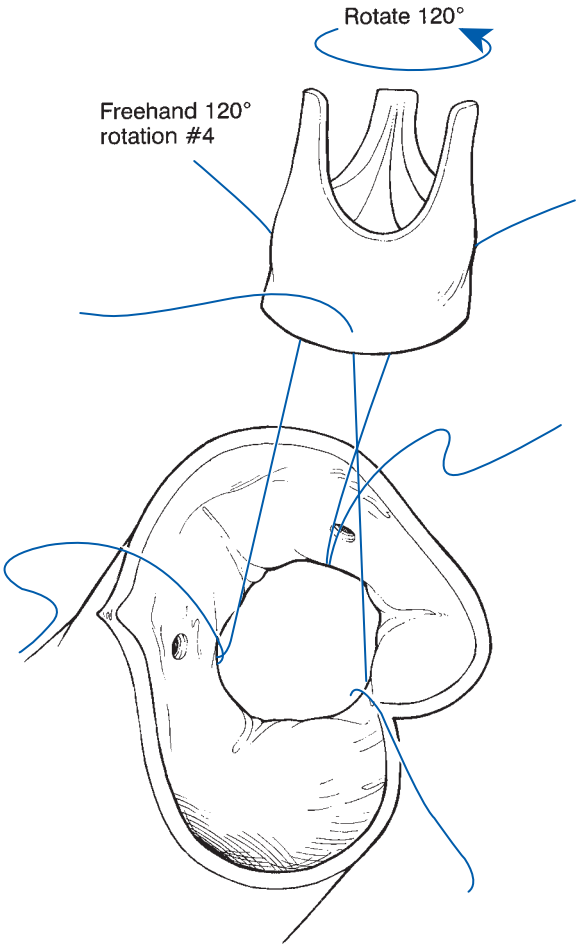

Figure 35-4. For the scalloped 120° rotation freehand technique, the allograft is rotated 120° counterclockwise so that the donor right sinus lies below the recipient left coronary sinus. Three orientation stay sutures are placed below the nadir of each cusp.

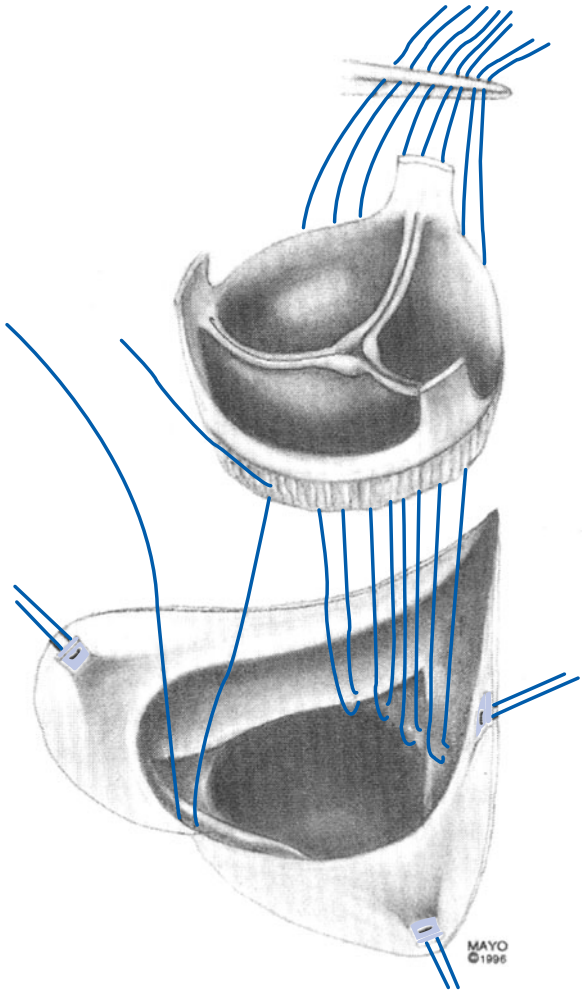

Figure 35-5. The inferior suture line with simple interrupted sutures. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

inside out to facilitate the lower suture line. In the area of the membranous septum, sutures are placed more superficially to avoid the conduction system.

As Dearani,[51] McGiffin,[52] and others[53,54] have emphasized, proper alignment of the commissures in the aortic root is absolutely critical for proper coaptation of the AV leaflets to ensure good long-term graft function. Accordingly, if the commissures are malaligned or kinked, the leaflets will not coapt properly and a regurgitant valve ensues. Moreover, if there is only slight malalignment initially with a competent valve, the free cusp edges may be subjected to increased stresses over time, leading to premature structural deterioration and aortic regurgitation (AR).[51] Similarly, size discrepancy between the donor allograft and the recipient sinotubular junction is likely to result in aortic insufficiency.[55] For these reasons, the scalloped 120° freehand rotation technique is considered more demanding than the other allograft placement techniques and may have poorer long-term results than the other methods of allograft placement.[44,51–54] Recognizing these technical and physiologic aspects of the scalloped subcoronary implant, it is a good technique for patients with small, symmetric aortic roots and sinotubular junctions, while it is a poor choice for those with dilated, asymmetric, or severely diseased roots or sinotubular junctions.

FREEHAND INTACT NONCORONARY SINUS TECHNIQUE: Scalloping of the right and left coronary sinuses while preserving the noncoronary sinus is a technical extension of the scalloped 120° subcoronary implant technique (Fig. 35-8). This modification increases stability of the homograft and maintains symmetry more easily. Furthermore, the risk for noncoronary cusp prolapse is reduced in patients with a dilated or abnormal sinotubular junction.[56] Accordingly, it is a reasonable choice for patients with mildly dilated or asymmetric aortic roots and those with AI. For the intact noncoronary sinus technique, the allograft is prepared as above, except the noncoronary sinus is preserved. The allograft is then inserted into the aortic root maintaining anatomic alignment without any rotation and is sutured as described above. Additionally, mattress sutures are placed through

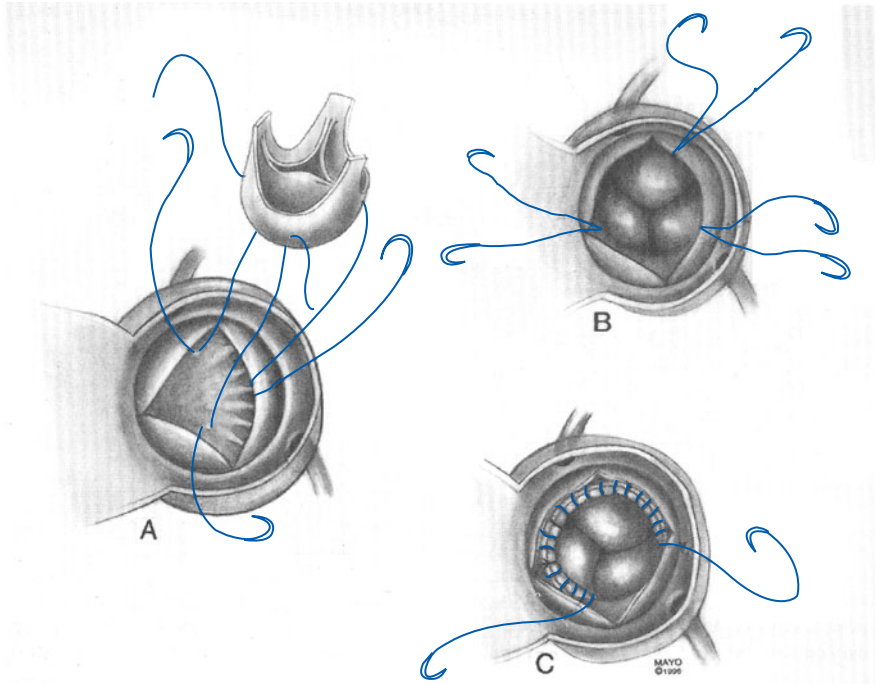

Figure 35-6. The inferior suture line with continuous suture. (A) The double-arm orientation stay sutures facilitate placement. (B) The allograft is inverted into the ventricle and the stay sutures are tied. (C) The stay sutures are then "run" in a clockwise manner to complete the lower suture line. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

the native aorta and the noncoronary sinus of the allograft to obliterate the space between the noncoronary sinus and the native aorta.

AORTIC ROOT REPLACEMENT: In patients who have dilated or geometrically distorted aortic roots, root replacement techniques are a good alternative. In many ways these techniques are technically easier to perform than the freehand techniques described above. Furthermore, a 2 to 3 mm disparity in donor-recipient root size is tolerated reasonably well, which increases the effective donor pool and reduces the probability of not having an allograft available. Despite earlier concerns about increased perioperative morbidity with root replacement techniques, recent reports from experienced surgeons do not support this.[51,57] Root replacement has become the most commonly used technique for placement of a homograft in the aortic position.

AORTIC ROOT REPLACEMENT WITH INCLUSION CYLINDER TECHNIQUE: Ross and others modified the aforementioned techniques to place the allograft as a sleeve or cylinder within the aortic root. The technique of implantation is very similar to that outlined above. For the inclusion cylinder technique, the sinuses are retained, and the cusp-sinus relationships are preserved (Fig. 35-9). Depending on the length of the cylinder, the recipient coronary ostia may need reimplantation into a buttonhole in the side of the allograft or directly into the donor coronary ostia. Conversely, if the distal aspect of the allograft is caudal to, or near the recipient coronary ostia, then minimal scalloping of the allograft wall will suffice to ensure coronary flow. We create the

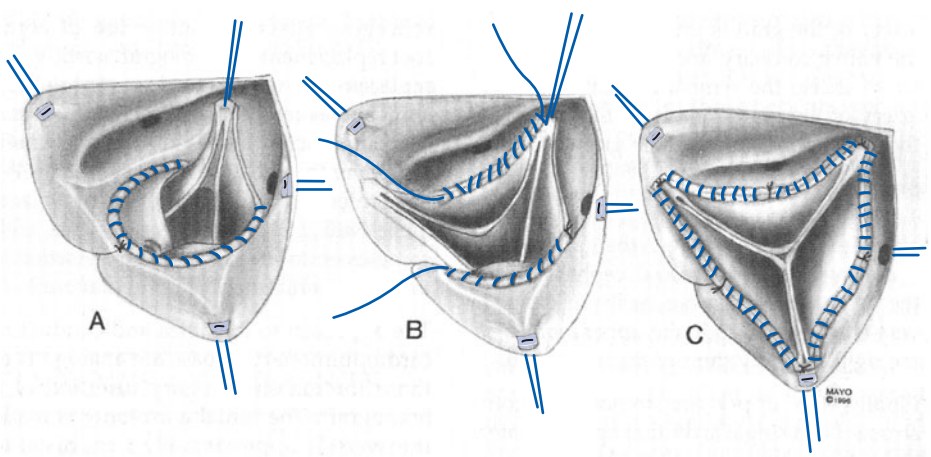

Figure 35-7. The downstream continuous suture line. (A) The allograft is everted after completion of the inferior suture line, by applying traction to the commissural posts. (B) A continuous suture completes the implantation. (C) Completed suture line. Philadelphia, Lippincott-Raven, 1998.*)

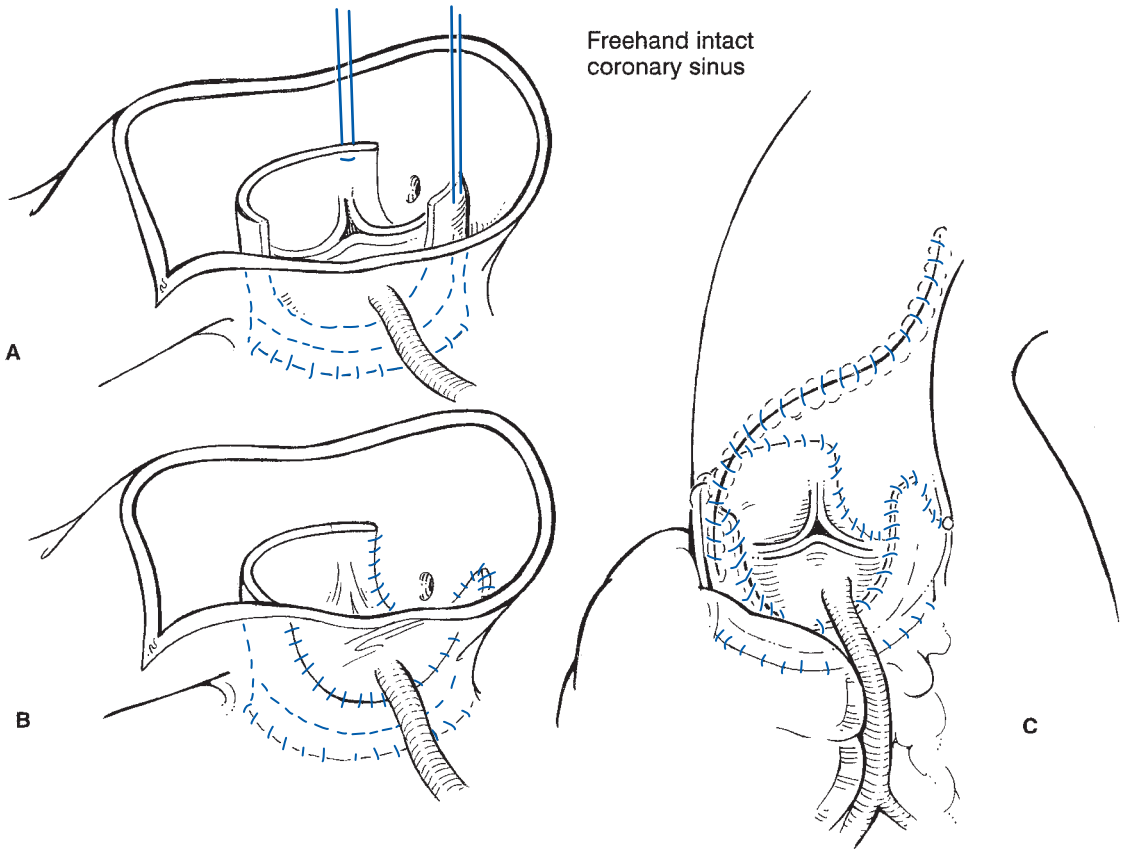

Figure 35-8. The intact noncoronary sinus technique. (A) This technique is nearly identical to the scalloped freehand technique, except the anatomic alignment of the donor allograft is maintained. (B) The noncoronary sinus is sutured to the corresponding aortic wall after partial closure of the aortotomy. This ensures minimal tension on this suture line. (C) The space behind the noncoronary sinus is obliterated with a U-stitch and the aortotomy is closed.

proximal suture line with everting, pledgeted horizontal mattress 2-0 Ticron sutures, and use a running 4-0 polypropylene suture for the distal suture line. The coronary buttons are reimplanted with a running 5-0 polypropylene suture.

AORTIC ROOT REPLACEMENT WITH FREESTANDING (INTERPOSITION) ROOT REPLACEMENT: The aforementioned techniques have been further modified to allow complete, or freestanding, replacement of the aortic root, now the most commonly used technique for allograft placement. To this end, the aortic root is completely excised and the homograft is interposed as a cylinder between the LVOT and the ascending aorta. Again, we use everting, pledgeted 2-0 Ticron horizontal mattress sutures for the proximal suture line, and a running 4-0 polypropylene suture for the distal suture line. The coronary arteries are reimplanted into the side of the allograft using a running 5-0 polypropylene suture. In all the aforementioned techniques, the aortotomy is closed with a running 4-0 polypropylene suture.

Postreplacement assessment

Intraoperative TEE with Doppler color-flow measurement is the most valuable postreplacement assessment tool, after the patient has been separated from CPB. The accuracy of the TEE assessment can be further enhanced with volume loading and administration of phenylephrine to effect vasoconstriction. Moreover, the transvalvular gradient, orifice area, subvalvular structures, and presence of regurgitation may all be accurately determined with TEE. With appropriate loading conditions, moderate to severe AI warrants reinstitution of CPB with inspection and revision of the allograft as needed. Mild AI is usually tolerated well and does not warrant re-exploration.

Postoperative management

Postoperative management following allograft placement is similar to that of other aortic valve replacements, and is dictated by the antecedent physiology that resulted from the aortic stenosis (AS) or regurgitation that required surgery. Aortic stenosis produces a hypertrophied, noncompliant ventricle that requires adequate preload and maintenance of sinus rhythm for adequate cardiac output.

In contrast, AI results in a dilated left ventricle that may be coincidentally hypertrophied. Again, ensuring adequate preload and aggressively treating arrhythmias is imperative. Since patients with AI are chronically vasodilated to maintain systemic perfusion, vasoconstricting agents may

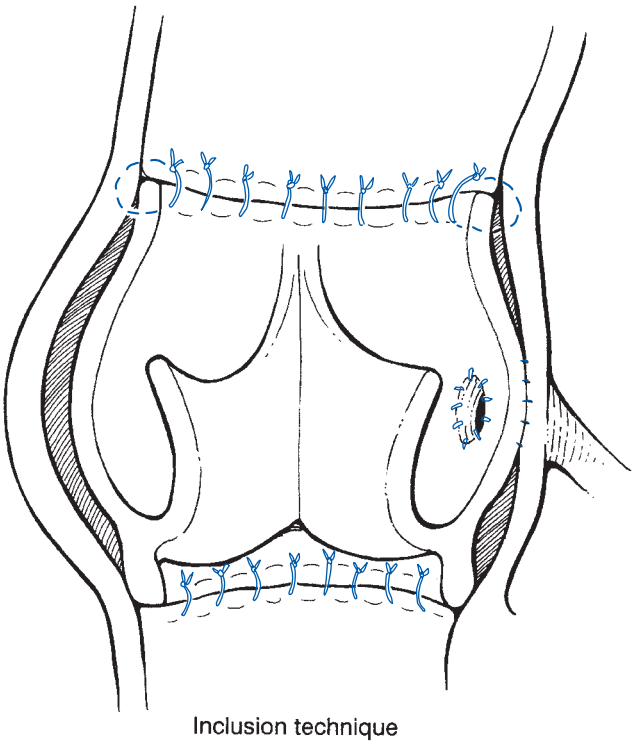

Figure 35-9. The inclusion cylinder technique for aortic root replacement. The cylinder retains the aortic allograft anatomic relationship. Depending on the length of the cylinder, the recipient coronary ostia may require reimplantation.

be required after the patient is normothermic in the intensive care unit.

In both of these groups, systolic hypertension should be treated aggressively to protect the aortic suture line. Other than atrial arrhythmias, which are treated aggressively to restore atrial-ventricular synchrony, these patients are also susceptible to heart block, since the atrioventricular node and left bundle lie in the membranous septum underneath the right coronary annulus. When this occurs, epicardial pacing is employed as needed, and when persistent beyond a few days, a permanent pacer may be placed.

Long-term anticoagulation is not required and once-daily aspirin suffices.

Results

Perioperative complications

In patients without endocarditis at the time of allograft placement, operative mortality is 1 to 5%.[43,44,57] Notably, numerous experienced and talented groups have reported that the root replacement technique does not impact early mortality.[44,57] In contrast, patients with endocarditis at the time of allograft valve placement have a much higher early mortality, from 8 to 16%.[19,44,59–61] In these patients, early mortality was higher in patients with cardiogenic shock,[61] or prosthetic valve endocarditis (18.8%) compared to native valve endocarditis (10%).[59]

Early postoperative AI occurs infrequently and most often results from technical factors, like inaccurate sizing of the allograft, or valve distortion during placement, particularly with the scalloped subcoronary implant technique. This complication should be appreciated intraoperatively with loading maneuvers and intraoperative TEE, as previously mentioned.

Hemorrhage, heart block, stroke, myocardial infarction, and infectious complications occur with similar frequency to those of other AVRs, and are not unique to homografts.

Long-term outcomes

As mentioned, 30-day mortality following homograft placement is less than 5% in patients without endocarditis. Crude survival at 10 and 20 years is reported to be 67 and 35%, respectively,[44] while in other studies actuarial survival at 10, 20, and 25 years is 81,[43] 58,[43] and 19%[57] (Table 35-2).

The durability of allografts is limited. Structural valve failure (aka, primary valve failure or deterioration) of allografts increases with time, and approximates 19 to 38% at 10 years and 69 to 82% at 20 years.[43,44] Structural deterioration appears to be age related, with earlier failure in younger recipients,[57] while Lund and associates have found that recipient age >65 and increasing donor age may increase structural failure.[44] Freedom from repeat AVR, for any reason, parallels structural valve failure and is 86.5% and 38.8% at 10 and 20 years, respectively.[43]

Importantly, when structural valve deterioration occurs, we have found reoperation and allograft valve/root excision to be technically quite demanding. Grossly, the allografts become severely calcified, which makes circumferential dissection very challenging, particularly at the coronary button ostia. While the coronary arteries themselves are usually normal-quality tissue, the proximal rim of the button is often calcified, making removal and reimplantation more challenging. Furthermore, because the base of the allograft also becomes heavily calcified, we have often found the annulus to be heavily scarred and calcified, and subsequently narrowed. Bearing in mind the concept of patient-prosthesis mismatch, and the goal of providing an effective orifice area index (>0.75 cm^2/m^2), we have had a low threshold for performing an annular enlargement procedure (both posterior and anterior). Taken together with the limited durability, relative to other currently available options with comparable versatility, we almost never use allografts for replacement of diseased AVs.

Hemodynamic characteristics of allografts are excellent at short- and medium-term follow-up, both at rest and during exercise.[62,63] However, progressive allograft dysfunction develops over time that coincides with deteriorating hemodynamic performance of a progressively abnormal valve.

Table 35–2.

Long-Term Follow-Up of Homograft Valves: Summary of Large Experiences

Reference	Patients (no.)	Follow-up (y)		Overall survival			Freedom from: Structural valve failure			Freedom from: Reoperation AVR			Freedom from: Thromboembolism		
		Max	Mean	10 y	15 y	20 y	10 y	15 y	20 y	10 y	15 y	20 y	10 y	15 y	20 y
Lund et al[44]	618	27.1	10.1	67%	48%	35%	62%	34%	18%	81%	55%	35%	89%	85%	80%
Langley et al[43]	200		15.6	81%	68%	58%	81%	62%	32%	87%	70%	39%	Overall,	99%	Freedom
O'Brien et al[57]	1022	29	7.3	77%	60%	42%				Overall, 87%			94%	92%	83%

AVR = aortic valve replacement.

Infectibility of allografts is low, with freedom from endocarditis at 10 years of 93 to 98%,[43,44] and at 20 years of 89 to 95%.[43,44,57] Similarly, freedom from thromboembolism at 15 and 20 years in patients undergoing AVR plus coronary artery bypass graft (CABG) is 92 and 83%, respectively.[57] O'Brien and colleagues found that neither preservation methods or implantation techniques affected overall 20-year rates of thromboembolism, endocarditis, or structural valve deterioration.[57]

In patients with active endocarditis requiring AVR, results are much poorer. Operative mortality is nearly twice that of patients without endocarditis, from 8 to 17%,[59–61] and is higher in patients with prosthetic valve endocarditis.[60] Late survival ranges from 58% at 5 years[59] to 91% at 10 years,[61] and is significantly lower in patients with prosthetic valve endocarditis (PVE).[60] Importantly, the risk of recurrent endocarditis is <4% up to 4 years postoperatively.[51,60,61] As a result of these acceptable outcomes in a high-risk group of patients, many consider allografts the preferred valve for aortic replacement in patients with active endocarditis.

Conclusions

Allograft replacement of an aortic valve has become less common with the increased availability of bioprosthetic valve alternatives. The aortic allograft is a versatile valve allowing placement as a valve or as an aortic root replacement, which is the most common insertion technique. Aortic allografts have many favorable attributes including low operative mortality rate, excellent early and midterm hemodynamics across the allograft, low valve-related noise, low thrombogenicity, and low infectibility. The primary, and significant, shortcoming of aortic allografts is progressive deterioration of valve structure and function over time, which limits its use in younger patients with long life expectancy. Limited availability and technical expertise for insertion are also limiting factors for more widespread utilization of aortic allografts. For patients with active endocarditis of either the native or prosthetic AV, allograft replacement is a reasonable option. Furthermore, with respect to biologic replacement of the aortic root, longer follow-up is needed for the currently available xenografts to determine the relative durabilities between aortic allograft root replacement and xenograft root replacement.

PULMONARY AUTOGRAFT

Theoretical Considerations

Replacement of a diseased aortic valve with a pulmonary autograft has a number of advantages including: (1) freedom from thromboembolism without the need for anticoagulation; (2) improved hemodynamics through the valve orifice without obstruction or turbulence; (3) growth of the autograft with time, particularly beneficial for young patients who continue to grow after receiving the aortic autograft;[64] and (4) the assumption that replacement of the AV with living autologous tissue is preferential to prosthetic or xenogeneic materials.

Patient Selection

In addition to individual surgeon experience, a number of patient factors influence consideration of the Ross procedure for replacement of a diseased AV. Table 35-3 summarizes the important patient factors to bear in mind when considering the Ross procedure. The only absolute contraindications are significant pulmonary valve disease, congenitally abnormal pulmonary valves (e.g., bicuspid or quadricuspid), Marfan syndrome, unusual coronary artery anatomy, and probably severe coexisting autoimmune disease, particularly if it is the cause of the aortic valve disease. Of note, bacterial endocarditis is not a contraindication for the Ross procedure, though when present, it

Table 35–3.

Patient Factors Influencing Ross Operation Selection

Favorable	Unfavorable
Young	Age <1 or >70 years
Anticoagulation contraindicated	No contraindications to anticoagulation
Good left ventricular function	Severe left ventricular dysfunction
Aortic stenosis	Aortic insufficiency
Small–normal aorta and aortic annulus	Larger than normal or dilated aorta or annulus
No pulmonic valve pathology	Pulmonic valve pathology
>20 Years life expectancy	Limited life expectancy
No other valvular disease	Other valvular disease present (e.g., mitral)
No systemic autoimmune disease present	Autoimmune disease

usually dictates that the root replacement technique be used. Additional minor considerations often come into play including patient age, associated medical conditions, physiologic reserve, suitability for anticoagulation, and underlying ventricular function, as the time on CPB is potentially long.

After 1988, there was a steady increase in the number of Ross procedures performed until the peak frequency in 1996, then a steady and small decline until 2000 (Fig. 35-10). The recent decline in the number of Ross procedures performed temporally coincides with the increased appreciation of abnormal flow dynamics across the components of the Ross repair, particularly the right ventricle to pulmonary artery conduit.

Technique

Since the initial description by Ross of the scalloped subcoronary implant, a number of modifications have been described, including the inclusion cylinder technique and the root replacement technique. These techniques are performed identically to those outlined above for aortic homografts. According to the Ross Procedure International Registry, the root replacement technique is the most

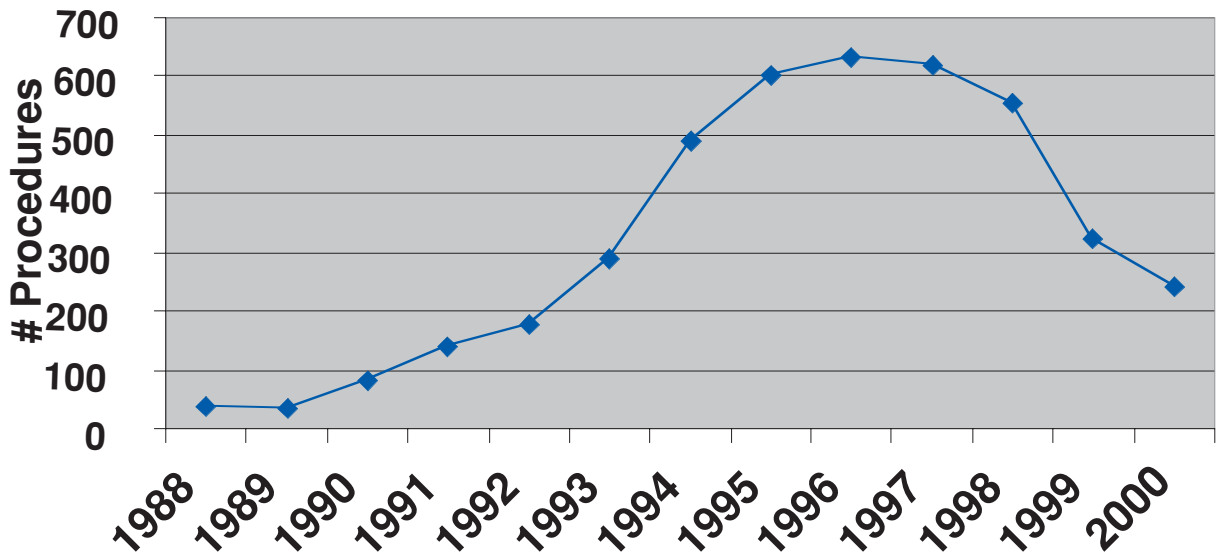

Figure 35-10. Ross procedures performed according to the Ross Registry 1988–2000. (*Adapted from the Ross Procedure International Registry; http://www.rossregistry.com.*)

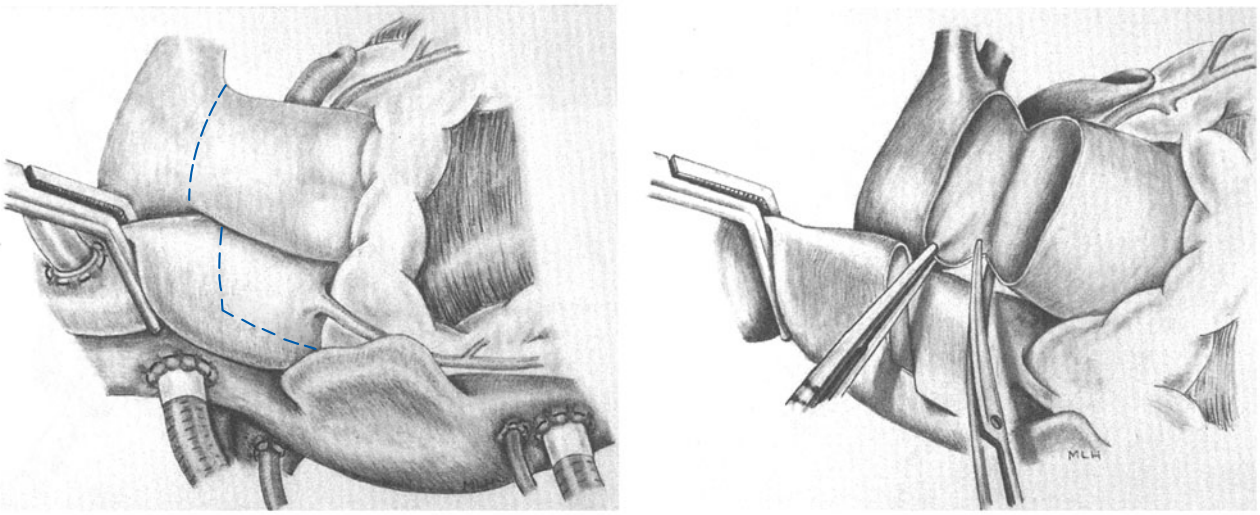

Figure 35-11. The distal pulmonary artery is incised at the origin of the right pulmonary artery. A transverse arteriotomy is made to allow careful inspection of the pulmonary artery. Shown from the surgeon's perspective, as though standing on the patient's right side. (*Reproduced with permission from Elkins RC: Aortic valve: Ross procedure, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

commonly performed variation owing to its superior versatility and possible decreased incidence of early and late graft failure.[65]

The conduct of the operation is similar to placement of an aortic homograft. Full CPB is utilized with arterial cannulation of the distal aorta. Again, the ventricular vent is placed through the right superior pulmonary vein. Cardioplegia is delivered antegrade and retrograde, via the coronary sinus catheter. A transverse or oblique reverse "lazy-S" aortotomy is performed similarly to placing an allograft. After retraction of the aorta, facilitated with stay sutures, the AV and root are inspected and the suitability of the pulmonary autograft for repair is confirmed. The AV is then excised, along with the coronary ostia as buttons. When the root replacement technique is used, the aortic root is excised as previously described for the allograft. Attention is then turned to the pulmonary artery (PA) and pulmonic valve.

The PA is mobilized to its bifurcation. The PA is then sharply divided transversely just proximal to the bifurcation (Fig. 35-11). This allows visual inspection of the pulmonic valve endoluminally, which is normally tricuspid, without fenestrations or atheroma (Fig. 35-12). The discovery of a bicuspid or quadricuspid valve, or the presence of large fenestrations or atheroma precludes use of the valve as an autograft. The mobilization of the PA then begins distally, near the transverse arteriotomy, and continues proximally toward the valve. The dissection is initiated posteriorly staying very close to the PA, taking care not to buttonhole the wall (Fig. 35-13). The left main

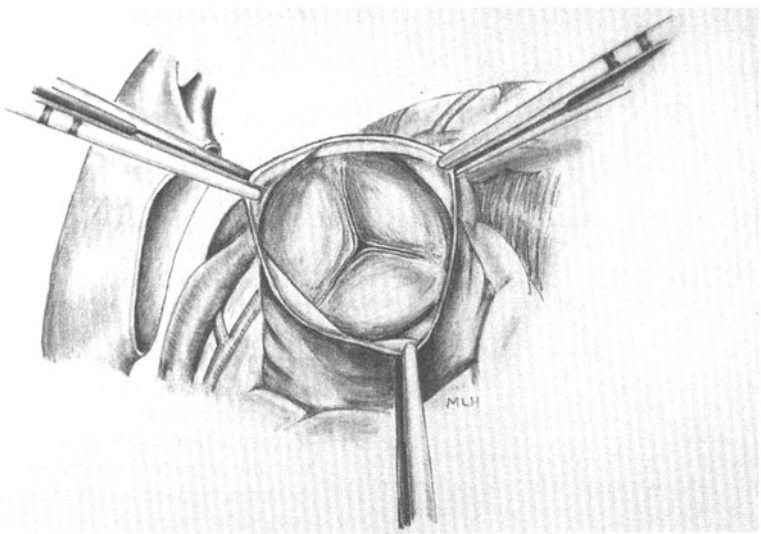

Figure 35-12. The normal trileaflet pulmonic valve with three equal sinuses and no fenestrations or other abnormalities. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

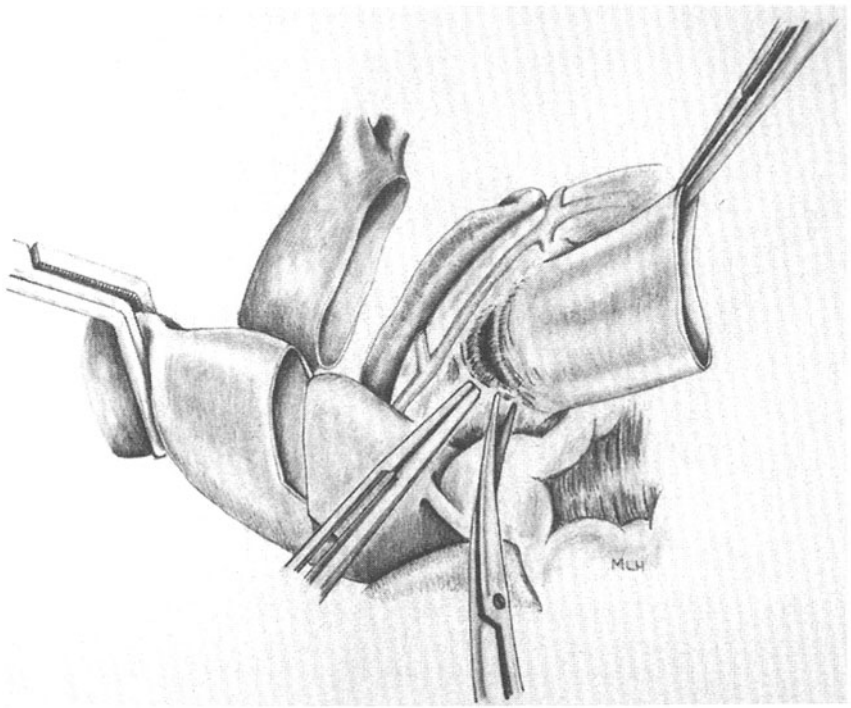

Figure 35-13. Dissection of the pulmonary autograft is initiated on the posterior aspect of the proximal pulmonary artery. Dissection is continued in this plane, adjacent to the pulmonary artery, until the septal myocardium is encountered. The left main coronary artery and left anterior descending artery are protected. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

coronary artery and its bifurcation into the left anterior descending (LAD) artery with the septal perforators, and circumflex arteries should be identified and avoided. When these are not easily appreciated, a probe may be placed into the left coronary os, through the aortotomy, to facilitate identification of the left main coronary artery and its branches. The dissection continues proximally until septal musculature is reached, taking care to avoid injury to the conal branch of the right coronary artery. A point 3 to 4 mm below the pulmonic annulus is identified, often facilitated by passing a probe through the pulmonic valve, and the right ventricular outflow tract (RVOT) is divided (Fig. 35-14). Where the RVOT meets the septum, the dissection must be kept superficial (i.e., on the right ventricular side) to avoid injury to the septal perforators of the LAD artery. The adventitia of the autograft is preserved. After complete

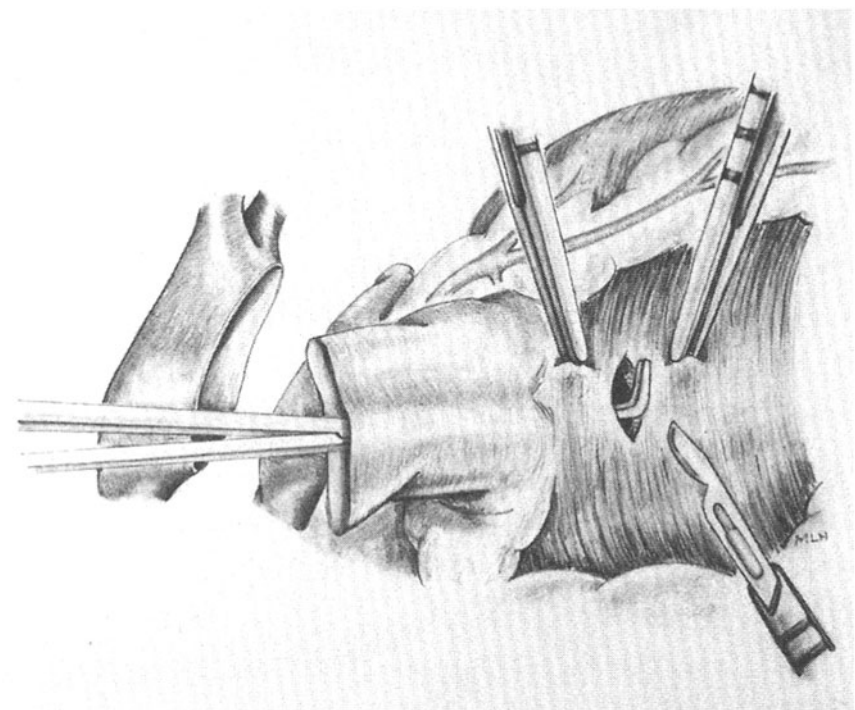

Figure 35-14. Identification of the anterior right ventriculotomy is facilitated by placement of a right-angled clamp through the pulmonary valve and indenting the myocardium 3 to 4 mm below the pulmonary valve annulus. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

division, the autograft is then accurately sized at its base, as well as the RVOT, and an appropriately sized allograft is obtained.

Root replacement technique

The autograft is oriented so that the posterior pulmonary sinus becomes the noncoronary sinus. The proximal suture line is performed first. In adults, this is performed with either everting pledgeted horizontal mattress 2-0 Ticron or a running 4-0 or 5-0 polypropylene. In children and adolescents, an absorbable monofilament suture (e.g., Maxon, Davis & Geck, Manati, Puerto Rico) is used, recognizing future growth of the autograft with the patient.[64] The left coronary artery is then implanted at the midpoint of the left coronary sinus, as previously described. Again, 5-0 polypropylene is used in adults and 6-0 Maxon is used in children. The distal suture line is then performed, after the autograft is trimmed 4 to 5 mm beyond the sinotubular junction of the autograft. A running 4-0 or 5-0 polypropylene suture is used in adults, while Maxon is used in children. The importance of similarly sized aortic and pulmonary valves has recently been suggested.[66] If a size or geometric mismatch between valves occurs, the diameter of the aortic annulus and/or sinotubular junction may be surgically reduced, with a reduction aortoplasty, as performed by Elkins.[67] Also, if the ascending aorta is aneurysmal, it may be replaced with an interposition Dacron graft bridging between the distal autograft and the ascending aorta just proximal to the innominate artery. This is followed by reimplantation of the right coronary artery, similar to that described for the left coronary artery. After the suture lines are inspected, the cross-clamp is removed and the operation is completed during rewarming.

A pulmonary homograft, oversized by 4 to 6 mm, is then obtained. The homograft is trimmed, and the proximal anastomosis is performed to the RVOT with running 4-0 polypropylene. Again, the left coronary artery and its branches lie close to the posterior aspect of the anastomosis, and sutures must be precisely placed in the endocardium to avoid kinking or injuring these structures. The distal suture line is then completed with a running 4-0 or 5-0 polypropylene suture. De-airing and weaning of CPB is performed in a standard fashion.

Inclusion cylinder technique

The inclusion cylinder technique is nearly identical to that previously described for the allograft (Figs. 35-15 and 35-16).

Results

Ross initially reported his results in 1991, setting the standard for outcomes after the Ross procedure.[68] He reported follow-up in 339 patients up to 24 years with an 80% survival and an 85% freedom from reoperation. More recently, a longer follow-up report from this initial series included 131 patients (long-term survivors) with a mean follow-up of 20 years (range 9 to 26 years).[69] In this report, freedom from reoperation was 76 and 62% at 10 and 20 years, respectively. Freedom from autograft replacement was 88 and 75% at 10 and 20 years, respectively. The main indication prompting autograft replacement was severe regurgitation in 28/30 patients. At 25 years, the pulmonary homograft was free of replacement in 69% of patients. Indeed, these outcome results have set the benchmark for AV repairs using autologous pulmonic valve. It is worth noting that most of the patients in Ross' series were repaired by the scalloped subcoronary implant technique, whereas the root replacement technique is the most commonly performed technique today.

Current data from the Ross Registry resemble Ross' initial results with a 68% survival, 84% freedom from RVOT repair/replacement, and an 82% freedom from autograft explant over 25 years.

Operative risk

With increasing experience and improved perioperative care, operative risk has declined since Ross first described this procedure. According to the International Ross Registry, overall perioperative mortality (i.e., <30 days) is now 4.1% (129 deaths in 3922 patients). Although 4.1% perioperative mortality is acceptable for some cardiac operations, many believe it is unacceptably high for the younger patients who are most often subjected to the Ross procedure. This controversial point highlights the need for individualized therapy with respect to valve replacement through consideration of all the risks and benefits associated with the available options. We do not believe that the risks of the Ross procedure are prohibitive in appropriately selected patients. Furthermore, as more experience is gained with this procedure, a volume-outcome relationship may be apparent, supporting regional specialization and referrals to "centers of excellence."

Pulmonary autograft dysfunction

Early autograft dysfunction occurs infrequently. Elkins reported early autograft dysfunction (<6 months) in 3/195 patients (1.5%).[64]

Late autograft dysfunction is an increasingly recognized phenomenon following the Ross procedure, although few studies have followed patients longitudinally with routine evaluations. A recent report of midterm follow-up (mean 2.47 years) in 132 consecutive patients who underwent routine echocardiographic evaluations of the pulmonary autograft revealed mild aortic insufficiency (graded 1/4) in 39.2 to 53.6% of patients, depending on follow-up interval.[70] Three percent of patients had moderate insufficiency early after surgery, increasing to 14.3% at 5 years. The mean transvalvular gradient across the AV was minimal (3 mm Hg) early and remained stable during follow-up.

In Elkins' series of 289 patients, 6% of the patients (16 patients) required autograft reoperation.[64] In the patients who received root replacement implants, 97% had no change in autograft function during follow-up, while only 1% had severe insufficiency (3+). In contrast, of those who received scalloped subcoronary or inclusion cylinder implants, 86% had no change in autograft function, while 8% had progressed to severe insufficiency (3+).

David and associates have provided additional insight into late autograft dysfunction following the Ross procedure,

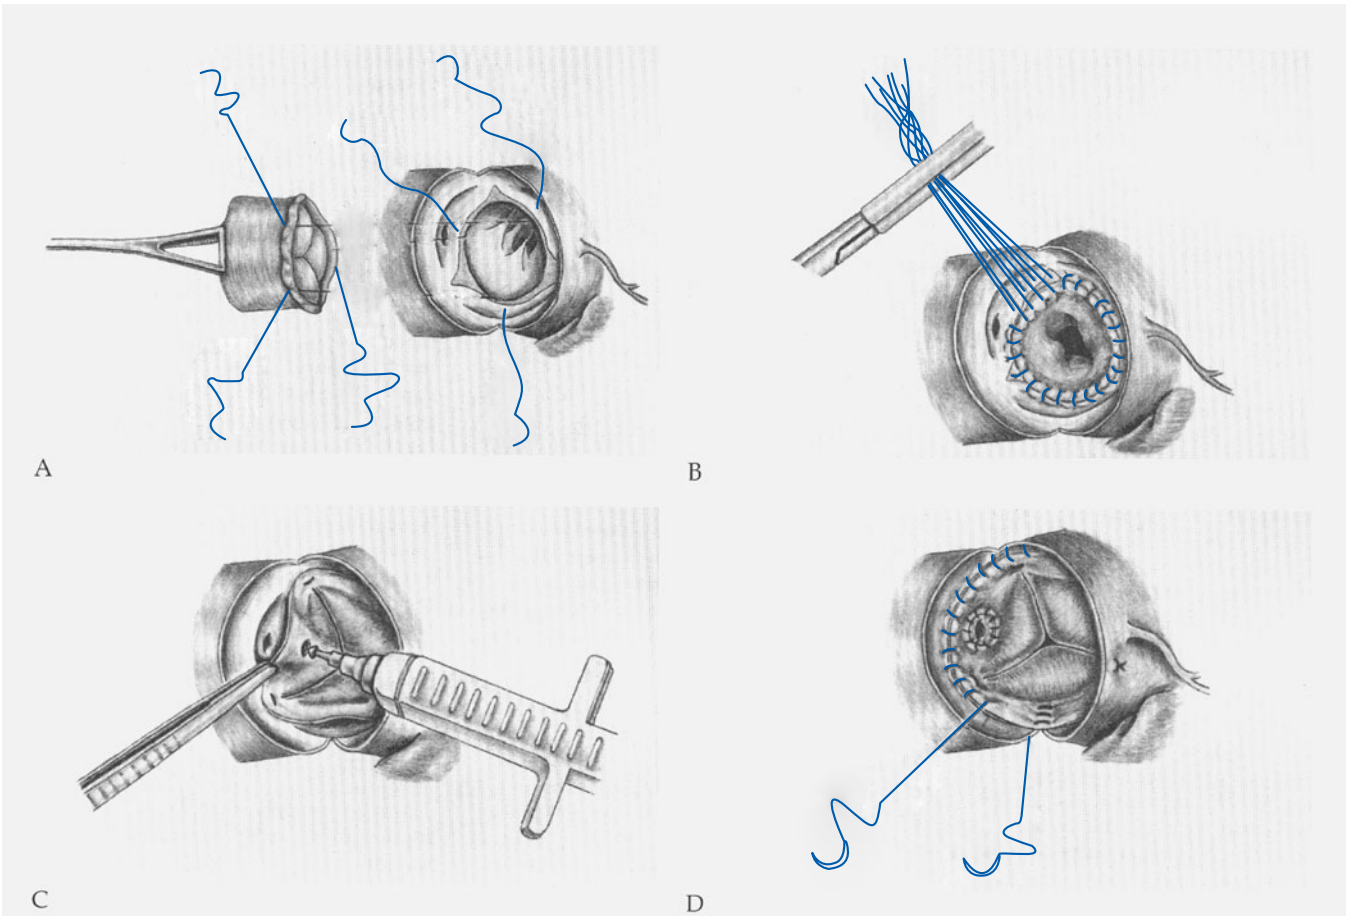

Figure 35-15. Inclusion cylinder technique. (A) Placement of three polypropylene sutures to orient the pulmonary autograft. The posterior sinus of the pulmonary autograft becomes the new left coronary sinus. (B) The autograft is inverted into the left ventricle and the proximal sutures are tied and divided. (C) The pulmonary autograft is reinverted. Horizontal mattress sutures are placed to secure the height and position of the autograft (but not tied until the right and left coronary arteries are implanted). An aortic punch (4 or 5 mm) is used to create an opening in the autograft to allow attachment of the coronary artery ostia. (D) Completion of coronary artery anastomosis. Commissural stay sutures are tied and divided, and the distal suture line is initiated at the commissure between the left and right coronary artery. This is continued to the aortotomy extension into the noncoronary sinus. This portion of the aortotomy is closed with a running suture line with the suture including a full-thickness bite of the noncoronary sinus of the pulmonary autograft. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

by assessing dilatation of the pulmonary autograft after the Ross procedure.[71] From 1990 to 1997, 118 patients with a mean age of 34 (17 to 57) underwent the Ross procedure. Of note, if there was ≥2 mm size mismatch between the aortic and pulmonic sinotubular junction or annuli, they were surgically reduced prior to implantation. The root replacement technique was most commonly used (71/118, 60%), followed by the root inclusion technique (45/118, 38%), and the subcoronary implant least commonly (2/118, 1.7%). Follow-up was 12 to 96 months (mean 44 months) including annual echocardiography. Over the observation period the diameter of the sinuses of Valsalva significantly increased from 31.4 to 33.7 mm. Furthermore, with respect to operative techniques, aortic root replacement was significantly positively correlated with increased risk of dilatation. No interpretable changes were seen in the aortic annulus over time. However, the diameter of the sinotubular junction increased in patients who had aortic root replacement and decreased in those subjected to root inclusion technique. During the observation period, only 5.9% (7/118) of patients developed moderate AI. However, all the patients with AI had dilatation of the aortic annulus and/or the sinotubular junction.

Taken together, these data indicate that the autologous pulmonic valve in the aortic position is quite durable and able to withstand the increased stresses at this position. Furthermore, although the valve effective orifice area (EOA) does not seem to change, up to 50% of patients may develop mild AI, which seems to increase with time, likely resulting from dilatation of the pulmonary autograft sinotubular junction and/or sinuses of Valsalva. Although it is suggested that this may be affected by surgical technique, it is unclear whether the use of the root replacement technique or root inclusion

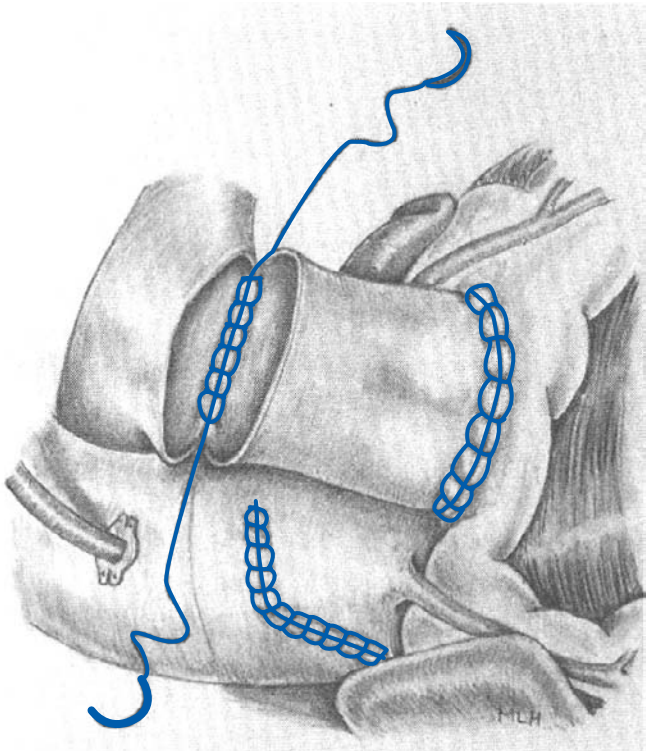

Figure 35-16. Completion of the closure of the aortotomy for the inclusion cylinder technique. The aortic cross-clamp is removed. The pulmonary homograft reconstruction of the outflow tract is accomplished with two continuous sutures of polypropylene. The proximal suture line is completed first. (*Reproduced with permission from Schaff HV, Cable DG: Aortic valve replacement with homograft, in Kaiser LR, Kron IL, Spray TL (eds): Mastery of Cardiothoracic Surgery. Philadelphia, Lippincott-Raven, 1998.*)

technique impacts the development of late pulmonary autograft dysfunction. Additional investigation is needed to elucidate risk factors for this complication and surgical interventions that may attenuate the frequency (e.g., reduction aortoplasty or Dacron banding of the aortic annulus and sinotubular junction).

Homograft dysfunction

Although the cryopreserved homograft has many advantages for a right ventricle to pulmonary artery conduit, it has become increasingly clear that it is susceptible to stenosis, degeneration, and calcification. Since current cryopreservation techniques result in varying degrees of donor cell viability, these effects may be immunologically mediated, although this remains controversial.[72] Again, the precise incidence of this phenomenon is likely underappreciated due to lack of routine echocardiographic screening.

Midterm echocardiographic follow-up results of 132 patients (mean follow-up 2.47 years) after the Ross procedure demonstrated early minimal transvalvular gradients (3 $\pm$ 4 mm Hg) with significant worsening (+6 $\pm$ 8 mm Hg) over time.[70] Furthermore, there was decreasing valve EOA (-0.74 ± 0.82 cm^2), mostly within the first 6 months. This resulted in 19.3% of patients having an EOA index of <0.85 cm^2/m^2 at 1-year follow-up. Put another way, after 2 years the pulmonary valve EOAs were, on average, 31% less than immediately following surgery. Through multivariate analysis, only small homograft size and hypertension were found to be significant negative predictors of EOA at 1 year follow-up.

Raanani and colleagues followed 109 consecutive patients after the Ross procedure to identify the incidence and risk factors for homograft stenosis.[73] Echocardiographic follow-up (mean 39 $\pm$ 20 months) was available in 105 (97%) patients. The primary abnormality identified was homograft stenosis. In support, they identified a peak systolic transvalvular gradient of $>$20 mm Hg in 28.5% (30/105) of patients and $>$40 mm Hg peak gradient in 3.8% (4/105) of patients. This obstruction occurred at all levels of the homograft, as opposed to just at anastomotic sites, and was associated with homograft thickening. Moderate or severe homograft insufficiency was identified in 9.5% (10/105) of patients. Through multivariate analysis, the only independent significant predictors of homograft stenosis were cryopreservation duration $<$20 months, donor age $<$30 years, and small homograft size, which approached statistical significance.

Taken together, these data indicate that pulmonary homograft stenosis may develop in up to 30% of patients following the Ross operation. More importantly, the clinical significance of these data is not clear. For example, in the context of congenital pulmonary stenosis, it appears that peak transvalvular gradients of $<$50 mm Hg are usually well tolerated.[74] However, it would be erroneous to extrapolate these data to the demographic of the Ross procedure, as many of these patients are into adulthood when they undergo this procedure. Furthermore, similar to the pulmonic autograft in the aortic position, the incidence and severity of pulmonic insufficiency appears to increase with time. Clearly, these data suggest that future endeavors to improve the Ross procedure should be directed to elucidating the mechanisms underlying the pulmonary homograft stenosis and toward therapy to minimize these untoward effects.

SUMMARY

The search for the ideal valve to replace the diseased AV is ongoing and available techniques are imperfect. Nonetheless, the Ross operation, whereby the pulmonic valve is transposed to the aortic position and the RVOT is replaced with cryopreserved allograft (most commonly), has proven to be a durable solution for complex congenital abnormalities and disease isolated to the AV, particularly in children and young adults.

Observations of the long-term durability of the pulmonic autograft in the aortic position affirm its ability to withstand the increased physical stresses at this location and maintain near normal hemodynamics over time, making it an excellent choice for replacement of a diseased AV. The incidence of AI is low and increases with time, likely resulting from dilatation of the pulmonary autograft sinotubular junction and/or the sinuses of Valsalva. Further

studies are needed to discern the risk factors for this occurrence, but utilizing the root replacement technique compared to the root inclusion technique may affect it.

The allograft in the pulmonic position is more susceptible to complications, namely stenosis, which occurs primarily within the first year. Up to 30% of patients may have a hemodynamically significant stenosis at this location that is likely immunologically mediated, though the clinical significance of these findings remains unclear. Small homograft size is consistently a risk factor for stenosis, thereby supporting the current practice of oversizing the homograft by 2 to 3 mm. Future attempts to improve outcome after the Ross procedure should be directed toward reducing homograft stenosis.

The Ross procedure remains a reasonable option for replacement of the diseased AV, particularly in children and young adults. For adults, given the alternatives for AV and root replacement, the utility of the pulmonary autograft is more limited. As longer follow-up continues to accumulate, the risks and benefits of this procedure relative to other treatment options for replacement of a diseased AV will be better characterized.

CHAPTER 36

Stentless Aortic Valve Replacement: Porcine and Pericardial

Paul Stelzer

HISTORY AND CONCEPT

The concept of replacing the aortic valve with a stentless device is not new. The very first replacement of the aortic valve ever done in the anatomic position was done with a stentless device, namely the aortic homograft.[1] However, because of the lack of availability and the logistics of preservation and distribution, homograft (human donor) valves and conduits were not a practical option for the majority of patients requiring aortic valve replacement. Initial attempts to expand the possibilities by using xenograft valves were fashioned on the freehand subcoronary homograft model.[2] Subsequent replacement devices that incorporated a support structure for mechanical or tissue valves were easier to implant but intrinsically obstructive by taking up space in the aortic annulus. With this history in mind, Tirone David first proposed and helped develop a modern-day heterograft equivalent which ultimately became the Toronto SPV (stentless porcine valve) (St. Jude Medical, Inc., St. Paul, MN).[3] From the beginning, it was appreciated that eliminating the stented support frame and sewing ring would eliminate some problems and create new ones. Not the least of these would be the need for different surgical techniques for implantation and the need to deal with the unpredictable changes in aortic root geometry on which the competency of these valves would often depend over time.

The logical place to begin was with a glutaraldehyde-preserved porcine aortic root simply extracting the valve in one piece from the root. Scalloping out the porcine sinuses of Valsalva and thinning down the porcine septal muscle left a structure that was friable in places, leading to the external polyester fabric covering which extends from the annulus to the top of each commissure of the Toronto SPV. The factory-prepared porcine tissue removed the need for muscle trimming by the surgeon and proved to be much less "floppy" and easier to handle than the homograft valve. However, it shared issues of sizing and the influence of more than just the annulus to support its function. So important was the influence of the native sinotubular junction (STJ) to the competence of the stentless valve that sizing was felt more appropriately based on this dimension than on the annulus itself. The patient with marked discrepancy between annulus and STJ became a challenge for this type of valve, requiring tailoring of the STJ or use of an alternative device.

Recognizing the range of aortic root variability and disease of the root itself, the concept of stentless valve replacement was expanded to replacement of the entire aortic root, paralleling the homograft experience.[4] This required development of entirely new technology to prepare and test porcine aortic roots to be used as total aortic root replacement. The Medtronic Freestyle Aortic Root Bioprosthesis (Medtronic Inc., Minneapolis, MN) and the Edwards Prima (Edwards Lifesciences LLC, Irvine, CA) provided alternatives that allowed the surgeon to use the entire root, modify it for intra-aortic use as an inclusion cylinder (root inclusion), or scallop it for a subcoronary implant. The subcoronary technique could be modified to leave the noncoronary sinus wall of the porcine root intact, which gave more predictable support to two of the three commissures.

The flexibility of these devices made them more broadly useful, but with flexibility inevitably comes complexity and initial enthusiasm was dampened by the perception of increased risk and technical difficulty. Early adopters became facile with experience while skeptics lauded the improvements in the simpler stented devices as equivalent to the advantages of stentless valves. With the advent of full root replacement with a bioprosthesis came the challenges of hemostasis and coronary reimplantation inherent in all aortic root surgery. The hemodynamic and potential durability advantages already proven for the aortic homograft root[5] were envisioned for the stentless porcine roots, but acceptance was slowed by risk/benefit ratio concerns. An early comparison of full root aortic homografts and the porcine stentless equivalent showed very favorable results for the

much more available bioprosthesis.[6] Surgeons experienced in root replacement found the stentless porcine root a logical extension of the scarce homograft and a welcome alternative to mechanical valved conduits or the more cumbersome proposition of sewing a stented or stentless tissue valve into a vascular graft.

DURABILITY ISSUES

General Considerations

One of the foremost concerns of any tissue valve is that of durability. From the very first experience with porcine valves, the Achilles heel of heterograft tissue has been structural degeneration, usually from calcification. This proved to be particularly true in the very young, for reasons which remain elusive. Improvements in tissue preservation technology were applied to both stented and stentless valves as they became available. Stentless porcine valves have the additional consideration of the porcine aortic wall which is an integral part of the device in addition to the leaflets themselves. This tissue does not respond in the same way as do the leaflets because of inherently different cellular and stromal structure. Devices made partially or wholly from bovine pericardium share many of the same constraints as porcine leaflets but not all to the same extent.

Impact of Fixation Pressure

Porcine valves were initially fixed in low concentrations of glutaraldehyde at high pressure (60 to 80 mm Hg) but later at low pressure (2 to 5 mm Hg). Attempts to demonstrate durability benefits of the lower pressure fixation have been inconclusive. The concept of zero-pressure fixation was first introduced in the Medtronic Freestyle, the total root design of which allowed instillation of glutaraldehyde solution from either end of the root at 40 mm Hg (diastolic pressure of the pig), which led to the term "physiologic pressure fixation," while the aortic leaflets were suspended in the middle with pressure on either side of the leaflet balanced out to zero.[7] The goal of this method was to preserve more normal morphology of the leaflets, which would allow more natural bending patterns through the cardiac cycle. Using a combination of accelerated wear testing in a pulse duplicator and biaxial mechanical testing of the tissue, Christie and colleagues demonstrated better preservation of both circumferential and radial stretch in the Freestyle leaflets compared to leaflets fixed even at low pressure, which flattens the native collagen crimp.[8]

Antimineralization

Antimineralization techniques were also introduced about the same time as the stentless valves. XenoLogiX (Edwards Lifesciences, Irvine, CA), No-React (Shelhigh, Inc., Union, NJ), AOA (two-alpha-amino oleic acid) (Biomedical Design, Inc., Atlanta, GA), and BiLinx (St. Jude Medical, Inc., St. Paul, MN) are among the agents used to mitigate the calcium deposition so often seen to hasten tissue valve degeneration. The juvenile sheep model and the rat subcutaneous implant model are the typical proving grounds for these methods before clinical application. An excellent review of ongoing efforts to solve the calcification problem was done by Schoen and Levy, the highlights of which follow.[9]

Surfactants such as sodium dodecyl sulfate act as detergents which largely remove acidic phospholipids from the cell membranes where calcium ions are known to react and form calcium phosphates. AOA binds in a covalent fashion through its amino linkage to residual aldehyde moieties in the tissue to inhibit calcium flux through the tissue. This agent has proven very effective at mitigating calcium deposition in porcine leaflets, but not aortic wall in rat subdermal implants.[10] Clinically, it seems to have positive effects on both, though less so on the aortic wall.

The proprietary No-React treatment was developed by Gabbay and colleagues.[11] It is reportedly a combination of aldehyde-based cross-linkage followed by a detoxification process and use of a surfactant. Despite good performance in the subdermal rat implants, extensive fibrous sheathing leading to cusp retraction was seen as well as failure to prevent calcification in the sheep model.[12]

Trivalent metal ions represented by iron (FeCl3) and aluminum (AlCl3) inhibit calcification of both pericardium and porcine cusps in the subdermal implant model. Part of this action may be due to complex formation with phosphates, decreasing their availability for calcium phosphate formation. They also inhibit the activity of alkaline phosphatase, which may be involved in the initial calcification process. Additional benefit from aluminum may come from its demonstrated ability to prevent calcification of elastin, a major molecule in porcine aortic wall whose structure is permanently altered by the trivalent aluminum ion. Aluminum is an essential part of the BiLinx treatment. The safety of using aluminum in this way has been demonstrated clinically in the new Toronto Root Bioprosthesis (St. Jude Medical, Inc., St. Paul, MN) with no change in serum aluminum levels at 6 months.[13]

Ethanol (80%) can be used to remove cell wall phospholipids and cholesterol from tissues treated with glutaraldehyde.[14] Ethanol is an active component of St. Jude's BiLinx and Edwards' XenologiX treatment, which has been shown experimentally to remove over 90% of phospholipids in both bovine pericardium and porcine leaflet tissue as a way of reducing sites for calcium attachment in vivo.[15]

Novel techniques such as dye-mediated photooxidation have been developed to provide alternative fixation methods which avoid glutaraldehyde altogether.[16] This method has been shown to prevent calcification in both leaflets and aortic wall in a bovine implant model at 3 and 6 months.[17] Clinical use of this method has not been pursued.

Combination treatments may hold the key to addressing the issue of differential behavior of the aortic wall and aortic leaflets in response to these calcium mitigants. A combination of AOA followed by ethylcarbodiimide treatment

takes advantage of both the amino and the carboxyl groups of the AOA for cross-linking and decreases calcification in both leaflets and aortic wall in the rat subdermal implant model.[18]

Development and clinical application of new methods of increasing tissue durability is an ongoing process. Animal models have proven helpful, but careful pathologic examination of explanted devices is essential, as only the human body provides the ultimate test of bioprosthetic durability.

Intrinsic Durability Advantage of Stentless Design

In addition to the fixation and calcium-mitigating treatments, the stentless valves have an additional theoretical durability advantage over stented valves. The intrinsically obstructive nature of the stented valves creates turbulent flow patterns through the left ventricular outflow tract into the proximal aorta which are not seen in the normal aortic root. Normal laminar flow patterns with reverse flow eddy currents in the sinuses of Valsalva are seen in stentless valve replacements. The lack of turbulent flow and presence of the eddy patterns which enhance gentle leaflet closure decrease the opening and closing stresses on both the commissures and the body of the leaflets. Any decrease in mechanical stress to these areas has a positive impact on durability. The best way to avoid mechanical stresses on the leaflets as well as optimizing their function may well be to use the full root replacement technique which has been shown to have durability and competency advantages over the long term with aortic homografts by O'Brien and colleagues in Brisbane, Australia.[19]

The Test of Time

Always in the minds of advocates and critics alike is the paradox of potential harm that may offset any potential long-term benefit. Most valves of either stentless or stented variety will last 7 years or longer. The real test of time does not come into the equation until 10 to 15 years. Therein lies the dilemma of adopting new techniques or devices long before data are available for the long term. Fully 13 years after the first modern stentless porcine valve was implanted, Jamieson predicted "The long-term performance advantages or disadvantages of stentless bioprostheses compared to stented bioprostheses will require at least another 5 to 7 years of cumulative stentless bioprostheses experience."[20]

Risk of Reoperation

Durability is important in tissue valves of any kind, primarily to avoid the undesirable event of reoperation. This must be taken into the perspective of other undesirable events with alternative (mechanical) valves, namely the double-edged sword of thromboembolic phenomena and anticoagulant-related hemorrhage. This is particularly important in the younger age group most likely to require reoperation if a tissue valve is implanted and most likely to participate in contact sports with greater injury potential. In a review of experience with 332 patients between the ages of 45 and 65 the group at Laval Hospital in Quebec City showed excellent survival and freedom from adverse events at 7 years across the tissue spectrum including 140 Freestyle, 54 aortic homografts, 76 Ross procedures, and 62 stented xenografts.[21] Freedom from bleeding, stroke, and endocarditis were >95% in all groups. Advances in reoperative techniques including anesthesia, perfusion, and myocardial protection strategies have made the prospect of a second valve replacement much less onerous than it was 20 years ago. In addition, simple maneuvers such as closing the pericardium at the first operation make sternal re-entry much safer for a second. With this in mind, there has been decreased use of the Ross procedure in the 40 to 60 age group in favor of stentless valves which are simpler. The perfect Ross may last for 40 years, but two operations with stentless valves may accomplish the same thing. (A home run has no scoring advantage over two doubles as long as the latter are both hit in the same inning.)

CLINICAL RESULTS

Hemodynamics, Survival, and Left Ventricular Mass Regression

Durability aside, the major potential advantage of the stentless valve is to more closely approximate the optimal hemodynamics of the normal human valve. A 10-year experience with 321 patients compared subcoronary stentless porcine with subcoronary aortic homograft valves. There were no differences detected at a mean of 4.9 years in survival, reoperation, endocarditis, or structural degeneration.[22] Coupled with those outcome measures are the dependent effects on left ventricular hypertrophy and mass regression and subsequent survival advantage. It is well known that virtually all the alternatives for replacing a highly stenotic aortic valve result in regression of left ventricular mass (LVM).[23] In a case-match study comparing the earliest years of the Toronto SPV to the Hancock II stented valve, David found a survival advantage at 8 years for the stentless device: 91 versus 69% ($p < 0.006$).[24] He felt this was due to superior hemodynamics of the stentless valve.

Westaby and colleagues with the independent statistical help of Grunkemeier compared survival in a group of 160 consecutive patients with subcoronary Freestyle valve implants with 247 contemporaneously matched patients with stented Carpentier-Edwards porcine valves. They found at 5 years a significant advantage in the stentless Freestyle group with 84% survival versus 69% in the stented group.[25]

In a 10-year retrospective review of 145 Toronto stentless patients and 106 Carpentier-Edwards stented patients, Van Nooten and colleagues in Belgium showed similar mass regression in the two groups, but there was a significant midterm survival advantage in the stentless group (84 versus 74% at 4 years and 78 versus 68% at 6 years; $p < 0.001$).[26] In a related publication this group explained

that the mass regression had a nadir at 3 years and an interesting slow increase which began at 5 years correlated with systemic hypertension in this age group.[27]

In Leipzig a slightly smaller study (but prospectively randomized) between 106 stentless and 74 stented aortic valves for aortic stenosis, the regression of LVM index at 6 months was significantly greater for the stentless group ($p < 0.05$).[28] The authors postulated the difference was due to better transvalvular hemodynamics.

An early study done in London showed the stentless porcine valve (Toronto SPV) to be equivalent to the aortic homograft and both to be superior to either stented or mechanical valves in measures of left ventricular recovery. These included mass regression, wall thickening, fractional shortening, and even diastolic relaxation by greater peak velocity of dimension lengthening.[29] Significant improvement occurred in all patients, but that improvement was greater and faster in the stentless/homograft group.

Cardiac magnetic resonance imaging (MRI) is more precise in measuring LVM than echocardiography, but is more difficult and costly to obtain. A small but prospectively randomized study of 39 patients found the expected significant LVM reduction at 6 months after aortic valve replacement (AVR) for aortic stenosis, with the degree of regression independent of prosthesis choices including stentless, stented, and mechanical valves.[30]

Carefully documented comparisons of stented and stentless valves is sparse in terms of exercise hemodynamics and quality-of-life measurements. A small study at St. Thomas' Hospital in London compared 21 patients with Toronto stentless valves to 29 patients with Perimount (Edwards Lifesciences LLP, Irvine, CA) stented valves using bicycle ergometry. They could detect no statistically significant differences between the two valve types in peak velocity, mean pressure difference, or effective orifice area at rest or on peak exercise.[31]

Operative Risk and Long-Term Complications

In order to take advantage of any potential hemodynamic and survival advantage of a stentless device, the operative risk must be low and the risk of adverse valve-related events also low, such as thromboembolism (TE), endocarditis, structural degeneration, and reoperation. In a large experience (404 patients) in Leicester, England, with 11 types of stentless valves (221 Medtronic Freestyle, 55 Shelhigh, 33 Shelhigh Composite conduits, 25 Sorin, 25 CryoLife O'Brien, 17 Aortec-Elan, and 5 others) by a single surgeon (A. W. Sosnowski) over 5 years showed an overall early mortality of only 4.2%.[32] The risk of isolated AVR was only 2.4%, that with concomitant coronary artery bypass graft (CABG) only 3.6%, and rates were higher for multiple valve surgery or Bentall procedures. Regression analysis revealed the usual predictors of operative death—ejection fraction (EF) <30%, active endocarditis, redo surgery, and cardiogenic shock. The only procedure-related risk was the Bentall operation. Five-year freedom from endocarditis, TE, hemorrhage, and reoperation ranged from 96 to 99%, with actuarial survival of 88%. These authors considered the stentless aortic valve to be the operation of choice for patients over 60 years of age.

The outcome bar has been set very high by O'Brien, who reported a remarkably low 30-day mortality rate of only 0.99% in a consecutive series of 402 patients over 10 years.[33] This was done in a typically older population (average age 73.5 years) with nearly one-half (46%) requiring concomitant CABG. Actuarial survival at 8 years was 70.8 ± 7.1%. The incidence of thromboembolic complications was rigidly documented (56 episodes in 40 patients), which led to permanent neurologic damage in only 18 patients. Of nine patients who developed endocarditis, five maintained complete competence of the replacement valve and three were cured of infection without surgery. Freedom from reoperation at 8 years was 96.7 ± 2.1%. A fascinating magnetic resonance study of 10 patients several years after surgery showed another potential benefit of this particular valve. Physiologic systolic stretching of the aortic annulus was restored.

Use of the full root replacement technique has been tempered by documented higher operative mortality rates in early series.[34] However, under the leadership of the superb aortic surgeon Hans Joachim Schafers, the team at Homburg-Saar, Germany, had excellent results despite a spectrum of serious aortic and associated problems. Overall mortality was 6.7% in a group of 149 that required replacement not only of the root, but of the ascending aorta in 22% and the arch in 13% with 32% requiring coronary bypass. The isolated aortic valve disease patients had only 1.8% mortality risk.[35]

IMPLANT TECHNIQUES

Subcoronary and Modified Subcoronary

It may seem too obviously simple, but the use of a transverse aortotomy as opposed to an oblique one is a distinct advantage in using the stentless valves. Early experience in South Africa with the Biocor stentless valve showed crowding of the two commissures on either side of an oblique aortotomy carried down into the noncoronary sinus.[36] Closure of the aortotomy caused a decrease in the effective size of the noncoronary sinus, pushing the two adjacent porcine commissures toward each other. Since the three-dimensional geometry of the native aortic root becomes a part of the functional geometry of the stentless valve, it makes sense to leave this structure as intact as possible.

Even a transverse aortotomy can be a problem if made too close to the sinotubular junction. At least 1 to 1.5 cm of clearance is needed to place the stentless device within the root and still close it above the tips of the commissures of the new valve. Complete transsection of the aorta is often helpful in gaining full exposure for implantation.

The proximal suture line is usually done with simple interrupted technique using 2-0 to 4-0 braided sutures. Approximately 20 to 30 sutures are used depending on the

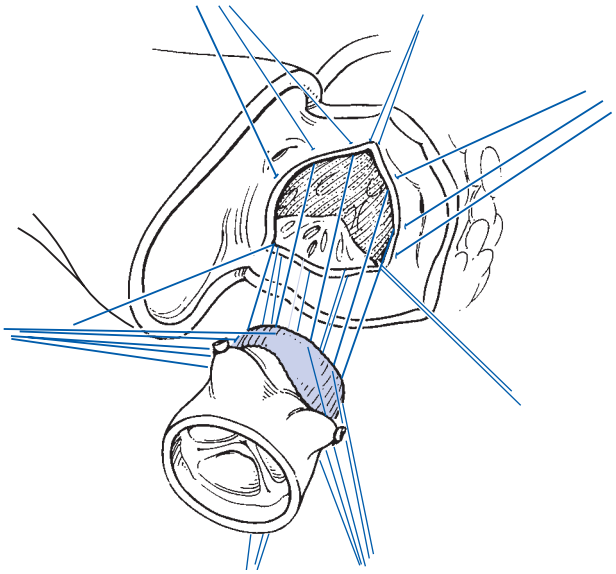

Figure 36-1. Modified subcoronary technique—proximal suture line. Interrupted sutures are placed in a circular plane coursing through the annulus itself at the lowest point of each sinus, but well below the commissures except anteriorly where the conduction system must be avoided. These are best organized on suture guides alternating colors, then divided in thirds and passed through the inflow end of the stentless valve. (*Modified and reproduced with permission from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

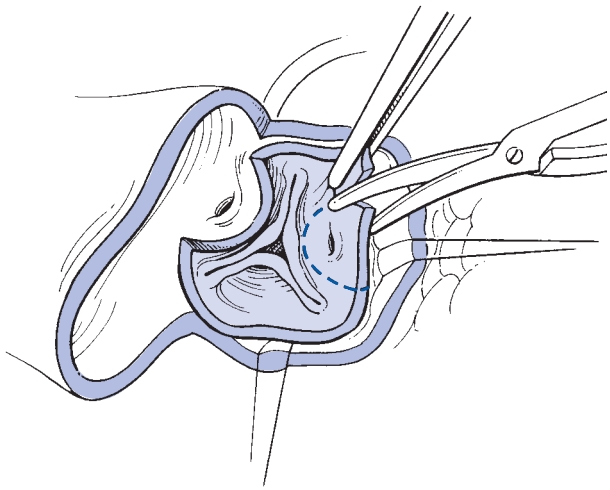

Figure 36-2. Modified subcoronary technique—preparing the sinuses. Either before or after the device is slid down and the proximal sutures tied, the sinuses facing the native left and right coronary ostia are scalloped out below the level of those recipient coronaries. Care is taken to avoid cutting into any cloth covering or getting too close to the leaflets of the new valve. (*Modified and reproduced with permission from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

size of the annulus (Fig. 36-1). Suture guides are very helpful in keeping these many sutures organized. The device is parachuted down into the root and the sutures tied and cut. The right and left sinuses are scalloped out either before or after this step (Fig. 36-2). A distal suture line of continuous small (4-0) caliber polypropylene suture is then constructed coursing below the coronary ostia, taking care not to buckle the stentless tissue or distort the positions of the commissural posts. Stay sutures can be placed at the top of each commissure to help maintain orientation. One suture is begun at the bottom of the left and another at the bottom of the right sinus and run up to the top of each commissure (Fig. 36-3). The porcine tissue and especially the cloth-covered portion of some devices must not encroach on the ostium of either coronary, as obstructive granulation tissue may form in this location. The top of the device is trimmed down to the level of the native aorta, taking care to stay above the top of each commissure. If the noncoronary sinus of the stentless valve is kept intact, the distal suture line can be completed by running along the top to join the two sutures. The aortotomy is closed with continuous suture incorporating the tops of the commissures and the retained noncoronary sinus edge. The completed concept of the complete and modified subcoronary implant technique is shown in Figs. 36-4 and 36-5.

Alternative methods of attaching the proximal end of a subcoronary implant were examined in Hungary using 102 Sorin Pericarbon stentless pericardial valves. It took

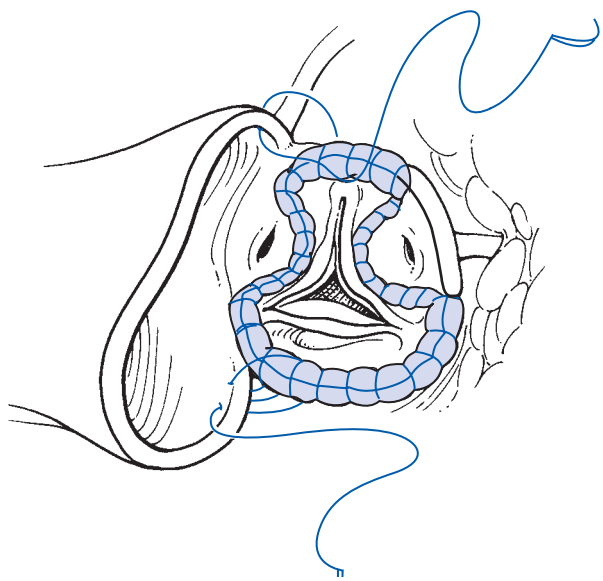

Figure 36-3. Modified subcoronary technique—distal suture line. A continuous 4-0 polypropylene suture is begun in the bottom of each sinus below the coronary ostium. This is brought around and up to the top of the adjacent commissures, where the top of the device is trimmed down to the level of the native aorta to allow completion of the suture line. This demonstrates the completed distal suture line and beginning of the aortic closure which incorporates the tops of the commissures again as well as the top of the retained noncoronary sinus. (*Modified and reproduced with permission from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

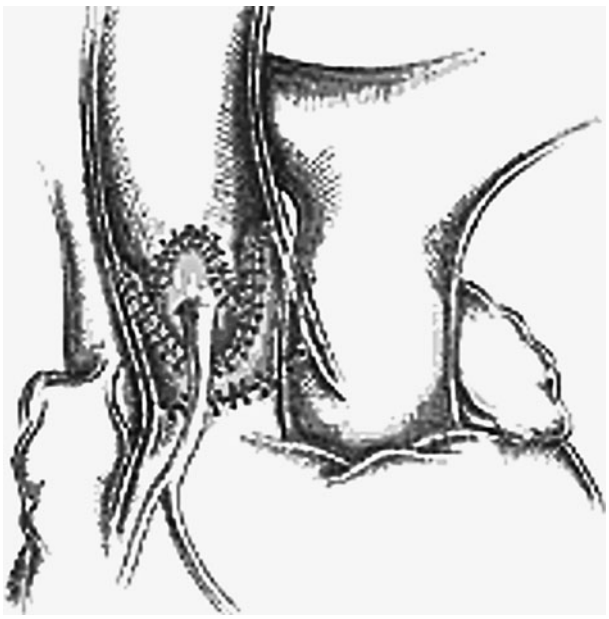

Figure 36-4. Subcoronary technique—final appearance. (*Used with permission of Medtronic Inc., Minneapolis, MN.*)

longer to use interrupted simple sutures than either interrupted mattress or continuous sutures, but there was no difference in operative mortality or transvalvular gradients in follow-up.[37]

An expanding hematoma in the space between the native and the porcine noncoronary sinus walls is undesirable, but a small fixed collection in this area usually resorbs over time. One technique to minimize this problem is to rotate the Freestyle root 120° to put the porcine right coronary stump in the patient's noncoronary sinus. A small cut in the sinus allows the porcine stump to be extruded to the outside of the native sinus where it is secured with a pledgeted mattress suture of 4-0 polypropylene.

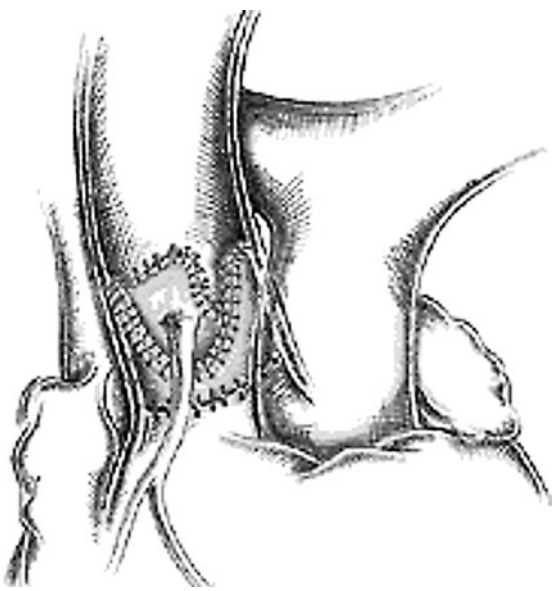

Figure 36-5. Modified subcoronary technique—final appearance. (*Used with permission of Medtronic Inc., Minneapolis, MN.*)

The subcoronary method has been preferred by most early adopters of the stentless valve since the first available, the Toronto SPV, was a completely scalloped device which required this method of implantation. Various technical observations have been made with experience to deal with the issue of sizing, which is very important with these valves. If the size chosen is too small, the inflow end becomes needlessly obstructive and the outflow end is stretched out to reach the native commissures with decreased leaflet coaptation and more regurgitation as a result. Oversizing to fit a larger sinotubular junction leads to buckling of the inflow end which can produce both relative stenosis and regurgitation as well as harmful turbulent flow. In short, how the device is sized and implanted can dramatically influence both its function and its durability. One attempt to standardize some of these variables was the development of a rigid template-style sizing instrument that could be placed in the root to precisely demonstrate how each size Toronto valve would fit.[38] This has not been widely adopted. The commercially available cylindrical sizers from each manufacturer have proven more practical in this regard as long as both the annulus and the sinotubular junction are measured. For minor discrepancies, the sinotubular junction should dominate. If there is a major difference (>3 mm), an alternative technique (root replacement) or device (stented valve) should be considered.

Root Inclusion

In an effort to completely preserve the three-dimensional geometry of the bioprosthetic root devices without completely replacing the native root, a minority of users have chosen to employ the root inclusion method. This involves a proximal suture line (continuous or interrupted) like the subcoronary technique in a circular plane coursing below the commissures. Generous openings are made by excising the sinuses facing the right and left main coronary ostia (Fig. 36-6). These are then tacked around the ostia much as a root inclusion Bentall procedure with continuous 4-0 polypropylene suture. The aortotomy is then closed in standard fashion after trimming the device top down as necessary to incorporate in the closure, making sure that the complete circle of the sinotubular junction is left intact. The only difference between the root inclusion method and the subcoronary technique is that the complete sinotubular ring of the stentless device is preserved, thus preventing any chance of dilatation at that level in the future. The top of the device is incorporated in the closure of the aortotomy (Fig. 36-7). Practically, this method is the most difficult and should not be used unless the root is large enough to place a 23-mm or larger device. It may, however, be the most desirable in a younger patient with a larger aortic root. The bioprosthetic sinotubular junction will not dilate over time, and at a subsequent operation, after gently removing this device, the entire native aortic root will be available for a complete range of replacement choices.

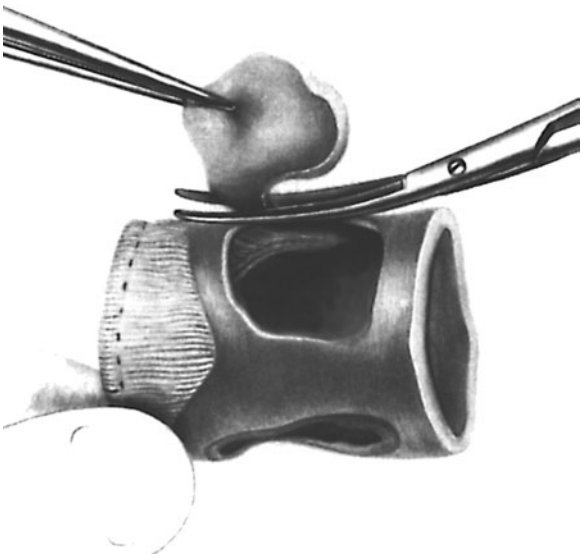

Figure 36-6. Root inclusion technique—trimming out sinuses. Very generous openings are made in the two appropriate sinuses facing the native coronaries without violating the sinotubular junction of the stentless valve. (*Modified and reproduced with permission from Krause AH: Technique for complete subcoronary implantation of the Medtronic Freestyle porcine bioprosthesis. Ann Thorac Surg 1997; 64:1495.*)

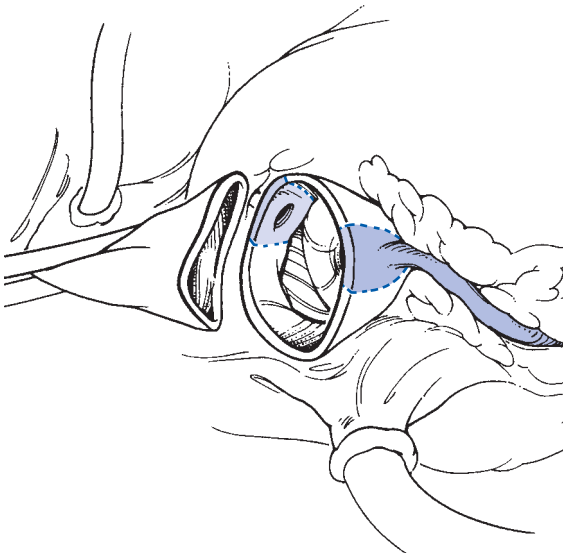

Figure 36-8. Full root technique—initial incisions. The aorta is transsected 1 to 1.5 cm distal to the coronary ostia, which are then mobilized from the root with "buttons" of aortic wall as indicated by the dashed lines. (*Modified and reproduced with permission from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

Full Root Replacement

In many ways, complete replacement of the native aortic root is the simplest method for those devices that can be used in this way. Since the tubular three-dimensional geometry of the device is not altered, its factory-tested performance is not affected by the implantation. The operation is done in exactly the same manner as the root replacement technique used to implant an aortic homograft or a valved conduit. The valve is excised and the root thoroughly débrided. If a cylindrical sizer of 23 mm fits through the annulus, a 25-mm bioprosthesis can always be used and usually a 27-mm bioprosthesis is easily placed. While the valve is being rinsed, the coronary arteries are separated from the root with generous "buttons" of aortic wall and mobilized with gentle cautery technique (Fig. 36-8). It is helpful to preserve a little extra aortic tissue at the top of each button to use for stay suture retraction and to maintain axial orientation.

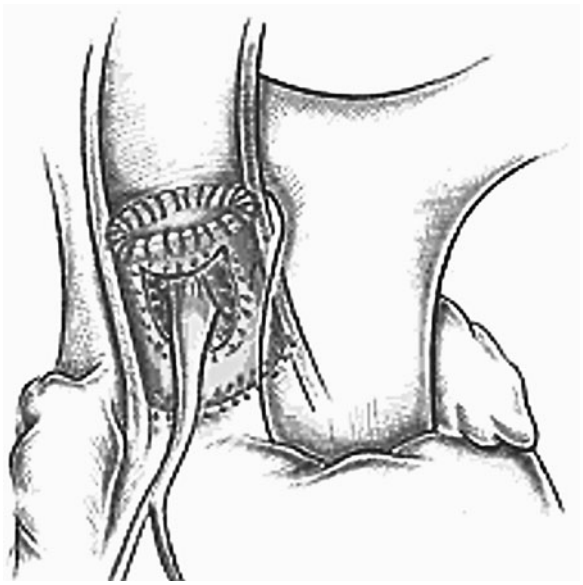

Figure 36-7. Root inclusion technique—final appearance. (*Used with permission of Medtronic Inc., Minneapolis, MN.*)

Depending on the height and position of the native right coronary artery, the device may be implanted anatomically or rotated to put the porcine left in the patient's right sinus. The proximal suture line is constructed with continuous polypropylene (3-0 or 4-0) suture beginning beneath the right-left commissure to assure proper alignment of the coronaries. Alternatively, interrupted sutures can be placed and organized on suture guides for precise distribution of sutures around the root. A strip of autologous pericardium or felt material can be incorporated into this suture line for hemostatic support if desired (Fig. 36-9). The continuous suture line is tightened with nerve hooks and tied securely if this method is used.

The coronary "buttons" are then reimplanted into the appropriate sinuses of the stentless root, cutting an orifice in the root slightly smaller than the button since the fixed tissue will not stretch. Continuous small (5-0) caliber polypropylene suture is used for these anastomoses. Extreme care must be taken to keep the right coronary high and to the patient's right to avoid kinking when the right ventricle fills up. Small conus or atrial branches may require sacrifice to protect the course of this vessel. Ironically, greater care must be taken if the right is a nondominant vessel, as it is more easily kinked.

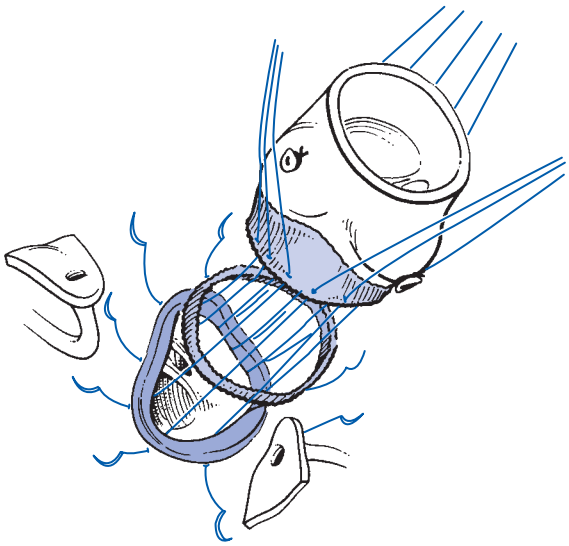

Figure 36-9. Full root technique—proximal suture line. This is the interrupted technique with a reinforcing "collar" of fabric or pericardium. (*Modified and reproduced with permission from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

The fat at the base of the right coronary should be fully mobilized prior to implantation to let this ride up freely.

The distal end of the bioprosthesis is usually smaller than the distal aorta but this difference can be gathered together and also helped by trimming the distal end of the device on a bevel with more trimmed posteriorly than anteriorly. The distal suture line is constructed with continuous polypropylene (Fig. 36-10). Some surgeons have found a thin layer of biological glue to be helpful in avoiding bleeding problems at these important suture lines exposed to aortic pressures. Strict avoidance of episodic hypertension after surgery is also important.

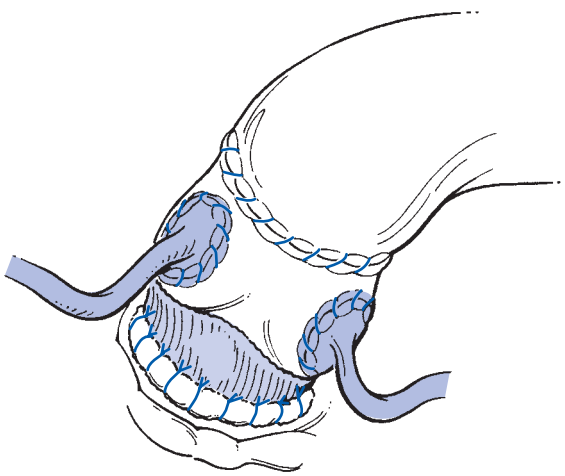

Figure 36-10. Full root technique—final appearance. The coronary "buttons" have been reimplanted and the distal end of the device attached to the native aorta. (*Modified and reproduced with permission from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

Single Suture Line

The appeal of a single suture line (common to the stented devices) has led to two separate approaches to allow this. The Shelhigh Superstentless and the 3F Therapeutics valve can be implanted with a proximal suture line that resembles a stented valve implant. The top of each commissure is equipped with a small patch that is then attached to the aortic wall at an appropriate location with the sutures tied on the outside. The Sorin Freedom Solo and the CryoLife O'Brien valves are placed with a more sophisticated supra-annular running suture line that places the stentless annulus securely above and along the scalloped course of the native annulus up and around each commissure (Fig. 36-11). Three sutures are begun (one at the nadir of each sinus) and brought progressively up to each commissural tip with the ends brought outside the aorta for tying (Fig. 36-12). (The use of a 3-0 polypropylene suture with a small taper cut half circle V5 needle facilitates secure attachment.) Sewing part of the way with each limb and then completing each allows better visualization of the native aortic wall in the deeper parts of the sinuses.

Choice of Technique

The very small root is difficult for intra-aortic techniques whether one uses a stentless or a stented valve. Petrachek describes a small root algorithm based on indexed effective orifice area (IEOA) expected for a given size. The expected superior hemodynamics (as opposed to stented valves) leads him to recommend a stentless subcoronary valve for most patients over 65 years of age. If this is hindered by anatomic constraints, a stented valve is acceptable if the IEOA is >0.85 cm^2/m^2. Root replacement is his next choice, but there is a

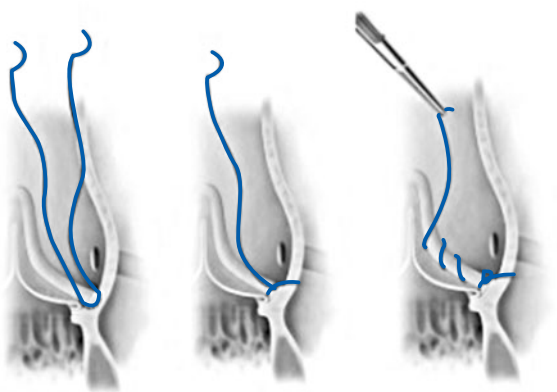

Figure 36-11. Single suture line technique—supra-annular stitches. Deep bites of aortic wall just above the annulus are joined to the entire depth of the aortic wall of the device beginning in the depths of each sinus. (*Modified and used with permission of Sorin Biomedica Cardio S.pA., Saluggia, Italy.*)

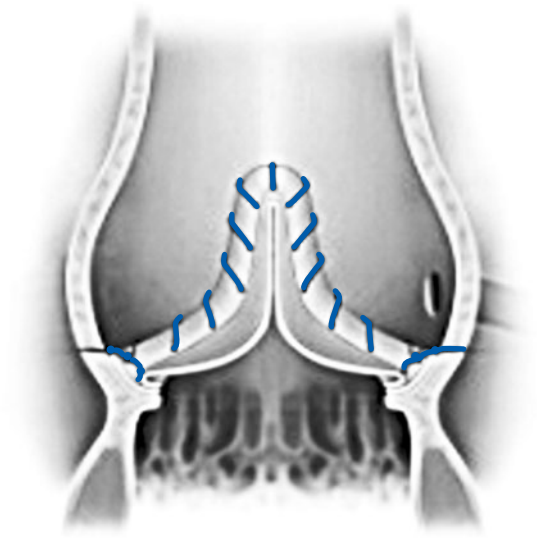

Figure 36-12. Single suture line technique—final appearance.The commissures of the replacement valve are superimposed over the native commissures and the attachment sutures are brought to the outside of the aorta to tie. (*Modified and used with permission of Sorin Biomedica Cardio S.pA., Saluggia, Italy.*)

perceived increase in operative risk.[39] He also points out the need to address subvalvular obstruction in the small root patient.

Several clinical scenarios make other techniques advisable. A large root in a young patient likely to outlive his valve is ideal for the root inclusion technique, which by preserving the native root should make reoperation easier. However, a severely diseased or aneurysmal root needs replacement. A very large root with distal dilatation is certainly a poor place for modified subcoronary technique and is better served by root replacement with a large stentless device. If complete root replacement is required in a very young patient, keeping the coronary buttons large will allow repeat root replacement with greater safety.

Calcification around the coronary ostia is a warning flag. Extensive calcification may interfere with suturing either of a button for full root or even the distal suture line of a subcoronary implant. This may be the place for a stented valve or a stentless valve that can be implanted with a single suture line just above the annulus.

Low lying coronary ostia make stentless porcine (but not necessarily pericardial) intra-aortic implant techniques difficult. If just the right ostium is low, rotating the device moves the higher porcine right sinus to the native noncoronary sinus, leaving the lower porcine left coronary to use for the right. The full root technique allows both to be moved up higher. Truly bicuspid valves with only two sinuses usually present with coronary ostia directly opposed. These are most difficult for intra-aortic techniques but can be handled quite easily with full root replacement and mobilization.

Anomalies of coronary origin present unique challenges and great care must be taken to avoid injury to the anomalous vessel, as it may run in the aortic wall for some distance. If concomitant coronary bypass grafting is done, the proximal anastomoses are best placed in the native aortic wall whenever possible. In the face of severe left main disease or ostial occlusion of either coronary, reimplantation can be ignored, the ostia sutured closed or ligated, and the coronary circulation supplied by appropriate grafts.

There is no need to compromise the outflow tract with a tiny valve or resort to root-enlarging procedures. Small roots (<23 mm) can be upsized at least one size (2 mm) and usually two by using the root replacement method. The distal aorta is almost always larger in these situations and will still be larger than the bioprosthetic root.

The issue of patient-prosthesis mismatch was studied in a group of 303 patients with small aortic roots in Lahr, Germany, with focus on quality of life as well as survival. IEOA <0.75 cm^2/m^2 was predictive of impaired quality of life ($p = 0.016$) and in patients with aortic regurgitation it negatively impacted survival ($p = 0.017$).[40] This certainly makes sense. Trading aortic regurgitation for relative aortic stenosis is not well tolerated since many of these ventricles have limited contractile reserve. The authors point out that use of the root replacement technique in these patients is preferable since mismatch is extremely rare with this technique.

ECHOCARDIOGRAPHY OF STENTLESS VALVES

Gradients and Their Time Course

Consistently found with subcoronary implantation of stentless porcine valves is an early drop in transvalvular gradients with a corresponding increase in effective valve orifice area. This is felt to be due to left ventricular outflow tract remodeling. The drop in gradient is most dramatic in the first 3 to 6 months after surgery, but some further drop may be seen up to 3 years later. Interestingly, this fall in gradient is less predictably seen in the fully pericardial stentless valves.[41] Perhaps this reflects the inherently thinner profile of the pericardial tissue in the aortic root. With the full root replacement valves, the gradients are very low from the outset and remain that way. Mean gradients in single digits are typical in all but the smallest sizes of these valves.

Echocardiographic Appearance of Stentless Valves

Intraoperative transesophageal echocardiography has become a widely accepted standard of valvular heart surgery both to document valve function and to assess ventricular function. With subcoronary implantation of stentless valves using interrupted braided sutures at the inflow end and continuous polypropylene at the outflow, small paravalvular jets of regurgitation are commonly seen. The prolific group led by Bach and Deeb at the University of Michigan looked at the echocardiographic consequences of these paravalvular leaks.

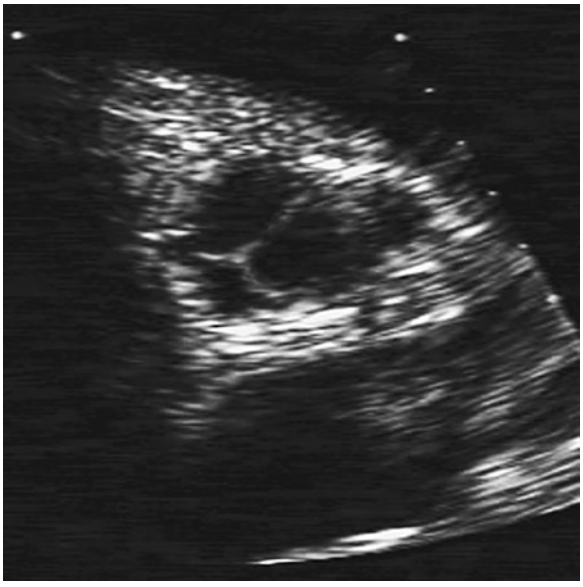

Figure 36-13. Short-axis echocardiogram of full root Freestyle valve. The aortic wall is slightly thicker than a native aorta.

As long as they are less than 2 mm wide, they resolve completely in the early postoperative period.[42] There is frequently an echo-free space between the porcine aortic wall and the native wall in the noncoronary sinus when the modified subcoronary technique is used. This should not have color flow within it and will resolve with time. Full root replacement technique produces such a natural flow pattern and gross appearance that the only clue to its bioprosthetic nature is the thicker wall of the aortic root (Figs. 36-13 and 36-14). The early drop in transvalvular gradients seen with subcoronary implants of porcine valves is not seen in full root replacements. A normal velocity envelope is the rule (Fig. 36-15).

SPECIFIC VALVES

Toronto SPV and Toronto Root

The Toronto SPV (St. Jude Medical, Inc., St. Paul, MN) was the first modern stentless valve available and has set the standards for its successors. It is a fully scalloped glutaraldehyde-fixed porcine valve with the entire external aspect covered with cloth (Fig. 36-16). It must be implanted with the full subcoronary technique. Given its early development, it has no antimineralization treatment, so its clinical advantages could be explained only by its stentless design. Follow-up for an early group of 200 Toronto SPV patients beginning in

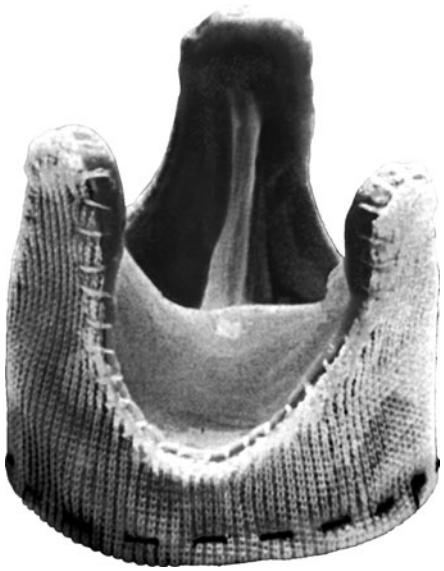

Figure 36-16. The Toronto SPV (*Used with permission of St. Jude Medical, Inc., St. Paul, MN.*)

1992 was reported by David and colleagues in 2004.[43] Operative mortality was only 2.5% in this group averaging 64.6 years of age with 34.5% requiring CABG. Actuarial survival at 5 and 10 years was 89.2 and 62%, respectively. Freedom from structural valve deterioration was 98.5% at 5 years, but turned sharply down at 10 years to only 77.9% with poorer results in patients with preoperative bicuspid aortic valves or primary aortic regurgitation. The behavior follows that of first-generation porcine tissue, which in fact this valve really is, but also reinforces the important role of the sinotubular junction which, when dilated over time, adversely affects both the competence and the durability of the subcoronary stentless valves. Reoperation was required in 12 patients (8 from structural deterioration) but the total incidence of adverse valve-related events was low. Six patients suffered thromboembolic episodes, five developed endocarditis, and one valve thrombosis occurred. The real message from this data is that porcine tissue may be less obstructive in the stentless form, but just like its stented cousin, it must be treated differently to gain a durability advantage.

The latest iteration of this device (currently in clinical investigation) is the Toronto Root Bioprosthesis. This takes advantage of modern anticalcification methods (BiLinx) and presents the surgeon with the complete range of implant flexibility from subcoronary to full root replacement (Fig. 36-17). With this development, the original SPV design will probably fade quickly from the clinical arena.

Edwards Prima and Prima Plus

The Edwards Prima and its successor the Prima Plus (Edwards Lifesciences LLC, Irvine, CA) is a porcine root with a thin cloth reinforcement over the muscle bar. The porcine coronaries were excised in the earlier version but preserved in the later version without ligation. A fine suture marks the limits of safe sinus excision to avoid injuring

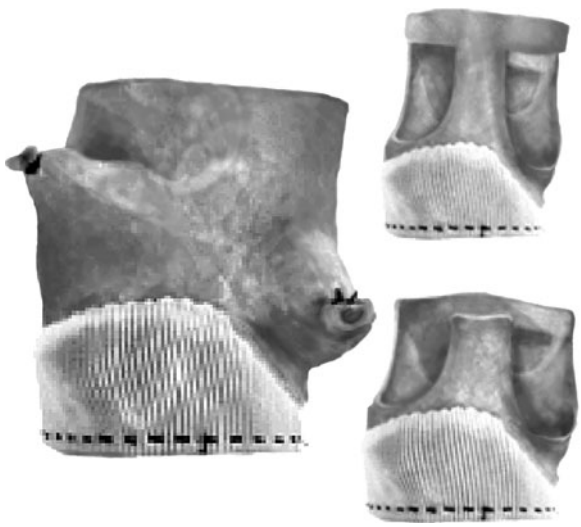

Figure 36-17. The Toronto Root. This can be used as a full root, inclusion root, or either subcoronary implant. (*Used with permission of St. Jude Medical, Inc., St. Paul, MN.*)

Figure 36-18. The Edwards Prima Plus. The dashed line is a marking suture delineating the safe extent of sinus excision so this can be used as a full root, inclusion root, or either subcoronary implant. (*Used with permission of Edwards Lifesciences LCC, Irvine, CA.*)

leaflets (Fig. 36-18). The Prima Plus is a low-pressure fixed valve with proprietary XenoLogiX treatment for calcium mitigation. Eight-year follow-up of these devices was reported by the Oxford Heart Centre in England.[44] Patients averaging 72 years of age at the time of surgery had survival rates of 82 ± 5% at 5 years and 72 ± 6% at 8 years. Freedom from structural valve failure was 97 ± 2 % at both 5 and 8 years. Valve gradients dropped early and showed no change after the third year. Mean discharge gradients of 9.7 ± 6.2 mm Hg dropped to 6.8 ± 4.4 mm Hg with a corresponding increase in effective valve orifice areas from 1.63 ± 0.71 to 1.91 ± 0.54 cm^2. Mild aortic regurgitation was seen in 17% but showed no progression over time, consistent with documented stability of normal aortic root geometry over that time in these patients.

Medtronic Freestyle

Clinical investigation of the Freestyle Aortic Root Bioprosthesis (Medtronic, Inc., Minneapolis, MN) began in 1992. It is a complete porcine root with ligated coronaries and a thin fabric "skirt" over the porcine septal muscle bar (Figs. 36-19 and 36-20). The cloth is extended around the inflow end with marking sutures for commissural orientation. The device is fixed with physiologic (40 mm Hg) pressure applied to the aortic wall but a net zero pressure across the leaflets. It is treated with alpha-amino-oleic acid as a calcium mitigant. This device was the first stentless xenograft that was intended to be implanted with the full spectrum of techniques from a fully-scalloped subcoronary valve implant to a total free-standing root replacement.

The original group of Freestyle investigators reported the 10-year results of 725 patients (668 >60 years of age). Of

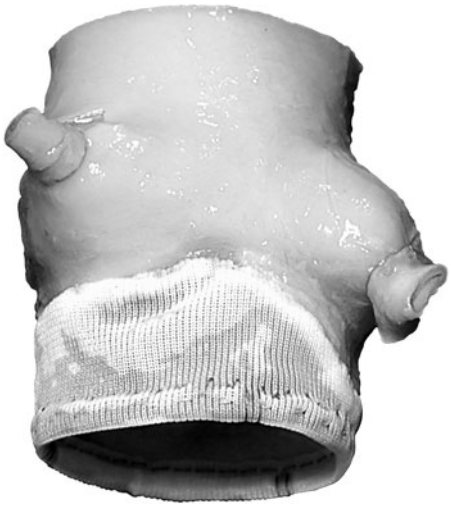

Figure 36-19. The Medtronic Freestyle Aortic Root Bioprosthesis. The longitudinal view shows the fabric covering of the porcine septal muscle and the associated higher position of the right coronary stump. (*Photographed by Stelzer, P and used with permission of Medtronic, Inc., Minneapolis, MN.*)

these, 509 had subcoronary, 178 full root replacement, and 38 root inclusion operations. Mean gradients were 10 mm Hg or less for all three implant methods, and were lowest in the full root group. Freedom from significant aortic regurgitation was better in the full root (97.7 ± 1.6%) than the subcoronary (87.2 ± 2.8%) patients at 10 years ($p < 0.005$).[45] Actuarial survival at 10 years was 94.5 ± 2.9%, 92.9 ± 5.8%, and 97.8 ± 12.5% for subcoronary, full root, and root inclusion patients, respectively, with none of these differences statistically significant. There were no significant differences in the small adverse event rates either. A total of 33 patients required reoperation including 10 for endocarditis and 10 for structural deterioration (only 3 with leaflet calcification). These are encouraging data in support of the tissue treatment conveying a durability advantage to these valves over the untreated stentless design.

In an important companion report, Kon and his Wake Forest team showed that exclusive use of the full root replacement method could be used safely (3.9% operative mortality) with superb results out to 8 years with 59.8% survival at that point.[46] There were no reoperations and no significant regurgitation developed in these valves with mean gradients only 6 to 7 mm Hg.

CryoLife-O'Brien

The CryoLife-O'Brien Model 300 (CryoLife International Inc., Kennesaw, GA) is a unique stentless device made by combining three carefully matched noncoronary sinuses with their leaflets into a single three-leaflet valve without any additional biologic or cloth support (Fig. 36-21). The tissue is fixed in glutaraldehyde but there is no specific antimineralization treatment of this valve. The design allows for supraannular implantation with a single suture line. Oversizing by 1 to 2 mm is possible, but excessive oversizing can cause buckling of tissue with resultant obstruction or regurgitation or both. The precise technical details of implanting this valve have been delineated by O'Brien himself.[47] The device must be placed above the native annulus with deep bites in the native aortic wall and extremely broad bites of the aortic wall of the prosthesis as close to the base of the leaflet as possible to avoid leaving space under the device.

A series of 206 patients averaging just under 73 years of age was studied over 8 years (mean 56 months) at the Klinikum Krefeld in Germany. The 30-day operative mortality of 4.8% is realistic for this age group with 35% undergoing concomitant coronary surgery. Of note, most patients received 25 mm or larger valves, but severe regurgitation resulted from too much oversizing, leading to early reoperation in three patients. The early decrease in

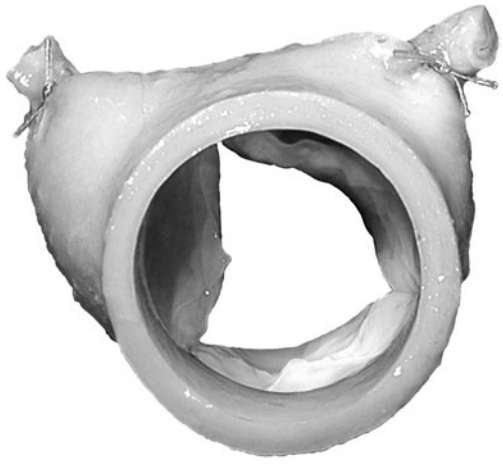

Figure 36-20. Top view of Medtronic Freestyle. The bulging porcine sinuses are visible and thickness of the tissue is apparent. (*Photographed by Stelzer, P and used with permission of Medtronic, Inc., Minneapolis, MN.*)

Figure 36-21. The CryoLife-O'Brien valve. This device has no cloth covering and no muscle because of its composite design. Sutures joining the three segments are obvious at each commissure. (*Used with permission of CryoLife Inc., Kennesaw, GA.)*

transvalvular gradients typical of stentless valves placed inside the native aortic root was observed with a significant increase in effective valve orifice areas in the first 6 months. Actuarial survival at 8 years was 82% ± 3% with none of the 12 late deaths being valve-related. There was no endocarditis and freedom from thromboembolic events was 93%.[48]

The progressive improvement in effective orifice area holds true even for the smaller sizes. Gelsomino and colleagues in Udine, Italy, followed 62 patients receiving 21- to 23-mm CryoLife O'Brien valves over a 7-year period. Nearly 80% of these were female. At discharge, 12 patients had IEOA $<0.85\ cm^2/m^2$, but only two persisted at 6 months and none at late follow-up. Patients with higher IEOAs demonstrated earlier concentric remodeling but after 1 year there was no difference. This is consistent with the improvement in gradient and increase in valve area over time and its favorable impact on regression of ventricular hypertrophy.[49]

It should be noted that the CryoLife-O'Brien 300 valve was originally called the Bravo Model 300 (Bravo Cardiovascular Inc., Irvine, CA) before the rights were obtained by CryoLife. This is not to be confused with the Bravo 400, which was a complete porcine root equipped with outflow reinforcement using equine pericardium.[50] The rights to this device were also obtained by CryoLife, but its production was discontinued.

Figure 36-22. The Sorin Pericarbon Freedom Valve. This is a completely pericardial construction designed for subcoronary implantation with a double suture line, but it can also be trimmed to allow a single suture line technique. The newer Freedom Solo is designed specifically for use with a single suture line. (*Modified and used by permission from Huysmans HA, David TE, Westaby S: Stentless Bioprostheses, 2nd ed. Oxford, UK, Isis Medical Media Ltd, 1999.*)

Sorin Pericarbon Freedom and Freedom Solo

The Sorin Pericarbon Freedom valve (Sorin Biomedica Cardio S.p.A., Saluggia, Italy) is a completely pericardial stentless valve constructed by sewing two sheets of bovine pericardium together and then making a tube out of the combination (Fig. 36-22). The inner sheet is shaped to provide "leaflets" and the outer sheet provides support for attachment. They are sewn together with a special tension-relieving cross-stitch at the commissures using pyrolite carbon-based impregnation of the suture material (Fig. 36-23). It was originally designed for implantation with a double suture line like the full subcoronary porcine devices.

In Hungary, a group of 102 Pericarbon stentless valves were implanted over the 3-year period of 2000 to 2002 and followed for a mean of 26 months. Early mortality was 6.8% with none of these valve-related. Similarly to porcine stentless valves implanted within the native aorta, these valves demonstrated a drop in transvalvular gradient over time. The mean gradient dropped from 12.8 ± 8.5 to 9.1 ± 2.3 mm Hg and peak gradient fell from 22.5 ± 13.9 to 16.1 ± 4.3 mm Hg. There was no more than trivial regurgitation in any patient but one developed early endocarditis and required reoperation.[51]

The question of implant suture technique with this valve was addressed at the Charité in Berlin with a prospective matched trial (not randomized) of 139 patients to compare continuous and interrupted suturing of the inflow end of the Sorin Pericarbon Freedom stentless valve. There was no difference in outcome but a slightly shorter clamp time for the continuous technique.[52]

The Sorin valve can also be implanted with a single suture line technique like the one used for the CryoLife O'Brien valve. The excess tissue is trimmed from the inflow end of the device and the sinuses are fully scalloped. Using this technique in Bergamo, Italy, Repossini and colleagues reported 65 consecutive patients operated on between 2002 and 2004.[53] They had a mean age of 69 and nearly one-half had concomitant procedures with only one early mortality. Clamp times averaged 76 minutes. Regurgitation was trivial in only four at operation and remained detectable in only one 6 months later. Gradients were respectable with mean 10.2 ± 7.1 and peak 18.1 ± 12.3 mm Hg. These were for 25 to 29 size valves with 25 and 27 being the most frequently implanted sizes. Experience like this led to the production of the Sorin Freedom Solo valve which is specifically designed for the single suture line implantation method.

Biocor Stentless

The Biocor Stentless aortic valve (Biocor Industria e Pesquisas LTDA, Belo Horizonte, Brazil) is a porcine aortic valve

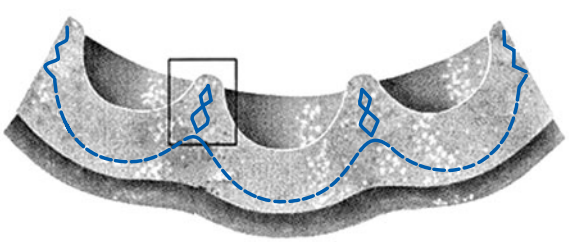

Figure 36-23. Unique construction of the Sorin Pericarbon Freedom Valve. Two sheets of bovine pericardium are sewn together and then formed into a cylindrical device with unique tension-relieving sutures at each commissure. (*Used with permission of Sorin Biomedica Cardio S.p.A., Saluggia, Italy.*)

treated with the No-React (Shelhigh Inc., Union, NJ) process. Initial experience from 1993 to 1995 in Hannover, Germany, showed this to be a hemodynamically attractive option in the small aortic root with shorter implant times compared to root enlargement procedures and low gradients compared to stented devices.[54] In a group of 247 patients operated on from 1990 to 2001 in Brazil with a mean follow-up of nearly 6 years, the Biocor stentless porcine valve performed extremely well, with mean gradients of 9.0 mm Hg and peak of 17 mm Hg. Freedom from reoperation was 99% and actuarial survival at 10 years 91%.[55]

Over a 10-year period, 112 patients had aortic valve replacement with the Biocor Stentless valve in Sweden.[56] The mean age was 78.5 and 31% had concomitant coronary surgery. Early mortality was 7%. Follow-up was 100% complete with a mean of 66 months. Using Swedish life tables for age and gender matching, these patients had no difference in actuarial survival from the normal population. Given the age of the patients, however, that translated to 5- and 9-year survivals of 74 ± 5% and 38 ± 7%, respectively. Freedom from reoperation was equal to freedom from structural degeneration at 96 ± 2% and 87 ± 6% at 5 and 9 years. Even though the average size implanted was only 23 mm, the transvalvular mean gradients at 9 years were very low at 7.3 ± 1.3 mm Hg. Slow progression of aortic regurgitation was the cause of reoperation in only two patients.

Shelhigh Superstentless and Shelhigh Bioconduit

A sister valve to the Biocor is the Shelhigh device, which shares the proprietary No-React tissue treatment. It is available in two forms, an isolated porcine aortic valve (Fig. 36-24), and a

Figure 36-24. The Shelhigh Superstentless valve. This device requires only an annular suture line and fixation of each commissure to the aortic wall. Small patches of pericardium are placed at each commissure to facilitate attachment. (*Used with permission of Shelhigh, Inc., Union, NJ.*)

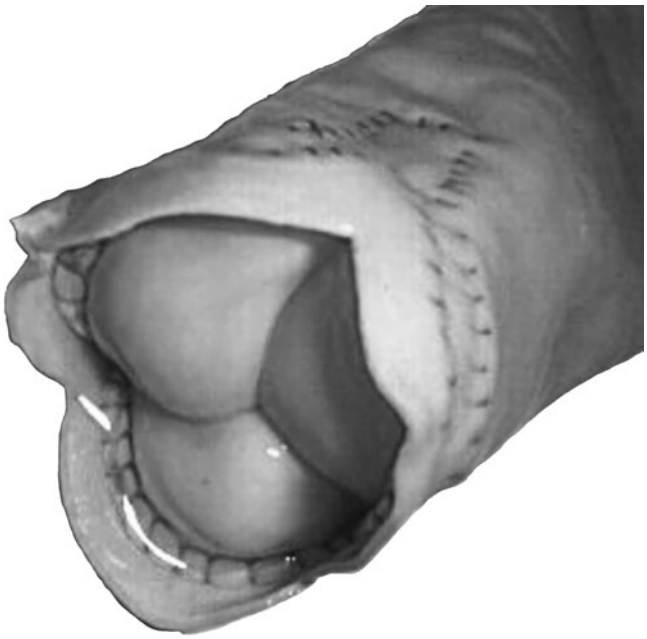

Figure 36-25. The Shelhigh Bioconduit. This shows the stentless porcine valve inside a pericardial tube without any cloth material. (*Used with permission of Shelhigh, Inc., Union, NJ.*)

valved conduit with a porcine valve enclosed in a bovine pericardial tube (Fig. 36-25). The basic valve is unusual in that it combines an annular suture line with simple commissural fixation without a formal distal suture line. This makes it technically easier to implant. The inflow end is reinforced with bovine pericardium and the commissural attachment patches are also bovine pericardium. The conduit version is made by suspending porcine leaflets in a long bovine pericardial tube to produce a valved conduit. Sizes from 21 to 31 mm are made. In Switzerland, 35 patients had complete aortic valve and root replacement with reimplantation of coronary arteries using this device.[57] There was only one early death, from persistent sepsis in the setting of methicillin-resistant *Staphylococcus aureus*. The hemostatic advantages of sewing to pericardial tissue were noted in this complex group of patients. Gradients were very low with means ranging from 14.2 down to 6.0 mm Hg, appropriate to the sizes of 21 to 29 mm. Only one patient had even minimal regurgitation. Important 1-year follow-up studies of aortic dimensions showed no dilatation of the pericardial tube in 15 patients. The potential disadvantage of a straight tube without sinuses of Valsalva in regard to leaflet wear and closing forces must await long-term follow-up evaluation.

3F Aortic Bioprosthesis

The 3F Aortic Bioprosthesis (3F Therapeutics, Lake Forest, CA) is a completely collapsible structure made from three equal pieces of equine pericardium joined together with a circular base reinforced with fabric and commissures equipped with small fabric patches for attachment to the aortic wall (Fig. 36-26). Initial clinical performance of this stentless valve was assessed in Frankfurt, Germany, in 24 patients. Contrary

Figure 36-26. The 3F Aortic Bioprosthesis. The device is made of three pieces of equine pericardium with a thin cloth inflow covering and attachment patches for each commissure. (*Used with permission of 3F Therapeutics, Lake Forest, CA.*)

to some of the bovine pericardial stentless devices these patients did show the typical early postoperative drop in transvalvular gradients to an average mean of 10.3 mm Hg and effective orifice area of 1.7 cm^2. The authors thought the device comparable to other stentless valves, but found its unique design a benefit in facilitating implantation.[58] The pliable nature of this valve was also felt to contribute to performance and ease of implantation at the Charité in Berlin, where 35 patients were equipped with this device. Cross-clamp times averaged under an hour and there was no mortality.[59] This device is not treated with any calcium mitigants and durability of equine as opposed to bovine pericardium has yet to be demonstrated.

SPECIAL SITUATIONS

Endocarditis

Endocarditis still presents surgeons with the dual challenge of adequate débridement of infected tissue and reconstruction with low risk of recurrent or persistent infection. In the aortic position, the aortic homograft has been a time-honored and sturdy option, but its limited availability makes the stentless bioprosthesis an attractive alternative. A number of reports have documented the versatility of this option. In a group of 25 patients with aortic annular abscess the Deutsches Herzzentrum Berlin used the Shelhigh Superstentless and its sister conduits and compared these to 68 historical controls whose endocarditis was treated with aortic homograft reconstruction. The operative mortality rates (16 versus 12%) were similar and recurrent infection afflicted 4% of each group.[60] The group in Osaka reported using the Freestyle root in five patients with complex aortic root endocarditis.[61] Five patients with similarly destructive root endocarditis were treated with Freestyle root replacement in Turkey without mortality or recurrent infection.[62] These reports of success are encouraging that the stentless devices may help fill the gap in these difficult situations.

Reoperation

Although experience is very limited, the Michigan group with extensive experience in stentless valve surgery reported experience with 10 patients who required reoperation, 7 for prosthetic valve endocarditis. These had all been implanted within the native aortic root, so it was possible to find a plane between the device and the native aortic wall by opening the distal suture line and using blunt dissection to separate this down to the proximal sewing ring. The proximal suture line was then divided sharply. Encouragingly, all patients survived reoperation.[63]

Ascending Aortic Aneurysm

In the setting of a true aneurysm of the ascending aorta (Fig. 36-27), complete resection of the abnormal tissue and replacement by a vascular graft is standard practice. The combination of these grafts factory-equipped with mechanical valves in various sizes is an option which is readily available, but results in the need for lifelong anticoagulation. In the elderly population and very active younger population, this option may not be desirable. The option of incorporating a Toronto SPV device into a vascular graft for this purpose was reported in 45 consecutive patients with no operative mortality.[64] Hemodynamics were excellent with mean gradients of only 8.5 mm Hg at

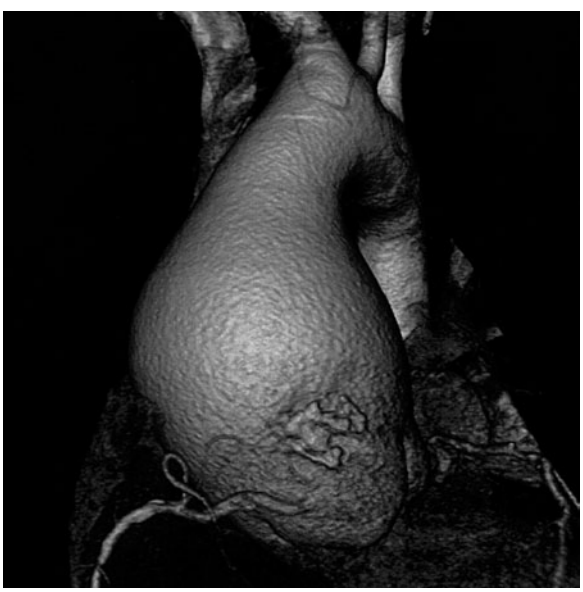

Figure 36-27. Aortic root aneurysm. This 64-slice CT reconstruction demonstrates a 7.9-cm diameter aneurysm in a 48-year-old male with aortic regurgitation through a three-leaflet aortic valve.

discharge and 8.0 mm Hg at follow-up which averaged 18 months.

The alternative of building a tissue valved conduit with a variety of valves and various size vascular grafts is an alternative that has been shown to be safe (mortality rate 5.1%) and durable (no reoperations for as long as 12 years) in 59 patients.[65] These patients were younger (mean 56 years) and mostly male (45), but 24 were emergency operations, predominantly type A dissections. The Toronto stentless valve was used inside a separate vascular graft in another German study to show an extremely safe and effective alternative method in 45 older patients (mean 69 years) with ascending aneurysm (42) or dissection (3) and no early mortality.[66] It is to this kind of alternative that the results of composite stentless root replacement must be compared.

A custom version of the Freestyle device with extended porcine aortic segment ("long neck") was used to replace the root and ascending aorta in six patients in Stuttgart, Germany.[67] This avoided the need for extension with a tubular graft and the potentially troublesome suture line between two nonliving structures. Advantages in cost, time, and hemostasis were realized, but it is extremely difficult to provide these conduits from a manufacturing standpoint. Very limited experience with the Shelhigh Bioconduit shows this, too, to be a possible option for complete biologic replacement of the root and ascending aorta.[68]

From Japan comes a report of using the Freestyle root replacement extended by a vascular graft. There were two early and three late deaths in this group of 24 patients with fairly long (210 minutes) ischemic times.[69] This technique was used successfully even in the setting of acute and chronic dissection in four patients at another Japanese institution.[70]

The simple composite alternative is very appealing and readily applicable. One can replace the root pathology with a stentless root bioprosthesis and extend it up to or into the arch with an appropriate diameter vascular graft (Fig. 36-28). This can often be a more timely way to do the operation. If the aorta can be clamped, work on the root can begin during cooling. The distal anastomoses of the graft to the arch can be done under circulatory arrest as soon as the temperature is low enough. This graft is then clamped and warming can proceed while the root reconstruction is completed.

Elderly

The perceived increase in risk of more complex procedures is particularly keenly felt when operating on elderly patients. John Pepper's group at the Royal Brompton Hospital in London retrospectively reviewed a group of 103 patients aged 75 to 91 (mean 79.8 years) who underwent stentless AVR.[71] (They included 29 patients with aortic homografts as well as 74 Toronto valves.) Although the group had multiple patients with multiple comorbidities and concomitant procedures, the overall 30-day mortality was just 11.6%. For elective cases it was 5.3% and for isolated, elective AVR only 2.5%. Mean follow-up was only 3.6 years, but actuarial survival was 52% at 5 years and 92% were in New York Heart Association functional class I or II despite their age. A multivariate model showed increasing age as the only independent predictor of mortality, both immediate and in follow-up.

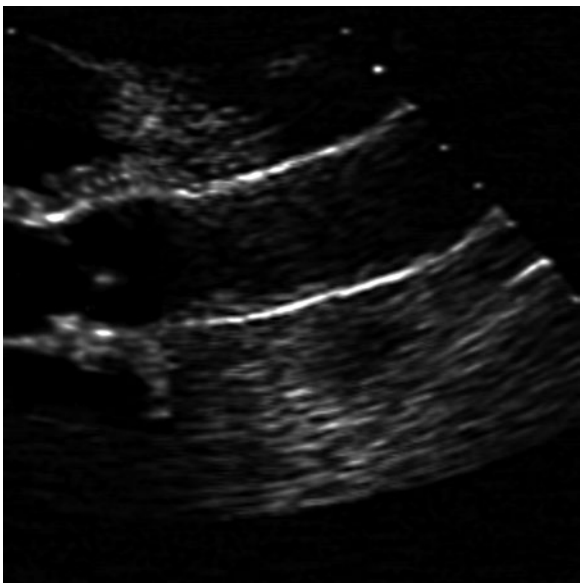

Figure 36-28. Composite reconstruction echocardiogram. The bright echodensity of the 26 mm vascular graft is seen attached to the distal end of a 29 mm Freestyle root replacement (long axis) of the patient shown in Fig. 36-27 on his fourth postoperative day when he was discharged home.

Poor Left Ventricular Function

In a small but very interesting study of stentless versus stented aortic valves in patients with poor left ventricular function (LVF), the Royal Brompton team in London demonstrated an immediate improvement in fractional shortening and decrease in LVM with the stentless but not the stented valves.[72] However, after a year the differences were not significant. One must always remember that long-term benefit is always dependent on short-term survival. Hence, the early difference may have a major impact in some of these sicker patients. This impact of residual obstructive gradients is dramatically demonstrated in the data from Quebec which demonstrated a very significant increase in short-term mortality with moderate or severe patient-prosthesis mismatch for AVR when EF was $<40\%$.[73] The risk in the group with moderate mismatch rose from 1.8 to 7.1%, and that for patients with severe mismatch went from 11.3 to 77.1%. Clearly, the combination of poor ventricular function and a replacement aortic valve that leaves significant obstruction is highly lethal. A small study in Italy compared stentless to stented or mechanical valves in 53 patients with LVEF $<35\%$. Despite the slightly longer cross-clamp times, the stentless aortic valve patients had significantly larger effective orifice areas and greater recovery of LVF without any increase in mortality.[74]

Diastolic Dysfunction

The problem of systolic dysfunction as an end-stage result of aortic stenosis is well recognized, but the earlier relaxation impairment of these hypertrophied ventricles is much more poorly understood and often ignored. The use of stentless valves has both a potential for increased long-term benefit and short-term risk in this setting. Complete removal of afterload by restoring normal size and flow to the left ventricular outflow tract (LVOT) with a stentless root replacement has immediate impact on left ventricular stroke work and maximal impact on LVM regression. Although the mechanism of diastolic dysfunction is poorly understood, the reduction of hypertrophy is of profound benefit to these patients. Those with long-standing interstitial fibrosis will benefit less, but removing the cause of hypertrophy as completely as possible seems an appropriate goal.

The problem comes from the fact that early after surgery, the stiff ventricle (often with hyperdynamic systolic function) (Figs. 36-29 and 36-30) can develop dynamic LVOT obstruction when the thick basal septum (albeit part of a concentric hypertrophy) catches the anterior mitral leaflet with systolic anterior motion as seen after some mitral valve repairs. This is most apt to occur in the setting of low systemic pressure, fast heart rate, and low-volume states. The worst possible scenario occurs with acute onset atrial fibrillation which causes all three of these effects. A stented valve holds the aortic annulus open, but a stentless valve does not provide such rigid resistance to dynamic LVOT obstruction. Hence, there is a much greater risk of disastrous consequences. This is most often seen in the elderly female patient with hypertension who is most likely to have diastolic dysfunction. (The unique impact of this condition was brought out by personal experience in the early part of the Freestyle investigation. Using the full root technique led to higher mortality rates, but a closer look at the deaths revealed all but one to be elderly female.)

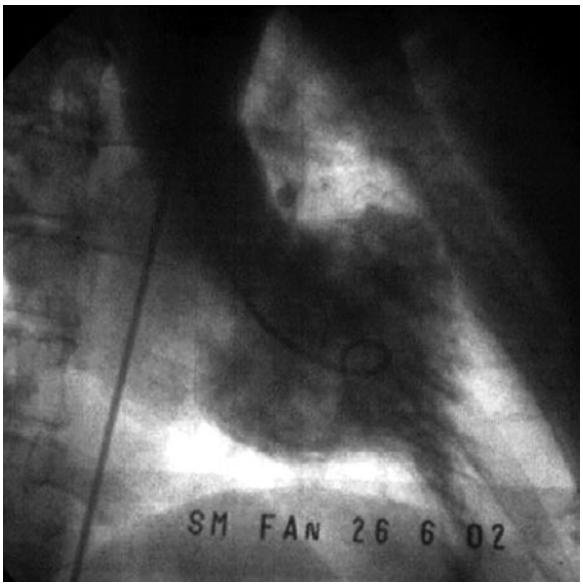

Figure 36-29. Hyperdynamic left ventricular function—diastole. Prominent papillary muscle shadows are seen in this hypertrophied ventricle, even in this diastolic frame.

Figure 36-30. Hyperdynamic left ventricular function—systole. Complete distal cavity obliteration is apparent in systole.

Unfortunately, the clinical picture of hypertension, dyspnea, oliguria, and peripheral signs of low forward output trigger knee-jerk responses of inotropes, diuretics, afterload reduction, and digitalis. All of these (which are helpful in systolic heart failure) can be counterproductive to the stiff heart. The bottom line is that the left ventricle must be kept full even though the lungs may object. Prompt restoration of sinus rhythm makes perfect sense in the setting in which E:A reversal of mitral inflow underscores the importance of the atrial "kick" in these patients (Fig. 36-31). A strategy of loading these

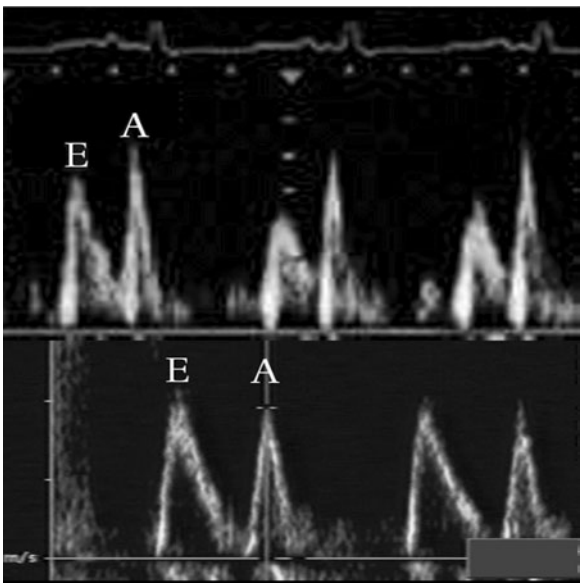

Figure 36-31. Mitral inflow patterns of abnormal relaxation. The lower panel shows nearly equal E and A waves, and the upper panel demonstrates clear reversal of the E:A ratio. With ventricular filling so dependent on atrial transport, new-onset atrial fibrillation can be devastating.

patients (on an outpatient basis) with amiodarone for a week prior to surgery might be advisable whenever possible to help prevent atrial fibrillation. Beta-blockers should also be used and perhaps verapamil or even disopyramide to treat the hyperdynamic left ventricle until its mass can be restored to more normal levels. Higher blood pressures should be tolerated, as this afterload helps prevent collapse of the LVOT. Lower cardiac indices must be accepted temporarily to avoid the counterproductive effects of using inotropes. Pulmonary artery pressures can be very misleading in these patients, as they can be very high in a setting in which the left ventricle is still underfilled. Echocardiography is essential in sorting out these issues and guiding therapy.

As a corollary to this issue, timing of AVR, particularly in older females, should be reconsidered. A Swedish study found that moderate to severe diastolic but not systolic dysfunction at the time of aortic valve surgery is predictive of long-term mortality risk and its significance tended to increase with time up to 12 years after AVR.[75] Waiting for the classic indication of symptomatology may be waiting for severe hypertrophy and its deadly diastolic consequences. Asking an 80-year-old woman with a valve area of 0.9 cm^2 to wait until she is 83 with an area of 0.7 cm^2 no longer makes sense but just multiplies risk. An EF of 85% should not be seen as good news, but rather as the "suicide" ventricle it really is. Guidelines need to be developed to encourage safer AVR at an earlier stage in the disease process. Clearly the durability of current devices is such that fear of structural deterioration should not delay surgery in these older patients.

FUTURE OF STENTLESS VALVES

It is ironic that one of the newest stentless valves is destined to be placed back on a stent and delivered to the aortic root by a catheter. It is also evident that the choice of equine pericardium for this purpose was made without any clinical experience or attempts to optimize the durability of this tissue with fixation or antimineralization technologies now used in the preparation of other surgically implanted alternatives.

More significant is the fact that adoption of stentless valves has been limited despite considerable enthusiasm and good data from the early adopters. The dual perceptions of increased surgical technical challenge and increased risk keep the low-volume valve surgeon from using these devices. Where possible, groups might benefit from consolidating specialized valve experience to fewer surgeons in order to optimize experience and outcomes. Training opportunities in and after residency must be provided to make the benefits of these devices more widely available to patients. With so much information freely accessible to the public electronically, more patients will come to surgical consultation already aware of stentless valve options. Their questions should not be dismissed but discussed intelligently. Continued careful trials of many alternatives must be encouraged to have the data to guide this joint decision-making process. Newer is not always better, but sometimes it really is. Surgeons of the twenty-first century must provide the answers to a lot of twentieth century questions.

CHAPTER 37

Aortic Valve Repair and Aortic Valve–Sparing Operations

Tirone E. David

FUNCTIONAL ANATOMY OF THE AORTIC VALVE

The aortic valve is a complex structure that is best described as a functional and anatomic unit, the aortic root. The aortic root has four components: aortic annulus, aortic cusps, aortic sinuses, and sinotubular junction. In addition, the triangles beneath the commissures of the aortic valve, although part of the left ventricular outflow tract, are also important for valve function.

The aortic annulus unites the aortic cusps and aortic sinuses to the left ventricle. The aortic annulus is attached to the ventricular myocardium (interventricular septum) in approximately 45% of its circumference and to fibrous structures (anterior leaflet of the mitral valve and membranous septum) in the remaining 55% (Fig. 37-1). The aortic annulus has a scalloped shape. Histologic examination of the aortic annulus reveals that it is a fibrous structure with strands attaching it to the muscular interventricular septum and has a fibrous continuity with the mitral valve and membranous septum. The fibrous tissue that separates the aortic annulus from the anterior leaflet of the mitral valve is the intervalvular fibrous body. An important structure immediately below the membranous septum is the bundle of His. The atrioventricular node lies in the floor of the right atrium between the annulus of the septal leaflet of the tricuspid valve and the coronary sinus. This node gives origin to the bundle of His, which travels through the right fibrous trigone along the posterior edge of the membranous septum to the muscular interventricular septum. At this point the bundle of His divides into left and right bundle branches that extend subendocardially along both sides of the interventricular septum.

The aortic cusps are attached to the aortic annulus in a scalloped fashion (see Fig. 37-1). The aortic cusps have a semilunar shape whereby the length of the base is approximately 1.5 times longer than the length of the free margin, as illustrated in Fig. 37-2. There are three cusps and three aortic sinuses: left, right and noncoronary. The aortic sinuses are also referred to as sinuses of Valsalva. The left coronary artery arises from the left aortic sinus and the right coronary artery arises from the right aortic sinus. The left coronary artery orifice is closer to the aortic annulus than is the right coronary artery orifice. The highest point where two cusps meet is called the commissure, and it is located immediately below the sinotubular junction. The scalloped shape of the aortic annulus creates three triangular spaces underneath the commissures. The two triangles beneath the commissures of the noncoronary cusp are fibrous structures, whereas the triangular space beneath the commissure between the left and right cusps is muscular. These three triangles are seen in Fig. 37-1. The sinotubular junction is the end of the aortic root. It is an important component of the aortic root because the commissures of the aortic valve are immediately below it and changes in the sinotubular junction can affect the function of the aortic cusps.

The geometry of the aortic root and its anatomic components varies among individuals, but the geometry of these components is somewhat interrelated.[1–4] For instance, the larger the aortic cusps, the larger the diameters of the aortic annulus and sinotubular junction.[2] The aortic cusps are semilunar (crescent-shaped) and their bases are attached to the annulus; the free margins extend from commissure to commissure, and the cusps coapt centrally during diastole. The size of the aortic cusps varies among individuals and within the same person, but as a rule, the noncoronary cusp is slightly larger than the right and left. The left is usually the smallest of the three. Because of the crescent shape of the aortic cusps and the fact that their free margins extend from commissure to commissure, the diameter of the aortic valve orifice must be smaller than the length of the free margins. Indeed, anatomic studies of fresh human aortic roots demonstrated that the average length of the free margins of the aortic cusps was one-third longer than the diameter of

Figure 37-1. A photograph of a human left ventricular outflow tract and aortic root.

the aortic orifice.[1] The diameter of the aortic annulus is 15 to 20% larger than the diameter of the sinotubular junction in normal aortic roots of young persons, but these diameters tend to become equal in older ones (see Fig. 37-2). All components of the aortic root are very elastic and compliant in young patients but this compliance decreases with age as elastic fibers are replaced by fibrous tissue.

The aortic annulus, the aortic cusps, and the sinotubular junction play an important role in maintaining valve competence. On the other hand, the aortic sinuses play no role in valve competence,[5] but they are believed to be important in minimizing mechanical stress on the aortic cusps during the cardiac cycle.[6–7]

AORTIC VALVE PATHOLOGY IN ADULTS

Anatomically normal aortic cusps may become calcified late in life and cause aortic stenosis. This type of lesion is called dystrophic calcification, senile calcification, or degenerative calcification. The range of histopathologic lesions includes

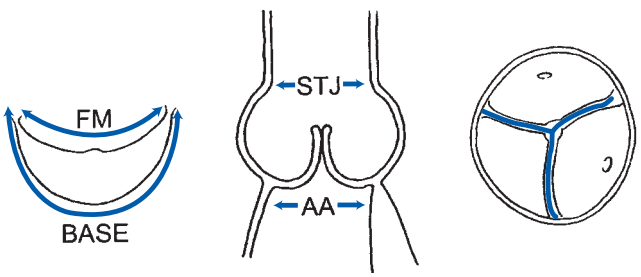

Figure 37-2. Geometric relationships of various components of the aortic root. The base of the aortic cusp is 1.5 times longer than its free margin (FM). The diameter of the aortic annulus (AA) is 10 to 15% larger than the diameter of the sinotubular junction (STJ) in children and young adults, but it tends to become equal with aging. Three semilunar cusps seal the aortic orifice. The height of the cusps must be longer than the radius of the aortic annulus.

calcification, chondroid and osseous metaplasia, neorevascularization, inflammation, and lipid deposition.[8] The pathogenesis of this lesion is not well understood. Aging is certainly the most important epidemiologic factor.[8–11] Degenerative calcification is an active inflammatory process with similarities and dissimilarities to atherosclerosis.[9–11] Aging and high levels of lipoprotein [a] were found to be correlated with aortic valve sclerosis.[9] Many studies have shown that treatment with 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) reduces the rate of progression of aortic valve stenosis,[12–13] but early results of a randomized trial did not confirm these findings.[14] Degenerative calcification of the aortic valve is the most common cause of aortic stenosis in elderly patients in North America.[15–16]

Bicuspid aortic valve occurs in 1 to 2% of the population and it is probably heritable.[17] It usually functions satisfactorily and does not cause hemodynamic problems until late in life when it becomes calcified and stenotic. Calcified bicuspid aortic valve is the second most common cause of aortic stenosis in elderly patients.[15] Bicuspid aortic valve can also cause aortic insufficiency, particularly in young patients in whom mild to moderate dilation of the aortic root is present.[18–19] Most patients with bicuspid aortic valve have three aortic sinuses. The two cusps are of different sizes and the larger one often contains a raphe instead of a commissure. The raphe extends from the mid-portion of the cusp to the aortic annulus, and its insertion in the aortic root is at a lower level than the other two commissures. Bicuspid aortic valves with two aortic sinuses and no raphe are uncommon. The right coronary is nondominant in most patients with bicuspid aortic valve.

Unicusp aortic valve is another congenital anomaly of the aortic valve. It often contains only one commissure and causes aortic stenosis. Bicuspid and unicusp aortic valves are frequently associated with premature degenerative changes of the media of the aortic root and ascending aorta. They increase the risk of aneurysms and type A aortic dissection.[20]

Quadricusp aortic valve is a rare anomaly that may cause aortic insufficiency. Three of the four cusps are usually of similar size and the other is hypoplastic.

Subaortic membranous ventricular septal defect (VSD) with aortic insufficiency is uncommon in adults. The interventricular septal defect (ISD) causes distortion of the aortic annulus, and the right aortic cusp is often elongated and may prolapse and cause aortic insufficiency.

Dilation of the aortic root is the most common cause of aortic insufficiency in North America.[15–16] Older patients with ascending aortic aneurysm may develop aortic insufficiency because of dilation of the sinotubular junction (Fig. 37-3). The aortic sinuses and aortic annulus may remain relatively normal in these patients. Aortic aneurysm in young patients usually begins with dilation of the aortic sinuses, which progresses into the sinotubular junction and ultimately aortic annulus. Annuloaortic ectasia is a term used to describe dilation of the aortic annulus. Aortic root aneurysm is common in patients with Marfan syndrome, which is an

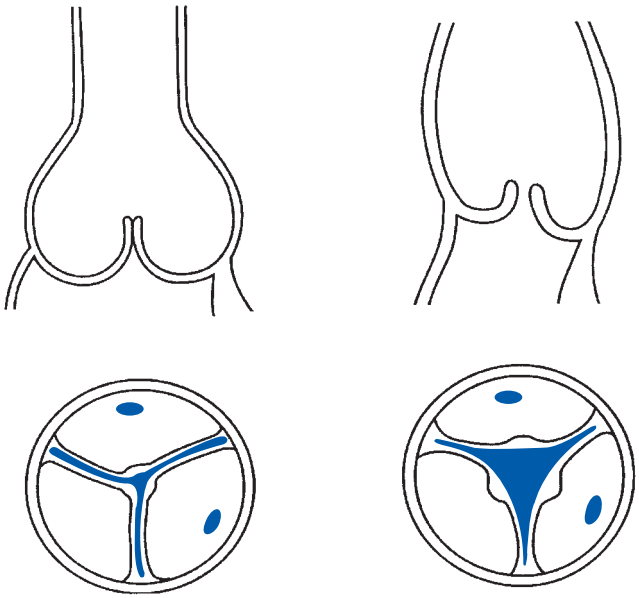

Figure 37-3. Dilation of the sinotubular junction causes aortic insufficiency because it displaces the commissures outward and prevents the cusps from coapting centrally.

autosomal dominant variably penetrant inherited disorder of the connective tissue that affects the cardiovascular, skeletal, ocular, and other systems. The prevalence is estimated to be around 1 in 3000 to 5000 individuals. It is caused by mutations in the gene that encodes fibrillin-1 on chromosome 15.

Aortic dissections involving the ascending aorta can cause aortic insufficiency because of preexisting aortic root aneurysm or by detachment of one or more commissures with consequent prolapse of the cusps.[21]

Numerous connective tissue disorders (e.g., ankylosing spondylitis, osteogenesis imperfecta, rheumatoid arthritis, Reiter syndrome, and lupus) can cause aortic insufficiency. The anorexigenic drugs phentermine and fenfluramine can also cause aortic insufficiency.[22]

Rheumatic aortic valve disease is still prevalent in developing countries. The rheumatic process causes fibrosis, thickening, and contraction of the aortic cusps, often with commissural fusion. In advanced cases, the cusps become calcified. It is possible that some postinflammatory aortic valve lesions are not rheumatic in origin.[23]

NATURAL HISTORY OF AORTIC VALVE DISEASE

Aortic Stenosis

Several studies showed that asymptomatic patients with aortic stenosis have a good prognosis.[24–25] Sudden death in asymptomatic patients is uncommon.[25] However, when symptoms develop, the prognosis becomes poor and the average survival is 2 to 3 years for patients with symptoms of angina and syncope, and 1 to 2 years for those with congestive heart failure (CHF).[26]

Aortic Insufficiency

The prognosis of symptomatic patients with aortic insufficiency is poor, with death occurring within 4 years after development of angina and within 2 years after the onset of CHF.[27]

Aortic Root Aneurysm

Aortic root aneurysm can cause aortic insufficiency, aortic dissections, or aortic root rupture. The degree of aortic insufficiency is dependent on dilation of the sinotubular junction and/or aortic annulus in patients with normal aortic cusps. If the cusps are abnormal, aortic insufficiency may be the dominant feature. The risk of aortic dissection and rupture is often related to the transverse diameter of the aortic sinuses. It is rare with diameters less than 50 mm except in cases of family history of dissection. The risk of dissection and/or rupture increases proportionally as the root dilates.

Ascending Aortic Aneurysm

Dilation of the ascending aorta increases the risk of dissection and/or rupture when its transverse diameter exceeds 50 mm. The median size of the ascending aortic aneurysm at the time of dissection or rupture was 59 mm in one study.[28] Dilation of the ascending aorta can cause secondary dilation of the sinotubular junction with consequent aortic insufficiency.[5]

DIAGNOSIS OF AORTIC VALVE DISEASE

Aortic Stenosis

Patients with aortic stenosis remain asymptomatic for many years. Symptoms usually appear late in the course of the disease. The symptoms are angina pectoris, syncope, and CHF. Coexisting coronary artery disease (CAD) is common in older patients, but more than half of all patients with aortic stenosis and angina pectoris have normal coronary arteries. The myocardial ischemia in these patients is the result of a combination of increased oxygen demands by the hypertrophic myocardium and a reduction of oxygen delivery resulting from the excessive compression of the coronary arteries.[29] Syncope is usually the result of cerebral hypoperfusion, but it can also be a result of arrhythmias such as transient ventricular fibrillation, atrial fibrillation, or transient heart block. Symptoms of CHF occur late in the course of this disease. Symptomatic patients with aortic stenosis are at risk of sudden death. Other less common symptoms are gastrointestinal bleeding (idiopathic or caused by angiodysplasia), infective endocarditis, and arterial thromboembolism.

On auscultation these patients have a harsh systolic murmur, sometimes with a thrill along the left sternal border,

often radiating to the neck. The second heart sound is soft, absent, or paradoxically split. The carotid pulses are diminished and delayed. The electrocardiogram reveals left ventricular hypertrophy in most patients with severe aortic stenosis. Echocardiography establishes the diagnosis; provides information regarding the ventricular function, ventricular thickness, and pulmonary hypertension; and estimates the aortic valve area and transvalvular gradient. Coronary angiography is an important part of the work-up in patients aged 40 years and older.

Aortic Insufficiency

The clinical presentation is dependent on the rapidity with which aortic insufficiency develops. Patients with chronic aortic insufficiency remain asymptomatic for many years while the heart slowly enlarges. Palpitations and head pounding may occur during exertion. Angina pectoris may occur, but it is not as common as with aortic stenosis. Syncope is rare. Symptoms of CHF are usually an indication of left ventricular dysfunction (LVD). Acute aortic insufficiency is frequently associated with cardiovascular collapse, with extreme fatigue, dyspnea, and hypotension resulting from reduced stroke volume and elevated left atrial pressure.

The major physical findings related to the wide pulse pressure are caused by the large stroke volume. The pulse is the water-hammer or collapsing type with a rapid rise and fall (Corrigan pulse). The patient's head may bob with each heartbeat (Musset sign). The systolic pressure is elevated and the diastolic pressure is low. A variety of peripheral artery auscultatory signs may be present: Traube sign (also known as "pistol shot sounds"), Muller sign (pulsations of the uvula), and Duroziez sign (a systolic murmur over the femoral artery when it is compressed proximally to where the stethoscope is placed). The apical impulse is prominent and displaced laterally. The aortic diastolic murmur is high pitched and decrescendo. The electrocardiogram usually demonstrates left ventricular hypertrophy. Chest x-ray demonstrates cardiomegaly. Echocardiography confirms the diagnosis and provides information regarding the cause of aortic insufficiency. Radionuclide imaging is useful in assessing the left ventricular function (LVF) at rest and during exercise, valuable information in asymptomatic patients. Coronary angiography is performed in older patients if surgery is being contemplated.

Aortic Root Aneurysm

Most patients with aortic root aneurysm are asymptomatic and have no physical signs if the aortic valve is competent. Some patients may complain of vague chest pain. Severe chest pain is suggestive of rapid expansion or intimal tear with dissection. Echocardiography establishes the diagnosis and gives information regarding the aortic cusps. Computed tomography (CT) scan and magnetic resonance imaging (MRI) of the chest are also diagnostic and useful to provide information regarding the thoracic aorta.

Ascending Aortic Aneurysm

Like patients with aortic root aneurysm, these patients usually remain asymptomatic until the aorta dissects or ruptures. Although echocardiography diagnoses ascending aortic aneurysm and gives information regarding the aortic cusps and root, a CT scan is necessary to determine the extent of the aneurysm. The transverse arch is often involved in patients with aneurysm of the ascending aorta.

INDICATIONS FOR AORTIC VALVE SURGERY

Aortic Stenosis

Patients with symptoms should undergo surgery. Asymptomatic patients with an aortic valve area of less than 0.6 cm^2 or a mean systolic gradient greater than 50 mm Hg with left ventricular hypertrophy should also be considered for surgery. An echocardiographic flow velocity across the aortic valve >4 m/s is also an indication for surgery.[30]

Aortic Insufficiency

Symptomatic patients should be operated on. Since aortic insufficiency may cause ventricular damage, asymptomatic patients should be operated on when ventricular function begins to deteriorate.[31] Assessment of ventricular function during exercise is useful to determine timing of surgery. Operation should be performed if left ventricular ejection fraction (LVEF) decreases during exercise.

Aortic Root Aneurysm

Since most patients with aortic root aneurysm are asymptomatic, surgery is recommended when the transverse diameter of the aortic root exceeds 55 mm.[32] If the aortic valve has normal cusps by echocardiography, surgery should be done when the aneurysm reaches 50 mm in diameter.[33] This size criterion is also used for patients with a family history of acute aortic dissection.[34]

SELECTION OF PATIENTS FOR AORTIC VALVE REPAIR

Only a small proportion of patients with aortic valve disease are candidates for aortic valve repair. Patients with advanced degenerative calcification of the aortic valve are best treated with aortic valve replacement; however, mildly or moderately stenotic aortic valves in patients in whom the primary indication for operation is myocardial revascularization are amenable to manual débridement to increase cusp mobility. The calcific deposits should be limited to small segments of one or two cusps and in proximity to the aortic annulus. Decalcification should be done mechanically and care must

be exercised to avoid damage to the cusps. The calcium on the annulus should also be removed to make it more pliable. Long-term therapy with statins may delay recurrence of the aortic stenosis. Ultrasound decalcification of aortic cusps was tried in the past and it failed because it causes scarring with retraction of the cusps with consequent aortic insufficiency within a few months after surgery.[35]

Most candidates for aortic valve repair have aortic insufficiency. Transesophageal echocardiography is the best diagnostic tool to study the aortic valve and the mechanism of aortic insufficiency. Each component of the aortic root must be carefully interrogated, in particular the aortic cusps. The number of cusps, their thickness, the appearance of their free margins, and the excursion of each cusp during the cardiac cycle must be examined in multiple views. The lines of coaptation of the aortic cusps should be interrogated by color Doppler imaging. The direction and size of the regurgitant jets should be recorded in many views. Information regarding the morphologic features of the aortic annulus, aortic sinuses, sinotubular junction, and ascending aorta should be obtained.

Obviously, the aortic cusps are the most important determinant of aortic valve repair. If the cusps are thin, mobile, and have smooth free margins, the feasibility of aortic valve repair is very high, including bicuspid aortic valve. Calcified or scarred and fibrotic aortic cusps preclude aortic valve repair unless glutaraldehyde-fixed pericardium is used for cusp augmentation.[36]

Patients with aortic root aneurysm often have normal or minimally stretched aortic cusps and reconstruction of the aortic root with preservation of the native aortic cusps is feasible. Larger aortic root aneurysms (e.g. >60 mm) often have overstretched, thinned out aortic cusps with stress fenestrations along the commissural areas and are not suitable for repair.

Patients with ascending aortic aneurysm and aortic insufficiency often have dilated sinotubular junction and normal or minimally altered aortic cusps. The aortic insufficiency is central and caused by outward displacement of the commissures of the aortic valve (see Fig. 37-3). Aortic valve repair is usually feasible in these patients.

Aortic insufficiency caused by prolapse of a single cusp in patients with tricuspid aortic valves is uncommon but correctable by means of aortic valve repair. Prolapse of one cusp in patients with bicuspid aortic valve is common and also suitable for repair.

TECHNIQUES OF AORTIC VALVE REPAIR

Cusp Perforation

Occasionally a cusp perforation is the sole reason for aortic insufficiency. The perforation may be iatrogenic, a sequela of healed endocarditis, or the result of resection of a papillary fibroelastoma. A simple patch of fresh or glutaraldehyde-fixed autologous pericardium is adequate to correct the problem. If fresh autologous pericardium is used, the patch should be larger than the defect because it retracts during healing. We use continuous 7-0 polypropylene to suture the patch around the defect on the aortic side of the cusp.

Cusp Extension

Cusp augmentation has been used to repair incompetent aortic valves due to rheumatic and congenital disease. Glutaraldehyde-fixed bovine or autologous pericardium has been used for this purpose.[36–37]

Cusp Prolapse

Cusp prolapse is due to elongation of the free margin. This is corrected by plication along the nodule of Arantius illustrated in Fig. 37-4. The degree of shortening is determined by examining the other cusps and the common level of coaptation.

Cusp with Stress Fenestration

Dilation of the sinotubular junction increases the mechanical stress along the free margin of the cusp and may cause a fenestration in the commissural area. This type of lesion has been successfully corrected by weaving a double layer of 6-0 expanded polytetrafluoroethylene suture along the free margin of the cusp as illustrated in Fig. 37-5.

Bicuspid Aortic Valve

The most commonly performed aortic valve repair in adults is for bicuspid aortic valve with prolapse of one cusp. Although the anatomic arrangement of the bicuspid aortic valve varies, most patients have an anterior cusp attached to the interventricular septum and a posterior cusp attached to the fibrous components of the left ventricular outflow tract (LVOT).

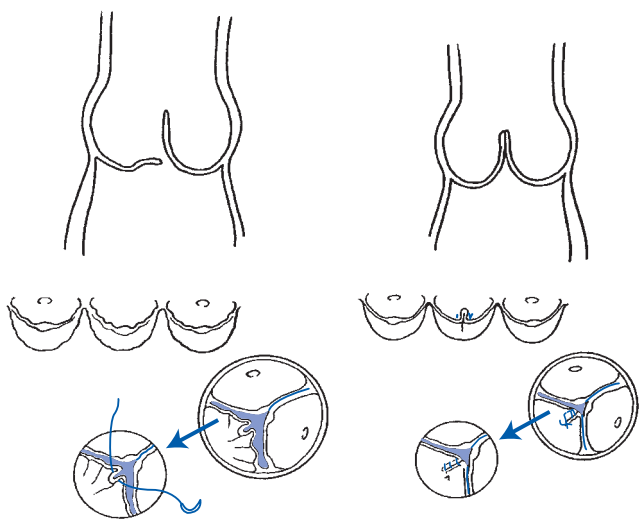

Figure 37-4. Repair of cusp prolapse. The free margin is shortened by plicating the area of the nodule of Arantius.

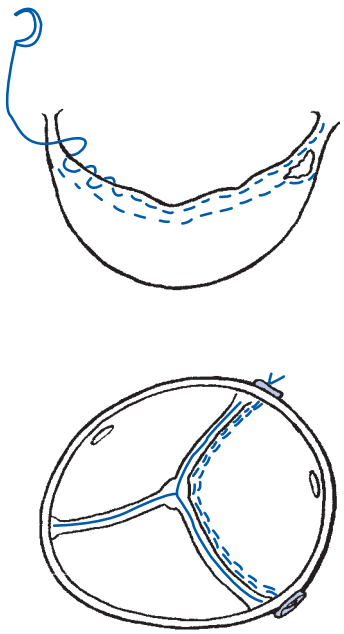

Figure 37-5. Reinforcement of the free margin with a double layer of 6-0 expanded polytetrafluoroethylene suture. This is often done in patients with stress fenestration.

The anterior cusp often contains a raphe at approximately where the commissure between the right and left cusps would be. This cusp is usually the one that is elongated and prolapsed. As long as the posterior cusp is normal, repair is feasible and relatively simple. The raphe is excised and the free margin of the anterior cusp is shortened with plicating sutures as illustrated in Fig. 37-6. The lengths of the free margins of both cusps should be similar and should coapt at the same level. Suspending the arterial walls immediately above the commissures and observing the level of coaptation of each cusp gives an estimate of the level of coaptation of the cusps.

Since most patients with incompetent bicuspid aortic valves have a dilated aortic annulus, an aortic valve–sparing operation may be a more appropriate procedure than simple cusp repair. However, if the aortic sinuses are not aneurysmal and the annulus is only mildly dilated, a reduction annuloplasty to increase the coaptation area of the cusps can be done. This is accomplished by plicating the subcommissural triangles using horizontal mattress sutures of 4-0 polypropylene with Teflon felt pledgets on the outside of the aortic root (Fig. 37-6). The suture is first passed from the outside to the inside of the aorta through the aortic annulus of both cusps 2 mm below their commissure. The same suture is passed again through the annulus and subcommissural triangle 4 or 5 mm below the first one and the ends are tied together over Teflon felt pledgets on the outside of the aorta.

AORTIC VALVE–SPARING OPERATIONS

Aortic valve–sparing operations include various procedures used to preserve the aortic cusps in patients with aortic root aneurysm or ascending aortic aneurysm with aortic insufficiency.[38–40] The complexity of these operations varies with the pathology of the aortic root. Elderly patients with ascending aortic aneurysm and aortic insufficiency often have dilated sinotubular junction, normal or minimally dilated aortic sinuses, and normal cusps, and all that is needed to restore valve function is reduction of the diameter of the sinotubular junction at the time of replacement of the ascending aorta. Younger patients with aortic root aneurysm

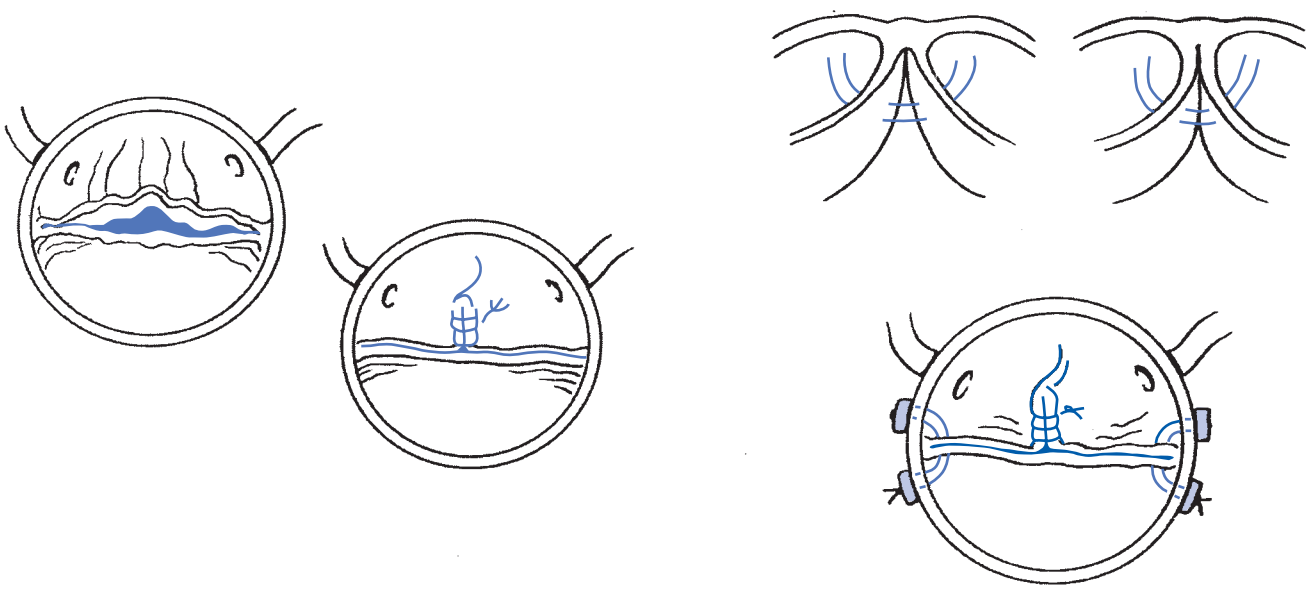

Figure 37-6. Repair of incompetent bicuspid aortic valve. The elongated cusp is shortened and the subcommissural triangles narrowed with sutures.

due to connective tissue disorders of the heart need more complex operations to save the aortic valve cusps.

Ascending Aortic Aneurysm with Aortic Insufficiency

Dilation

Dilation of the sinotubular junction displaces the commissures of the aortic valve outward and prevents the cusps from coapting during diastole (see Fig. 37-3). These patients are often in the sixth, seventh, and eighth decade of their lives and have ascending aortic aneurysms. The dilation of the sinotubular junction is asymmetrical, and often the commissures of the noncoronary aortic cusp are more affected than the other two. If the other components of the aortic root are normal, simple adjustment of the sinotubular junction restores valve competence. This is accomplished by transsecting the ascending aorta 5 mm above the sinotubular junction and pulling the three commissures upward and close to each other until the cusps coapt. The three commissures form an imaginary triangle. The diameter of a circle that contains this imaginary triangle is the diameter of the graft that should be used to reconstruct the sinotubular junction. Because the aortic cusps and sinuses have different sizes, this triangle is not always equilateral and the commissures must be spaced according to the length of the free margin of each cusp. The diameter of the graft and the space between commissures are determined by sizing the diameter of the circle that contains all three commissures with a transparent valve sizer, such as the one used for the Toronto SPV bioprosthesis (St. Jude Medical, St. Paul, Minn). That particular sizer has three equidistant marks, and one can determine the space between the commissures by comparing them to the distance between marks. The tubular Dacron graft is sutured right at the level of the sinotubular junction with a continuous 4-0 polypropylene suture (Fig. 37-7). If after adjusting the sinotubular junction the cusps do not coapt at the same level, one or more cusps may be elongated and the free margin has to be shortened as illustrated in Fig. 37-4. Aortic valve competence can be tested at this time by injecting cardioplegia into the graft under pressure and observing the left ventricle for distention.

If the noncoronary aortic sinus is dilated or altered by aortic dissection, a neo-sinus can be created by tailoring the graft with a tongue of tissue that is sutured directly to the aortic annulus as illustrated in Fig. 37-8. The height of the neo-sinus of Dacron should be 3 or 4 mm more than the diameter of the graft, and the width should be 3 or 4 mm more than the estimated intercommissural distance.

Grafts smaller than 24 mm in diameter should be avoided in adult patients because they may increase left ventricular afterload, particularly if long segments are used, such as with concomitant transverse arch replacement using the elephant trunk technique. If the estimated diameter of the sinotubular junction is less than 24 mm, a larger graft should be used and the end that is anastomosed to the aortic root to recreate the sinotubular junction should be reduced by plicating the graft in the area of the anastomosis.

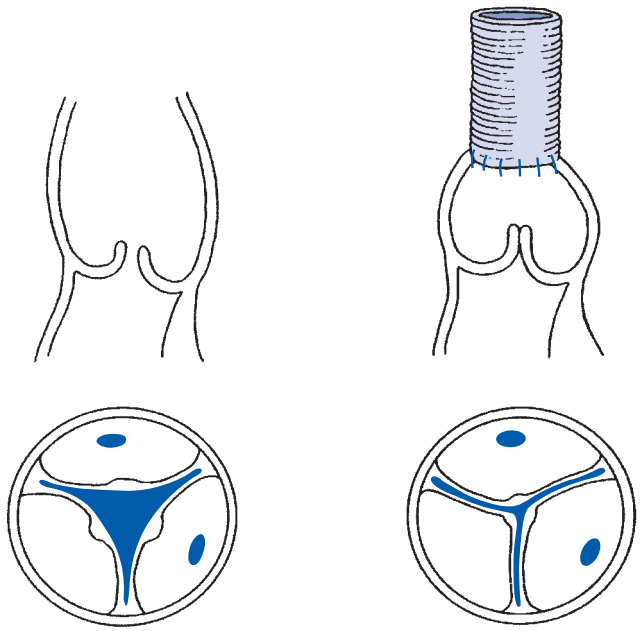

Figure 37-7. Dilation of the sinotubular junction causes aortic insufficiency. Correction of the dilation with a tubular Dacron graft of appropriate diameter corrects aortic insufficiency.

Aortic Root Aneurysm

The indication for surgery in patients with aortic root aneurysm is more often due to the diameter of the root at the level of the aortic sinuses than due to the severity of aortic

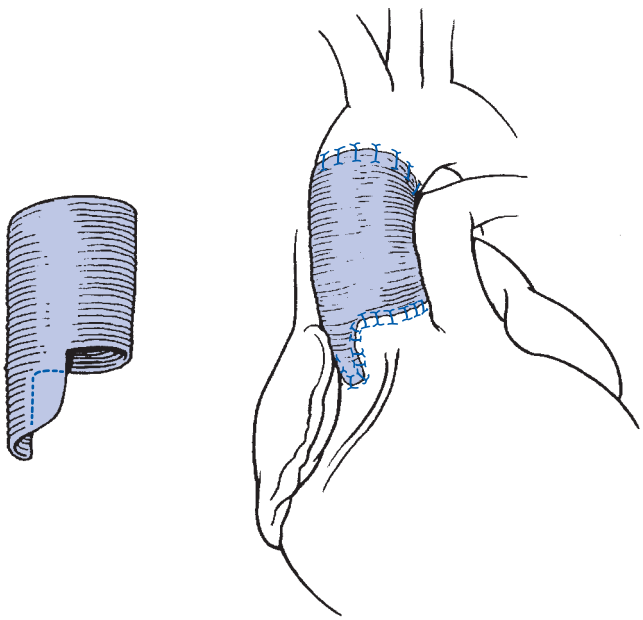

Figure 37-8. Correction of the sinotubular junction and replacement of the noncoronary aortic sinus.

insufficiency. Thus, a large proportion of patients have none, trace, or mild aortic insufficiency at the time of surgery. The aortic cusps are normal or minimally stretched in patients with aortic root aneurysm and mild aortic insufficiency. Even in those with severe aortic insufficiency one or more cusps may remain nearly normal. Stress fenestration along the commissural areas is common in the aortic cusps. In our experience, reinforcement with a double layer of 6-0 expanded polytetrafluoroethylene suture prevents cusp prolapse after the valve repair.

It is not always simple to determine if the free margin of a cusp is normal or elongated. The knowledge that the length of the base of the aortic cusp is 1.5 times longer than the length of its free margin is useful, but application of this anatomic finding requires some experience. Pulling upward on the commissures without causing distortion of the scallop-shaped annulus and observing the level of the nodule Arantius is a useful maneuver to assess cusp prolapse. Normally, the level of the central portion of the free margin should lie closer to the level of the commissures than to the level of the nadir of the aortic annulus. In our experience, almost one-half of all patients who had aortic valve–sparing operations had some degree of cusp prolapse that required shortening of the length of the free margin.

Assessing dilation of the aortic annulus is even more difficult than assessing cusp prolapse. The transverse diameter of the aortic annulus at its nadir is proportional to the area of the cusps, but the relationship between them is variable.[1] However, the transverse diameter of the aortic annulus has to be smaller than the average length of the free margins of the cusps, and the radius of the aortic annulus must be smaller than the average height of the cusps. Using these two parameters, it is possible to estimate whether the annulus is dilated or not.

There are two types of aortic valve–sparing operations for patients with aortic root aneurysm: remodeling of the aortic root and reimplantation of the aortic valve.[39]

Remodeling of the aortic root

The ascending aorta is transsected and the aortic root is dissected circumferentially down to the level of the aortic annulus. All three aortic sinuses are excised, leaving approximately 4 to 6 mm of arterial wall attached to the aortic annulus and around the coronary artery orifices as illustrated in Fig. 37-9. The three commissures are gently pulled vertically and approximated until the cusps coapt. The three commissures form a triangle and the diameter of the circle that contains that triangle is the diameter of the graft to be used for remodeling. In our experience, most grafts are 24, 26, or 28 mm in diameter. Here again the sizers of the Toronto SPV bioprosthesis are very useful to determine the diameter of the graft and also the distance between commissures because they may not be equidistant. The spaces in between the commissures are marked in one of the ends of the graft, and the graft is tailored to create three neo-aortic sinuses (Fig. 37-10). The heights of these neo-sinuses should be approximately equal to the diameter of the graft. The three commissures are

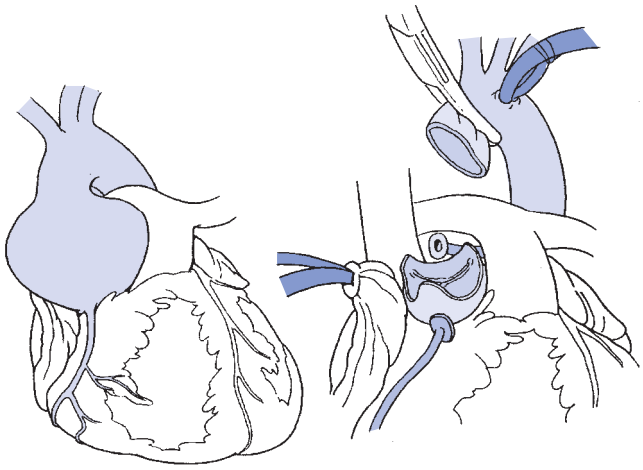

Figure 37-9. Remodeling of the aortic root. The aortic sinuses are excised leaving 4 to 6 mm of arterial wall attached to the aortic annulus and around the coronary arteries.

suspended in the graft (see Fig. 37-10), which is then sutured to the aortic annulus and remnants of the aortic wall with continuous 4-0 polypropylene sutures. The coronary arteries are reimplanted into their respective neo-sinuses. The aortic cusps are inspected to make sure that all three coapt at the same level and well above the nadir of the aortic annulus. If one or more cusps is prolapsing, the free margin is shortened as described above. If one or two cusps have stress fenestra-

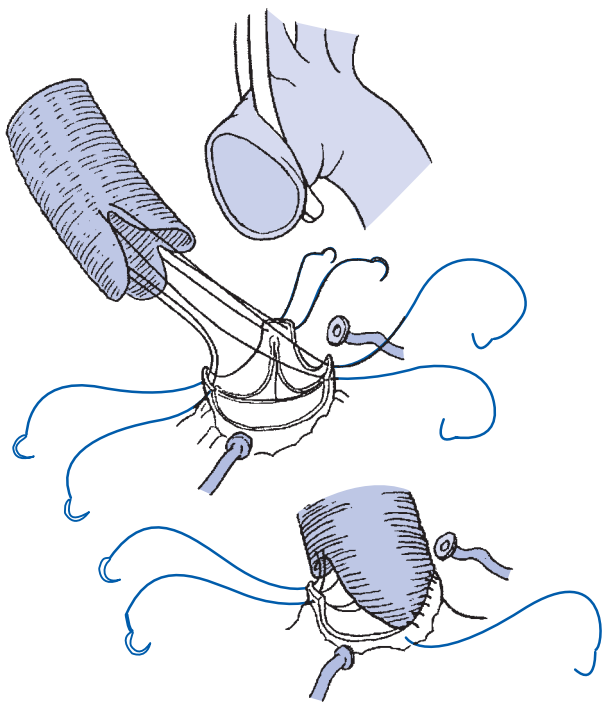

Figure 37-10. A graft of diameter equal to the diameter of the sinotubular junction is tailored to recreate three aortic sinuses. The three commissures are suspended into the tailored graft and the neo-aortic sinuses are sutured to the aortic annulus and remnants of arterial wall.

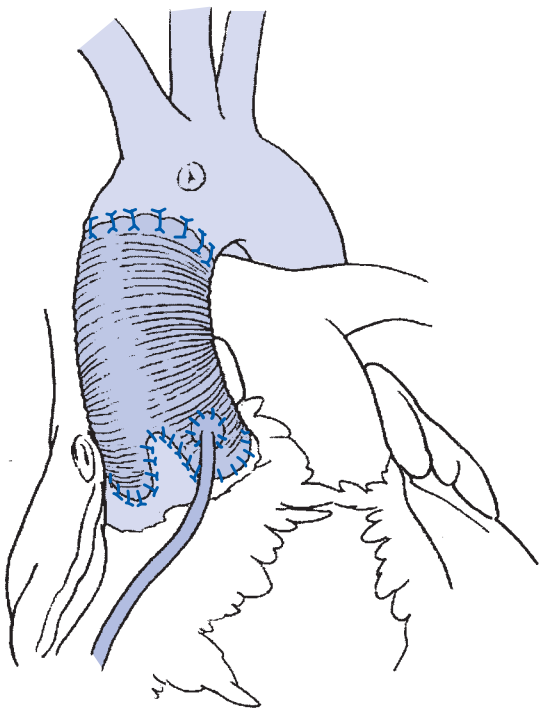

Figure 37-11. Remodeling of the aortic root. The coronary arteries are reimplanted into their respective neo-aortic sinuses and the graft anastomosed to the distal aorta.

tions, the free margin should be reinforced with a fine expanded polytetrafluoroethylene suture. Aortic valve competence can be assessed by injecting cardioplegia under pressure into the reconstructed aortic root and observing the left ventricle for distention or by turning the echocardiography machine on. The graft is then anastomosed to the distal ascending aorta or transverse aortic arch graft, depending on the extent of the aneurysm (Fig. 37-11).

Remodeling of the aortic root may be inappropriate for patients with Marfan syndrome or annuloaortic ectasia because the annulus may continue to dilate and cause aortic insufficiency.[33,40] An aortic annuloplasty along the fibrous component of the LVOT did not prevent late dilation of the aortic annulus in patients with Marfan syndrome.[33] Thus, reimplantation of the aortic valve may be a better operative procedure for patients with annuloaortic ectasia (Fig. 37-12).

Reimplantation of the aortic valve

This procedure can be performed in all patients with aortic root aneurysm, but it is particularly valuable in patients with annuloaortic ectasia and in those with acute type A aortic dissection.

This procedure is more difficult than remodeling of the aortic root because it requires greater knowledge of the functional anatomy of the aortic root since the aortic annulus, the aortic sinuses, the sinotubular junction, and even the aortic cusps are reconstructed. In the original description of this procedure, the aortic valve was reimplanted into a

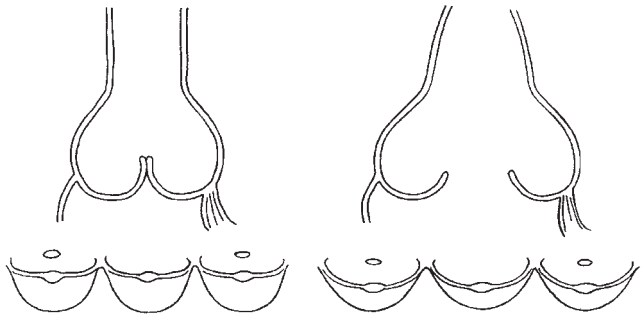

Figure 37-12. Annuloaortic ectasia. The subcommissural triangles of the noncoronary aortic cusp are flattened by dilation of the fibrous tissue.

tubular Dacron graft and no neo-aortic sinuses were created.[39–40] Some studies suggested that the presence of the aortic sinuses is important for normal cusp motion, and potentially, cusp durability.[6–7,42] Several modifications to the reimplantation procedure were introduced to create neo-aortic sinuses.[43] There is now a commercially available graft with sinuses;[44] however, it distorts the aortic annulus because the sinuses in that graft are spherical, and although crescent-shaped, the normal aortic annulus develops along a single horizontal plane.

Following is a description of this procedure as we have been performing it during the past decade with excellent functional results. The three aortic sinuses are excised as described for the remodeling procedure (see Fig. 37-9). Multiple horizontal mattress sutures of 2-0 or 3-0 polyester are passed from the inside to the outside of the LVOT, immediately below the nadir of the aortic annulus, through a single horizontal plane along the fibrous portion of the outflow tract and along its scalloped shape in the interventricular septum as illustrated in Fig. 37-13. If the fibrous portion is thin, sutures with Teflon felt pledgets should be used. A tubular Dacron graft of diameter equal to double the average height of the cusps is selected and three equidistant marks placed in one of its ends. A small triangular segment is cut off along the mark that corresponds to the subcommissural triangle of the left and right cusps (see Fig. 37-13). The sutures previously placed in the LVOT are now passed through the graft. The sutures should be spaced symmetrically if the aortic annulus is not dilated. If there is obvious dilation of the aortic annulus, the sutures should be spaced symmetrically along the muscular interventricular septum and the nadirs of the aortic annulus, but closer together beneath the subcommissural triangles of the noncoronary cusp, because that is where dilation occurs in patients with connective tissue disorders. The sutures are then tied on the outside of the graft. Care must be exercised not to purse-string this suture line. The graft is then cut to a length of approximately 5 cm and pulled gently, and the three commissures are also pulled vertically and temporarily secured to the graft with transfixing 4-0 polypropylene sutures, but they are not tied. Once the three commissures are suspended inside the graft, the

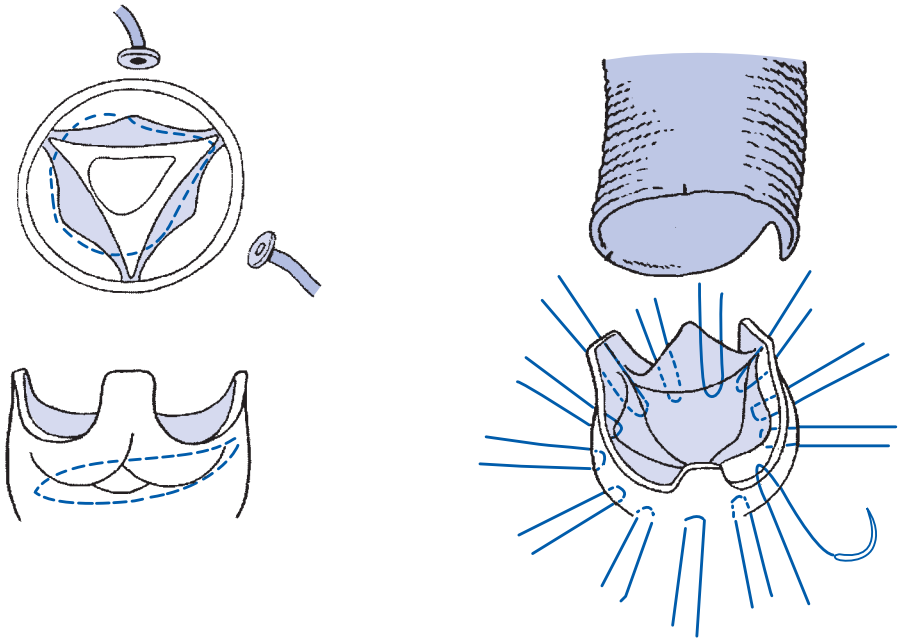

Figure 37-13. Reimplantation of the aortic valve. Sutures are passed below the aortic annulus in a single horizontal plane along the fibrous portion of the left ventricular outflow tract and following the scalloped shape of the aortic annulus along the muscular interventricular septum. These sutures are also passed from the inside to the outside of a tubular Dacron graft.

commissures and the cusps are inspected to make sure they are all correctly aligned. Next, the sutures are tied on the outside of the graft and used to secure the aortic annulus into the graft. This is accomplished by passing the suture sequentially from the inside to the outside right at the level of the annulus and from the outside to the inside at the level of the remnants of the arterial wall. We start at the level of the commissure and stop at the nadir of the aortic annulus where the sutures are tied together. The coronary arteries are reimplanted into their respective sinuses (Fig. 37-14). The coaptation of the aortic cusps is inspected and prolapse is corrected if necessary. It is important that the coaptation level is well above the aortic annulus. Neo-aortic sinuses are created by plicating the graft at the level of the commissure as illustrated in Fig. 37-15. Valve competence can be assessed by injecting cardioplegia into the graft and inspecting the ventricle for distention or by echocardiography. The mean graft size in our patients was 31 mm, range 26 to 34 mm.

RESULTS OF AORTIC VALVE REPAIR

Repair of Incompetent Bicuspid Aortic Valve

The largest published series on aortic valve repair for aortic insufficiency due to prolapse of bicuspid aortic valve came from Cleveland Clinic.[45–46] Casselman and colleagues reported on 94 patients with a mean age of 38 years. The freedom from reoperation was 84% at 7 years.[46] The only factor predictive of reoperation was residual aortic insufficiency at the time of repair.

We compared the clinical outcomes of aortic valve repair with those of aortic valve replacement with biologic valves in patients with incompetent bicuspid aortic valve in a case-match study.[47] The 5-year freedom from reoperation was 91 ± 5% for repair and 94 ± 6% for replacement (p = 0.2), whereas the freedom from moderate or severe aortic insufficiency was 79 ± 8% for repair and 94 ± 6% for

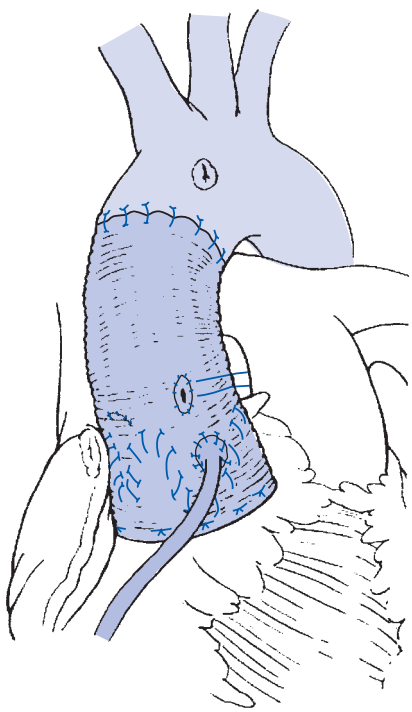

Figure 37-14. Reimplantation of the aortic valve. The commissures and the aortic annulus are sutured inside the graft and the coronary arteries reimplanted.

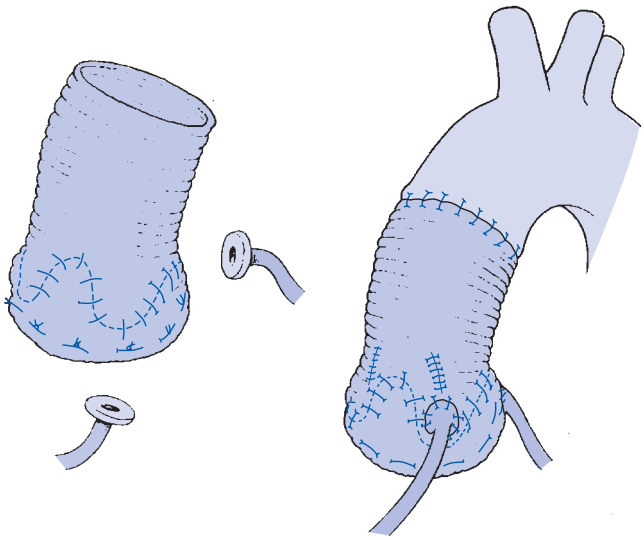

Figure 37-15. Reimplantation of the aortic valve. Neo-aortic sinuses can be created by plicating the graft in the spaces in between the commissures at the level of the sinotubular junction.

replacement ($p = 0.024$). That study indicated that freedom from reoperation underscored freedom from recurrent aortic insufficiency and that the clinical outcomes of aortic valve repair may not be superior to those for aortic valve replacement with biologic valves. In a subsequent study we compared the outcomes of simple aortic valve repair with those of aortic valve–sparing surgery for incompetent bicuspid aortic valve and concluded that since most patients have annuloaortic ectasia, aortic root reimplantation may be more appropriate than simple valve repair.[48] However, Aicher and associates reported a 5-year freedom from recurrent aortic insufficiency of 96%, and a freedom from reoperation of 98% after the remodeling procedure in patients with incompetent bicuspid aortic valve and dilated aortic root.[49]

The appropriateness of aortic valve repair in patients with incompetent bicuspid aortic valve remains unknown. Competent bicuspid aortic valves are durable because a large proportion of patients who require aortic valve replacement for aortic stenosis in their fifth, sixth, and seventh decades of life are found to have bicuspid aortic valve.[15] Thus, aortic valve repair for incompetent bicuspid aortic valves is a reasonable surgical approach in young adults, but the best type of repair remains to be determined. Based on our clinical experience, patient selection is probably even more important than the type of repair because of the heterogeneity of the pathology.

Ascending Aortic Aneurysm with Aortic Insufficiency

We recently reviewed our experience with aortic valve repair in patients with ascending aortic aneurysm, normal or minimally dilated aortic sinuses, and moderate or severe aortic insufficiency.[50] There were 103 patients whose mean age was 65 ± 12 years and 53% were men. The aneurysm extended into the transverse aortic arch in 60% of the patients and 20% had mega-aorta syndrome. The aortic valve repair consisted of adjusting the diameter of the sinotubular junction in all patients. In addition, repair of cusp prolapse was needed in 36 patients, and replacement of the noncoronary aortic sinus in 8. Associated procedures were: replacement of the transverse aortic arch in 62 patients, coronary artery bypass in 28, and mitral valve repair or replacement in 7. The follow-up was complete at 5.8 ± 2.3 years. There were 2 operative and 30 late deaths. The survival at 10 years was 54 ± 7%. Independent predictors of late death were transverse arch aneurysm, the use of elephant trunk technique to replace the arch, and mega-aorta syndrome. Only two patients required aortic valve replacement: one for endocarditis and one for severe aortic insufficiency. The freedom from aortic valve replacement at 10 years was 98%. Only one patient developed severe and six developed moderate aortic insufficiency during the follow-up. The freedom from severe or moderate aortic insufficiency at 10 years was 80 ± 7%. These findings suggest that aortic valve repair in these patients is an excellent alternative to valve replacement, and that the repair remains stable in most patients during the follow-up. Late survival was suboptimal because of the extensiveness of the vascular disease.

Aortic Root Aneurysm

We recently reported our experience with aortic valve–sparing operations for aortic root aneurysm in 220 patients.[51] Their mean age was 46 ± 15 years, 78% were men, and 40% had Marfan syndrome. In addition, 17% had type A aortic dissection, 7% had bicuspid aortic valve, and 22% had transverse arch aneurysm. Previous replacement of the ascending aorta had been done in 10 patients and the Ross procedure in 2. Sixteen patients had severe mitral insufficiency. Approximately one-half of the patients had moderate or severe aortic insufficiency before surgery. The technique of remodeling of the aortic root was used in 53 patients and the reimplantation of the aortic valve in 167. The follow-up was complete at 5.2 ± 3.7 years. All patients had echocardiographic studies during the follow-up. There were 3 operative and 13 late deaths. Patient survival at 10 years was 88 ± 3% and was similar to that of the general population of Ontario. Age >65 years, advanced functional class, and ejection fraction <40% were independent predictors of death. Seven patients developed moderate and five developed severe aortic insufficiency. Overall freedom from moderate or severe aortic insufficiency at 10 years was 85 ± 5%, but it was 94 ± 4% after reimplantation of the aortic valve and 75 ± 10% after remodeling of the aortic root ($p = 0.04$). Five patients required aortic valve replacement; the freedom from aortic valve replacement at 10 years was 95 ± 3%. One patient developed endocarditis 11 years postoperatively, and 8 suffered thromboembolic events. At the latest follow-up 88% of the patients were in functional class I and 10% were in class II. These findings suggested that reimplantation of the aortic

valve provides more stable aortic valve function than remodeling of the aortic root.

Yacoub and colleagues,[52] who exclusively used the remodeling of the aortic root to treat 158 patients with aortic root and ascending aortic aneurysms, reported a freedom from aortic valve replacement of 89% at 10 years, and moderate aortic insufficiency in one-third of the patients.

There were no other long-term studies on clinical outcomes of aortic valve–sparing operations at the time of this writing. There are several reports on early clinical and hemodynamic outcomes of these two types of aortic valve–sparing procedures.[41–42,49,52–58] Most comparative studies suggest that the reimplantation of the aortic valve provides a more stable aortic valve function than the remodeling of the aortic root.[41,54,56,57] Hemodynamic studies suggest that cusp motion and flow patterns across the reconstructed aortic root is more physiologic after remodeling of the aortic root than after reimplantation of the aortic valve.[7,42,44,55,58] In patients who had the reimplantation procedure, flow patterns and cusp motion are better with neo-aortic sinuses than without.[44,55,47] However, in our series of reimplantation of the aortic valve there was no difference in aortic valve function after 10 years in patients with a straight tube or with neo-aortic sinuses. Aortic sinuses seem to decrease the mechanical stress on the aortic cusps, but it is not clinically apparent during the first decade of follow-up.

Another important question regarding aortic valve–sparing operations is whether they are better than the Bentall procedure with mechanical valves.[59] There has been no randomized clinical trial comparing these two procedures for the treatment of aortic root aneurysms or ascending aortic aneurysm, but retrospective studies in patients with Marfan syndrome suggest that the outcomes may be similar.[33,60] In our series, the long-term survival was similar to that of the general population, and the rates of thromboembolism, bleeding, and endocarditis were much lower than what have been reported for mechanical valves.[59,61]

We believe that aortic valve–sparing operations offer an ideal method for treating patients with aortic root aneurysm and normal or minimally diseased aortic cusps. When correctly performed, they provide excellent results and are associated with very low rates of valve-related complications. However, as they are technically demanding operations, only surgeons with extensive experience in aortic surgery should perform them. The surgeon must have a sound knowledge of anatomy and pathology of the aortic valve and be able to apply the concepts of functional anatomy to create an anatomically and functionally satisfactory new aortic root.

CHAPTER 38

Surgical Treatment of Aortic Valve Endocarditis

Tirone E. David

DEFINITION

Infective endocarditis is a disease in which a microorganism colonizes a focus in the heart, producing fever, heart murmur, splenomegaly, embolic manifestations, and bacteremia or fungemia. Early diagnosis of this condition is extremely important because it almost invariably leads to devastating complications and death if not treated with antibiotics, combined or not with surgery.

EPIDEMIOLOGY

Predisposing factors for infective endocarditis are cardiac abnormalities that disrupt the endocardium by means of a jet injury, as well as the presence of blood-borne microorganisms that colonize these abnormal surfaces. Congenitally bicuspid aortic valve is the most common predisposing lesion for endocarditis of the aortic valve.[1] Other congenital abnormalities of the aortic valve, degenerative calcific aortic stenosis, aortic insufficiency secondary to connective tissue disorders, and rheumatic aortic valve disease, are also predisposing lesions for infection. Depending on the virulence of the offending microorganism, normal aortic valves can also be affected. Patients with prosthetic heart valves have a constant risk of developing infective endocarditis.

It is difficult to determine the incidence and prevalence of native aortic valve endocarditis in the general population because this disease is continuously changing.[2] The annual incidence of infective endocarditis is estimated to range from 1.7 to 7.0 episodes per 100,000 person-years in North America.[3–5]

Patients with prosthetic aortic valves are reported to have an incidence of infective endocarditis of 0.2 to 1.4 episodes per 100 patient-years, which varies with the type of aortic valves.[6–12] Approximately 1.4% of patients undergoing aortic valve replacement develop prosthetic valve endocarditis during the first postoperative year.[13]

The incidence of nosocomial endocarditis is increasing because more patients undergo invasive procedures. Infective endocarditis in hemodialysis patients is relatively infrequent, but it is associated with high mortality.[14]

Dental extractions have been demonstrated to produce bacteremia; however, even simple mastication, tooth brushing or cleaning, and oral irrigation can produce transient bacteremia. Endoscopic procedures may also produce bacteremia. Intravenous drug users are particularly susceptible to infective endocarditis, which often occurs in structurally normal heart valves.

PATHOGENESIS AND PATHOLOGY

In 1928, Grant and colleagues[15] theorized that platelet-fibrin thrombi on the heart valve served as a nidus for bacteria adherence. In 1963, Angrist and Oka[16] introduced the term "nonbacterial thrombotic endocarditis" to describe sterile vegetations on a heart valve and provided experimental animal evidence supporting the role of these vegetations in the pathogenesis of endocarditis. Experimental inoculation in animals with preexisting "nonbacterial thrombotic endocarditis" produced by mechanical abrasion of the endothelial covering of heart valves causes a prompt leukocytic infiltration of the thrombi.[17] As the microorganism multiplies, more leukocytes and thrombotic material accumulate in the area and a verrucous vegetation begins to form.

Depending on the virulence of the microorganism and the resistance of the host, the aortic valve can be destroyed and the infection may spread into the annulus and surrounding structures with abscess formation. The abscess may rupture into the pericardial cavity or into a cardiac cavity.

Infective endocarditis of the aortic valve not only causes destruction of the aortic cusps, paravalvular abscess, and cardiac fistulas, but also can cause coronary and systemic embolization of vegetations.[18] Cerebral infarction, either ischemic due to arterial occlusion or hemorrhagic due to rupture of the mycotic aneurysm, is common in these patients.[19,20] Mycotic aneurysms, infarcts, and abscesses of other organs such as spleen, liver, kidneys, and limbs are also common.[17] Aortic valve endocarditis with a large vegetation that prolapses into the left ventricle and comes in contact with the anterior leaflet of the mitral valve can cause secondary involvement of this valve.[21,22]

Infection of a mechanical heart valve is usually located in its sewing ring.[23,24] Infection of a porcine or pericardial valve may involve the cusps, the sewing ring, or both.[25,26] Infection in aortic valve homografts and pulmonary autografts resembles that of the native aortic valve: it begins in the aortic cusps and destroys them, causing aortic insufficiency, but it may also extend into surrounding structures.[27] Endocarditis after aortic root replacement with mechanical valves frequently causes dehiscence of the valve from the aortic annulus with consequent false aneurysm.[28]

MICROBIOLOGY

The microbiology of infective endocarditis of the aortic valve depends on whether the valve is native or prosthetic, and whether the infection is hospital- or community-acquired. *Staphylococcus aureus* and *Streptococcus viridans* are the most common microorganisms responsible for native aortic valve endocarditis.[29–33] *S. aureus* is extremely virulent and able to cause infection in patients with normal aortic valves. *S. viridans* is not as virulent and causes infection that often follows a protracted course. *Staphylococcus epidermidis* and various other streptococci can also cause endocarditis.

Endocarditis due to gram-negative bacteria is uncommon, but it is often resistant to antibiotic therapy and may cause serious complications. *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella* (the HACEK group) are gram-negative bacilli grouped together due to their characteristic fastidiousness requiring a prolonged incubation period before growth. Endocarditis due to the HACEK group is also uncommon. Fungal endocarditis is rare but extremely serious. *Candida albicans* and *Aspergillus fumigatus* are the usual agents.

The microbiology of prosthetic aortic valve endocarditis is different from that of the native valve.[24,29–34] Prosthetic valve endocarditis has been arbitrarily classified as *early* when it occurs within the first 2 months after surgery, and *late* when it occurs after 2 months.[35] However, it is possible that many cases of prosthetic valve endocarditis that occur during the first year after surgery are acquired at the time of implantation of the artificial heart valve. This may be particularly true when the infection is caused by the HACEK group of bacteria. Early prosthetic valve endocarditis is caused by contamination of the valve at the time of implantation by perioperative bacteremia.[13,34] *Staphylococcus epidermidis, S. aureus,* and *Enterococcus faecalis* are among the more common microorganisms responsible for early prosthetic valve endocarditis.[13,29–34] The sources of late prosthetic valve endocarditis are more difficult to determine. Bacteremia is probably the principal cause of late endocarditis. Although streptococci and staphylococci are commonly encountered in these patients, a myriad of microorganisms can cause late prosthetic valve endocarditis.[24,29,34]

Nosocomial infections are often caused by *S. aureus* or other staphylococci.

In a small proportion of cases of aortic valve endocarditis, no microorganism can be cultured from either the blood or surgical specimens.[29–34] This is called "culture-negative endocarditis," but it is important to rule out fastidious microorganisms and every effort should be made to identify them.

CLINICAL PRESENTATION AND DIAGNOSIS

It is helpful to classify infective endocarditis as acute and subacute because there are major differences between these two clinical presentations. Subacute endocarditis is often caused by less virulent microorganisms such as *S. viridans.* When this organism affects a diseased aortic valve, the clinical course is protracted and antibiotics alone cure most cases. On the other hand, acute endocarditis is frequently caused by a virulent microorganism such as *S. aureus* and may affect a normal aortic valve. The clinical course is acute, and antibiotics alone seldom cure the infection.

The onset of subacute endocarditis in most cases is subtle, with low-grade fever and malaise. Patients think they have the "flu" and are often treated with oral antibiotics for a week to 10 days with improvement of symptoms. However, in most cases the symptoms recur a few days after stopping antibiotics. In the majority of cases no predisposing factor is identified. An aortic valve murmur is present in nearly all patients because they have preexisting aortic valve disease. Splenomegaly is common. Clubbing of the fingers and toes may develop in long-standing cases. Skin and mucous membrane signs occur late in this form of endocarditis. Petechiae appear on any part of the body. Small areas of hemorrhage may be seen in the ocular fundi. Hemorrhages in the nail beds usually have a linear distribution near the distal end, hence the name splinter hemorrhages. Osler nodes are acute, tender, barely palpable nodular lesions in the pulp of the fingers and toes. Bacteria have been cultured from these lesions. Embolization of large vegetation fragments may cause dramatic clinical events such as acute myocardial infarction (AMI), stroke, or splenic or hepatic infarcts. Any other organ also may be involved. Destruction of the aortic cusps causes aortic insufficiency and heart failure. The blood pathology is not distinctive in subacute endocarditis. Anemia without reticulocytosis develops in patients untreated for more than a few weeks. The leukocyte count is moderately elevated. Blood cultures frequently identify the offending microorganism.

The clinical course of acute endocarditis is often fulminating. A preexisting source of bacteremia may be

identified. This form of endocarditis can present with all the symptoms and signs described under subacute endocarditis, but they are more acute and patients are often sicker with overwhelming signs of sepsis. Early metastatic infections are common. Two physical signs are seen only in acute endocarditis: the Janeway lesion (a painless red-blue hemorrhagic lesion a few millimeters in diameter found in the palms of the hands and in the soles of the feet) and the Roth spot (an oval pale area surrounded by hemorrhage near the optic disc). Acute endocarditis is common in patients with no preexisting aortic valve disease. Early cardiac decompensation due to aortic insufficiency is common. Paravalvular abscess is also common, and depending on the location of the abscess, the electrocardiogram may show an increased PR interval or heart block. The blood picture is one of acute sepsis. Blood culture often isolates the infecting agent.

Prosthetic valve endocarditis may present as acute or subacute endocarditis.

Doppler echocardiography is extremely useful in the diagnosis and management of infective endocarditis.[36–39] Transesophageal echocardiography is usually better than transthoracic echocardiography, and multiplane is better than monoplane for the diagnosis of endocarditis. Echocardiography can detect vegetations as small as 1 or 2 mm in size, but it is more reliable in native than in prosthetic valve endocarditis. It is more useful for tissue than for mechanical valves because of the acoustic shadowing of ball, disc, or leaflet motion of mechanical heart valves. Echocardiography is also extremely sensitive for detecting paravalvular abscess and cardiac fistulas.[39,40]

Clinical investigators from Duke University proposed certain criteria for confirming or rejecting the diagnosis of infective endocarditis.[41] These criteria have been confirmed by other investigators and their limitations addressed by others.[42–44] A modified version of the Duke criteria has been proposed[44] and it is shown in Table 38-1.

Table 38–1.

Modified Duke criteria for the diagnosis of infective endocarditis

Major criteria

- Blood culture positive for infective endocarditis
  Typical microorganisms consistent with infective endocarditis from two separate blood cultures: *Streptococcus viridans, S. bovis*
  HACEK group, *S. aureus,* or community-acquired enterococci, in the absence of a primary focus, or
  Microorganisms consistent with infective endocarditis from a persistently positive blood culture, defined as follows:
  At least two positive cultures of blood drawn >12 hours apart, or
  All of three or a majority of >4 separate cultures of blood (with the first and last samples drawn at least 1 hour apart)
  Single positive blood culture for *Coxiella burnetii* or phase I IgG antibody titer to *C.burnetii* >1:800

- Evidence of endocardial involvement:
  Echocardiogram positive for infective endocarditis: TEE recommended in patients with prosthetic valves, rated at least as "possible endocarditis" by clinical criteria, or complicated endocarditis, such as endocarditis with paravalvular abscess;
  TTE as the first test in other patients as follows:
  Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation;
  Abscess;
  New partial dehiscence of prosthetic valve
  New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor criteria

- Predisposition, predisposing heart condition, or injection drug use
- Fever
- Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctiva! hemorrhages, and Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
- Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above, or serological evidence of active infection with an organism consistent with infective endocarditis
- Echocardiographic minor criteria eliminated

Definite endocarditis = 2 major criteria, or I major + 3 minor criteria, or 5 minor criteria
Possible endocarditis = 1 major + 1 minor, or 3 minor criteria
HACEK group = Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, and Kingella; TEE = transesophageal echocardiography; TTE = transthoracic echocardiography.
Source: Used with permission from Li et al.[44]

Heart catheterization and coronary angiography increase the risk of embolization in patients with aortic valve vegetations and should be avoided. Newer computed tomography (CT) imaging techniques to diagnose coronary artery disease are useful in these patients.

TREATMENT

An appropriate antibiotic is the most important aspect of the management of patients with infective endocarditis.[18,29,30] Antibiotic therapy should be started soon after obtaining several blood cultures. The initial choice of antibiotics is based on clinical circumstances and the suspected source of infection. Patients who had recent dental work should receive antibiotics to counteract bacteria from the oral cavity; those who had recent urinary or colonic procedures should be treated with antibiotics that are effective against gram-negative bacteria.

Intravenous drug users are usually infected with *S. aureus* or *S. epidermidis*, and antibiotics should be chosen accordingly. Once the microorganism is identified by blood cultures and its sensitivity to specific antibiotics is known, antibiotic therapy is adjusted accordingly. A combination of two or three antibiotics that potentiate each other is often needed in the treatment of endocarditis caused by virulent microorganisms. Intravenous antibiotic therapy is continued for 6 weeks.

It is difficult to eradicate infection caused by virulent microorganisms with antibiotics alone because these microorganisms often destroy the native aortic valve very rapidly and cause aortic insufficiency and congestive heart failure (CHF). These infections are usually due to *S. aureus, Pseudomonas aeruginosa, Serratia marcescens*, or fungi.

Surveillance blood cultures are performed in 48 hours to monitor the efficacy of antibiotic therapy. The patient must be watched closely for signs of CHF, coronary and systemic embolization, and persistent infection. Daily electrocardiograms and frequent echocardiograms are performed during the first 2 weeks of treatment. With any evidence of increasing aortic insufficiency, enlarging vegetations, recurrent embolism, paravalvular abscess, or persistent infection, surgery should be immediately performed. It is important to operate on patients before they develop intractable heart failure, cardiogenic or septic shock, or extensive aortic root abscesses. Patients with vegetations larger than 10 mm present a clinical problem because they are more likely to develop serious complications and early surgery is justifiable.[36–38]

Anticoagulation is not effective in preventing embolization of vegetations in native and biologic valves and is associated with an increased risk of neurologic complications.[45,46]

Early surgical treatment should be considered in patients with signs of CHF, acute valve dysfunction, paravalvular abscess or cardiac fistulas, recurrent systemic embolization when aortic valve vegetations are present, and persistent sepsis despite adequate antibiotic therapy for more than 4 to 5 days. Prosthetic valve endocarditis is best treated by early surgery, particularly in patients with mechanical valves.[25,31,32] Acute endocarditis of the aortic valve due to *S. aureus* is also best treated with early surgery because of the destructive power of the bacteria.[29,30]

Patients with neurologic deficits should have CT or magnetic resonance imaging performed to determine if the cerebrovascular accident is ischemic or hemorrhagic. Ischemic damage is far more common than hemorrhagic damage, but both are associated with increased mortality and morbidity.[45–48] Mycotic aneurysms should be treated before valve surgery. Aortic valve replacement should be postponed for 2 weeks after an ischemic stroke and 4 weeks after a hemorrhagic stroke if possible.[48]

SURGICAL TREATMENT

Patients who need surgery are often very sick and may be in CHF. For this reason and because they often require complex and long surgical procedures, myocardial protection is of utmost importance. Another important aspect of surgery for endocarditis is avoidance of contamination of the surgical field, instruments, drapes, and gloves with vegetations and pus. Instruments used to extirpate contaminated areas in the heart should be discarded before reconstruction of the ventricle and aortic root begins. In addition, local drapes, suction equipment, and surgical gloves should all be changed.

When the infection is limited to the cusps of the native aortic valve or a bioprosthetic valve, complete removal of the valve and implantation of a biologic or mechanical valve usually resolves the problem. There is no evidence that bioprostheses are better than mechanical valves in patients with active infective endocarditis.[33] Some investigators believe that aortic valve homograft is ideal for patients with active endocarditis,[49–51] but the fact is that it can become infected like other valves.[52] Some surgeons favor the pulmonary autograft, particularly in young patients.[53]

If the aortic annulus is involved in the infective process, resection of the necrotic or inflamed area is needed before a prosthetic valve can be implanted. The defect created by the resection should be patched before a prosthetic valve is implanted. We prefer to use fresh autologous pericardium to patch small defects (1 or 2 cm wide) in the aortic root and LVOT, and glutaraldehyde-fixed bovine pericardium for larger defects.[54,55] Some surgeons also use Dacron fabric to reconstruct the aortic root.[55–57] Here again, aortic valve homograft is believed to be ideal for reconstruction of the aortic root and LVOT.[50,58–60] The mitral valve of the aortic valve homograft can be used to patch defects in the LVOT by correctly orienting the homograft. However, an aortic valve homograft is by no means a substitute for radical resection of all infected tissues, because persistent infection can occur with this biologic valve.[61,62] The pulmonary autograft has also been used in cases of extensive destruction of the aortic root,[63] but again, this valve is no substitute for radical resection of all infected tissues.

Surgery for aortic root abscess and/or cardiac fistulas is challenging. The most important aspect in the surgical treatment of these patients is radical resection of all infected tissues.[25,31,55] We believe that the type of valve implanted is less important than complete extirpation of all infected and edematous tissues.[55] These patients frequently require replacement of the entire aortic root and reconstruction of the surrounding structures that are also involved by the abscess. These operations must be individualized because the pathology of aortic root abscess is variable. Extensive resection and reconstruction may be needed.[54,55] Thus, patching of the interventricular septum, dome of the left atrium, intervalvular fibrous body, right atrium, and pulmonary artery may be necessary, as well as repair of the left and/or right coronary arteries. The aortic root is often replaced with a valved conduit.

Aortic root abscess extending into the intervalvular fibrous body or into a prosthetic mitral valve is particularly difficult to treat.[64] In these cases, the resection and reconstruction can be performed through the aortic root and dome of the atrium.[64,65] When an aortic valve homograft is used for this type of reconstruction, the anterior leaflet of the mitral valve of the homograft can be used as patch material for the new fibrous body between the aortic and mitral valves. Actually, aortic and mitral valve homografts in a single bloc of tissue have been used to treat this condition.[66]

Postoperative complications are common after surgery for active infective endocarditis. Septic patients may have severe coagulopathy and may bleed excessively after cardiopulmonary bypass. Antifibrinolytic agents, particularly aprotinin, should be used. Transfusion of platelets, cryoprecipitate, and fresh frozen plasma are often necessary to obtain hemostasis. Radical resection of aortic root abscess may cause heart block, for which a permanent pacemaker will be needed postoperatively. Depending on the patient's clinical condition before surgery, multiorgan failure may develop postoperatively. Neurologic deterioration may occur in patients with preexisting cerebral emboli. Pulmonary, splenic, hepatic, and other metastatic abscesses seldom require surgical treatment. Large metastatic abscesses may have to be drained, and in the case of the spleen, splenectomy should be performed because of the risk of rupture.[67]

Clinical Results

The prognosis of aortic valve endocarditis depends largely on when the disease is diagnosed, on the offending microorganism, and how promptly it is treated.[29,68] Patients with prosthetic aortic valve endocarditis have a more serious prognosis than patients with native aortic valve endocarditis,[29,30] and nosocomial infections are associated with higher mortality than community-acquired infections.[69–70] The results of surgery for infective endocarditis have improved significantly during the past three decades.[18] The operative mortality for patients with infection limited to the cusps of the aortic valve is largely dependent on the patients' presentation at the time of surgery, age, and comorbidities. Most reports indicate that the operative mortality is under 10%.[30–31] The operative mortality is higher for prosthetic valve endocarditis and ranges from 20 to 30%.[25,31–34] Surgery for aortic root abscess is also associated with higher operative mortality.[55–58]

The 10-year survival after surgery for infective endocarditis is around 50 to 60%.[31,32]

Patients operated on for active infective endocarditis have a higher risk of developing endocarditis again than do patients with prosthetic valves who never had endocarditis.[31,32] In a series from our unit, 8 of 122 patients developed recurrent infection after a mean interval of 47 months; freedom from recurrent endocarditis at 10 years was 79% ± 9%.[31] In most of these patients, a different microorganism caused the second episode of endocarditis.

CHAPTER 39

Minimally Invasive Aortic Valve Surgery

Prem S. Shekar • Lawrence H. Cohn

Valvular heart disease has dominated cardiac surgery since its beginning along with coronary artery bypass grafting (CABG). Traditionally, valvular heart surgery has generally been performed via a full sternotomy incision with cardiopulmonary bypass. However, the increase in numbers of older patients and patients with multiple comorbidities has spurred the need for developing techniques that are less invasive in order to hasten postoperative recovery by reducing incisional pain, improving respiratory function, and producing an overall reduction in trauma. Indeed, the emergence of possible percutaneous options for management of valvular heart disease has demanded the development of alternative, more attractive surgical options.

REASONS AND PRINCIPLES: MINIMAL ACCESS AORTIC VALVE SURGERY

For purposes of simplicity, we will focus a large initial part of the discussion on patients undergoing primary aortic valve surgery. We will speak about reoperative minimal access aortic valve surgery toward the end of this chapter.

There are a variety of reasons to perform minimal access aortic valve surgery:

1. It provides a cosmetically superior incision.
2. There is reduced postoperative pain.
3. There is faster postoperative recovery.
4. There is improved postoperative respiratory function due to preservation of a part of the sternum and the integrity of the costal margin.
5. It can be performed with the same degree of ease and speed as a conventional operation, with no difference in mortality.
6. It provides access to the relevant parts of the heart and reduces dissection of other areas.
7. It greatly facilitates a reoperation at a later date, as the lower part of the pericardium remains closed.

The principles of these approaches are the same:

1. The ability to safely apply a stable aortic cross-clamp.
2. The ability to visualize the aortic valve completely and perform a successful replacement with standard techniques.
3. The ability to achieve the same degree of myocardial protection as through a midline sternotomy approach.
4. The ability to deal with issues of the aortic root, the ascending portion, and the arch of the aorta with relative ease and without conversion.
5. The ability to quickly convert to a standard midline sternotomy if compromising situations arise.

Minimal access aortic valve surgery can be safely performed if the following important adjuncts are available and criteria are met.

1. Experienced cardiac anesthesiologists are available.
2. Transesophageal echocardiography (TEE) is available in every case and an experienced echocardiographer is present to interpret findings.
3. The ability to place pulmonary artery catheters with pacing capabilities and transjugular coronary sinus catheters.
4. The ability to place percutaneous arterial and venous cardiopulmonary bypass cannulae.
5. The ability to use vacuum-assisted venous drainage on cardiopulmonary bypass.
6. Minimal access retractors and other relevant instruments that facilitate this surgery are available.
7. The ability to remotely monitor myocardial protection and distention by TEE.
8. Surgeons experienced with conventional aortic valve surgery and minimal access surgery are available.

There are at least four different minimal access surgical approaches to the aortic valve: (1) upper hemisternotomy, (2) right parasternal approach, (3) right anterior thoracotomy, and (4) transverse sternotomy.

THE UPPER HEMISTERNOTOMY APPROACH

This is undoubtedly the most popular of all minimal access approaches to the aortic valve, and has been popularized by the surgeons of the Cleveland Clinic and Brigham and Women's Hospital.[1,2]

It is performed through a 6- to 10-cm vertical midline incision over the upper part of the sternum, starting at or just above the level of the manubriosternal angle. The sternotomy is performed with the standard saw starting at the level of the sternal notch up to the level of the third or fourth intercostal space. The sternotomy is then continued into the right or left third or fourth intercostal space using a narrow-blade oscillating saw, taking care not to cut too deeply to avoid injuring mediastinal or pericardial structures (Fig. 39-1). The decision to cut into the third or fourth intercostal space can be made preoperatively with the chest x-ray being a guide to the amount of exposure you will need. We would favor the fourth interspace, as this almost always produces the most ideal exposure. It is very important to ensure that the sternotomy is absolutely midline and that the midline sternotomy is not carried beyond the level of the transverse portion. Failure to adhere to these principles will result in either a lateral fracture, resulting in three sternal fragments, or a continued lower extension of the midline fracture with retraction that produces severe intraoperative bleeding and difficulty in closure. There is no need to prophylactically divide the right or left internal mammary arteries (LIMAs) with this incision. If care is taken not to damage them, they will usually gently retract away.

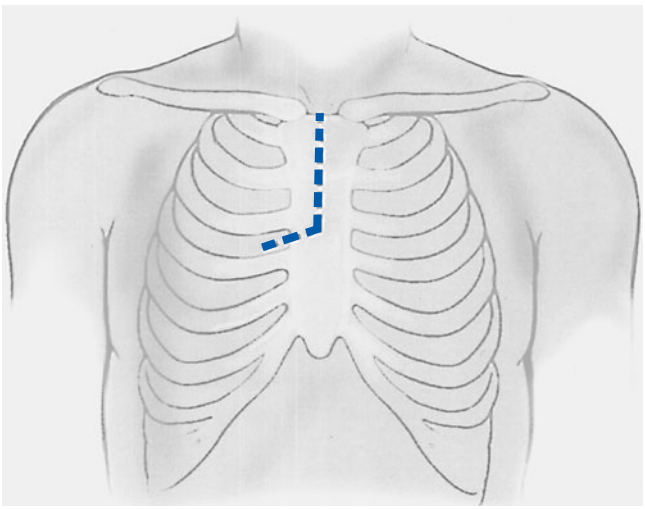

Figure 39-1. Incision for minimally invasive aortic valve surgery via upper hemisternotomy.

We use a Koros-Baxter retractor to retract the sternal edges. The pericardium is opened in the midline and carried inferiorly, and at least three pericardial stay sutures are applied to either side with the needles left on. The retractor is removed and the pericardium is tacked to the dermis of the skin and tied down. This facilitates exposure by elevating the pericardial contents forward into the operating field. The Koros-Baxter retractor is then replaced. Care must be taken when reopening the retractor, as sudden retraction with elevated cardiac structures could impede venous return causing a sudden drop in cardiac output which could lead to refractory arrhythmias in patients with severe aortic stenosis.

We perform an epiaortic ultrasound to exclude atheromatous disease in the ascending aorta before proceeding to systemic heparinization and ascending aortic cannulation in the standard fashion. We favor placement of a percutaneous venous cannula via the right or left femoral vein. There are a variety of custom long venous cannulae that are available (usually 20F or 22F) and they are inserted using the Seldinger technique. The cannula is guided into the right atrium and the tip can be placed in the superior vena cava under TEE guidance. Alternatively, when an adequate amount of the right atrial appendage is seen via the hemisternotomy incision, it may be directly cannulated with the appropriate cannula. We do not favor this approach unless there is difficulty with percutaneous cannulation, as it does increase clutter in this relatively small incision. The patient is then placed on cardiopulmonary bypass. We use tepid bypass with core cooling to 34 to 35°C. We cannot overemphasize the need for vacuum-assisted venous drainage to facilitate this operation.

A retrograde cardioplegia catheter can be placed in the coronary sinus via the right atrial appendage. This may require a minor adjustment to reduce the angulation of the catheter and its insertion can be facilitated by the use of TEE. Alternatively, this catheter can be placed by the anesthesiologists prior to incision via the transjugular route. Although we routinely use a transaortic left ventricular vent, a right superior pulmonary vein or a left atrial dome vent can be easily placed via this incision.

The operation then proceeds as usual. The aorta is cross-clamped and cardioplegia is delivered antegrade through the aortic root. Usually 1 L of cold blood cardioplegia is delivered. TEE is used to monitor left ventricular distention in patients who may have aortic insufficiency. Additional cardioplegia is delivered into the coronary sinus in a retrograde fashion and directly into the coronary arteries upon aortotomy. Standard aortic valve replacement is then carried out through an oblique aortotomy (Fig. 39-2). Upon completion of the procedure, the patient is rewarmed and the aortotomy is closed. A de-airing needle is placed in the ascending aorta before removal of the aortic cross-clamp and performance of appropriate de-airing maneuvers.

The heart nearly always recovers spontaneous sinus rhythm. If the heart goes into ventricular fibrillation, it will need to be cardioverted using the external defibrillator pads placed prior to commencement of the operation.

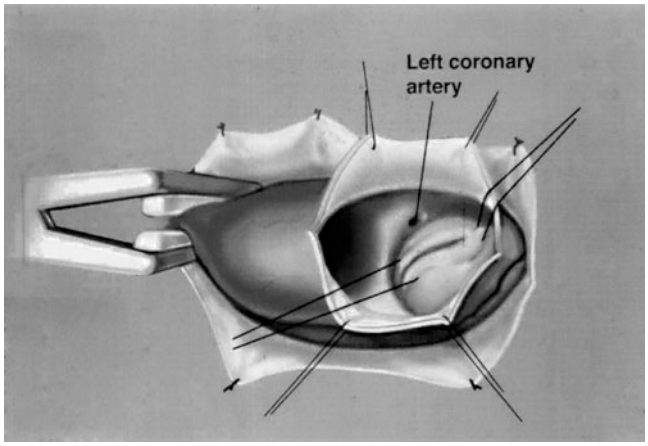

Figure 39-2. Exposure through an upper hemisternotomy incision.

Cardioversion can be facilitated by turning the cardiopulmonary bypass flows down to decompress the heart and appropriate drugs given. It is usually quite difficult to introduce internal defibrillator blades through this incision, although pediatric blades can sometimes be successfully placed. Appropriate preoperative placement of external defibrillator pads cannot be overemphasized. The heart is de-aired using TEE guidance. In the absence of the ability to reach in and agitate the heart, a combination of ventricular filling, table positioning, and external compression is used to successfully de-air the left heart. While this can always be successfully completed, patience may be an important part of facilitating this.

Prior to emergence from bypass, pacing wires and drainage tubes will have to be placed. Invariably, there is adequate atrial and ventricular myocardium exposed to place pacing wires. We usually bring these wires out in the right inframammary area through the right side. We place fluted silastic drains from a subxiphoid approach. It is very important to perform these placements with the heart decompressed on bypass in order to prevent injury. Small incisions are made in the subxiphoid area and long grabbing forceps are used to make two retrosternal tunnels, one of which will puncture the pericardium to facilitate placement of a pericardial drain, and the other will remain in the retrosternal plane. These are placed with a combination of tactile and visual control. In cases in which drains were not placed before removal from bypass and decannulation, we recommend opening the right or left pleural space and placement of transpleural drainage tubes. Placement of subxiphoid drains is not recommended after the heart is full. Weaning from cardiopulmonary bypass is then performed in the standard fashion followed by decannulation and protamine administration.

We usually leave the pericardium open. While checking the area for bleeding, some of the important sites to inspect are the coronary sinus due to the placement of the retrograde catheter (which will need full sternotomy conversion for control), areas of pacing wire placement and drainage tube entry (which may or may not require institution of bypass for visualization and control), sites of left ventricular vents, the lower edge of the sternotomy/pericardiotomy, and the internal mammary vessels on the side. The sternum is closed using three or four horizontal sternal wires and an oblique wire placed between the lower intact segment of the sternum and the angular segment of the incision.

Minimally invasive aortic valve replacement via the upper hemisternotomy approach was originally developed by Cosgrove and Sabik at the Cleveland Clinic[1] and soon after by Cohn and colleagues at the Brigham and Women's Hospital in Boston.[2] Gillinov and colleagues reported their excellent results in 365 cases by 2000[3] and today upper hemisternotomy is the approach of choice for isolated aortic valve surgery at the Cleveland Clinic. Mihaljevic[4] and colleagues from the Brigham group reported their experience with 1000 minimally invasive valve operations between 1996 and 2003, of which 526 were aortic valve procedures. They reported low levels of morbidity and mortality that were equal to or better than those seen with conventional techniques.

Recently, numerous authors have published their results with upper hemisternotomy minimal access aortic valve replacement. Most, if not all, report excellent outcomes. In their experience, Liu and associates[5] reported easier surgical access, less pain, shorter respiratory support time, lower blood loss, decreased incidence of infection and sternal dehiscence, and shorter hospital stay. In a prospective randomized study, Bonacchi and colleagues[6] reported similar findings in 2002. Sharony and coworkers[7] reported their experience with minimally invasive aortic valve surgery in the elderly and were able to demonstrate its safety in this fragile population with morbidity and mortality comparable to those of standard techniques.

THE RIGHT PARASTERNAL APPROACH

The first foray into the world of minimal access aortic valve surgery was with use of this approach. This approach seemed to be the most logical and elegant at a time when the focus was on the morbidity of the sternotomy, and surgeons were compelled to come up with this alternative.

This was performed via a vertical upper right parasternal incision. The second, third, and fourth costal cartilages were removed and the right internal mammary vessels were usually ligated and divided. It provided a similar approach to the aortic valve, and techniques of cannulation, cardiopulmonary bypass, myocardial protection, and valve replacement were the same. It soon gave way to the more elegant and simple upper hemisternotomy approach. One problem associated with the right parasternal approach was the high incidence of lung herniation, which was not only physiologically disturbing, but also was cosmetically disfiguring, and often required a second operation and mesh closure of the defect.

Cohn and colleagues[8] and Minale and associates[9] described their experiences with the right parasternal incision for aortic valve replacement in 1998. They reported low mortality and morbidity rates and recommended the approach for minimal access aortic valve surgery. Lung herniation led to hemisternotomy.

THE RIGHT ANTERIOR THORACOTOMY APPROACH

This incision is usually performed via the second right intercostal space. Due to the relatively high nature of the thoracotomy, it never continues around to become a true anterolateral thoracotomy. One can see why this would be unappealing for a female patient, as the incision would traverse horizontally across the upper part of the right breast which could lead to scarring and disfigurement. The incision is carried to the right sternal edge, and through this incision the right side of the aorta is easily visualized, and with strategically placed pericardial retraction sutures, the area of interest can easily be moved into the operative field. Aortic and venous cannulation could be performed centrally or peripherally. The rest of the operation is fairly routine as for any other minimal access aortic valve surgery. Special cross-clamps may be required to facilitate this procedure.

This operation is useful for patients requiring isolated aortic valve surgery in whom sternotomy needs to be avoided at all costs. A unique subset of such patients are those who are disabled and routinely ambulate with the use of shoulder crutches. These patients can ambulate early with their crutches without the risk of sternal dehiscence. Another possible subset of patients includes those with a heavily irradiated sternum.

The exposure via this incision could be optimized in cases with poor exposure by extending it across the sternum with a transverse sternotomy just below the manubriosternal angle. Reoperative aortic valve replacement is particularly difficult via this incision and the authors strongly discourage this approach for a reoperation.

Yakub and coworkers[10] and Benetti and colleagues[11] reported their results of minimally invasive aortic valve replacement via the right anterior thoracotomy approach. They reported excellent operative exposure and low mortality and morbidity. Minale and associates[12] reported a small series using a submammary right thoracotomy approach to aortic valve replacement in women with excellent results, especially cosmetically.

THE TRANSVERSE STERNOTOMY APPROACH

There are anecdotal reports of use of this incision for minimal access aortic valve surgery.

Typically an 8- to 10-cm transverse incision is made over the manubriosternal angle extending onto either side. Bilateral second costal cartilages are excised and both internal mammary pedicles are ligated and divided. A transverse sternotomy is performed across the sternal angle. The retractor is placed and the sternal edges are retracted in a craniocaudal plane. Adequate exposure is obtained through this incision to permit central aortic cannulation and a routine aortic valve replacement; however, venous cannulation, retrograde coronary sinus catheter placement, and left ventricular vent placement (except transaortic) may have to be performed percutaneously. Because the mammary arteries are sacrificed, this incision never gained much popularity.

Lee and associates,[13] De Amicis and colleagues,[14] and Aris and coworkers[15] reported that their small series with the transverse sternotomy approach yielded good results. However, Bridgewater and colleagues[16] reported an unacceptably high incidence of morbidity (i.e., re-exploration for bleeding, paravalvular leaks, and longer hospital stay) and mortality with this approach.

REOPERATIVE MINIMAL ACCESS AORTIC VALVE SURGERY

The Brigham and Women's Hospital routinely performs minimal access reoperative aortic valve replacement in patients who have previously undergone coronary artery bypass grafting or other cardiac surgery.

According to the STS database, patients requiring a reoperative aortic valve replacement following previous coronary artery bypass grafting have a mortality risk of about 8 to 12% with the procedure. The high risks are associated with the performance of a reoperation in an older patient with more comorbidities and patent or diseased bypass grafts.

There are several indications for this operation.

1. There is a definite subgroup of patients that has undergone coronary bypass surgery who had mild or no aortic stenosis at the time of their original operation, who will eventually progress to have severe aortic stenosis over time. This has sparked a discussion about the management of moderate aortic stenosis in those with coronary artery disease (CAD).[17]
2. These patients are older and sicker, and have many comorbid conditions.
3. They need a simple, safe, and effective operation.
4. The area of interest is the ascending aorta and aortic root.
5. Dissection of the rest of the heart and bypass grafts provides no additional benefit and can be potentially harmful.
6. Clipping the LIMA is not mandatory with alternative protection strategies.

Operative Strategy

Preoperatively, a computed tomogram of the chest with angiography and three-dimensional reconstruction is performed to ascertain the exact location of the old bypass grafts and their location relative to the sternum (especially the LIMA).[18] Coronary angiography and percutaneous coronary and graft intervention with drug-eluting stents are done as appropriate in order to optimize the revascularization as much as possible. Heart failure is controlled medically.

All cases need intraoperative TEE and a pulmonary artery catheter with atrial and ventricular pacing wire placement, and these should ideally be placed prior to incision. Accurate placement of external defibrillator pads is necessary, as internal paddles cannot be introduced in these cases.

All cases will need peripheral cannulation for cardiopulmonary bypass. We prefer right axillary and percutaneous femoral venous cannulation. Appropriate arterial line placement is needed to facilitate circulatory arrest and antegrade cerebral perfusion if required.[19] A standard upper hemisternotomy incision is made that extends into the right fourth intercostal space (Fig. 39-3). The anterior table split is performed using an oscillating saw, while the posterior table split is performed on cardiopulmonary bypass using straight Mayo scissors starting from the top down (preferably from the assistant's side of the table). When the LIMA graft is close to the left side or the middle of the sternum, a preplanned one- or two-third sternotomy to the right is performed. The right pleural space is widely opened. Only 5–10 mm of dissection is performed underneath the left sternal edge, enough to facilitate the placement of the Koros-Baxter retractor. The rest of the mediastinal and aortic dissection is performed on cardiopulmonary bypass. Care is taken not to injure the saphenous vein or radial arterial bypasses. It is not necessary to visualize the LIMA graft.

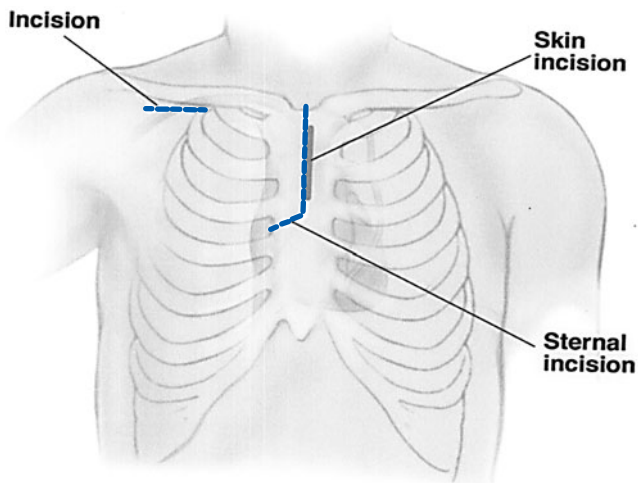

Figure 39-3. Incisions for reoperative minimal access aortic valve replacement.

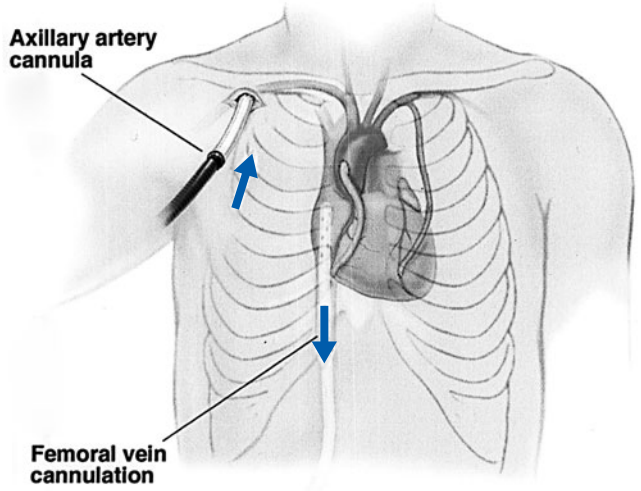

Figure 39-4. Setup for reoperation minimal access aortic valve replacement.

We start core cooling to 25°C only after it is possible to place an aortic cross-clamp. Moderate to deep hypothermia facilitates a low-flow state and reduces myocardial oxygen demand, which is important, as the LIMA will perfuse the heart for the duration of the operation. A retrograde coronary sinus catheter is placed through the right atrial appendage using TEE guidance. Usually, enough right atrial appendage can be seen to place this catheter. Alternatively, a transjugular catheter can be placed prior to incision. After cross-clamping the aorta, 1 L of antegrade cold blood cardioplegia is delivered through the aortic root (Fig. 39-4). Thereafter, 500 mL of cold retrograde blood cardioplegia is used. Simultaneously, systemic hyperkalemia is achieved by instilling 40 mEq of potassium into the cardiopulmonary bypass. Systemic hyperkalemia will achieve diastolic arrest in the left anterior descending artery territory that is perfused by the LIMA distal to the aortic cross-clamp. Throughout the operation, frequent doses of antegrade cardioplegia are delivered through the coronaries and grafts using perfusion cannulae, and 10 to 20 minute doses of retrograde cardioplegia are delivered as well. Systemic hyperkalemia is maintained at a level of 6.0 to 7.0 mEq/L. This will keep the myocardium fairly quiescent during the procedure. Needless to say, heavy doses of potassium may leave the patient with severe hyperkalemia that may not be cleared in the setting of renal dysfunction. In addition to being judicious in such cases, it is imperative that the perfusionists be able to provide ultrafiltration as well.

The aortotomy will be dictated by the location of previous bypass grafts. While in some cases a standard oblique aortotomy can be made, most cases will require a modified aortotomy like a lazy S or a lateral vertical aortotomy. The exposure should be adequate and expeditious valve replacement is the key to success. We aim to keep the cross-clamp time under 60 minutes. There will be continuous flow through the left main orifice due to perfusion from the

LIMA. During débridement and suture placement in the left coronary area, the bypass flows can be reduced or briefly turned off to facilitate exposure. Rewarming is started after the valve is seated. The aortotomy is closed in the standard fashion and a de-airing needle is placed before removal of the aortic cross-clamp. The heart often recovers spontaneous sinus rhythm. Defibrillation is achieved via the external pads if required. De-airing and weaning from cardiopulmonary bypass is as described before.

Drainage tubes are always placed through the right pleural space and subxiphoid placement is not possible and strongly discouraged. Rarely, when the right pleural space is completely fused, the silastic drain could be brought out in the supraclavicular area. It may be possible to place atrial pacing wires, but placement of ventricular wires is almost always quite difficult. We have routinely switched to the use of pulmonary artery catheter–based pacing leads with good success. Closure is fairly standard as described above and care must be taken during the placement of wires on the left side of the sternum and the oblique lower wire.

Byrne and associates[20,21] first published the Brigham experience with reoperative minimal access aortic valve replacement in patients who had previously undergone CABG or other cardiac surgery. Our experience has now grown to over 120 patients and we have had low mortality (<2%) and morbidity rates. This compares very favorably to the mortality and morbidity statistics of patients undergoing reoperation aortic valve replacement using standard techniques.

Conclusion

Minimally invasive aortic valve replacement is safer, effective, and reproducible and should be considered in especially elderly patients without CAD or after previous coronary bypass with intact grafts.

CHAPTER 40

Percutaneous Aortic Valve Interventions

Michael J. Davidson • Donald S. Baim

The number of patients with clinically significant aortic stenosis (AS) or regurgitation—2 to 3% of the elderly population with calcific AS, including 1 to 2% with congenital bicuspid aortic valve disease—is far greater than the 50,000 annual surgical aortic valve replacements would suggest. Some patients with aortic valve disease defer surgery in light of mild symptoms, whereas others are deemed too ill to undergo cardiac surgery. The latter currently are treated expectantly or by balloon aortic valvuloplasty (BAV), but this 20-year-old technique offers poor magnitude and durability of the physiologic improvement in aortic valve orifice area.

Recent technological advances, however, now indicate that catheter techniques similar to those used for BAV can be used for *percutaneous aortic valve replacement*, avoiding open cardiac access or the use of cardiopulmonary bypass. This new era is truly in its infancy, with most relevant devices still in preclinical testing or phase I human clinical evaluation. As the technology matures, though, it is almost certain to alter the treatment landscape for aortic valve intervention significantly. Implementation of this new technology, however, is going to require close ongoing collaboration among cardiac surgeons, cardiac anesthesiologists, and interventional cardiologists.

Given the outstanding current results of open surgical valve replacement, the principal indication for percutaneous aortic valve intervention probably will remain those patients with severe disease who are deemed inoperable because of comorbid conditions. The broader application of these new percutaneous technologies to good surgical candidates will demand prospective, randomized clinical trials with demonstration of similar prolonged safety and efficacy to surgical valve replacement.

BALLOON AORTIC VALVULOPLASTY

Following successful percutaneous dilation of pulmonary and mitral valves, the first adult BAV was performed by Alain Cribier in 1985.[1] Early experience in the mid-1980s showed that BAV was safe, but it also showed that the technique provided a far smaller increment in aortic valve area (AVA) (i.e., from 0.6 to 0.9 cm^2) than provided by surgical valve replacement.[2,3] The basic technique has not changed significantly since this time, but the procedure has been aided by advances in guidewire and balloon design, as well as newer imaging modalities such as transesophageal and intracardiac echocardiography. The classic retrograde approach has been used most commonly but may present difficulty with crossing a severely stenotic valve or complications caused at the arterial entry site by insertion of large-caliber devices. The antegrade approach is a more recent alternative, in which left atrial access is obtained via the femoral vein using standard transseptal puncture, following which a balloon flotation catheter and guidewire are advanced through the mitral valve, to the left ventricular apex, and then through the aortic valve.

Once a 0.035 to 0.038 inch guidewire has been positioned appropriately using either approach, an 18 to 23 mm valvuloplasty balloon then is advanced over the wire and across the stenotic valve, and it is inflated with dilute contrast material (Fig. 40-1). Rapid ventricular pacing (i.e., 180 to 200 beats per minute) can be initiated to transiently lower cardiac output and allow balloon inflation without the risk of balloon migration. The mechanism of action initially was assumed to be reopening of fused valve commissures, but pathologic investigation reveals little commissural fusion, with the dominant mechanism being fracture of calcified nodules along the leaflets with elastic expansion of the aorta.[4] While nodule fracture allows initially greater leaflet mobility, the effect is modest and relatively short lived as the aorta recoils and the nodule fractures go on to heal.

Early enthusiasm for the technique stemmed from its relative ease compared with surgical valve replacement, and some proponents hoped that BAV might supplant many

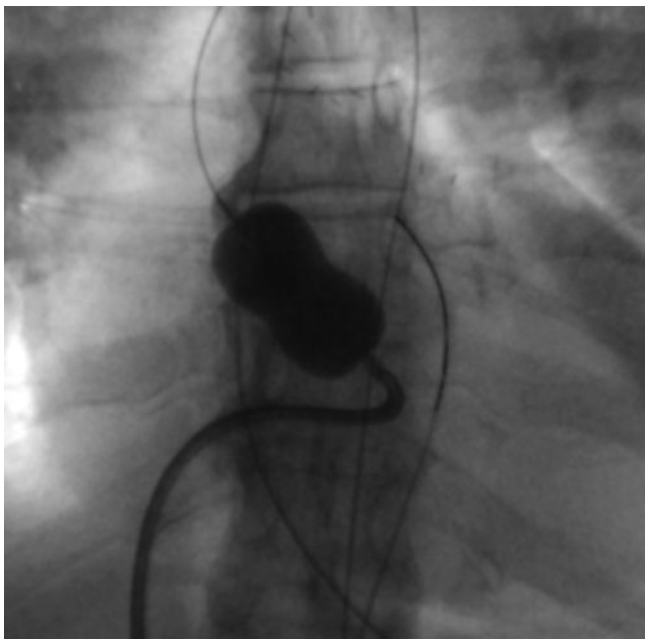

Figure 40-1. Percutaneous balloon aortic valvuloplasty using an antegrade transseptal approach. Native aortic valve calcium is visible at level of balloon "waist."

elective valve replacements. On average, however, AVA increased from 0.6 to 0.9 cm^2 and frequently reverted to severe stenosis over a matter of months. The overall 1-year survival was 65%, and the 1-year survival free of death, aortic valve replacement (AVR), or repeat BAV was 40%.[5] In addition, given the selected patient population, hospital mortality may be as high as 14%, with one-third having periprocedural complications,[3] including vascular access-site problems, arrhythmia, heart block, and stroke. At the present time, then, BAV is indicated only in select patients with severe AS and no surgical options. If stenosis recurs, repeat BAV can be performed.[6] BAV also may be used as a bridge to AVR in hemodynamically unstable patients or in those requiring urgent noncardiac surgery.[7]

VALVED STENTS

The impetus for the development of percutaneous AVRs thus lies in the need for an intervention that is more durable than BAV and that can be used in patients who are too high risk for surgical valve replacement. As in the percutaneous treatment of coronary artery disease (CAD), where simple balloon dilation was replaced by stent implantation to resist vessel recoil, the basic concept of percutaneous valve replacement hinges on the use of an outer stentlike structure to resist the tendency of the aortic annulus and diseased native leaflets to recoil following BAV. In addition, that stentlike structure is used to support three internal leaflets that together constitute a functioning valvular prosthesis. The first known embodiment of a stent-mounted valve was the

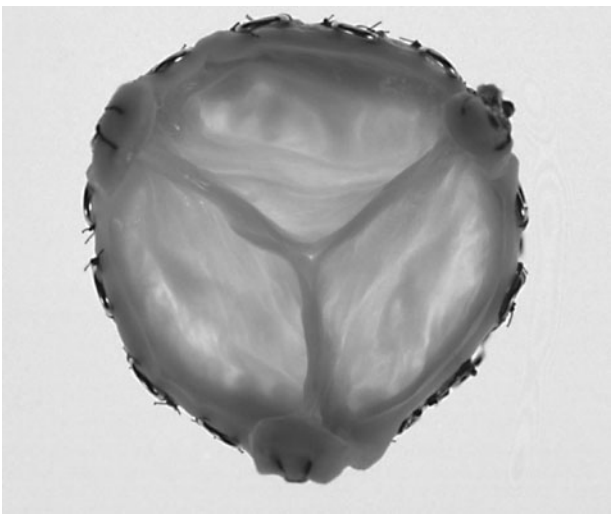

Figure 40-2. The Anderson valve consists of a trileaflet porcine valve mounted in a steel stent structure. The stent could be crimped onto a delivery balloon for percutaneous delivery. Initial use was in the heterotopic (i.e., Huffnagel) position.

Anderson valve, as described in 1992[7] (Fig. 40-2). While not initially optimized for orthotopic catheter-based valve replacement, the concept of a tissue valve mounted within a balloon-expandable stent formed the basis of subsequent percutaneous aortic valve intervention. Refinements in this concept ultimately led to the first human percutaneous aortic valve replacement, performed by Cribier in France in April 2002.[8]

Two devices are currently in active clinical use for percutaneous AVR: the balloon-expandable Cribier-Edwards valve and the self-expanding *Corevalve* prosthesis. A number of other second-generation devices are in various stages of development. All, however, face a common set of technical challenges.

PROCEDURAL AND DEVICE DESIGN CHALLENGES

The first procedural challenge concerns vascular access. The valved stents are, by necessity, significantly larger than most existing percutaneous cardiac catheters and devices. The first-generation delivery catheters are on the order of 22F to 24F, requiring direct femoral or iliac arterial access via surgical exposure if a retrograde approach is used. While an antegrade transseptal approach may enable percutaneous femoral venous access with some, the large sheath size still may predispose to vascular injury. While second-generation devices have reduced the size of the delivery catheter below 20F (by using the lower-profile self-expanding platform and by modifying the valve leaflets), issues with aortic, iliac, and femoral anatomy still may limit the retrograde introduction of even these smaller devices. Other options include retrograde implantation via axillary artery

cutdown or the descending thoracic aorta or antegrade introduction via minimally invasive or thoracoscopic left ventricular transapical puncture.[10] Overcoming vascular access issues is likely to be a central concern as device development continues.

A second design challenge for these devices is the potential for interference with other cardiac structures. The combination of fluoroscopy and transesophageal echocardiography offers limited control of the delivery catheter and makes precise three-dimensional (3-D) positioning difficult. Only the position of the valve prosthesis above the native aortic annulus can be adjusted, with no control of the orientation of the prosthetic leaflets relative to the native commissures. Unlike the pulmonary valve, a prosthesis within the aortic annulus has the potential to impede coronary flow, impinge on anterior mitral leaflet mobility, and apply pressure against the atrioventricular conduction system in the upper ventricular septum.[11,12] In current designs, avoiding interference with the coronary ostia relies on the calcified native aortic leaflets serving as "stand-off" from the coronary ostia; i.e., they preserve the space between the stent wall and the sinuses of Valsalva into which blood can flow from the ascending aorta to the coronary ostia. Rare cases have been described, however, where a large calcified nodule can block a coronary ostium or embolize calcium fragments into the coronary artery. Some stent architectures may extend to the tubular ascending aorta above the sinuses and potentially interfere with future catheter access to the coronary arteries and thus future catheter-based coronary artery interventions. Placement of the valve prosthesis too low in the left ventricular outflow tract (LVOT) can impede mitral leaflet mobility or cause heart block by impinging on the conduction system. Moreover, the first-generation devices are *single-shot implants*, with no possibility for recapture and repositioning, if needed. Second-generation designs, however, emphasize the ability to retrieve and reposition the device as needed during deployment. In addition, newer imaging modalities, including real-time computed tomography (CT) and magnetic resonance imaging (MRI) and 3-D echocardiography may aid in more accurate device placement.

The third challenge facing these devices is that of secure seating within the aortic annulus. First, the valve must be able to deploy accurately in the nonarrested heart. Initial approaches to this have included rapid ventricular pacing (at rates of up to 220 beats per minute) and the use of peripheral cardiopulmonary bypass to temporarily suspend left ventricular ejection. Each of these has potential pitfalls, and some second-generation devices thus are designed to allow stable seating of the valve prosthesis without interrupting cardiac output. Once the valve is placed, it must maintain a stable position within the annulus without risk of embolization. At this point, the valve is not retrievable, necessitating placement in a nonanatomic position (i.e., descending aorta) as a salvage maneuver. Moreover, the irregular surfaces of native calcified aortic leaflets may provide an advantage in serving as a "spacer" from the coronary ostia, but they also predispose to perivalvular leak (Fig. 40-3). In this sense, percutaneous AVR differs from open surgical AVR, where complete decalcification is performed prior to valve insertion to ensure proper valve seating. Options to improve sealing include the use of larger-diameter devices (i.e., 26 mm rather than 23 mm) to overstretch the aortic root into a rounder configuration or use of static or dynamic seals on the outside of the support stent to block potential paths for perivalvular leakage.

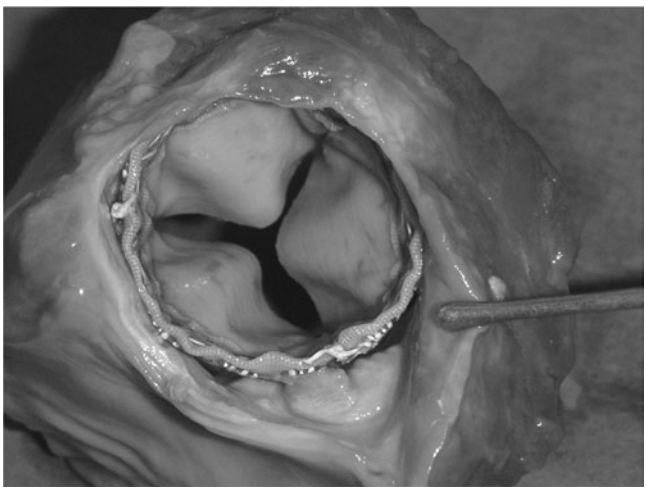

Figure 40-3. Postmortem specimen following placement of Cribier-Edwards valve. This patient suffered from severe perivalvular leak and resulting aortic regurgitation. The valve is positioned appropriately, but there is space present between the stent and the native valve leaflets.

Finally, the durability of these devices must be investigated thoroughly prior to their widespread use. While the initial applications have been in nonsurgical candidates with limited life expectancy, these valves may find use in a broader population. The biomaterials used for leaflet construction often have limited prior clinical application; these materials include equine and porcine pericardium, bovine jugular vein, and tissue-engineered leaflets. Furthermore, the long-term effects of bioprosthetic leaflets striking a rigid metal frame have not been established. Experience with aortic root replacement suggests that accelerated leaflet degradation may occur when valve cusps repeatedly strike a foreign surface.[13] In addition, if indications for these new devices move beyond nonsurgical candidates, the inevitable ingrowth of stent into aortic wall may preclude future simple surgical valve replacement and instead will necessitate full root replacement.

The initial clinical successes with these devices, however limited, have demonstrated that percutaneous AVR is possible and thereby have spawned an enormous professional and commercial impetus to overcome the challenges just described. The second-generation devices now in preclinical testing have begun to address many of the problems faced by early designs, and the pace of innovation in this arena is accelerating.

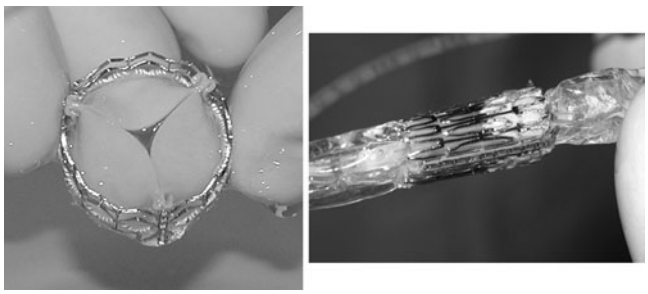

Figure 40-4. The Cribier-Edwards valve consists of three pericardial leaflets sewn to a stainless-steel stent. The valve is stored in the open position to avoid damage to the leaflets (*left panel*) and must be hand-crimped to the delivery balloon (*right panel*) immediately prior to implantation.

BALLOON-EXPANDABLE VALVES

The largest single-center experience to date has been reported from France by Alain Cribier using what is now termed the *Cribier-Edwards 23 mm balloon-expandable aortic valve prosthesis*[9,14,15] (Edwards Lifesciences, Irvine, CA) (Fig. 40-4). The valve consists of three pericardial leaflets (originally equine, now bovine) sewn inside a stentlike stainless-steel structure. The valve is stored in the open position to avoid damage to the leaflets and must be hand-crimped onto a deployment balloon catheter just prior to insertion. The initial approach in the most recent series from France almost exclusively has been antegrade. A transseptal puncture is performed, and a stiff guidewire is passed via the left ventricle and aortic valve into the descending aorta, where it is externalized through a femoral arterial sheath using a snare. After initial antegrade BAV over this wire, the Cribier-Edwards valve is crimped onto a Numed delivery balloon and advanced antegrade until it lies at the level of the native aortic valve calcifications. During rapid ventricular pacing, the balloon is inflated and deflated rapidly, leaving the prosthesis deployed at the level of the aortic annulus (once the valve has been deployed, it may not be retrieved or repositioned). Injection of contrast material into the aortic root confirms valve competence (Fig. 40-5).

Both the pilot phase of the clinical trial (termed I-REVIVE) and the subsequent trial (termed RECAST) have enrolled patients deemed not to be surgical candidates, having been turned down for valve replacement by two independent surgeons. Accordingly, this group of 40 patients had multiple comorbidities and had an average Euroscore of 13 and Parsonnet score of 47. Technical success was reported in 17 of the initial 20 patients (85%), with failures including two procedural deaths.[16] The mean gradient fell from 43 to 8.5 mm Hg, with AVA rising from 0.56 to 1.69 cm^2. This large effective orifice area is achieved by associated expansion of the aortic annulus and the absence of any struts or sewing ring so that it approaches the orifice of the best stentless surgical bioprosthetic valves. While no patients have experienced prosthetic valve dysfunction per se up to 26 months, moderate to severe perivalvular leak has been documented in one-half the patients.[16]

The North American experience with this approach, however, has been mixed. A small U.S. pilot study used an antegrade approach and the 23 mm Cribier-Edwards valve

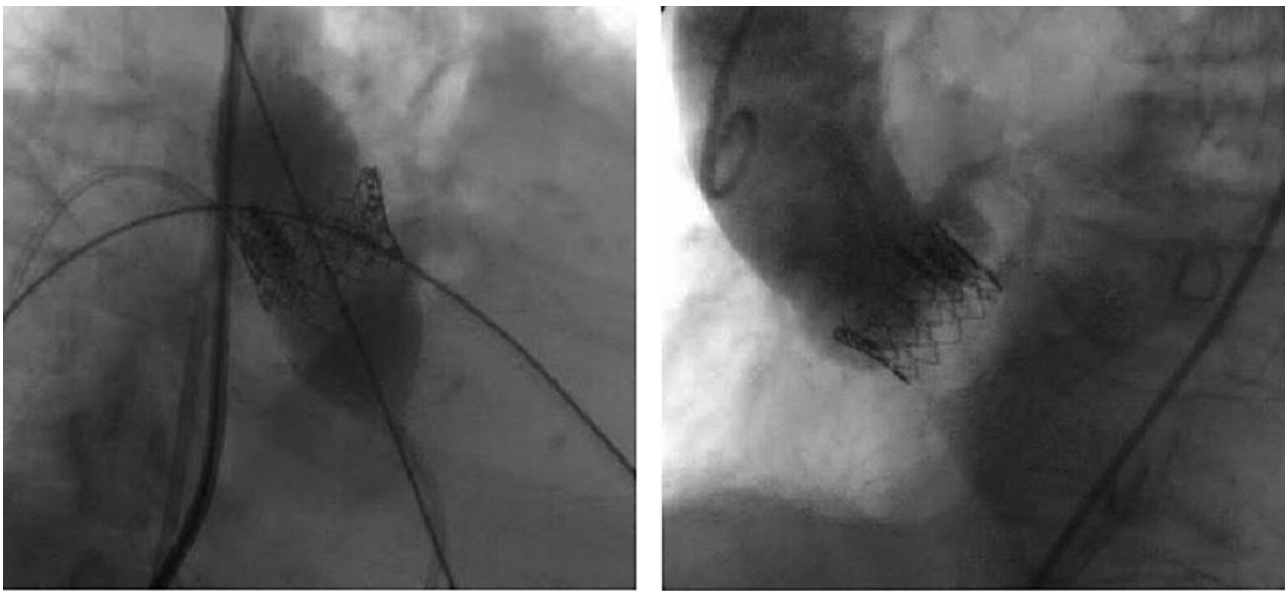

Figure 40-5. Fluoroscopic appearance of Cribier-Edwards valve placement. Stent is expanded by balloon at the level of the native aortic valve using calcification as a guide (*left panel*). Rapid ventricular pacing at 220 beats per minute transiently inhibits cardiac output to allow accurate valve placement. Aortic root injection after successful placement of the valve (*right panel*). Note nonobstructed flow to the coronary arteries and the presence of aortic insufficiency, suggesting perivalvular leak.

(analogous to that used in I-REVIVE and RECAST) but encountered a number of complications due to both the antegrade access and the limited valve size. Two cases of pericardial tamponade and two cases of injury to the anterior mitral leaflet caused periprocedural mortality, whereas several patients experienced significant perivalvular leak and valve migration. In contrast, a series of more than 20 insertions performed by Dr. John Webb in Vancouver, British Columbia, used the retrograde approach with a new, lower-profile deflectable delivery catheter that allows translation around the aortic arch and assists in crossing the stenotic valve. In addition, the Vancouver trial has used a larger 26 mm valve, which has reduced the number of perivalvular leaks. Complications have included two valve embolizations (treated by completing implantation in the descending aorta) and one case of fatal obstruction of the left main coronary artery owing to adverse positioning of a large calcified nodule during device expansion.[17] The U.S. pilot trial has resumed (December 2005) using a similar approach. The total experience with the Cribier-Edwards bioprosthesis—a first-generation device—demonstrates that percutaneous transcatheter AVR is possible but illustrates the significant technical challenges described earlier.

Additional balloon-expandable valved stents have been developed but have not yet entered clinical use.[18] Bonhoeffer and colleagues—the first to use valved stents successfully in humans—have modified the bovine jugular vein valve used in the pulmonary position for aortic use (Fig. 40-7C) and are in the stage of preclinical testing.[11] Other balloon-expandable valve stents likely will enter preclinical testing, but design emphasis has shifted toward self-expanding stent design because of the potentially lower device profile.

SELF-EXPANDING VALVES

A number of other devices have used a self-expanding frame rather than the balloon-expandable platform.[19–25] Of these, the Corevalve revalving system has undergone the largest amount of clinical application. This system uses a nitinol cage housing a valve constructed of porcine pericardial leaflets (Fig. 40-6). The delivery sheath is 21F and has been used in a retrograde fashion from surgical exposure of either the iliac artery, femoral artery, or axillary artery. The patients enrolled in this trial, like those receiving the Cribier-Edwards valve, have been deemed nonsurgical candidates, with an average Euroscore-predicted mortality of 22%. The technique uses peripheral cardiopulmonary bypass in lieu of rapid ventricular pacing for stable device deployment. To date, at least 20 patients have undergone attempted Corevalve placement by Dr. Eberhard Grube. Of the initial 21 patients, 17 had acute procedural success, and 10 of these were discharged from the hospital without major adverse cardiovascular events. There were seven periprocedural deaths (33%) in the early patients but a 90% procedural success rate and 10% mortality in the most recent 10 patients.[25]

Figure 40-6. The Corevalve system consists of pericardial leaflets attached to a self-expanding nitinol frame. In the deployed state. The flared distal end assists in anchoring in the ascending aorta. The stent covers the coronary ostia, but cell size is designed to allow later coronary catheterization.

A number of other devices using the self-expanding frame concept are in various stages of development and preclinical testing but have yet to be implanted in humans (Fig 40-7). These valve designs attempt to overcome several of the limitations faced by earlier generation valves, including embolization, perivalvular leak, inaccurate positioning, and unproven durability. The Sadra Lotus valve (Fig. 40-7A) uses a unique nitinol wire frame whose intrinsic self-expansion can be enhanced by active shortening of the axial length to generate considerable radial force to aid in seating. This can be reversed to allow the valve to be retrieved and repositioned during deployment, and the device includes an outer dynamic sealing system to reduce perivalvular leak. The AorTx design (Fig. 40-7B) suspends pericardial leaflets in a convex triangular nitinol frame that unrolls into a cylindrical shape to anchor in the annulus. This design is also repositionable and retrievable and may confer a leaflet durability advantage because the valve cusps do not come in contact with the frame during valve opening. Another design also achieves this goal but avoids the use of a metal frame altogether; the Direct Flow Medical device uses an inflatable cylindrical support that anchors within the native aortic valve. Additional self-expanding valves intended for aortic use have been developed for a direct left ventricular transapical approach via left thoracotomy or thoracoscopy.[10] While not currently adapted for catheter-based use, it is likely that these and other balloon-expandable valved stents will be modified for a percutaneous platform. Finally, while the vast majority of percutaneous AVR concepts have used biologic tissue for valve leaflets, some early preclinical attempts have been made to implant a mechanical prosthesis percutaneously.[26]

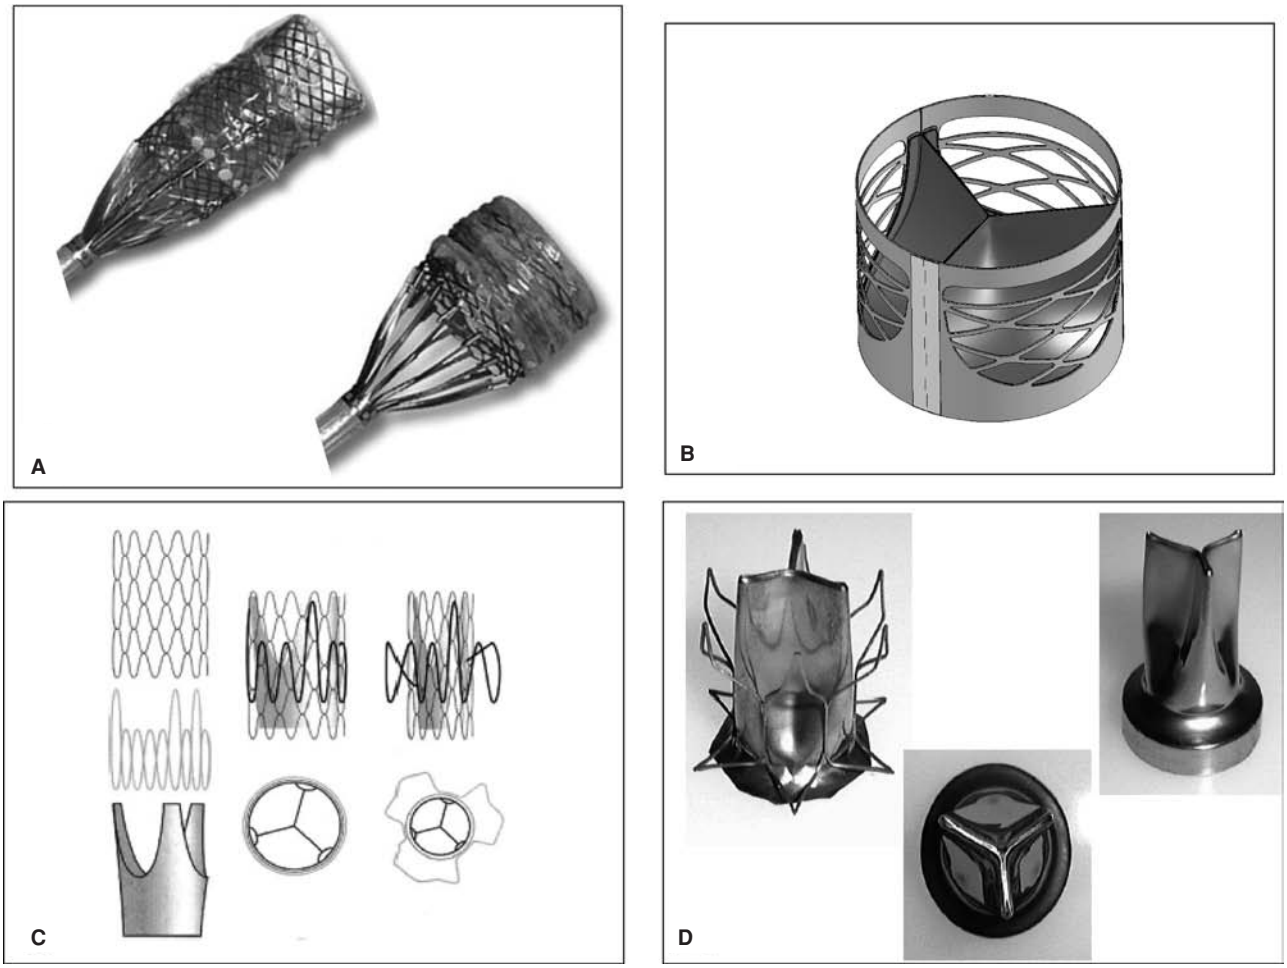

Figure 40-7. Percutaneous aortic valve replacement devices in preclinical development. (A) The Sadra self-expanding Lotus valve uses a nitinol frame that shortens as it is deployed, generating radial force for anchoring. (B) The AorTx valve uses a solid frame structure rather than traditional stent architecture to avoid damage to biologic leaflets. (C) The Bonhoeffer valve uses both self-expanding nitinol and balloon-expandable platinum-iridium components to achieve anchoring in the annulus. (D) The eNitinol thin membrane PercValve is a completely mechanical valve using nitinol leaflets that could become covered with native endothelium.

OTHER CONCEPTS

More radical designs include one by Palmaz and Bailey that uses nanoprocessing to create a valve consisting solely (including the leaflets) of nitinol (Fig. 40-7D). This might allow for rapid ingrowth of native endothelium and has the advantage of deliverability through a 10F sheath. A final percutaneous aortic valve intervention is that conceived at Corazon, which uses a chemical demineralization of the leaflets rather than valve replacement. This concept is to bathe the aortic valve in hydrochloric acid at a pH of 1 for 30 minutes to allow leaflet decalcification. This has been tested in humans during concomitant cardiac surgery, and a percutaneous embodiment was in development before initial capital was exhausted.

TRANSAPICAL APPROACH

The transapical approach offers to overcome vascular access issues as well as the challenges with crossing a stenotic valve and accurate positioning. A small left anterior thoracotomy is performed, and a sheath is placed in the left ventricular apex with a purse-string suture. A guidewire is passed through the native valve under fluoroscopic guidance, and the remainder of the procedure is performed in a manner similar to the transfemoral approach. This approach was validated initially in an animal model[10,27] and has been used clinically in at least 50 patients using the Cribier-Edwards valve.[28] While necessarily more invasive than a transfemoral approach, the shorter catheter length and antegrade approach may afford more stable control of the device for deployment.

CONCLUSION

Although definitive catheter-based AVR is clearly in its infancy (with a total of fewer than 200 patients treated worldwide over the past 3 years), it is clear that a number of percutaneous approaches can allow this procedure. The field is likely to develop rapidly over the next several years, with refinement of the early approaches and emergence of still newer technologies. Guided by clinical results, these devices ultimately may expand beyond the current target of patients with no surgical option to treat high-risk patients, patients with stenosis of a prior aortic valve bioprosthesis, or even as an alternative to surgery. Indeed, pilot studies of valved stent deployment inside previously placed bioprosthetic valves have been promising. Procedures likely will be performed by only a subgroup of "structural" cardiologists and surgeons who possess the training and skills to understand valve pathology more completely, to work transseptally, and to integrate fluoroscopic with 3-D transesophageal and intracardiac echocardiographic images. The remaining engineering obstacles do not appear to be insurmountable but clearly will require the close collaboration of interventional cardiologists with cardiac surgeons (who best understand the valve pathology and repair methods) and engineering teams who must turn these concepts into clinically usable devices.[29]

CHAPTER 41

Pathophysiology of Mitral Valve Disease

James I. Fann • Neil B. Ingels, Jr. • D. Craig Miller

THE NORMAL MITRAL VALVE

Anatomy

The mitral annulus is a pliable junctional zone of discontinuous fibrous and muscular tissue that joins the left atrium and left ventricle and anchors the hinge portion of the anterior and posterior mitral leaflets.[1–11] The annulus has two major collagenous structures: (1) the right fibrous trigone, which is part of the central fibrous body and is located at the intersection of the membranous septum, the mitral and tricuspid annulus, and the aortic annulus, and (2) the left fibrous trigone, which is located near the aortic annulus under the aortic left coronary cusp (Fig. 41-1). The anterior mitral leaflet spans the distance between the commissures (including the trigones) and is in direct fibrous continuity with the aortic annulus under the left and noncoronary aortic valve cusps, including the fibrous triangle between the left and noncoronary aortic valve cusps. Fine tendon-like collagen bundles, the fila of Henle, extend out circumferentially from each fibrous trigone a variable distance toward the corresponding side of the mitral orifice. The posterior half to two-thirds of the annulus, which subtends the posterior leaflet, is primarily muscular with little or no fibrous tissue.[10] This muscle is arranged mainly perpendicularly to the annulus, and a less prominent group of muscle fibers is arranged parallel to the annulus.

The mitral valve has two major leaflets, the larger anterior (or aortic or septal) leaflet and the smaller posterior (or mural) leaflet; the latter usually contains three or more scallops separated by fetal clefts or "subcommissures," which are developed to variable degrees in different individuals.[12] The portions of the leaflets near the free margin on the atrial surface are called the *rough zone,* with the remainder of the leaflet surface closer to the annulus being termed the *smooth* (or *bare* or *membranous*) *zone.* The ratio of the height of the rough zone to the height of the clear zone is 0.6 for the anterior leaflet and 1.4 for the posterior leaflet because the clear zone on the posterior scallops occupies only about 2 mm.[12] The two leaflets are separated by the posteromedial and anterolateral commissures, which usually are distinctly developed but occasionally are incomplete. Individual leaflet commissural scallops also can exist.

The histologic structure of the leaflets includes three layers: (1) the fibrosa, the solid collagenous core that is continuous with the chordae tendineae, (2) the spongiosa, which is on the atrial surface and forms the leaflet leading edge (it consists of few collagen fibers but has abundant proteoglycans, elastin, and mixed connective tissue cells), and (3) a thin fibroelastic covering of most of the leaflets.[10] On the atrial aspect of both leaflets, this surface (the atrialis) is rich in elastin. The ventricular side of the fibroelastic cover (the ventricularis) is much thicker, is confined mostly to the anterior leaflet, and is densely packed with elastin. The fibroelastic layers become thickened with advancing age owing to elaboration of more elastin and more collagen formation; similar accelerated changes also accompany the progression of myxomatous (degenerative or "floppy") mitral valvular disease. In addition to these complex connective tissue structures, the mitral leaflets contain myocardium, smooth muscle, contractile valvular interstitial cells, and blood vessels, as well as both adrenergic and cholinergic afferent and efferent nerves.[13–28] Leaflet contractile tissue is neurally controlled and may play a role in mitral valve function.[6,16–19,29–35] The atrial surface of the anterior leaflet exhibits a depolarizing electrocardiogram spike shortly before the onset of the QRS complex, and the resulting contraction of leaflet muscle, along with contraction of smooth muscle and valvular interstitial cells, possibly aids leaflet coaptation before the onset of systole, as well as stiffens the leaflet in response to rising left ventricular (LV) pressure.[16–19,33,35–39] Mitral leaflet stretch of 10% or more also leads to an action potential that initiates leaflet muscle contraction.[37,40]

Annular Size, Shape, and Dynamics

The average mitral annular cross-sectional area ranges from 5.0 to 11.4 cm^2 in normal human hearts (average is 7.6 cm^2).[41] The annular perimeter of the posterior leaflet is longer than that subtending the anterior leaflet by a ratio of 2:1; i.e., the posterior annulus circumscribes approximately two-thirds of the mitral annulus.[12] Annular area varies during the cardiac cycle and is influenced directly by both left atrial (LA) and LV contraction, size, and pressure.[4,42] The magnitude of change in mitral annular area is 20 to 40% during the cardiac cycle.[4,8,9,42–49] Annular size increases beginning in late systole and continues through isovolumic relaxation and into diastole; maximal annular area occurs in late diastole around the time of the P wave on the electrocardiogram.[4,8,44,46,47,50] Importantly, half to two-thirds of the total decrease in annular area occurs during atrial contraction (thus *presystolic*); this component of annular area change is smaller when the PR interval is short and is abolished completely when atrial fibrillation is present or when the ventricle is paced. Annular area decreases further (if LV end-diastolic volume is not abnormally elevated) to a minimum in early to middle systole.[4,7,8,42,44]

The normal human mitral annulus is roughly elliptical (or kidney-shaped), with greater eccentricity (i.e., being less circular) in systole than in diastole.[3,4,8,41,42,46,48,51] In its most elliptical configuration, the ratio of minor to major diameters is approximately 0.75. In three-dimensional space, the annulus is somewhat saddle-shaped (or, more precisely, a hyperbolic paraboloid), with the highest point (farthest from the LV apex) located anteriorly in the middle of the anterior leaflet; this point is termed the *fibrosa* in the echocardiography literature and the *saddle horn* by surgeons and is readily identified in echocardiographic images owing to the common junction with the aortic valve. The low points are located posteromedially and anterolaterally near the commissures, and another less prominent high point is located directly posterior.[4,52,53] The ratio of annular height to commissure-commissure width is highly conserved across species and thought to be an important modulator of systolic leaflet stresses.[54] During the cardiac cycle, annular regions adjacent to the posterior leaflet (where the leaflet attaches directly to the atrial and ventricular endocardium) move toward (during systole) and away (during diastole) from the relatively immobile anterior annulus.[4,48] Certain annular segments located near the left fibrous trigone (area of aortic-mitral continuity), however, actually may lengthen slightly during LV ejection, at least in canine and ovine hearts.[55]

The mitral annulus moves upward into the left atrium in diastole and toward the LV apex during systole; the duration, average rate, and magnitude of annular displacement correlate with (and perhaps influence) the rate of LA filling and emptying.[4,8,44,47,56,57] The annulus moves slightly during late diastole (2 to 4 mm toward the left atrium during atrial systole). This movement does not occur in the presence of atrial fibrillation and may be an atriogenic contractile property. The annulus moves a greater distance (3 to 16 mm toward the LV apex) during isovolumic contraction and ventricular ejection. This systolic motion, which aids subsequent LA filling, occurs in the presence or absence of atrial fibrillation and is related to the extent of ventricular emptying; thus it is likely driven by LV contraction.[4,8,46,47,56–62] Subsequently, the annulus moves very little during isovolumic relaxation but then exhibits rapid recoil back toward the left atrium in early diastole. This recoiling increases the net velocity of mitral inflow by as much as 20%.[9,47]

Dynamic Leaflet Motion

The posterior mitral leaflet is attached to thinner chordae tendineae than the anterior leaflet, and its motion is restrained by chordae during both systole and diastole.[12,56] Regions of both leaflets are concave toward the left ventricle during systole,[63–65] but leaflet shape is complex, and anterior leaflet curvature near the free margin actually may be convex to the left ventricle during systole, thus resulting in a sigmoid shape.[50,52,53,66] Leaflet opening does not start with the free margin but rather in the center of the leaflet; leaflet curvature flattens initially and then becomes reversed (making the leaflet convex toward the left ventricle) while the edges are still approximated.[50,64,65] The leading edge then moves into the left ventricle (like a traveling wave), and the leaflet straightens. The leaflet edges in the middle of the valve appear to separate before those portions closer to the commissures, and posterior leaflet opening occurs approximately 8 to 40 ms later.[65–68] Once reaching maximum opening, the edges exhibit a slow to-and-fro movement (like a flag flapping in a breeze) until another less forceful opening impulse

occurs, associated with the *a* wave. During late diastole, the leaflets move gradually away from the LV wall.

Valve closure starts with the leaflet bulging toward the atrium at its attachment point to the annulus. The closure rate of the anterior leaflet is almost twice that of the posterior leaflet, thereby ensuring arrival of both cusps at their closed positions simultaneously (since the anterior leaflet is opened more widely than the posterior leaflet at the onset of ventricular systole).[68] The anterior leaflet actually arrives at the plane of the annulus in a bulged shape (concave to the ventricle), but as the closing movement proceeds and the leaflet ascends toward the atrium, this curvature appears to run through the whole leaflet, from the annulus toward the edge, in a rolling manner. The leaflet edge is the last part of the leaflet to approach the annular plane. Leaflet curvature is more pronounced with the onset of systolic ejection.[64,65]

Mitral valve closure is completed 10 to 40 ms after the initial systolic rise of LV pressure, but leaflet opening motion actually may precede the diastolic pressure crossover point by up to 60 ms.[65,69,70] While the onset of mitral valve closure at the end of diastole appears to be initiated by atrial contraction, competent leaflet closure requires an increase in ventricular pressure above that in the atrium (irrespective of whether or not a normal atrial electrical and mechanical sequence is present) and a proper valve annular size to permit apposition of the valve leaflets at the onset of and during ventricular ejection.[16,42,68]

Chordae Tendineae and Papillary Muscles

Epicardial fibers in the left ventricle descend from the base of the heart and proceed inward at the apex to form the two papillary muscles, which are characterized by vertically oriented myocardial fibers.[11,71] The anterolateral papillary muscle usually has one major head and is a more prominent structure; the posteromedial papillary muscle can have two or more subheads and is flatter.[12] A loop from the papillary muscles to the mitral annulus is completed by the chordae tendineae continuing into the mitral leaflets, which then are attached to the annular ring. The distance from the tip of the human papillary muscle to its corresponding mitral annulus averages 23.5 mm from the tip of the anterolateral papillary muscle to the left trigone and 23.2 mm to the point between the anterior and middle scallops of the posterior leaflet.[72] The distance from the tip of the posteromedial papillary muscle to the right trigone is 23.5 mm and to the annular point between the middle and posteromedial scallops of the posterior leaflet is 23.5 mm. The posteromedial papillary muscle usually is supplied by the right coronary artery (or a dominant left circumflex artery in 10% of patients); the anterolateral papillary muscle is supplied by blood flow from both the left anterior descending and circumflex coronary arteries.[11,73,74]

The posteromedial and anterolateral papillary muscles give rise to chordae tendineae going to both leaflets[12] (Fig. 41-2). The chordae are divided classically and functionally into three groups.[11,75] First-order chordae originate near the papillary muscle tips, divide progressively, and insert on the leading edge of the leaflets; these primary chordae prevent valve-edge prolapse during systole. The second-order chordae (including two or more larger and less branched "strut" chordae) originate from the same location and tend to be thicker and fewer in number[12,75]; they insert on the ventricular surface of the leaflets at the junction of the rough

J Thorac Cardiovasc Surg 1999; 118: 636.*)

and clear zones, which is demarcated by a ridge corresponding to the line of leaflet coaptation. The second-order chordae (including the strut chordae) serve to anchor the valve, are more prominent on the anterior leaflet, and are important for optimal ventricular systolic function; second-order chordae also may arborize from large chordae that also give rise to first-order chordae. The third-order chordae, also called *tertiary* or *basal chordae,* originate directly from the trabeculae carneae of the ventricular wall, attach to the posterior leaflet near the annulus, and can be identified by their fan-shaped patterns.[75] Additionally, distinct commissural chordae and cleft chordae exist in the commissures. Chordae contain nerve fibers, and some chordae, considered to be immature forms, may contain muscle tissue.[17] In total, about 25 major chordal trunks (range 15 to 32) arise from the papillary muscles in humans, equally divided between those going to the anterior and posterior leaflets; on the other end, over 100 smaller individual chordae attach to the leaflets.[75] Recent studies of porcine mitral valves demonstrate that the chordae have different microstructures based on chordal type.[76] The presence of vessels characterizes the chordae as complex living components that work in coordination with the other elements of the valvular and subvalvular apparatus. The strut chordae on the anterior leaflet have an increased degree of vascularization compared with the other chordae. There also appears to be higher levels of DNA and collagen content in the anterior and posterior marginal chordae compared with the other chordae.[76]

During diastole, the papillary muscles form an inflow tract. During systole, they create an outflow tract that later becomes obliterated owing to systolic thickening of the papillary muscles, thereby augmenting LV ejection by volume displacement.[71] The contribution of the papillary muscles to LV chamber volume is 5 to 8% during diastole but 15 to 30% during systole.[71,77] The anterior and posterior papillary muscles contract simultaneously and are innervated by both sympathetic and parasympathetic (vagal) nerves.[78,79]

Previous analyses of papillary muscle function during the cardiac cycle yielded widely discordant results.[78,80–83] Although the papillary muscles shorten at some point during systole (by upwards of one-fourth their maximum length), this contraction may be isometric or substantially less than that of the LV free wall fibers.[80–82,84–87] In addition, there is no consensus as to the exact timing of papillary muscle contraction and elongation during the cardiac cycle.[78–80,82,83,85,86] Some workers suggest that the papillary muscles contract before the LV free wall so that the mitral valve leaflets are supported during early LV ejection[83]; others, however, report that papillary muscles lengthen during isovolumic contraction and shorten during ejection, as well as during isovolumic relaxation.[79,82] From the standpoint of electromechanics, although papillary muscle excitation occurs simultaneously with the rest of the endocardial surface of the ventricle, the papillary muscles may contract just after the onset of LV contraction.[78,85] Maximal shortening and elongation of the papillary muscle may follow thickening and thinning of an adjacent LV free wall segment.[85,86] Papillary muscle shortening throughout isovolumic relaxation may play a role in opening the mitral valve, and elongation in late diastole may be necessary to permit proper valve closure.[85]

It has been shown experimentally that both papillary muscles closely mimic general LV dynamics; i.e., the papillary muscles shorten during ejection, lengthen during diastole, and change length minimally during the isovolumic periods[80] (Fig. 41-3). These findings suggest that earlier studies suggesting that papillary muscle lengthen during isovolumic contraction and shorten during isovolumic relaxation may have been confounded by some form of myocardial injury or surgical trauma during instrumentation.[80]

MITRAL STENOSIS

Etiology

Mitral stenosis generally is the result of rheumatic heart disease.[88–94] Nonrheumatic causes of mitral stenosis or LV inflow obstruction include severe mitral annular and/or leaflet calcification, congenital mitral valve deformities, malignant carcinoid syndrome, neoplasm, LA thrombus, endocarditic vegetations, certain inherited metabolic diseases, and those cases related to previous commissurotomy or an implanted prosthesis[91–96] (Fig. 41-4). A definite history of rheumatic fever can be obtained in only about 50 to 60% of patients; women are affected more often than men by a 2:1 to 3:1 ratio. Nearly always acquired before age 20, rheumatic valvular disease becomes clinically evident one to three decades later. The association of pregnancy and the clinical onset of symptoms of mitral stenosis is common.

Approximately 20 million cases of rheumatic fever occur in third-world countries annually, with a correspondingly high incidence of advanced mitral stenosis later in life.[97] In the United States, western Europe, and other developed countries, the prevalence of mitral stenosis has decreased markedly. The etiologic agent for acute rheumatic fever is group A beta-hemolytic streptococcus, but the specific immunologic and inflammatory mechanisms leading to the valvulitis are less clear.[97–100] Streptococcal antigens cross-react with human tissues, known as *molecular mimicry,* and may stimulate immunologic responses. Differences in the cellular and extracellular proteins of the many strains of group A streptococcus may be important in the development of rheumatic heart disease. Components implicated in the organism's virulence include the hyaluronic acid capsule and the antigenic streptococcal M protein and its peptides.[97–99] Recent studies show mimicry between streptococcal antigens and heart tissue proteins, combined with high inflammatory cytokine and low interleukin 4 (IL-4) production, leads to the development of autoimmune reactions and cardiac tissue damage.[98,99] The chronic phase of rheumatic valve disease is associated with ongoing serum inflammatory mediators that correlate with the severity of valve involvement and scarring.[100] Along with the individual's immunologic responsiveness, other genetic factors are likely to be involved in the susceptibility to disease development or progression.

In addition to affecting the valves, rheumatic heart disease is a pancarditis affecting to various degrees the endocardium, myocardium, and pericardium[88–90] (Fig. 41-5). In rheumatic valvulitis, mitral valve involvement is the most common (isolated mitral stenosis is found in 40% of patients), followed by combined aortic and mitral valve disease, and least frequently, isolated aortic valve disease, with or without tricuspid involvement. Pathoanatomic changes characteristic of mitral valvulitis include commissural fusion, leaflet fibrosis with stiffening and retraction, and chordal fusion and shortening.[89] Leaflet stiffening and fibrosis can be exacerbated over time by increased flow turbulence.

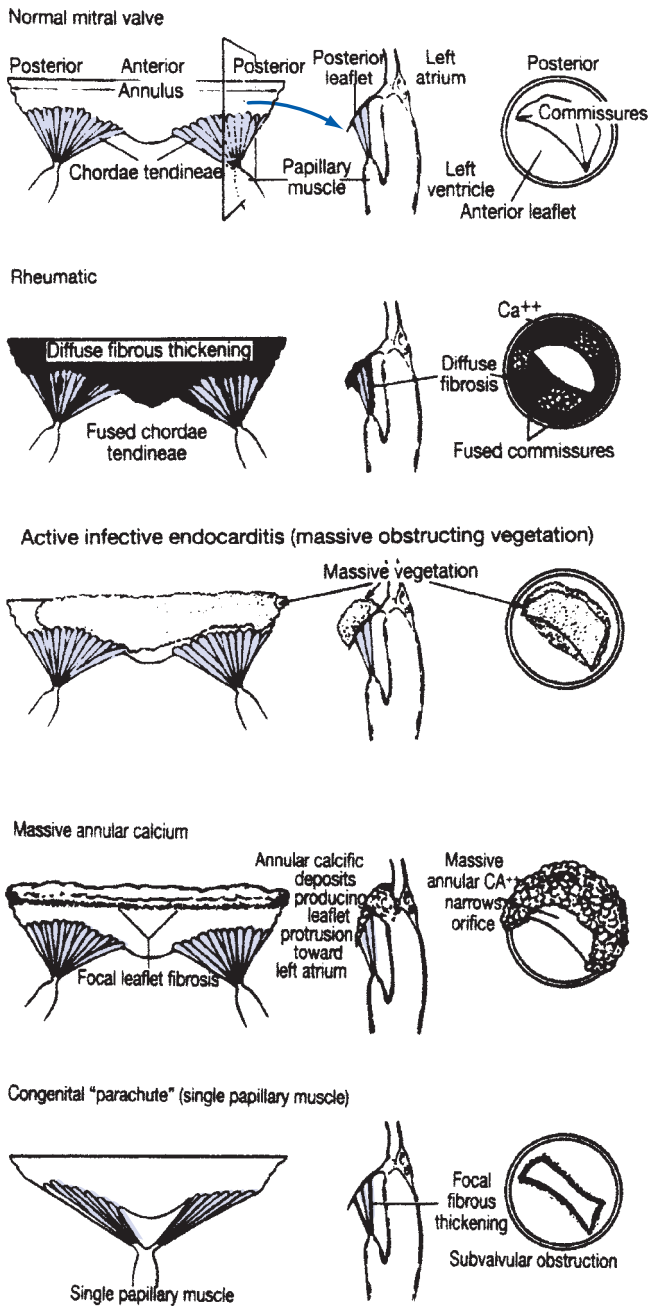

Figure 41-4. Diagrams demonstrating causes of mitral stenosis, including rheumatic heart disease, active infective endocarditis, massive mitral annular calcification, and congenital single papillary muscle syndrome. (*Modified from Waller BF, Howard J, Fess S: Pathology of mitral valve stenosis and pure mitral regurgitation, part I. Clin Cardiol 1994; 17:330. Valvular regurgitation can develop owing to chordal fusion and shortening. The chordae tendineae may become so retracted that the leaflets appear to insert directly into the papillary muscles. The degree of calcification varies; it is more common and of greater severity in men, older patients, and those with a higher transvalvular gradient.[90] In some

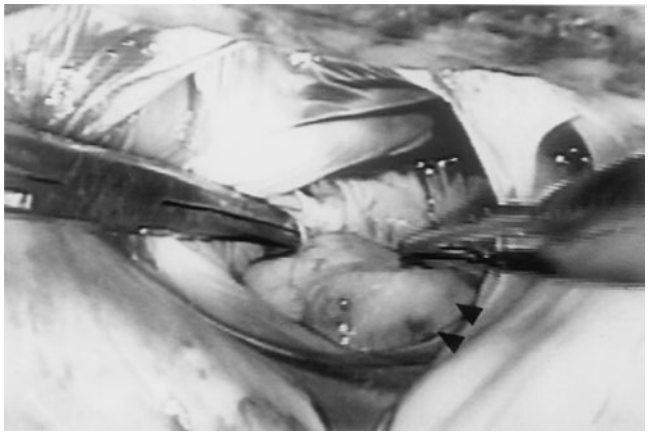

Figure 41-5. Intraoperative photograph of mitral stenosis as a result of rheumatic heart disease. The mitral leaflets are markedly restricted. The arrowheads point to the anterior leaflet near the anterolateral commissure.

cases, rheumatic myocarditis results in cardiac dilatation and progressive heart failure.

Mitral annular calcification may progress to mitral sclerosis and eventually stenosis in elderly patients.[96] The anterior leaflet can become thick and immobile; LV inflow obstruction also results from calcification of the posterior mitral valve leaflet. Calcific protrusions into the ventricle and extension of the calcium into the leaflets further narrow the valve orifice, resulting in mitral stenosis.[96] In these cases, the left ventricle typically is small, hypertrophied, and noncompliant.

Hemodynamics

In patients with mitral stenosis, an early, middle, and late diastolic transvalvular gradient is present between the left atrium and ventricle; as the degree of mitral stenosis worsens, a progressively higher gradient occurs, especially late in diastole.[91,101–103] The average left atrial pressure in patients with severe mitral stenosis may be in the range of 15 to 20 mm Hg at rest, with a mean transvalvular gradient of 10 to 15 mm Hg.[101,103] With exercise, the LA pressure and gradient rise substantially. LV end-diastolic pressure usually is normal.

Another physiologic measurement in patients with mitral stenosis is the (derived) cross-sectional valve area, which is calculated from the mean transvalvular pressure gradient and cardiac output. The transvalvular pressure gradient is a function of the square of the transvalvular flow rate; e.g., doubling the flow quadruples the gradient. At a given flow rate, a smaller valve area corresponds to a higher pressure gradient. Mitral transvalvular flow depends on cardiac output and heart rate. An increase in heart rate decreases the duration of transvalvular LV filling during diastole; the transvalvular mean gradient increases, and consequently, so does LA pressure.[102,104] A high transvalvular gradient may be associated with a normal cardiac output; conversely, if cardiac output is low, only a modest transvalvular gradient may be present.

Because of effective atrial contraction, the mean LA pressure in patients with mitral stenosis and normal sinus rhythm is lower than that in patients with atrial fibrillation.[105,106] Sinus rhythm further augments flow through the stenotic valve, thereby helping to maintain adequate forward cardiac output. The development of atrial fibrillation decreases cardiac output by 20% or more; atrial fibrillation with a rapid ventricular response can lead to acute dyspnea and pulmonary edema.[88,105,106]

Ventricular Adaptation

In patients with isolated mitral stenosis and restricted LV inflow, LV chamber size (end-diastolic volume) is normal or decreased, and the end-diastolic pressure typically is low.[91,107,108] The peak filling rate is reduced, as is stroke volume. Cardiac output thus is diminished as a result of inflow obstruction rather than LV pump failure.[109] LV mass is normal or slightly subnormal in the majority of these patients.[107] During exercise, the ejection fraction may increase slightly; however, LV filling is compromised by the shorter diastolic periods at higher heart rates, resulting in a smaller end-diastolic volume (or LV preload). Therefore, stroke volume and a blunted increase (or even decrease) in cardiac output can occur.[108]

Approximately 25 to 50% of patients with severe mitral stenosis have LV systolic dysfunction as a consequence of associated problems (e.g., mitral regurgitation, aortic valve disease, ischemic heart disease, rheumatic myocarditis or pancarditis, and myocardial fibrosis).[90,103,108] In these patients, LV end-systolic and end-diastolic volumes may be larger than normal. Also, because right ventricular afterload increases as pulmonary hypertension develops in these patients, right ventricular systolic performance deteriorates.[91,110] Clinically, however, increased right ventricular afterload as a result of mitral stenosis usually is associated with normal right ventricular contractility.[91]

Atrial Adaptation

In patients with mitral stenosis who are in normal sinus rhythm, the LA pressure tracing is characterized by an elevated mean LA pressure with a prominent *a* wave, which is followed by a gradual pressure decline.[88,106] The *a*-wave pressure largely reflects the kinetic energy dissipated in overcoming the resistance across the valve. Because of the stenotic valve, coordinated LA contraction is important in maintaining transvalvular flow.[106] The high LA pressure gradually leads to LA hypertrophy and dilatation, atrial fibrillation, and atrial thrombus formation.[90,108,111] The degree of LA enlargement and fibrosis does not correlate with the severity of the valvular stenosis partly because of the marked variation in duration of the stenotic lesion and atrial involvement by the underlying rheumatic inflammatory process.[108] Disorganization of atrial muscle fibers is associated with abnormal conduction velocities and inhomogeneous refractory periods. Premature atrial activation owing to increased

automaticity or reentry eventually may lead to atrial fibrillation, which is present in over half of patients with either pure mitral stenosis or mixed mitral stenosis and regurgitation.[111,112] Major determinants of atrial fibrillation in patients with rheumatic heart disease include older age and larger LA diameter.[111]

Pulmonary Changes

In patients with mild to moderate mitral stenosis, pulmonary vascular resistance is not increased, and pulmonary arterial pressure may remain normal at rest, rising only with exertion or increased heart rate.[101] In severe chronic mitral stenosis with elevated pulmonary vascular resistance, pulmonary arterial pressure is elevated at rest and can approach systemic pressure with exercise. A pulmonary arterial systolic pressure greater than 60 mm Hg significantly increases impedance to right ventricular emptying and produces high right ventricular end-diastolic and right atrial pressures.

LA hypertension produces pulmonary vasoconstriction, which exacerbates the elevated pulmonary vascular resistance.[90,110] As the mean LA pressure exceeds 30 mm Hg above oncotic pressure, transudation of fluid into the pulmonary interstitium occurs, leading to reduced lung compliance. Pulmonary hypertension develops as a result of passive transmission of high LA pressure, pulmonary venous hypertension, pulmonary arteriolar constriction, and eventually, pulmonary vascular obliterative changes. Early changes in the pulmonary vascular bed may be considered protective in that the elevated pulmonary vascular resistance protects the pulmonary capillary bed from excessively high pressures; however, the pulmonary hypertension worsens progressively, leading to right-sided heart failure, tricuspid insufficiency, and occasionally, pulmonic valve insufficiency.[91,110] Severe mitral stenosis ultimately causes irreversible pulmonary vascular changes; cardiac output is low at rest and remains subnormal during exercise.[101]

Clinical Evaluation

Because of the gradual development of mitral stenosis, patients may remain asymptomatic for many years.[88,101,112] Characteristic symptoms of mitral stenosis eventually develop and are associated primarily with pulmonary venous congestion or low cardiac output, e.g., dyspnea on exertion, orthopnea, or paroxysmal nocturnal dyspnea and fatigue. Dyspnea often is precipitated by events that elevate LA pressure, such as physical or emotional stress or atrial fibrillation. In patients with mild mitral stenosis, symptoms usually occur only with extreme exertion. With progressive stenosis (valve area between 1 and 2 cm^2), patients become symptomatic with less effort. When mitral valve area decreases to about 1 cm^2, symptoms become more pronounced. As pulmonary hypertension and right-sided heart failure subsequently develop, signs of tricuspid regurgitation, hepatomegaly, edema, and ascites can be found.

As a result of high LA pressure and increased pulmonary blood volume, hemoptysis may develop secondary to rupture of dilated bronchial veins (or submucosal varices).[88,110] Over time, pulmonary vascular resistance becomes higher, and the likelihood of hemoptysis decreases. Hemoptysis also may result from pulmonary infarction, which is a late complication of chronic heart failure. Acute pulmonary edema with pink frothy sputum can occur owing to rupture of alveolar capillaries.

Systemic thromboembolism, occurring in approximately 20% of patients, may be the first symptom of mitral stenosis; recurrent embolization occurs in 25% of patients.[88,113,114] The incidence of thromboembolic events is higher in patients with mitral stenosis or mixed mitral stenosis–mitral regurgitation than in those with pure mitral regurgitation. At least 40% of all clinically important embolic events involve the cerebral circulation, approximately 15% involve the visceral vessels, and 15% affect the lower extremities.[88,115] Embolization to coronary arteries may lead to angina, arrhythmias, or myocardial infarction; renal embolization can result in hypertension.[88] Factors that increase the risk of thromboembolic events include low cardiac output, LA dilatation, atrial fibrillation, left atrial thrombus, absence of tricuspid or aortic regurgitation, and the presence of echocardiographic "smoke" in the atrium, an indicator of stagnant flow. Patients with these risk factors should be anticoagulated.[88,113–115] If an episode of systemic embolization occurs in patients in sinus rhythm, infective endocarditis, which is more common in mild than in severe mitral stenosis, should be considered.

Patients with chronic mitral stenosis are often thin and frail (cardiac cachexia), indicative of long-standing low cardiac output, congestive heart failure, and inanition.[88] The peripheral arterial pulse generally is normal, except in patients with a decreased LV stroke volume, in which case the pulse amplitude is diminished. Heart size usually is normal, with a normal apical impulse on chest palpation. An apical diastolic thrill may be present. In patients with pulmonary hypertension, a right ventricular lift can be felt in the left parasternal region. Auscultatory findings include a presystolic murmur, a loud S_1, an opening snap, and an apical diastolic rumble.[88,116–118] The presystolic murmur, which occurs because of closing of the anterior mitral leaflet, is a consistent finding and begins earlier in those in sinus rhythm than in those in atrial fibrillation.[118] S_1 is accentuated in mitral stenosis when the leaflets are pliable but diminished in later phases of the disease when the leaflets are thickened or calcified. As pulmonary artery pressure becomes elevated, S_2 becomes prominent.[119] With progressive pulmonary hypertension, the normal splitting of S_2 narrows because of reduced pulmonary vascular compliance. Other signs of pulmonary hypertension include a murmur of tricuspid and/or pulmonic regurgitation and an S_4 originating from the right ventricle. Best heard at the apex, the early diastolic mitral opening snap is due to sudden tensing of the pliable leaflets during valve opening and is absent when the leaflets are rigid or immobile.[88,116,117] In mild mitral stenosis, the diastolic

rumble is soft and of short duration; a long or holodiastolic murmur indicates severe mitral stenosis. The intensity of the murmur does not necessarily correlate with the severity of the stenosis; indeed, no diastolic murmur may be detectable in patients with severe stenosis, calcified leaflets, or low cardiac output.[118]

On chest radiography, LA enlargement is the earliest change found in patients with mitral stenosis; it is suggested by posterior bulging of the left atrium seen on the lateral view, a double contour of the right heart border seen on the posteroanterior film, and elevation of the left main stem bronchus.[101] The overall cardiac size often is normal. Prominence of the pulmonary arteries coupled with LA enlargement may obliterate the normal concavity between the aorta and left ventricle to produce a straight left heart border. In the lung fields, pulmonary congestion may be recognized as distension of the pulmonary arteries and veins in the upper lung fields and pleural effusions. If mitral stenosis is severe, engorged pulmonary lymphatics are seen as distinct horizontal linear opacities in the lower lung fields (Kerley B lines).

The electrocardiogram is not accurate in assessing the severity of mitral stenosis and in many cases may be completely normal. In patients with severe mitral stenosis and in normal sinus rhythm, LA enlargement is the earliest change (a wide notched P wave in lead II and a biphasic P wave in lead V_1).[101,120] Atrial arrhythmias are more common in patients with advanced degrees of mitral stenosis. In those with pulmonary hypertension, right ventricular hypertrophy may develop and is associated with right-axis deviation, a tall R wave in V_1, and secondary ST-T-wave changes; however, the electrocardiogram is not a sensitive indicator of right ventricular hypertrophy or the degree of pulmonary hypertension.[120] Because multivalvular disease may be present in patients with rheumatic heart disease, signs of left and right ventricular hypertrophy can be identified on the electrocardiogram in cases of combined mitral and aortic stenosis. Right atrial enlargement and right ventricular dilatation and hypertrophy, however, also can mask the changes indicative of LV hypertrophy on the electrocardiographic tracing in patients with multivalvular disease.[120]

Echocardiography has become the primary diagnostic method for assessing mitral valve pathology and pathophysiology.[121–125] Cross-sectional valve area and LA and LV dimensions can be quantified using two-dimensional transthoracic echocardiography (TTE). Best appreciated in the parasternal long-axis view, the features of rheumatic mitral stenosis include reduced diastolic excursion of the leaflets and thickening or calcification of the valvular and subvalvular apparatus (Fig. 41-6). M-mode findings include thickening, reduced motion, and parallel movement of the anterior and posterior leaflets during diastole. The mitral valve area can be planimetered directly in the short-axis view, but this measurement has limited clinical value. Doppler echocardiography accurately determines peak and mean transvalvular mitral pressure gradients that correlate closely with cardiac catheterization measurements.[88,122] To estimate mitral valve area, the pressure half-time (time required for the initial diastolic gradient to decline by 50%) has been employed; the more prolonged the half-time, the more severe is the reduction in orifice area.[122] Using the pressure half-time determination, mitral valve area is equal to 220 (an empirical value) divided by the pressure half-time. Deriving mitral valve area using the pressure half-time method, however, generally has fallen out of favor. In patients with combined aortic regurgitation and mitral stenosis, the pressure half-time method may be unreliable because the regurgitant jet may interfere with the valve-area calculation.[122] The mean mitral gradient at rest and with bicycle or supine exercise measured using Doppler echocardiography is more useful clinically than estimating mitral valve area; the simultaneous increase in right ventricular systolic pressure (estimated from continuous-wave or pulse-wave Doppler envelopes of the tricuspid regurgitation signal) during exercise is also very revealing. Recently, the mitral separation index, which is the average of the maximum separation of the mitral leaflet tips in diastole in parasternal and apical four-chamber views, shows good correlation with mitral valve area measured by planimetry and pressure half-time and may be able to discriminate between hemodynamically significant and insignificant mitral stenosis.[126] TEE can provide even more information in the evaluation of mitral stenosis; it is better than the transthoracic approach for visualizing details of valvular pathology, such as valve mobility and thickness, subvalvular apparatus involvement, and extent of leaflet or commissural calcification.[122,124] TEE also is more reliable in detecting LA thrombi.

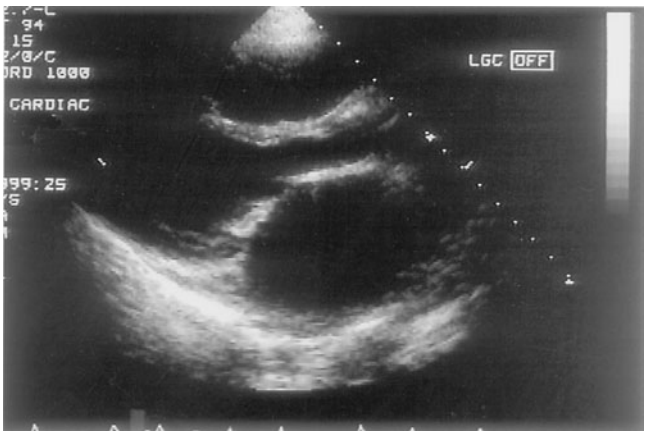

Figure 41-6. Echocardiogram (long axis) of a patient with severe mitral stenosis owing to rheumatic heart disease. A thickened, stenotic valve separates an enlarged left atrium (*right*) and the left ventricle (*left*) and outflow tract (*above*).

Three-dimensional echocardiography may facilitate spatial recognition of intracardiac structures and has been used to evaluate cardiac valvular and congenital heart disease using both real-time three-dimensional TTE as well as offline reconstructed TEE images.[127,128] The addition of color-flow Doppler to this modality has provided better visualization of regurgitant lesions and promises improved quantitative assessment of such lesions. Measurements of LV volume using three-dimensional echocardiography

correlate with those obtained using both contrast ventriculography and magnetic resonance imaging (MRI). Dynamic three-dimensional reconstruction currently is limited by the quality of the original two-dimensional cross-sectional images, which can be adversely affected by minimal patient movements, breathing, and cardiac arrhythmia.[128] Advances in transducers and software components will enhance image acquisition and image quality. Current MRI technology remains inferior for the depiction of valvular morphology and motion. Inherent constraints of MRI, such as pacemakers, morbid obesity, and claustrophobia, hinder the wide use of MRI in cardiac patients. Multidetector computed tomography (CT) may emerge as a technique that can evaluate both cardiac structure and function. Recent experience with gated multidetector CT has yielded good visualization of valve leaflets, commissures, and mitral annulus.[129] Main limitations of this technology include image noise, the time for postprocessing the acquired data, and the radiation dose.

Cardiac catheterization is not necessary to establish the diagnosis of mitral stenosis; however, it can provide information regarding coronary artery status.[130] Historically, left ventriculography permits assessment of the mitral valve and LV contractility and calculation of ejection fraction, but its role has been replaced by echocardiography. Left-sided heart catheterization allows determination of LV end-diastolic pressure; right-sided heart catheterization is performed to measure cardiac index and the degree of pulmonary hypertension. Rarely, cardiac catheterization is used to evaluate the reversibility of severe pulmonary hypertension using pharmacologic interventions, including inhaled nitric oxide when indicated.

Postoperative Outcome

Whereas LV systolic function is used to predict the natural history and postoperative prognosis of patients with other valvular lesions, there are few data linking LV function to outcome in those with mitral stenosis. Not surprisingly, the best indicator is related to the degree of clinical impairment. Surgical intervention (e.g., open mitral commissurotomy or mitral valve replacement) substantially improves the functional capacity and long-term survival of patients with mitral stenosis; 67 to 90% of patients are alive at 10 years.[120,131–133] If there is not excessive scarring of the subvalvular mitral apparatus, mitral valve replacement using chordal-sparing techniques should be performed in patients with rheumatic valve disease, particularly those with mixed stenotic and regurgitant lesions; this results in a reduction in LV end-systolic and end-diastolic volumes and preservation of LV systolic pump performance.[134,135] For those who undergo an open or surgical commissurotomy for advanced rheumatic disease, the rate of reoperation at 10 years is higher than in those who undergo mitral valve replacement (42% versus 4%).[133]

Generally, a valve area of 1 cm^2 is considered critical mitral stenosis and is associated with significant symptoms and morbidity. In physically active or larger patients, somewhat larger valve areas ($\leq$1.2 cm^2) may produce symptoms.[91] Despite a higher operative risk for patients with severe pulmonary hypertension and right-sided heart failure, these individuals usually improve postoperatively with a reduction in pulmonary vascular pressures.[91,136]

Summary

Mitral stenosis generally is due to rheumatic heart disease. In rheumatic valvulitis, the mitral valve is involved most commonly, followed by combined aortic and mitral valve disease. With worsening mitral stenosis, a progressively higher transvalvular pressure gradient occurs. Mitral transvalvular flow depends on cardiac output and heart rate; an increase in heart rate decreases the duration of transvalvular filling during diastole and reduces forward cardiac output, causing symptoms. In mild to moderate mitral stenosis, pulmonary vascular resistance may not be elevated; pulmonary arterial pressure may be normal at rest and rise only with exercise or increased heart rate. In patients with severe mitral stenosis with elevated pulmonary vascular resistance, the pulmonary arterial pressure usually is high at rest. Characteristic symptoms of mitral stenosis are associated with pulmonary venous congestion or low cardiac output. Echocardiography remains the best technique for assessing mitral valve pathology. Surgical intervention can improve the functional capacity and long-term survival of patients with mitral stenosis substantially.

MITRAL REGURGITATION

Etiology

The functional competence of the mitral valve relies on proper, coordinated interaction of the mitral annulus and leaflets, chordae tendineae, papillary muscles, left atrium, and left ventricle, what we refer to as the *valvular-ventricular complex.*[11,73,137–141] Normal LV geometry and alignment of papillary muscles and chordae tendineae permit leaflet coaptation and prevent prolapse during ventricular systole. Dysfunction of any one or more of the components of this valvular-ventricular complex can lead to mitral regurgitation. Regurgitation also can occur in diastole (*presystolic mitral regurgitation*) owing to delayed ventricular contraction or permanent pacing, but this phenomenon appears to have few clinical implications.[142]

Important causes of systolic mitral regurgitation include ischemic heart disease with ischemic mitral regurgitation (IMR), dilated cardiomyopathy [in which the general term *functional mitral regurgitation* (FMR) is used], myomatous degeneration, rheumatic valve disease, mitral annular calcification, infective endocarditis, congenital anomalies, endocardial fibrosis, and collagen-vascular disorders.[90,93,143–145] IMR is considered a specific subset of FMR.

In general, four different types of structural changes of the mitral valve apparatus may produce regurgitation: leaflet

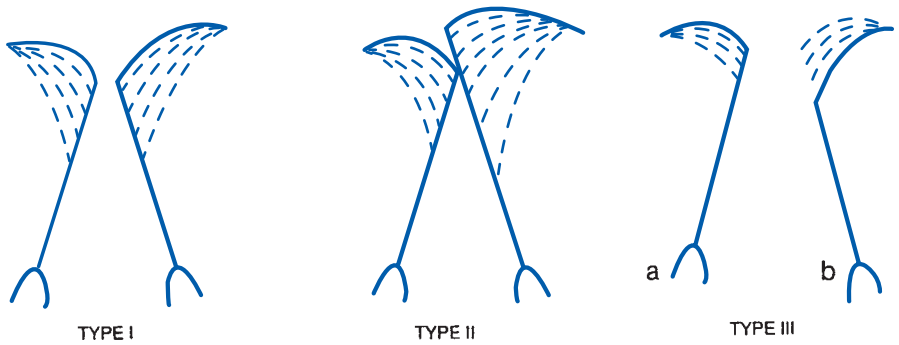

Figure 41-7. Carpentier's functional classification of the types of leaflet and chordal motion associated with mitral regurgitation. In type I, the leaflet motion is normal. Type II mitral regurgitation is due to leaflet prolapse or excessive motion. Type III (restricted leaflet motion) is subdivided into restriction during diastole (a) or systole (b). Type IIIb typically is seen in patients with ischemic mitral regurgitation. The course of the leaflets during the cardiac cycle is represented by the dotted lines. (*Modified with permission from Carpentier A: Cardiac valve surgery: The "French correction." J Thorac Cardiovasc Surg 1983; 86: 323.*)

retraction from fibrosis and calcification, annular dilatation, chordal abnormalities (including rupture, elongation, or shortening), and LV dysfunction with or without papillary muscle involvement.[11,73,146–153] Carpentier classified mitral regurgitation into three main pathoanatomic types based on leaflet and chordal motion: normal leaflet motion (type I), leaflet prolapse or excessive motion (type II), and restricted leaflet motion (type III).[146,147] Type III is further subdivided into types IIIa and IIIb based on leaflet restriction during diastole (type IIIa) in rheumatic disease or during systole (type IIIb) as seen in IMR (Fig. 41-7). Mitral regurgitation with normal leaflet motion can be the result of annular dilatation, which is often secondary to LV dilatation; as a rule, incomplete mitral leaflet coaptation is present at the free edges of the leaflets, e.g., patients with dilated cardiomyopathy or ischemic cardiomyopathy. Normal leaflet motion also includes patients with leaflet perforation secondary to endocarditis. Leaflet prolapse typically results from a floppy mitral valve with chordal elongation and/or rupture but can be seen in patients with coronary artery disease, who rarely have papillary muscle elongation or rupture. Mitral regurgitation owing to restricted leaflet motion is associated with rheumatic valve disease (types IIIa and IIIb), ischemic heart disease (IMR with type IIIb restricted systolic leaflet motion owing to apical tethering or tenting resulting from papillary muscle dislocation, with or without annular dilatation), and dilated cardiomyopathy (type IIIb plus annular dilatation).[147,148]

Functional and ischemic mitral regurgitation

Functional mitral regurgitation (FMR) is the result of incomplete mitral leaflet coaptation in the setting of LV dysfunction and dilatation with or without annular dilatation (e.g., dilated cardiomyopathy or ischemic cardiomyopathy).[149–153] Similar degrees of LV systolic dysfunction and dilatation also may be associated with long-standing mitral regurgitation as a consequence of chronic LV volume overload. Most commonly, the etiology of nonischemic cardiomyopathy is unknown or idiopathic; the second most common etiology is advanced valvular disease. FMR occurs in 40% of patients with heart failure owing to dilated cardiomyopathy.[153] The natural history is progressive valvular insufficiency and more volume overload, LV dilatation, and heart failure. In the past, FMR was thought to be associated with morphologically normal valve leaflets, but recent studies show that the leaflets are biochemically different, with extracellular matrix changes that may be influenced by the altered cardiac dimensions.[154,155] In recipient hearts obtained at the time of transplantation, mitral leaflets have up to 78% more deoxyribonucleic acid, 59% more glycosaminoglycans, 15% more collagen, but 7% less water than autopsy control leaflets.[154] Additionally, radially oriented anterior mitral leaflet strips from failing hearts are 61% stiffer and 23% less viscous.[155] The stiffness of circumferentially oriented anterior leaflet strips is 50% greater than that of control leaflets. Leaflet extensibility is reduced 35%, and the chordae are 16% stiffer. Thus it appears that the mitral valve in heart failure has altered intrinsic structural properties, suggesting that the permanently distended and fibrotic tissue is unable to stretch sufficiently to cover the valve orifice.[155] These findings of secondary leaflet and chordal remodeling argue that mitral regurgitation in these patients may not be purely functional and that these leaflets should not be considered normal morphologically.

IMR, a subset of FMR, is becoming widely appreciated as the population ages and more patients survive acute myocardial infarction. In those with acute myocardial infarction, IMR occurs in approximately 15% of patients with anterior wall involvement and up to 40% of patients with an inferior infarct.[92,93,156] Generally, the severity of mitral regurgitation is related to the size of the area of LV akinesia or dyskinesia. The pathophysiology of IMR is complex but becoming better defined.[146,149,150,156–169] Changes in global and regional LV function or geometry, alterations in mitral annular geometry, abnormal leaflet motion and malcoaptation,

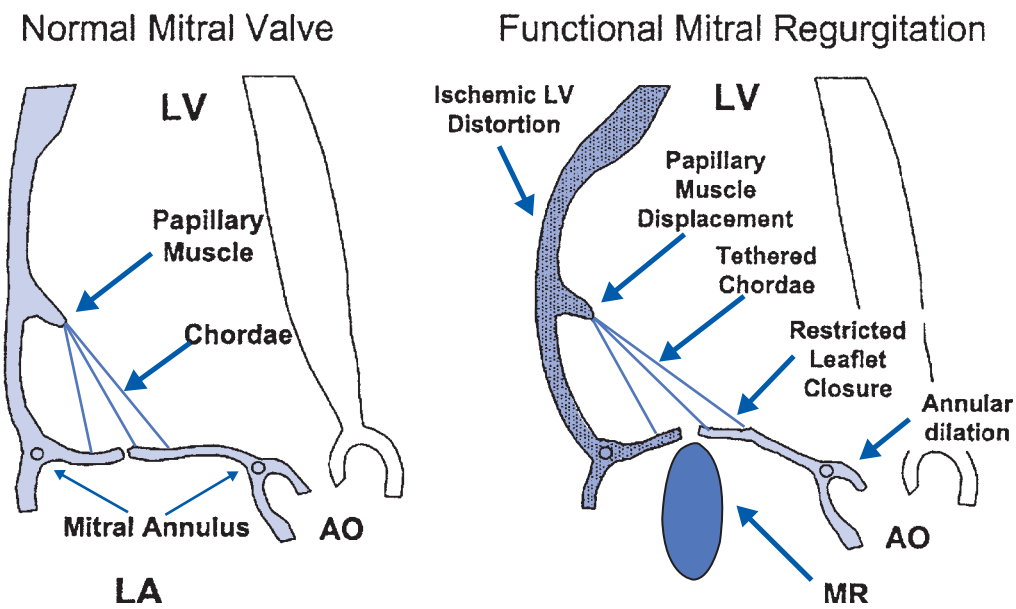

Figure 41-8. Mechanism of functional and ischemic mitral regurgitation. MR = mitral regurgitation; LA = left atrium; LV = left ventricle, AO = aorta. increased interpapillary distance, and papillary muscle malalignment may lead to apical tethering or tenting of the leaflets and mitral incompetence associated with restricted systolic leaflet motion (type IIIb) (Fig. 41-8). Annular dilatation from LV enlargement may further cause incomplete mitral leaflet coaptation. Because of the interdependence of the numerous elements constituting the valvular-ventricular complex in IMR, perturbation of any specific component, such as LV function and geometry, annular geometry, leaflet motion, and papillary and chordal relationship, may result in dysfunction of the valvular-ventricular complex and cause mitral regurgitation.

LEFT VENTRICULAR FUNCTION AND GEOMETRY: Although LV dilatation and dysfunction are less pronounced in the setting of inferior myocardial infarction than in infarcts affecting the anterior wall, the incidence and severity of mitral regurgitation are greater in the former.[92,93,156,158,161] Over time, as the left ventricle dilates and changes shape after the ischemic event (postinfarction remodeling), the degree of IMR progresses.[151,152,161] Infarct size and location contribute to the anatomic manifestation of LV remodeling, with anteroapical infarcts leading to apical thinning and akinesia and inferior infarcts causing inferior akinesia or dyskinesia and progressive IMR. The development of IMR thus may be a manifestation of rather than a stimulus for progressive LV remodeling.[161] Mechanistically, the valve and subvalvular apparatus work in a tightly coupled and coordinated fashion. Geometric changes associated with ventricular remodeling, such as posteromedial papillary muscle dislocation in the lateral axis, may lead to leaflet tenting or tethering, as reflected by a larger distance from the middle of the anterior annulus (saddle horn or fibrosa, an echocardiographic landmark) to the posteromedial papillary muscle tip and increased annular diameter.[151,152,162,163] As a result of inferior myocardial infarction, the posteromedial papillary muscle tethering distance contributes to the mitral regurgitant jet area.[156] At the ventricular level, myocardial infarction associated with chronic IMR leads to greater perturbations in LV systolic torsion and diastolic recoil than myocardial infarction without chronic IMR.[170] These abnormalities may be linked to more LV dilatation, which possibly reduces the effectiveness of fiber shortening on torsion generation. Altered LV torsion and recoil thus are likely to contribute to the "ventricular disease" component of chronic IMR, with increased gradients of myocardial oxygen consumption adversely affecting cardiac efficiency and impaired early diastolic filling. Investigation of patients with ischemic heart disease using MRI has demonstrated mitral regurgitation, diminished LV systolic function, annular stretching (involving both the anterior and posterior annuli around the entire valve circumference), valvular dilatation in the septolateral axis (also known as the *anteroposterior axis,* which is perpendicular to the line of leaflet coaptation), flattening of the height of the annulus near the midanterior annular saddle horn, abnormal LV geometry and shape, and papillary muscle displacement responsible for leaflet tenting and IMR.[158]

ANNULAR GEOMETRY: In individuals with IMR, mitral annular area increases, septolateral annular dimension increases, the posteromedial papillary muscle is displaced in the lateral direction, and the posterior leaflet becomes apically tethered with restricted closing motion, all of which contribute to leaflet malcoaptation and IMR[159,162,163,168] (Fig. 41-9). LV dilatation and larger annular dimensions after inferior myocardial infarction require the mitral leaflets to cover

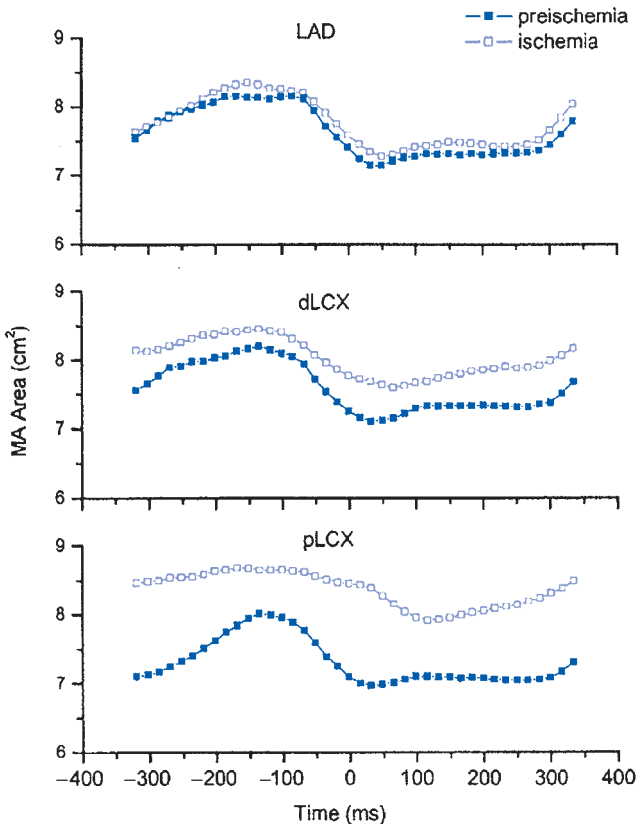

Figure 41-9. Average mitral annular area (in cm^2) before (*solid squares*) and during (*open circles*) acute LV ischemia induced by balloon occlusion of either the LAD artery (*top*), the dLCx coronary artery (*middle*), or the pLCx coronary artery (*bottom*). A 650-ms time interval centered at end-diastole ($t = 0$) is shown. MA = mitral annular; LAD = proximal left anterior descending artery; dLCx = distal to second obtuse marginal artery; pLCx = proximal to second obtuse marginal artery. (*Reproduced with permission from Timek TA et al: Ischemia in three left ventricular regions: Insights into the pathogenesis of acute ischemic mitral regurgitation. J Thorac Cardiovasc Surg 2003; 125:559.*)

more area during closing, exceeding their normal redundancy or "reserve," which is exacerbated by restricted leaflet closure owing to apical tenting (type IIIb). Based on MRI, septolateral annular dilatation and diminished LV systolic function determine mitral systolic tenting area, which, in turn, is predictive of the severity of the IMR.[158] Additionally, the normal annulus has a distinctive saddle shape, which becomes accentuated during systole.[171–173] In IMR, this accentuation of the saddle shape, as measured by the annular height to commissural width ratio, is eliminated, suggesting an association between maintaining the saddle shape and valvular competence.[171] Thus deformation of the saddle shape of the annulus in conjunction with valve tenting contributes to the development of IMR.[172,173]

In patients with IMR, three-dimensional echocardiographic investigations show an increase in anterior and posterior annular perimeters and annular orifice area (9.1 cm^2 compared to 5.7 cm^2 normally) accompanied by an increase in the intertrigonal (anterior) annular distance and restriction of annular motion.[163] Furthermore, annular flattening with tenting of the leaflets, along with greater tenting lengths and volume, is appreciated.[172–174] The strongest echocardiographic determinant of leaflet tenting height is the distance from the tips of the papillary muscles to the saddle horn of the anterior mitral annulus; LV end-diastolic volume is only weakly correlated with tenting height.[175] The importance of annular size is pronounced in patients with dilated cardiomyopathy, in whom three-dimensional echocardiography showed that annular dilatation is the best predictor of FMR.[164] Additionally, mitral valve regurgitant volume correlates with annular area, LA volume, and LV end-diastolic volume.

LEAFLET MOTION: Acute IMR owing to proximal left circumflex artery occlusion in an animal model results in delayed valve closure in early systole (termed leaflet *loitering*) and increased leaflet edge separation throughout ejection in three leaflet coaptation sites across the valve, specifically near the anterior commissure, the valve center, and near the posterior commissure).[157,159] In addition, there is lateral displacement of the central scallop of the posterior leaflet, suggesting that interscallop malcoaptation can contribute to IMR in certain circumstances.[169] The primary geometric mechanism underlying scallop malcoaptation in acute IMR appears to be annular dilatation in the septolateral axis, which hinders leaflet coaptation by drawing the individual scallops apart.[169] Clinically, chronic IMR is associated with apical systolic restriction of the posterior leaflet, thereby effectively preventing competent valve closure. Chronic IMR is also associated with posterior leaflet displacement in the posterior direction and lateral displacement of both leaflets. When the position of each leaflet edge is assessed independently, the anterior leaflet is not displaced apically after inferior infarction, although with more time and further remodeling, apical restriction of this leaflet may occur.[162]

PAPILLARY MUSCLE AND CHORDAL RELATIONSHIPS: The papillary-annular distances in the LV long axis remain relatively constant in normal hearts throughout the cardiac cycle.[150] During acute ischemia, however, these distances change, which reflects repositioning or dislocation of the papillary muscle tips with respect to the mitral annulus; this can also contribute to apical tenting of the leaflets during systole.[146,150,162,165] With proximal circumflex artery occlusion and resulting IMR in an ovine model, the interpapillary distance and LV end-diastolic volume both increase. There is also increased mitral annular area and displacement of both (but predominantly the posterior) papillary muscle tips away from the septal annulus throughout ejection and at end-systole.[162,165] Posteromedial papillary muscle tip displacement probably results from failure of the ischemic posterior papillary muscle to shorten during systole, lengthening of the ischemic papillary muscle over time, and also dyskinesia of the ischemic LV wall subtending the papillary muscle. Since posterior papillary muscle displacement in the apical and posterior directions also occurs in sheep that did not develop substantial degrees of IMR, the additional posterior

papillary muscle displacement in the lateral direction is a dominant factor in the development of IMR.[162] In the setting of posterolateral ischemia, a larger distance from the papillary muscle tips to the midseptal annulus is an important determinant of mitral regurgitant volume. The nonischemic anterior papillary muscle also may play a role in apical leaflet restriction because this normally shortening anterior papillary muscle is displaced apically at end-systole relative to baseline. In sheep with mitral regurgitation, posterior papillary muscle tethering distance, papillary muscle depth, and papillary muscle angle are unchanged, and the anterior papillary muscle depth and papillary muscle angle decrease with decreasing ejection fraction.[165] Reduced systolic shortening of either papillary muscle in isolation, on the other hand, does not result in mitral regurgitation; thus the previous notion that papillary muscle dysfunction by itself is responsible for IMR is not correct. In fact, papillary muscle dysfunction paradoxically can decrease mitral regurgitation owing to inferobasal ischemia by reducing leaflet tethering to improve leaflet coaptation.[176] It is likely that a further insult to the LV wall underlying the papillary muscles is needed before valvular incompetence occurs. Finally, acute IMR owing to posterior LV ischemia is associated with focal chordal and leaflet tethering at the nonischemic commissural portion of the mitral valve and a paradoxical decrease of the chordal forces and relative prolapse at the ischemic site of the anterior leaflet.[166] Thus a combination of systolic annular dilatation and shape change and altered posteromedial (and possibly anterolateral) papillary muscle position and motion contributes to incomplete leaflet coaptation and IMR during acute inferior or posterolateral ischemia.

PAPILLARY MUSCLE ISCHEMIA: Papillary muscle dysfunction in patients with coronary artery disease has been thought to contribute to mitral regurgitation, although the significance of its role in IMR has been challenged.[11,73,74,92,93,150,162,165,176] The papillary muscles are particularly susceptible to ischemia, more so the posteromedial papillary muscle (generally supplied by the posterior descending artery) than the anterolateral papillary muscle (customarily supplied by branches of the left anterior descending and the circumflex arteries).[11,73,74,177] The posteromedial papillary muscle is perfused by one major coronary artery in 63% of cases and by two vessels in the remainder; on the other hand, the anterior papillary muscle has two-vessel perfusion in 71% of normal individuals.[74]

Myocardial infarction leading to papillary muscle dysfunction occurs more frequently when the blood supply to the papillary muscle is provided by one vessel, as is more often the case with the posteromedial papillary muscle after an inferior myocardial infarction. Also, coronary artery disease involving both the right and circumflex coronary arteries (as opposed to single-vessel disease) can cause posteromedial papillary muscle dysfunction.[177] Although papillary muscle necrosis can complicate myocardial infarction, frank rupture of a papillary muscle is rare. Total papillary muscle rupture usually is fatal owing to the resulting severe mitral regurgitation and LV pump failure; survival long enough to reach the operating room in reasonable condition is possible with rupture of one or two of the subheads of a papillary muscle, which is associated with a lesser degree of mitral regurgitation. Papillary muscle rupture usually occurs 2 to 7 days after myocardial infarction; without urgent surgery, approximately 50 to 75% of such patients may die within 24 hours.[178,179]

Myxomatous degeneration

Myxomatous degeneration of the mitral valve, also known as *floppy mitral valve* or *mitral valve prolapse,* is the most common cause of mitral regurgitation in patients undergoing surgical evaluation in the United States.[11,180–183] The etiology of mitral valve prolapse is both acquired (*fibroelastic deficiency* in older patients) and congenital or heritable, with excess spongy, weak fibroelastic connective tissue constituting the leaflets and chordae tendineae[90,184–187] (Fig. 41-10). Recent genotypic analyses show an autosomal dominant mitral valve prolapse locus mapped to chromosome 13.[187] Some degree of mitral valve prolapse is seen echocardiographically in 5 to 6% of the normal female population[184,185,188]; it can be familial or associated with hypertension. The risk of endocarditis is increased only if valvular regurgitation is present and accompanied by a murmur. Although mitral valve prolapse appears to be more widespread in women, severe mitral regurgitation owing to mitral valve prolapse is more common in men. Subtle signs of heart failure, usually manifest as declining stamina and fatigue, may be the presenting complaint in 25 to 40% of symptomatic patients with mitral valve prolapse. The syndrome of mitral valve prolapse includes palpitations, chest pain, syncope, and dyspnea; in younger patients, the initial clinical sign is a midsystolic click, which later evolves into a click followed by a late systolic murmur.[184,185] This latter scenario is seen typically in patients with Barlow syndrome, in which large amounts of excessive leaflet tissue and marked annular dilatation are coupled with extensive hooding and billowing of both leaflets.

Figure 41-10. Intraoperative photograph of mitral regurgitation owing to floppy mitral valve.

Pathologically, the atrial aspect of the prolapsing mitral leaflet often is thickened focally, whereas the changes on the ventricular surface of the leaflet consist of connective tissue thickening primarily on the interchordal segments with proliferation of fibrous tissue into adjacent chordae and onto the ventricular endocardium.[90,184,186] Myxomatous degeneration commonly involves the annulus, resulting in annular thickening and dilatation. The leaflets become thickened, spongy in texture, and opaque, occasionally with yellow plaque formation. Histologically, elastic fiber and collagen fragmentation and disorganization are present, and acid mucopolysaccharide material accumulates in the leaflets. All these changes are very pronounced in young patients with the Barlow syndrome but can be minimal in older subjects with fibroelastic deficiency, in whom the leaflets are normal and thin (termed *pellucid* by Carpentier), with only minimal thickening of the chordae. It is important to recognize that these two distinct varieties of mitral valve prolapse exist and can be segregated on clinical grounds, even if pathologists have difficulty discriminating between the two. The main visual and pathologic difference is the extent and degree of degenerative changes. The surgical implications of these two distinct subtypes of mitral valve prolapse are noteworthy. Certain centers, such as the Mayo Clinic, encounter mainly elderly patients with coronary artery disease and fibroelastic deficiency (78% of their surgical "flail" leaflet population are over 60 years old and/or require concomitant coronary artery bypass grafting), in whom the valvular pathology is limited, and repair techniques, such as the small McGoon triangular excision of the middle scallop of the posterior leaflet, are applicable.[189] This is in contrast to other referral centers, where the majority of mitral valve prolapse patients are much younger and have the Barlow syndrome or severely myxomatous mitral valves, circumstances that demand much more extensive repair techniques. As a corollary, the long-term results after mitral repair also will differ substantially between these two cohorts owing to the adverse effects of advanced age and ischemic heart disease.

Only 5 to 10% of patients with mitral valve prolapse progress to severe mitral regurgitation, and the majority remain relatively asymptomatic.[184,185] Mechanisms accounting for severe mitral regurgitation in those with mitral valve prolapse include annular dilatation and rupture or elongation of the first-order chordae (58%), annular dilatation without chordal rupture (19%), and chordal rupture without annular dilatation (19%).[186] Chordal rupture probably is related to defective collagen, underlying papillary muscle fibrosis or dysfunction, or bacterial endocarditis.[11,73,90,92,93,144,190,191] Elongation without rupture of other first-order as well as many second-order chordae frequently accompanies chordal rupture. Chordal rupture typically is the culprit when mitral regurgitation develops acutely in patients without any previous symptoms of heart disease or suddenly becomes worse in those with known mitral valve prolapse.[92,144] Chordal rupture is evident in 14 to 23% of surgically excised purely regurgitant valve specimens; in 73 to 93% of these patients, the underlying pathology is degenerative or floppy mitral valve syndrome.[92,93,144] Posterior chordal rupture was the most frequent finding, followed by anterior chordal rupture and then combined anterior and posterior chordal rupture.[92,93,144]

Rheumatic disease

Although its incidence is decreasing in the United States, rheumatic fever remains a common cause of mitral regurgitation around the world.[11,92–94,143–145,192] It is unknown why rheumatic fever leads to valvular stenosis in some patients and pure regurgitation in others. The pathoanatomic changes of the purely regurgitant rheumatic valve differ from those in a stenotic valve. In chronic rheumatic mitral regurgitation, the valves have diffuse fibrous thickening of leaflets with minimal calcific deposits and relatively nonfused commissures; chordae tendineae usually are not extremely thickened or fused.[92,93] There also may be shortening of the chordae tendineae, fibrous infiltration of the papillary muscle, and asymmetric annular dilatation that develops primarily in the posteromedial portion. During the first episodes of rheumatic fever (average age is 9 years), patients may develop acute mitral regurgitation, which is related more frequently to prolapse of the anterior or posterior mitral valve leaflet.[192] Those with anterior leaflet prolapse tend to improve with medical management; however, those with prolapse of the posterior leaflet have a less favorable outcome and often require early surgical repair.[192]

Mitral annular calcification

Mitral annular calcification is a degenerative disorder that usually is confined to elderly individuals; most patients are older than 60 years of age, and women are affected more often than men.[11,96] The pathogenesis of mitral annular calcification is not known, but it appears to be a stress-induced phenomenon; annular calcification also can be associated with systemic hypertension, hypertrophic cardiomyopathy, aortic stenosis, and occasionally, advanced Barlow disease. Other predisposing conditions include chronic renal failure and diabetes mellitus. Aortic valve calcification is an associated finding in 50% of patients with severe mitral annular calcification.

The gross appearance of mitral annular calcification may vary from small, localized calcified spicules to massive, rigid bars up to 2 cm in thickness.[96] Initially, calcification begins at the midportion of the posterior annulus; as the process progresses, the leaflets become upwardly deformed, stretching the chordae tendineae, and a rigid curved bar of calcium surrounding the entire posterior annulus or even a complete ring of calcium may encircle the entire mitral orifice. Invasion of the calcific spurs into the LV myocardium and the conduction system can result in atrioventricular and/or intraventricular conduction defects. Annular calcification causes mitral regurgitation by displacing and immobilizing the mitral leaflets (thereby preventing their normal systolic coaptation) or impairing the presystolic sphincteric action of the annulus.[96] As the degree of mitral regurgitation

worsens over time, LV volume overload can lead to heart failure. Systemic embolization can occur if the annular calcific debris is extensive and friable.

Hemodynamics

The pathophysiology of acute mitral regurgitation differs from that of chronic mitral regurgitation. Acute regurgitation may result from spontaneous chordal rupture, myocardial ischemia or infarction, infective endocarditis, or chest trauma.[11,73,178,179,190] The clinical impact of acute mitral incompetence is modulated largely by the compliance of the left atrium and the pulmonary vasculature. In a normal left atrium with a relatively low compliance, acute mitral regurgitation results in high LA pressure, which can lead rapidly to pulmonary edema. Such is not the situation in patients with chronic mitral regurgitation, in whom compensatory changes over time increase LA and pulmonary venous compliance so that symptoms of pulmonary congestion may not occur for many years.

With mitral regurgitation, the impedance to LV emptying is lowered because the mitral orifice is in parallel with the LV outflow tract.[11,103,193] The volume of mitral regurgitation depends on the square root of the systolic pressure gradient between the left ventricle and the atrium, the time duration of regurgitation, and the effective regurgitant orifice (ERO).[11,175,194,195] The ERO is determined echocardiographically using two-dimensional color Doppler imaging to measure the cross-sectional area of the vena contracta, the proximal isovelocity surface area (PISA) method, or continuous-wave Doppler measuring the ratio of regurgitant volume to regurgitant time-velocity integral.[175,196] Regurgitation into the left atrium increases LA pressure and reduces forward cardiac output. LA pressure rises significantly during ventricular systole, followed by an abrupt decline in early diastole. LA pressure even may remain elevated at end-diastole (transient 5- to 10-mm Hg transvalvular gradient), representing a functional gradient associated with the increased diastolic flow rate.

If the mitral annulus is not rigid, various diagnostic and therapeutic interventions can alter ERO. Altered loading conditions (elevated preload and afterload) and decreased contractility result in progressive LV dilatation and a larger ERO.[197] When LV size is reduced by medical management (e.g., digoxin, diuretics, and most important, arteriolar vasodilators), ERO and regurgitant volume fall.[198,199] Stress echocardiography using an inotropic drug such as dobutamine usually decreases ERO and the degree of mitral regurgitation in patients with FMR and IMR because the LV chamber is smaller at beginning systole (or end diastole) and throughout systole secondary to enhanced LV contractility.[200]

Ventricular Adaptation

The loading conditions induced by mitral regurgitation promote more LV ejection because ventricular preload is increased, whereas afterload is normal or decreased owing to backward flow across the mitral valve. In terms of cardiac energetics, reduced LV impedance in patients with mitral regurgitation allows a greater proportion of contractile energy to be expended in myocardial fiber shortening than in tension development.[11,193] Because increased fiber shortening is less of a determinant of myocardial oxygen consumption than other components, such as tension (or pressure) development and heart rate, mitral regurgitation causes only small increases in myocardial oxygen consumption.[193] Simultaneous reductions in developed tension owing to lower LV systolic wall stress (or afterload) associated with mitral regurgitation allow the ventricle to adapt to the substantial regurgitant volume by increasing LV end-diastolic volume to maintain adequate forward output. Along with lower afterload, this substantial increase in preload (LV end-diastolic volume or, more precisely, LV end-diastolic wall stress) allows the heart to compensate for chronic mitral regurgitation for long periods of time before symptoms occur.[11,201,202] A fundamental response of the ventricle to increased preload is augmented stroke volume and stroke work, although effective forward stroke volume may be normal or even subnormal. High LV preload eventually leads to LV dilatation and shape changes of the ventricle, i.e., more spherical LV remodeling, owing to replication of sarcomeres in series as a consequence of chronic elevation of LV end-diastolic wall stress.[201,202] This is in contrast to LV hypertrophy secondary to chronic pressure overload (elevated systolic wall stress), which leads to sarcomere replication in parallel. In chronic mitral regurgitation, LV mass also increases; however, the degree of hypertrophy correlates with the amount of chamber dilatation so that the ratio of LV mass to end-diastolic volume remains in the normal range (unlike the situation in patients with LV pressure overload).[203–205] The contractile dysfunction that ultimately evolves owing to chronic LV volume overload is accompanied by increased myocyte length as well as reduced myofibril content.[202,203] The basic changes thus are a combination of myofibrillar loss and the absence of significant hypertrophy in response to the progressive decrease in ventricular pump function. Experimental work indicates that the defect is intrinsic to the myocyte per se, but changes in the extracellular matrix undoubtedly also play a role.[206] Conversely, in acute mitral regurgitation, the ratio of LV mass to end-diastolic volume is reduced because chamber dilatation occurs suddenly, and the LV wall becomes acutely thinned; this increase in LV end-diastolic volume is associated with sarcomere lengthening along the length-tension curve.[202]

After the initial compensatory phase, LV systolic contractility becomes progressively impaired with chronic mitral regurgitation.[204–207] Because of the low impedance during systole, however, ejection-phase indexes of LV systolic function, such as ejection fraction and fractional circumferential fiber shortening (%FSc), still can be normal even if severely depressed contractility is present.[206,208,209] An ejection fraction of less than 55 to 60% or %FSc less than 28% in the presence of severe mitral regurgitation indicates an advanced degree of myocardial dysfunction. The ejection-phase indexes commonly

used clinically to estimate LV pump performance, e.g., ejection fraction, %FSc, cardiac output, stroke volume, stroke work, etc. are all affected by changes in LV preload and afterload. It should be remembered that changes in LV loading conditions accompany all forms of valvular heart disease.

To avoid the pitfalls imposed by abnormal LV loading conditions, load-independent indexes of LV contractility [e.g., end-systolic elastance derived from the end-systolic pressure-volume relationship (ESPVR)] or preload-recruitable stroke work (PRSW, also termed *linearized Frank-Starling relationship*) are preferred to measure LV systolic function and mechanics in the setting of mitral regurgitation.[204,205,210–213] In hypertrophied and dilated hearts, as seen in chronic mitral regurgitation, however, the utility of end-systolic elastance may be limited owing to the geometric LV chamber shape and size changes and hypertrophy that occur; using the end-systolic stress-volume relationship in these circumstances is necessary. One other problem inherent in the use of end-systolic elastance or stress-volume data is that end-systole and end-ejection are dissociated in patients with mitral regurgitation. End-ejection is defined as minimum LV volume and end-systole as the instant when LV elastance reaches its maximal value. Because of this temporal dissociation of end-systole from minimal ventricular volume, end-ejection pressure-volume relations do not correlate with maximal elastance values derived using isochronal methods.[211] End-systolic dimension or LV end-systolic volume (LVESV) is less dependent on LV loading conditions than is ejection fraction, is a better measure of LV systolic contractile function, and varies directly and linearly with afterload.[210,214–217] The larger the LVESV becomes, the worse is the LV contractility. Correcting LVESV for chamber geometry, wall thickness and afterload [i.e., end-systolic wall stress (ESS)], and body size [LV end-systolic volume index (LVESVI)] provides good indexes of LV systolic function that are less influenced by loading conditions and variation in patient size.[214,215] Preoperative LVESV or LVESVI is a better predictor of postoperative outcome in terms of postoperative LV systolic performance and cardiac death than is ejection fraction, end-diastolic volume, or end-diastolic pressure.[217]

Based on load-independent indexes of LV contractility in experimental preparations of mitral regurgitation, the normalized end-systolic pressure-volume and end-systolic stress-volume relationships decline after 3 months of mitral regurgitation.[204] The LV preload-recruitable stroke work (the relation of stroke work to LV end-diastolic volume) and preload-recruitable pressure-volume area (the relation of stroke work to LV pressure-volume area) also decrease. The efficiency of energy transfer from pressure-volume area to external pressure-volume work at matched LV end-diastolic volume also falls. Furthermore, there is deterioration in ventriculoarterial coupling over time; i.e., a mismatch develops between the ventricle and the total (forward and regurgitant) vascular load. Although the overall (systemic plus LA) effective arterial elastance is decreased, there is a proportionally greater reduction in LV end-systolic elastance. Thus LV systolic mechanics become impaired along with deterioration in global LV energetics and efficiency, and a mismatch develops in coupling between the left ventricle and the arterial bed.[204] Further analysis shows that progression from acute to chronic mitral regurgitation (3 months) is associated with a decrease in maximum LV systolic torsional deformation from 6.3 to 4.7 degrees and a decrease in early diastolic LV recoil from +3.8 to –1.5 degrees[218] (Fig. 41-11). Because torsion is a mechanism by which the left ventricle equalizes transmural gradients of fiber strain and oxygen demand, a decrease in torsion in chronic mitral regurgitation may play a role in the inexorable and progressive decline of LV performance over time. Less systolic LV torsion would be associated with a larger transmural gradient of fiber strain and an imbalance of oxygen supply and demand such that decreased torsion may contribute to a deleterious feedback loop of ventricular mechanics.[218] The left ventricle responds to decreased forward cardiac output owing to mitral regurgitation by dilating. Ventricular dilatation tends to equalize the lengths of the endocardial and epicardial radii and thereby decreases systolic LV torsion. The associated increase in transmural gradient of fiber strain and oxygen supply-demand imbalance results in a further decrease in forward cardiac output, leading to more LV dilatation, thus continuing the vicious cycle.

LV diastolic function also is affected by chronic mitral regurgitation.[219–223] Diastolic inflow into the ventricle must increase as total stroke volume increases during evolution of mitral regurgitation during which the left ventricle dilates. With acute mitral regurgitation, mitral regurgitation enhances LV diastolic function by increasing the early diastolic filling rate and decreasing chamber stiffness. Flow across the mitral valve during early diastole is determined by the LA-LV pressure gradient, even though other factors, such as diastolic restoring forces and LV diastolic recoil (creating LV suction) during isovolumic relaxation also influence early LV filling.[219] In middle and late diastole, the lower LV chamber stiffness in patients with acute mitral regurgitation (evidenced by a shift of the LV diastolic pressure dimension or pressure-volume relationship to the right) allows the LV mean and end-diastolic pressures (and stresses) to remain in the normal range.

In patients with chronic mitral regurgitation and preserved ejection fraction, LV chamber stiffness is also lower, similar to that during acute mitral regurgitation; conversely, in those with impaired LV systolic function, chamber stiffness usually is normal.[221] During the period of passive filling, maximal rates of LV circumferential fiber lengthening and strain are increased only in those with a normal ejection fraction. The absence of augmented filling rate in patients with depressed LV systolic function probably reflects underlying myocyte abnormalities. In general, chronic mitral regurgitation causes a decrease in LV systolic contractile function but an increase in early diastolic function (as evidenced by an increase in early diastolic filling rate and a decrease in chamber stiffness).[222,224] The reduced chamber stiffness may be the result of altered ventricular geometry (more spherical or less eccentric shape); this shape change

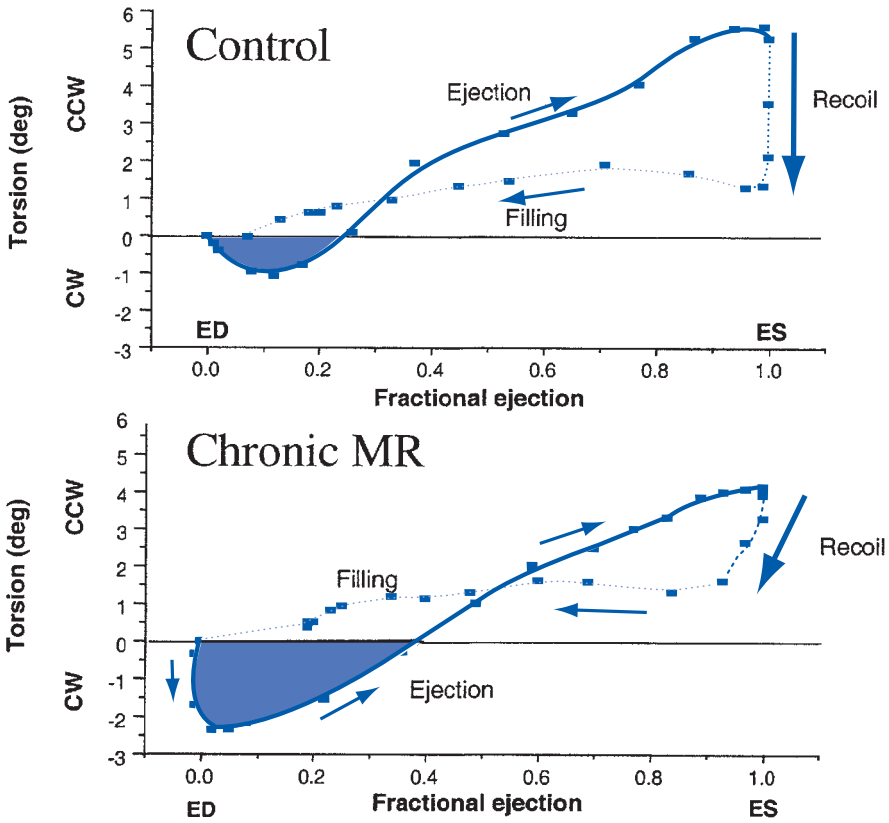

Figure 41-11. Torsional deformation versus fractional ejection with acute (*top*) and chronic (*bottom*) mitral regurgitation in a representative animal. With acute mitral regurgitation, systole (*solid line*) is characterized by a slight clockwise rotation followed be counterclockwise torsion that peaks at end-ejection. Early diastole (*dashed line*) shows steeper torsional recoil than middle to late diastole (*dotted line*). With chronic mitral regurgitation, the initial clockwise torsion is larger, the maximum positive torsion is decreased, and less recoil occurs during early diastole. (*Reproduced with permission from Tibayan FA, Yun KL, Lai DTM, et al: Torsional dynamics in the evolution from acute to chronic mitral regurgitation. J Heart Valve Dis 2002; 11:39.*)

can exacerbate the degree of mitral regurgitation by distorting annular dimensions and dislocating the papillary muscles.[221,225] Although the LV chamber stiffness is less owing to the change in geometry, the LV myocardium may be stiffer owing to myocyte hypertrophy and interstitial fibrosis.[221,222]

Regarding the impact of mitral regurgitation on right ventricular contractility, reduction in right ventricular systolic function is associated with a worse prognosis, emphasizing the adverse impact of pulmonary hypertension in this disease.[226] Patients with a right ventricular ejection fraction of less than 30% are at risk for a suboptimal outcome.

Atrial Adaptation

Regurgitant flow into the left atrium leads to progressive atrial enlargement, the degree of which does not correspond directly with the severity of mitral regurgitation.[107,193] Also, the LA *v* wave in mitral regurgitation does not correlate with LA volume. Compared with patients with mitral stenosis, LA size can be larger in patients with long-standing mitral regurgitation, but thrombus formation and systemic thromboembolization occur less frequently because of the absence of atrial stasis.[107,110] Atrial fibrillation occurs less often in those with mitral regurgitation than in individuals with mitral stenosis.[110]

LA compliance is an important component of the patient's overall hemodynamic status if mitral regurgitation is present.[11,190,193,227,228] With sudden development of mitral regurgitation owing to chordal rupture, papillary muscle infarction, or leaflet perforation, LA compliance is normal or reduced. The left atrium is not enlarged, but the mean LA pressure and *v* wave are high. Gradually, the LA myocardium becomes hypertrophied, proliferative changes develop in the pulmonary vasculature, and pulmonary vascular resistance rises. As the mitral regurgitation becomes chronic and more severe, LA compliance increases, and LA enlargement occurs. In patients with severe, long-standing mitral regurgitation, the left atrium is markedly enlarged, atrial compliance is increased, the atrial wall is fibrotic, but LA pressure remains normal or only slightly elevated.[227] In this situation, pulmonary artery pressure and pulmonary vascular resistance usually are still in the normal range or are elevated only modestly. Atrial fibrillation and a low cardiac output, however, can occur.

Pulmonary Changes

Because chronic mitral regurgitation is associated with LA enlargement and only mild elevations in LA pressure, pronounced increases in pulmonary vascular resistance usually do not develop. In patients with acute mitral regurgitation with normal or reduced LA compliance, a sudden increase in LA pressure initially elevates pulmonary vascular resistance, and occasionally, acute right-sided heart failure occurs.[11,190]

Pulmonary edema is seen less frequently in patients with chronic mitral regurgitation than in those with mitral stenosis because elevated LA pressure is uncommon. Pulmonary vascular resistance is higher more often in patients with mitral stenosis than in those with mitral regurgitation owing to the chronically elevated LA pressure in the former. In patients with IMR and heart failure, however, acute pulmonary edema is associated with the dynamic changes in IMR and the resulting increase in pulmonary vascular pressure.[229] Exercise-induced changes in ERO, transtricuspid pressure gradient, and LV ejection fraction are independently associated with the development of pulmonary edema.[229] From the standpoint of pulmonary parenchymal function and respiratory mechanics in patients with chronic mitral regurgitation, there is a decline in vital capacity, total lung capacity, forced expiratory volume, and maximal expiratory flow at 50% vital capacity.[230] These patients also may have a positive response to methacholine challenge; this bronchial hyperresponsiveness may result from increased vagal tone owing to long-standing pulmonary congestion.

Clinical Evaluation

Patients with mild to moderate mitral regurgitation may remain asymptomatic for many years as the left ventricle adapts to the increased workload and maintains normal forward cardiac output. Gradually, symptoms reflecting decreased cardiac output with physical activity and/or pulmonary congestion develop insidiously, such as weakness, fatigue, palpitations, and dyspnea on exertion. If right-sided heart failure appears late in the course of the disease, hepatomegaly, peripheral edema, and ascites occur and can be associated with rapid clinical deterioration.[112,114] Conversely, acute mitral regurgitation usually is associated with marked sudden pulmonary congestion and pulmonary edema. Patients with coronary artery disease can present with myocardial ischemia or infarction and associated mitral regurgitation. Acute papillary muscle rupture may mimic the presentation of a patient with a postinfarction ventricular septal defect.[231]

On physical examination, the cardiac impulse in patients with mitral regurgitation is hyperdynamic and displaced laterally; the forcefulness of the apical impulse is indicative of the degree of LV enlargement. In patients with chronic mitral regurgitation, S_1 usually is diminished. S_2 may be single, closely split, normally split, or even widely split as a consequence of the reduced resistance to LV ejection; a common finding is a widely split S_2 that results from shortening of LV systole and early closure of the aortic valve.[232] An S_3 gallop may be appreciated owing to the increased transmitral diastolic flow rate during the rapid filling phase. The apical systolic murmur of mitral regurgitation can be blowing, moderately harsh, or even soft and usually radiates to the axilla and left sternal border and occasionally to the neck or to the vertebral column.[232] The murmur is best appreciated in early systole in patients with FMR or IMR and can be difficult to discern even if a large degree of mitral regurgitation exists. With rupture of the posterior leaflet first-order chordae, the mitral regurgitation jet is directed superiorly and impinges on the atrial septum near the base of the aorta, which can produce a murmur heard best along the right sternal border and radiating to the neck.[232,233] In cases of ruptured anterior leaflet first-order chordae, the leakage is aimed laterally and toward the posterior LA wall; the murmur may be transmitted posteriorly. Although there is no correlation between the intensity of the systolic murmur and the hemodynamic severity of the mitral regurgitation, a holosystolic murmur is characteristic of more regurgitant flow.[232] Because of the relatively noncompliant left atrium in acute mitral regurgitation, the murmur is often early and midsystolic.[11] In patients with Barlow syndrome (severe bileaflet mitral billowing and prolapse), early in the disease process, a characteristic midsystolic click is heard, followed by a late systolic murmur; as the annulus and left ventricle dilate, the murmur over time becomes holosystolic, and the midsystolic click may become inaudible.

On chest radiography, cardiomegaly indicative of LV and LA enlargement is found commonly in patients with long-standing moderate to severe mitral regurgitation.[130] Acute mitral regurgitation often is not associated with an enlarged heart shadow and may produce only mild LA enlargement despite an elevated LA pressure. Chest x-ray findings of congested lung fields are less prominent in patients with mitral regurgitation than in those with mitral stenosis, but interstitial edema is seen frequently in individuals with acute mitral regurgitation and those with progressive LV failure secondary to chronic mitral regurgitation.

Changes on the electrocardiogram are not particularly useful and depend on the etiology, severity, and duration of the mitral regurgitation.[120,232] Atrial fibrillation can occur late in the natural history of the disease and usually causes sudden symptoms. In cases of chronic mitral regurgitation, LV volume overload leads to LA and LV dilatation and, eventually, to LV hypertrophy owing to the chronic volume overload. Electrocardiographic evidence of LV enlargement or hypertrophy occurs in half of patients, 15% have right ventricular hypertrophy owing to increased pulmonary vascular resistance, and 5% have combined left and right ventricular hypertrophy.[120] Ventricular arrhythmias may be noted on ambulatory Holter recordings, especially in patients with LV systolic dysfunction. In those with acute mitral regurgitation, LA and/or LV dilatation may not be evident, and the electrocardiogram may be normal or show only nonspecific findings, including sinus tachycardia or ST-T-wave alterations.[120] Findings of myocardial ischemia or infarction, more commonly noted in the inferior leads, may be present when acute mitral regurgitation is related to acute inferior myocardial infarction or myocardial ischemia; in these cases, first-degree AV block is a common coexisting finding.

In the majority of individuals with mitral valve prolapse, particularly those who are asymptomatic, the resting electrocardiogram is normal.[120,188,234] In symptomatic patients, a variety of ST-T-wave changes, including T-wave inversion and sometimes ST-segment depression, particularly

in the inferior leads, can be found.[184,188] QTc prolongation also may be seen. Arrhythmias may be observed on ambulatory electrocardiograms, including premature atrial contractions, supraventricular tachycardia, AV block, bradyarrhythmias, and premature ventricular contractions.[188] Atrial arrhythmias may be present in upwards of 14% of patients, and ventricular arrhythmias are present in 30% of patients.[147] Age correlates with the incidence of atrial arrhythmias; female gender and anterior mitral valve thickening are predictors of ventricular arrhythmias.[147]

Today, transthoracic echocardiography (TTE) is the clinical mainstay in patients with valvular heart disease, and real-time three-dimensional echocardiography is now used extensively for patients with mitral valve disease in many echocardiography laboratories. In those with chronic mitral regurgitation, echocardiography is used to follow the progression of LA and LV dilatation and changes in the amount of mitral regurgitation and leaflet morphology.[11,121,123,196,235] Two-dimensional echocardiography confirms chamber enlargement, and color Doppler imaging characterizes many features of the regurgitant leak(s). Two-dimensional echocardiography also identifies abnormalities in leaflet and chordal morphology and function, including myxomatous degeneration with or without leaflet prolapse, restricted systolic leaflet motion (as in IMR) or diastolic opening motion (as in rheumatic valve disease), lack of adequate coaptation owing to annular dilatation or rheumatic valvulitis (fused subvalvular apparatus), and leaflet destruction by endocarditis[11,122,196,235] (Fig. 41-12). Chordal rupture or elongation causing a flail leaflet is characterized by excessive motion of the leaflet tip backward into the left atrium beyond the normal saddle-shaped three-dimensional leaflet coaptation zone. Papillary muscle rupture following myocardial infarction and annular dilatation can be visualized by echocardiography (Fig. 41-13). Pulsed-wave or continuous-wave Doppler echocardiography tends to overestimate the severity of mitral regurgitation in patients with depressed LV ejection fraction and low cardiac output; it is extremely

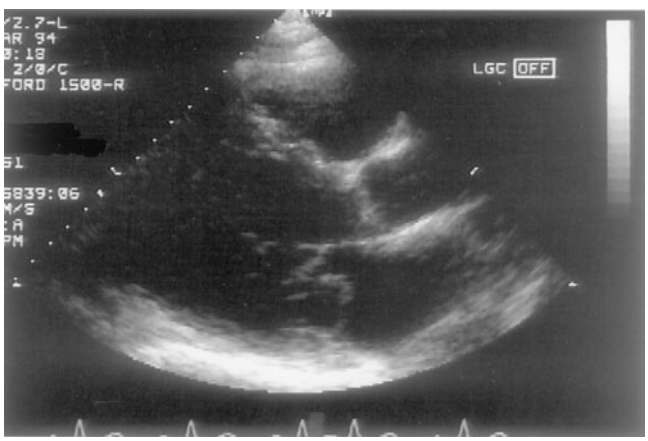

Figure 41-12. Echocardiogram (long-axis) of a patient with mitral regurgitation owing to floppy mitral valve. The leaflets billow back into the left atrium during systole.

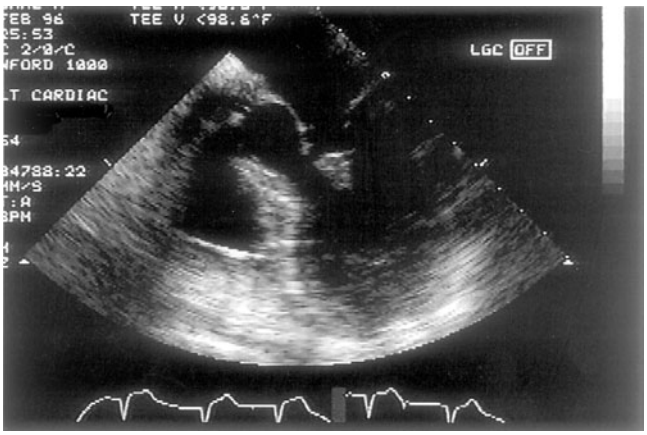

Figure 41-13. Echocardiogram (two-chamber view) of a patient with mitral regurgitation owing to ruptured papillary muscle.

sensitive and specific in diagnosing mild or severe mitral regurgitation but not as accurate in assessing the degree of mitral regurgitation.[11] The most commonly used method to assess the degree of regurgitation is two-dimensional color Doppler echocardiography, which permits visualization of the origin, extent, direction, duration, and velocity of disturbed backward flow of the regurgitant leak or leaks into the left atrium.[122,196,235,236] In patients with IMR or FMR, apical systolic tenting or tethering of the leaflets, tenting area and height, and leaflet opening angles can be quantitated, including important pathoanatomic differences between ischemic cardiomyopathy and idiopathic dilated cardiomyopathy[175,194,196,237] (Fig. 41-14). The cardinal distinctions between IMR and FMR in a recent study by Kwan and colleagues are (1) the pathologic changes are symmetric across the valve (from commissure to commissure) in patients with FMR and asymmetric in those with IMR, in whom the largest derangements are located on the medial side of the

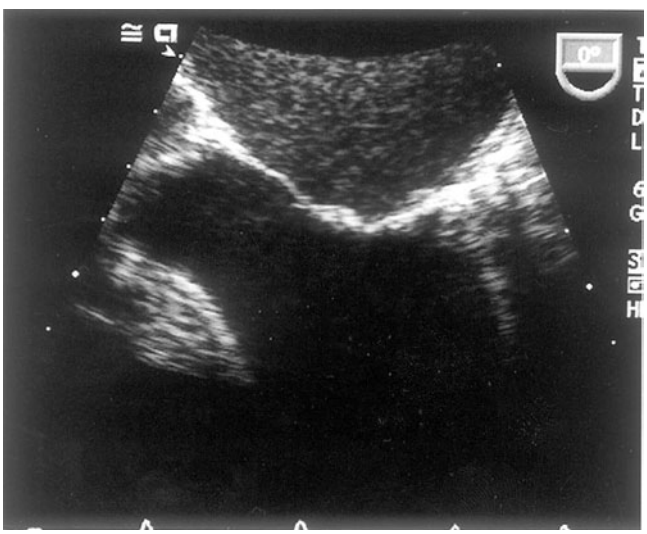

Figure 41-14. Echocardiogram of a patient with ischemic mitral regurgitation and apical systolic leaflet tenting.

valve, and (2) the magnitude of the changes is greater in the FMR group with idiopathic dilated cardiomyopathy than in those with IMR.[237] When the regurgitant leak is due in part or totally to annular dilatation, usually in the septolateral dimension (or clinically in the anteroposterior axis), the coaptation height of the anterior and posterior leaflets can be measured. Incomplete mitral leaflet coaptation is seen commonly in patients with FMR and IMR and can contribute to the mitral regurgitation in patients with long-standing prolapse. The regurgitation caused by annular dilatation and incomplete leaflet coaptation is directed straight back into the left atrium; successful repair includes restoring a normal amount of leaflet coaptation when an annuloplasty ring is used.

In any form of mitral regurgitation, ERO and regurgitant volume can be estimated quantitatively in many but not all patients using two-dimensional color Doppler echocardiography.[175,195,196] ERO has been demonstrated to be an important predictor of outcome in patients with mitral regurgitation treated medically and has been proposed as an indicator of when to proceed with mitral repair in asymptomatic patients with prolapse, which will be discussed below.[195] However, accurate quantification of the degree of mitral regurgitation using ERO and regurgitant volume is demanding and time-consuming and may not be possible at all institutions. The hemodynamic magnitude or severity of the mitral regurgitation also can be estimated semiquantitatively by calculating mitral and aortic stroke volumes, with regurgitant volume being the difference between these two stroke volumes. Notably, cardiac MRI is an accurate method to measure regurgitant volume and regurgitant fraction; it should be remembered that if aortic regurgitation also exists, the regurgitant volume and regurgitant fraction represent the combined effects of both valves leaking with respect to forward output.

Renewed interest in the timing of the regurgitant leak (and murmur) has helped clinicians discern subtle details about the pathologic mechanism(s) responsible for the mitral regurgitation (which then guide the specific mitral repair techniques used), infer information about the overall hemodynamic burden imposed by the LV volume overload, and predict the likelihood of successful and durable mitral repair. IMR is primarily an early-systolic leak, and the regurgitation in patients with FMR occurs during early and middle systole (biphasic pattern); prolapse is associated with late-systolic leaks. While detected by pulse-wave and continuous-wave Doppler echocardiography for years, the timing of the mitral regurgitation has become more widely appreciated owing to a resurgence of interest in color Doppler M-mode echocardiography, which has a much faster temporal resolution (sampling frequency) than does two-dimensional color Doppler echocardiography. Cardiac surgeons should study these color Doppler M-mode images regularly because the duration of the regurgitant leak is a major determinant of the overall magnitude of the regurgitation.

When necessary, such as when high-quality TTE images cannot be obtained owing to patient habitus or advanced emphysema, transesophageal echocardiography (TEE) provides superior image quality and can reveal additional anatomic and pathophysiologic information, including details of the valvular pathoanatomy and the mechanism, origin, direction, timing, and severity of the regurgitant leak.[11,123,196,235,238] TEE can detect small mitral vegetations, ruptured chordae, leaflet perforations or clefts, calcification, and other inflammatory changes and can be useful in patients with annular or leaflet calcification. TEE also is useful in patients with a previously implanted aortic valve prosthesis that can interfere with TTE assessment of mitral regurgitation owing to acoustic shadowing. Although intraoperative TEE during mitral valve repair is essential, a major limitation must always be remembered: The vascular unloading effects of general anesthesia downgrade the severity of mitral regurgitation.[239,240] The judgment about how much mitral regurgitation is present (and whether surgical repair is necessary) must be made on the basis of an awake TTE study when the patient has a normal ambulatory blood pressure. This concept is imperative in assessing the degree of mitral regurgitation in patients with IMR when deciding whether to add mitral valve surgery at the time of planned coronary artery bypass grafting. For patients in whom the degree of mitral regurgitation has been downgraded by the effects of anesthesia before or after valve repair, intraoperative TEE provocative testing using vasoconstrictor drugs with or without volume infusion is mandatory to guide surgical decision making. Testing consists of reproducing the patient's normal awake or active ambulatory hemodynamic condition with preload challenge and afterload augmentation.[239,240] Preload challenge is performed after aortic cannulation for cardiopulmonary bypass by rapidly infusing volume from the pump until the pulmonary capillary wedge pressure reaches 15 to 18 mm Hg. If severe mitral regurgitation is not produced, LV afterload is increased by intravenous boluses of phenylephrine until the arterial systolic pressure climbs to the 130- to 150-mm Hg range. In patients undergoing coronary artery bypass grafting, if both tests are negative, or if regurgitation is induced but associated with new regional LV systolic wall motion abnormalities (i.e., the regurgitation is due to acute ischemia of viable myocardium), the valve may not require visual inspection because coronary revascularization usually is all that is necessary if the inferior wall myocardium is viable. If these tests confirm the presence of moderate to severe mitral regurgitation, the valve is inspected and usually is repaired using an undersized annuloplasty ring specifically designed for IMR, e.g., Edwards ETlogix, Edwards Geoform, or St. Jude Medical RSR (rigid saddle ring), at the time of coronary revascularization. All these IMR rings are complete and rigid (made of titanium) with the septolateral dimension disproportionally downsized compared with the commissure-commissure annular dimension, thereby correcting the key abnormality (septolateral dilation) in IMR and FMR.

Real-time three-dimensional echocardiography is now available clinically and shows promise in the assessment of congenital and acquired valvular disease.[127] This technique

facilitates spatial recognition of moving intracardiac structures. In patients with mitral regurgitation, three-dimensional echocardiography is fairly accurate in elucidating the dynamic mechanisms of the regurgitant leak(s). The addition of color-flow Doppler to three-dimensional imaging provides improved visualization and may offer improved quantitative assessment of regurgitant valvular lesions.[127] Additionally, three-dimensional echocardiography may provide more insight into the geometric deformities of the mitral leaflets and annulus, maximum tenting site of the mitral leaflet, and quantitative measurements of mitral valve tenting and annular deformity in patients with IMR.

Historically, cardiac catheterization and left ventriculography have been used in the assessment of mitral regurgitation, but modern echocardiography has eliminated the need for left-sided heart catheterization in the vast majority of patients.[11,119,201] It usually is indicated only to determine coronary artery anatomy in older patients with prolapse prior to repair and those with IMR. Other techniques, such as calculating mitral regurgitant fraction (regurgitant volume determined as the difference between total LV angiographic stroke volume and the effective forward stroke volume measured by the Fick method), are limited. By measuring rest and exercise (supine bicycle) pulmonary artery pressures and cardiac output, right-sided heart catheterization can be useful occasionally to identify patients with primary myocardial disease who present with LV dilatation and relatively mild degrees of mitral regurgitation (who may not have a high likelihood of benefiting from mitral valve surgery) and those with severe mitral regurgitation who deny symptoms to see if they develop pulmonary hypertension with exercise.

MRI is a noninvasive modality that can be employed to assess the cardiovascular system, including cardiac structure and function.[241–243] Specialized MRI techniques, such as moving-slice velocity mapping, the control-volume method, or real-time color-flow MRI, have been used to evaluate and quantify the degree of mitral regurgitation. The presence of valvular regurgitation can be determined, LV volumes and mitral regurgitant fraction estimated, and information obtained concerning mitral and coronary anatomy. Quantitative MRI measurements, e.g., LV end-diastolic and end-systolic volumes and regurgitant fraction, correlate well with those determined at cardiac catheterization. Current MRI technology remains inferior to echocardiography for assessing valvular morphology and leaflet motion. Constraints of MRI, such as pacemakers or implantable cardiodefibrillators, morbid obesity, and claustrophobia, hamper the wider use of cardiac MRI. Recently, multidetector CT has emerged as an imaging technique that can fully evaluate both cardiac structure and function, including coronary artery anatomy; this new technology has yielded good visualization of valve leaflets, commissures, and mitral annulus.[129] Limitations still include image noise, requirement for a regular rhythm and a slow heart rate during imaging, time required for postprocessing data analysis, and radiation dose; nonetheless, this technology is very promising.

Postoperative LV Function and Surgical Outcomes

General

Successful mitral valve repair or replacement usually is associated with clinical improvement, augmented forward stroke volume with lower total stroke volume, smaller LV end-diastolic volume, and regression of LV hypertrophy.[182,244–246] Surgical correction of chronic mitral regurgitation can preserve LV contractility, particularly in patients with a normal preoperative ejection fraction who have minimal ventricular dilatation and those without significant coronary artery disease. On the other hand, in patients with impaired LV contractile function preoperatively, improvement in LV systolic function may not necessarily occur after operation.[245] An LVESVI exceeding 30 mL/m^2 is associated with decreased postoperative LV function.[217,245] Thus patients with chronic mitral regurgitation should be referred for mitral valve surgery when LVESVI does not exceed 40 to 50 mL/m^2 (or when LV end-systolic dimension is 4 cm or less according to the newly updated ACC/AHA 2006 guidelines[246]); otherwise, a poor outcome is likely.[217] LVESVI corrected for LV wall stress, a single-point ratio of end-systolic wall stress to end-systolic volume index, or ESS:LVESVI, is a good index of LV systolic function and accurately predicts surgical outcome in patients with mitral regurgitation.[214,215] Specifically, an ESS:LVESVI ratio of less than 2.6 portends a poor medium-term prognosis, whereas a normal or high ESS:LVESVI ratio is associated with a favorable outcome, suggesting that LV contractile function had been relatively preserved before operation.[215] Significant determinants of increased operative risk also include older age, higher New York Heart Association (NYHA) functional class, associated coronary artery disease, increased LV end-diastolic pressure, elevated LV end-diastolic volume index, elevated LV end-systolic dimension, reduced LV ESS index, depressed resting ejection fraction, decreased fractional shortening, reduced cardiac index, elevated capillary wedge or right ventricular end-diastolic pressure, concomitant operative procedures, and previous cardiac surgery.[217,245–252]

Experimentally, normalization of LV contractile function is associated with increased myocyte length, augmented myocyte cross-sectional area, and increased contractile protein content.[203] The abnormal LV diastolic properties (including early diastolic filling rate, myocardial relaxation, chamber stiffness, myocardial stiffness, and end-diastolic pressure) also may be reversible after mitral valve surgery.[222] If surgical correction of mitral regurgitation is carried out before the volume-overload cardiomyopathy reaches an irreversible stage, LV diastolic filling characteristics and systolic contractile function return toward normal values. Furthermore, LV volume and the LV volume:mass (or dimension:thickness) ratio usually normalize postoperatively, but mild LV hypertrophy may persist.[222]

The decline in ejection fraction after mitral valve replacement for chronic mitral regurgitation is believed to be a result of the postoperative increase in afterload, which

historically was thought to be secondary to closure of the low-resistance early-systolic "pop-off" into the left atrium and surgical excision of the subvalvular apparatus. A spherical mathematical model of the left ventricle has been used to define the relations between LV end-diastolic dimension, systolic wall stress, and ejection fraction.[253] This model has been validated in patients undergoing mitral valve replacement with or without chordal-sparing techniques; postoperative changes in systolic stress are related directly to changes in chamber size, and LV afterload may decrease postoperatively if chordal-preservation valve replacement techniques are used. In terms of exercise performance after mitral valve surgery for nonischemic mitral regurgitation, although patients generally report symptomatic improvement, cardiopulmonary exercise testing at 7 months actually is not better than preoperatively, and abnormal neurohumoral activation persists, probably reflective of incomplete recovery of LV contractility[254] (Table 41-1). Plasma renin activity, aldosterone, and atrial natriuretic peptide (ANP) decrease after surgery but are still elevated compared with control values. Neurohumoral activation may contribute to the impairment of exercise performance in patients with heart failure by limiting exercise-induced vasodilatation or by contributing to maldistribution of peripheral blood flow.[254] With respect to long-term clinical outcome, risk factors portending postoperative cardiac deterioration include larger LV end-diastolic dimension, increased LV end-systolic dimension, increased LVESV, diminished fractional shortening, reduced LV ESS index, large LA size, decreased LV wall thickness/cavity dimension at end-systole, and associated coronary artery disease.[217,247,250,251,255]

Patients with mitral regurgitation owing to flail leaflet frequently are asymptomatic, yet this entity is associated with a risk of progressive LV dysfunction and a suboptimal prognosis if not treated surgically. If treated conservatively with medical management, mitral regurgitation owing to flail leaflet is associated with high annual mortality risk (6.3%) and morbidity rates.[183,256] In these patients, the strategy of early operation results in improved long-term survival. Mitral valve repair for patients with myxomatous mitral regurgitation is feasible in the large majority of patients in certain experienced centers and offers excellent early and late functional results.[182,257–259] Because fewer complications and lower operative mortality risk are associated with valve repair compared with valve replacement in this patient population, operation should be considered earlier in the natural history of the disease if the pathologic anatomy is judged favorable for valve repair.[147,182,183,247,256,257,260,261] For instance, in a recent study from Toronto, patients undergoing mitral valve repair for floppy mitral valve disease had a 15-year survival rate of 61% for all patients and 76% for asymptomatic patients, along with a freedom from reoperation rate of 91%[182] (Fig. 41-15). Predictors of late death included age, NYHA functional class, ejection fraction greater than 40%, preoperative stroke or transient ischemic attack, previous cardiac surgery, and severe obstructive lung disease. Early mitral repair in asymptomatic patients with degenerative mitral regurgitation thus is recommended if valve repair can be performed reliably with low operative mortality and morbidity rates.[182]

A landmark study published in 2005 from the Mayo Clinic focused on the management of asymptomatic patients with organic mitral regurgitation.[195] Four hundred fifty-six asymptomatic patients with at least mild holosystolic mitral regurgitation defined echocardiographically were enrolled prospectively from 1991 to 2000. Follow-up averaged 2.7 years under medical management and 5.1 years under medical and surgical management. At entry, baseline ejection fraction was 70%, LV end-systolic dimension was 3.4 ± 6 cm, LV end-diastolic dimension was 5.6 ± 8 cm,

LVESVI was 33 ± 130 mL/m^2, and regurgitant volume was 66 ± 40 mL/beat. Management was at the discretion of the primary physician, including when to proceed to valve surgery. At 5 years, 54% of patients had been operated on after an average of 1.2 ± 2 years of medical treatment when symptoms occurred or when worrisome echocardiographic findings were detected (based on 1998 ACC/AHA valve disease practice guidelines). Among the 230 patients who underwent a mitral valve procedure, 209 (91%) received a valve repair. Operative mortality rate was low at 1%. The patients were stratified by degree of regurgitation; mild, moderate, and severe were defined as regurgitant volumes of less than 30, 30 to 59, and 60 or more mL/beat, and ERO was defined as less than 20, 20 to 39, and 40 or greater mm^2, respectively. For the medically treated patients, 5-year survival compared with U.S. Census life tables was significantly inferior for those with moderate regurgitation (ERO of 20 to 39 mm^2, 66% versus 84%) and severe regurgitation (ERO of 40 mm^2 or more, 58% versus 78%).[195] Independent risk factors for death in the medically treated patients were advancing age, diabetes mellitus, and larger ERO. Even when adjusted for age, gender, diabetes, atrial fibrillation, and ejection fraction, ERO still predicted survival. The influence of ERO also held true for predicting cardiac deaths and all cardiac events. The 5-year cardiac death rate was 36% for patients with an ERO of 40 mm^2 or greater compared with 20% for those with an ERO of 20 to 39 mm^2 and only 3% for those with an ERO of less than 20 mm^2. Mitral valve operation was an independent determinant of fewer deaths, cardiac deaths, and cardiac events, especially in those with a larger ERO.[195] This important study, which focuses on the predictive effects of the severity of the regurgitation instead of the response of the ventricle, has prompted a rethinking in our approach to asymptomatic patients with mitral regurgitation. All asymptomatic patients with an ERO of 40 mm^2 or greater should be referred for consideration of early surgical repair. Those with an ERO in the 20 to 39 mm^2 range should be monitored closely using serial echocardiography. Finally, those with the smallest ERO (<20 mm^2) can be followed more conservatively and are at low risk of developing cardiac complications while being managed medically. Despite the valuable information in this study, future larger prospective trials are necessary to validate these results. Notably, the critical ERO threshold for mitral regurgitation owing to degenerative disease and prolapse (40 mm^2) in patients with preserved LV systolic function is twice the 20 mm^2 critical value of ERO that predicts an adverse outcome in patients with LV systolic dysfunction and IMR or FMR (see below).[175,194] In other words, it only takes a regurgitant orifice one-half as large to portend an unfavorable outcome if one has impaired LV function owing to ischemic or idiopathic cardiomyopathy.

When a large preoperative LVESVI or echocardiographic end-systolic dimension indicates the presence of LV systolic dysfunction, every effort should be made to repair the valve, or at least preserve all chordae tendineae (to both the anterior and posterior leaflets) if valve replacement is necessary.[246,262] Importantly, these surgical technical details have been emphasized in the 2006 update of the American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines; furthermore, these guidelines state how important it is that patients with mitral regurgitation be referred to surgical centers that have demonstrated track records of excellence for mitral repair, including long-term repair durability.[246] In the United Kingdom, this thrust emphasizing surgical quality and reliability has reached the point where standards for mitral repair best practice have been promulgated with recommended regionalization of surgical expertise and minimum surgeon and hospital annual volume benchmarks.[263] The recently updated ACC/ AHA practice guidelines include an overall strategy in the management of patients with severe chronic mitral regurgitation, incorporating symptoms, LV systolic function, reparability of the valve, and the likelihood of total chordal preservation if valve replacement were necessary[246]

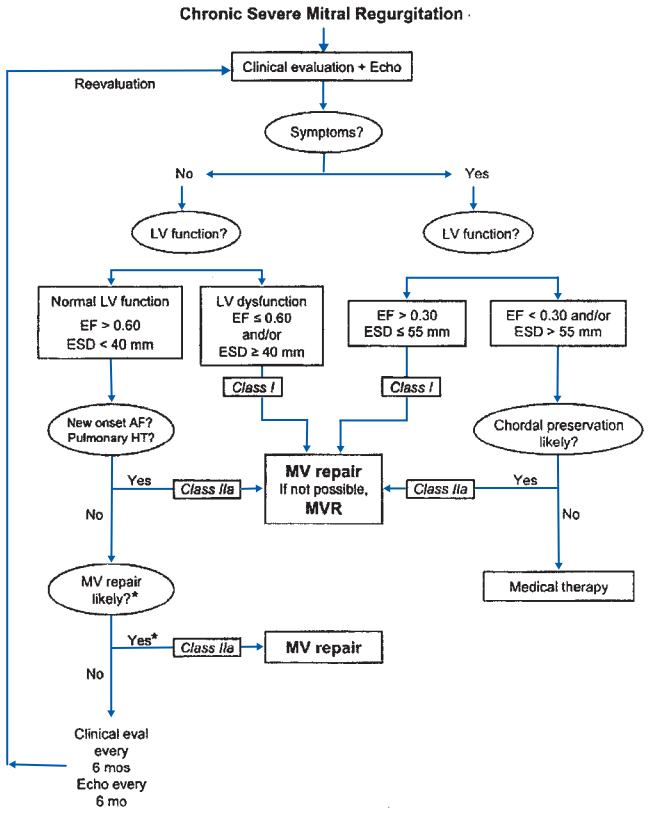

Figure 41-16. Management strategy for patients with chronic severe mitral regurgitation. *Mitral valve repair may be performed in asymptomatic patients with normal left ventricular function if performed by an experienced surgical team and if the likelihood of successful repair is greater than 90%. MV = mitral valve; LV = left ventricular; AF = atrial fibrillation; EF = ejection fraction; ESD = end-systolic dimension; eval = evaluation; HT = hypertension; MVR = mitral valve replacement. (*Reproduced with permission from Bonow RO et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. J Am Coll Cardiol 2006; 48:e1.*)

(Fig. 41-16). It is noteworthy that the threshold for LV end-systolic dimension for when to consider operation is now 4 cm, smaller than the 4.5-cm criterion in the previous 1998 guidelines. Needless to say, to reach consensus on this controversial issue has been an arduous challenge and is based on scientific evidence supporting each decision step. The defined strategy is thoughtful and should be studied.

Because many patients with a substantial mitral regurgitation report no symptoms, and because symptoms have been the mainstay of when to consider surgical repair, cardiopulmonary exercise testing has been used to evaluate asymptomatic patients with organic mitral regurgitation (owing to prolapse in 93% of cases) at the Mayo Clinic.[264] Of 134 asymptomatic patients with an average ejection fraction of 73%, 57% had severe mitral regurgitation with a regurgitant volume of 68 ± 24 mL/beat (range of 30 to 146 mL/beat) and an ERO of 35 ± 14 mm^2 (range 14 to 83 mm^2). Surprisingly, functional capacity was markedly reduced (defined as 84% or less than expected) in 19% of these "asymptomatic" patients. Those with impaired functional capacity were roughly equally distributed according to regurgitant volume of less than or greater than 60 mL/beat and ERO of less than or greater than 40 mm^2. When patients with extraneous reasons for impaired functional capacity were excluded, 14% had a reduced functional capacity, and their regurgitant volume and ERO were larger than those with a normal functional capacity. Determinants of reduced functional capacity were impaired LV diastolic function, lower forward stroke volume, and atrial fibrillation; ERO had no significant influence on functional capacity.[264] Thus it was the consequences of chronic mitral regurgitation and not the magnitude of the leak that predicted impaired functional capacity. Follow-up at over 2 years revealed that 66% of patients with impaired functional capacity sustained some adverse event or required mitral surgery (versus 29% of those with normal functional capacity) after adjusting for age, ERO, gender, and ejection fraction. Although the results need to be validated prospectively, this evidence argues that asymptomatic patients with substantial mitral regurgitation should undergo periodic cardiopulmonary exercise testing to detect subclinical impairment in functional capacity and that mitral valve repair should be recommended to those with impaired capacity.

Even after mitral valve surgery for chronic mitral regurgitation, some patients continue to be limited by heart failure symptoms and have a less than optimal long-term postoperative outcome. Based on evidence from the Mayo Clinic, the incidence of congestive heart failure in patients who survive surgery (combined series of valve repair and valve replacement) for pure mitral regurgitation has been 23%, 33%, and 37% at 5, 10, and 14 years.[266] Valve repair is not a predictor of decreased incidence of congestive heart failure; however, using a combined endpoint of congestive heart failure and death, valve repair compared with valve replacement in patients with mitral regurgitation appears to confer a survival advantage. Patient survival after the first episode of congestive heart failure is dismal, being only 44% at 5 years. Causes of congestive heart failure include LV dysfunction in two-thirds of patients and valvular problems in the remaining one-third. Predictors of postoperative heart failure are lower preoperative ejection fraction, coronary artery disease, and higher NYHA functional class.[266] Importantly, preoperative functional class III/IV symptoms are associated with markedly decreased postoperative medium- and long-term survival independent of all other baseline characteristics.[267]

Despite the trend of advocating earlier operation for patients with chronic mitral regurgitation even if they are minimally symptomatic or asymptomatic if the valve is reparable, some clinicians still adhere to the earlier, more conservative ACC/AHA practice guidelines. The cardiology unit at the Medical University of Vienna followed 132 asymptomatic patients with severe degenerative mitral regurgitation for a median of 69 months between 1995 and 2002.[268] Indications for operation were consistent with the 1998 ACC/AHA practice guidelines, including onset of symptoms or, if asymptomatic, the development of LV

enlargement (LV end-systolic dimension greater than 4.5 cm, or greater than 2.6 cm/m^2), LV systolic dysfunction (ejection fraction of less than 60%), pulmonary hypertension (pulmonary systolic pressure greater than 50 mm Hg), or recurrent atrial fibrillation. Thirty-eight of the 132 patients ultimately developed an indication for mitral surgery, yielding an actuarial freedom from surgery of 55% at 8 years. Of the 34 patients who underwent surgery, 83% received valve repair. There were no operative deaths. All patients benefited symptomatically, but 4 of 35 patients had impaired LV function postoperatively that was judged to be secondary to valve replacement (chordal preservation technique not stated) in 2 and coronary artery disease after repair in 2. The conclusion was that it was safe to treat patients with severe degenerative mitral regurgitation medically as long as they were monitored carefully on a regular basis.[268] Although vigilance and close follow-up were the key to safe patient management in the Vienna experience, an editorialist noted that this level of care might not be available or reliably accessible to many patients.[269] The editorialist also highlighted the importance of the timing and duration of the "severe" mitral regurgitation in terms of the overall volume overload imposed on the left ventricle and wondered if the regurgitation in the study patients was as severe as the investigators believed it was. More information about the severity of the regurgitant leak can be obtained by echocardiographic continuous-wave Doppler tracings or color Doppler M-mode recordings or, better yet, resorting to quantitative parameters such as ERO and regurgitant volume.[175,195,196]

Historically, it has been thought that mitral valve surgery would not benefit patients with pronounced LV dilatation and severe global LV systolic dysfunction. Satisfactory results have been reported, however, after mitral valve repair using an undersized flexible annuloplasty ring with resulting decreased LV volume and sphericity and increased ejection fraction in patients with dilated or ischemic cardiomyopathy and congestive heart failure.[270–272] In 200 patients with cardiomyopathy and severe mitral regurgitation who underwent valve repair using an undersized annuloplasty ring, Bolling and colleagues reported an operative mortality rate of 4.5% with 26 late deaths and 2 patients subsequently requiring transplantation.[272] The 1- and 5-year survival rates were 82% and 52%, respectively. A follow-up observational study suggests that although mitral valve repair may be performed safely for patients with end-stage cardiomyopathy, the long-term outcome may be limited.[273] In assessing the effects of mitral valve repair in patients with mitral regurgitation and LV dysfunction, the risk factors for death, left ventricular assist device placement, or heart transplant included the presence of coronary artery disease and decreased renal function.[273] Factors that reduced risk included use of angiotensin-converting enzyme inhibitors and beta blockers. Mitral valve repair by itself did not have an impact on long-term outcome. Therefore, no mortality benefit conferred by mitral annuloplasty for FMR or IMR with severe LV dysfunction could be demonstrated.[273] Similarly, in the Mayo Clinic experience, in which the operative mortality also was low (2.3%), mitral valve procedures in patients with nonischemic cardiomyopathy yielded less than satisfactory long-term results, with a 5-year survival rate of only 33%.[153] A randomized, prospective trial is needed to clarify further the issue of whether a mitral valve procedure in these patients is beneficial over the long term. Alternatively, evolving technology focused on catheter-based interventional methods of altering the course of FMR or IMR and cardiomyopathy are currently being investigated and may play a role in the management of these patients in the future.[153,273,274]

Ischemic mitral regurgitation

To risk stratify patients after myocardial infarction, detecting and quantifying IMR are essential.[194,275–278] In a report from the Mayo Clinic, medically managed patients who developed IMR late after myocardial infarction had a very high mortality rate (62% at 5 years) compared with those with an infarction who did not develop IMR (39% at 5 years).[194] Medium-term survival for patients with IMR and LV systolic dysfunction was inversely related to the ERO and regurgitant volume. After 5 years, the survival rate was 47% for patients with an ERO of less than 20 mm^2 and 29% for those with an ERO of 20 mm^2 or greater. Survival at 5 years was 35% when the regurgitant volume was 30 mL/beat or greater compared with 44% for those with a regurgitant volume of less than 30 mL/beat. The relative risk ratio for cardiac death for patients with IMR was 1.56 for patients with an ERO of less than 20 mm^2 versus 2.38 for those with an ERO of greater than 20 mm^2. Conversely, the ERO threshold was twice as large (40 mm^2 or greater) in patients with prolapse or flail leaflets.[195] An ERO of more than 40 mm^2 was considered to reflect severe regurgitation in either disease, but the compound injury of coexisting LV dysfunction made the prognostic impact of even a "mild" leak (ERO of about 20 mm^2) very strong in patients with IMR.[278] In patients with myocardial infarction, the incidences of congestive heart failure and congestive heart failure or cardiac death were high even in patients with no or minimal symptoms at baseline and even higher in patients with IMR.[277] Determinants of congestive heart failure were ejection fraction, sodium plasma level, and presence and degree of IMR. At 5 years, the rate of congestive heart failure was 18% without IMR compared with 53% if IMR was present. If the ERO was less than 20 mm^2, the incidence of congestive heart failure was 46% compared with 68% when the ERO was 20 mm^2 or greater. The relative risk of congestive heart failure was 3.65 if IMR was present but 4.42 if ERO was 20 mm^2 or greater. At 5 years, the rate of congestive heart failure or cardiac death was 52%; the relative risk of congestive heart failure or cardiac death was 2.97 if IMR was present and 4.4 if ERO was 20 mm^2 or greater[277] (Fig. 41-17). Moderate or severe IMR was associated with a relative risk of 3.44 for congestive heart failure and 1.55 for death among 30-day survivors independent of age, gender, ejection fraction, and Killip class.[276]

In patients with IMR and LV systolic dysfunction, quantitative assessment of exercise-induced changes in the degree of mitral regurgitation provides additional prognostic

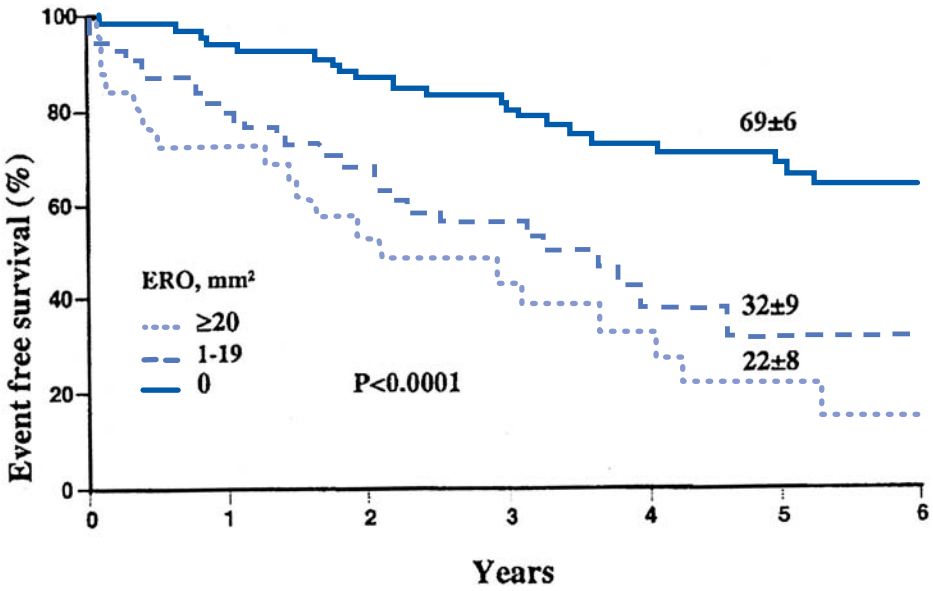

Figure 41-17. Survival free of congestive heart failure or cardiac death (event-free survival) in asymptomatic patients after myocardial infarction according to degree of mitral regurgitation measured by effective regurgitant orifice (ERO) of 20 mm^2 or more (*continuous line*), 1 to 19 mm^2 (*dashed line*), and no mitral regurgitation (ERO = 0) (*dotted line*) at diagnosis. The events at 5 years are indicated ± standard error. information.[279] Exercise-induced increases in mitral regurgitation unmask patients at higher risk of poor outcome. Similarly, low-dose dobutamine echocardiography may predict benefit from coronary revascularization in patients with IMR if regional LV wall motion improves.[200] Reduction of IMR has been associated with improvement in regional (inferior) systolic wall motion but not with changes in the anterior wall motion or global LV volume and function.[200] A pitfall of dobutamine stress echocardiography in assessing IMR, however, is that the ventricle becomes smaller at end-diastole and end-systole if viable myocardium is present; thus the mitral annulus is smaller at end-diastole (recall that IMR is an early-systolic leak, not holosystolic or late systolic), and increasing dobutamine dose paradoxically reduces the magnitude of the IMR. This result is predictable and should not be used as an excuse not to inspect the valve at the time of coronary bypass grafting because undersized ring annuloplasty frequently is needed.

Mitral repair or replacement for patients with IMR has been associated with higher operative risk (4 to 30%) than for patients with nonischemic chronic mitral regurgitation, which reflects the concomitant adverse consequences of previous myocardial infarction and ischemia.[280–289] The Yale group postulated that isolated coronary artery bypass grafting without valve repair is adequate in most patients with ischemic cardiomyopathy and mild to moderate mitral regurgitation, yielding survival rates of 88% at 1 year and 50% at 5 years; however, this study was small, and only a few patients had clinically important degrees of IMR.[290] Most investigators believe that coronary revascularization alone in the setting of moderate or severe IMR leaves many patients (up to 40%) with significant residual mitral regurgitation and heart failure symptoms.[149,291–293] Mitral regurgitation may be dynamic postoperatively, and it is influenced by LV afterload. Immediately postoperatively, IMR is absent or mild in 73% and severe in 6%; on the other hand, by 6 weeks, only 40% of patients have absent or mild mitral regurgitation, and 22% have severe mitral regurgitation[293] (Fig. 41-18). Postoperative residual or recurrent IMR is not associated with the preoperative extent of coronary artery disease or LV dysfunction. The 5-year survival rate of patients without IMR undergoing coronary artery bypass grafting only is 85% compared with 73% for patients with moderate IMR.[293] Because moderate IMR does not reliably resolve with coronary artery bypass grafting alone, valve repair (or even chordal-sparing valve replacement) should be considered in these patients because it potentially can reduce cardiac morbidity and may improve long-term survival.[149,291–293] Others argue that patients with moderate IMR undergoing coronary revascularization and concomitant mitral annuloplasty have less postoperative IMR but no improvement in long-term survival.[161,283,284,294] For patients with moderate or moderately severe IMR, isolated coronary artery bypass grafting and coronary revascularization combined with mitral annuloplasty provide similar long-term outcome with survival rates of 82 to 84% at 1 year, 40 to 68% at 5 years, and 37% at 10 years[282–284,295] (Fig. 41-19). Predictors of long-term mortality are older age, prior myocardial infarction, unstable angina, chronic renal failure, atrial fibrillation, absence of an internal mammary artery graft, lack of beta blocker use, lower ejection fraction, smaller left atrial size, global LV wall motion abnormalities, mitral leaflet restriction, and fewer bypass grafts.[282,284] Combined mitral valve repair and coronary revascularization does not emerge as a predictor of long-term survival. Whereas some workers report that annuloplasty can be added to coronary artery bypass grafting in high-risk patients without increasing early mortality, the potential benefit with respect to late survival and functional status may be limited owing to the underlying ischemic cardiomyopathy.[282–284,294]

In a previous Brigham and Women's Hospital experience, patients with IMR and annular dilatation or type IIIb

restricted systolic leaflet motion (not chordal or papillary muscle rupture) who underwent valve repair and coronary revascularization had a worse long-term outcome than those who underwent valve replacement plus coronary revascularization.[280] These authors concluded that the pathophysiology or cause of the IMR was a stronger determinant of long-term survival than was the type of valve procedure. Conversely, the New York University group reported a higher complication-free survival rate (64% at 5 years) for patients undergoing mitral valve repair compared with 47% at 5 years for those in whom the valve had to be replaced.[296] The analysis of the early mortality risk for patients with IMR undergoing mitral valve repair versus valve replacement was confounded by many other factors, including functional disability and angina. Excluding these two variables, further analysis showed that the early mortality rate was lower for patients undergoing valve repair than for those undergoing valve replacement.[296] Based on propensity-score analysis, the Cleveland Clinic group found that in the lower-risk quintiles of patients with IMR, valve repair conferred a survival advantage (58% at 5 years) over those who underwent valve replacement (36% at 5 years); however, in the highest-risk patients, late survivals after valve repair and valve replacement were similarly poor, and valve replacement actually conferred a small survival advantage.[297] This thoughtful analysis highlights the soberingly poor prognosis of patients with IMR and how the patient's clinical condition and LV function status are more powerful determinants of outcome than operative procedure performed. Analysis of etiology of the mitral regurgitation (degenerative versus ischemic) in patients with coronary artery disease after combined mitral valve repair and coronary revascularization showed that those with IMR had more extensive coronary artery disease, worse ventricular function, more comorbidities, and more preoperative symptoms.[298] Unadjusted 5-year survival estimates were 64% and 82% for patients with IMR and degenerative mitral regurgitation, respectively; however, matched pairs had equivalent but poor 5-year survival rates (66% and 65%, respectively). Long-term survival varied widely among patients with degenerative mitral regurgitation and coronary artery disease, depending largely on ischemic burden and extent of LV dysfunction. These findings have been corroborated by a Duke study in which the large survival discrepancy between patients with IMR and those with degenerative mitral regurgitation combined with coronary artery disease was attributed to patient-related differences.[286] Only the number of preoperative comorbidities and advanced age emerged as predictors of survival, whereas ischemic etiology, gender, ejection fraction, NYHA functional class, coronary artery disease, reoperation, and year of operation did not achieve statistical significance.[286] Because survival was not different between patients with IMR and those with nonischemic mitral regurgitation after routine use of a rigid-ring annuloplasty during coronary artery bypass grafting, long-term patient survival was more influenced by baseline patient characteristics and comorbidity than by the etiology of the mitral regurgitation per se[286] (Fig. 41-20). In another

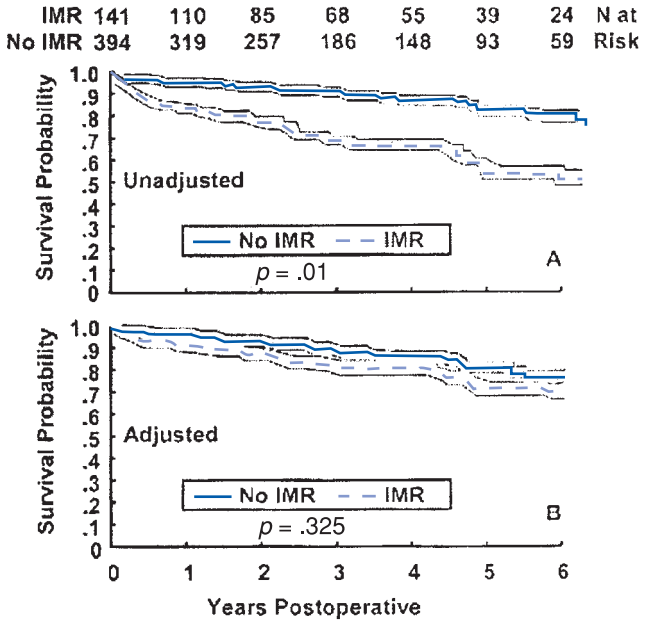

Figure 41-20. Survival of patients undergoing mitral valve repair with ischemic mitral regurgitation versus nonischemic mitral regurgitation before (*A*) and after (*B*) adjustment for differences in baseline patient characteristics. IMR = ischemic mitral regurgitation; NMR = nonischemic mitral regurgitation. (*Reproduced with permission from Glower DD et al: Patient survival characteristics after routine mitral valve repair for ischemic mitral regurgitation. J Thoracic Cardiovasc Surg 2005; 129:860.*)

Mayo Clinic analysis, the authors concluded that the decision as to whether to repair or replace the valve should be based on patient condition and should not be biased by whether mitral regurgitation is due to ischemia.[285] Older age, ejection fraction of 35% or less, three-vessel coronary artery disease, mitral valve replacement, and residual mitral regurgitation at discharge were risk factors for death. The cause of the mitral regurgitation, ischemic versus degenerative, was not a predictor of long-term survival, class III or IV congestive heart failure, or recurrent regurgitation.[285] Survival after mitral valve surgery and coronary artery bypass grafting thus is determined more by the extent of coronary artery disease and LV systolic dysfunction and the success of the valve procedure.[285,286]

A compelling explanation for the poor long-term outcome of patients who undergo mitral valve repair for IMR is the presence of residual and/or recurrent mitral regurgitation postoperatively.[299–301] Persistence of IMR after annuloplasty is due predominantly to augmented posterior leaflet apical tethering with no improvement in anterior leaflet tethering and no increase in coaptation length.[301] In a recent Cleveland Clinic report of annuloplasty (95% with concomitant coronary artery bypass grafting) for IMR, the proportion of patients with 0 or 1+ mitral regurgitation decreased from 71% preoperatively to 41% postoperatively, but the proportion with 3+ or 4+ residual or recurrent IMR increased from 13 to 28% during the first 6 months after

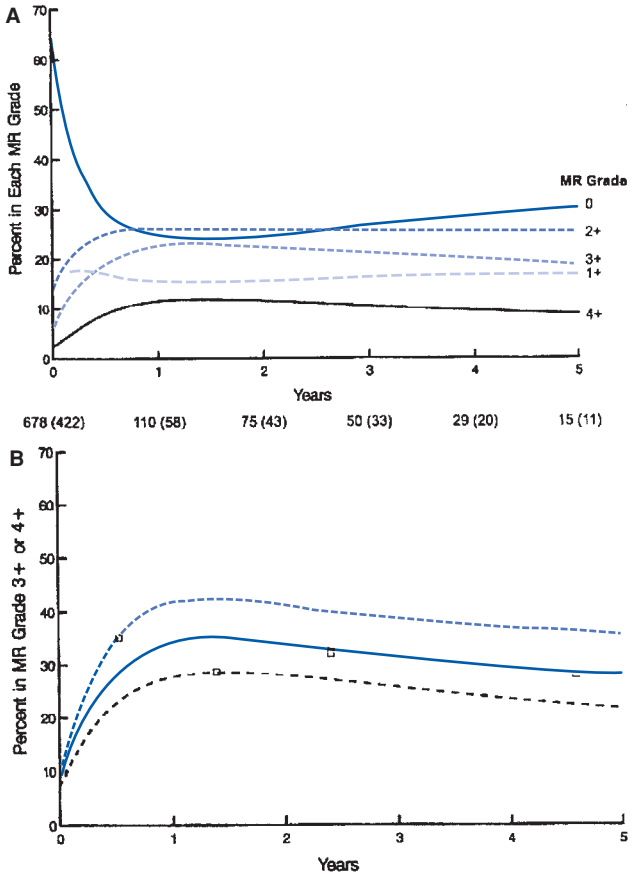

Figure 41-21. Progression of mitral regurgitation after surgical annuloplasty overall. *A.* All grades of mitral regurgitation. Curves for each regurgitation grade represent average temporal prevalence, and they sum up to 100% at each point in time. Numbers below the horizontal axis represent echocardiograms available at various time points, with the number of patients in parentheses. *B.* Prevalence of regurgitation grades 3+ or 4+. Dashed lines are 68% confidence limits of average prevalence. MR = mitral regurgitation. repair[299] (Fig. 41-21). The temporal pattern of development of severe regurgitation was similar for those who received a Cosgrove partial, flexible band or a semirigid, complete Carpentier ring (25%), but it was substantially worse for those who received a strip of glutaraldehyde-preserved xenograft pericardium for annuloplasty (66%).[299] Smaller annuloplasty ring size apparently did not influence postoperative mitral regurgitation. These compelling results underscore how much additional work lies ahead in terms of developing new techniques and procedures in order to achieve a more durable valve repair.

Remodeling in ischemic mitral regurgitation

The development of IMR may not cause adverse LV remodeling, and some workers have proposed that IMR may be a manifestation rather than an important impetus for postinfarct remodeling, the extent of which may be determined by infarct size and location.[161] Anteroseptal and anteroapical infarcts lead to anterior akinesis (and in the days before thrombolysis or stenting for acute myocardial infarction, LV aneurysms); inferior and posterobasal infarcts more commonly cause progressive IMR. The extent of ventricular remodeling is a profound indicator of longevity. Mitral ring annuloplasty is fairly effective in treating IMR after inferior infarction at the time of surgical revascularization; however, annuloplasty may not induce favorable effects with respect to LV remodeling or survival.[161] Recurrence or progression of mitral regurgitation after ring annuloplasty coincides with LV volume increases (more adverse remodeling) and a more spherical ventricle; the only predictor of late postoperative mitral regurgitation was end-systolic LV sphericity index.[302] Restrictive mitral annuloplasty (undersizing by two ring sizes) may facilitate reverse remodeling, but this process is limited by the extent of preoperative LV dilatation.[289] In the study from Leiden, The Netherlands, a preoperative LV end-systolic dimension of 51 mm or less and an end-diastolic dimension of 65 mm or less predicted salutary reverse remodeling; however, the patients with IMR in this series were not typical.[289] The majority had sustained only one prior infarction relatively recently before operation, which might explain the excellent survival and favorable reverse LV remodeling observed. The gradual reductions in LA dimension and LV reverse remodeling were time-dependent processes in patients with IMR and ischemic cardiomyopathy who underwent coronary revascularization and valve repair with undersized annuloplasty. LV end-systolic dimension was smaller in 73% of patients, but LV end-diastolic dimension fell in only 56%; in those with larger LV dimensions preoperatively, no reduction in LV end-systolic or end-diastolic dimensions was seen in 27% and 42% of patients, respectively.[289] Since pronounced LV dilatation may be irreversible, it is logical to postulate that earlier mitral valve intervention to eliminate the chronic volume overload might halt the progression of LV dysfunction and mitigate the dismal prognosis.

Surgical considerations in ischemic and functional mitral regurgitation

Given the diversity of potential mechanisms contributing to the development of IMR and ischemic cardiomyopathy, current surgical therapy consisting of mitral annuloplasty with an undersized ring does not always provide a predictable or durable repair.[158,272,273,281,289,303] Because of the geometric interdependence of the entire valvular-ventricular complex, any intervention that remodels the annulus or alters LV geometry also would affect papillary muscle position and motion. Unfortunately, ring annuloplasty may not protect against recurrent IMR in patients with substantial outward (lateral) displacement of the posteromedial papillary muscle, as commonly seen after an inferior infarction. Although annuloplasty can improve both annular and subvalvular geometry in patients with IMR, leaflet apical tethering (type IIIb) often persists owing to posteromedial papillary muscle displacement, the severity of which may predict annuloplasty

failure because leaflet tenting and regional LV myocardial scarring are important contributing factors.[272,273,281,289,303] The higher incidence and greater severity of IMR in patients with inferior compared with anterior myocardial infarction is related to more severe geometric changes in the mitral subannular apparatus and greater lateral displacement of the posteromedial papillary muscle.[156] Understanding these changes has therapeutic implications in terms of infarct plication and leaflet or chordal elongation to minimize leaflet tethering. Surgical techniques that focus on LV reshaping in the segments adjacent to the papillary muscles, such as papillary muscle relocation, papillary muscle sling, and infarct restraint procedures, may have an impact on the degree and recurrence of IMR.[156,158,165]

Experimentally, a partial, flexible posterior annuloplasty ring has been shown to be just as effective as a complete semirigid ring in limiting septolateral annular dilatation during acute myocardial ischemia.[304] Another experimental procedure that may restore mitral competence during acute ischemia is the Paneth suture annuloplasty, which maintains normal annular and leaflet dynamic motion; this approach corrects ischemia-induced end-systolic distortions of the valvular-ventricular complex (i.e., interleaflet separation, mitral annular dilatation in both axes, and papillary muscle displacements) and abolishes acute IMR independent of any changes in LV end-systolic size.[305,306] In experimental chronic IMR, on the other hand, the mitral valve and subannular geometry are markedly distorted with leaflet tethering, and a complete, rigid annuloplasty ring is superior to a partial ring annuloplasty technique.[303] A novel rigid annuloplasty ring (Edwards Geoform) that radically downsizes the septolateral annular dimension and elevates the midposterior annular region has been introduced that it is claimed reduces IMR more reliably.[307]

Other experimental approaches have been proposed to treat IMR and FMR as a result of ischemic or dilated cardiomyopathy, such as infarct reduction using external plicating sutures, infarct restraint with an external mesh patch, external repositioning of the displaced posteromedial papillary muscle using an epicardial synthetic patch containing an inflatable balloon, internal papillary muscle repositioning using interpapillary sutures, or placement of subvalvular chord to reduce the annular septolateral dimension.[152,308–320] In a model of posterolateral myocardial infarction with resulting annular septolateral dilatation, posteromedial papillary muscle lateral displacement, and posterior leaflet tethering, septolateral annular cinching (SLAC, a simple transannular suture anchored to the midseptal annulus and externalized through the midlateral annulus) successfully moved the lateral annulus and the posteromedial papillary muscle closer to the septum and reduced IMR in both acute and chronic preparations[309–311,320] (Fig. 41-22). This Stanford SLAC suture concept has been developed further recently using a catheter-based device.[321] In an ovine model of rapid-pacing heart failure and FMR, the PS^3 device (Ample Medical, Foster City, CA) achieved septolateral cinching using a supra-annular

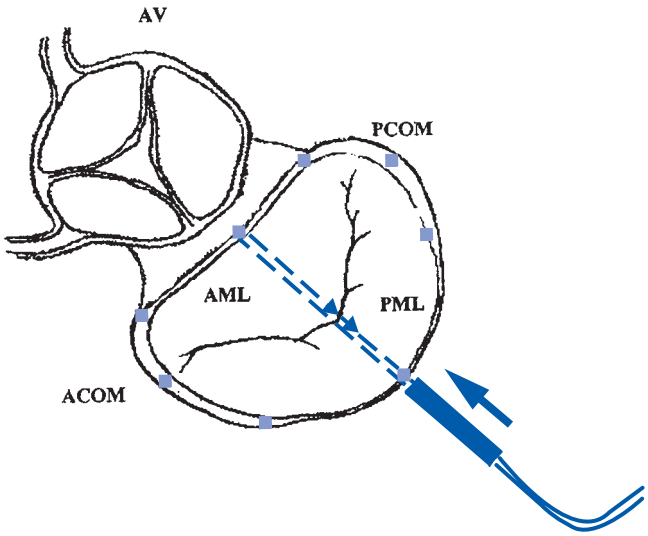

Figure 41-22. Schematic illustration of the mitral valve with annular and leaflet markers. Septolateral annular cinching suture (*dashed line*) spans the annular septolateral dimension and was externalized to an epicardial tourniquet. Arrow shows the direction of annular cinching. SLAC = septolateral annular cinching; AV = aortic valve; ACOM = anterior commissure; PCOM = posterior commissure; AML = anterior mitral leaflet; PML = posterior mitral leaflet. tightening member crossing the septolateral axis of the valve inside the left atrium. Based on the SLAC concept, the Coapsys device (Myocor, Inc., Maple Grove, MN), consisting of epicardial anterior and posterior pads connected by a transventricular chord, reduces septolateral annular diameter and relocates the posteromedial papillary muscle, thereby improving regurgitation in a cardiomyopathy model.[314,315] Clinically, applying the Coapsys device at the time of coronary revascularization reduced IMR and LV dimensions with no hemodynamic compromise or structural damage to the mitral apparatus. After 1 year, there was no grade 3+ to 4+ recurrent IMR, and no patient required reoperation for valve repair.[315] The Coapsys device coupled with off-pump coronary artery bypass grafting is now being compared prospectively (RESTOR-MV trial) with on-pump CABG and conventional undersized mitral ring annuloplasty.[319] Another experimental approach that corrects the end-systolic displacement of the posteromedial papillary muscle tip during acute ischemia and reduces IMR is tightening an exteriorized suture placed between the right fibrous annular trigone and posteromedial papillary muscle tip to reposition the papillary muscle.[322] A less invasive treatment in patients who have bundle-branch block (prolonged QRS > 120 ms), congestive heart failure, and functional mitral regurgitation or IMR is cardiac resynchronization therapy (CRT) with biventricular pacing. CRT can result in reverse LV remodeling, improved ejection fraction, and less IMR, but only fewer than half of patients respond favorably.[323–325] CRT may improve FMR

in some patients without any effect on LV size or systolic function by reducing LV dyssynchrony.

Because the second-order chordae tendineae anchor the valve leaflet and are more prominent on the anterior leaflet, transposition of posterior leaflet second-order chordae to the anterior leaflet has been used to correct anterior mitral valve leaflet prolapse. Recently, surgical division of the second-order chordae subtending the infarcted wall (usually those originating from the posteromedial papillary muscle) has been proposed to treat patients with chronic IMR.[326,327] If the apical systolic tethering is eliminated, the normal redundancy of the mitral leaflet area then creates better coaptation. The intact first-order or marginal chordae continue to prevent leaflet prolapse. On the other hand, division of the mitral chordae, especially the second-order or "strut" chordae, is known to impair LV systolic function.[160,328,329] Dividing the second-order chordae in an acute ovine preparation is associated with regional LV systolic dysfunction near the chordal insertion sites and neither prevents nor decreases the severity of acute IMR, septolateral annular dilatation, leaflet tenting area, or leaflet tenting volume.[160,328] Cutting the anterior mitral leaflet second-order chordae alters LV chamber long-axis and subvalvular geometry, remodels end-diastolic transmural myocardial architecture in the equatorial lateral LV region, perturbs systolic transmural LV wall-thickening mechanics (thereby decreasing subendocardial "microtorsion") and wall thickening, changes systolic temporal dynamics with delayed ejection, and impairs global LV systolic function (decreased end-systolic elastance and PRSW).[329] These findings demonstrate the importance of the chordae for LV structure and function; therefore, we believe that caution is necessary when considering procedures that cut second-order chordae to treat IMR because this may compromise LV systolic function in ventricles that are already impaired.[160,328,329]

Because IMR may be a consequence and not a cause of postinfarction LV remodeling, prevention of infarct expansion has been proposed as a more promising therapeutic target. It is possible that infarct expansion and LV stretching are the critical inciting phenomena that drive postinfarction remodeling.[161] Experimentally and clinically, prophylactic ventricular restraint or ventricular wrapping may reduce infarct expansion, attenuate adverse LV remodeling, preserve ejection fraction, and reduce the severity of IMR.[317,330,331] Prevention of IMR by prophylactic ring annuloplasty may not influence LV remodeling, but ventricular wrapping may be effective in preventing the development of IMR.[317,331]

Mitral Subvalvular Apparatus in LV Function

Originally proposed by Lillehei and colleagues in 1964, the mitral subvalvular apparatus (or valvular-ventricular complex), including chordal and papillary muscle function, is important for optimal postoperative LV geometry and systolic pump function.[137–141,204,205,332–338] After mitral valve replacement with total chordal excision, LV performance declines with depression of regional and global LV elastance, dyssynergy of contraction, and dyskinesia at the papillary muscle insertion sites; conversely, valve replacement with total or partial chordal preservation maintains LV contractile function.[137–140,224,338] Experimentally, severing either the anterior or the posterior leaflet chordae impairs global LV systolic function, as evidenced by reduced maximal elastance, but this is reversible if chordal reattachment is carried out.[139] The contributions of the chordae subtending the anterior mitral leaflet are slightly greater than the contributions of the posterior leaflet chordae, but these components are additive.[138] In a canine model of chronic mitral regurgitation, mitral valve replacement with chordal preservation (compared with chordal severing) optimized postoperative LV energetics and ventriculovascular coupling in addition to enhancing systolic performance.[205] Chordal interruption decreased global LV end-systolic elastance and depressed the end-systolic stress-volume relationship. In terms of myocardial energetics, the slopes of the LV stroke work–end-diastolic volume and pressure-volume area–end-diastolic volume relations also declined, indicating a reduction in external stroke work and mechanical energy generated at any given level of preload.

Clinically, mitral valve replacement with chordal division is associated with reduced rest and exercise LV ejection fraction owing in part to an increase in LV ESS.[337] Mitral valve repair does not perturb rest and exercise ejection indexes of LV function primarily as a consequence of reducing ESS and maintaining a more ellipsoidal chamber geometry. Mitral valve replacement with complete chordal transection results in no postoperative change in LV end-diastolic volume, an increase in LVESV, an increase in ESS, and a decrease in ejection fraction.[336] Patients who undergo chordal-sparing valve replacement, on the other hand, have a smaller LV end-diastolic volume and LVESV, decreased ESS, and unchanged ejection fraction. These findings suggest that reduced chamber size, reduced systolic afterload, and preservation of ventricular contractile function act in concert to maintain ejection performance after chordal-sparing mitral valve procedures. In contrast, increased LV chamber size, increased systolic afterload, and probable reduction in LV contractile function leading to reduced ejection performance occur in patients who undergo valve replacement with chordal transection.[336] Indeed, the 2006 ACC/AHA valve practice guidelines now stipulate that the subvalvular apparatus be preserved whenever possible when the mitral valve must be replaced, including chordae to both mitral leaflets.[246]

The loss of ventricular function after mitral valve replacement with chordal division may be due to heterogeneity of regional LV wall stress and not to local depression of regional contractile function.[339] After valve replacement with chordal transection in an experimental model, outward displacement of the ventricular wall and transverse shearing deformation were observed in the LV region papillary muscle insertion during isovolumic contraction.[339] Circumferential and radial strains during ejection were maintained at the basal LV site and enhanced in the apical LV site. Chordal

transection augmented regional myocardial loading at the papillary muscle insertion site; the resulting heterogeneity of regional systolic function might be the mechanism for reduced global LV function and slowed ventricular relaxation. Anterior chordal transection with mitral valve replacement caused impaired regional LV function and also impaired regional right ventricular function,[340] whereas radionuclide angiography before and after mitral valve repair showed that LV ejection fraction did not change and right ventricular ejection fraction improved. In the region of the anterolateral papillary muscle insertion, local LV contractile function deteriorated after valve replacement with chordal transection, and right ventricular apicoseptal region was similarly impaired.[340]

Summary

The functional competence of the mitral valve relies on the interaction of the mitral annulus and leaflets, chordae tendineae, papillary muscles, left atrium, and left ventricle. Dysfunction of any one or more components of this valvular-ventricular complex can lead to mitral regurgitation. Important causes of mitral regurgitation include ischemic heart disease with IMR, dilated cardiomyopathy leading to FMR, myomatous degeneration and prolapse, rheumatic valve disease, mitral annular calcification, and infective endocarditis. Four structural changes of the mitral valve apparatus may produce regurgitation: leaflet retraction from fibrosis and calcification, annular dilatation, chordal abnormalities, and LV systolic dysfunction with or without papillary muscle involvement. In IMR, changes in global and regional LV function and geometry, alterations in mitral annular geometry, abnormal leaflet (type IIIb) motion, leaflet malcoaptation, increased interpapillary distance, and papillary muscle lateral displacement and malalignment all may result in apical tenting of the leaflets and mitral incompetence.

With mitral regurgitation, the impedance to LV emptying is lower because the mitral orifice is in parallel with the LV outflow tract. Reduced LV impedance allows a greater proportion of contractile energy to be expended in myocardial fiber shortening than in tension development. After the initial compensatory phase, LV contractility becomes progressively more impaired with chronic mitral regurgitation owing to the chronic LV volume overload. Importantly, because of the low impedance during systole, clinical indexes of systolic function, such as ejection fraction, can be normal even if depressed LV contractility is already present. LVESV is less dependent on preload than is ejection fraction and is a better measure of LV contractile reserve. Preoperative LVESV is a good predictor of postoperative outcome. Surgical mitral valve repair (or, if repair is judged not to be durable, mitral valve replacement with total chordal preservation) for chronic mitral regurgitation can preserve LV contractility, particularly in patients with a normal preoperative ejection fraction who have minimal ventricular dilatation and those without major coronary artery disease. In patients with impaired LV contractility preoperatively, LV systolic function may not necessarily improve after operation and certainly will not if the chordae are divided during mitral valve replacement.

IMR is associated with a higher operative risk than is nonischemic chronic mitral regurgitation. In patients with ischemic cardiomyopathy and mild mitral regurgitation, isolated coronary artery bypass grafting may suffice if most of the ventricle is still viable. Other workers argue that coronary revascularization alone in the setting of moderate IMR leaves many patients with substantial residual mitral regurgitation, heart failure symptoms, and a grave prognosis. Because moderate IMR does not resolve reliably with coronary revascularization alone, valve repair (undersized mitral annuloplasty with or without other adjunctive techniques) should be considered because it can reduce complications and possibly may improve long-term survival. Survival after mitral valve surgery and coronary artery bypass grafting may be more determined by the extent of coronary artery disease and LV dysfunction than by the etiology of mitral regurgitation. IMR may be a manifestation rather than an important impetus for postinfarct LV remodeling. Surgical procedures that focus on LV reshaping and/or external cardiac constraint may have an impact on the degree and recurrence of mitral regurgitation.

The mitral subvalvular apparatus is a key component of LV ejection performance; an intact mitral subvalvular apparatus, including chordae to both leaflets, is necessary to maintain optimal postoperative LV geometry and optimize postoperative systolic pump function. After mitral valve replacement with chordal transection, LV systolic performance declines (depressed regional and global LV elastance, dyssynergy of contraction, and dyskinesia at the papillary muscle insertion sites). A large cascade of experimental and clinical findings suggests that reduced LV chamber size, reduced LV systolic afterload, and preservation of ventricular contractile function act in concert to maintain ejection performance if mitral valve repair or chordal-sparing valve replacement techniques are employed.

CHAPTER 42

Mitral Valve Repair

Frederick Y. Chen • Lawrence H. Cohn

Sir Thomas Lauder Brunton, a Scottish physician, first introduced the concept of surgical repair of the mitral valve in 1902.[1] Twenty-one years later, Elliot Cutler, the future Moseley Professor of Surgery at the Peter Bent Brigham Hospital in Boston, performed the world's first successful mitral valve operation in 1923 by carrying out a transventricular commissurotomy with a neurosurgical tenotomy knife. A new era in surgery was introduced as well as the reality of mitral valve repair.[2] Cutler had worked assiduously on this problem in the Surgical Research Laboratories of Harvard Medical School before turning his attention to a critically ill, bedbound 12-year-old girl, performing mitral valvulotomy on May 20, 1923. With that seminal operation, the idea of surgically restoring normal anatomy to the pathologic mitral valve came to fruition. Subsequent attempts at transventricular valvulotomy with a cardiovalvutome to produce graded mitral regurgitation resulted in several deaths and Cutler eventually abandoned the procedure.[3] Of Cutler's contemporaries, Henry Souttar of England performed a single successful transatrial finger commissurotomy in 1925, but received no further referrals.[4] After Souttar there remained little activity in mitral valve repair until Dwight Harken, then the Chief of Cardiothoracic Surgery at the Peter Bent Brigham Hospital, published his groundbreaking series of valvuloplasty patients for mitral stenosis[5] along with Charles Bailey in Philadelphia.[6]

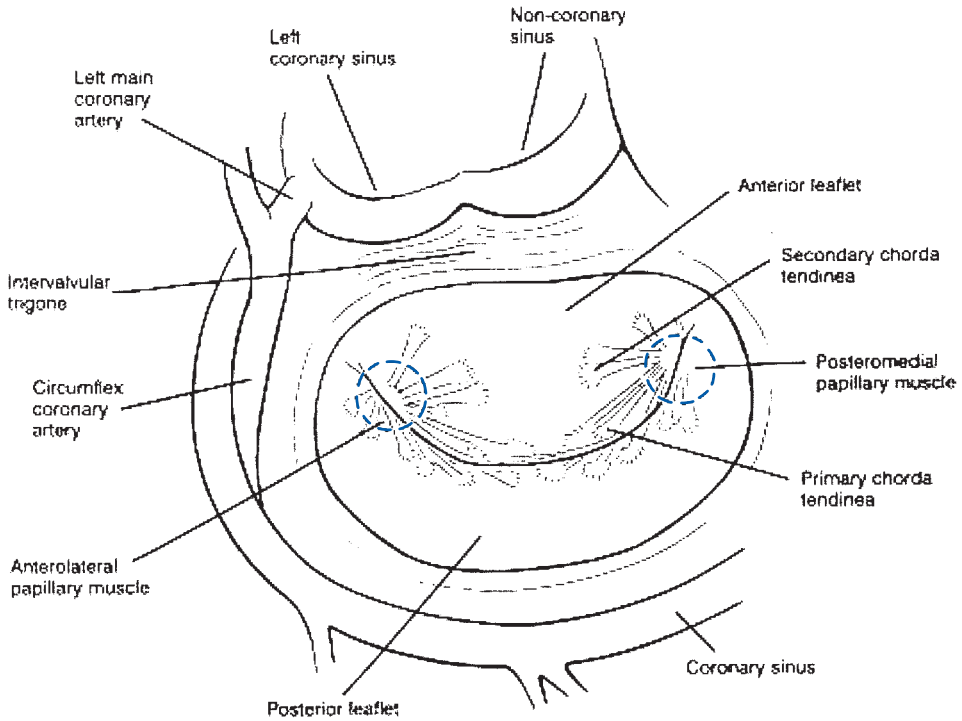
That early era focused on mitral stenosis created by rheumatic heart disease, which was extremely common at the time. Surgical treatment of mitral regurgitation for prolapse was first introduced in the 1950s[7–9] but with limited success. Later, in the '60s, '70s, and '80s, the visionary concepts and ideas first disseminated by Carpentier[10] and Duran,[11] and later promulgated by others,[12–14] stimulated the field. Initially, those ideas, like any other groundbreaking idea, were met with resistance that has gradually dissipated as long-term results by these surgeons have been validated. In particular, the idea that repair of mitral regurgitation might damage a weakened left ventricle by eliminating the left atrium as a low-resistance "pop-off" valve[15] proved a significant barrier to referral that only in the past decade has been overcome. What has now become firmly established is the significant contribution to overall left ventricular function of the papillary muscle–annular interaction.[16] As a result of these contributions, mitral valve repair, if technically possible, has now become recognized as the procedure of choice for mitral valve pathology of any etiology, even for patients with cardiomyopathy and heart failure,[17] to the extent that mitral valve repair is always considered first in virtually any clinical situation in which the mitral valve is regurgitant.

This chapter will focus on repair of the myxomatous, degenerated valve with some consideration of the repair of the rheumatic mitral valve. Repair of ischemic or infected mitral valves is presented in Chapters 30 and 44, respectively. Detailed pathophysiology of the mitral valve is presented in Chapter 41.

ANATOMY OF THE MITRAL VALVE

A surgical dictum is that form follows function and this is particularly apropos for the mitral valve. The bicuspid mitral valve is one of the most complex structures of the human heart; its complexity lies in its multifaceted anatomy. Because each part of the anatomy is intimately related to function, there are a variety of pathways whereby regurgitation may be created. If one part of the valvular apparatus fails, regurgitation results. There are five discrete components to the mitral valve complex: the annulus, the two leaflets (anterior and posterior), the chordae, the papillary muscles, and the left ventricle itself (Fig. 42-1A).

As part of the fibrous skeleton of the heart, the annulus is the circular area where the mitral valve leaflets attach to the intersection of the left atrium and ventricle. It is surrounded



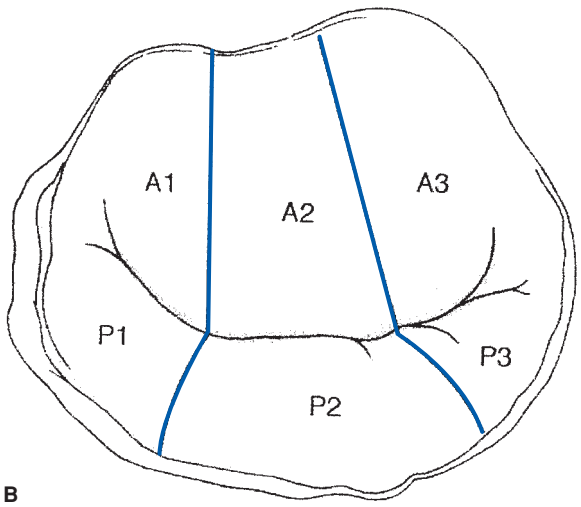


Figure 42-1. Surgical anatomy of the mitral valve. Panel A depicts critical structures that the cardiac surgeon must recognize, including the circumflex coronary artery, the coronary sinus, the atrioventricular node, and aortic root. Note that the left and right trigones are superior to the commissures. Panel B depicts the conventional terminology used to describe the pathoanatomic parts of the anterior and posterior leaflets.

by vitally important structures that the cardiac surgeon must avoid for safe surgery: the circumflex coronary artery laterally, the coronary sinus medially, the aortic root superiorly, and the atrioventricular node superior-medially. In myxomatous disease it is the posterior annulus that usually dilates.[18] Previous dictum held that the anterior annulus does not dilate, but recent data suggest that it may dilate a limited amount.[19] Of critical importance to the surgeon are the right and left fibrous trigones. These are intimately related to the anterior annulus and are contiguous with the aortic valve curtain and must be identified during surgery. The trigone points form anchoring points for ring annuloplasty.

The anterior leaflet of the mitral valve (AML) is in continuity with the left and noncoronary cusps of the aortic valve and is located directly beneath the left ventricular outflow tract (LVOT). It typically accounts for approximately 40% of the circumference of the annulus with the posterior leaflet accounting for the rest.[20] The posterior mitral valve leaflet (PML) is crescent-shaped and dilates more commonly in degenerative disease. For surgical decision making and analysis, both the anterior and posterior leaflet are divided into three parts, corresponding to the typical three scalloped areas of each leaflet (A1, A2, A3 for the anterior leaflet; P1, P2, and P3 for the posterior leaflet; 1 refers to the leftmost, or lateral scallop; 2 the middle scallop; and 3 the rightmost, or medial scallop; Fig. 42-1B).

There are two papillary muscles, the anterolateral and the posteromedial. Each muscle is attached to the leaflets by the chordae tendinae, chords of stringlike fibrous connective tissue. Primary chords are those that attach to the edge of the

leaflet. Secondary chords are those that attach to the underside of the leaflet. Tertiary chords (only the posterior leaflet has tertiary chords) are those that attach to the undersurface of the leaflet directly from the ventricular wall instead of from the papillary muscle. The papillary muscles each give off chordae to both leaflets and correspond to the anterolateral and posteromedial commissures of the mitral valve. The anterolateral papillary muscle receives blood from both the left anterior descending artery as well as the circumflex artery; the posteromedial one receives blood usually from only the posterior descending artery or a branch of the circumflex artery. Because of its single coronary blood supply, the posteromedial papillary muscle is more susceptible to infarction and rupture than the anterolateral one.

The left ventricle acts in concert with the papillary muscles via the chordae to pull in the leaflet edges during systole, thereby maintaining the line of coaptation and therefore valve competency. If the left ventricle dilates or is ischemic, the competency of the valve may be affected adversely and regurgitation created.

MYXOMATOUS MITRAL VALVE DISEASE

Etiology and Pathophysiology

The underlying etiology of myxomatous disease is a defect in the fibroelastic connective tissue of the valvular leaflets, chordae, and annulus.[21] The myxomatous defect leads to an abnormal elongation and redundancy of valve tissue and chordae. Each particular anatomic redundancy creates mitral regurgitation in its own particular manner. Annular dilatation (Fig. 42-2) obliterates the normal coaptation line between the anterior and posterior leaflet, causing regurgitation. Because of primarily posterior annular dilatation there is a separation in the middle of the valve between the two leaflets and blood leaks through during ventricular contraction. Leaflet redundancy results in a movement of the redundant leaflet into the left atrium during diastole. If severe enough, that movement leads to a compromised coaptation line and mitral regurgitation (MR) then occurs. Elongation of the chordae also causes leaflet tissue to move into the atrium during diastole, also resulting in compromised coaptation. Ruptured or flail leaflets are often the result of systolic stresses fracturing weakened chordae, causing severe regurgitation.

Mitral regurgitation represents pure volume overload for the left ventricle.[22] In myxomatous disease, MR is typically of the chronic compensated variety.[23] A vicious circle is perpetuated whereby the excess volume load over time results in ventricular failure. Ventricular failure itself implies ventricular dilatation, which results in a greater degree of MR. Thus, MR begets more MR, so a vicious downward spiral is created.[16] MR created by left ventricular failure occurs primarily by ventricular dilatation. Successful repair will result in left ventricular mass reduction.[24] By dint of the papillary muscles, ventricular dilatation "pulls" or "tethers" the leaflets open, thereby impinging on coaptation. In degenerative disease of the mitral valve, however, the left ventricle itself per se does not primarily cause MR in the early course of the disease.

Carpentier has developed a mitral valve analysis protocol and surgical philosophy for repair of all types of valves (Fig. 42-3). Myxomatous disease has become the pathology responsible for the vast majority of mitral regurgitation in the United States.[25] Currently, mitral valve prolapse, as a part of the spectrum of degenerative disease, is present in about 5% of the general population,[26] with about 10% of these patients exhibiting severe MR requiring surgery.[27] Whatever the ultimate pathologic pathway creating regurgitation, 80 to 90% of all degenerative disease should be amenable to successful repair.

Diagnostic Work-Up and Indications for Operation

Patient presentation is typically quite varied depending on the degree of MR as well as the chronicity of the disease. Patients may be floridly symptomatic or completely asymptomatic. Symptomatology is usually of two varieties. Failure symptoms are secondary to pulmonary venous hypertension as well as fluid retention. This may include shortness of breath, limited exertional capacity, fluid overload, and in the

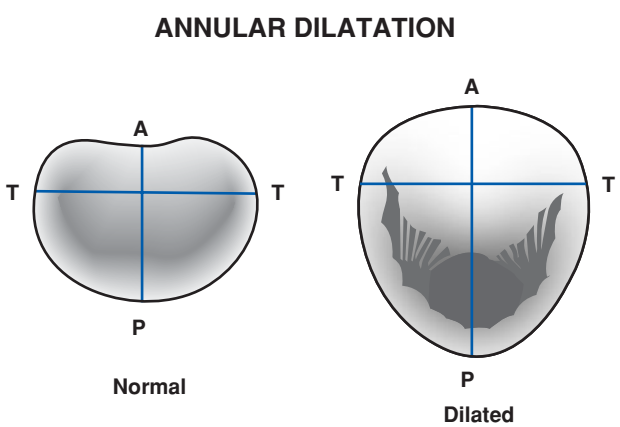

Figure 42-2. Annular dilatation. A = anterior; P = posterior; T = trigone.

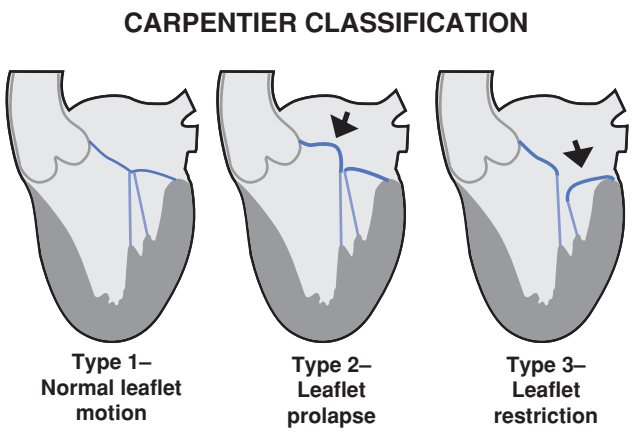

Figure 42-3. Carpentier classic mitral valve classification.

late stage of the disease, heart failure. Embolization sequelae and arrhythmias form a second set of symptoms and include atrial fibrillation and increased stroke risk;[28] regurgitation predisposes the valve to infectious endocarditis.[29] Abnormal hemodynamics create pathologic shear stresses and turbulence that generates vulnerability to infection in the valve.

The critical question for any valvular pathology is the timing of surgery. The first consideration is the MR itself. Echocardiography remains the gold standard for assessing mitral regurgitation. The key information obtained is the degree of MR, its associated pathophysiology, cardiac chamber dimensions, and left ventricular functional analysis. Transthoracic echocardiography is usually the first modality employed. However, if images from transthoracic echocardiography are of insufficient quality, then transesophageal echocardiography (TEE) is required. Mitral regurgitation is graded on a scale from mild to severe with severe typically referring to a reversal of pulmonary venous blood flow in the left atrium.[30] Methods used to determine the degree of regurgitation commonly include regurgitant volume, regurgitant fraction, and orifice area.[30] Echocardiographic analysis of the MR (e.g., flail leaflet, ruptured chordae, or anterior or posterior prolapse) is extremely helpful in planning the operative intervention. Other crucial information obtained by the preoperative echo includes left atrial size, ventricular function, ventricular dilatation, aortic valve function, and tricuspid valve function. Ventricular function is a key component in assessing operative candidacy; a left ventricular ejection fraction below the norm of 60% indicates some degree of myocardial decompensation secondary to volume overload.

What, precisely, are the indications for operation? The past decade has seen a tremendous improvement in the practice and science of cardiac surgery, such that patients who would never have been considered for surgery a decade ago are now routinely being offered repair surgery at much earlier stages of their disease. The indications for mitral valve repair have broadened as the success of repair has so dramatically improved over the last several years. Better myocardial protection and cardiopulmonary bypass technology, minimally invasive incisions, increased incidence of repair, and better intensive care unit care have all contributed to the phenomenon.[31] The biggest change has been an overall broadening of the indications for mitral valve repair and lowering of the threshold for operation because of these factors.[32]

Repair itself, as opposed to replacement, is now accepted as the superior treatment for mitral regurgitation. Out of a long laboratory and clinical experience has come the conclusions that repair is associated with better survival, enhanced preservation of ventricular function (by preserving the chordae and papillary muscles), durability of repair, and decreased late thromboembolic complications.[33–36]

Whether or not a patient is offered valve repair depends on the degree of regurgitation, the pathophysiology of the regurgitation, ventricular function, and surgeons' consistent ability to perform mitral valve repair. At Brigham and Women's Hospital, virtually any patient with severe MR is offered mitral valve repair, regardless of symptoms and ventricular function, unless other comorbidities make repair problematic. Asymptomatic patients are offered valve repair if evidence exists of myocardial decompensation by echocardiography, such as cardiac chamber enlargement or pulmonary hypertension. Such patients will usually demonstrate left ventricular or left atrial dilatation or both. For all patients with moderate to severe MR and decreased ventricular function (left ventricular ejection fraction $<60\%$) valve repair is offered, as the ventricle has exhibited signs of decompensation even with a lesser degree of MR; repair in this setting is much more urgent, as severe decompensation can occur in a matter of months as left ventricular function begins to deteriorate.

The intermediate situation of moderate mitral regurgitation and preserved ventricular function is the one in which the most judgment must be exercised. Consider the situation of a structurally normal mitral valve with moderate MR, but with concomitant critical aortic stenosis. The patient is to undergo and aortic valve replacement. Should the mitral valve be repaired? Perhaps not, as the moderate MR here is likely secondary to that patient's aortic stenosis, and correcting the aortic stenosis would likely eliminate the MR in this structurally normal valve. However, only a ring annuloplasty would be needed to correct the posterior annular dilatation. If the same situation exists, however, with a structurally abnormal valve, such as a prolapsed P2 or markedly dilated mitral annulus, then mitral repair should be undertaken, because there is a structural abnormality that aortic valve replacement will not correct. What of moderate MR secondary to myxomatous disease (and not ischemia) in a patient who is to undergo coronary bypass grafting? That patient would likely be offered concomitant valve repair, as bypass grafting would not impact on the pathophysiology of the MR in this case. What of the situation of moderate to severe, isolated MR secondary to myxomatous disease and borderline normal ventricular function? Even without symptoms of heart failure, this patient should have repair performed on an elective basis. Once left ventricular function begins to deteriorate from the normal 60 to 70% left ventricular ejection fraction, decline may be unpredictably rapid and hence intervention warranted. Increasingly, moderate ischemic, as well as degenerative, MR is thought to be detrimental for long-term survival.[37,38]

In general, no matter what the chronological age, adequate functional status before valve repair is preferred. If symptoms of heart failure exist before surgery, optimal diuresis should be undertaken before operation. If the procedure involves coronary artery bypass grafting, the conduit status should be determined. Dental clearance on all patients should be obtained before any valvular procedure. If neurologic symptoms exist or if the patient has a history of a previous cerebrovascular disease, then preoperative carotid noninvasive studies are warranted to assess carotid arterial stenosis. All patients over 40 should undergo coronary angiography. Since the late 1990s patients with MR without coronary artery disease are offered minimally invasive valve repair as the standard procedure at Brigham and Women's Hospital.[39,40]

Whatever the scenario, the decision to operate and repair the valve is a decision made preoperatively as opposed to intraoperatively. Once the patient is under anesthesia, loading conditions are not physiologic and the mitral regurgitation assessed then is inevitably underestimated. Maneuvers used to "bring out the MR," such as increasing afterload with vasoactive drugs, do not reflect true physiology, but should be used in surgical decision making and may be helpful in some situations. Recent discussions of earlier referral for the treatment of MR clearly depend on a high rate of valve repair in any center.[41,42]

Operative Philosophy

Despite the success of mitral valve repair in specialized centers, there still persists a general reluctance to perform repair, particularly in the severe Barlow variety of degenerative disease. In 2003, for example, the Society of Thoracic Surgeons database indicated that only 36% of valves that could be repaired actually were repaired,[43] although this percentage has recently improved.

Beginning in the 1990s, we have developed what we think is a simple, reproducible algorithm that can be used to repair the degenerative mitral valve in most patients. Overriding this philosophy is the belief that mitral valve repair is not an esoteric "art form" that is difficult to explain, perform, or learn. Rather, we think it is a procedure like any other that should and can be simplified, disseminated, and reproduced with success. In keeping with this philosophy, we have reduced complicated bileaflet prolapse to a competent valve with simplified and straightforward maneuvers that we have found effective with good long-term results. Our overall philosophy and technique is as follows:

1. Expose the valve well through the complete development of the Sondergaard groove, division of pericardial attachments of the superior and inferior venae cavae.
2. Assess the valve through saline injection and corroborate the intraoperative findings with transesophageal echocardiography.
3. Perform basic, obvious leaflet repair procedures first (e.g., quadrangular resections to the posterior leaflet).
4. Implant the annuloplasty ring sized by the height of the anterior leaflet (not the trigones or commissures).
5. Test the repair.
6. Perform additional reparative procedures as needed.

With the above maneuvers, we estimate that approximately 90% of all degenerative valves can be repaired. If after placing the ring some residual leak remains on passive testing, further techniques may be used.

Collaborative involvement with cardiac anesthesia colleagues is essential in utilizing the invaluable tool of transesophageal echocardiogram monitoring for pre and postrepair assessment. In our clinic, standard TEE monitoring (either two-dimensional or three-dimensional) is now utilized for every patient undergoing mitral valve repair. In addition to documenting the efficacy of repair, TEE is essential in preventing and assessing the potential or persistence of systolic anterior motion of the anterior valve.

Operative Exposure

Because the mitral valve is such a complex anatomic structure and the maneuvers involved in correcting a regurgitant valve may vary from the simple to the very complex, adequate exposure is an absolute requirement in every operative plan. This becomes more important if minimally invasive techniques are employed. The first critical aspect to the standard valve repair is the complete and thorough development of the Sondergaard plane reflecting the right atrium off the left atrium to the atrial septum, as depicted in Fig. 42-4. This was first described in the 1950s by the Danish surgeon Sondergaard[44] to expose the atrial septum for noncardiopulmonary bypass treatment of atrial septal defects. In 1990 we stressed the importance of this particular technique for exposure in mitral valve surgery.[45] Regardless of even previous procedures, it should always be possible to dissect out the groove without significant difficulty. The complete and full development of the groove is a most important aspect to obtain adequate exposure of the mitral valve. With this technique, via blunt and sharp dissection we have not needed any other incision for mitral valve repair or replacement, whether for primary surgery or reoperation. This incision brings the surgeon very close to the mitral valve even in the most difficult anatomic situations. Once the right atrium is dissected off the left atrium, a generous incision in the left atrium is made, avoiding the atrial septum.

Minimally Invasive Technique

With the development of minimally invasive incisions for adult cardiac surgery this past decade, mitral valve surgery has undergone an evolution. The standard isolated mitral valve repair incision offered at Brigham and Women's Hospital since 1996 is a minimally invasive, lower hemisternotomy

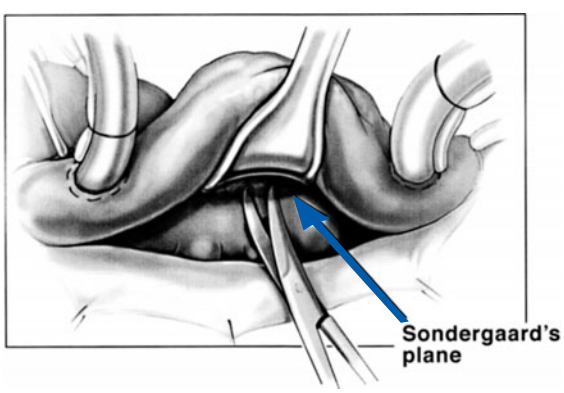

Figure 42-4. Dissection of Sondergaard's plane. Sondergaard's plane should be dissected at least 2 to 4 cm from the right superior pulmonary vein for adequate exposure of the mitral valve.

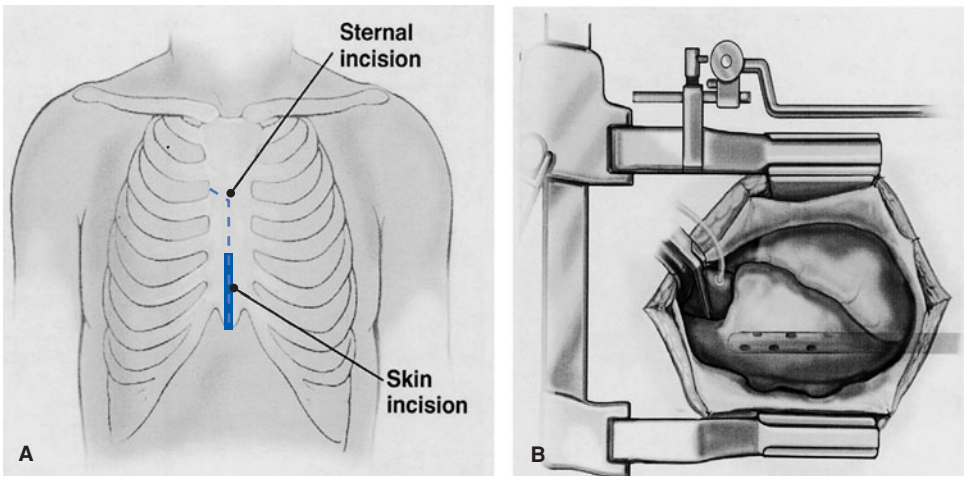

Figure 42-5. Minimally invasive mitral valve repair. (A) Via a 6- to 8-cm skin incision, a lower hemisternotomy through the right second interspace is performed. (B) Venous cannulation is percutaneous with vacuum assist. Aortic cannulation, cross-clamping, and cardioplegia administration are performed in the standard manner.

via a 6- to 8-cm skin incision[39] (Fig. 42-5A). Cannulation is typically performed with a percutaneous venous cannula via the femoral vein and vacuum-assisted drainage is employed (Fig. 42-5B). The vacuum applied never exceeds 80 mm Hg of suction. TEE guidance is used to place the venous cannula into the superior vena cava through the right atrium. The aorta is cannulated directly with a flexible 20F aortic perfusor. If venous drainage is inadequate even with vacuum assist, we cannulate the superior vena cava with an additional cannula. Details of other minimally invasive techniques are detailed in Chapter 45.

Cardiopulmonary Bypass

For cardiopulmonary bypass, we use a 22F percutaneous femoral vein venous catheter placed into the right atrium via the right femoral vein with TEE control. The cannula can even be advanced into the superior vena cava if desired. Because the cannula has multiple holes, is flexible and thus can still drain the inferior vena cava, this one cannula is sometimes all that is needed for drainage of both the superior and inferior vena cava. If performing a concomitant bypass procedure requiring a full sternotomy, then venous cannulation should be bicaval via the atria. One venous cannula should be placed in the superior vena cava above the right atrial/superior vena caval junction and the other through the lowest part of the right atrium into the mouth of the inferior vena cava. The arterial cannula should be placed directly into the distal ascending aorta.

Once on cardiopulmonary bypass, systemic temperature is allowed to drift to 34°, the ascending aorta is cross-clamped, and the heart arrested by cold blood cardioplegia. For isolated valve repair, some debate still exists regarding the use of retrograde or antegrade blood cardioplegia after cross-clamping. If there is concomitant coronary artery disease, myocardial protection in this circumstance should be antegrade and retrograde, as the coronary artery bypass graft/mitral operation presents one of the highest-risk operative settings in cardiac surgery.[34]

After the heart is arrested, the left atrium is opened well above the right superior pulmonary vein near the septum inferiorly. Retractors are placed (Fig. 42-6). The patient's bed is placed head up with a tilt to the left. A wire-reinforced suction catheter is placed in the left inferior pulmonary vein (the most dependent portion of the left atrium in this position) for drainage of collateral blood flow. Carbon dioxide is infused to minimize intracardiac air.

Alternate exposures can be obtained by the transseptal approach through the right atrium[46] or the superior septal approach.[47] The transseptal approach is a perfectly

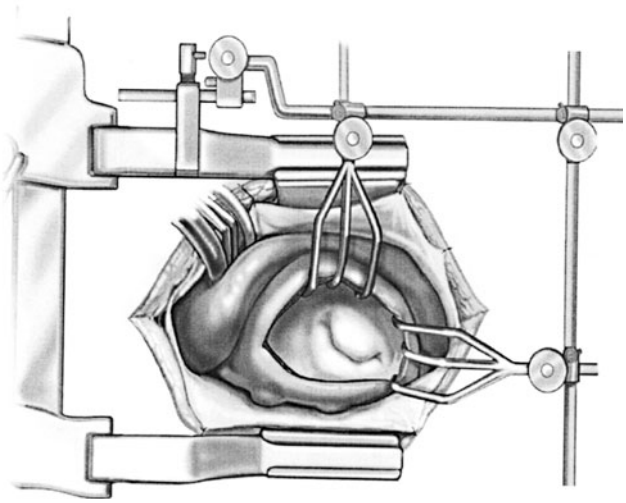

Figure 42-6. Minimally invasive operative exposure. After the retractors are placed, the patient is positioned with head up and the operative bed tilted to the left. Exposure is excellent.

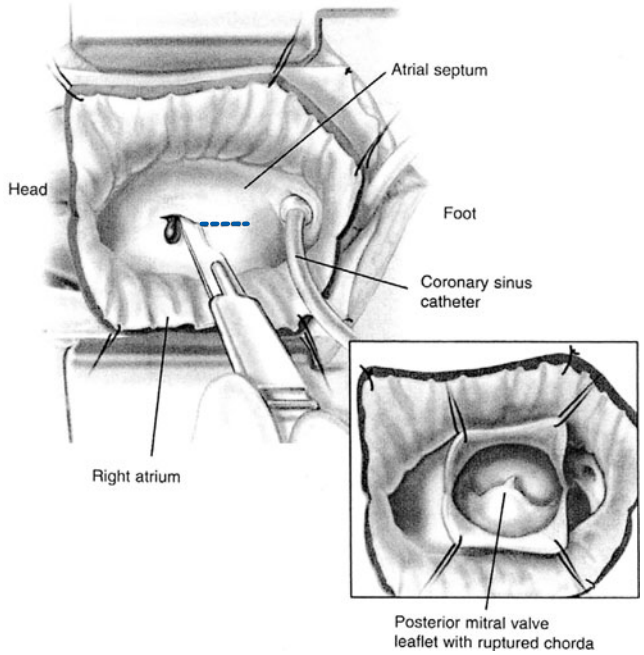

Figure 42-7. Transseptal exposure of the mitral valve. After the right atrium is incised, the septum is divided across the fossa ovalis, and stay sutures are placed. This incision allows very good access to the mitral valve and is an alternative to the Sondergaard plane.

acceptable incision that allows the cardiac surgeon to be close to the mitral valve by carrying the incision through the fossa ovalis (Fig. 42-7) and up into the superior vena cava. Retraction sutures and other types of retraction devices can be utilized to expose the mitral valve exceedingly well, particularly in these minimally invasive cases. This approach may also be helpful in patients who have had previous operations on the mitral valve or when concomitant procedures on the tricuspid valve are required.

Examination of Valve and Valve Analysis

Once exposure is obtained and a self-retaining retractor is in place, inspection of the valve is carried out. Valve analysis takes a few minutes utilizing nerve hooks, forceps, and insufflation of the ventricle with saline to determine and corroborate the pathology already diagnosed by intraoperative TEE. Valve analysis may reveal ruptured chordae or simply a prolapse of the valve with elongated chords and one or more prolapsed sections of the valve. The anterior leaflet, though frequently advertised as part of "bileaflet prolapse," often has normal-length chordae and may be without specific leaflet or subvalvular pathology. Prolapse of the commissures may be found, and calcified nodules may exist that may present difficulty in mitral valve repair and may need excision. There may be healed endocarditic vegetations on one or more parts of the valve. The annulus will almost always appear to be distorted, dilated, or deformed in long-standing cases, particularly in Barlow syndrome.

Repair Strategy

After the analysis of the valve is carried out, a detailed reparative strategy can be deduced from the pathologic analysis. In a broad generalization, degenerative disease of the mitral valve creates what amounts to a posterior mitral valve leaflet that is too large, with or without flail segments, in an annulus that is functionally too small for the anterior leaflet. In degenerative disease, most commonly the posterior leaflet is usually pathologic while the anterior leaflet usually is not. The first principle of the repair is to reduce or obliterate the enlarged posterior segments and to reduce the overall height of the posterior leaflet to prevent systolic anterior motion (SAM) of the anterior leaflet. If the height of the posterior leaflet is too high, it will push the anterior leaflet into the LVOT and create SAM. In general, the height of the posterior leaflet should be no more than 1 to 1.5 cm in average-sized patients once the repair is complete. Once the posterior leaflet reduction is performed, one must ensure that the anterior leaflet coapts with the subsequently reduced posterior leaflet within the correct plane. The resulting repair should result in a coaptation line at the level of the annulus during systole. Specific methods to lower the height of the posterior leaflet and anterior leaflet will be addressed below.

The second principle is that a remodeling annuloplasty ring is essential for all repairs. This is a fundamental concept of Carpentier[18] and Duran,[48] both of whom developed mitral valve annuloplasty rings early in the history of mitral valve regurgitation surgery and advocated remodeling of the distorted annulus as a key principle of mitral valve repair. The annulus, after many years of regurgitation, is often deformed and in myxomatous disease, it is floppy and dilated. The best approach to conceptualize the floppy and dilated annulus in myxomatous disease is to consider it functionally too small for the anterior leaflet. Why too small if it is floppy and dilated? If floppy with redundant tissue, the annulus will not provide the relatively stable skeleton necessary for the anterior leaflet to spread out completely and thus coapt at the correct line and in the correct plane with the posterior leaflet. Rather, the floppy annulus will buckle and have an effectively smaller radius, and cause the anterior leaflet to appear as though it is "prolapsing" because the leaflet cannot spread out correctly. In reality the pathology is within the annulus. That is why we believe that oversizing the ring in degenerative disease is important. The ring then re-creates the relatively rigid, broad annulus that allows the anterior leaflet to spread out and coapt in the correct plane, at the correct coaptation line, without "prolapsing." A structurally sound annulus is necessary for the correct physiologic function of the anterior leaflet. Hence, our protocol is to place the annuloplasty ring after posterior leaflet repair and then reassess for any anterior or complex leaflet pathology afterward. Our belief is that annular pathology often falsely gives the appearance of leaflet pathology, and by following the steps outlined above, many unnecessary procedures are prevented.

By utilizing the two principles outlined above, we believe that the proper and necessary attention is given to the

correct physiologic functioning of the valve in a manner that is surgically relevant. The height of the posterior leaflet is reduced to prevent SAM as well as to allow the correct coaptation plane. The two leaflets are made to coapt at the correct line by reinforcing the annulus with a remodeling ring. As outlined above, in our experience at the Brigham and that of others,[49] many times the so-called bileaflet prolapse is completely eliminated by adequate posterior leaflet resection and a large remodeling annuloplasty ring without any further anterior leaflet intervention.

There is clear evidence supporting the integral and essential necessity of the ring for a lasting repair. In an early paper on mitral valve repair, we compared a repair group that had no annuloplasty ring to another group in whom a ring was implanted at the time of valve repair.[50] All valves were competent at the time of surgery, but after several years of follow-up, the rate of mitral regurgitation in the no-ring group was five times that of the ring group. Thus, a remodeling ring is critical to a long-lasting physiologic mitral valve repair.

SPECIFIC SURGICAL TECHNIQUES

Posterior Leaflet Quadrangular Resection

The most common mitral valve pathologies (approximately 80%) encountered in the myxomatous, degenerated valve are ruptured and elongated chords from the middle section of the posterior leaflet (Fig. 42-8A). In one approach limited resection of this diseased section of leaflet is shown in Fig. 42-8B. To fill the gap produced by removing the pathologic section, leaflet advancement of the remaining leaflet sections is carried out (Fig. 42-8C and D) and the cut edges of the valve are reapproximated with running monofilament suture (Fig. 42-8E, F, and G). An annuloplasty ring is then implanted (Fig. 42-8H, I, and J). This scenario is the most common pathophysiology encountered and operative strategy employed. Interestingly, recent results by Perier[51] and Lawrie[52] have reported successful results with use of only artificial polytetrafluoroethylene (PTFE) chords to preserve the posterior leaflet instead of resecting it, a technique that has traditionally been applied only to the anterior leaflet.

For cardiac surgeons who perform a modest number of valve repairs, incising the posterior leaflet off the annulus may be somewhat daunting. In our own experience, a prolapsed leaflet without ruptured chordae at P2 may simply be obliterated by a few sutures to bring the leading edge of the prolapsed leaflet to the underside of the annular connection, thus reducing the height, preserving all the chords, and accomplishing what might be done with a resection.

If the repair includes a resection of a flail segment, then some form of the leaflet advancement technique popularized by Carpentier should be employed.[53] In this technique the two remaining sections are advanced upon each other to close the gap produced by the resected area. This includes separating each remaining segment off the annulus for a short segment. Of all the traditional techniques, this is the one that has produced some concern for surgeons who perform only moderate numbers of valve repairs because of the necessity of incising the posterior leaflet off the annulus and then reanastomosing the leaflet to the annulus.

We have evolved a simplified technique for limited PML resections in which leaflet advancement may be more easily performed, and yet still accomplish the exact same result in much less time. We have named this the "fold-over leaflet advancement." In this technique the remaining enlarged segments of P2, on either side of the elongated resected leaflet with supporting chordae, are simply folded over by a continuous polypropylene suture to the annular gap produced by the limited posterior leaflet resection, without any further incision (Fig. 42-9). The fold-over advancement accomplishes the same goals as the traditional leaflet advancement. The small gap distance, created by the small area of resected flail segment, is eliminated and the height of the posterior leaflet is reduced. We have found the fold-over advancement to be extremely effective for small resections of the posterior leaflet in any position without the necessity of incising the leaflet off the annulus.

That being stated, many situations exist with true Barlow syndrome with elongation and elevation of almost the entire posterior leaflet. In essence, the whole posterior leaflet is elongated. In these particular pathologic situations, the classic techniques are mandatory. The entire posterior leaflet on both sides of the resected area, including P1 and P3, must be incised off the annulus and a careful and detailed valve advancement carried out, beginning at each commissure, with running 4-0 polypropylene (see Fig. 42-8C and D). The height of the leaflet is lowered to avoid creation of SAM and provide a good coaptation point for the anterior leaflet. Because some of these leaflets may be as high as 3 to 4 cm, if the height of the leaflet is not shortened significantly, SAM is highly likely. While performing the leaflet advancement, imbrication of PML segment areas may also be effective if there is focal enlargement at a particular area of the leaflet. This simplifies the surgical technique, reduces operative time, and achieves the same result. Multiple interrupted mattress sutures may be used.

Commissural Prolapse

As the most straightforward example of pathologic valve prolapse, chordal rupture or elongation at the anterior-lateral or posterior-medial commissure provides the surgeon with the most obvious strategy of repair. Many surgeons still recommend resection of this area, but commissuroplasty is by far the most simple, direct, and efficient way to handle this particular problem. The prolapsed area is obliterated by one to three polypropylene mattress stitches (Fig. 42-10), eliminating the regurgitation at that point. A small obliteration of this area at A1 and P1 or A3 and P3 will not make any significant difference in the overall cross-sectional area of the mitral valve, so mitral stenosis is of no concern with this technique. Several other surgical groups[54,55] have also used this technique as an effective and long-lasting method to treat commissural prolapse.

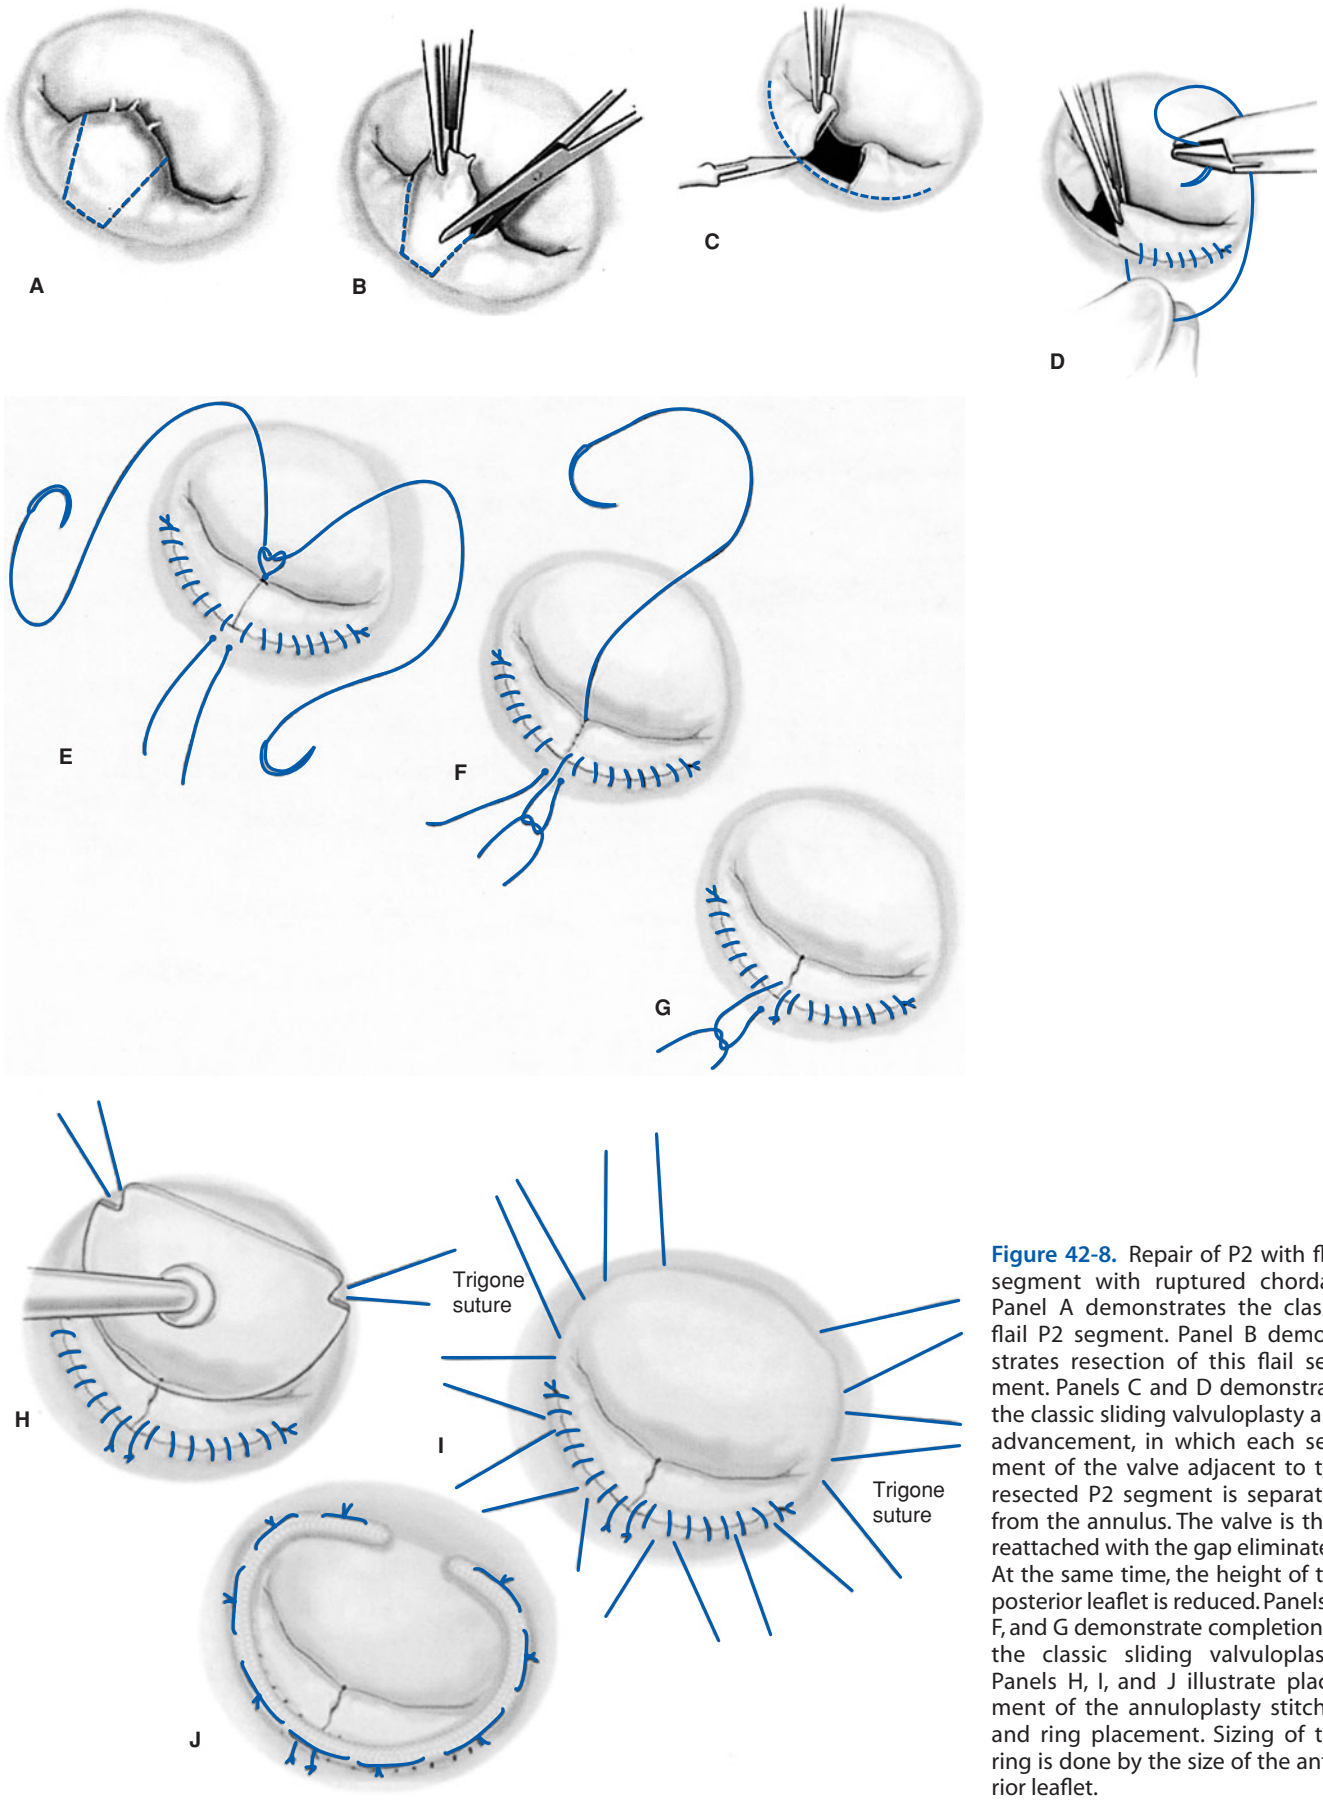

Figure 42-8. Repair of P2 with flail segment with ruptured chordae. Panel A demonstrates the classic flail P2 segment. Panel B demonstrates resection of this flail segment. Panels C and D demonstrate the classic sliding valvuloplasty and advancement, in which each segment of the valve adjacent to the resected P2 segment is separated from the annulus. The valve is then reattached with the gap eliminated. At the same time, the height of the posterior leaflet is reduced. Panels E, F, and G demonstrate completion of the classic sliding valvuloplasty. Panels H, I, and J illustrate placement of the annuloplasty stitches and ring placement. Sizing of the ring is done by the size of the anterior leaflet.

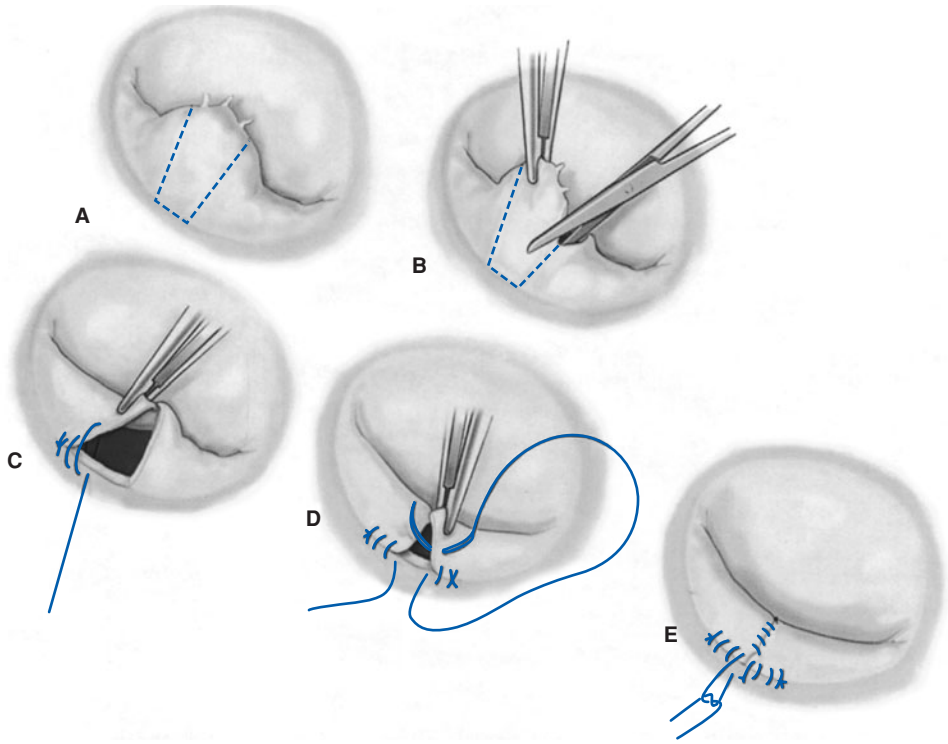

Figure 42-9. The fold-over leaflet advancement. Performed for a prolapsed and flail P2 segment here, the fold-over advancement accomplished the same goals as the classic sliding valvuloplasty, but with simpler surgical techniques. After resection of the flail P2 segment (panel B), the cut edges of each side of the resulting gap are sewn to the annulus as they are "folded down." This is done for each side of the gap for half of the original height of each side. The top halves are then sewn together (panel E). The result is that the leaflet gap is eliminated and the height of the leaflet reduced.

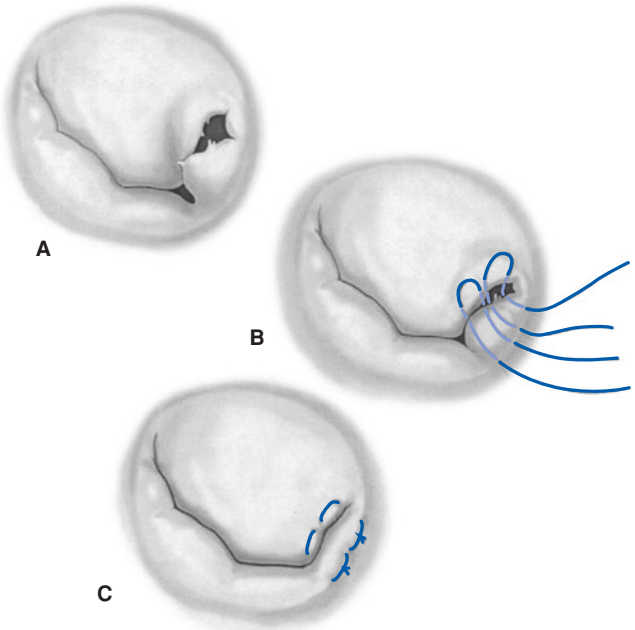

Figure 42-10. Commissuroplasty. Simple horizontal mattress stitches placed in the ruptured commissure eliminate regurgitation without need for further leaflet resection, even with ruptured chordae.

Anterior Leaflet Prolapse

Though uncommon, true prolapse of the anterior leaflet engenders significant concern to surgeons because such pathology is associated with less successful long-term repair results than posterior leaflet pathology. A recent report by David[56] substantiates this finding again. The height of the chordae underlying the anterior leaflet must be assessed and chords may be grossly elongated or ruptured and make the AML flail. This problem may be addressed by a variety of techniques and the long-term follow-up on many of these techniques has been quite promising. There are four basic techniques to repair true prolapse of the anterior leaflet. They are: (1) reduction of the chordal height by implantation techniques; (2) artificial PTFE chordae; (3) chordal transfer from the posterior to anterior leaflet; and (4) the edge-to-edge technique.

Chordal shortening by implantation into papillary muscles

One of the first techniques developed by Carpentier[10] of chordal shortening involves incising the papillary muscle, placing the redundant anterior leaflet chords within the muscle, and then sewing the papillary muscle over the chord, thus entrapping the chordae and shortening it (Fig. 42-11). This is

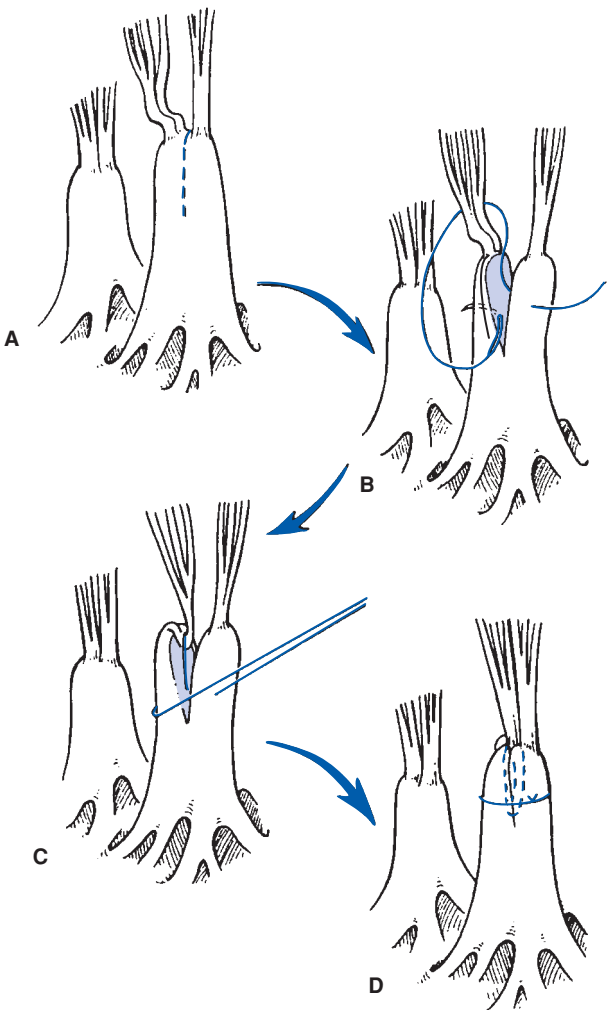

Figure 42-11. Anterior leaflet chordal shortening. The papillary muscle is incised and the redundant chord folded into it. The excess chord is held in place with pledgeted sutures.

a simple technique, but it has gone out of favor, as reports by Cosgrove and coworkers[57] have demonstrated that additional chordal ruptures may occur after use of this technique. They postulate that the potential sawing action of the papillary muscle on the buried chord is the cause. Other techniques of this type include papillary muscle repositioning[58] and chordal plication and free edge (AML) remodeling.[59]

Artificial chordae

Artificial chordae with PTFE is the technique that is perhaps the most popular current technique for AML pathology. Originally described by Frater and Zussa,[60,61] this technique has grown in popularity over the past several years.[56,62] Lawrie[52] has also recently reported excellent results in applying PTFE neochords for the anterior and posterior leaflet repair. Furthermore, Duran has devised a method for more precise measurement of the correct height for these new chordal structures.[62] This technique (Fig. 42-12) involves placing a mattress suture with a pledget on the papillary muscle to which the redundant or ruptured chord has been attached. The two ends of the double-armed PTFE are then brought up through the edge of the leaflet that needs to be lowered. The critical part of this technique is determining the degree to which the leaflet is lowered and hence how tightly the stitch is tied down. This is determined by ascertaining the optimal position of the two leaflets in systole. Both the anterior and posterior leaflets should be in apposition at this point, and thus the leaflet's height in systole should be the level to which the chords are adjusted. We have used tenting of the posterior leaflet as our guide while carefully tying down the chord (Fig. 42-12B). Whatever the technique employed, the end result should be that the anterior leaflet now coapts at the same level as the posterior leaflet with left ventricular contraction.

Chordal transfer

The third technique for true anterior prolapse is chordal transfer from the posterior leaflet to the anterior leaflet. This was originally described by Carpentier[10] and has been popularized by the Cleveland Clinic[57] and Duran and coworkers.[63] Figure 42-13 illustrates the operative steps. A resection of the flail chordae of the anterior leaflet is carried out, and an adjacent segment of the posterior leaflet is then resected from the posterior leaflet and then transferred to the gap produced by the anterior leaflet resection. This technique has had good long-term results, but may involve both leaflets when only single-leaflet pathology exists.[64]

Edge-to-edge technique

The edge-to-edge repair is a technique in which the anterior leaflet and posterior leaflet are sewn together at the coaptation line, producing a double-orifice mitral valve.[65] This has gained considerable popularity and even percutaneous interventional attempts to emulate this surgical maneuver are being pursued.[66] Developed by Alfieri and coworkers,[67] their theory is that with Barlow syndrome or truly redundant anterior leaflets, apposition of the mid-portion of the anterior leaflet to the mid-portion of the posterior leaflet will prevent the elevation of the anterior leaflet above the level of the posterior leaflet, thus eliminating mitral regurgitation. This technique greatly simplifies the repair of the true bileaflet prolapse and has been adopted as standard therapy for AML pathology by several groups. In particular, with anterior leaflet chordal rupture or marked elongation of the chordae to the anterior leaflet, repair consists of a single stitch carefully placed.

Figure 42-14 illustrates our technique. A figure-of-eight braided polyester suture is placed at the apposition points of the anterior and the posterior leaflet. We use this stronger suture, as there have been reports of the more commonly used polypropylene sutures rupturing. An important point of the surgical technique is our strong belief that the stitch should be placed only with myxomatous valves, so as to avoid producing mitral stenosis as has been the case with ischemic MR.[68] To ensure the adequacy of each orifice created by the edge-to-edge technique, we also measure the diameter of each orifice and confirm that it is at least 2 cm

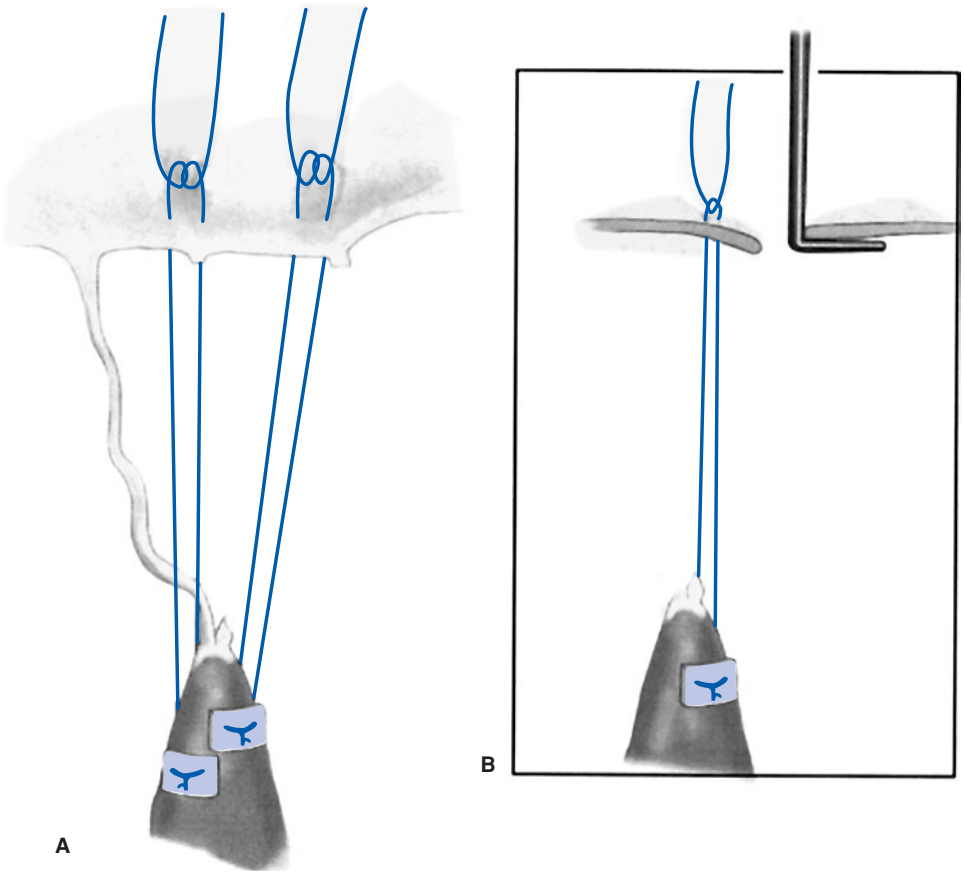

Figure 42-12. Artificial PTFE chords for the anterior leaflet. (A) Pledgeted PTFE stitches are placed through a papillary muscle and brought through the leading edge of the anterior leaflet. Using the tented-up posterior leaflet (B), the correct length of artificial chord is created.

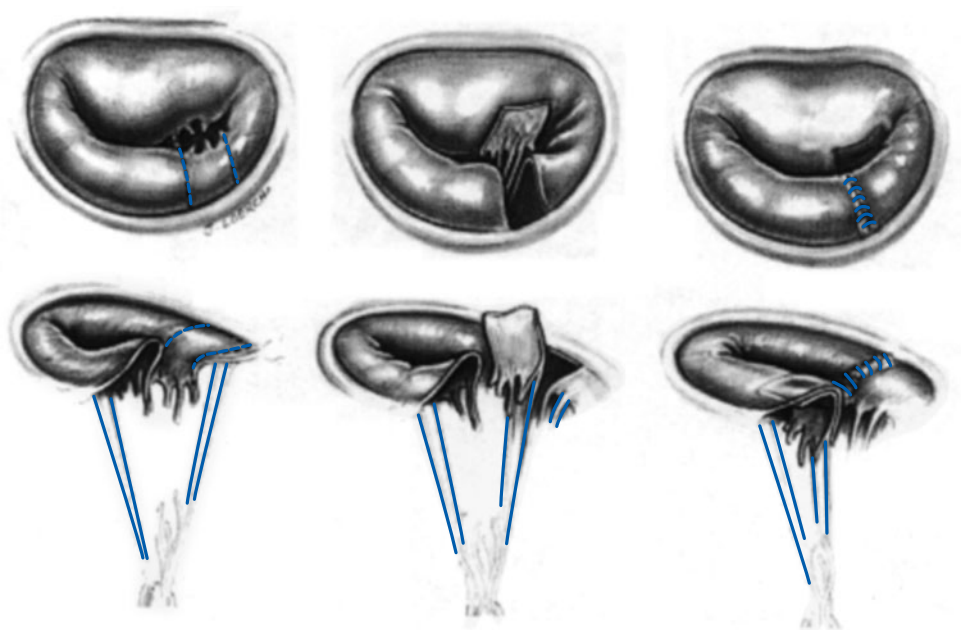

FIGURE 42-13. Chordal transfer. For an isolated flail anterior leaflet segment, first the prolapsed section of anterior leaflet is resected. An adjoining section of posterior leaflet is then resected and transposed over to the gap created by the anterior resection.

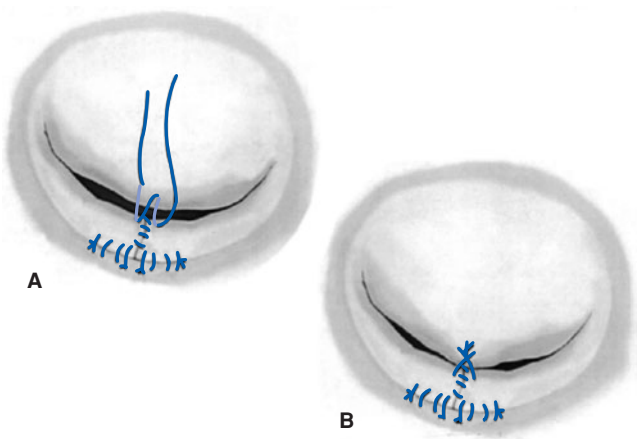

Figure 42-14. Edge-to-edge technique. The technique involves a braided polyester figure-of-eight stitch at apposition of A2 and P2.

in diameter. If the orifices are less than 2 cm in diameter, the technique is abandoned. This technique is a very valuable adjunct in patients who have the potential for systolic anterior motion of the mitral valve.[69,70] In fact, prevention of SAM may be the best utilization of this technique at present. In our small series of 20 patients with SAM potential, all were treated and SAM was prevented in all patients. A competent mitral valve was maintained in all at 8 years at postoperative follow-up.[69]

Medium-term results of this surgical maneuver are satisfactory and compatible with all other commonly used repair techniques, according to studies by Alfieri and coworkers,[67,71] but there have been no comparative, prospective, randomized studies comparing the classic repair techniques to this approach in the long term.

Resection of the anterior leaflet

It has been well established that the body of the anterior leaflet should be treated with great respect, and preservation of AML tissue is important. Resections can be carried out, but only as a small triangular resection for ruptured chords to reduce the bulk of a large anterior leaflet.[72] For anterior mitral valve prolapse associated with idiopathic hypertrophic subaortic stenosis, or as an alternative technique for reduction of the AML height, creation of a longitudinal perianular anterior leaflet resection with reconstruction of the leaflet has also been advocated to reduce the height of the anterior leaflet with some success.[73,74]

SPECIAL PROBLEMS AND CONSIDERATIONS

The Calcified Annulus

Calcification, particularly of the posterior annulus, is a complicating aspect of mitral valve repair. Calcification makes repair more difficult, as stitches are more difficult to place and the risk of paravalvular leak is increased. Severe calcification, however, does not necessarily rule out an effective mitral valve repair. Partial or total removal of the calcified bar may be done safely. Carpentier has promulgated removal of the entire calcified bar in radical fashion, which in essence partially detaches the left ventricle from the left atrium.[75] Partial and selective calcification removal may also be quite effective and potentially safer.[76] Partial removal of calcium with leaflet advancement can be performed without the need for a radical débridement in many patients. Only the amount of calcium should be removed that allows adequate stitch placement and leaflet and annular flexibility. Obviously, calcification of the chordae or a substantial part of the leaflet tissue is a poor prognostic factor for long-term freedom from valve repair, and an extensively calcified valve usually indicates valve replacement.

Systolic Anterior Motion of the Mitral Valve

As mentioned above, persistent systolic anterior motion of the anterior leaflet is an adverse outcome after valve repair. In this condition, the anterior leaflet obstructs the LVOT. Clearly, increased redundancy of leaflet tissue is a risk factor with a small annuloplasty ring. After repair, if the line of leaflet coaptation is displaced anteriorly, then the anterior leaflet will be displaced into the LVOT and cause LVOT obstruction.[77,78] The etiology is usually inadequate reduction of the height of the posterior leaflet, which then pushes the anterior leaflet into the LVOT. SAM is particularly prevalent in patients with bileaflet prolapse or those with extremely enlarged anterior leaflets. Thus, the PML height reduction has to be meticulously carried out, and in myxomatous valve disease, an upsizing rather than a downsizing of the mitral valve annuloplasty ring should be done. As indicated above, if the anterior leaflet is supported by a relatively small annulus, the anterior leaflet will not spread out and instead will appear to have redundant tissue above the correct plane of coaptation, predisposing to SAM.[69]

Several investigators have looked at the potential echocardiographic risk factors for systolic anterior motion. Echocardiographic details that are associated with a high risk of systolic anterior motion include proximity of the mitral valve coaptation point to the interventricular septum, as well as asymmetry between the anterior and posterior leaflets. If the posterior leaflet is relatively large with respect to the anterior leaflet, then SAM is potentiated. We look for this information pre-repair and take such data into account as the repair strategy is finalized in the operating room.[69,70]

If the probability is high that SAM will occur, our practice is to use the Alfieri edge-to-edge technique to reduce such a risk.[69] By forcing the coaptation line to be correct with a single stitch in the situation of high SAM probability, the probability of SAM is reduced. Another strategy to consider in this circumstance is implantation of PTFE anterior chordae to lower the AML. That will reduce the height of the anterior leaflet, and thus further reduce the potential of

SAM. In our own experience long-term competency is maintained in this group.

If SAM appears by TEE following what appears to be an excellent repair, filling the left ventricle with fluid volume post–cardiopulmonary bypass will relieve systolic anterior motion in approximately 90% of patients. In rare circumstances, if an adequate reduction of the posterior leaflet has not been carried out, more posterior leaflet may have to be resected or the ring size increased. The most common alternative in our clinic is the edge-to-edge technique, as mentioned above, for situations where post-repair SAM still exists despite all techniques to reduce it.[69]

Remodeling Ring Annuloplasty

Remodeling the annulus by ring annuloplasty after mitral valve repair is essential to a complete and long-lasting repair. The remodeling concept, promulgated by Carpentier[17] and Duran[43] is that the distorted mitral annulus requires restorative structural support. There is debate on which type of ring should be used for remodeling: rigid or soft, full circle or C-ring. Our thought is that it is not critical which type of ring is utilized for myxomatous valve degeneration as long as there is a relative upsizing of the ring and a secure attachment to the trigone area of the anterior mitral leaflet. There is some evidence to suggest that flexible rings may incur less possibility of SAM and that open-ended rings, such as a C-ring, are safer with respect to SAM.[79] As none of this has been studied in a prospective randomized fashion, these opinions will continue to exist. Though we prefer the Cosgrove ring for mitral valve prolapse, our belief based on over 2000 mitral valve repairs is that the existing evidence is not compelling for any particular ring, and that the type of ring implanted is far less important than a correctly performed operation and appropriate sizing of the ring.

The technical aspects of ring implantation are important to avoid circumflex artery compromise, atrioventricular dissociation, or dehiscence of the ring. Implantation of currently available annuloplasty rings requires the placement of mattress sutures, parallel to the annulus, at the conjunction of the posterior leaflet and the annulus. Radially oriented bites are to be avoided because by definition they exert radial stresses and thus will pull to some extent on the circumflex artery. Bites should be deep with the needle entering the annulus, then into the left ventricular cavity, and then coming out on the atrial side again. Of paramount importance is the requirement that the plane of the needle bite should be orthogonal to the annular plane. If this is done, it is impossible for the stitch to impinge or distort the circumflex artery. That is why such bites may be made deep. Wide bites are taken such that there is not an excess number of sutures. A mitral C-ring should require approximately 9 to 12 sutures depending on the size of the annulus. The sutures are not pledgeted unless there is extreme fragility of the annular structures. Annular integrity will of course depend on the pathology. Sutures are then passed through the fabric part of the ring. The mandrill of the ring is kept in place to maintain the ring shape while the sutures are tied down, thus preventing crimping of the cloth rings in the nonrigid or semi-rigid rings.

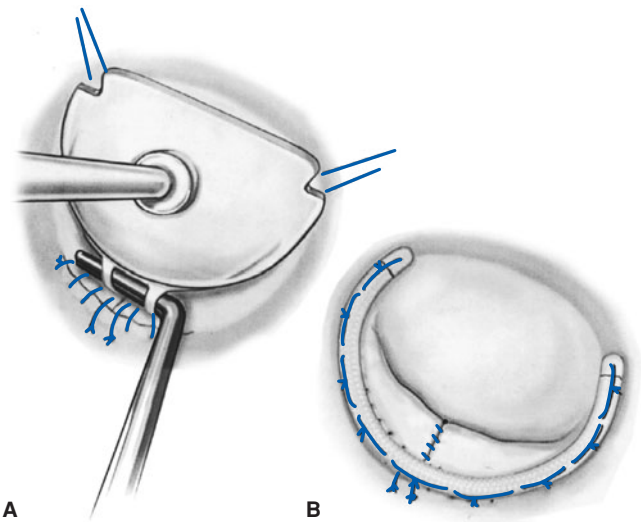

Figure 42-15. Ring annuloplasty sizing and insertion. The ring for degenerative disease should be slightly oversized. Sizing should be done to match the height of the anterior leaflet, not the distance between the trigones or commissures. Nine to eleven mattress sutures are usually needed.

Sizing is the most important aspect of ring placement. We believe that slight oversizing of the ring in myxomatous degenerated disease is appropriate. This corrects for the degenerative annulus that is functionally too small. Sizing is typically done by two techniques. Placement of aortic trigonal stitches (Fig. 42-15) allows for measurement of the intertrigonal distance. Many ring-sizing devices have notches on the rings to facilitate this. Except in rheumatic disease, we do not rely on this measurement. In myxomatous disease, our belief is that the height of the anterior leaflet from the annulus to the highest point on the leaflet when it is stretched is the most important criterion for sizing, a concept originally espoused by Carpentier.[10] This height of the leaflet is the critical dimension that must be carefully measured so that during systole there is minimal redundancy that may lead to SAM. Using trigonal sizing may, in fact, downsize the ring and cause either systolic anterior motion or ring dehiscence because of the huge disparity between ring size and annulus size. In our re-repair series, either improved sizing or placing the ring below the commissures were the most common remedies.[80] Therefore, using the sizer to evaluate anterior leaflet size is the most critical maneuver. Echocardiographic dimensions of the anterior leaflet correlate well with in vivo sizing, and calculating the anterior leaflet size by standard echocardiogram techniques is performed in every case. Deployment of a ring matching the anterior leaflet size in our experience has been most efficacious and has rarely led to systolic anterior motion.[69]

Results

Based on long-term studies the probability of mitral valve repair being intact at 10 years is greater than 90%.[36,42,50,56,81] Thromboembolic incidence is also exceedingly low; long-term anticoagulation is not required unless patients are in atrial fibrillation.

RHEUMATIC MITRAL VALVE DISEASE

The incidence of rheumatic fever and its valvular sequelae have dropped precipitously in North America and Europe during the last few decades. This has resulted in far fewer rheumatic valves requiring surgery. The disease is still seen, however, in individuals from undeveloped countries where rheumatic valve disease is still quite prevalent.[82] The primary lesion of rheumatic mitral valve disease is mitral stenosis caused by a fibrotic restriction at both commissures of the mitral valve. Open commissurotomy evolved from the early efforts in the 1940 and 1950s with closed mitral valvotomy and commissurotomy (Harken)[83,84] and was carried out successfully with a very low rate of recurrence and with a high probability of symptom relief.

Over the last several years, balloon mitral valvuloplasty has been the treatment of choice for noncalcified rheumatic mitral stenosis.[85] This technique has been widely used and has proven to be extremely efficacious in the noncalcified, nonregurgitant mitral valve. Nonetheless, there are still a number of patients with rheumatic valve disease who present primarily with severe mitral regurgitation secondary to varying degrees of restricted leaflet motion, thickening of the subvalvular apparatus, and commissural fusion. In most instances, if the valve is severely calcified and there is obliteration of the subvalvular chordal structure by fibrosis, repair will be fruitless and replacement carried out. In younger patients, with preservation of the chordal apparatus and minimal calcification, a satisfactory repair for mitral regurgitation can be carried out. Thickening of the valve may require, however, some thinning of the valve by removal of some of the rheumatic scarification process.

Techniques of rheumatic repair should always employ commissural incisions of the stenosis leaving a 2- to 3-mm edge to the annulus. Débridement of calcium and scar and incising the papillary muscles and chordae may improve mobility. Several European surgeons, particularly Duran and colleagues,[86] have devised techniques that include lengthening the anterior leaflet of the mitral valve, and even in some instances the use of PTFE chords to improve the flexibility of the posterior leaflet and retraction due to the chordal scarring and fibrosis.

Particularly in patients with severe mitral regurgitation related to rheumatic mitral disease, a remodeling annuloplasty ring will be necessary. Repair is possible with combined mitral stenosis and regurgitation since alleviation of stenosis may improve the mobility of the anterior leaflet, which then allows for a corrective operation rather than replacement. Finally, the absence or presence of fibrosis of the subannular chordal structure may often determine mitral valve replacement versus mitral valve repair. In young patients, however, every effort should be made to repair these valves by the techniques outlined above, as repair results are better in the long term than valve replacement.[87]

SUMMARY

Mitral valve repair for degenerative disease has undergone a virtual revolution in the previous 30 years. What was once viewed skeptically is now well accepted as the ideal treatment for mitral regurgitation based on improved physiology and lower valve-related morbidity than valve replacement. In major valve referral centers, repair is commonplace and routine. However, for many cardiac surgeons mitral valve repair is still surrounded by mystical references to such surgery as "a special art," one that is difficult to understand and one that requires special esoteric skills to master. Repair should be part of every cardiac surgeon's standard toolbox and should be considered as simply another procedure to be mastered.

CHAPTER 43

Mitral Valve Replacement

Tomas Gudbjartsson · Tarek Absi · Sary Aranki

HISTORICAL BACKGROUND

Mitral valve surgery in the twentieth century began with Elliot Cutler's first operation at the Peter Bent Brigham Hospital in 1923.[1] This was a mitral valvulotomy that he had worked on for two years in the laboratory with Samuel Levine, a Boston cardiologist. Two years later, Dr. Suttar, an English surgeon, performed a mitral valvulotomy using his fingers to open up the commissures.[2] The patient made an uneventful recovery, but Dr. Suttar did not perform any more mitral valvulotomies. It took two more decades until Dwight Harken and Charles Bailey independently continued the development of digital valvulotomy for rheumatic mitral stenosis.[3,4] The results were dramatic, and the operation gained popularity. This launched the modern area of cardiac surgery. But recurrence of the stenosis still was a major problem, even after the development of cardiopulmonary bypass in the early 1950s, which enabled more complete open valvulotomy.

The next major step in the development of mitral valve surgery was the development of reliable, quality-controlled prosthetic heart valve devices in the late 1950s and early 1960s. For the first time, devices were available that could effectively replace a diseased, nonreparable mitral valve with relative ease of implantation and assurance that the hemodynamic abnormalities from either mitral stenosis or mitral regurgitation were corrected and maintained indefinitely.

The first successful prosthetic mitral valve was a device implanted by Nina Braunwald at the National Institutes of Health in 1959.[5] This was a homemade device with artificial chordae made of polyurethane. Two years later, the first reliable device for replacement of the mitral valve was produced on a commercial basis. This was the Starr-Edwards ball-and-cage mitral valve that resulted from the collaboration of Albert Starr, a cardiac surgeon in Portland, and Lowell Edwards, a mechanical engineer in southern California.[6] This prosthesis was a great success and became the "gold standard" for many years, until the late 1960s, when second- and third-generation prosthetic valves began to appear. Although reliable hemodynamically, it was soon found that the Starr-Edwards valve had significant thromboembolic potential, particularly in the small ventricle, and aggressive anticoagulation was required to control thromboembolic events.[7] The Silastic ball in the original prosthesis also had to be replaced because of inadequate durability.

During the next decade, a large number of different ball-and-disk valves were developed, and their profile was considerably reduced by alterations in both the height of the valve and the type of occluder (Fig. 43-1).

After a number of experimental valves were evaluated [without Food and Drug Administration (FDA) supervision], one valve emerged as the leading prototype for the 1970s: the Björk-Shiley tilting-disk valve, which was developed by Viking Björk in Stockholm and Earl Shiley in California.[8] This valve had better hemodynamics (larger cross-sectional area and less hemolysis) than the Starr-Edwards valve and consequently had a lower thromboembolic potential.[9,10] However, problems with thrombosis occurred when the anticoagulation was altered. When an engineering change was made to correct this problem in a later model (a concave-convex disk), a fracture in the strut ensued, and the Björk-Shiley prosthesis was taken off the market.[11]

A third-generation prosthetic valve was developed in the late 1970s that became the valve of the 1980s: the bileaflet St. Jude Medical valve, which had improved hemodynamics compared with older valves with less stagnation of blood, more complete opening of the leaflets, and reduced incidence of thromboembolism.[12–17] Several other disk prostheses are available currently (see Fig. 43-1), all with flow characteristics similar to the St. Jude valve but still with a small but definite risk of hemorrhage related to anticoagulant therapy and thromboembolism.

As the first, second, and third generations of prosthetic valves were developed, biologic or tissue replacement devices

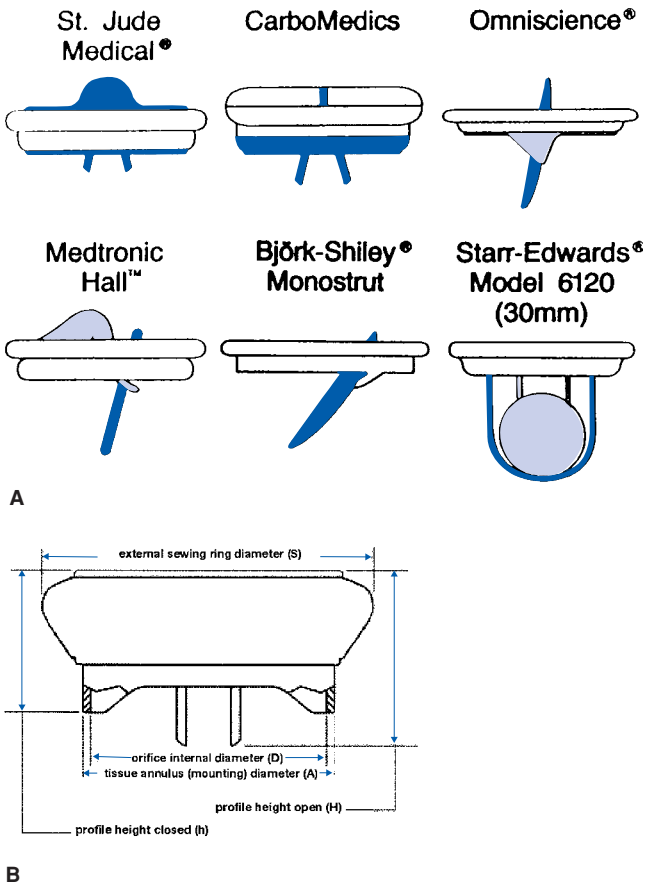

Figure 43-1. *A.* Profiles of mechanical mitral valve prostheses. *B.* Profile of the On-X mitral valve.

were developed concomitantly. The biologic valves showed a much lower frequency of thromboembolism, and long-term anticoagulation seemed to be unnecessary.

In the 1960s, investigators began to use formalin fixation to sterilize and fix fresh heterograft tissue.[18] However, when it became apparent that this fixation was unreliable because of collagen breakdown in valve cusps resulting in fibrosis and calcifications, glutaraldehyde fixation of porcine tissue began.[19] This fixative stabilized collagen bonding in the valve cusps and led to increased durability. The glutaraldehyde-fixed porcine aortic valve, principally developed by Hancock in the United States (1970) and Carpentier in Paris (1976), was the first commercially available bioprosthetic valve.[20,21] These valves revolutionized mitral valve surgery by providing a biologic alternative that allowed long-term use without the need for lifelong warfarin anticoagulation. Both the Hancock and the Carpentier-Edwards valves became enormously popular in the 1970s, and studies showed excellent 5-year durability (95%). In the early 1980s, however, structural valve dysfunction (SVD) became more apparent, with 15 to 20% of the prostheses failing within 10 years. The rate of deterioration seemed to accelerate in younger patients, with the valve gradually wearing down as a result of different biologically mediated dysfunctional processes.[22–26]

The first- and second-generation biologic valves were constructed from porcine aortic valves. Because of limited durability, these valves mostly have been replaced by the third generation of biologic valves, which still include porcine valves in addition to biomechanically engineered bovine pericardial valves. For this third generation of valves, new technology has been incorporated aimed at improving valve longevity and hemodynamic function This has resulted in better midterm and long-term results.[27–33] These techniques include low-pressure or no-pressure fixation, antimineralization processes of the tissues, and low-profile, semiflexible stents that better define the biomechanical properties of the leaflets.

This chapter discusses the surgical indications, operative techniques, and early and late follow-up after implantation of mechanical and bioprosthetic mitral valve devices. The valves that are discussed are those that are currently (2006) approved by the FDA. Figure 43-2 shows the current FDA-approved prosthetic mitral valve devices, including the Starr-Edwards ball-and-cage valve, the Omnicarbon tilting-disk valve, the Medtronic Hall tilting-disk valve, the St. Jude Medical bileaflet valve, the Carbomedics bileaflet valve, the ATS bileaflet valve, and the On-X bileaflet valve. The FDA-approved bioprosthetic valve devices are shown in Fig. 43-3 and include the Hancock II porcine valve, the Carpentier-Edwards porcine valve, the Carpentier-Edwards pericardial valve, the Mosaic porcine valve, and the Biocor porcine valve.

INDICATIONS FOR MITRAL VALVE REPLACEMENT

The indications for mitral valve replacement are variable and undergoing evolution. Because of increasing use of reparative techniques, particularly for mitral regurgitation, replacement or repair of a mitral valve often depends on the experience of the operating surgeon. Current indications for valve replacement pertain to those types of valve problems that are unlikely to be repaired by most surgeons or which have been shown to have poor long-term success after reconstruction. Indications are discussed according to (1) pathophysiologic states for needing operation and (2) type of valve required (i.e., mechanical or bioprosthetic).

Mitral Stenosis

Mitral stenosis is almost exclusively caused by rheumatic fever, even though a definite clinical history can be obtained in only about 50% of patients. The incidence of mitral stenosis has decreased substantially in the United States in the last several decades because of effective prophylaxis of rheumatic fever. In some African and Asian countries, especially India, mitral stenosis is still very common. Two-thirds of patients with rheumatic mitral stenosis are female.

The pathologic changes in rheumatic valvulitis are mainly fusion of the valve leaflets at the commissures, shortening and fusion of the cordae tendinae, and thickening of

the leaflets owing to fibrosis with subsequent stiffening, contraction, and calcification. Approximately 25% of patients have pure mitral stenosis, but an additional 40% have combined mitral stenosis and mitral regurgitation.[34]

Stenosis usually develops one or two decades after the acute illness of rheumatic fever with no or slow onset of symptoms until the stenosis becomes more severe. Limitation of exercise tolerance usually is the first symptom, followed by dyspnea that can progress to pulmonary edema. New-onset atrial fibrillation and the risk for thromboembolism, hemoptysis, and pulmonary hypertension are other common symptoms in patients with mitral stenosis.

The diagnostic workup of the symptomatic patient with mitral stenosis should include a complete cardiac catheterization, including coronary angiography in any patient over the age of 40. Under age 40, echocardiographic findings of the mitral valve suffice in most symptomatic patients for the definition of mitral valve pathology unless there is a history of chest pain or coronary artery disease. Cardiac catheterization establishes the extent of mitral valve stenosis by determining valve gradients and valve area. Pulmonary artery pressure, which may be extremely high in long-standing cases of mitral stenosis, is also documented. In general, operation is prescribed

when the mean valve area is 1.0 cm^2 or less[35] (normal mitral valve area is 4 to 6 cm^2); however, with a "mixed" lesion of mitral stenosis and mitral regurgitation, the valve area in symptomatic patients occasionally may be as large as 1.5 cm^2. Asymptomatic patients generally are not considered for surgery,[36] but some authors recommend operation in asymptomatic patients with significant hemodynamic mitral stensosis[37] (see Chap. 36). The degree of pulmonary artery pressure elevation secondary to mitral stenosis continues to be an area of concern for the mitral valve surgeon. Is there any level of pulmonary hypertension that is too high for mitral valve replacement in the current surgical era of improved intraoperative and postoperative care? There is still no definitive answer to this question, but most surgeons operate on patients with severe pulmonary hypertension (suprasystemic) with the knowledge that intensive postoperative respiratory and diuretic therapy is necessary to maintain relatively dry lungs and to reduce the risk of severe right ventricular failure. It has been known for over 40 years that after mitral valve replacement for mitral stenosis, pulmonary artery pressure decreases within hours in most patients and decreases more gradually over weeks to months in others.[41–43]

The reason for this is not known. However, recently it has been suggested that valve prosthesis-patient mismatch (defined as indexed effective orifice area of 1.2 cm^2/m^2 or less and pulmonary artery hypertension of 40 mm Hg) might be important in preventing the regression of pulmonary artery hypertension after mitral valve replacement.[42]

The success with closed commissurectomies after World War II and the development of the Starr-Edwards valve in the early 1960s led to an enormous increase in operations for rheumatic mitral valve disease; this pattern began a decrease as rheumatic disease declined. In recent years, a small resurgence in rheumatic valve disease has been observed in emigrés from Southeast Asia and Latin America. In the 1990s, balloon dilation of fibrotic, stenotic mitral valves became increasingly common.[43,44] At the present time, percutaneous mitral balloon valve dilation is used in most cases of symptomatic noncalcified, fibrotic mitral stenosis. But even though this technique has been shown to be equivalent in the short run to closed mitral commissurectomy, especially in young patients, it is only indicated in a minority of patients, i.e., those with optimal valvular characteristiscs.[36,45] Open mitral commissurotomy and valvuloplasty for such patients can be a successful operation,[46,47] but

other studies have shown better long-term results with mitral valve replacement using a mechanical valve.[48] Many patients with chronic mitral stenosis now require valve replacement because the valve has developed significant dystrophic changes, including marked thickening and shortening of all chordae, obliteration of the subvalvular space, agglutination of the papillary muscles, and calcification in both annular and leaflet tissue. Aggressive decalcification and heroic reconstructive techniques for these extremely advanced pathologic valves generally have produced poor long-term results; nevertheless, some surgeons still advocate aggressive repairs in this subset of patients.[49]

Mitral Regurgitation

The etiology of mitral regurgitation is very diverse, and the decision to recommend operation for patients with mitral regurgitation is more complex than for patients with mitral stenosis, except in cases of acute ischemic mitral regurgitation and endocarditis, where indications are more straightforward. The pathologic subsets that produce mitral regurgitation are related to a number of metabolic, functional, and anatomic abnormalities.[36] These can be categorized into degenerative (e.g., mitral prolapse and ruptured/elongated chordae), rheumatic, infectious, and ischemic diseases of the mitral valve. Most of these entities are now amenable to mitral valve repair and reconstruction with or without the use of annuloplasty rings, as mentioned in Chap. 37.

For any of the preceding major pathologic subsets, indications for surgery in patients with mitral regurgitation vary from the asymptomatic patient with an enlarging but well-functioning left ventricle and atrium to severely depressed left ventricular function. Any symptomatic patient with significant mitral regurgitation (3+ to 4+) should be operated on, and operation should be considered in any relatively symptom-free individual if there is objective evidence of left ventricular deterioration and documented and significant increases in left ventricular end-systolic and end-diastolic volumes.[50–55]

Regurgitation through the valve usually is measured with Doppler echocardiography, but magnetic resonance imaging (MRI) is another noninvasive technology for measuring the regurgitant flow and can provide measurements of ventricular end-diastolic/systolic volumes and ventricular mass.[56,57] Left ventricular angiography can be helpful but is otherwise indicated for evaluating the coronary arteries preoperatively in patients older than 40 years.

It is important to stress that depressed ejection fraction is a poor indicator of left ventricular function in patients with mitral regurgitation. Ejection fraction can be preserved in patients with irreversible left ventricular failure because of regurgitant flow through the valve.[58,59] Depressed cardiac output (<40%) therefore usually indicates severe left ventricular dysfunction, and results of surgery are not as favorable in these patients as they are in patients with normal ventricles.[60,61] Compared with ejection fraction, measurements of end-systolic volume and diameter are more reliable noninvasive parameters to evaluate the status of the left ventricle and determine the optimal time for operation[62,63] (see Chap. 36).

Once the valve is exposed, indications for mitral valve replacement in patients with mitral regurgitation depend on the extent of the pathology in each patient and the reparative experience of the operating surgeon. Thus, in regurgitation from degenerative prolapsing myxomatous valves that have a high probability of reconstruction, mitral valve repair is indicated if the prolapse is generalized, and local findings that decrease the probability of a successful repair are absent.[64–68] Similarly, if rheumatic mitral regurgitation, calcific deposits throughout the leaflet substance, and shortened chordae and papillary muscles are encountered, mitral valve replacement is often the most prudent operation because the probability of successful repair is low.[69] However, good results with reconstructive surgery in this patient group have been reported.[70] In ischemic mitral regurgitation, pathology that precludes satisfactory repair includes restrictive valve motion from shortened, scarred papillary muscles, an acutely infarcted papillary muscle, and rupture of chordae associated with extensive calcification of valve leaflets.[71–73] In endocarditis, mitral valve replacement may be required because of destruction of the valve leaflets and subvalvular mechanisms and annular abscess formation. Although repair of the valve and avoidance of prosthetic material are very desirable in septic situations, the extent of the destruction may preclude repair. Therefore, mitral valve replacement is required after careful débridement of the infectious tissue and reconstruction of the valve annulus.[74–76]

CHOICE OF VALVE TYPE

Indications for Mechanical Valve Replacement

Currently available prosthetic valves in the United States, in descending order of popularity, are the bileaflet, the tilting-disk, and the ball-and-cage valve. For young patients, patients in chronic atrial fibrillation who require long-term anticoagulation, and any patient who wants to minimize the chance of reoperation, a prosthetic valve should be chosen if valve replacement is required. The St. Jude Medical bileaflet valve is the most widely used prosthetic mitral valve at present because it has good hemodynamic characteristics and is easy to insert. Indications to choose one prosthetic or another vary primarily by surgeon preference and occasionally depending on the state of the annulus and whether or not there have been multiple previous operations. For example, infrequently, the mitral annulus provides poor anchorage with subsequent perivalvular leak with the bileaflet or tilting-disk valve, which requires an everting-suture technique. In this instance, a valve with a bulky sewing ring may be chosen to reduce the probability of subsequent perivalvular leak. A low-profile mechanical valve is preferable in a patient with a small left ventricular cavity to prevent obstruction of left ventricular outflow and impingement of the myocardium.

Indications for Bioprosthetic Valve Replacement

Patients in any age group in sinus rhythm who wish to avoid anticoagulation may prefer a bioprosthetic valve. This is especially true for patients in whom anticoagulation is contraindicated, e.g., patients with a history of gastrointestinal bleeding or those who have a high-risk occupation or lifestyle.[36] A bioprosthetic valve is preferred in patients over age 70 and in sinus rhythm because these valves deteriorate

more slowly in older patients.[77] In addition, some 60-year-olds may not outlive their prosthetic valves because of comorbid disease.[78,79] Specifically, patients who require combined mitral valve replacement and coronary bypass grafting for ischemic mitral regurgitation and coronary artery disease have significantly reduced long-term survival as compared with patients who do not have concomitant coronary artery disease.[80–85] These individuals may avoid anticoagulation with little risk of reoperation.

As 20-year results have become available for various bioprostheses, it is clear that structural valve degeneration (SVD) is the most prominent drawback of these valves.[24,27,86–91] The durability of porcine valves is less with mitral bioprostheses than with aortic bioprostheses. The more rapid deterioration of mitral bioprostheses may be due to higher ventricular systolic pressures against the mitral cusps compared with the diastolic pressures resisted by aortic bioprosthetic leaflets.[23] Durability of bioprosthetic valves is directly proportional to age[87]; deterioration occurs within months or a few years in children and young adults and only gradually over years in septuagenarians and octogenarians.[23,27,29,30,33,86,92] Essentially all valves implanted into patients younger than 60 years of age have to be replaced ultimately, and valve failure is prohibitively rapid in children and adults younger than 35 to 40 years of age; therefore, bioprostheses are not advisable in these age groups.[36,93] Nevertheless, there are still indications for mitral porcine bioprosthetic valves in young patients. In a woman who desires to become pregnant, a bioprosthesis may be used to avoid warfarin anticoagulation and fetal damage during pregnancy.[94–97] In patients with chronic renal failure and hypercalcemia related to hyperparathyroidism, bioprostheses have extremely limited durability and therefore should be avoided.

Over the last decade, there were several reports, mainly from European centers, on the use of unstented cryopreserved homografts[98–101] and stentless heterografts[102–105] for mitral valve replacements, particularly in patients with endocarditis. The prosthetic valve is transplanted, donor papillary muscles are reattached to recipient papillary muscles, and the annulus is sutured circumferentially. This technique has been shown to be safe and reproducible, but it does not always provide durable results and therefore should not be used in young patients.[102] Other reports suggest that these operations may be a feasible alternative to stented valve replacement in patients with endocarditis. Pulmonary autografts also have been used for replacing the mitral valve (Ross II procedure), but these series are small, and follow-up is relatively short.[106–108]

HEMODYNAMICS OF MITRAL VALVE DEVICES

Mechanical Prostheses

The designs of mechanical and bioprosthetic heart valves have evolved over the last five decades in an effort to develop the ideal replacement for the pathologic mitral valve. Biochemical and engineering advances have produced hemodynamic improvements and reduced morbidity from valve-related complications. The ideal valve, however, is not available, and the positive and negative characteristics of current valves must be considered when choosing the most appropriate valve for an individual patient. The optimal heart valve exerts minimal resistance to forward blood flow and allows only trivial regurgitant backflow as the occluder closes. The design must cause minimal turbulence and stasis in vivo during physiologic flow conditions. The valve must be durable enough to last a lifetime and must be constructed of biomaterials that are nonantigenic, nontoxic, nonimmunogenic, nondegradable, and noncarcinogenic. The valve also must have a low incidence of thromboembolism.

The opening resistance to blood flow is determined by the orifice diameter; the size, shape, and weight of the occluder; the opening angle; and the orientation of leaflet or disk occluders with respect to the plane of the mitral annular orifice for any given annular size. Least resistance to transvalvular blood flow during diastole for valves in the mitral position is provided by a large ratio of orifice to total annular area. A wide opening angle also improves the effective orifice area and results in decreased diastolic pressure gradients. With an increasing orifice diameter, however, more energy is lost across the valve as more backflow passes through the valve at end diastole and early systole. Table 43-1 shows hemodynamic assessments of each of the FDA-approved mitral valve prostheses for the most commonly used mitral valve sizes.[12,15,17,109–141] The results of in vivo assessments at rest by invasive (catheterization) or noninvasive (Doppler echocardiography) techniques are tabulated.

Blood turbulence flowing across mitral valve devices results from impedance to forward or reverse flow. This impedance can be minimized by occluder design and orientation, central flow through the orifice, and limited struts or pivots extending into flow areas (Fig. 43-4). Hemolysis is the product of red blood cell destruction that is caused by cavitation and shearing stresses of turbulence, high-velocity flow, regurgitation, and mechanical damage during valve closure.[142] Areas of perivalvular blood stagnation and turbulence increase platelet aggregation, activation of the coagulation proteins, and thrombus formation.

Dynamic regurgitation is a feature of all prosthetic valves and is the sum of the closing volume during occluder closure and the leakage volume that passes through the valve while it is closed. The closing volume is a function of the effective orifice area and the time needed for closure. Closure time is influenced by the difference between the opening and closing angles of the occluder and valve ring. Leakage volume is inherent to the design of the valve and depends on the amount of time the valve remains in the closed position.[143] A small amount of regurgitant volume can be beneficial by minimizing stasis and reducing platelet aggregation; this decreases the incidence of valve thrombosis and valve-related thromboembolism.[123]

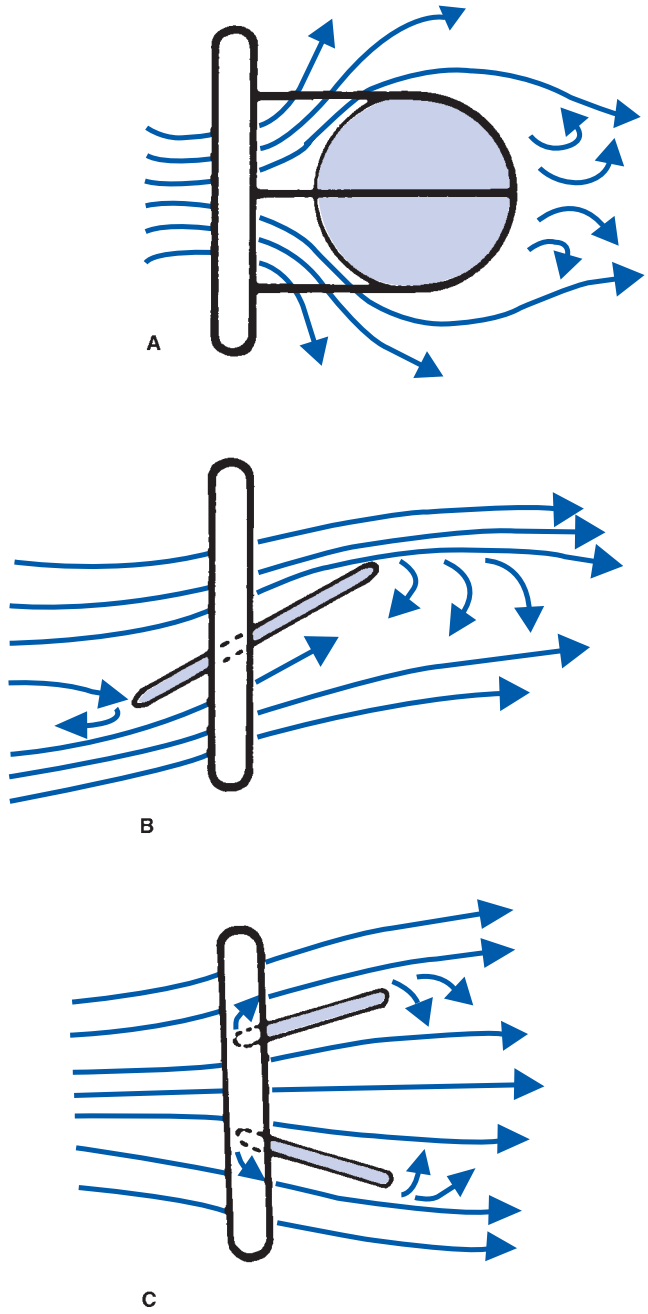

Figure 43-4. Flow characteristics of different mechanical valve designs. *A.* Ball-and-cage. *B.* Tilting-disk. *C.* Bileaflet.

The Starr-Edwards Model 6120 is the only ball-and-cage mitral valve prosthesis currently approved for use in the United States by the FDA. It was introduced with its current design in 1965 after undergoing several engineering modifications and has been in use longer than any other type of mechanical valve (see Fig. 43-2*A*). The occluder is a barium-impregnated Silastic ball in a Stellite alloy cage that projects into the left ventricle. This valve has a large Teflon/polypropylene sewing ring that produces a relatively smaller effective orifice and larger diastolic pressure gradients than other prosthetic valves of similar annular sizes. Leakage volumes are not inherent in the ball-and-cage design, and in contrast to other mechanical valves, the presence of regurgitation may indicate a pathologic process. The central ball occluder causes lateralization of forward flow and results in turbulence and cavitation that increase the risk of hemolysis and thromboembolic complications (see Fig. 43-4*A*). The incidence of thromboembolism has been shown to be higher with the Starr-Edwards valve than with bileaflet valves in some studies[144,145] but not in others.[146] Because the cage projects into the left ventricle, it is unwise to implant this valve in small left ventricles, where the cage may contact the ventricular wall or cause ventricular outflow obstruction.

Tilting-disk mitral valve prostheses have better hemodynamic characteristics than ball-and-cage valves (see Fig.43-4*B*). The Medtronic Hall central pivoting-disk valve was introduced in 1977 and is based on engineering design modifications of the earlier Hall-Kaster valve[147] (see Fig. 43-2*B*). The axis of the tilting disk was moved more centrally to allow greater blood flow through the minor orifice and to reduce stagnation in areas of low flow. The opening angle originally was increased to 78 degrees to decrease resistance to forward flow and later narrowed to 70 degrees when in vitro studies revealed an unacceptable regurgitant volume. The opening angle of 70 degrees produced regurgitation volumes of less than 5% of left ventricular stroke volume without significantly compromising forward flow. The disk occluder was allowed to slide out of the housing at the end of the closing cycle to provide a gap through which blood could flow to minimize stasis at the contact surfaces.[147] The large opening angle and slim disk occluder, along with a thinner sewing ring, provide improved hemodynamics with comparably larger effective orifice areas and lower mean diastolic pressure gradients for each valve size. During implantation, the larger orifice should be oriented posteriorly when using the larger valve sizes to minimize the potential for disk impingement. Smaller valves (27 mm or less) should be oriented with the larger orifice anteriorly to optimize in vivo hemodynamics.[116,148]

The Omniscience tilting-disk valve is a second-generation device derived from improvements to the design of the Lillehei-Kaster pivoting-disk valve.[149] This low-profile device has a pyrolytic disk located eccentrically in a one-piece titanium housing attached to a seamless Teflon sewing ring. Introduced in 1978, the Omniscience prosthesis includes several engineering modifications from prior devices in an effort to improve its hemodynamic function. The orifice-to-annular-area ratio was increased to minimize resistance to forward flow. The opening angle of 80 degrees is relatively large to allow flow reserve in patients with high cardiac outputs and during exercise. Resulting increases in regurgitant volumes are minimized by the disk design. Turbulence is reduced by the curvature of the disk, and areas of stasis and shear stress are reduced by the eccentric location of the pivot axis in an effort to decrease the risk of thrombosis, thromboembolism, and hemolysis. Retaining prongs are not used, and the lower profile reduces the risk of impingement.[131] A potential hemodynamic disadvantage that has been the subject of debate is the possibility of incomplete disk opening in vivo. Clinical studies

report postoperative mean opening angles of between 44.8 degrees[116] and 75.9 degrees.[150] Implicated factors causing this variation include valve sizing, orientation during implantation, and anticoagulation status.[150,151] A subsequent generation of the Omniscience valve is the all-carbon Omnicarbon monoleaflet valve that was released in 2001 in the United States but has been in clinical use in Europe since 1984 (see Fig. 43-2*C*). The housing material is made of pyrolytic carbon instead of titanium. As a result of this change, the incidence of thromboembolism, valvular thrombosis, and reoperations was decreased significantly compared with the Omniscience valve protheses.[152] For all the tilting-disk valves, meticulous surgical technique is important because retained leaflets or chordae can cause subvalvular interference and leakage.

The unique design of the bileaflet St. Jude Medical valve was introduced in 1977, and it is currently the prosthesis used most commonly worldwide (see Fig. 43-2*D*). Two separate pyrolytic carbon semidisks in a pyrolytic carbon housing are attached to a Dacron sewing ring. The housing has two pivot guards that project into the left atrium. The bileaflet design produces three different flow areas through the valve orifice that provide overall a more uniform, central, and laminar flow than in the caged-ball and monleaflet tilting-disk designs. The improved flow results in less turbulence and decreased transmitral diastolic pressure gradients[143,153] (see Fig. 43-4*C*) at any annulus diameter size and cardiac output compared with the caged-ball and single-leaflet tilting valves.[154] The favorable hemodynamics in smaller sizes makes it especially useful in children.[36] The central opening angle is 85 degrees, with a closing angle of 30 to 35 degrees, which, along with a thin sewing ring, provides a large effective orifice area for each valve size at the expense of greater regurgitant volumes, especially at low heart rates. Asynchronous closure of the valve leaflets in vivo also contributes to the regurgitant volume.[155] The design of this prosthesis provides excellent hemodynamic function even in small sizes in any rotational plane.[156] The antianatomic plane, however, with the central slit between the leaflets oriented perpendicular to the opening axis of the native valve leaflets decreases the potential risk of leaflet impingement by the posterior left ventricular wall.[157]

The Carbomedics bileaflet valve was approved by the FDA in 1986 (see Fig. 43-2*E*). This low-profile device is constructed of pyrolytic carbon and has no pivot guards, struts, or orifice projections to decrease blood flow impedance and turbulence through the valve.[143] It has a rotatable sewing cuff design and is available with a more generous and flexible sewing cuff (the OptiForm variant) that confirms more easily to different patient anatomies and allows sub-, intra-, or supra-annular suture placement. The leaflet opening angle is 78 degrees, which, with the bileaflet design, provides a relatively large effective orifice area and transvalvular diastolic pressure differences only slightly greater than the St. Jude Medical bileaflet valve. Rapid synchronous leaflet closure reduces closing regurgitant volumes to less than that of the Björk-Shiley pivoting-disk prosthesis, which has an opening angle of 60 degrees. Leakage volume, however, is greater with Carbomedics valves because of backflow through gaps around pivots. Because of its narrow closing angle and large leakage volume, the Carbomedics valve does not reduce the relatively large regurgitant volume associated with the bileaflet design. Although this valve has good hemodynamic function overall, in the mitral position, the 25-mm Carbomedics valve has a relatively high diastolic pressure gradient and large regurgitant energy loss across the valve, especially at high flows. Hemodynamic studies suggest that the Carbomedics valve should be avoided in patients with a small mitral valve orifice.[143]

The ATS (Advancing The Standard) mechanical prosthesis has been in clinical use in the United States since 2000. Similar to the Carbomedics valve, the ATS valve is a low-profile bileaflet prosthesis with a pyrolytic housing and pyrolytic carbon leaflets containing graphite substrate (see Fig. 43-2*F*). The pivot areas are located entirely within the orifice ring, and the valve leaflets hinge on convex pivot guides on the carbon orifice ring. This design minimizes the overall height of the valve and provides a wider orifice area, and the absence of cavities in the valve ring theoretically reduces stasis or eddy currents that may develop. Valve noise, a bothersome problem for some patients, also is reduced by this design.[158] The opening angle is up to 85 degrees, and the sewing cuff is constructed of double velour polyester fabric that is mounted to a titanium stiffening ring, which enables the surgeon to rotate the valve orifice during and after implantation.

The On-X prosthesis was approved by the FDA in 2002. It has a bileaflet design similar to the St. Jude Medical, Carbomedics, and ATS prostheses with comparable hemodynamic performance, i.e., a relatively large orifice diameter and a wide opening angle (90 degrees) (see Fig. 43-2*G*). Instead of silicon-alloyed pyrolytic carbon, as used in the other mechanical prostheses, the On-X valve is made of pure pyrolytic carbon. This material is stronger and tougher than silicon-alloyed carbon[159] and allows incorporation of hydrodynamically efficient features into the valve orifice, such as increased orifice length and a flared inlet that reduces transvalvular gradient.[115] Early clinical results are promising,[160,161] and the valve produces very little hemolysis with postoperative levels of serum lactate dehydrogenase in the normal range.[161,162]

Bioprostheses

Porcine valves

The porcine bioprosthetic mitral valves are designed to mimic the flow characteristics of the in situ aortic valve. The Hancock I mitral valve bioprosthesis was introduced in 1970. It has three glutaraldehyde-preserved porcine aortic valve leaflets on a polypropylene stent attached to a Dacron-covered silicone sewing ring. The design allows for central laminar flow through the valve, which tends to decrease diastolic pressure gradients and minimize turbulence.[153] The stent, however, impedes forward flow and results in relatively large diastolic pressure gradients across the bioprosthesis. The stent and the large sewing ring contribute to effective orifice areas that are smaller than those of size-matched mechanical valves (see Table 43-1).

The Hancock II porcine bioprosthesis (see Fig. 43-3*A*) is the more modern version of the Hancock I prosthesis. The stent is made of Delrin with a scalloped sewing ring and reduced stent profile. The leaflets are fixed in glutaraldehyde at low pressure and subsequently for a prolonged period at high pressure. To retard calcification, the leaflets are treated with sodium dodecyl sulfate.

The Carpentier-Edwards porcine valve uses a flexible stent to decrease the stress of leaflet flexion while maintaining its overall configuration (see Fig. 43-3*B*). The effective orifice-to-total-annulus-area ratio for the Carpentier-Edwards valve is relatively small, but exercise studies show that the effective orifice area increases significantly with increased blood flow across the valve; diastolic gradients also increase, although to a lesser degree.[127,132,163] Porcine bioprostheses in the mitral position should be avoided in patients with small left ventricles because of the possibility of ventricular rupture or left ventricular outflow obstruction caused by the large struts.[163]

The Mosaic porcine bioprosthesis is a third-generation bioprosthesis using the Hancock II stent (see Fig. 43-3*C*). It was introduced in the United States in 2000 and has a Delrin stent, scalloped sewing ring, and reduced stent profile. The valve tissue is pressure-free fixed with glutaraldehyde, and the prosthesis is treated with alpha-oleic acid (AOA) to retard calcification.

The prosthesis approved most recently by the FDA in 2005 is the Biocor porcine bioprosthesis (St Jude Medical); however, it has been used and investigated for almost two decades in Europe.[30] It belongs to the third generation of bioprostheses, and the valve tissue is pretreated in glutaraldehyde at very low pressure (<1 mm Hg), making the valve cusps less stiff with less tendency to tissue fatigue.

Pericardial valves

Previous studies indicated poor durability of pericardial valves, namely, the Ionescu-Shiley valve, caused by leaflet tearing. This led to significant changes in design, including mounting of the pericardium completely within the stent, causing less leaflet abrasion and increased durability. The Carpentier-Edwards pericardial valve uses bovine pericardium as material to fabricate a trileaflet valve that is cut, fitted, and sewn onto a flexible Elgiloy wire frame for stress reduction (see Fig. 43-3*D*). The tissue is preserved with glutaraldehyde with no applied pressure, and the leaflets are treated with the calcium mitigation agent XenoLogiX. Compared with the Carpentier-Edwards porcine bioprosthesis, the stent profile is reduced. Long-term durability for the Carpentier-Edwards pericardial valve is strong, and compared with third-generation porcine valves, valve-related complications are similar (see discussion later in this chapter).

Hemodynamically, pericardial valves provide the best solution to flow problems. The design maximizes use of the flow area, which results in minimal flow resistance.[164] Figure 43-5*A* shows how the cone shape of the open valve and circular valve orifice minimize flow disturbance compared with the more irregular cone shape of the porcine valves that allow for central unimpeded flow (see Fig. 43-5*B*).

Structural valve deterioration is seen after long-term follow-up of patients with both porcine and pericardial bioprostheses and results in mitral stenosis or regurgitation or both. Hemodynamic studies early after operation and at 5 years reveal higher average diastolic pressure gradients and smaller effective orifice areas when compared in the same patients at the follow-up study. In some patients, these changes are sufficiently severe to require reoperation as soon as 4 to 5 years postoperatively, and by 10 years, the rate of primary tissue failure averages 30%. It then accelerates, and by 15 years postoperatively, the actuarial freedom from bioprosthetic primary tissue failure has ranged from 35 to 71%[28,29,31–33,86,88,90,91,111,120,124,134,138,165–176] (Table 43-2). Most of these patients show hemodynamic evidence of valvular deterioration prior to any clinical signs or symptoms.[132] Bioprosthetic valves have the advantage of low thrombogenicity, which must be weighed against poor long-term durability and subsequent hemodynamic deterioration and the risk of reoperation.

OPERATIVE TECHNIQUES

Preoperative Management and Anesthetic Preparation

Congestive heart failure secondary to mitral stenosis usually can be treated with aggressive diuretic therapy and sodium restriction preoperatively. If the patient is in rapid atrial

fibrillation, digoxin, beta blockers, and calcium channel antagonists can be used to slow down the ventricular rate. Patients with acute mitral regurgitation often are in cardiogenic shock, and they can be stabilized preoperatively with inotropes and arterial vasodilators to reduce systemic afterload. Intra-aortic balloon counterpulsation also can be used for this purpose. Symptoms of congestive heart failure in patients with chronic mitral regurgitation are treated with diuretics and oral vasodilators. The vasodilators lower the peripheral vascular resistance, and forward cardiac output is increased by reducing the regurgitant volume into the left atrium.

Preferred anesthesia for mitral valve replacement typically involves a combination of narcotic and inhalational agents. Ultimately, anesthetic management is dictated by the wide range of functional disabilities and hemodynamic abnormalities of patients who present for mitral valve replacement. For example, a cachectic patient with functional class IV mitral stenosis and severe pulmonary hypertension may require postoperative positive-pressure mechanical ventilation for 1 or 2 days to remove excess pulmonary fluid by diuresis, facilitate bronchial toileting, and provide optimal conditions for adequate gas exchange. Alternatively, young patients who require mitral valve surgery and present with less preoperative comorbidity may benefit from a short-acting, balanced anesthetic that can facilitate extubation within 6 hours of surgery.[177]

Monitoring should include arterial and venous lines, a urinary catheter, and a pulmonary artery catheter placed before bypass to measure pulmonary pressures and cardiac output. Following valve replacement, occasionally a left atrial catheter directly inserted through the left atrial incision can be helpful to allow measurement of pulmonary vascular resistance, but we do not use it routinely. Preoperative intravenous prophylactic antibiotics are administered to all patients and are continued for 2 postoperative days until lines are removed.

Temporary ventricular pacing wires are placed, and in many instances, temporary atrial pacing wires are placed for possible pacing or diagnosis of various atrial arrhythmias.

Management of Cardiopulmonary Bypass for Mitral Valve Replacement

Cardiopulmonary bypass is instituted by placing two right-angle cannulas into the superior and inferior venae cavae. We place a small (22F) plastic or metal cannula directly into the superior vena cava, above the sinoatrial node. The inferior caval cannula is placed at the entrance of the inferior vena cava, low in the right atrium. These insertion sites keep the caval catheters out of the operative field and yet maintain excellent bicaval drainage. An arterial cannula is placed in the distal ascending aorta. Bypass flows are approximately 1.5 L/m^2 per minute, and moderate hypothermia 28 to 32°C is used with vacuum-assisted suction. Myocardial protection includes antegrade and retrograde blood cardioplegia and profound myocardial hypothermia.[178] Retrograde cardioplegia is useful for all valve surgery to protect the ischemic left ventricle and to help remove ascending aorta bubbles. Antegrade cardioplegia, used as an initial loading dose, is augmented by intermittent retrograde cardioplegia every 20 minutes. This provides safer delivery of cardioplegia because when the atrium is retracted during valve replacement, the aortic valve is distorted, and antegrade cardioplegia tends to fill the ventricle.

Exposure of the Mitral Valve

Evolution of meticulous and complicated methods of mitral valve repair and reconstruction has required optimal exposure of the mitral valve. In primary operations, median sternotomy, development of Sondergaard's plane, and incision of the left atrium close to the atrial septum provide excellent exposure[179,180] (Fig. 43-6). This incision is a ubiquitous one, and we have rarely seen indications for use of other incisions, such as the superior approach through the dome of the left atrium,[181,182] the so-called biatrial incision popularized by Guiraudon and colleagues,[183] division of the superior vena cava,[184,185] and the less common but occasionally useful trans–right atrial septal incision.[139,186] The trans–right atrial incision has in some studies been related to higher incidence of junctional and nonsinus rhythm postoperatively,[187] although this has not been confirmed by other studies.[188]

Minimally Invasive Mitral Valve Replacement

Following advances in videoscopic and other minimally invasive techniques in many areas of surgery in the 1990s, similar techniques are now being used increasingly in cardiac surgery, especially in mitral valve surgery. In 1996, we began minimally invasive valve surgery for patients who have isolated valvular pathology without concomitant coronary artery disease. Our experience at Brigham and Women's Hospital now totals over 1000 patients, including mitral valve repairs and aortic and mitral valve replacements.[189]

The minimally invasive approach for mitral valve surgery usually is accomplished with a 5- to 7-cm midline skin incision. The superior margin of the incision is 2 cm distal to the angle of Louis, and the incision then extends caudally to a point that is 2 cm proximal to the sternoxyphoid junction. Partial lower sternotomy is performed with an oscillitating saw from the xyphoid process up to the manubrium with an angled incision made into the right second intercostal space. The pericardium is incised vertically, and pericardial stay sutures are placed at the right side of the pericardial edge. Suspension of the right side of the pericardial cradle to the sternal edges allows better exposure of the base of the heart. This approach allows excellent exposure of the left and right atrium and proximal ascending aorta. A slightly different approach is to access the right atrium through a right parasternal incision, excising the third and fourth costal cartilage. This approach, which was used in some of the early cases of minimally invasive mitral surgery, was associated with significant incidence of lung herniation and has been abandoned.

Cardiopulmonary bypass can be established in several different ways depending on the exposure of the ascending aorta and superior vena cava. The exposure depends on the habitus of the patient, as well as on the relative sizes of the right atrium and ascending aorta. If easily accessible, the ascending aorta can be cannulated directly using a Seldinger technique with a flexible aortic cannula. Both femoral and internal jugular veins are cannulated percutaneously. Percutaneous venous cannulation allows better visualization of the operative field because none of the cannulas exit the sternotomy incision. We routinely use vacuum-assisted venous drainage, which allows the use of smaller-diameter cannulas (i.e., 21F femoral venous cannula and 14F right internal jugular cannula). Tips of the cannulas are positioned in the distal parts of the superior and inferior venae cavae, respectively. The positioning of the cannulas is done under transesophageal echocardiographic guidance. After fibrillating the heart, the aortic cross-clamp is applied, and antegrade blood cardioplegia is administered through the aortic root. Systemic temperature is lowered to 28°C. The valve is approached through the left atrium as described earlier or more often the right atrium with a transseptal incision. After the valve has been replaced with a standard technique, the atrium and septum (if opened) are closed with running 4-0 Prolene. Intracardiac air is always monitored by transesophageal echocardiography, and alternate filling is used to evacuate the air by manipulating the volume of the heart on bypass. Figure 43-7 demonstrates minimally invasive reoperative mitral valve replacement.

Safety and efficacy of minimally invasive mitral valve surgery have been confirmed in several reports.[68,188–190] Trauma seems to be less with the minimally invasive incisions, which is beneficial in regard to infections (including mediastinitis) and bleeding from the incision and the operative field, leading to lesser usage of homologous blood.[190] There is also improved cosmesis with these incisions, and postoperative pain seems to be considerably less than in

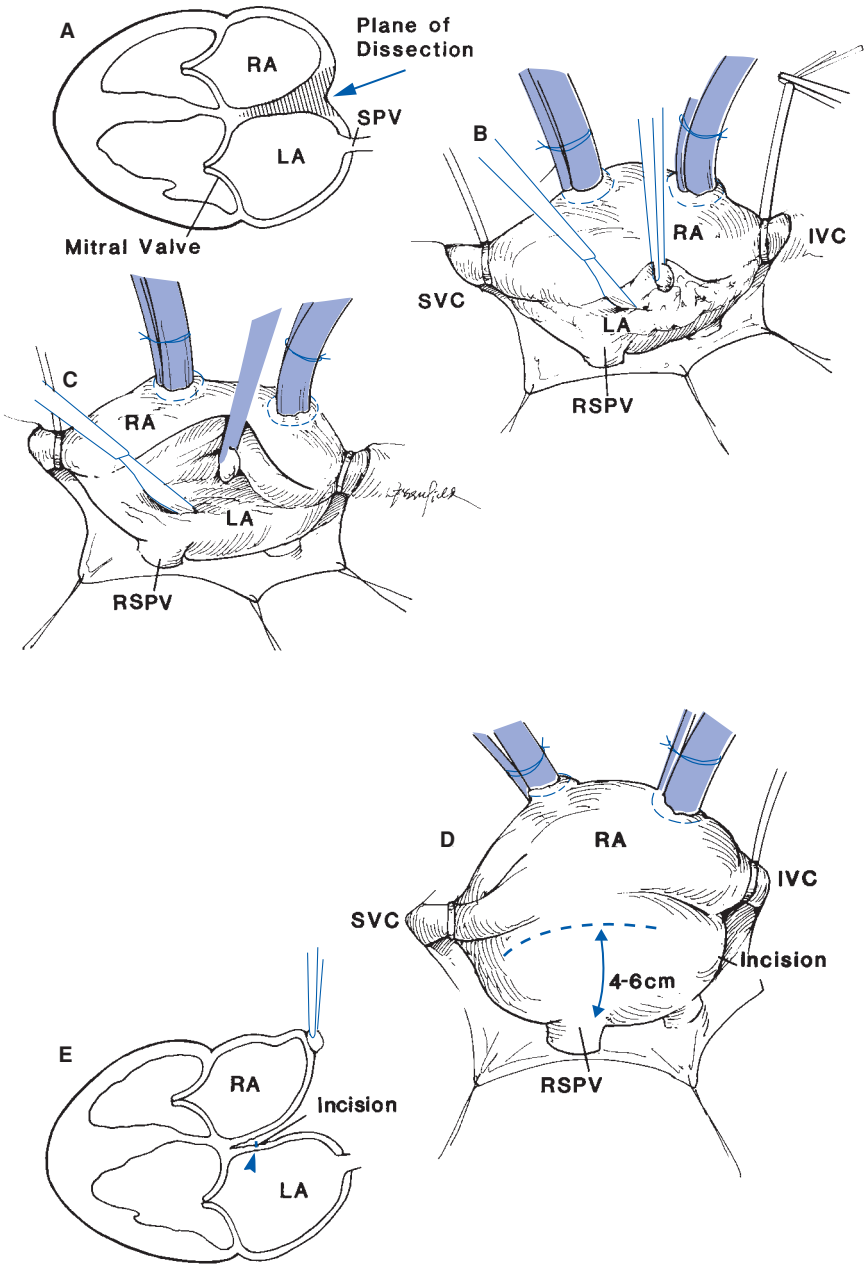

Figure 43-6. Exposure of the mitral valve. *A.* Location of Sondergaard's plane. *B,C.* Development of the interatrial plane. *D.* Location of the left atrial incision. *E.* Cross-sectional view.

patients with the median sternotomy. This can result in less requirement for pain medication and faster return to normal activity with less dependence on after-hospital stay and after-hospital care without compromising results.

Femoral arterial and venous cannulation are tolerated well in the vast majority of patients and are associated with minimal morbidity. One of the important technical aspects of cannulation is the use of a limited (2 to 3 cm) oblique suprainguinal incision just above femoral vessels. This incision, in contrast to the standard vertical incision, has been associated with minimal discomfort and a low wound infection rate because it does not transverse the inguinal skin crease and is not exposed to stretching during hip flexion and ambulation. One of the rare potential risks of femoral arterial cannulation is the development of retrograde aortic dissection or retrograde plaque embolization in patients with severe atherosclerotic disease of the descending aorta. We perform routine assessment of the descending aorta with transesophageal echocardiography prior to cannulation. If concomitant coronary artery bypass grafting is needed, a full sternotomy is necessary.

Intracardiac Technique

Operation entails secure fixation of a valve prosthesis to the annulus by reliable suture techniques without damage to adjacent structures or myocardium and without tissue interference with valve function. Implantation should prevent

injury to anatomic structures surrounding the mitral valve annulus. Figure 43-8 shows the proximity of important cardiac structures near the mitral valve annulus. These include the circumflex coronary artery within the atrioventricular (AV) groove, the left atrial appendage, the aortic valve in continuity with the anterior mitral curtain, and the AV node.

An accumulation of laboratory and clinical evidence indicates that preservation of papillary muscle–chordal attachments to the annulus is important for

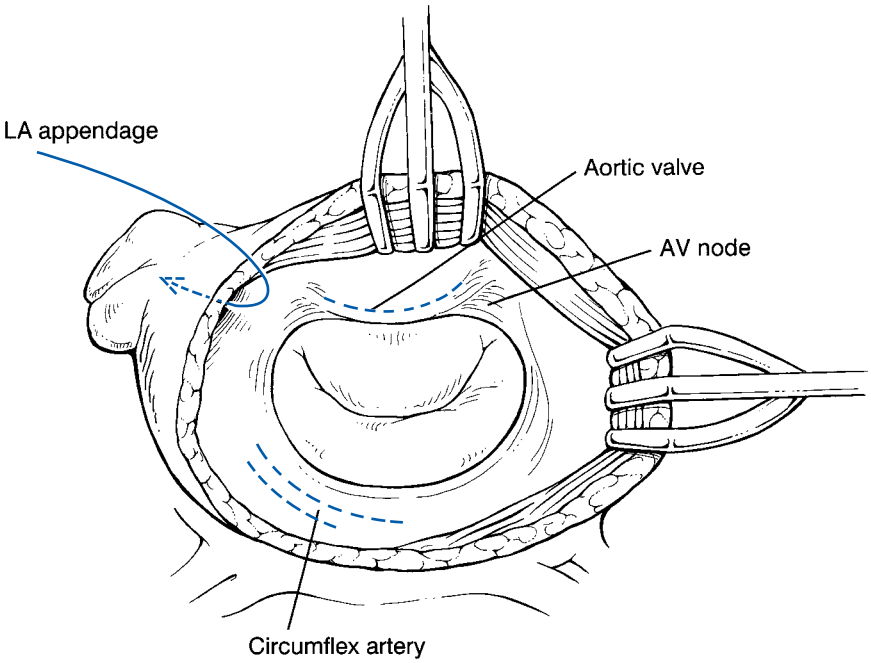

Figure 43-8. Location of important structures surrounding the mitral annulus. (*Courtesy of David Bichell, M.D.*)

maintenance of left ventricular function. In patients with mitral stenosis with agglutinated, fibrotic chordae and papillary muscles, preservation of these structures probably has little effect on left ventricular dysfunction but does protect the AV groove from rupture by preserving the posterior leaflet. However, preservation of the posterior mitral leaflet may preclude use of an adequately sized prosthesis. If fibrotic, agglutinated chordae and the posterior leaflet are excised, placement of artificial Gore-Tex chordae to reattach the papillary muscles to the annulus may improve early and late preservation of cardiac output.[191] In patients with mitral regurgitation, however, it is important to preserve as much of the papillary muscle and annular interaction as possible. This can be achieved by a variety of techniques, as shown in Fig. 43-9. The anterior leaflet may be partially excised and brought to the posterior leaflet[192] (see Fig. 43-9*A*) or can be partially excised and "furled" to the anterior annulus by a running Prolene suture[193,194] (see Fig. 43-9*B*).

Experimental and clinical evidence suggest that preservation of the conical shape of the ventricle is important to maintain normal cardiac output[195–198] and that assumption of a globular shape from cutting papillary muscles is deleterious to left ventricular function. Furthermore, preservation of the posterior leaflet and chordae has reduced the incidence of perforation of the left ventricle and atrioventricular separation dramatically during mitral valve replacement.[48,199,200]

Suturing techniques vary according to the type of valve that is implanted. The bioprosthetic valve is inserted preferentially with the sutures placed from ventricle to atrium (noneverting or subannular). This has been shown to be the strongest type of suturing technique to the mitral annulus and is used with this valve and with the central-flow Starr-Edwards ball-and-cage valve[201] (Fig. 43-10*A*).

To ensure adequate function of bileaflet or tilting-disk valves, everting sutures (atrium to ventricle to sewing ring) should be used (see Fig. 43-10*B*). This technique pushes the prosthetic valve out into the center of the orifice and minimizes any tissue interference of the prosthetic valve leaflets. This is particularly important if annular-chordal attachments are preserved. Teflon pledgeted sutures, particularly with the thin sewing rings of the currently available bileaflet and tilting-disk valves, should be used. If a bioprosthetic valve is inserted, a dental mirror is used to ensure that no annular suture is wrapped around a stent strut. A running Prolene suture for implantation of mitral valves has been advocated by some surgeons.[202,203] This technique makes a very clean suture line with minimal knots but runs the risk of valve dehiscence if an infection occurs.[204]

Prior to closure, the left atrial appendage is ligated by suture or stapled to prevent clot formation in patients with chronic atrial fibrillation, enlarged left atrium, or left atrial thrombus.[205] The atrium is closed by a running Prolene suture, making sure that endocardial surfaces are approximated. If needed, a left atrial catheter can be inserted through the suture line.

Associated Operations/Procedures

Coronary bypass is the most common procedure performed with mitral valve replacement and should be performed first. This reduces lifting of the heart after the rigid mitral valve prosthesis is in place, which can cause rupture of the myocardium or the atrioventricular

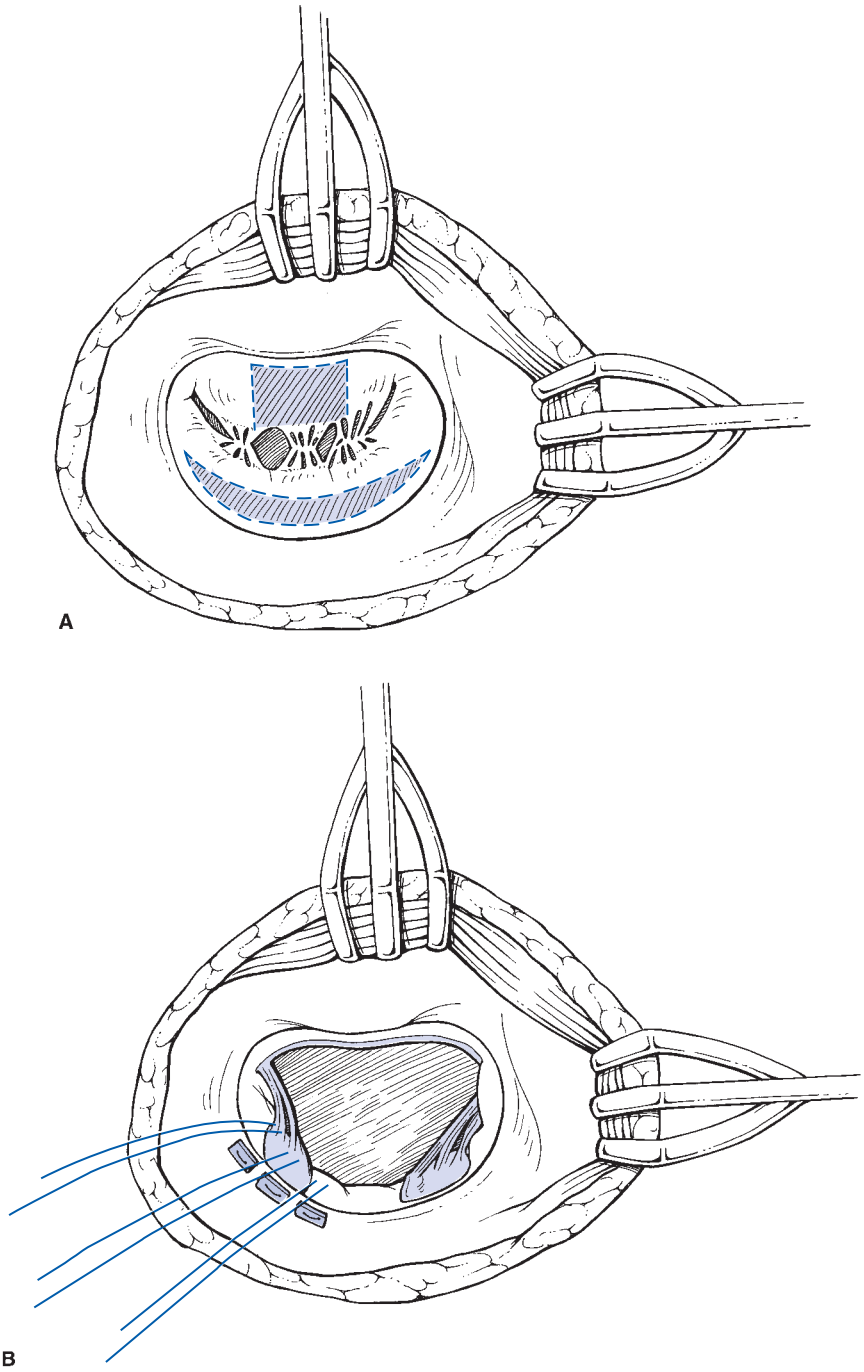

Figure 43-9. Techniques to maintain annular–papillary muscle continuity. *A.* An ellipse is removed from the posterior leaflet, and a flap is cut from the central portion of the anterior leaflet. The anterior flap is flipped to the posterior annulus and tacked to the caudad edge of the posterior leaflet and the posterior annulus. Sutures anchoring the prosthesis include the annulus and anterior and posterior leaflet remnants to which chordae are attached. *B.* The anterior leaflet is partially excised, and remnants are "furled" to the annulus by sutures used to insert the prosthesis.

groove. This also allows cardioplegia to be delivered through the bypass grafts.

Tricuspid valve repair or replacements usually are performed after replacing the mitral valve. In these cases, the mitral valve often is approached through the right atrium and a transseptal incision. After the mitral valve prosthesis is in place, the septum is closed, and the aortic cross-clamp is removed before proceeding with the tricuspid valve procedure.[206]

When both the aortic and mitral valves are replaced at the same operation, most surgeons begin with excising the aortic valve before proceeding with the mitral valve procedure. When excising the anterior mitral valve leaflet, care must be taken not to injure the aortic annulus and the intra-annular region. The aortic valve then is sewn in after the mitral valve is in place.

Weaning Off Cardiopulmonary Bypass

We use transesophageal echocardiography for every valve operation and particularly for mitral valves, where excellent images can be obtained. If transesophageal echocardiography is contraindicated (e.g., because of esophageal disease), direct epicardial echocardiography can be used. The echocardiograms

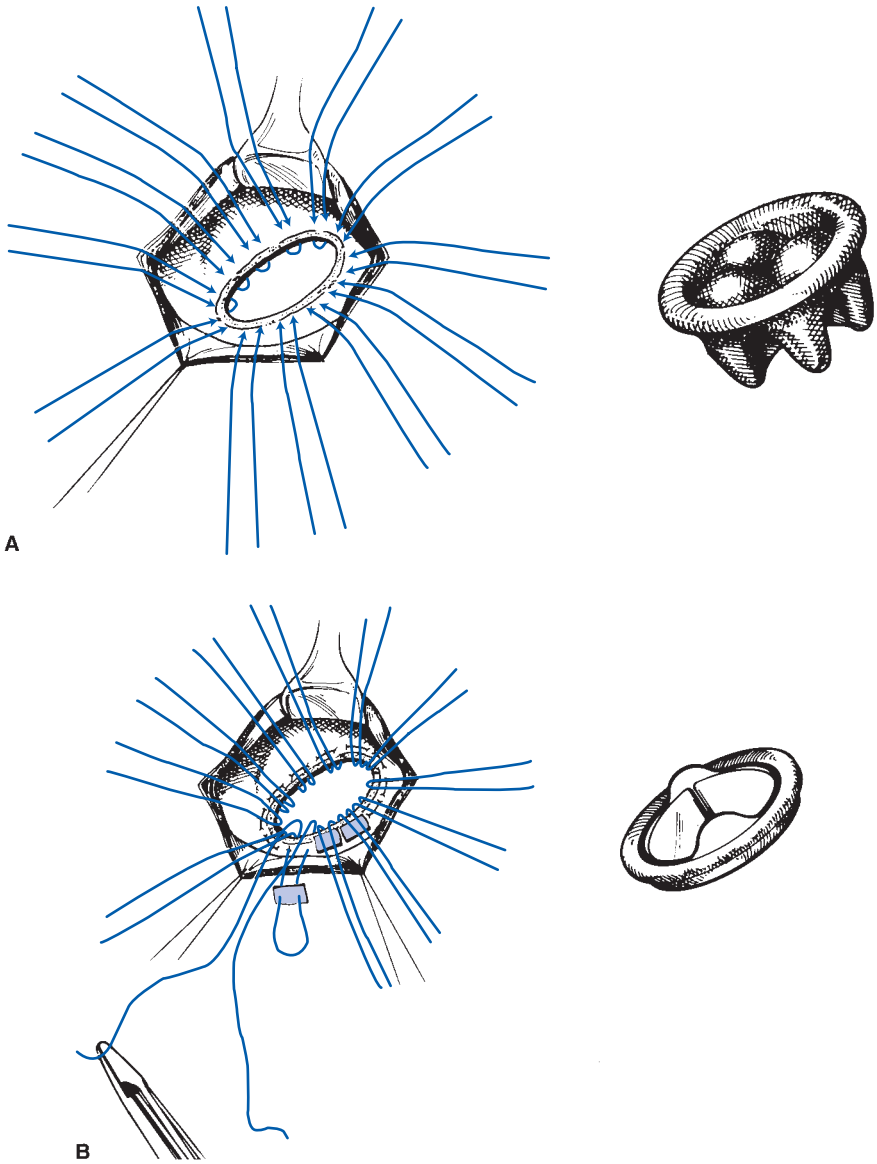

Figure 43-10. Suturing techniques for prosthetic mitral valve implantation. Noneverting (subannular) sutures placed from ventricle to atrium for bioprosthetic or Starr-Edwards valves. Everting (supra-annular) sutures placed from atrium to ventricle for bileaflet or tilting-disk valves.

provide information about valve and left ventricular function, possible retained material in the left atrium including thrombus, and removal of intracardiac air.

A careful deairing at the end of the operation is essential. The heart is vented through the left atrium and the ascending aorta and sometimes the left ventricle. Before the aortic cross-clamp is removed, the patient's head is lowered and the lungs inflated carefully to dislodge any air bubbles in the pulmonary vein. The operating table then is tilted from side to side, the left atrial appendage is inverted, and the cardiac chambers are aspirated if necessary. Once deairing maneuvers are completed, and after the patient is completely rewarmed, venous return is partially occluded, and the heart is gradually volume loaded. Pulmonary artery pressures are monitored carefully. Pharmacologic agents, such as amrinone or dobutamine, particularly for right ventricular overload, are used frequently.

Deairing the heart after a minimally invasive approach is more complex because the heart is only partially visible through the 5- to 7-cm sternal incision, and the apex of the heart is not accessible. Flooding the operative field with continuous CO_2 can be beneficial in reducing intracardial air.[207] In addition, by filling the left ventricle with cardioplegia through the left atriotomy suture line, and by manipulating the volume of the heart on bypass and alternating the position of the patient, air can be evacuated effectively.

POSTOPERATIVE CARE

Postoperative care is directed toward the resumption of normal cardiac output, respiratory function, temperature

control, electrolyte management, adequate renal flow, and prophylaxis against bleeding. Patients with low cardiac output are managed with a variety of pharmacologic agents after providing adequate volume loading. Left atrial and especially pulmonary arterial catheters are particularly helpful in determining optimal balancing of volume loading and myocardial function in the first hours following operation.

Reduction of pulmonary interstitial fluid is pursued aggressively by diuresis in the intensive-care unit in patients with severe pulmonary hypertension. Most patients with severe pulmonary hypertension can be extubated within 48 hours of surgery. Nutritional, respiratory, and general metabolic support is provided. Many patients with severe, long-standing mitral valve disease are cachectic and, despite preoperative nutritional support, are severely catabolic at the time of operation. These patients generally require longer periods of ventilatory support owing to lack of respiratory muscle strength. They need aggressive nutritional support with nasogastric hyperalimentation to increase respiratory muscle strength. In patients with severe pulmonary hypertension and cardiac cachexia who require prolonged intubation, tracheostomy may be necessary to reduce ventilatory dead space and facilitate faster weaning and better pulmonary toilet. Tracheostomy usually is performed by the end of the first postoperative week.

Postoperative atrial arrhythmias are so common that their absence is unusual. Arrhythmias vary from rapid supraventricular tachycardias, usually atrial fibrillation, to junctional rhythm and heart block. These arrhythmias are treated by pharmacologic agents, pacemakers, or both. If rapid atrial fibrillation cannot be controlled pharmacologically and is destabilizing hemodynamically, emergency cardioversion is done to improve cardiac output. Pharmacologic management of supraventricular tachycardia usually is required but may precipitate the need for a prophylactic transvenous pacemaker if severe slowing of the heart rate occurs.

Anticoagulation is prescribed for all patients undergoing mitral valve replacement with either a mechanical or a bioprosthetic valve. In the first 6 weeks following operation, the incidence of atrial and other arrhythmias is high; thus these fluctuating rhythms mandate anticoagulation even if the basic rhythm is sinus. In addition to rhythm concerns, the left atrial incisions and the possibility of stasis in the left atrial appendage justify full anticoagulation with warfarin for all patients. Some surgeons advocate immediate intravenous heparin until therapeutic warfarin doses can be reached.[208,209] Low-molecular-weight heparin (LMWH) also can be used.[210,211]

The therapeutic international normalized ratio (INR) after mitral valve replacement is 2.5 to 3.5 depending on the type of valve, cardiac rhythm, and presence or absence of the aforementioned intraoperative risk factors for thromboembolism.[35,205,209,210] Anticoagulation levels are in the low range for patients in sinus rhythm who received tissue valves. Patients who have mechanical valves need lifelong anticoagulation. Patients who have bioprosthetic valves are evaluated at 6 to 12 weeks for cardiac rhythm abnormalities. If they are in predominantly sinus rhythm, warfarin is stopped, and one aspirin tablet is given daily indefinitely. If the patient has continuous atrial fibrillation or fluctuating rhythms, anticoagulation with warfarin is continued. This is also true for patients with a history of previous embolism or in whom thrombus is found in the left atrium at operation.

Warfarin usually is started on the second postoperative day. Addition of aspirin, 80 to 150 mg daily, to the warfarin may reduce the risk of thromboembolism[212,213] and may have a role in patients with prosthetic valves.[214]

RESULTS

Early Results

The hospital mortality for mitral valve replacement with and without coronary bypass grafting has decreased significantly since the inception of mitral valve surgery. The current risk (2006) of elective primary mitral valve replacement with and without coronary bypass grafting is 5 to 9% in most studies (range 3.3 to 13.1%).[15,17,27–29,90,91,111,138,172,195,215–223] Operative (30-day) mortality is related to myocardial failure, multisystem organ failure, bleeding, respiratory failure in the chronically ill, debilitated individual, diabetes, infection, stroke, and very rarely, technical problems.[65,82] Mortality is correlated with preoperative functional class, age, and preexisting coronary artery disease.[216,224,225]

Published results on mitral valve surgery have improved in recent years,[226] probably because of preservation of papillary muscles, preventing midventricular rupture,[199,200] and preservation of the normal geometry of the left ventricle, which aids in the maintenance of early postoperative cardiac output.[195,196,227] Mitral valve replacement and coronary artery bypass surgery 20 to 25 years ago had an associated mortality of about 10 to 20%.[81,228] This mortality risk also has decreased as myocardial protection has improved with the use of blood cardioplegia and retrograde methods of administration.[178,229] Some studies have indicated that the risk of combined mitral valve replacement–coronary artery bypass grafting is now no greater than that of mitral valve repair with an annuloplasty ring or mitral valve replacement without coronary artery bypass grafting.[195,230] Other studies have shown significantly increased morbidity and mortality with the addition of coronary artery bypass grafting.[85,231] Figures from the database of the Society of Thoracic Surgeons indicate that both reoperation and emergency operation increase operative mortality[232] (Fig. 43-11).

Late Results

Functional improvement

In over 90% of patients following mitral valve replacement, functional class improves to at least class II. A small group of

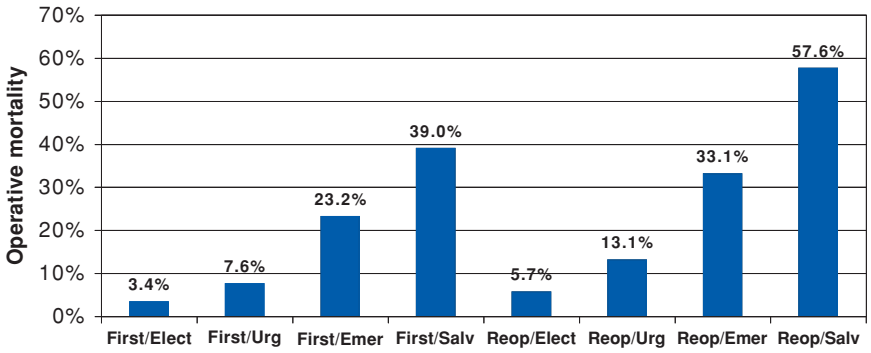

Figure 43-11. Operative mortality for elective, urgent, emergency, and salvage procedures for primary operations and reoperations for mitral valvular replacements. (*Data used with permission from Society of Thoracic Surgeons.*)

patients remains in class III or IV depending on left ventricular function prior to surgery or other coexisting morbidity.

Survival

The causes of late death in patients following mitral valve replacement are primarily chronic myocardial dysfunction, thromboemboli and stroke, endocarditis, anticoagulant-related hemorrhage, and coronary artery disease. The extent of left ventricular dysfunction and patient age, particularly if myocardial and coronary diseases are combined, also correlate with late mortality. The probability of survival after mitral valve replacement at 10 years is usually around 50 to 60% (range 42 to 81%)[15,17,22,23,27–29,31–33,86,90,91,111,112,117,120,134,135,138,145,146,166,170–172,174–176,215,216,218–220,222,223,233–259] (Table 43-3). Long-term patient survival seems to be similar for patients with biologic and mechanical mitral valves.[260–263] Unlike patients with severe aortic regurgitation or aortic stenosis, arrhythmias seldom cause sudden death in patients following mitral valve replacement; however, a few patients die from thromboembolic stroke owing to chronic atrial fibrillation.[244] The fact that more than 50% of patients following mitral valve replacement are in chronic atrial fibrillation increases the propensity for thromboembolic stroke despite anticoagulation and for mechanical valve thrombosis if the anticoagulation protocol is altered. In addition, patients with older types of prosthetic valves who receive higher-intensity anticoagulation may develop severe anticoagulant hemorrhage.[264]

In patients with bioprosthetic valves, one of the important determinants of mortality is reoperation secondary to structural valve degeneration[27,29,31–33,90,91,111,120,124,134,166–168,170,173–175,256,265–268] (Table 43-4). Reoperative mitral valve replacement mortality has decreased significantly in the last 15 years to under 10%, even in patients who have required multiple mitral valve reoperations.[229,269] At the Brigham and Women's Hospital, operative mortality was less than 6% for reoperative mitral valve operations from 1990 to 1995.[229] Improved myocardial protection, earlier selection of patients for reoperation, and better perfusion techniques, including frequent femorofemoral bypass to protect the right ventricle during incision and dissection of the heart, are factors contributing to decreased mortality.[195,229,270–272]

Late morbidity

The major morbidity in patients following mitral valve replacement is structural valve deterioration of a bioprosthetic valve and thromboembolism and anticoagulant hemorrhage with a mechanical prosthesis. Both valve types develop perivalvular leak and infection.

THROMBOEMBOLISM: Thromboembolism is perhaps the most common complication of both biologic and mechanical mitral prostheses but is more frequent in patients with mechanical valves. Chronic atrial fibrillation and local atrial factors, discussed earlier, increase the risk of thromboembolism in patients with mitral prostheses.[13,22,24,240,273] A number of recent studies have summarized the thromboembolic potential of various valves[13,17,22,27,29,31–33,91,111,112,117,134,136,138,141,144,145,150,160,162,165,166,168,172–174,209,215–217,222,223,234–237,239,240,245,246,248,250,252–256,257–259,266,274–286] (Table 43-5), and it appears that the better the valve hemodynamics, the lower is the probability of thromboemboli. The incidence of thromboemboli in currently available bileaflet and tilting-disk valves is similar to that in bioprosthetic valves—about 1.5 to 2.0% per patient-year. Thromboembolism in patients with mitral valve replacement is lower in those with a small left atrium, sinus rhythm, and normal cardiac output. It is much higher in patients with a large left atrium, chronic atrial fibrillation, and the presence of intra-atrial clot.[205,287] Thrombosis of a mechanical valve, once a feared complication of tilting-disk valves,[288,289] is now relatively rare unless anticoagulation is stopped for any period of time. Valve thrombosis can be treated with thrombolytic agents if the patient is not in cardiogenic shock but requires surgery if the circulation is inadequate.[290,291]

ANTICOAGULANT HEMORRHAGE: Bleeding related to anticoagulation is seen most commonly in the gastrointestinal, urogenital, and central nervous systems and usually is proportionate to the INR. The incidence of anticoagulant-related hemorrhage has decreased markedly with hemodynamic improvements in mitral valve prostheses. New valves do not require the intensity of anticoagulation of older prostheses. For example, the distinctive Starr-Edwards ball-and-cage valve requires an INR of 3.5 to 4.5.[264] Patients with streamlined bileaflet or tilting-disk valves require an

INR of between 2.5 and 3.5; thus the incidence of anticoagulant hemorrhage is reduced significantly in the newer, hemodynamically improved prostheses.[238,292] Table 43-5 lists the incidence of anticoagulant hemorrhage with various bioprostheses and mechanical valves.[13,17,22,27,29,31–33,91,111,112,117,134,136,138,141,144,145,150,160,162,165,166,168,172–174,209,215–217,222,223,234–237,239,240,245,246,248,250,252–256,257–259,266,274–286]

Structural valve degeneration

Structural valve degeneration (SVD) is the most important complication of the bioprosthetic valve. The probability of structural failure with currently available porcine valves (Hancock or Carpentier-Edwards) begins to increase 8 years after operation and reaches over 60% at 15 years.[27,88,90,170,267] This finite durability is a major impediment to long-term success of these biologic prostheses, even though the failure rate in a patient 70 years of age or older is significantly less than in younger age groups[22,27,29,31–33,88,111,166,167,169,172,174] (Table 43-6). Structural valve degeneration presents as either mitral regurgitation from leaflet tear or calcific mitral stenosis owing to calcification of valve leaflets or as both. The appearance of a new murmur with new congestive symptoms should prompt a noninvasive investigation of the prosthesis and elective re-replacement if dysfunction is documented. Structural valve degeneration leading to reoperation is the cause for at least two-thirds of the reoperations in patients with bioprostheses.[22,270,271] The probabilities of structural

valve degeneration at 5, 10, and 15 years of the six most commonly used biologic prostheses are shown in Table 43-2. With current quality controls, the incidence of structural valve degeneration is virtually zero for bileaflet, tilting-disk, and ball-and-cage valves.

Perivalvular leak

Perivalvular leak is an uncommon complication that usually depends on technical factors. Patient-related factors such as endocarditis and calcifications involving the annulus are also important. Perivalvular leak usually causes refractory hemolytic anemia in contrast to the milder chronic hemolysis seen after implantation of some of the mechanical valves, especially the tilting-disk valves.[293]

Because of improved surgical techniques and the use of Teflon pledgets, the incidence of perivalvular leak has fallen and is about 0 to 1.5% per patient-year for both mechanical and biologic valves.[13,247,259,276,286,294] Perivalvular leak is slightly more common with the bileaflet valve than with the porcine valve because of the need for the everting suture technique and less bulky sewing ring.[295,296] Surgery should be offered to all symptomatic patients and even patients with mild symptoms who require blood transfusions.[294]

Endocarditis

Endocarditis is a feared complication after valve replacement, and prosthetic mitral valve endocarditis often presents difficult management problems related to timing of opera-

tion, type of operation, ability to fix the prosthesis securely, and operative and late survival. Mitral valve endocarditis is considerably less common than aortic prosthetic valve endocarditis,[297] but when it does appear, it may present as septicemia, malignant burrowing infections, abscess formation, and septic emboli. With better antibiotic prophylaxis at the time of mitral surgery and improved prophylaxis for all patients having dental or other surgical procedures, the incidence of endocarditis is relatively low.

The incidence of prosthetic endocarditis is usually higher during the initial 6 months after surgery and thereafter declines to a lower but persistent risk.[36] The probability of freedom from this morbid event is shown in Table 43-7 for both mechanical and bioprosthetic valves.[15,22,27,29,31–33,91,111,112,117,120,124,134,138,144,145,160,162,165–168,170–172,174,175,215–217,219,222,223,234–237,239,240,242–246,248,250,252,253,255–259,265,274–276,279–284,298–301]

Biologic and mechanical valves seem to have a similar incidence of endocarditis, except for the initial months after valve implantation, when mechanical prostheses carry a greater risk of infection.[302]

The diagnosis and treatment of mitral perivalvular endocarditis are related to the infecting organism. The diagnosis is made by symptoms or the appearance of a new murmur, a septic embolus, or a large vegetation on echocardiogram. Blood cultures usually are positive, although a small percentage of patients have culture-negative endocarditis. Echocardiograms may show a rocking motion of the prosthesis and the presence of vegetations. The most frequent organisms are still *Streptococcus* and *Staphylococcus;* the latter is usually hospital-acquired. Antibiotic therapy depends on the sensitivity of the organisms, but immediate high-dose intravenous therapy must begin as soon as possible. Experience indicates that a number of patients with bioprosthetic valvular endocarditis can be "cured" of low-potency organisms such as *Streptococcus.* However, it is unlikely that antibiotics alone can sterilize more virulent mitral valve infections, particularly *Staphylococcus.* These infections usually require urgent and sometimes emergent surgery because of invasion of the cardiac exoskeleton.

The surgical indications for mitral valve prosthetic endocarditis are persistent sepsis, congestive failure, perivalvular leak, large vegetations, or systemic infected emboli.[75,76,303] Operative technique is similar to other mitral procedures with respect to anesthesia, monitoring, cardioplegia, left atrial incision, and exposure of the valve. Usually biologic valves are used for patients older than 65 years of age or younger patients with short life expectancy.[76] Mechanical valves can be used in younger patients. Excision of the valve and débridement of the annulus and abscesses must be meticulous and extensive. All necrotic and infected tissue must be removed. After local application of an antibacterial solution such as Betadine and local antibiotic irrigation, the annulus and areas of tissue loss are reconstructed using autologous pericardium. Pericardium must be used to reconstruct the mitral valve annulus, and all sutures must be placed through the pericardial-lined annulus to obtain secure anchorage of the new prosthesis. Autologous pericardial pledgets can be made and used instead of conventional cloth pledgets to avoid synthetic material as much as possible. Examples of operative techniques for closure and repair of local abscesses and infectious destruction of the mitral valve annulus are shown in Figs. 43-12 and 43-13.[304]

Postoperative care should include at least 6 weeks of appropriate intravenous antibiotics. Hospital mortality is related primarily to ongoing sepsis, multisystem organ failure,

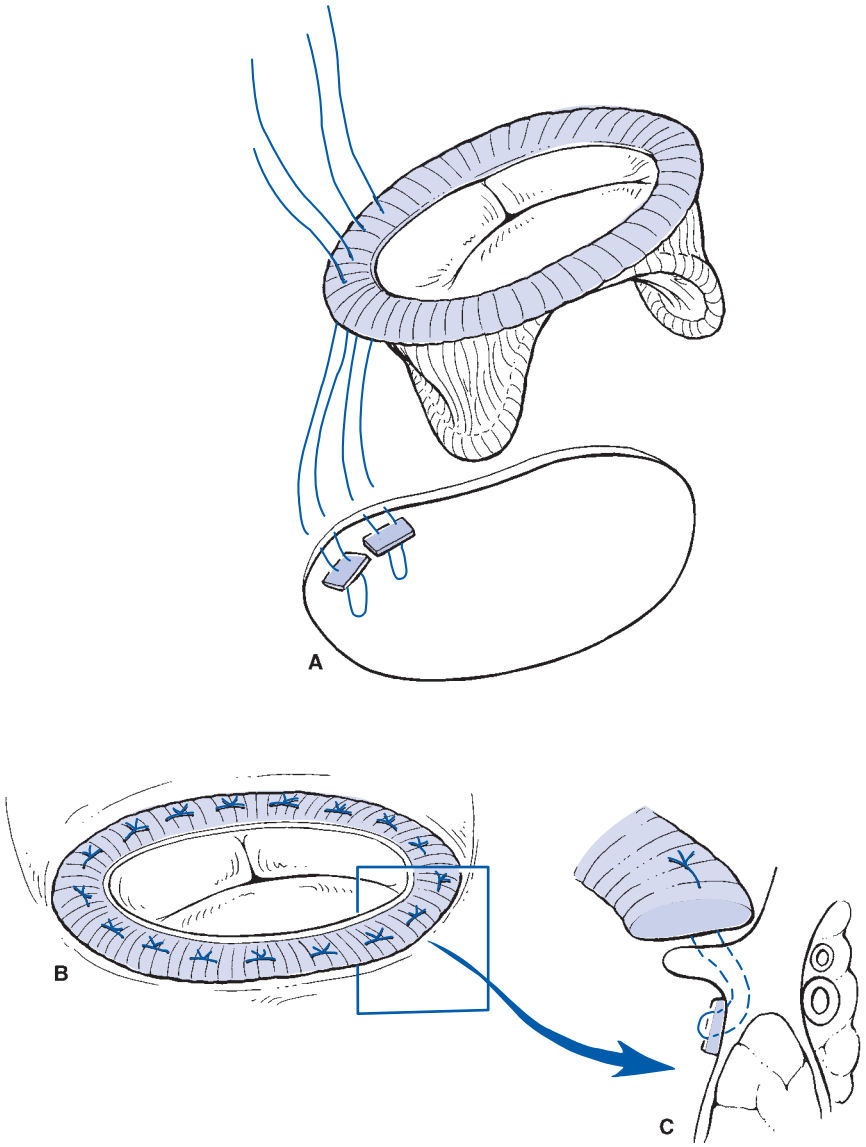

Figure 43-12. Preferred technique for inserting a mitral bioprosthesis in a patient with bacterial endocarditis. Pledgets are made from pericardium to minimize foreign material.

or failure to eradicate the local infection and subsequent recurrent perivalvular leak.[305,306] Recurrence of infection depends on the type of organism and the surgeon's ability to remove all areas of infection completely. Recurrence of infection is the single most important long-term complication.

CONCLUSION

Mitral valve replacement by mechanical or bioprosthetic valves revolutionized the care of patients with severe mitral valve disease. Reconstructive operations of the mitral valve now have assumed an equally important role for mitral regurgitation. A number of advanced lesions of the mitral valve still require mitral valve replacement with reliable devices. The bileaflet, tilting-disk, and ball-and-cage prosthetic valves are extremely reliable in terms of durability but require long-term anticoagulation and have a high risk of thromboembolism or thrombosis without anticoagulation. Bioprosthetic porcine valves, conversely, in patients in sinus rhythm do not need long-term anticoagulation and are used mainly in elderly patients who are not likely to outlive the valve and in women who plan to become pregnant and do not wish to accept the risks of warfarin or heparin. The long-term durability of these valves is limited, and the probability of valve failure at 15 years is at least 40%. Improvements in mechanical valve design and biologic valve preservation of collagen structure and resistance to calcification are ongoing and are the hopes for the future. In addition, there is renewed interest in homograft mitral valves, which may offer better long-term durability, as has been observed with cryopreserved homograft aortic valves. Improved valve

design and development of better biomaterials eventually will improve clinical results; however, current FDA restrictions on the development and evaluation of new prosthetic valves have an important impact on this process.

CHAPTER 44

Surgical Treatment of Mitral Valve Endocarditis

Sotiris C. Stamou • Gosta Petterson • A. Marc Gillinov

Mitral valve infective endocarditis is one of the more devastating complications of heart valve disease. Although the distribution of causes of mitral valve dysfunction has changed in recent years, the incidence of infective endocarditis has remained constant over the past several decades.[1] Underlying rheumatic valvular disease, which was a frequent predisposing factor to infective endocarditis in the 1980s, is now rare in industrialized nations.[2] Other predisposing factors more frequently encountered today include intravenous drug abuse, immunosuppression, degenerative valvular disease, intravascular prostheses and devices, hemodialysis catheters, and nosocomial infections. Several of these predisposing factors are consequences of advances that characterize modern medicine.[3]

Today, major improvements in surgical technique, increased experience, and more effective antimicrobial agents have improved the early and long-term outcomes of patients treated for infective endocarditis. However, endocarditis is still associated with high rates of morbidity and mortality and frequently requires operation for cure.[4]

PATHOLOGY

Native Mitral Valve Endocarditis

Native valve endocarditis (NVE) refers to infectious endocarditis involving a patient's own (native) heart valve. Crude incidence of NVE is 6.2 per 100,000 people per year, and is highest in the older age groups.[5] The pathogenesis of NVE begins with endocardial trauma resulting in alteration of the valvular endocardial surface; this allows deposition of fibrin and platelets with subsequent attachment of bacteria. Endocardial injury may be secondary to rheumatic valvulitis or other leaflet disease, or valvular or annular calcification.[5] Common reasons for bacteremia or fungemia predisposing to NVE include use of long-term indwelling catheters, intravenous drug abuse, and fungemia associated with prolonged antibiotic therapy.[6,7] Although vegetations may be seen anywhere on the leaflets or the chordae, the usual site at which infective NVE of the mitral valve causes valvular destruction and invasion is at the base of the atrial aspect of the mitral valve leaflets. Annular or subannular invasion may cause separation at the atrioventricular (AV) junction (Fig. 44-1). Invasion into the AV groove fat with abscess formation may necessitate radical débridement. Destruction of the fibrous trigones and intervalvular fibrosa between the anterior mitral valve leaflet and the aorta is usually a consequence of aortic valve endocarditis with secondary mitral involvement. Occasionally, "drop lesions" from an infected aortic valve seed the anterior mitral leaflet or the tensor apparatus of the mitral valve, resulting in double-valve endocarditis; the mechanism may be a large vegetation directly infecting the mitral leaflet or a jet lesion that becomes infected.

Prosthetic Mitral Valve Endocarditis

Prosthetic valve endocarditis (PVE) or replacement device endocarditis is infectious endocarditis involving a surgically implanted heart valve. The number of cases of PVE is on the rise as the number of patients with prosthetic heart valves continues to increase. In contradistinction to NVE, wherein the mitral valve is more likely to be infected,[8] PVE is more common in the aortic than in the mitral position.[9] The risk of PVE appears to be greatest at approximately 5 weeks following valve implantation and thereafter declines.[10–13]

PVE identified within the first postoperative year is considered early endocarditis, and those cases appearing more than 1 year after operation are termed late.[13,14] The incidence of early PVE is 1%.[14] Once past the early phase, the incidence of late PVE is 0.5 to 1% per year.[15–18] The type of prosthesis (mechanical versus bioprosthetic) does not influence the risk of PVE.

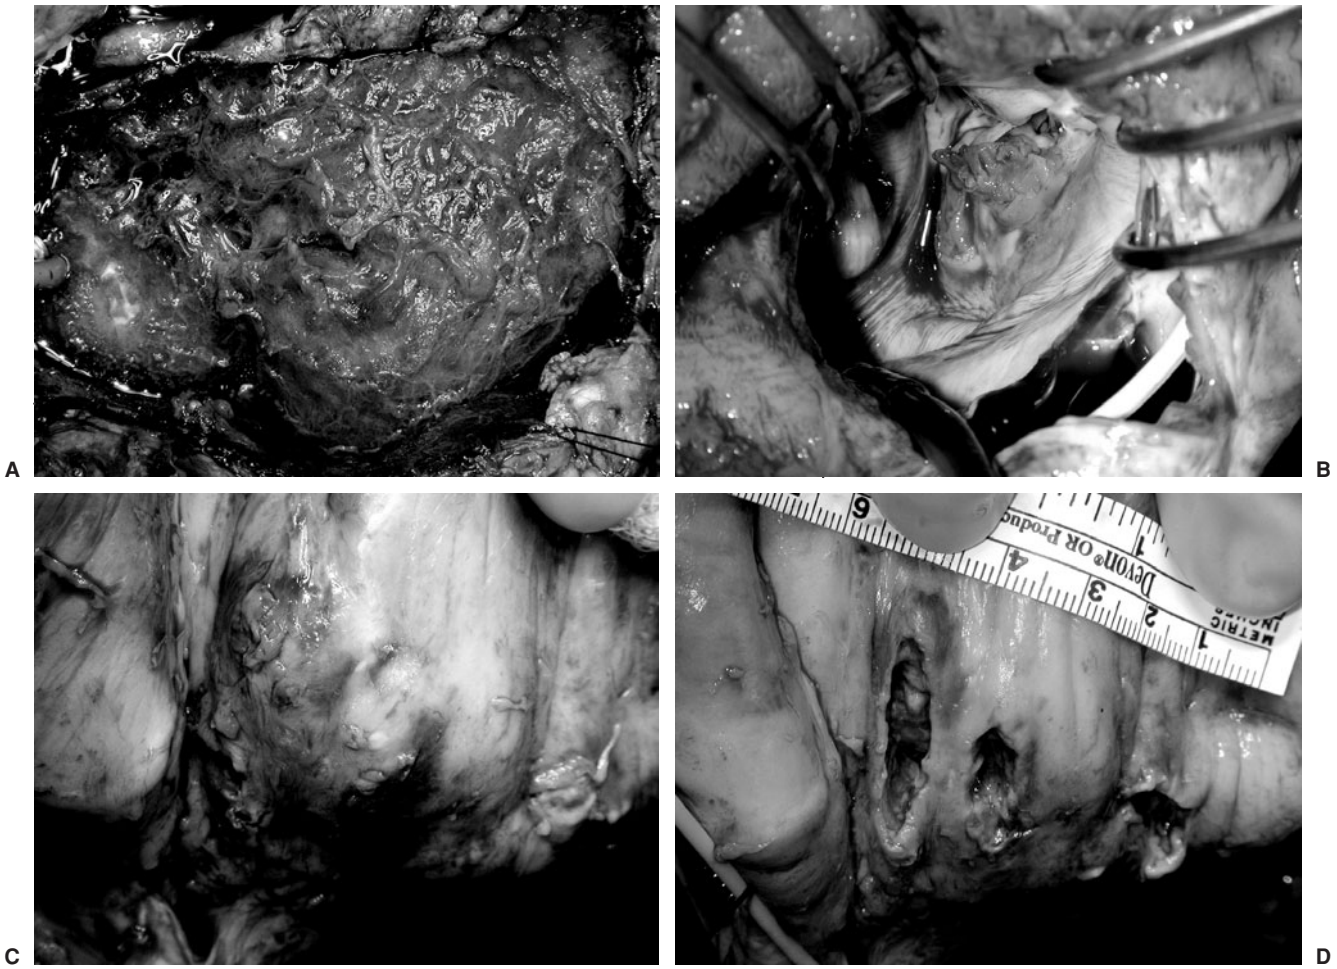

Figure 44-1. (A) Severe hemorrhagic pericarditis with a thick fibrin coat on the heart. (B) Left atrial view, showing vegetation on the posterior leaflet of the mitral valve. (C) Outside view of the inferior basal wall of the left ventricle, showing atrioventricular groove abscess. (D) Outside view of the atrioventricular groove after débridement, showing three contiguous areas of perforation related to mitral valve abscess. (*Reproduced with permission from Atik et al.*[54])

Early PVE is usually the result of intraoperative infection.[19] Common portals of entry for bacteria that cause PVE are intravascular catheters and skin infection.[20,21] Nosocomial infections contribute to late PVE, particularly in patients with medical comorbidities that require frequent hospital admission or instrumentation (e.g., hemodialysis patients) or immunosuppression (e.g., organ transplantation).[19]

Early PVE usually affects the sewing ring or the interface of the prosthetic valve and the annulus (often a site of clot formation), resulting in periprosthetic leak. Progression of the infection may lead to abscess formation. Mitral PVE may extend anteriorly to the fibrous trigone or posteriorly, causing AV separation. PVE may be classified into different subgroups based on the anatomic distribution of the infection. According to this classification, PVE cases are classified as those involving the prosthesis alone, those involving the prosthesis–native annular junction (annular infection), and those extending beyond the annulus (extensive infection).[13,19] Another useful classification that applies to both NVE and PVE involves the distinction between *active* and *healed* endocarditis. The latter includes cases in whom organisms cannot be demonstrated but remote infection is still presumed.[13,22]

MICROBIOLOGY

Endocarditis of native valves is most often caused by *Streptococcus viridans, Staphylococcus aureus* or *epidermidis,* or *Enterococci.* The distribution of microorganisms responsible for early PVE includes coagulase-negative staphylococci (52%), *S. aureus* (10%), *Enterococci* (8%), *S. viridans* (5%), and gram-negative organisms (6%).[19] Fungi account for 10% of cases of early PVE (*Candida albicans* in 8 of 10). Although gram-positive cocci are dominant in both early and late PVE,

in early PVE staphylococci predominate while in late PVE streptococci are the most common organisms isolated.[9] *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae* are collectively termed the HACEK group and account for 3% of culture-negative late PVE.[23] Patients with PVE and negative cultures may be infected by fastidious organisms. In general, late PVE is more amenable to successful antibiotic therapy than is early PVE; however, PVE always warrants surgical consideration.

DIAGNOSIS

Clinical Presentation

The most common clinical finding is fever;[9] however, it is nonspecific. Other findings include a new murmur or a change in an existing murmur. Embolic phenomena may cause petechiae, Roth spots, Osler nodes, and Janeway lesions. Splenomegaly may be present in both NVE and PVE.

Laboratory findings include a white blood cell count $>12{,}000/mm^3$, anemia (hematocrit $<34\%$), and hematuria.[9] Blood cultures from separate sites are usually positive in patients with bacterial endocarditis; two of three positive cultures is considered diagnostic. However, cultures in patients with fastidious organisms or fungi may take more than 3 weeks to become positive. Blood cultures should be drawn before antibiotics are started.

Electrocardiographic Findings

Conduction abnormalities are present in up to 23% of patients with NVE and 47% of patients with PVE. This usually indicates extension of the infection and formation of a paravalvular abscess.[24]

Echocardiographic Findings

The present gold standard diagnostic modality for documenting infective endocarditis is transesophageal echocardiography. Specificity for transesophageal echocardiography is approximately 90% and sensitivity is 95%.[26,27] In contrast, transthoracic echocardiography is more operator-dependent and its images may be compromised by surrounding structures; it is only 50% sensitive and 90% specific for infective endocarditis.[25] Echocardiographic findings of endocarditis include vegetations, periprosthetic leak in patients with PVE, intracardiac fistulae, and abscesses. The echocardiographic examination is very good at evaluating the valve function but less reliable for assessing the severity and invasiveness of the infection. A negative echocardiogram does not exclude the diagnosis of endocarditis. In situations with strong suspicion of endocarditis, the diagnosis may be pursued by magnetic resonance imaging (MRI). In the majority of patients with endocarditis, MRI will demonstrate abnormal consistency of tissue in the annulus. Metastatic infection is a possibility and patients with infective endocarditis and abdominal symptoms should be investigated with computed tomography (CT) scanning to rule out splenic or hepatic abscesses. Metastatic infection of viscera is typically caused by staphylococcal organisms.[5] The brain is the most frequent site for emboli.[28,29] Any neurologic deficit or abnormality should trigger investigation with CT or MRI of the brain, funduscopic examination, and occasionally cerebrospinal fluid examination. CT or MRI of the brain is also justified in the absence of symptoms if there are stigmata of other embolic events. Preoperative coronary angiography is indicated in patients with coronary artery disease or history of previous revascularization procedures and in patients in whom coronary embolization is suspected.

Duke Criteria

The Duke University criteria were developed to improve the specificity and sensitivity of the diagnosis of infective endocarditis. These criteria include echocardiographic results along with clinical, microbiologic, and pathologic findings.[30] Most authorities accept a modification of these criteria for PVE that includes progressive heart failure in the presence of positive blood cultures and new conduction disturbances (Table 44-1). The Duke criteria are classified as "major criteria" (typical positive blood culture and positive echocardiogram) and "minor" criteria (predisposition, fever, vascular phenomena, immunologic phenomena, suggestive echocardiogram, suggestive microbiologic findings, and new-onset heart failure or conduction disturbances). There are three diagnostic categories: (1) patients with a *low clinical likelihood of infective endocarditis* are those with resolution of manifestations of endocarditis with antibiotic therapy for 4 days or less, or no pathologic evidence of infective endocarditis at surgery or autopsy after antibiotic therapy for 4 days or less; (2) patients with *possible endocarditis* have one or two minor clinical criteria of the Duke classification system; and (3) patients with a *definite* diagnosis of infective endocarditis are those (a) in whom pathologic specimens from surgery or autopsy reveal positive histology and/or culture, (b) who have two major criteria, (c) who have one major and three minor criteria, or (d) who have five minor criteria.[30] Understandably, the Duke criteria are not particularly relevant in patients who have had surgical treatment, those in whom the diagnosis is based on surgical findings, and those with analysis of surgical specimens by microscopy, culture, and polymerase chain reaction.

INDICATIONS FOR SURGERY

Surgery plays a pivotal role in the management of native mitral valve endocarditis. Indications for surgical intervention in patients with NVE and PVE are presented in Table 44-2. Congestive heart failure is the most common indication for surgery.

Table 44–1.

Duke Criteria for Native Valve Endocarditis and Prosthetic Valve Endocarditis

Major criteria
Positive blood cultures for infective endocarditis
Typical microorganism for infective endocarditis from two separate blood cultures: *Streptococcus viridans, S. bovis,* and HACEK group or community-acquired *Staphylococcus aureus* or enterococci in the absence of a primary focus, or
Persistently positive blood cultures, defined as recovery of a microorganism consistent with infective endocarditis from Blood cultures drawn >12 hours apart or All of three or most of four or more separate blood cultures, with the first and last drawn at least 1 hour apart
Evidence of endocardial involvement
Positive echocardiogram for infective endocarditis Oscillating intracardiac mass on valve or supporting structures or in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation, abscess, new partial dehiscence of prosthetic valve, or new valvular regurgitation (increase or change in preexisting murmur not sufficient)
Minor criteria
Predisposition: predisposing heart condition or intravenous drug use
Fever: temperature ≥38°C (100.4°F)
Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, and Janeway lesions
Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
Microbiologic evidence: positive blood culture but not meeting major criterion as noted previously or serologic evidence of active infection with organisms consistent with infective endocarditis
Echocardiogram: consistent with infective endocarditis but not meeting major criterion as noted previously
New-onset heart failure
New conduction disturbances

HACEK group = Haemophilus spp., Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella kingae
Source: Modified with permission from Perez-Vasquez et al.[55]

The majority of patients with PVE require surgery.[31,32] Indications for surgical intervention in patients with PVE include heart failure, new heart block (possibly secondary to a myocardial abscess), ongoing sepsis, valve dehiscence, recurrent systemic embolism, relapse of infection, and fungal infection. Operation for large mobile vegetations to prevent embolization in both NVE and PVE remains a controversial indication in the absence of hemodynamic compromise or other surgical indications. Fungal PVE is uncommon but is more difficult to cure than is PVE caused by other organisms. The operative strategy should include perioperative intravenous amphotericin B, radical débridement of infected tissue, reconstruction using biologic tissue whenever possible, and lifelong oral suppressive antifungal therapy after completion of intravenous therapy.[33]

TIMING OF SURGERY

Many patients with NVE and the majority of patients with PVE require surgical intervention, and the challenge for the surgeon is to determine the appropriate timing of surgery.[31] In most cases, the operation should not be delayed once surgical indications are present. Patients with PVE caused by *S. aureus,* even without periannular abscess formation, should have early operation to prevent an aggressive infection with rapid progression and invasion. The same principle

Table 44–2.

Surgical Indications for Native Valve Endocarditis and Prosthetic Valve Endocarditis

1. Severe mitral regurgitation, with or without symptoms of congestive heart failure
2. Uncontrolled sepsis despite proper antibiotic therapy
3. Presence of an antibiotic-resistant organism
4. Fungal endocarditis or endocarditis caused by *Staphylococcus aureus* or gram-negative bacteria
5. Presence of mitral annular abscess, extension of infection to intervalvular fibrous body, or formation of intracardiac fistulas
6. Onset of a new conduction disturbance
7. Large vegetations (>1 cm), particularly those that are mobile and located on the anterior leaflet, and thus at high risk for embolic complications
8. Multiple emboli despite appropriate antibiotic therapy

applies to fungal infective endocarditis, as a mortality rate as high as 93% has been reported.[9]

However, delaying repair is usually advised in the presence of central nervous system complications.[28] Before undergoing valve surgery, patients with endocarditis should have careful neurologic evaluation and significant findings should be evaluated by head CT or MRI. Occasionally, angiography is required to exclude a mycotic aneurysm. Patients with hemorrhagic strokes should have surgery delayed for 4 weeks to reduce the risk of further intracranial bleeding during heart surgery. Intracranial hemorrhage in the setting of PVE has been associated with mortality as high as 28 to 69%.[35] The main concern with nonhemorrhagic embolic stroke is transformation of an ischemic infarct into a hemorrhagic infarct as a complication of the anticoagulation required during cardiopulmonary bypass.[34] Patients who suffered recent ischemic stroke should have their operation delayed for 2 to 4 weeks, particularly if the stroke is large.[36,37] The risk of worsening neurologic symptoms as a consequence of operation is time-related, decreasing with increasing interval from the initial neurologic event. This risk must be weighed against the indications for surgery and the risk of additional emboli during the waiting period.

OPERATIVE TECHNIQUES

General Principles

Operations for endocarditis are guided by some basic principles: optimal timing of surgery as discussed above, good exposure of the valve, radical débridement, optimal choice for reconstruction of the heart and repair or replacement of the valve, and adequate postoperative antibiotic treatment. Radical débridement with removal of all infected and necrotic tissue and foreign material is more difficult to accomplish in mitral cases with AV groove invasion and abscess formation, particularly when compared to aortic root infections. In addition, reconstruction after invasion of the AV groove and AV separation entails closing off the infected space, leaving it without drainage.

Native Mitral Valve Endocarditis

Intraoperative transesophageal echocardiography should be performed in all cases to evaluate the valve before commencing the procedure. Surgical treatment options for NVE affecting the mitral valve include valve replacement and valve repair. Although there is some experience with the mitral valve allograft for treatment of mitral valve endocarditis, there are too few data available to support this strategy.[38]

Most operations for NVE are best conducted through a full median sternotomy. Cannulation for cardiopulmonary bypass involves arterial return via the ascending aorta and bicaval cannulation for venous return. In case of large mobile vegetations, it is advisable to arrest the heart before placing transatrial retrograde cardioplegia. Protection is achieved using antegrade and retrograde substrate-enhanced cardioplegia.[39]

The mitral valve is exposed via a left atriotomy through the interatrial groove or transseptally. If the left atrium is small, an extended transseptal approach is employed. Once exposure of the mitral valve is accomplished, the valve is evaluated to assess for presence of paravalvular abscesses, intracardiac fistulae, or intervalvular fibrous body/ventricular involvement. Radical resection of all necrotic tissue is performed with a margin of normal tissue. All grossly infected tissue is removed without concern for the possibility of repair. Specimens are sent for microbiologic analysis and culture.

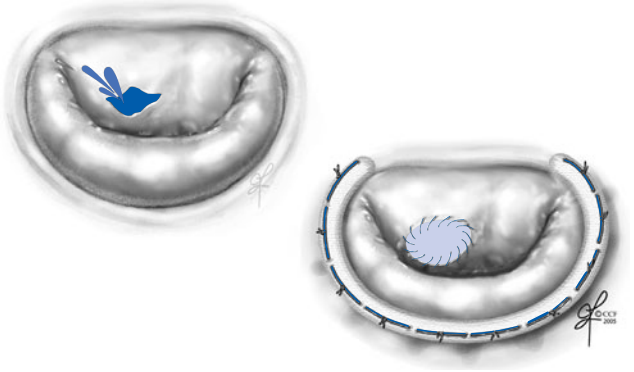

Figure 44-2. Repair of anterior leaflet perforation by patch with autologous pericardium followed by annuloplasty.

For NVE, our approach is to attempt repair if feasible. Mitral valve repair can be performed safely provided there is sufficient remaining tissue to allow valvular reconstruction without tension.[40–44] In the event of extensive destruction of the subvalvular apparatus, prosthetic valve replacement is performed. Regardless of the mitral procedure performed, all patients with active infection receive 6 weeks of postoperative antibiotic therapy.

Anterior leaflet repair

"Drop lesions" of the anterior leaflet encountered in association with aortic endocarditis can be repaired with autologous or glutaraldehyde-preserved pericardium.[38] A patch of pericardium is fixed to the remaining tissue of the anterior leaflet with running polypropylene suture (Fig. 44-2). The smooth surface of the patch should face the atrium to decrease the risk of thromboembolic complications.[37] More extensive destruction involving both the aortic valve and the anterior leaflet of the mitral valve can be repaired using a free-standing aortic root homograft with the anterior leaflet of the mitral valve still attached. The homograft's attached aortomitral curtain can be used to reconstruct the base of the native anterior mitral leaflet.[37,45]

Involvement of the free margin of the anterior leaflet can be managed with triangular resection and closure with interrupted fine sutures. Anterior leaflet chordal rupture can be repaired with chordal transposition from the posterior leaflet or with secondary chordal transfer to the free margin of the anterior leaflet. Artificial chordae may also be used to replace ruptured anterior leaflet chordae.

Posterior leaflet repair

The middle scallop (P_2 segment) of the posterior segment is frequently affected by the infectious process. Repair can be performed with quadrangular resection of the middle scallop, and a sliding repair is frequently required to close the gap between the remaining two scallops (Fig. 44-3). Extensive destruction of the posterior annulus requires removal of all devitalized tissue and annular reconstruction with autologous pericardium. Occasionally, repair of the annulus and

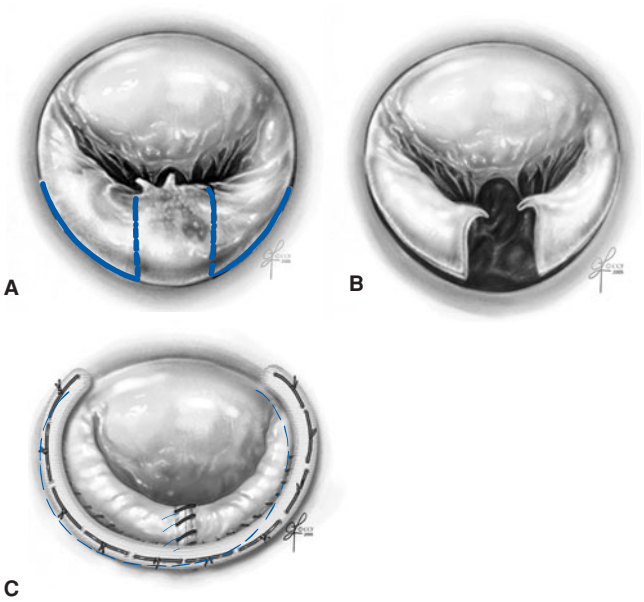

Figure 44-3. Quadrangular resection and sliding repair for posterior leaflet vegetation with ruptured chordae. (A,B) Segment of posterior leaflet is resected and a portion of leaflet detached from the annulus. (C) Leaflet remnants are sutured to the annulus, taking deep bites to reduce leaflet height. Leaflet edges are reapproximated in the center. Annuloplasty completes the repair.

the posterior leaflet can be accomplished with the same patch if chordal support to the leaflet is good. A running polypropylene suture is used on the ventricular, atrial, and valvular aspects of the patch. If replacement is required, a mechanical or bioprosthetic valve may then be inserted, affixing the prosthesis to the patch.[45] It is important that the patch is generous enough to minimize tension on the sutures in ventricular muscle.

The use of prosthetic ring annuloplasty in NVE is controversial. Favoring repair over replacement, we use a ring whenever the annulus is not infected.

Prosthetic Valve Endocarditis

Surgical approach

Operations for PVE are reoperations, usually performed via a median sternotomy. An alternative approach is right anterolateral thoracotomy in the fourth intercostal space; this is particularly useful in patients with multiple previous sternotomies, bypass grafts near the sternum, or a history of mediastinal radiation and/or mediastinitis.[46,47] However, a right thoracotomy for mitral reoperations allows limited access, sometimes denies aortic cross-clamping, and may be associated with a risk of stroke.

Myocardial protection

Cardiopulmonary bypass is instituted using the ascending aorta and bicaval cannulation. A transatrial retrograde cardioplegia cannula is used and myocardial protection is achieved using antegrade and retrograde cardioplegia.

Mitral valve exposure

The main issues in achieving mitral valve exposure are related to obtaining mobility of the right atrium and vena cavae.[19] Our usual approach to obtain mitral valve exposure is to use an extended transseptal approach. If the left atrium is large and adhesions modest, a standard left atriotomy may be employed. Exposure may be enhanced by division of the superior vena cava and extending the left atriotomy toward the aortic root. This approach provides good exposure even when the left atrium is small.

Reconstruction of the mitral annulus

Once exposure of the mitral valve is obtained, the infected prosthesis is removed. Mitral valve PVE may produce an abscess cavity separating the left atrium, left ventricle, and prosthesis. In these situations the operation includes débridement of the annulus with subsequent annulus reconstruction using autologous or glutaraldehyde-fixed bovine pericardium (David technique).[48,49] With this technique, a semicircular pericardial patch is used to reconstruct the annulus with one side of the patch sutured to the endocardium of the left ventricle and the other side to the left atrium. This patch closes off the cavity, which must be thoroughly débrided before the patch is affixed. The new valve prosthesis is affixed to this reconstructed annulus (Fig. 44-4). In most situations with annular reconstruction we employ a bioprosthesis because of the larger and softer sewing ring and to avoid anticoagulation in the postoperative period.

An alternative technique for mitral annular reconstruction is the technique described by Carpentier and colleagues.[50] This technique involves using figure-of-eight atrial and ventricular sutures to reconstruct the AV junction. Exerting traction on these sutures reduces the size of the annulus and closes the AV groove without injury to the circumflex vessels. The main potential disadvantage of this technique is that sutures may pull through stiff and noncompliant ventricular tissue.[19]

Reconstruction of the fibrous trigones

Extension of PVE into the intervalular fibrosa/fibrous trigones may necessitate replacement of both mitral and aortic valves. This usually occurs in the setting of PVE affecting both the aortic and the mitral valves and seldom with isolated mitral valve endocarditis. Reconstruction of the intervalvular fibrosa as well as replacement of both the aortic and mitral valve are required (Fig. 44-5). In such circumstances the fibrous trigones may be reconstructed with autologous or bovine pericardium that is used to secure the new prosthesis.[13,19] Perfect exposure is mandatory whether it is provided by the extended transseptal approach or by dividing the superior vena cava and extending the left atriotomy from anterior to the right superior pulmonary vein toward the dome of the

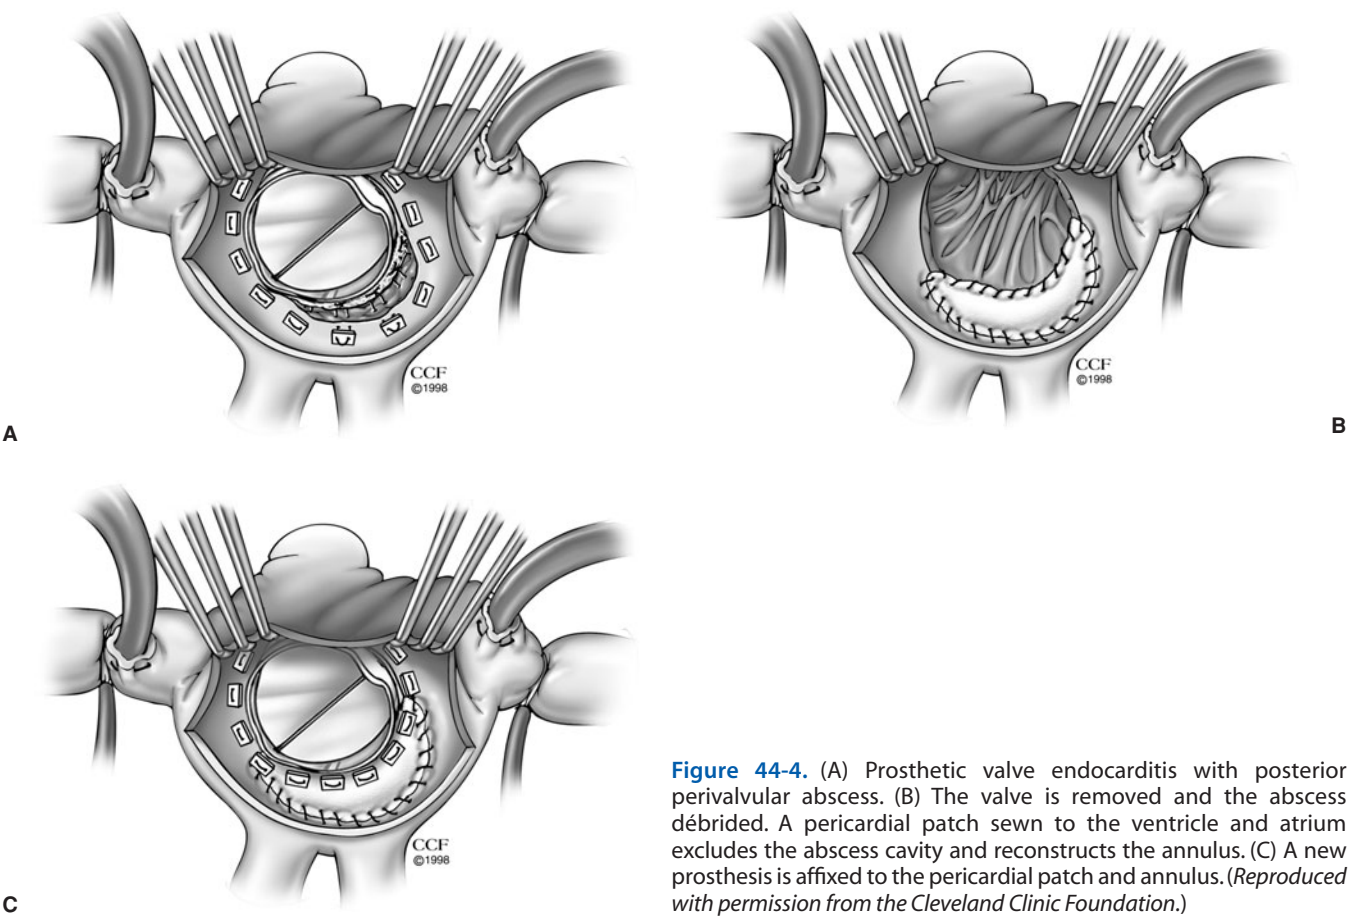

Figure 44-4. (A) Prosthetic valve endocarditis with posterior perivalvular abscess. (B) The valve is removed and the abscess débrided. A pericardial patch sewn to the ventricle and atrium excludes the abscess cavity and reconstructs the annulus. (C) A new prosthesis is affixed to the pericardial patch and annulus. (*Reproduced with permission from the Cleveland Clinic Foundation.*)

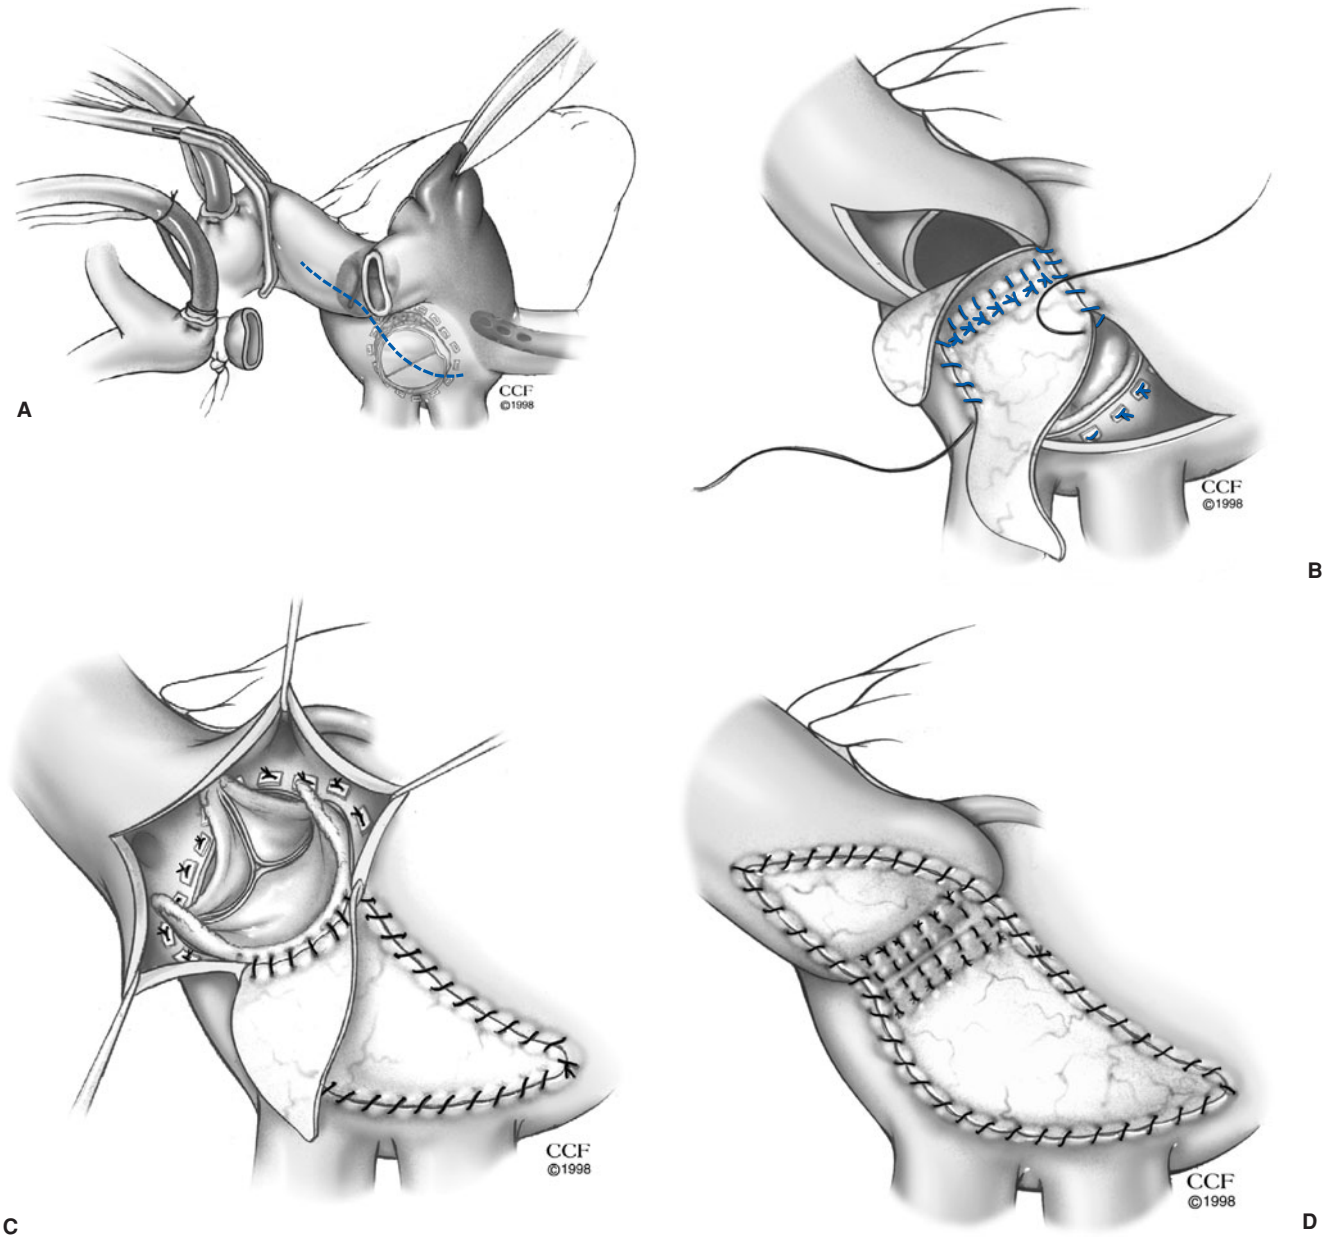

Figure 44-5. Reconstruction of the fibrous trigones. (A) Infection involves the mitral and aortic valves. Division of the superior vena cava facilitates exposure of the aortic valve, mitral valve, and fibrous trigones. (B) The new prosthetic mitral valve is sewn to the annulus posteriorly, medially, and laterally, but the superior portion of the mitral valve annulus is reconstructed by a pericardial patch that recreates the fibrous trigone. The valve is then sewn to this patch with horizontal mattress sutures. (C) Once the mitral valve prosthesis is in place, the aortic valve prosthesis is secured throughout most of the annulus. The pericardial patch reconstructs the medial part of the aortic valve annulus and the aortic valve is then sewn to the patch. (D) After the valve replacements are complete, the pericardial patch is extended to finish the closure of the aorta and the left atrium. (*Reproduced with permission from the Cleveland Clinic Foundation.*)

left atrium. This approach allows débridement of both the aortic and mitral valves, as well as the fibrous trigones. The prosthetic mitral valve is then sewn to the annulus posteriorly, medially, and laterally, and the superior portion of the mitral valve annulus is reconstructed with a pericardial patch that replaces the fibrous trigones. The valve is then sewn to the patch with horizontal mattress sutures. Once the mitral valve is secured in place, the aortic valve prosthesis is affixed to the aortic annulus. The pericardial patch is used to reconstruct the medial part of the aortic valve annulus. The aortic valve is then sewn to that patch.[13,19] An alternative option is aortic valve and root replacement in an anatomic position, suturing the intervalvular fibrosa/mitral valve of the homograft to the mitral valve prosthesis.

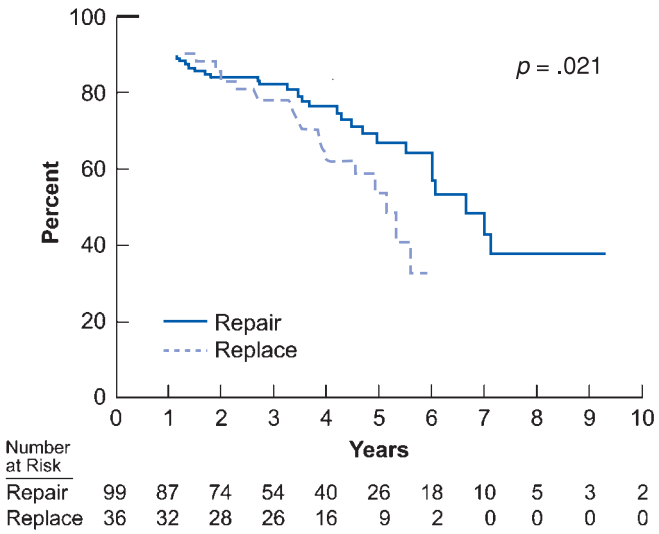

Figure 44-6. Event-free survival for all patients undergoing mitral valve repair or replacement. (*Reproduced with permission from Muehrcke et al.*[43])

RESULTS

Native Mitral Valve Endocarditis

In patients with NVE, mitral valve repair is preferable to mitral valve replacement, since repair has been associated with lower hospital mortality and improved long-term survival (Fig. 44-6).[43,51] In our series of 146 patients having surgery for NVE, patients undergoing repair had a lower hospital mortality ($p = .008$) and improved long-term survival ($p = .05$) compared to those having replacement.[43] Several recent series have reported excellent results with valve repair in the setting of mitral valve endocarditis, with mortality rates ranging between 0% and 9%.[40–43] The infection-free survival is also better for mitral valve repair compared to replacement with a less than 1% per year reinfection rate.[43] The likely explanations for these excellent outcomes are the avoidance of prosthetic material in the infected field and the preservation of left ventricular function associated with repairing mitral valves.[43] Second, the replacement group contains the sickest patients with the most advanced and destructive disease.

Prosthetic Valve Endocarditis

PVE is associated with a much higher operative mortality than is native valve endocarditis.[24,49,52,53] Despite improved antimicrobial regimens, outcomes of medical therapy only without reoperation are poor in PVE, particularly for patients with annular involvement or early endocarditis after valve surgery.[13] The success of homografts in the aortic position has led to attempts to use mitral valve homografts to treat mitral valve PVE. The outcomes of that experimental strategy are at present unknown.

For all patients with mitral valve PVE, prolonged postoperative treatment with intravenous antibiotics is required. Most patients with active endocarditis are treated for at least 6 weeks after surgery and are followed with transesophageal echo studies. In comparison to aortic valve endocarditis, radical débridement and drainage of posterior mitral annulus abscesses is far more difficult. Patients with fungal endocarditis require 2 months of intravenous antifungal therapy followed by indefinite oral antifungal therapy.[33]

CHAPTER 45

Minimally Invasive and Robotic Mitral Valve Surgery

W. Randolph Chitwood, Jr. • Evelio Rodriguez

Surgeons and their patients are now seeing the benefits and extended possibilities of minimally invasive mitral valve surgery (MIMVS). Until 1995, cardiac surgery lagged far behind other specialties in the development of minimal access methods. Then, Cohn and Cosgrove, along with several European surgeons, first modified cardiopulmonary bypass techniques and reduced incision sizes to enable safe, effective minimally invasive aortic and mitral valve surgery.[1–3] Concurrently, Port-access methods using endoaortic balloon occluders were developed and had a period of popularity.[4,5] However, procedural complexity, cost, and complications inhibited widespread adoption of the endoballoon technique. Despite expanding enthusiasm for minimally invasive valve surgery, many surgeons remained skeptical and became critical of complex operations done through small incisions, owing to possibilities of unsafe operations, unknown operative complexities, and inferior results.[6–9]

Despite circumspect reticence, significant advances were made and impressive clinical series emerged. Most surgeons who performed MIMVS in this era selected either a variation of a sternal incision or a minithoracotomy, and used direct vision with longer instruments. Simultaneous advances in cardiopulmonary perfusion, intracardiac visualization, instrumentation, and robotic telemanipulation then hastened a technological shift with more surgeons adopting minimally invasive valve surgery in their practice. Today, both replacing and repairing cardiac valves through small incisions have become a standard practice for many surgeons as patients have become more aware of its increasing availability. Clearly, cardiologists have set a new standard for the least invasive approach to cardiac care, and its increasing use will now follow.

EVOLUTION OF MINIMALLY INVASIVE MITRAL VALVE SURGERY

To perform the ideal cardiac valve operation (Table 45-1) surgeons need to operate in restricted spaces through tiny incisions, which requires assisted vision and advanced instrumentation. Although this goal has not been achieved widely, MIMVS has continued to evolve toward video-assisted or video-directed operations. Moreover, new robotic methods offer endoscopic possibilities for mitral valve surgeons that heretofore were impossible. Via both video-assisted and direct vision, MIMVS now is within the reach of most cardiac surgeons. Yet the steep learning curve still can be an impediment to its more widespread adoption.

Minimally invasive cardiac surgery has not enjoyed a standardized nomenclature. The terms *minimally invasive*, or *limited access*, cardiac surgery have suggested reduced size of the incision, the avoidance of a sternotomy, the use of a partial sternotomy or minithoracotomy, or lack of need for cardiopulmonary bypass. The development of less invasive heart surgery may be considered analogous to a Mount Everest ascent, embarking from a conventional median sternotomy operation or "base camp" and advancing progressively toward less invasiveness through experience and methodologic acclimatization. The nomenclature that parallels this "mountaineering" analogy is shown in Table 45-2. In this schema entry levels of technical complexity are mastered before advancing past small-incision, direct-vision approaches (Level 1), toward more complex video-assisted procedures (Level 2 or 3), and finally to robotic valve operations (Level 4). With the constant evolution of new technology and surgical expertise, many established surgeons already have attained serial "comfort zones" along this trek. It is interesting that advancements in robotic surgery have allowed more and more surgeons to flatten this curve, favoring robotic mitral repairs.

Level 1: Direct Vision

The first steps were to establish safety and efficacy of less invasive cardiac operations. Early minimally invasive valve operations were based solely on modifications of previous

Table 45–1.

The Ideal Cardiac Valve Operation

Tiny incisions and endoscopic ports
Central antegrade perfusion
Tactile feedback
Clear visualization
Facile, secure valve attachment
Intracardiac access
No instrument conflicts
Minimal requirements for: Cardiopulmonary perfusion Blood product usage Ventilation and ICU care Extended hospitalization
Same or better quality as open procedures: Valve repairs in 60 to 80% Few reoperations (1 to 2%) Low mortality (1 to 2%)
Computerized surgical pathway memory
Instrument navigation systems

incisions, and nearly all operations were done under direct vision. In 1996 the first truly minimally invasive aortic valve operations were reported.[1–3,10–12] At that time surgeons found that minimal access incisions also provided adequate exposure of the mitral valve.[10,11,13,14] Using either a mini-sternal or parasternal incision, Cosgrove, Cohn, Gundry, and Arom showed encouraging results with low surgical mortality (1 to 3%) and morbidity.[1,2,11,15] In Cosgrove's first 50 minimally invasive aortic operations, perfusion and cardioplegia times approximated those of conventional operations, and his operative mortality was 2%. Over half the patients were discharged by postoperative day 5.[2] In early 1997 Cohn described 41 minimally invasive aortic operations and first defined the economic benefits of these operations.[1]

Table 45–2.

Levels of Ascent in Minimally Invasive Cardiac Surgery

Level 1 Direct vision: Mini (10- to 12-cm) incisions
Level 2 Video-assisted: Micro (4- to 6-cm) incisions
Level 3 Video-directed and robot-assisted: Micro or port incisions (1 cm)
Level 4 Robotic telemanipulation: Port incisions (1 cm)

In early 1996, the Stanford group performed the first MIMVS using intra-aortic balloon occlusion (Port-access) and cardioplegia.[13,15–17] Subsequently, surgeons at the University of Leipzig reported 24 mitral valve repairs done through a minithoracotomy using Port-access techniques.[4] This group later reported a high incidence of retrograde aortic dissections and neurologic complications, which seemed to be related to new catheter technology and limited surgeon experience.[18] By early 1997 Colvin and Galloway had performed 27 direct-vision, Port-access mitral repairs or replacements with a single death. Their patients experienced no aortic dissections, and 63% of patients had mitral valve repairs with no reoperations for leakage.[19] By December 1998, Cosgrove had done 250 minimally invasive mitral valve operations using either a ministernotomy or parasternal incision with no mortality.[3] The successes of these early MIMVS procedures became the springboard to the current direct-vision techniques described herein.

Level 2: Video-Assisted

The radical endoscopic surgical techniques of the 1980s became routine general, urologic, orthopedic, and gynecologic operations in the 1990s. This was related primarily to successes with extirpative or ablative endoscopic operations. In contrast, fine vascular anastomotic and complex reparative procedures are the centerpieces of cardiac surgery. Because of difficulty in acquiring the fine video-assisted dexterity needed for these operations, cardiac surgeons were reluctant to explore the benefits of operative video assistance.

As mentioned, most Port-access, sternal modification, and parasternal mitral valve operations have been done using direct vision. In early 1996, Carpentier performed the first video assisted mitral valve repair through a minithoracotomy using hypothermic ventricular fibrillation.[20] Shortly thereafter, we reported the first video-assisted mitral valve replacement, done through a minithoracotomy, using a percutaneous transthoracic aortic clamp and retrograde cardioplegia.[21,22] This clamping and visualization technique was simple, cost-effective, and has remained the mainstay of isolated mitral valve operations at several centers.[18,23]

In 1997 Mohr reported 51 minimally invasive mitral valve operations, done using Port-access cardioplegia techniques, a 4-cm incision, and for the first time three-dimensional (3-D) videoscopy.[24] In this series 3-D assistance aided mitral

replacement; however, these surgeons found that even simple reconstructions were significantly more difficult than those done through a sternotomy. At about the same time Loulmet and Carpentier deployed an intracardiac "mini-camera" for lighting and subvalvular visualization; however, they also concluded that two-dimensional (2-D) visualization was inadequate for detailed repairs.[25] Concurrently, our group reported 31 successful mitral valve operations done using 2-D video-assistance [26] Complex repairs were possible, and these included quadrangular resections, sliding valvuloplasties, chordal transfers, and synthetic chordal replacements. Our initial results were encouraging.

Level 3: Video-Directed

In 1997 Mohr first used the Aesop 3000 voice-activated camera robot (Intuitive Surgical, Inc., Mountainview, Calif) in minimally invasive videoscopic mitral valve surgery.[24] Six months later we began using the Aesop 3000 routinely to perform both video-assisted and video-directed minimally invasive mitral valve repairs.[27] We have continued to use this device during most isolated mitral valve operations, including reoperations. This device provides surgeon camera-site voice activation, precluding translation errors inherent with verbal transmission to an assistant. Camera motion has been shown to be much smoother, more predictable, and requires less lens cleaning than during manual direction. Currently, we are able to do over 90% of a mitral repair under video direction with the Aesop 3000. Mohr first termed this method "solo mitral surgery" and reported 8 patients undergoing successful mitral repairs using this robotic technique.[24] Vanermen has perfected a method to perform repairs completely endoscopically with excellent results. In nearly 1000 mitral valve operations, he and his colleagues have shown that after a significant learning curve totally video-directed repairs could be done with excellent results using long instruments.[28,29]

Level 4: Robotic (Computer Telemanipulation)

In June 1998 Carpentier and Mohr did the first true robotic mitral valve operations using the da Vinci surgical system.[30,31] In May 2000 the East Carolina University group performed the first da Vinci mitral valve repair in the United States.[32] This computer-driven system provides both tele- and micromanipulation of tissues in small spaces. The surgeon operates from a console through end-affecter, microwrist instruments, which are mounted on robotic arms that are inserted through the chest wall (Fig. 45-1). These devices emulate human X-Y-Z axis wrist activity throughout seven full degrees of manipulative excursion. These motions occur through two joints that each affect pitch, yaw, and rotation. Additionally, arm insertion and rotation, as well as variable grip strength, give additional freedom to the operating "wrist."[31,33] Grossi and associates performed a partial mitral valve repair but had limited ergonomic freedom using the Zeus system.[34] Lange and associates in Munich were the first to perform a totally robotic mitral valve repair using only 1-cm ports and the da Vinci device.[35] To date, Chitwood, Murphy, and Smith have the largest experiences with robotic mitral valve repairs, and independently have shown da Vinci to be very effective, even for performing complex bileaflet repairs.[33,36] Repairs are done routinely using only ports and a 3- to 4-cm mini-incision, and are performed with greater facility than endoscopic level III operations. To this end, we are on the cusp of developing a closed-chest operation that can be done by many surgeons.

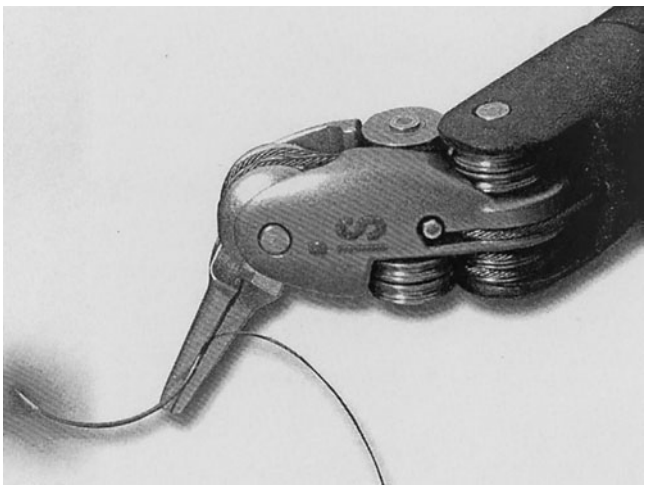

Figure 45-1. The da Vinci microwrist needle-holder instrument. This instrument is inserted into the robotic arm and controlled from the surgeon's console.

INCISIONS

The type and size of the musculoskeletal incision remains central to minimally invasive cardiac surgery discussions. A myriad of modified small sternal, parasternal, and thoracotomy incisions have been used for cardiac valve access. In the largest patient series modified sternal incisions were used.[37–39] Although many surgeons prefer the hemi-sternotomy approach, a right minithoracotomy yields excellent exposure for both direct-vision and videoscopic mitral valve access (Fig. 45-2A and B). To access the left atrium for direct vision, using a limited access minithoracotomy, a 4- to 6-cm submammary incision is placed along the anterior axillary line. The pectoralis and intercostal muscle fibers are divided, and the thorax is entered through the fourth intercostal space with minimal rib distraction and no rib cutting. The New York University group has been quite successful in combining this incision, Port-access methods, and direct vision for both mitral and tricuspid repairs/replacements.[40,41] A smaller 4- to 5-cm incision with minimal rib retraction can be used in video-assisted cases and is large enough for prosthesis passage (Fig. 45-3). Vanermen and Mohr perform video-assisted mitral operations routinely through 4-cm,

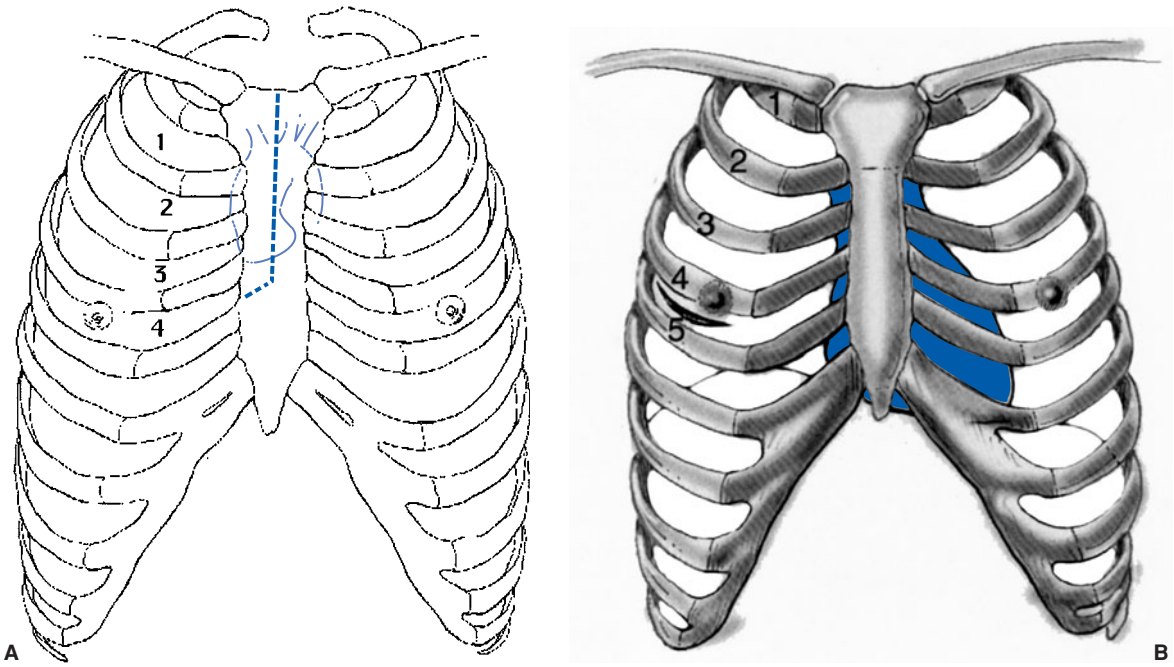

Figure 45-2. (A) The hemisternotomy, used for minimally invasive mitral and aortic valve surgery. (B) The minithoracotomy, used for minimally invasive mitral valve surgery.

nonretracted thoracic incisions with excellent results[42–44] (Fig. 45-4). Minimal rib spreading, prevention of intercostal nerve injury, and intraoperative local anesthetics are the keys to minimizing postoperative discomfort. We generally use a soft tissue retractor to obviate any rib spreading. Tricuspid operations can be performed through this incision when combined with bicaval cannulation with isolation. Murphy and colleagues in Atlanta prefer a more lateral approach for access in robotic mitral valve surgery.[45]

We consider the term "minimally invasive" to include the size of the actual cardiac incision. Most superior and transseptal mitral valve approaches, through a hemi-sternotomy, require a larger cardiac incision. For aortic, mitral, and tricuspid valve operations, surgeons at the Cleveland Clinic use a hemisternotomy, extended only to the fourth interspace, with direct aortic arch and right atrial cannulation.[3,12] To access the mitral valve, they extend the atriotomy

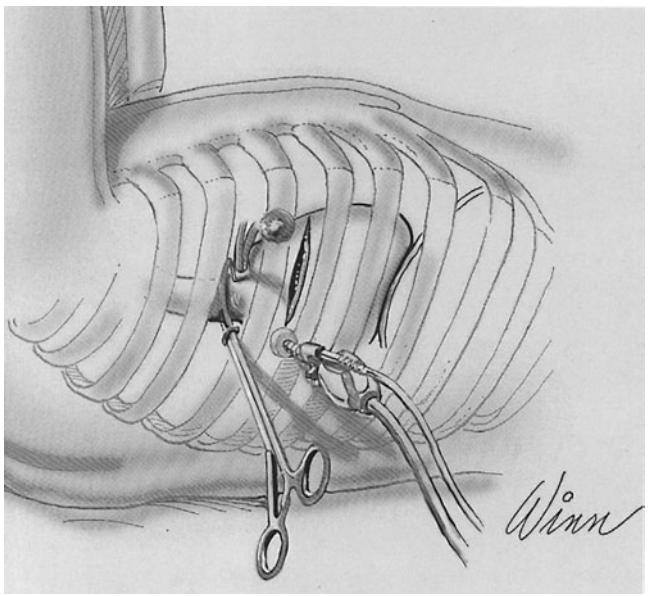

Figure 45-3. Right minithoracotomy and video access. The right minithoracotomy allows aortic access for the transthoracic clamp shown here as well as the video camera. With this arrangement minimal rib spreading is needed to perform mitral surgery.

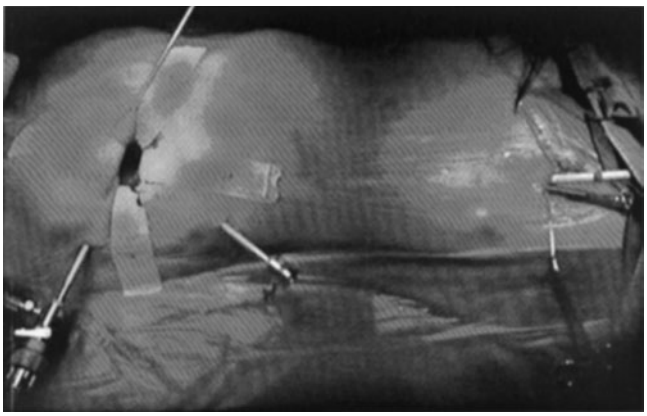

Figure 45-4. Small nonretracted minithoracotomy for video-directed mitral surgery. Using videoscopic techniques, a small nonretracted minithoracotomy provides excellent access for long instrument manipulation. Here, a soft tissue retractor mobilizes skin edges away from the incision. (*Courtesy of Dr. H. Vanermen.*)

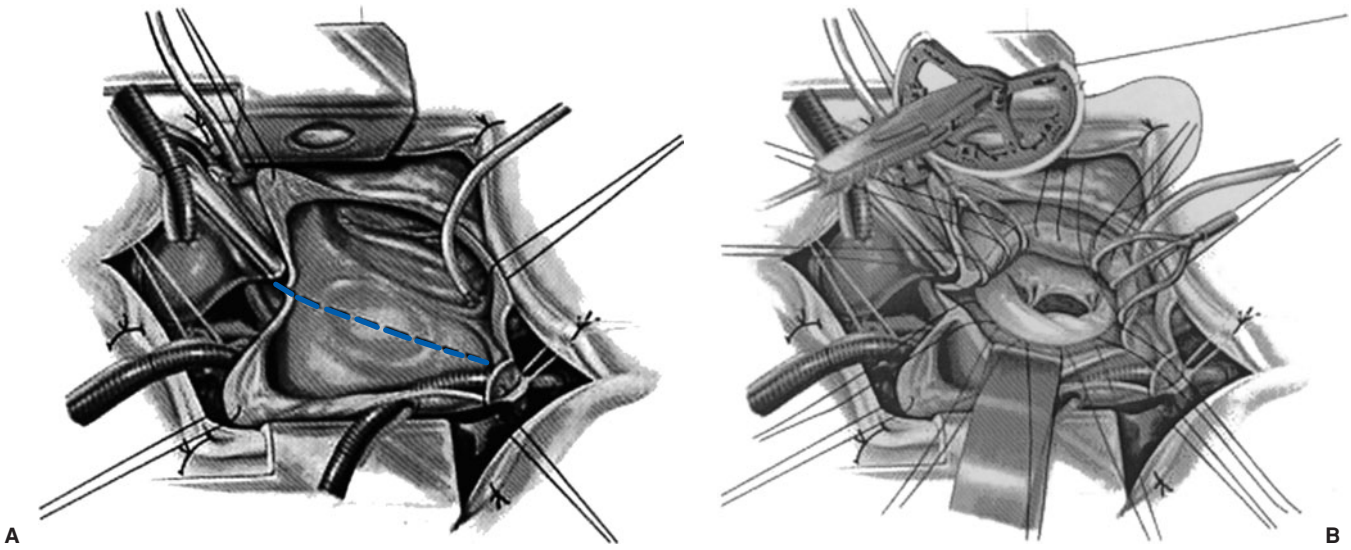

Figure 45-5. (A) Hemisternotomy with an extended atrial incision. Popularized by Dr. Cosgrove, the incision begins along the ventral right atrium and extends over the dome of the left atrium and through the left atrial wall and interatrial septum. (B) Mitral valve exposure is excellent through this hemisternotomy with an extended atrial incision, and complex repairs are similar in difficulty to full-sternotomy operations. (*Courtesy of Dr. D.M. Cosgrove.*)

from the right atrium, across the left atrial roof, and continuing caudally to divide the interatrial septum (Fig. 45-5A and B). This incision provides excellent exposure for aortic, mitral, and tricuspid valve replacements as well as repairs. Although the septal artery is divided, the incidence of atrial arrhythmias seems to parallel traditional interatrial groove atriotomies. For mitral and aortic surgery, Gundry suggested a similar hemisternotomy with single right atrial cannulation. This provides similar exposure to that described by opening the atrial roof, between the superior vena cava and aorta, without entering the right atrium.[15] Cohn now prefers a lower hemisternotomy for mitral surgery and uses a transseptal approach for valve exposure.[46] Loulmet and Carpentier reported using a midsternal, C-shaped, partial sternotomy for exposing mitral valves through the interatrial septum.[25] All of these incisions provide generous direct-vision exposure, if combined with pericardial retraction.

PERFUSION AND MYOCARDIAL PROTECTION

Cannulation for cardiopulmonary perfusion can be done in a number of ways for MIMVS. By combining modified traditional perfusion methods and new technology, surgeons have been able to speed the development of less invasive mitral operations. Thin-walled arterial and venous cannulas, transthoracic aortic cannulas, endoaortic balloon occluders, modified aortic clamping devices, percutaneous coronary sinus cardioplegia catheters, and assisted venous drainage all have aided in evolution of these operations.

We prefer to establish arterial access via femoral cannulation, employing small wire-wound Bio-Medicus (Medtronic, Inc., Minneapolis, Minn) arterial cannulas (17 to 21F) inserted over a guidewire (Fig. 45-6). Exposure of the femoral artery is gained through a 1.5-cm incision placed in the right groin crease. We ask our referring cardiologists to perform cardiac catheterizations via the left groin to avoid hematoma and scar formation. However, if the right groin vessels were used at catheterization, we still use the right femoral vessels for cannulation, as a better trajectory exists when introducing cannulas into the femoral-iliac venous system. Minimal dissection of the femoral vessels is performed without encircling the vessels. Lessened dissection has reduced seroma formation, which is now rare. For both venous and arterial cannulations, we believe that transesophageal echocardiographic guidance is mandatory to ensure proper guidewire insertion, prior to dilator and cannula passage. In our patients excellent flow rates have been attained with acceptable perfusion pressures in over 800 cases. Using this method, we have had only one retrograde aortic dissection and it was in a reoperative case. Mitral valve patients having either peripheral atherosclerosis or small iliac vessels may require direct aortic cannulation either through the incision or via a transthoracic Seldinger approach. Alternatively, cannulation of the right axillary artery has proven very successful for ascending aortic dissection surgery and could be used here as well.

Venous cannulation and drainage can be established in a variety of ways. At the Brigham and Women's Hospital, the right atrium is cannulated directly either through the incision or via a separate skin incision. Cosgrove introduces a small (23F) cannula directly into the right atrium through

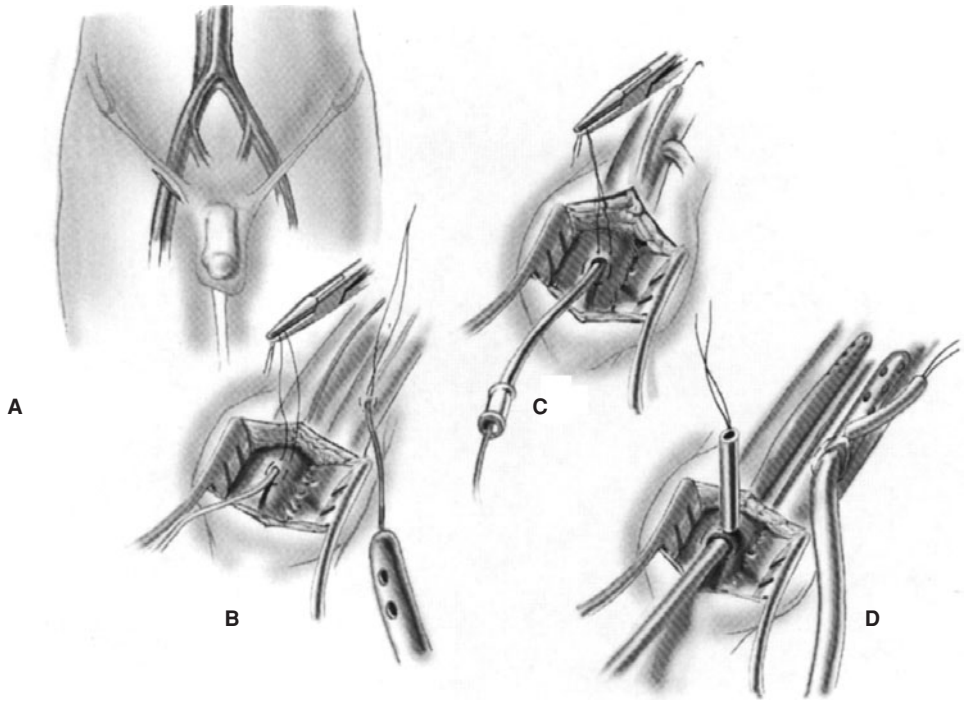

Figure 45-6. Thin-walled arterial perfusion cannula from Bio-Medicus (Medtronic Inc., Minneapolis, Minn) and percutaneous Carpentier dual-stage venous drainage cannula. (Medtronic Inc., Minneapolis, Minn). These cannulas are inserted from the femoral approach using the Seldinger guidewire method.

the ministernotomy.[47] Konertz and Gundry insert an oval-flat or "pancake" cannula into the right atrium to maximize hemisternotomy exposure.[12,15] Assisted venous drainage has been a major advance, as this technique enhances the efficiency of smaller cannulas. At our institution we use the Bio-Medicus centrifugal vortex pump to create variable negative pressures for venous drainage. Similarly, by combining wall suction (<40-cm H_2O pressure) and a closed-bag or hard-shell cardiotomy reservoir, a safe, simple, and economical assisted venous drainage system can be developed.[47] For superior caval drainage a 15 to 17F Biomedicus cannula is placed by the anesthesia team via the right internal jugular vein using the Seldinger technique with the tip positioned at the pericardial-caval junction (Fig. 45-7). In addition, a 22 or 25F Cardiovations (Johnson & Johnson, Inc., Sommerville, NJ) or a 21 or 23F Biomedicus cannula is inserted via the right femoral vein and advanced over a guidewire into the right atrium. Again, it is important to use transesophageal echocardiographic guidance for proper cannula placement and safety.

Myocardial preservation techniques used with MIMVS are similar to those used in sternotomy-based operations. We cool systemically to 28°C, as the ambient cardiac temperature generally is warmer than during conventional valve operations. With either a ministernotomy or mini-thoracotomy, a retrograde coronary sinus cardioplegia catheter can be inserted directly into the right atrium and position confirmed echocardiographically. Also, Port-Access technology provides a percutaneous retrograde cardioplegia

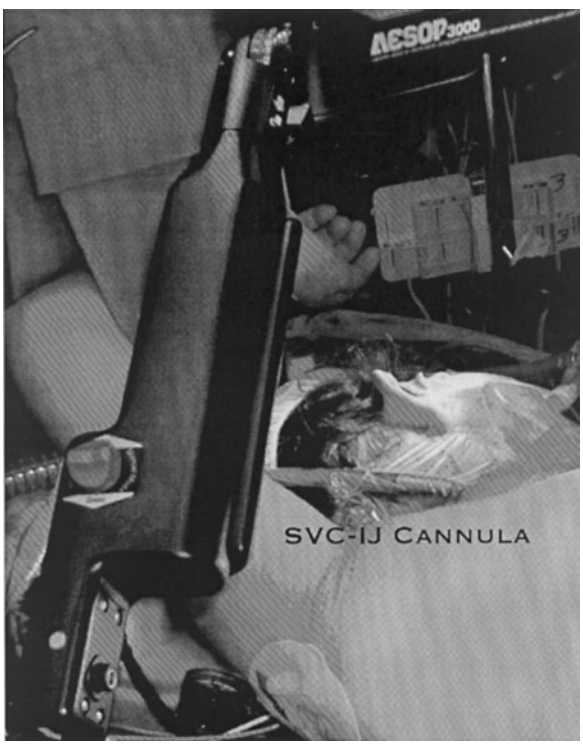

Figure 45-7. A right internal jugular venous catheter (15 or 17F) is combined with femoro-atrial active venous drainage for full bicaval access. This is important during atrial retraction in a near closed chest where the cavae can be kinked with distraction. The Aesop 3000 robotic camera arm is seen in the foreground.

catheter, which is introduced using echo via the internal jugular vein preoperatively. Although retrograde cardioplegia seems preferable, to ensure uniform cardiac cooling and even distribution of cardioplegia solutions, we have found antegrade cardioplegia efficient and preferable. In the presence of significant aortic insufficiency, a retrograde cardioplegia catheter is inserted before bypass is established. After aortic clamping, cold antegrade blood cardioplegia is infused every 15 minutes into the aortic root via a vent/cardioplegia cannula passed through the incision. An extra long Medtronic cardioplegia catheter facilitates aortic root positioning. During both videoscopic and robotic mitral surgery, we place a flexible sucker via the left atriotomy directly into the left superior pulmonary vein to clear residual blood from the surgical field.

For most minimally invasive mitral valve surgery, aortic occlusion is done using a standard cross-clamp placed through the incision. Cosgrove developed a flexible-handle aortic clamp to increase exposure through the hemi-sternotomy while minimizing inadvertent dislodgment (Fig. 45-8). For minithoracotomy mitral operations, we use a percutaneous transthoracic aortic cross-clamp. The clamp is inserted through a 4-mm incision placed in the right lateral third intercostal space. The posterior immobile "tine" of the clamp is positioned through the transverse sinus dorsal to the aorta (see Fig. 45-3; Fig 45-9A and B).[48] During placement, attention is necessary to prevent injury to the left atrial appendage and right pulmonary artery behind the aorta. This clamp has provided very secure occlusion without any aortic injuries. Occasionally we will apply this clamp in the "verso" direction with the mobile tine posterior to the aorta in the transverse sinus. In a short aorta this approach provides more length for cardioplegia needle insertion, and also arches the clamp away from the atriocaval junction, enabling atrial septal ventral retraction. The "verso" approach introduces a somewhat greater risk of pulmonary artery injury, and thus excellent visualization during deployment is essential.

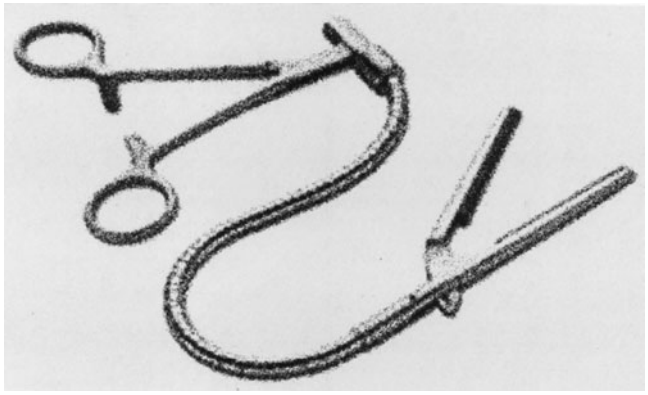

Figure 45-8. Flexible arm Cosgrove Aortic Clamp (V Muller Inc.). This mobile arm clamp allows complete aortic occlusion through limited access incisions, such as the ministernotomy. We have also used it for transthoracic aortic occlusion in mitral valve surgery.

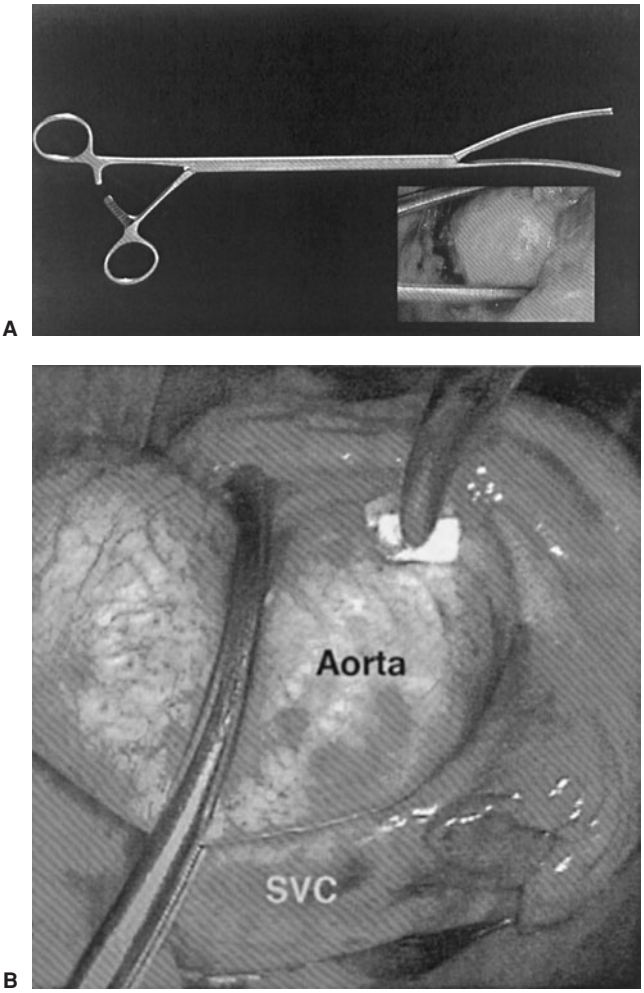

Figure 45-9. (A) The Chitwood transthoracic aortic cross-clamp (Scanlan International Inc., Minneapolis, Minn). The shaft is 4 mm in diameter and is passed through the third intercostal space (inset). The posterior or fixed prong of the clamp is passed through the transverse sinus under direct or video visualization to avoid injury to the right pulmonary artery, left atrial appendage, or left main coronary artery. The mobile prong is passed ventral to the aorta as far as the main pulmonary artery. (B) A videoscopic view of the deployed transthoracic aortic clamp. The aorta is fully compressed and an antegrade cardioplegia needle is shown in position just distal to the right coronary artery origin.

Vanermen, Murphy, Colvin, and Hargrove continue to be strong advocates for intra-aortic balloon occlusion for minimally invasive and robotic mitral surgery.[28,29,45,49] Most commonly these devices are introduced retrograde through the femoral artery. The occlusive balloon should be positioned, under echocardiographic control, just above the tubulosinus ridge in the ascending aorta[4,50] (Fig. 45-10). Balloon pressures often approximate 300 torr during complete occlusion, and the catheter tip position must be monitored continuously. Antegrade cardioplegia is given via the catheter central lumen. Balloon dislodgment can cause innominate artery occlusion, potentially causing neurologic injury, or prolapse into the left ventricle with inferior

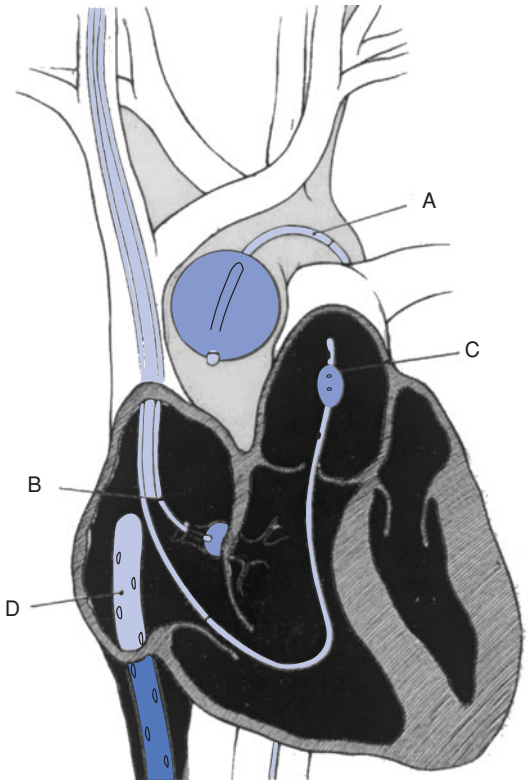

Figure 45-10. Port-Access system with transfemoral artery endoaortic balloon occluder (A), percutaneous internal jugular retrograde coronary sinus cardioplegia catheter (B), pulmonary artery vent (C), and femoral venous drainage catheter (D). (*Courtesy Cardiovations, Ethicon, Inc., Norwalk, Conn.*)

myocardial preservation. Thus, continuous echocardiographic monitoring is essential to detect any balloon migration. However, balloon occlusion has some advantages when there is limited access to the aorta compared to the transthoracic clamp method. Reichenspurner and colleagues demonstrated increased morbidity, cost, and operative/cross-clamp times when the endoballoon technique was used for mitral valve surgery.[23]

Meticulous cardiac air removal is most important in these operations, as difficulty exists in manipulating and deairing the cardiac apex. Also, in the right anterolateral minithoracotomy, air tends to be retained along the more dorsal ventricular septum and in the right pulmonary veins. Continuous carbon dioxide (CO_2) insufflation has been helpful in minimizing cardiac air and should be begun before cardiac chambers are opened. CO_2 is much more soluble in blood than air and displaces it very efficiently. We infuse CO_2 continuously (4 to 5 L/min) into the thorax via a 14-gauge angiocath, and prior to cross-clamp release, ventilate both lungs vigorously to draw the gas deep into all pulmonary veins. After atriotomy closure and following cross-clamp release, suction is applied to the aortic root vent, and the right coronary artery origin is compressed during early ejection. As the heart beats, nonatherosclerotic aortas can be partially reclamped to expel residual air into the vent suction. Constant transesophageal echocardiographic monitoring is essential to ensure adequate air removal before weaning from cardiopulmonary bypass. We have found that during ventral retraction fixed transthoracic atrial retractors distort the aortic root sinuses, causing air introduction. The robotic retractor can be positioned to minimize this problem.

Mitral Valve Exposure

Using a hemisternotomy, exposure of the mitral valve is best established using either extended right to left atrial incision or the transseptal approach championed by Cosgrove and Cohn, respectively (see Figs. 45-2A and 45-5A and B). A hand-held retractor placed through the incision facilitates valvular exposure using these incisions. For endoscopic and robotic mitral repairs most of us have used a fixed-blade transthoracic retractor immobilized by a table-mounted clamp. Blades of various sizes are available; however, after fixed-retractor deployment, movement to provide additional exposure is limited. For reoperative mitral surgery through a minithoracotomy, we prefer to use the hand-held retractor shown in Fig. 45-11. It allows variable access to all parts of the left atrium and subvalvular structures; moreover, it can provide access in very deep chests. Recently, a fourth arm robotic retractor for the da Vinci system was developed (Fig. 45-12). Using a separate robotic arm retractor, activated alternately through the left instrument arm control, blade positions

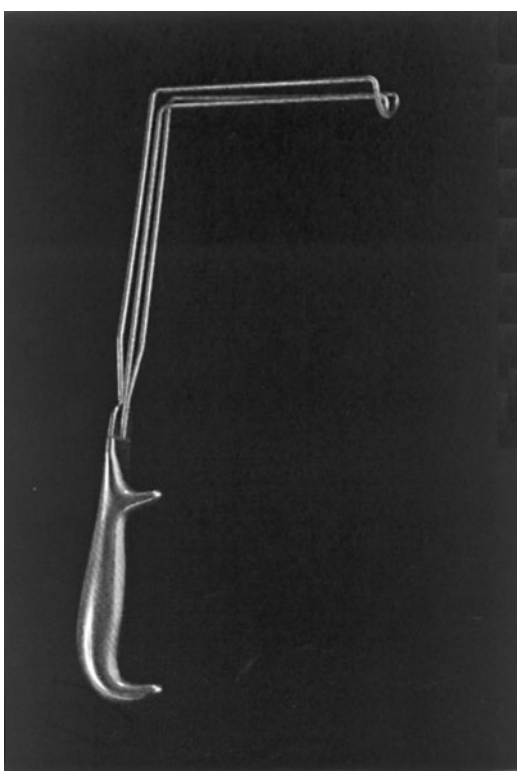

Figure 45-11. Chitwood hand-held left atrial retractor.

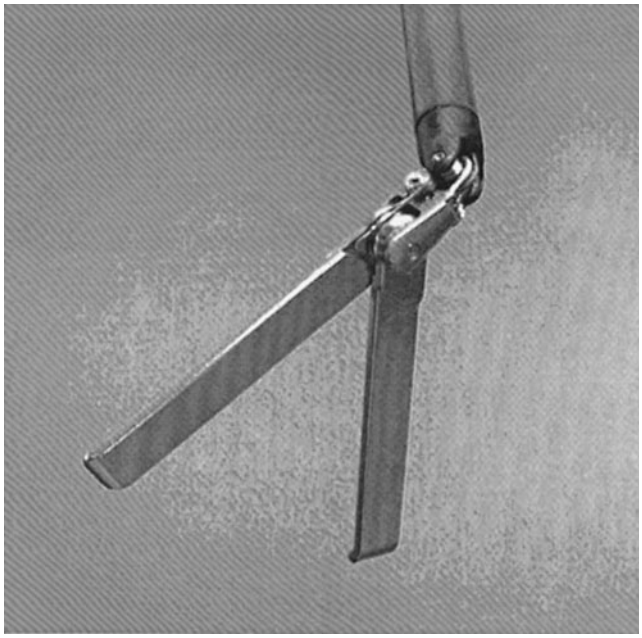

Figure 45-12. Left atrial endowrist retractor for the da Vinci system.

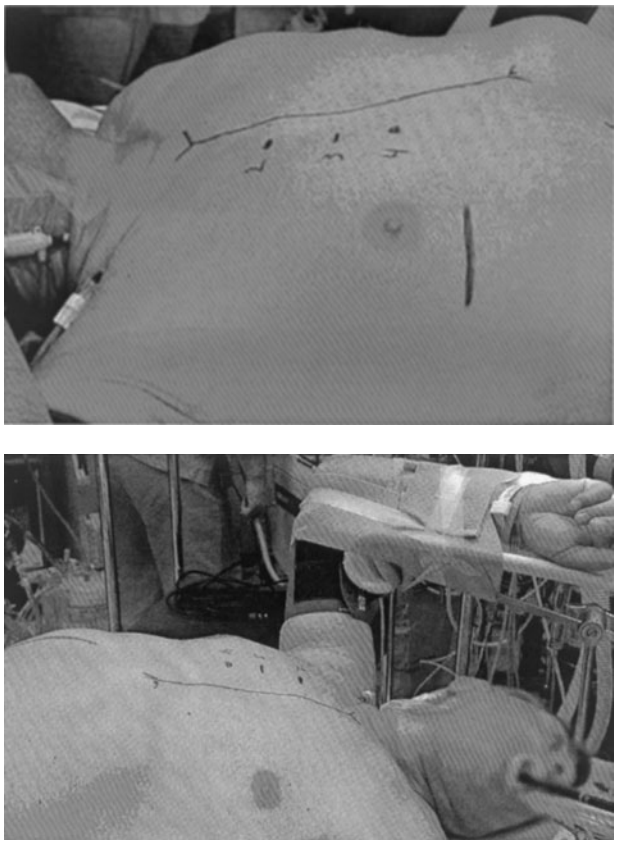

Figure 45-13. (A) The sternum and intercostal spaces are marked. A 3- to 4-cm incision is made in the inframammary fold. The chest is entered via the fourth intercostal space. (B) The patient is positioned in the semi–left lateral decubitus position. In most patients the arm is best left on the side, obviating the need for an arm rest, which allows more room for positioning the da Vinci robotic arms.

and length can be altered dynamically. The retractor arm is inserted via a third interspace port, medial to the anterior axillary line. We have used it in over 50 mitral repairs and have found that this device enables these operations greatly.

Robotic Mitral Valve Surgery

For both video-assisted and robotic mitral surgery we position the patient as shown in Fig. 45-13A and B. However, in larger patients the right arm is best left by the side, requiring the cross-clamp to be placed through the mid-axilla. The Aesop 3000 computed-activated camera manipulator has remained a pillar of control for our minimally invasive video-assisted approach. Figure 45-14A and B shows how this device is positioned during these operations. Even though automatic vision control has proved valuable, using this video-assistance method, surgeons still must operate with long instruments in a 2-D operative field (Fig. 45-15). Knots are tied and sutures cut using specialized hand-held shafted instruments (Figs. 45-16A and B and 45-17) The da Vinci surgical system is comprised of three components: a surgeon console, an instrument cart, and a visioning platform (Fig. 45-18A and B).[51] This device provides intracardiac telepresence and tissue micromanipulation. The operative console is removed physically from the patient and allows the surgeon to sit comfortably, resting the arms ergonomically with his or her head positioned in a 3-D vision array. The surgeon's finger and wrist movements are registered, through sensors, in computer memory banks, and then these actions are transferred efficiently to an instrument cart, which operates the synchronous end-effecter instruments (Fig. 45-19). Through 1-cm ports, instruments are positioned near cardiac operative sites in the thorax, and the camera is passed via a 4-cm working port used for suture and prosthesis passage (Fig. 45-20A). Every analog finger movement, along with inherent human tremor at 8 to 10 Hz/s, is converted into binary digital data, which are smoothed and filtered to increase micro-instrument precision. Wrist-like instrument articulation emulates precisely the surgeon's actions at the tissue level, and dexterity becomes enhanced through combined tremor suppression and motion scaling. This allows both increased precision and dexterity with the surgeon becoming truly ambidextrous. A clutching mechanism enables re-adjustment of hand positions to maintain an optimal ergonomic attitude with respect to the visual field. This clutch acts very much like a computer mouse, which can be reoriented by lifting and repositioning it to reestablish unrestrained freedom of computer activation. The 3-D digital visioning system enables natural depth perception with high-power magnification (10×). Both 0° and 30° endoscopes can be manipulated electronically to

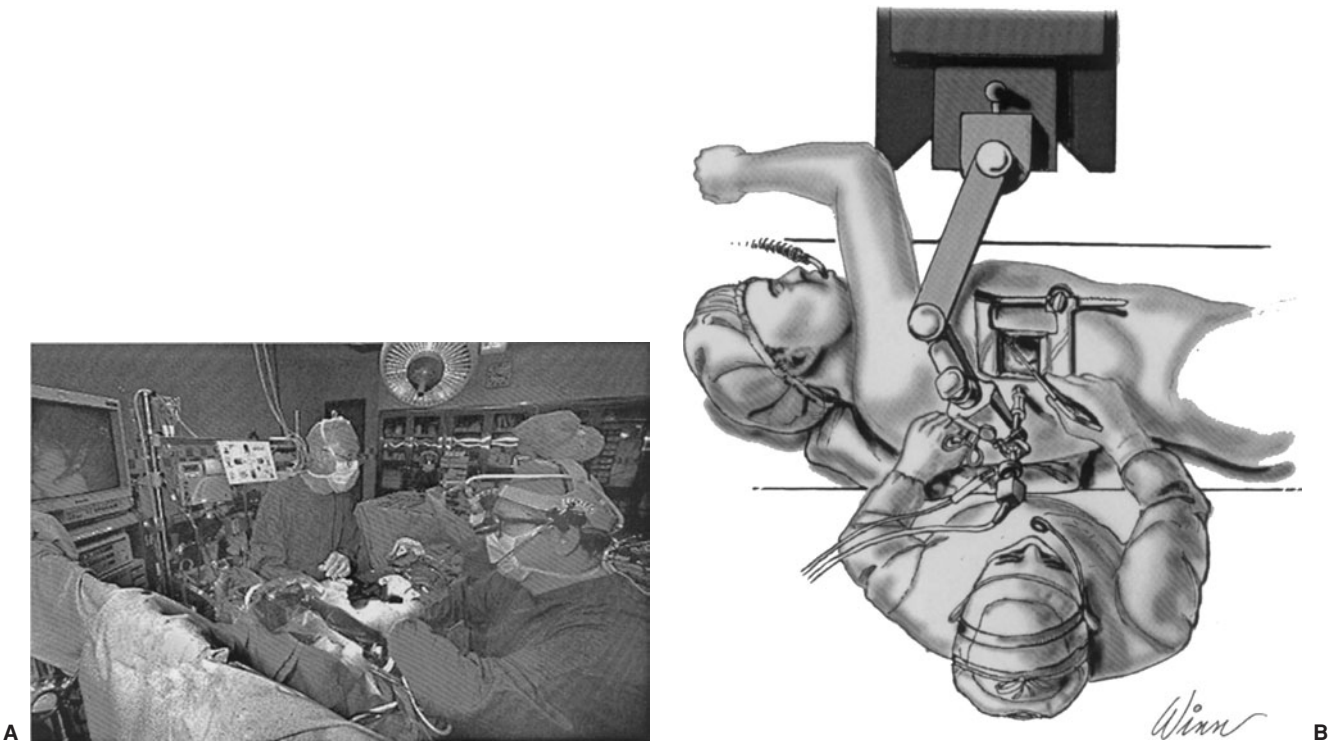

Figure 45-14. (A, B) During minimally invasive video-assisted mitral surgery, the camera is voice activated and positioned by the surgeon using the Aesop 3000 robot. Operative maneuvers are made through the 5-cm incision using long instruments and secondary vision.

look either "up" or "down" within the heart. Access to and visualization of the internal thoracic artery, coronary arteries, and mitral apparatus have been shown to be excellent. The operator becomes ensconced in the 3-D operative topography and can perform extremely precise surgical manipulations, devoid of traditional distractions. Figure 45-20B shows the surgeon's operative field during a da Vinci mitral repair. Perfusion technology is the same as described above for video-assisted operations and a larger mini-thoracotomy.

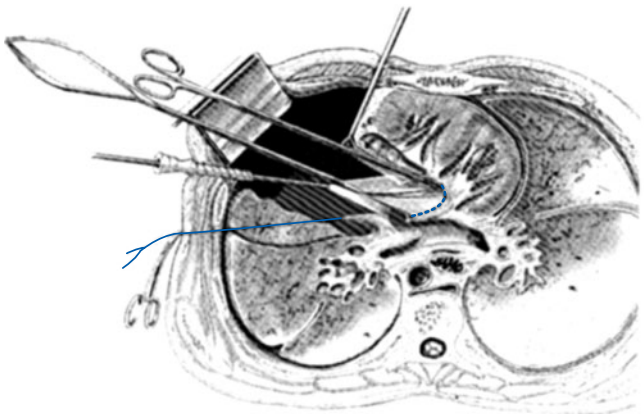

Figure 45-15. Mini right thoracotomy approach for mitral surgery. Long instruments are required to operate in a two-dimensional operative field.

Complex Mitral Valve Repairs with the da Vinci System

Heretofore, many surgeons avoided repairing valves with large bileaflet defects. However, we have found that repairs of these maladies are particularly amenable to robotic telemanipulation because of high-definition 3-D magnified vision and the ability to translocate multiple individual chordae tendineae to new leaflet sites. After the first 50 mitral repairs our group began to repair more complex valves as well as develop and use new adjunctive technology during robotic surgery. Figures 45-21 through 45-27 illustrate the variety of methods we use routinely for both simple and complex repairs. The mainstay of our repairs for posterior leaflet prolapses, secondary to ruptured or redundant chordae, has been a modification of the classic quadrangular resection. As seen in Fig. 45-21, a trapezoidal or triangular resection is made of the central portion of redundant posterior leaflet segment. This conserves annular distance that must be closed and limits tension along the posterior annulus, especially when one of the scallops is much larger than the others. This is often the case in P_2 prolapse, where P_1 and P_3 may be diminutive. The minor base of the trapezoid is closed with a figure-of-eight braided suture (2-0 Cardioflon [Peters, Inc., Paris, France]). Often we conserve leaflet tissue by decreasing the size of P_2, and when the leading edges are approximated, chordae are shortened effectively as they assume a new angle with the leaflet insertions, thus reducing the prolapse to below the annular plane. When there is an

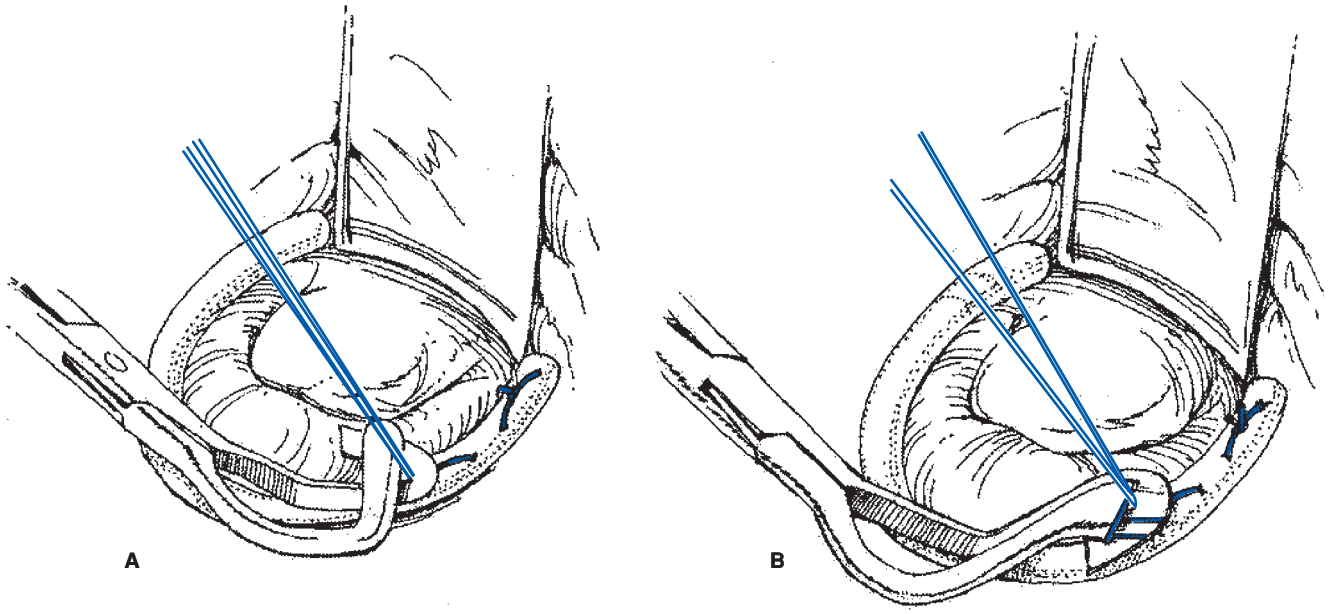

Figure 45-16. Knot pusher (A) and cutter (B).

isolated anterior leaflet prolapse, chordae can either be transferred from the posterior leaflet (Fig. 45-22A and B) or the redundancy reduced using PTFE neochords (Fig. 45-23A and B). When any posterior leaflet scallop is radially higher than 2 cm or the anterior leaflet is longer than 3 cm, there is a greater chance of systolic anterior motion of the anterior leaflet occurring. This is especially true when the aortic outflow is narrowed by a thickened interventricular septum or a relatively acute angle between the aortic and mitral valve planes. Generally, systolic anterior motion can be avoided by reducing the posterior leaflet height with a sliding-plasty

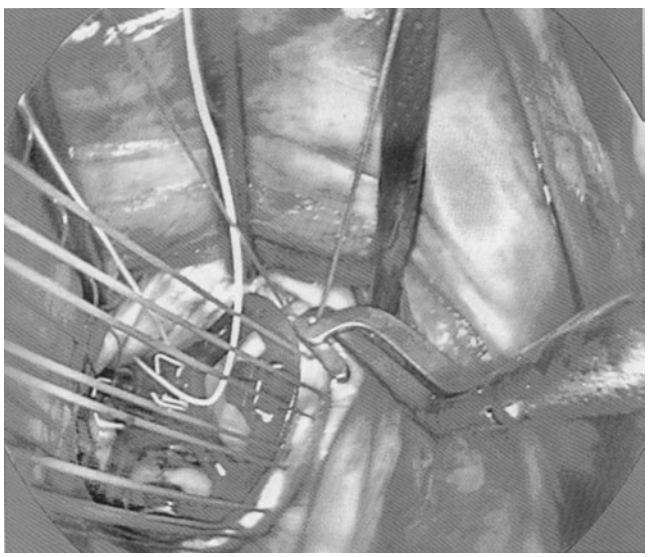

Figure 45-17. Knot pusher used to secure knots during annuloplasty band placement.

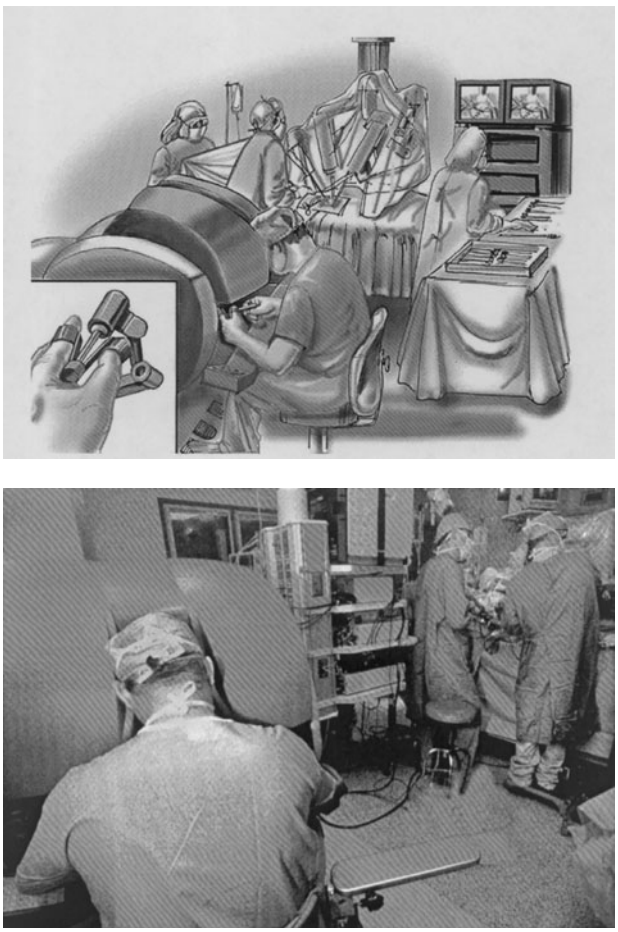

Figure 45-18. (A) The da Vinci Robotic Telemanipulation System. The operative console is in the foreground while the instrument cart is at the table. Both the operating surgeon and patient-side assistant are shown. (B) da Vinci robotic mitral valve repair. The surgeon is positioned approximately 10 feet from the patient. The instrument cart is placed on the left side of the tilted patient with arms entering the right thorax.

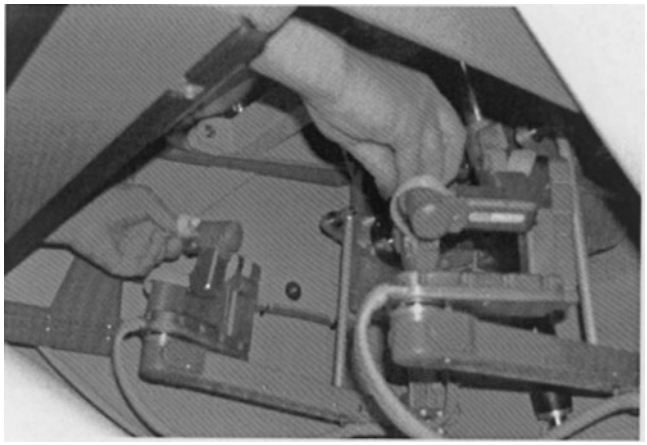

Figure 45-19. The operating surgeon manipulates affecter instrument tips in the patient's thorax via ergonomic handpieces that transfer filtered digitized data into smoothed movements.

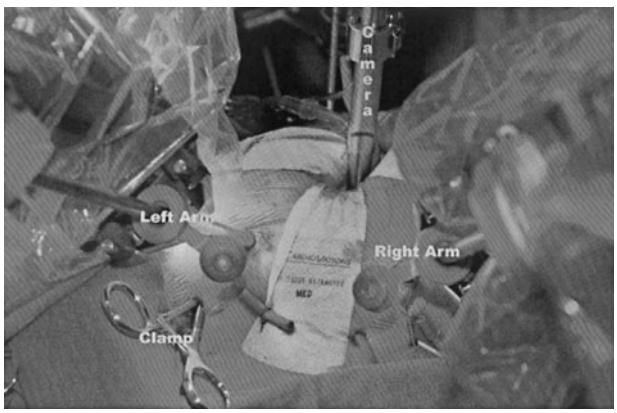
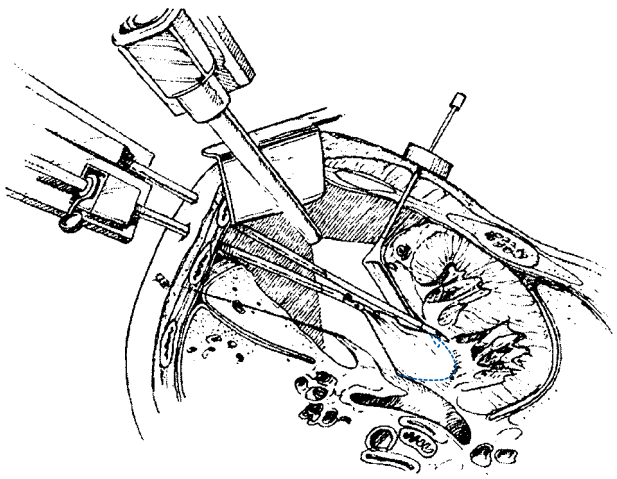


A



B

Figure 45-20. (A) da Vinci bedside setup for mitral valve surgery. (B) This thoracic cross-section during a da Vinci mitral operation shows how both instrument arms and the visual field converge at the operative plane to allow an unobstructed topographic view with full access to valvular and subvalvular structures.

after prolapsing segments are resected (Fig. 45-24A through E). In patients with bileaflet prolapse or Barlow's disease, part of resected segments from the posterior leaflet is transposed to the redundant anterior leaflet segments and attached with monofilament 4-0 sutures. Again, "swinging" a chord-bearing piece of posterior leaflet to the undersurface of the anterior leaflet generally reduces the prolapse of the latter (Fig. 45-25A through E). To date, all of our robotic repairs have been supported by an annuloplasty using a Cosgrove-Edwards band (Edwards Lifesciences, Inc., Irvine, Calif). We have used two suturing methods to attach the band. We either use single-arm 2-0 braided sutures as shown in Fig. 45-26 A or nitinol U-clips (Medtronic, Inc., Minneapolis, Minn) as shown in Figs. 45-26B and C and 45-27. For insertion of a band alone or when a limited resection is done, we prefer to use the U-clips, which enable faster deployment. However, when tension is applied, as in larger resections and sliding-plasties, the compressive force of sutures provides seemingly better reinforcement of the repair.

CURRENT STATUS OF MINIMALLY INVASIVE MITRAL VALVE SURGERY

Cosgrove and Gundry have been consistent proponents of using the hemisternotomy for mitral valve surgery. They have considered the ministernotomy technique to be more reproducible for surgeons with variable experiences and abilities. Both complex replacements and repairs have been done through this incision and to date few repair failures have resulted from this exposure method. Between 1996 and early 2002, Cosgrove and his Cleveland Clinic group performed 1427 minimally invasive mitral operations, using direct vision, the upper hemi-sternotomy, and modified perfusion methods. As noted earlier, the extended atriotomy, first proposed by Guiardon and used continually by the Cleveland Clinic group, apparently has caused excessive atrial arrhythmias. Of these patients, 82% had degenerative and 9% had rheumatic disease. Of all mitral valves 90% were insufficient and nearly all were repaired, with 98% having a band annuloplasty and 85% undergoing leaflet resections. Perfusion and aortic occlusion times averaged 80 and 60 minutes, respectively, and were shorter than those of many experienced surgeons using a full sternotomy. Moreover, since 1996 perfusion times have decreased more significantly than arrest times. Their series presents impressive mortality (0.3%) and complication rates (bleeding [3.1%], strokes [1.8%], and respiratory insufficiency [0.8%]). Conversions to a full sternotomy have fallen at the Cleveland Clinic from 5% in 1997 to 0.5% in 2002 (1.5% mean), and most of these were related to poor exposure and not bleeding. Only 7% of patients were transfused, and the mean hospitalization was 6.5 days with 20% being discharged in less than 4 days.

After initially using a right parasternal incision with bicaval cannulation and left atrial entry via the interatrial septum, Cohn and associates now prefer a lower hemi-

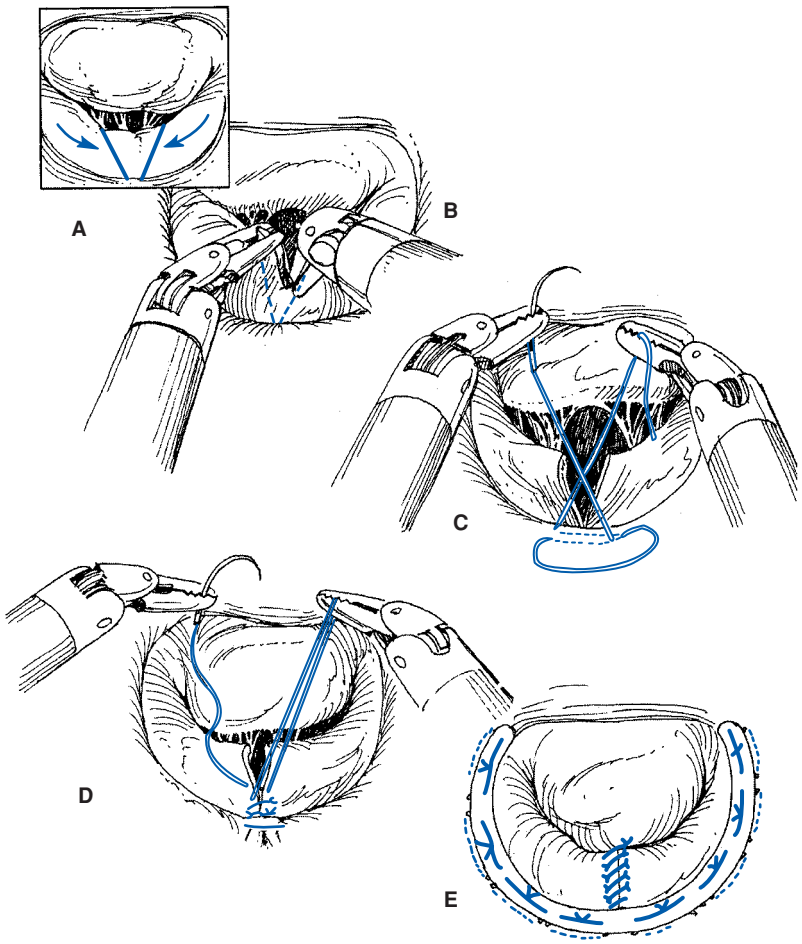


Figure 45-21. Triangular or trapezoidal resection of the central portion of a redundant P_2 segment.

sternotomy for mitral valve surgery. Of the 411 mitral patients operated between 1996 and early 2002, 201 had hemisternotomies and 201 had parasternal incisions, with 8 having a minithoracotomy. Myxomatous (81%), rheumatic (10%), and endocarditis (4%) were the most common etiologies. In 88% repairs were done, and in the remaining 12% replacements were done using mechanical valves (84%). Their operative mortality was 0.2% with no deaths in the repair group. Bleeding occurred in 2% and 38% were transfused with an average of one unit of packed cells per patient. Strokes occurred in 2.2% of patients and myocardial infarctions in 1.0%. Patients were hospitalized for a mean of 6 days and 8.3% required additional rehabilitation prior to discharge. Recently, this series was updated to a total of 1000 minimally invasive valve operations (526 aortic and 474 mitral procedures). In the mitral group 416 had repairs while 58 patients had replacements. They compared this group to a cohort of 337 patients undergoing mitral valve surgery via a sternotomy. The median perfusion and cross-clamp times were 121 minutes and 82 minutes for the minimally invasive group versus 125 minutes and 87 minutes ($p < .01$) for the sternotomy cohort, respectively. In the sternotomy group 18 patients (5%) had perioperative myocardial infarction compared with 2 patients (0.4%) in the minimally invasive group. Also, the minimally invasive group had a shorter length of stay (5 versus 7 days) and was discharged home more frequently.[52] Both of these large series demonstrate benefits using a less invasive approach and that repair results are comparable to operations done through a full sternotomy. Wound healing has not presented a problem using a modified sternotomy.

Grossi and associates at New York University compared 100 minimally invasive mitral operations, done through a 6- to 8-cm mini-thoracotomy, using direct vision and Port-access methods, to a cohort of 100 conventional mitral operations.[40] They reported a perioperative mortality of 1.0%. In these patients 80% had a posterior leaflet repair and 30% had an anterior leaflet reconstruction. Their results suggested that minimally invasive mitral operations can be done safely using Port-access methods with similar results as conventional operations and with no added mortality or morbidity. At the same time they had fewer transfusions, shorter lengths of hospital stay, and fewer septic complications, despite longer cardiopulmonary bypass times. In a multi-institutional analysis of 491 Port-access mitral repairs from 104 centers, Glower reported that 86% of all valves were repaired with aortic cross-clamp times of 90 minutes and perfusion times of 137 minutes.[53,54] The overall

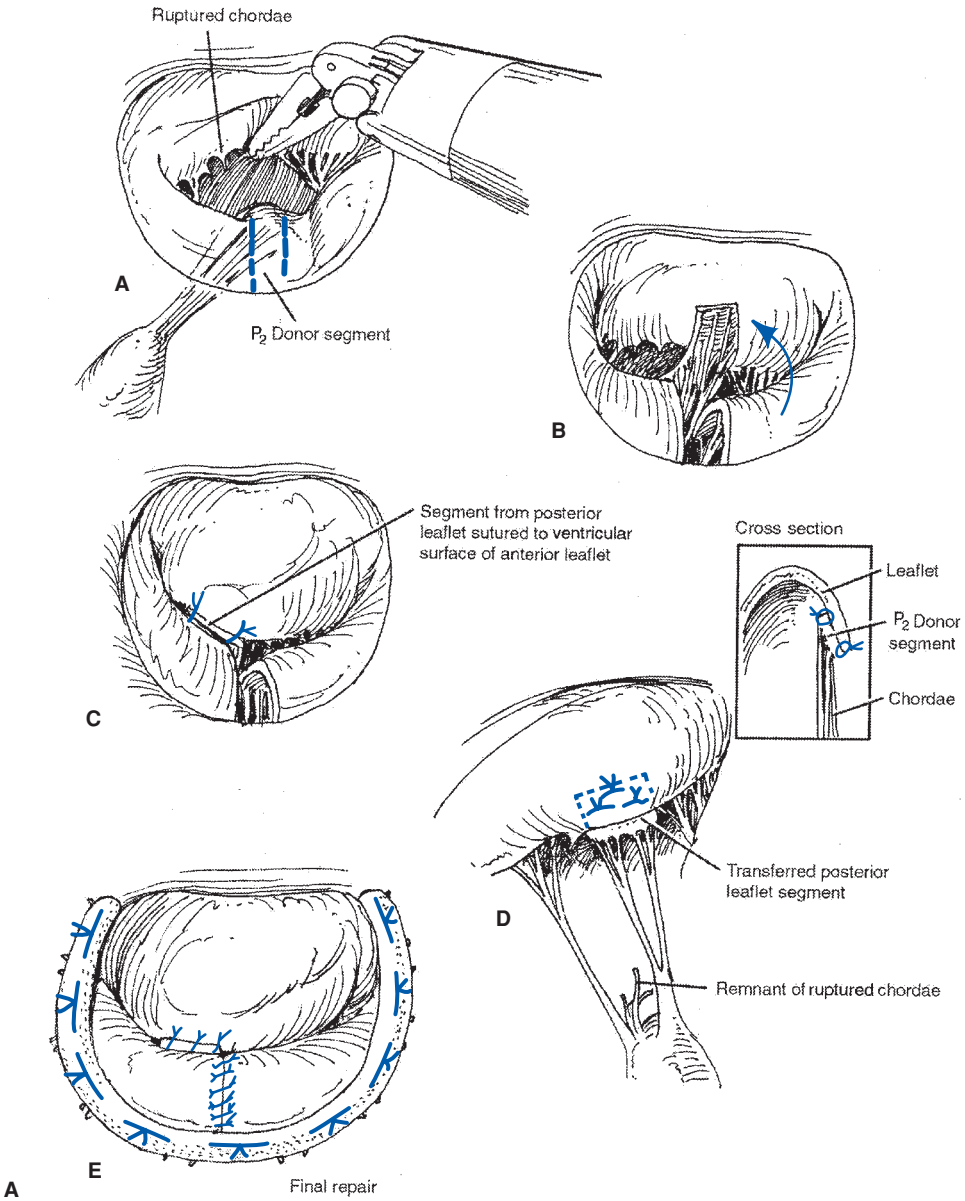

Figure 45-22. (A, B) Chordal transfer from posterior leaflet for the treatment of isolated anterior leaflet prolapse.

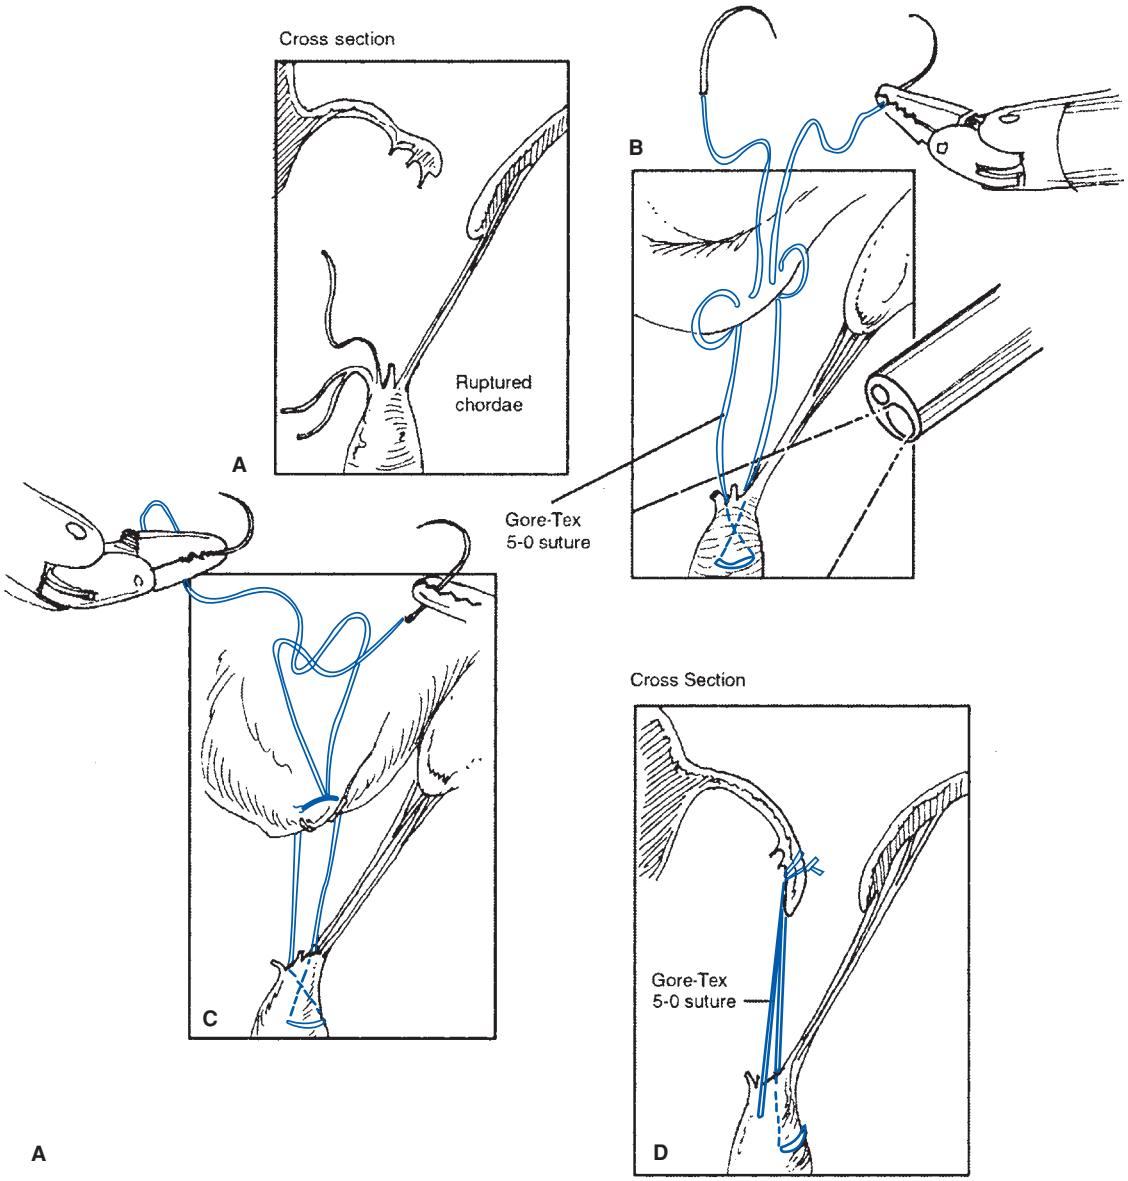

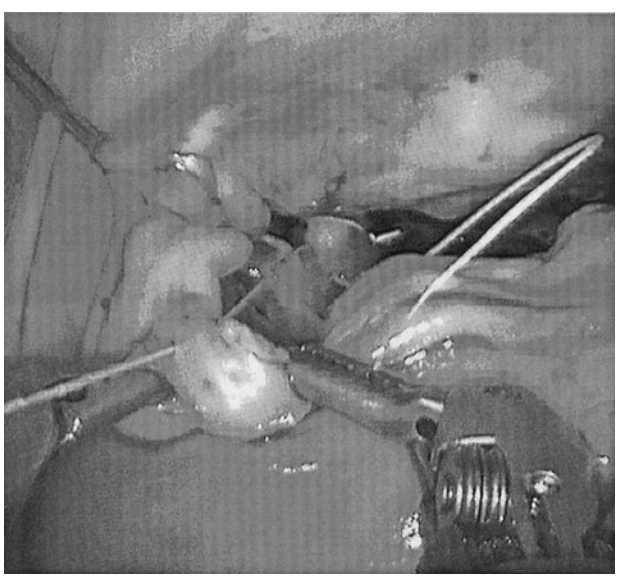

Figure 45-23. (A, B) Gore-Tex neochords are used for treating leaflet prolapse and/or for the replacement of ruptured chords.

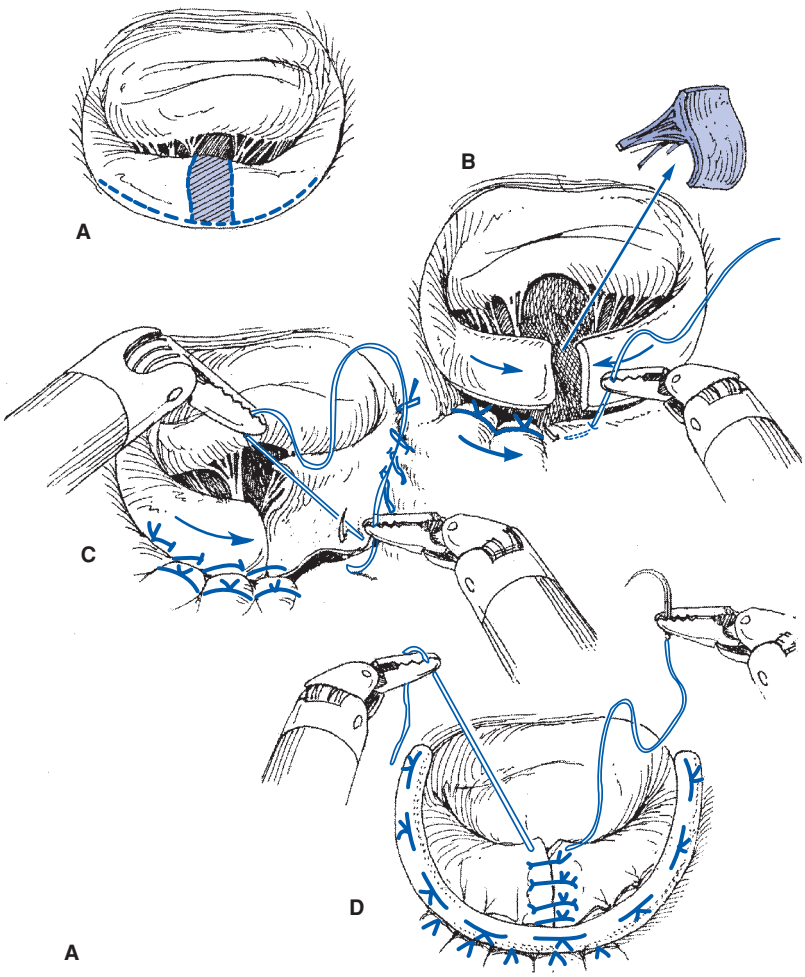

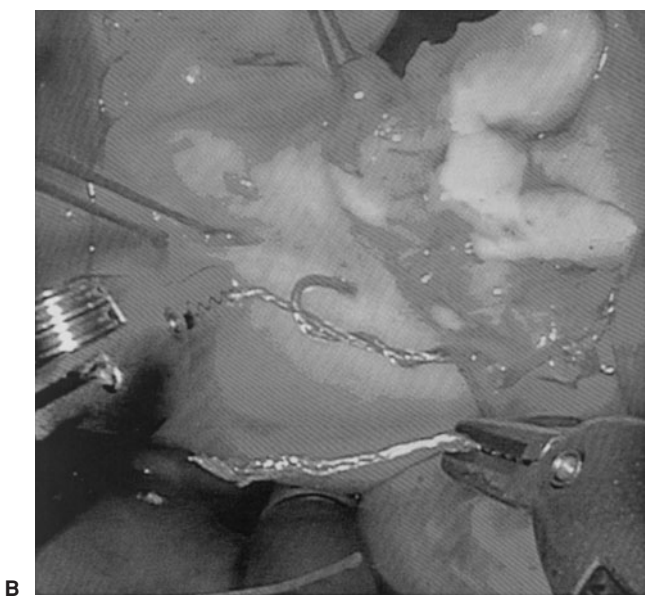

Figure 45-24. A da Vinci mitral valve repair. (A) The P_2 segment of the posterior leaflet is being resected by robotic microscissors. (B) The annulus is reduced, the sliding-plasty is completed (C), and both P_1 and P_3 are approximated (D). (E) Instrument arms of the da Vinci device are used for tying sutures intracorporally.

mortality for repairs was 1.6% and was 5.5% for replacements. Age was the only independent predictor of strokes (2.7%) in these patients. Neurologic complications associated with early use of this technique have diminished with the advent of better devices and more experience. The overall length of stay for this large group of mitral patients was 7 days.

In early 2001 the East Carolina University group reported 128 successful video-assisted mitral valve operations.[27] At first, patients with anterior leaflet pathology and

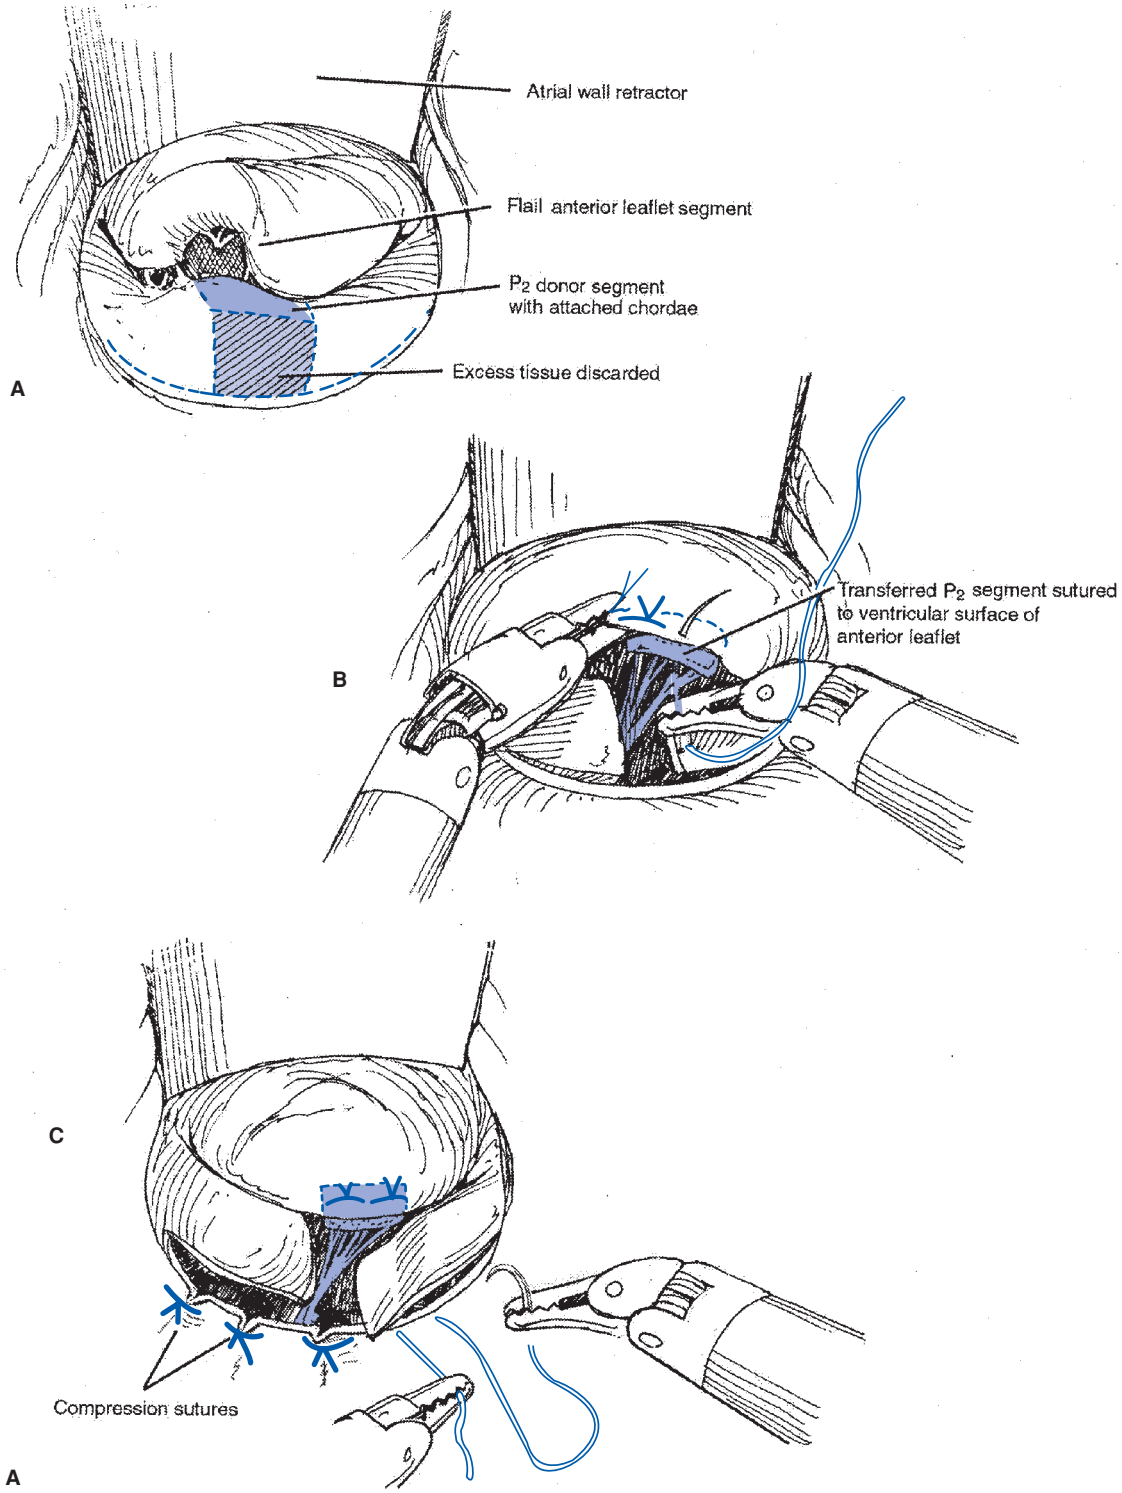

Figure 45-25. Repair of Barlow's or bileaflet disease. Resection of P_2 maintaining the chordal apparatus intact is performed (A) followed by transfer of this segment to the anterior leaflet (continued)

annular calcification were avoided. However, these patients are now operated on using video-assisted technique. Table 45-3 details our current criteria for patient selection. In this series repairs included quadrangular resections, annuloplasties, and complex chordal procedures. The majority of patients had degenerative disease and 61% of the total group underwent a repair. When the early series was combined with the next 100 video-assisted mitral operations, repairs increased to 81% of all mitral patients. The operative and 30-day mortalities for our entire series have been 0.4% and 1.7%,

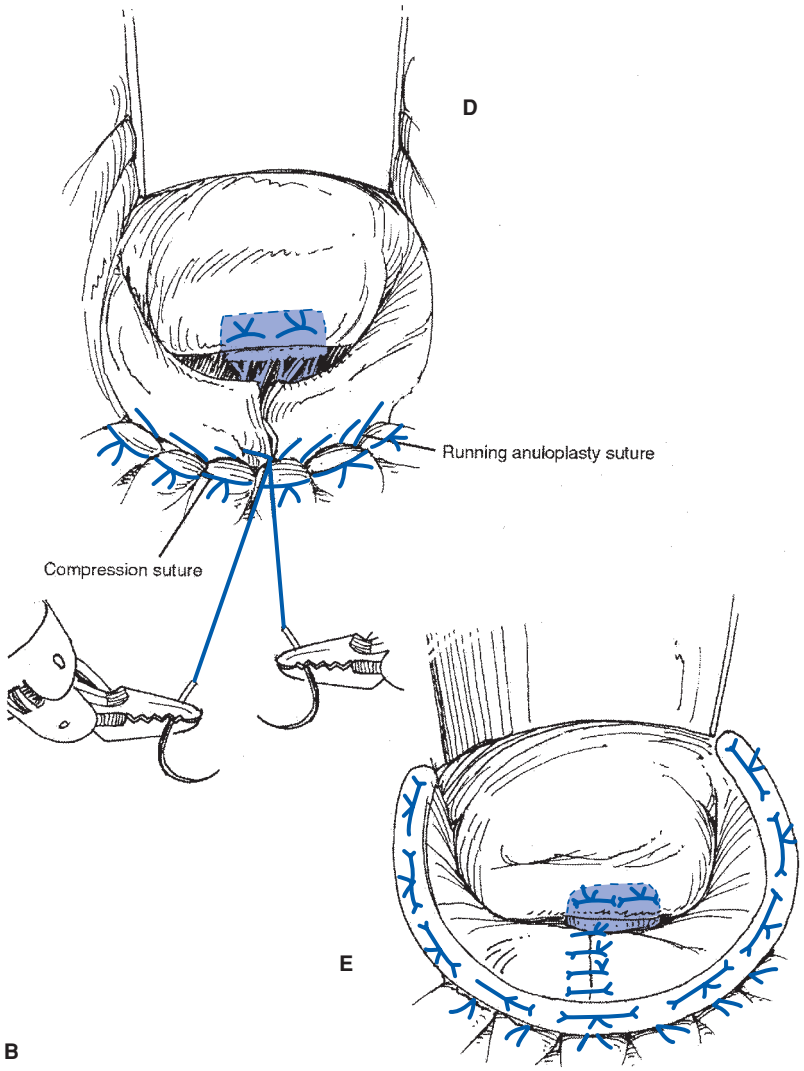

Figure 45-25. *(continued)* (B). The posterior annulus is then reduced (C). The sliding-plasty is then completed (D) followed by approximation of P_1 and P_3 (E).

respectively. After we adopted the Aesop 3000 robot for voice-activated endoscopic camera control, cross-clamp and perfusion times fell secondary to improved visualization and reduced lens cleaning. However, in the latter half of the early series cross-clamp (90 minutes) and perfusion times (143 minutes) still remained longer than those of conventional operations. Currently at our institution cardiac arrest and perfusion times have fallen to 70 and 100 minutes, respectively, for video-assisted mitral operations. Interestingly, we have seen no difference in bleeding and transfusion requirements between our conventional and minimally invasive cases. However, the hospital lengths of stay have averaged 4.9 days compared to 8 days for conventional operations. Of these 324 patients there were 2 (0.6%) operative deaths, 9 (2.8%) in-hospital deaths, 2 (0.6%) conversions to a sternotomy, 3 (0.9%) strokes, 14 (4.3%) re-explorations for bleeding, 3 (0.9%) perioperative myocardial infarctions, and 1 (0.3%) aortic dissection. A total of 31.8% of the patients received a blood product transfusion. In this series, 14 patients (4.3%) have required a mitral valve reoperation. We have operated on 71 patients (31 mitral valve repairs and 40 mitral valve replacements) having had prior coronary or mitral surgery. These patients underwent video-assisted reoperations with a 9.8% mortality as well as four re-explorations for bleeding and one stroke (1.4%).[55]

Mohr and associates reported 154 video-assisted mitral valve operations using Aesop 3000 robotic camera control.[24,31,56] In these patients the aortic cross-clamp and perfusion times were similar to those of their conventional operations, and the operative mortality was 1.2%. They considered 3-D visualization to be the key to excellent results during videoscopic valve reconstructions. In a study comparing the Port-access technique to transthoracic clamping, Wimmer-Greinecker obtained similar repair results but with faster operations, fewer technical difficulties, and lower cost using the latter method.[57] In early 2002, Vanermen described 187 patients undergoing totally video-directed repairs using the Port-access method and no rib spreading. He used a 2-D endoscopic camera to perform complex repairs with excellent results at follow-up 19 months later.[43] The hospital mortality was 0.5%, and there were two conversions to a sternotomy for bleeding. Freedom from reoperation was 95% at 4 years. Over 90% of patients had minimal postoperative pain. Although this and other series have not been randomized,

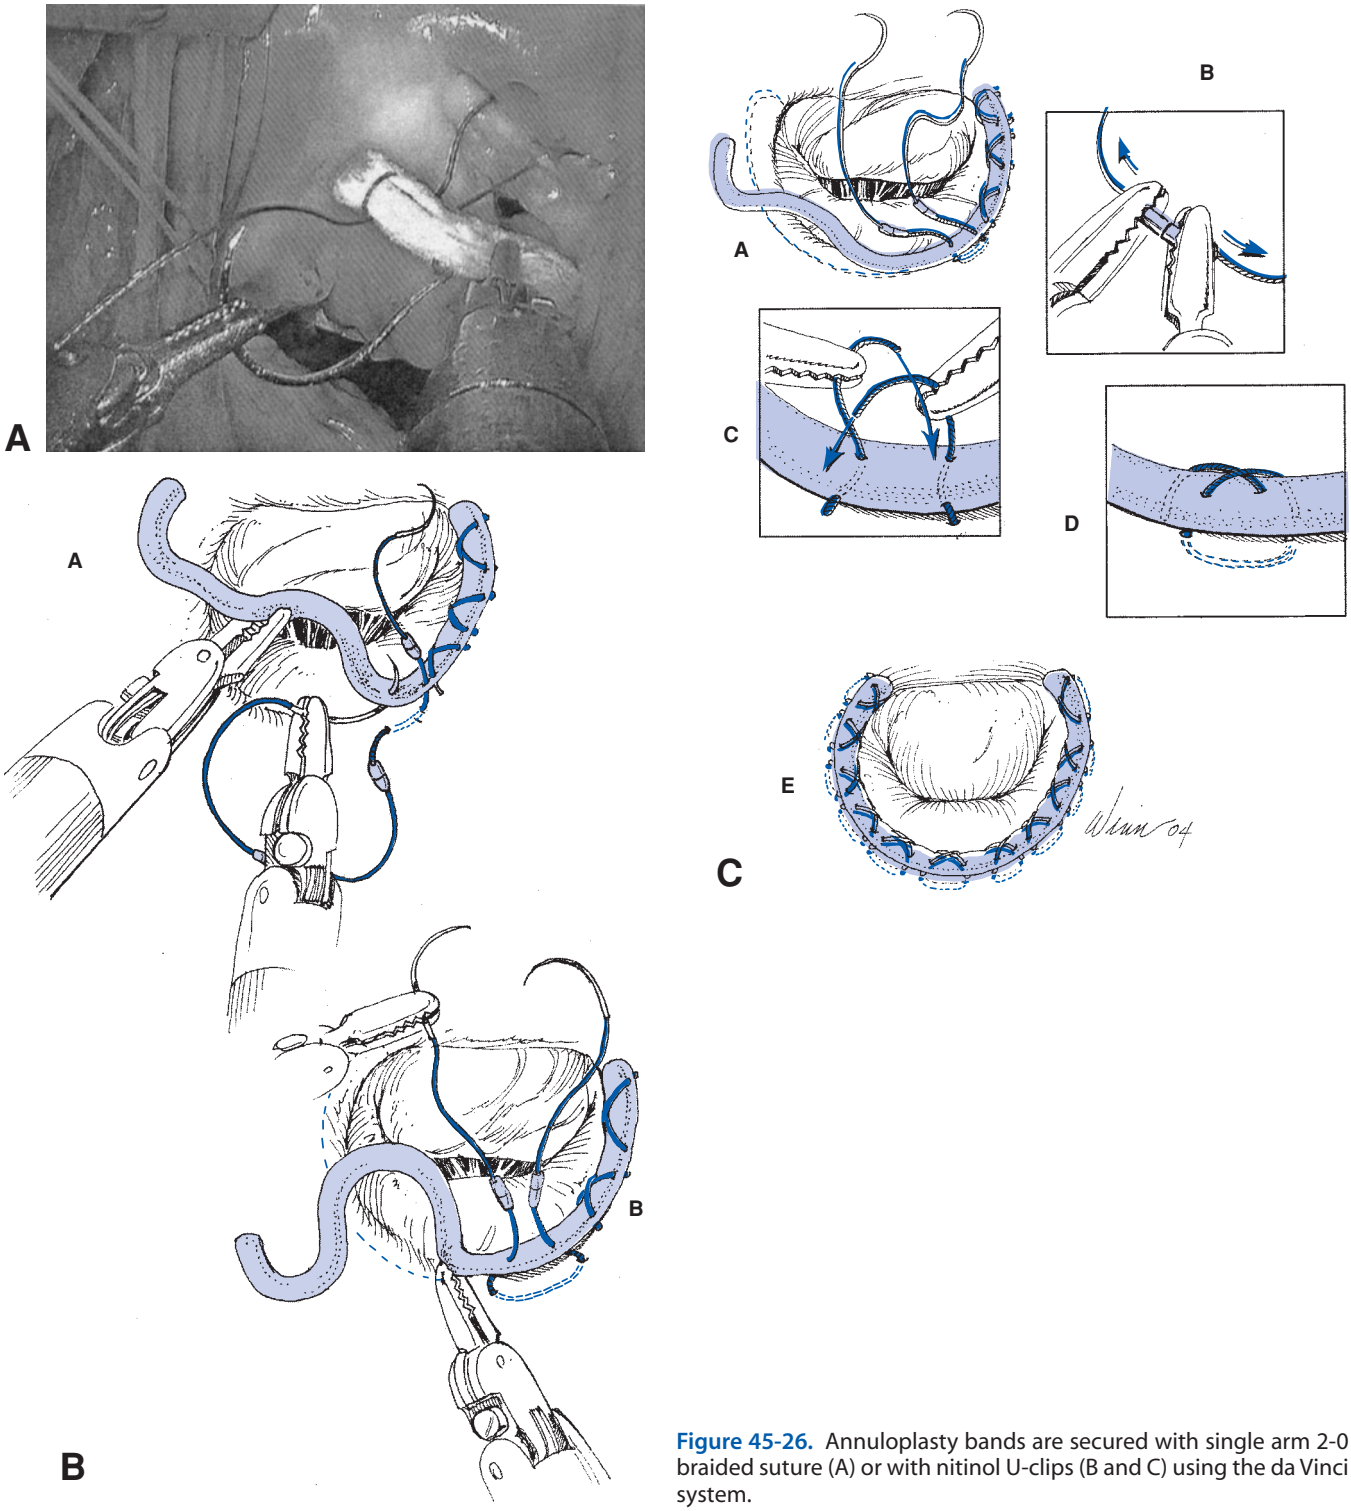

Figure 45-26. Annuloplasty bands are secured with single arm 2-0 braided suture (A) or with nitinol U-clips (B and C) using the da Vinci system.

there are strong suggestions that mitral valve surgery has entered a new era and that video techniques can facilitate these operations.

In 2003 Vanermen and associates updated their results in 306 mitral patients (226 repairs and 80 replacements). Six patients were converted to median sternotomy because of peripheral cannulation complications, and there was a 1% (n = 3) 30-day mortality. In this series 46% of patients were back to work within 4 weeks, and the overall freedom from reoperation was 91% at 4 years. Their results continued to suggest that endoscopic mitral valve surgery is safe with excellent results.[58]

Hargrove at the University of Pennsylvania–Presbyterian Hospital has performed over 530 video-assisted minimally invasive mitral valve operations since 1998. The mean age for his first 520 patients (437 repairs and 83 replacements) was 60 years in 271 male and 249 female patients. Mean perfusion and cross-clamp times were 142 and 102

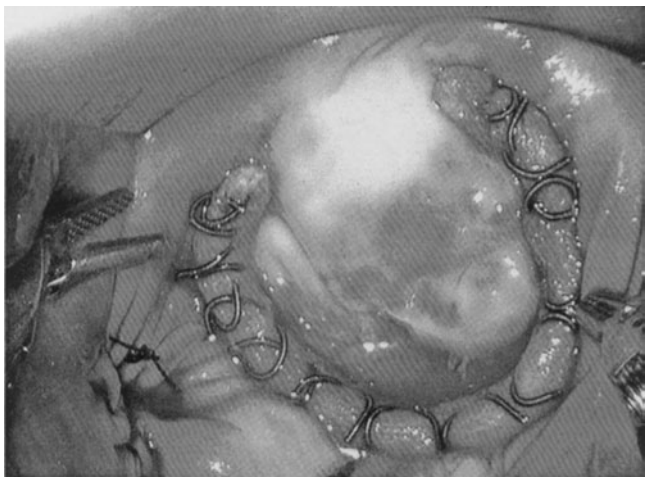

Figure 45-27. Completed repair using nitinol U-clips to secure the annuloplasty band.

minutes, respectively. Of his patients 19 were operated on using hypothermic fibrillatory arrest at a mean perfusion time of 122 minutes. Postoperative repair transesophageal echocardiograms showed no leak in 305 patients, 1+ regurgitation in 129 patients, and 2+ insufficiency in 3 patients. There were 11 (2%) deaths, 14 (2.6%) strokes, and 32 (6.1%) re-explorations for bleeding. The average length of stay was 8 days and freedom from reoperation 97%. Hargrove has become convinced that small-incision and videoscopic mitral surgery is safe, effective, economical, and better accepted by patients than conventional sternotomy operations. The long-term results of all of the above series continue to confirm that minimally invasive mitral operations already have taken a prominent place in the evolution of cardiac surgery.

Table 45–3.

Current Patient Selection: Videoscopic or Video-Assisted Mitral Valve Surgery

Unsuitable candidates
Highly calcified mitral annulus
Severe pulmonary hypertension, especially with a small right coronary artery
Significant untreated coronary disease
Severe peripheral atherosclerosis
Prior right chest surgery
Suitable candidates
Patients with primary mitral valve disease
Reoperative mitral valve patients
Bileaflet and/or anterior leaflet disease
Combined tricuspid and mitral operations
Mild annular calcification
Obese or large patients
Elderly patients

Robotic Mitral Valve Surgery

The East Carolina University group performed the first da Vinci system robotic mitral valve repair in North America in May 2000. Since then, we have performed over 270 robotic mitral valve repairs. The first Food and Drug Administration (FDA) safety and efficacy trial was conducted at our institution in 2000 and included 20 patients.[33,59] Leaflet resections, sliding-plasties, chordal transfers, neochord insertions, and annuloplasties all were performed successfully. This initial study demonstrated that although operative times were longer, when compared with conventional mitral valve surgery, the results were comparable. There were no device-related complications. Postoperative hospital stays averaged 4 days, and all patients returned to normal activity by 1 month following surgery. Early postoperative echocardiograms at 3 months demonstrated that none of the patients had more than trace mitral regurgitation.

These initial results were encouraging and prompted a phase II multicenter FDA trial, which was completed in 2002.[60] A total of 112 patients were enrolled at 10 different institutions and all types of repairs were performed. Following surgery nine patients (8%) had grade 2 or higher mitral regurgitation, and six patients (5%) required a reoperation. Although the reoperative number was high for the number of patients, failures were distributed evenly among centers, with some centers having performed fewer than 10 procedures. There were no deaths, strokes, or device-related complications. These results prompted FDA approval (2002) of the da Vinci system for mitral valve surgery. Subsequently, at the 2005 American Heart Association meeting, we reported results in our first 200 robotic mitral repair patients.[61] The average patient age was 57 years with total operative time of 285 minutes, cardiopulmonary bypass time of 156 minutes, and cross-clamp time of 119 minutes. Repairs included quadrangular resections, sliding-plasties, chordal transfers, chordal shortening, neochord insertion, and annuloplasties. There was only one (0.5%) operative death secondary to a protamine reaction and no device- or perfusion-related complications. In addition, there were 3 (1.5%) in-hospital deaths. The hospital length of stay was 4.8 ± 0.2 days. Postoperative echocardiograms showed that 187 patients (93.5%) had no mitral regurgitation, 6 patients (3%) demonstrated trace mitral regurgitation, 5 patients (2.5%) had moderate mitral regurgitation, and 2 patients (1%) had systolic anterior motion of the anterior leaflet. A total of 5 patients (2.5%) required a reoperation for failed repairs.

We have also used the da Vinci system to perform mitral valve replacements as well as combined mitral valve repairs with atrial fibrillation ablation.[62] As we continue to perform further robotic mitral operations, the operative times have continued to decrease. In addition, we are able to repair more complex valves due to the enhanced visualization and fine dexterity offered by the da Vinci system.

MINIMALLY INVASIVE HEART VALVE SURGERY: CONCLUSIONS

The above information suggests that minimally invasive valve surgery is well on the way to becoming reality. Although operative philosophies, patient populations, and surgeon abilities differ among centers, the compendium of recent results remains very encouraging. The advent of true 3-D vision with tactile instrument feedback will be the major bridge to truly tele-micro-access operations. Also, to perform these operations optimally, extracorporeal surgeons and engineers will need to continue to improve methods by which instruments are directed by computers. Recent successes with direct-vision, videoscopic, and robotic minimally invasive surgery all have reaffirmed that this evolution can be extremely fast, albeit through various pathways. In fact, catheter-based technology is even moving toward treating aortic valve disease, and mitral annuloplasties have been done experimentally through the coronary sinus.[63]

Patient requirements, technology developments, and surgeon capabilities all must become aligned to drive these needed changes. In addition, we must work closer with our cardiology colleagues in these developments. This is an evolutionary process, and even the greatest skeptics must concede that progress has been made. However, curmudgeons and surgical scientists alike must continue to interject their concerns. Caution cannot be overemphasized. Traditional valve operations enjoy long-term success with ever-decreasing morbidity and mortality, and remain our measure for comparison. Surgeons and cardiologists must remember that less invasive approaches to treating valve disease cannot capitulate to poorer operative quality or unsatisfactory valve and/or patient longevity.

CHAPTER 46

Percutaneous Catheter-Based Mitral Valve Repair

Michael J. Davidson • Donald S. Baim

While mitral stenosis and regurgitation traditionally have been addressed by surgical means, both now have emerging percutaneous treatment options. Mitral stenosis, although now relatively uncommon in developed countries, represents the first heart valve pathology to be treated by surgical techniques (in 1923[1]) and by percutaneous techniques (in 1982[2]). While percutaneous balloon mitral valvuloplasty for rheumatic mitral stenosis now has a 20-year track record with excellent success in patients with suitable valvular and subvalvular morphology,[3,4] heretofore there have been no clinically viable percutaneous treatment options for patients with mitral regurgitation.

One subset that might benefit from percutaneous mitral valve repair consists of patients with ischemic or functional mitral regurgitation. Moderate to severe mitral regurgitation is present in up to half of patients with significant congestive heart failure largely as the result of leaflet malapposition owing to annular dilatation combined (in some patients) with downward traction on the posterior leaflet by outward displacement of the lateral papillary muscle by lateral wall infarction.[5] The resulting chronic volume overload of mitral regurgitation begets further left ventricular dilatation, thus worsening mitral regurgitation, in a classic vicious cycle.[6] Several studies have shown that the presence of significant mitral regurgitation is an independent predictor of mortality in congestive heart failure and that surgical correction with an undersized mitral annuloplasty ring may improve both left ventricular enlargement and survival.[7–9] On the other hand, surgical mitral valve repair in this population carries a nontrivial procedural risk,[9,10] and significant mitral regurgitation may recur over 1 to 5 years despite an initially successful surgical repair.[11] There thus has been a growing interest in percutaneous techniques for the reduction of ischemic mitral regurgitation to see if such procedures could be performed with less associated morbidity.[3,12]

A second subset that potentially might benefit from percutaneous mitral valve repair consists of patients with degenerative or structural mitral regurgitation. Traditionally, these patients have been referred for surgery when they become symptomatic. Since most are free of coronary artery disease or other cardiac lesions, they usually can be approached through minimally invasive surgical valve repair techniques (i.e., limited partial sternotomy and valve repair rather than replacement). Insofar as a percutaneous catheter-based approach avoids the use of cardiopulmonary bypass and the morbidity of an open-heart procedure, it can be seen as a further extension of this trend toward minimally invasive mitral repair. Given the excellent surgical results for open repair of degenerative valve disease, however, it is unlikely that percutaneous techniques will replace surgery for operable symptomatic patients with degenerative mitral valve disease. However, the development of a less morbid technique may enable intervention at an earlier stage in the disease process, particularly if it leaves the options for later surgical repair intact, if needed.

BALLOON MITRAL VALVULOPLASTY

The first catheter-based technique for the treatment of mitral stenosis was performed by Inoue in 1982[2] and almost concurrently by Lock and colleagues.[13] This technique now has been applied to thousands of patients, and its success has caused it to supplant surgical open commissurotomy or valve replacement in patients with isolated mitral stenosis and suitable anatomy. Patients are evaluated by echocardiography to ensure the absence of left atrial thrombus and the presence of appropriate valve anatomy.[3] The technique has changed little since its inception; a venous approach with transseptal puncture is used, and a guidewire is advanced through the valve into the left ventricle. The valve then can be dilated using one of several devices. The most popular

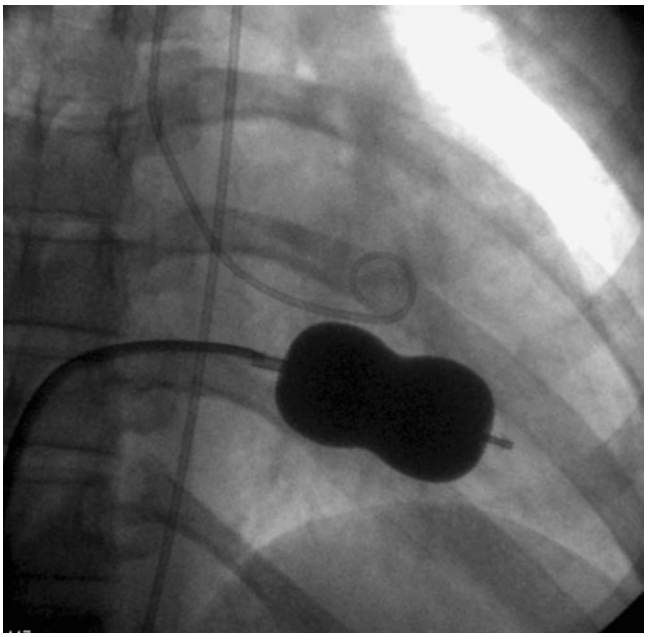

Figure 46-1. Transcatheter mitral commissurotomy. Inoue single-balloon mitral commissurotomy via a transseptal approach. Note the balloon "waist" as the valve is dilated.

and technically simple approach uses the Inoue single balloon, which allows progressive dilation to diameters of 23 to 28 mm at various inflation volumes (Fig. 46-1).

A second alternative is the double-balloon technique using side-by-side 18- to 20-mm-diameter balloons, which has the same efficacy as the Inoue technique but a tendency for higher complication rates (especially ventricular perforation). Lastly, Cribier has used a metal commissurotomy device modeled on the Tubbs dilator. The primary advantage is that the device is reusable, allowing broader application in developing countries, although it is technically more difficult than balloon techniques and carries a higher risk of cardiac perforation.

Complications of all these techniques include failure to relieve stenosis, creation of mitral regurgitation, perforation with hemopericardium, and systemic embolization.[3,4] Immediate surgery may be required in approximately 1% of procedures for resolution of technical complications such as hemopericardium or creation of severe mitral regurgitation. When there is insufficient resolution or recurrence of stenosis, repeat balloon valvuloplasty or elective mitral valve replacement can be performed. Most patients with immediate procedural success (approximately 90% of patients) have continued good functional results at 10 years after treatment.[4]

PERCUTANEOUS TREATMENT OF MITRAL REGURGITATION

The percutaneous approaches currently being evaluated attempt to emulate one or more of the components of surgical mitral valve repair,[14] e.g., annular reduction and edge-to-edge repair (Alfieri stitch).[15] On the other hand, these catheter techniques currently cannot duplicate some of the other aspects of surgical repair (including quadrangular or sliding leaflet resection and chordal modification).[14] Moreover, the catheter-based therapies for mitral repair are currently in their very earliest stages (animal testing or in some cases early human pilot trials). Thus it is not clear whether they can offer the *same level of improvement and durability* as the current open surgical approaches, nor how large a subset of patients with mitral regurgitation each catheter therapy will be able to address. It seems likely that each of the catheter approaches may be suitable for only a particular anatomic subset (e.g., prolapse with a normal annulus size or a dilated annulus without prolapse) and (as with the surgical techniques) that some patients will require more than one catheter approach used in concert to achieve an adequate repair. Finally, it is not clear whether the regulatory pathway will require the randomized demonstration of noninferiority to surgical repair (more likely with devices that may make subsequent surgical repair more complex)[16] or simply demonstration of improved indices of cardiac function (e.g., ventricular diameters, mitral regurgitation grade, and peak oxygen consumption during exercise—as used in heart failure trials). It is clear, however, that a large patient population (>1 million/year) would stand to benefit from a safe and effective percutaneous means of reducing or eliminating mitral regurgitation in the setting of congestive heart failure, with more than a dozen approaches being developed to achieve that goal.

ANNULOPLASTY APPROACHES (USING THE CORONARY SINUS)

The predominant surgical approach is implantation of an *annuloplasty ring,* which reshapes the circumference of the annulus and reduces the septolateral annular dimension.[17] This moves the posterior annulus and posterior valve leaflet closer to the anterior leaflet, allowing better systolic leaflet coaptation in patients with annular dilatation. Several companies currently are exploring percutaneous approaches that emulate surgical annuloplasty. Several are doing so by implanting a device in the coronary sinus—the main venous drainage of the myocardium—which fortuitously runs just outside and roughly in the same plane as the posterior mitral annulus (Fig. 46-2). A device that is placed in the coronary sinus thus may be able to plicate or straighten the coronary sinus and thereby therapeutically deform the posterior mitral annulus.

Most coronary sinus devices (e.g., MitraLife-Edwards, Edwards Monarc, and Cardiac Dimensions) use anchors that are placed in the anterior (i.e., the great cardiac vein, near the entry of the anterior interventricular vein) and posterior (near the ostium) portions of the coronary sinus. These two points typically lie adjacent to the mitral commissures and even may approach the fibrous trigones of the cardiac skeleton.

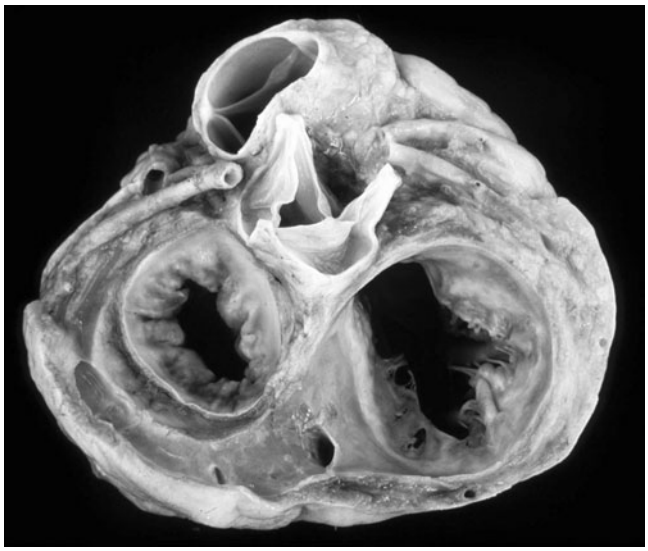

Figure 46-2. Relationship of the coronary sinus to the posterior mitral annulus and circumflex artery. The coronary sinus wraps around the atrioventricular groove behind the posterior mitral leaflet, extending nearly from its medial to lateral commissure. In this image, the circumflex coronary artery lies *outside/on top of* the coronary sinus, but it often courses *under* the coronary sinus and might be susceptible to compression during placement of a coronary sinus annuloplasty device.

The MitraLife device undergoes a shape change that reduces the commisure-to-commissure dimension (Fig. 46-3). In 2002, this device was placed on a temporary basis (i.e., the device then was restraightened and withdrawn following measurements) in Caracas. Modifications have been made to the shape of the device to also push the midportion of the posterior annulus forward, and the base intellectual property now has been acquired by Edwards. Clinical testing, however, has not yet resumed.

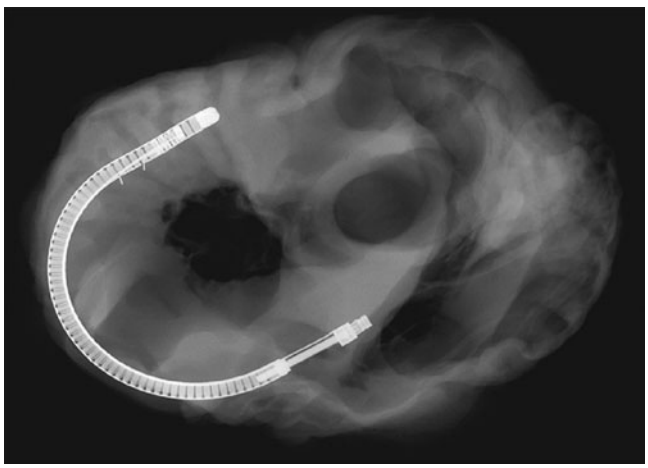

Figure 46-3. The MitraLife-Edwards device is a rod-like catheter that can change from straight to curved configuration once placed in the coronary sinus. This radiograph shows the device placed and curved within an explanted heart specimen. The commissure-to-commissure compression may not improve leaflet coaptation, and a new device shape is being considered to move the posterior leaflet forward.

The Edwards MONARC device (previously the JoMed-Edwards Viking device) is based on a patent by Jan Solem and consists of a pair of self-expanding nitinol anchoring stents located at the ends of the device and joined to each other by a connecting element that undergoes delayed shortening over 3 to 4 weeks after placement. It can be placed via a 12F jugular venous access and has shown significant reduction in animal models of mitral regurgitation induced by pacing tachycardia or left coronary artery microsphere embolization. The potential advantage of this device is that it allows stabilization of the anchors by tissue ingrowth prior to tensioning. A disadvantage is that the amount of annular reduction is uncontrolled, and the device cannot be adjusted or retrieved once deployed. Clinical trials were begun in Sweden and Canada in 2005 but were suspended after the first patient experienced device separation and return of 3+ mitral regurgitation at 3 months after an initially favorable reduction.[18] A modified device now has reentered clinical trials.

The Cardiac Dimensions Carillon device[19,20] consists of two different-sized self-expanding figure-of-eight nitinol loops located at either end of a fixed-length (6-cm) stainless-steel connector. The smaller distal loop is deployed in the anterior coronary sinus, and the device and delivery system are withdrawn to test the stability of that anchor and its ability to support plication of the coronary sinus. After demonstrating plication, reduction in mitral regurgitation, and a lack of circumflex coronary arterial compression, the proximal anchor then can be deployed to maintain this degree of plication (Fig. 46-4). At any point up to final release of the device, both anchors can be recaptured by the delivery system and the device withdrawn. Thus, unlike the Edwards MONARC, the device may be removed if it does not correct mitral regurgitation adequately. The early tensioning, however, may predispose to slipping of the anchors.

Animal testing in an ovine tachycardia model showed significant reductions in mitral annular diameter (4.2 to 3.2 cm) and echocardiographic mitral regurgitation, and acute human placements were performed in several patients in Australia during early 2005, showing safe deployment, anchoring, tensioning, and recapture. The COMPETENT single-arm safety and efficacy pilot trial began in mid-2005 at seven sites in the United States, enrolling patients with 3 to 4+ functional mitral regurgitation, class II to IV stable heart failure, and an enlarged diastolic left ventricular diameter with a left ventricular ejection fraction below 40%. Early difficulties with stability of the distal anchor during plication may require device enhancements or selection of patients with smaller coronary venous diameters before the pilot study can be concluded and a pivotal trial can be conducted to secure Food and Drug Administration approval.

Another coronary sinus approach, the Viacor device,[21,22] is used to place one or more straightening rods within a catheter that is positioned in the coronary sinus via the right subclavian or internal jugular vein. Although these rods do not plicate the coronary sinus per se, they do "bend" the sinus in a

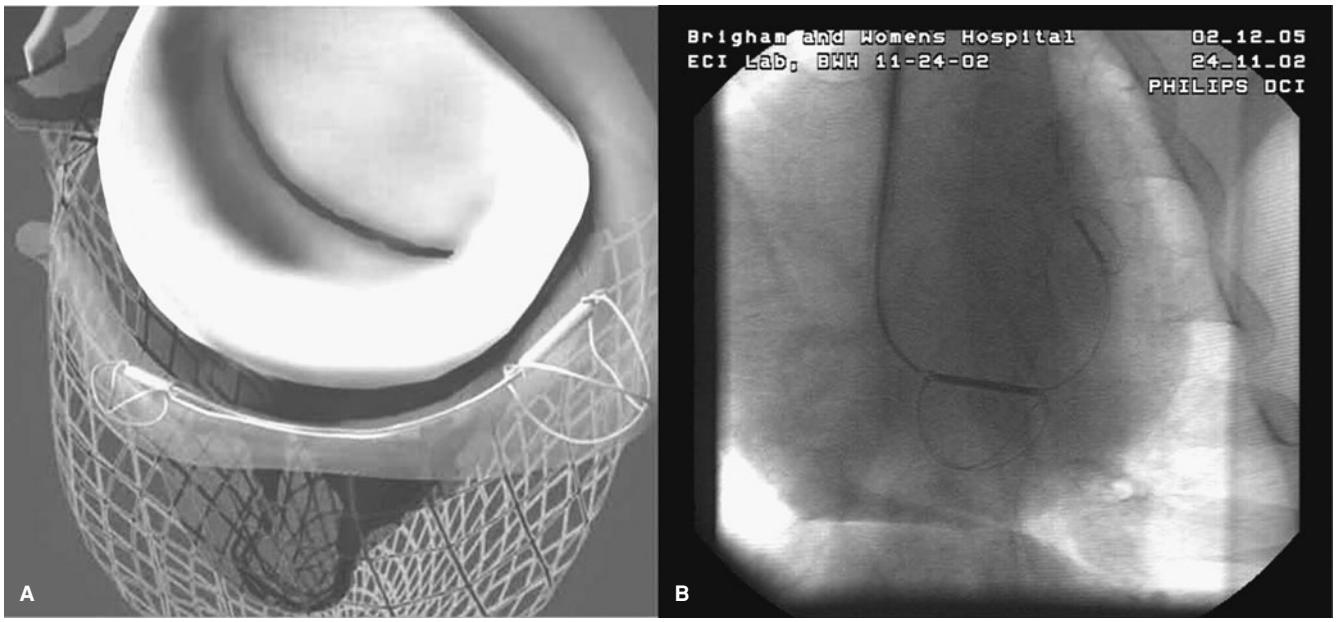

Figure 46-4. The Cardiac Dimensions device consists of a smaller distal and a larger proximal anchor joined by a 6-cm fixed-length metallic member. The device is tensioned after the distal anchor is "set," following which the proximal anchor can be set to maintain tension, and the device can be released if the effect is adequate and there is no circumflex compression (otherwise, it can be recaptured and removed). *A.* Schematic representation of the device in the coronary sinus. *B.* Fluoroscopic image of the device deployed in an in vivo animal model.

manner that pushes the posterior leaflet forward relative to the location of the commissures. In animal studies performed in an ovine multiple circumflex ligation model, this device produced a 5- to 7-mm decrease in anteroposterior mitral annular diameter with a significant reduction in echocardiographic mitral regurgitation. Several temporary placements have been performed at the Cleveland Clinic during planned surgical mitral valve repair surgery, showing the feasibility of implantation and the expected reduction in mitral regurgitation. In a permanent implant, the amount of stiffness in the device could be adjusted at the time of implantation (or readjusted chronically) to maximize benefit.

The coronary sinus devices are appealing in that catheter access is relatively straightforward from the internal jugular or subclavian vein (i.e., not requiring either transseptal puncture or extensive catheter manipulation) and conceivably could be done by most interventional cardiologists as an outpatient procedure. The challenges, however, include the fact that the coronary sinus does not have a fixed relationship with the mitral annulus—it is a mobile structure that is situated at various distances above the plane of the mitral annulus, overlying the posterior left atrial surface in many cases (see Fig. 46-2). When deformed or tensioned, this mobility actually could allow the coronary sinus to move further up onto the atrial wall, significantly limiting the efficacy of annular modification. Moreover, the walls of the coronary sinus are very thin, raising concerns that long-term placement of aggressive anchoring devices might lead to erosion, perforation, thrombosis, or denial of access for other interventions (such as the placement of biventricular cardiac resynchronization devices). Finally, computed tomographic (CT) angiograms suggest that up to half of patients may have a major circumflex coronary arterial branch that runs *under* (rather than on top of) the coronary sinus, making it vulnerable to compression during a coronary sinus plication procedure.

ANNULOPLASTY APPROACHES (I.E., TRANSVENTRICULAR, TRANSATRIAL, AND EPICARDIAL)

One other investigational approach is retrograde (i.e., transventricular suture plication of the posterior mitral annulus). In the approach developed by Guided Delivery Systems, a flexible partial annuloplasty ring is placed on the left ventricular side of the mitral annulus and secured to the annulus by a series of anchors. No further public disclosure regarding this device or animal testing has been made.

The Mitralign device represents another transventricular approach based on the earlier surgical Paneth-Burr suture annuloplasty technique.[23–26] A magnetic catheter is first placed in the midcoronary sinus; an opposing-pole magnet–tipped catheter then is placed retrograde into the left ventricle and slid up the posterior left ventricular wall behind the posterior mitral leaflet until it lies under the mitral annulus and is "locked" magnetically against the coronary sinus magnet. This left ventricular catheter then is used to place a series of anchors along the posterior annulus, which are plicated and locked together to affect

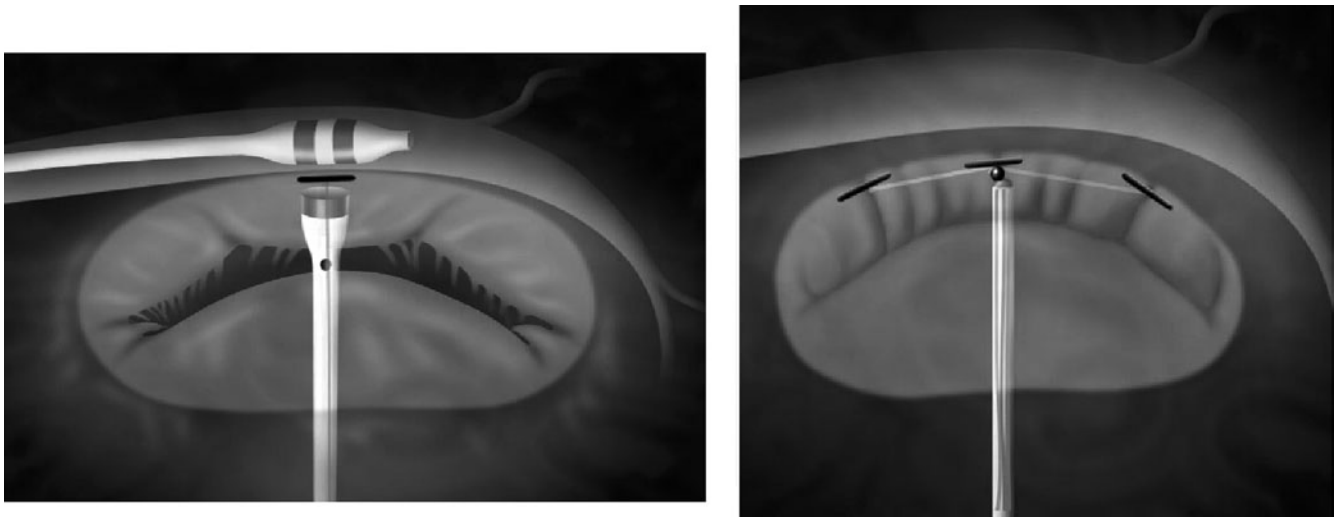

Figure 46-5. The Mitralign approach uses magnetic attraction between a retrograde left ventricular catheter (positioned between the posterior mitral leaflet and the posterior left ventricular wall) and a reference catheter positioned in the coronary sinus to securely locate the ventricular aspect of the annulus. The left ventricular catheter is then used to place a series of anchors into the posterior annulus that are drawn together to plicate the annulus, akin to the Paneth-Burr suture annuloplasty.

reduction in annular circumference (Fig. 46-5). These locked anchors remain in place as the left ventricular and coronary sinus catheters are removed. This device is still in early animal testing.

The Myocor Surgical Coapsys system uses a pair of epicardial pads connected by a rod to reduce the septolateral dimension of the subannular ventricle and mitral annulus[27] (Fig. 46-6). Clinical evaluation of 32 patients in the TRACE (Treatment of Functional Mitral Regurgitation without Atriotomy or CPB Clinical Evaluation) study has shown reduction of mitral regurgitation grade from 2.65 to 0.85 following implantation, with preserved benefit through 3-month follow-up. A nonsurgical version of this device (iCoapsys interventional mitral valve repair) has been developed in which the epicardial pads are applied lateral to the left anterior and posterior descending coronary arteries via a pericardial approach and connected to an adjustable external "deflector" that overlies the lateral wall. Shortening of the connections to the deflector thus reduces septolateral dimension, as has been demonstrated in animal implants.

The percutaneous septal sinus shortening approach (Ample Medical) uses magnetic coupling of a transseptal catheter to a coronary sinus catheter to place a suture through the interatrial septum that is coupled to an anchor positioned in the posterior coronary sinus. The suture is tensioned and secured by an atrial septal closure device to provide a reduction in the septolateral mitral annular dimension. Animal studies have suggested good maintenance of septolateral dimension, as well as of induced mitral regurgitation, with this device.[28]

Quantun Cor has performed animal testing with a multielectrode coronary sinus catheter that, although not an implant, can deliver radiofrequency energy to the mitral annulus. Heating the tissue to 65°C can cause collagen contraction of the posterior annulus. No further data on this approach are available.

There are some animal data suggesting that severing basal chordae can reduce the tethering of the valve leaflets caused by posterior wall infarction,[29,30] and potential percutaneous devices for cutting these cords have been envisioned. The benefit of chordal cutting, however, at best has not been validated in experimental models[31] and at worst may be detrimental to cardiac function. Development of a percutaneous approach thus may be premature.

EDGE-TO-EDGE REPAIR

Although it is usually done in conjunction with placement of an annuloplasty ring, the edge-to-edge (or Alfieri stitch) repair, in which the midportions of the anterior and posterior mitral leaflets are connected, sometimes is used as an adjunctive or even primary repair modality in patients with predominant leaflet prolapse.[15,32] The bulk of the percutaneous experience mimicking this surgical procedure has been obtained using the Evalve edge-to-edge clip prosthesis[33,34] (Fig. 46-7). More than 130 implants have been performed since mid-2003, mostly in the six-site phase I U.S. registry known as EVEREST (Endovascular Valve Edge-to-edge Repair Study) 1.[35] The majority had degenerative structural (i.e., leaflet prolapse) rather than functional (i.e., dilated annulus) regurgitation. The special grasping clip is manipulated with a transseptal delivery catheter using fluoroscopic and transesophageal echocardiographic guidance to confirm that the midportions of the anterior and posterior leaflets had been grasped and that the amount of mitral regurgitation had

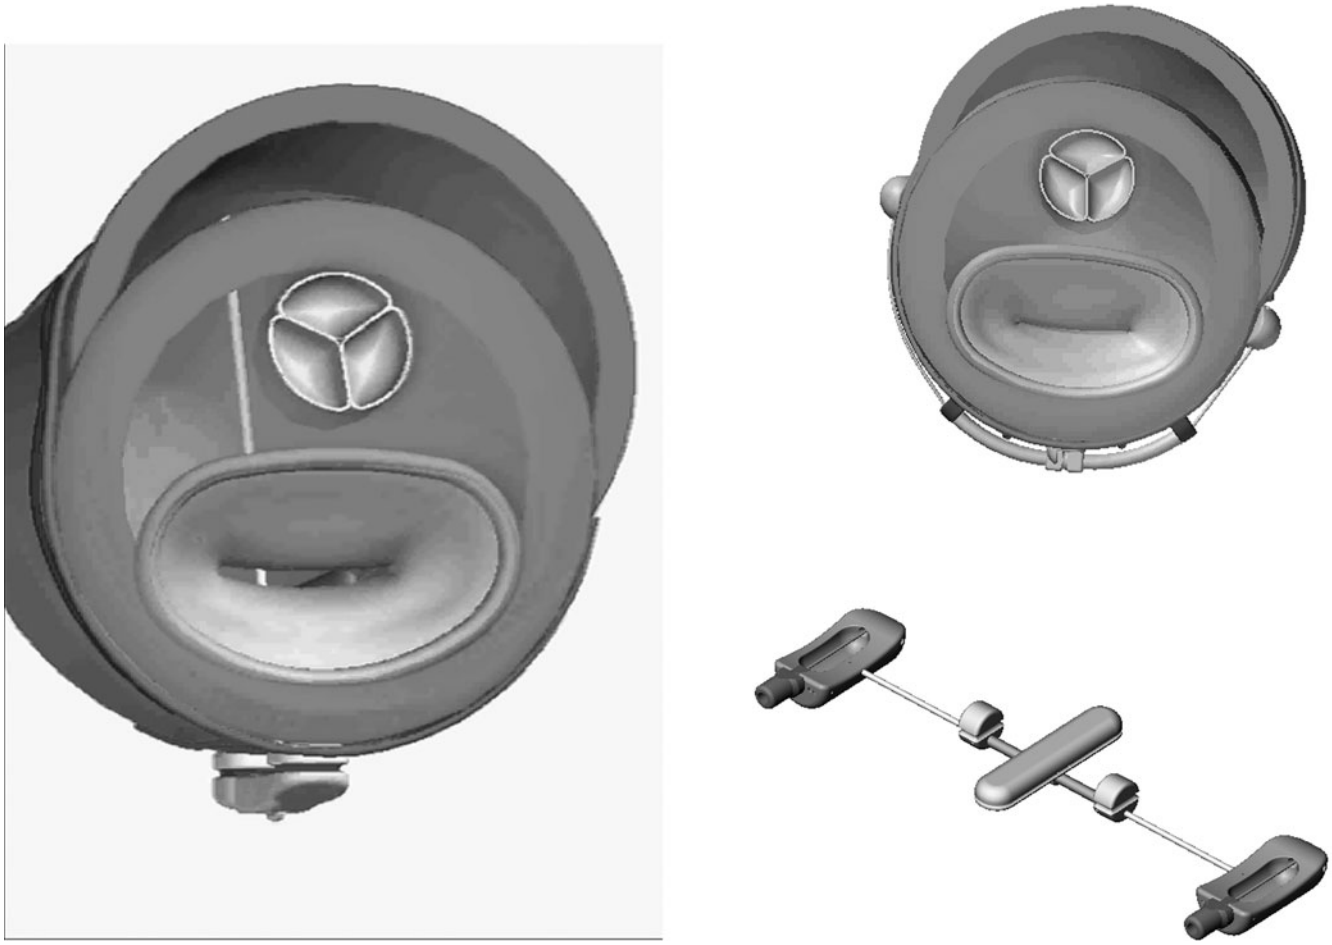

Figure 46-6. The surgical Coapsys device (*left*) uses an intracavitary shortening rod connecting two external pads (placed over the lateral and septal walls of the left ventricle) to decrease the septolateral dimension of the left ventricle and mitral annulus. The minimally invasive iCoapsys device (*right*) is designed for transpericardial insertion, fixing anterior and posterior pads on the epicardium adjacent to the left anterior descending and posterior descending coronary arteries connected to an anteroposterior deflector element positioned on the lateral wall. Tightening the connecting chords pulls the lateral wall inward, also decreasing septolateral dimension.

Figure 46-7. The s/b Evalve device consists of a clip that can be positioned via a transseptal puncture and oriented so that it can be pulled back to catch the tips of anterior and posterior leaflets simultaneously. The clip can be closed to evaluate the effect on mitral regurgitation and then either reopened to be repositioned more effectively or released as a permanent implant. The left panel depicts the clip mechanics, and the right panel shows it after long-term animal implantation with the classic double-orifice valve.

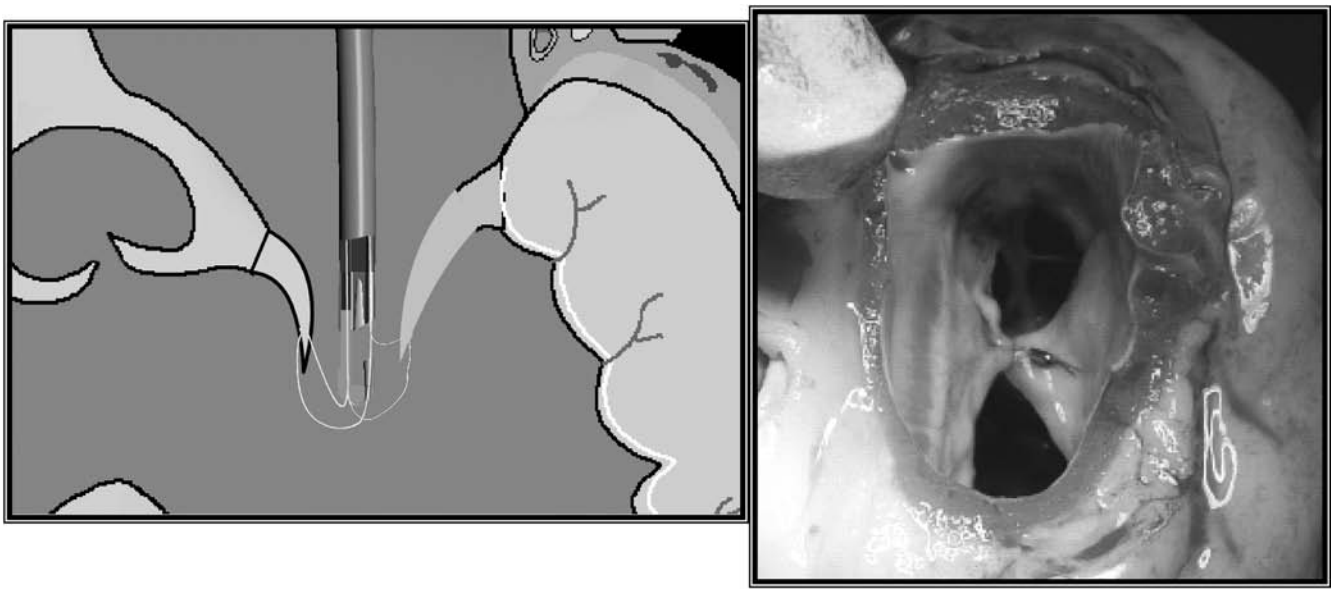

Figure 46-8. The Edwards MOBIUS device is also placed within the mitral orifice by transseptal puncture and uses suction to capture and pass a suture through first one and then the other mitral leaflet. The sutures are drawn together, locked in place, and cut to effect edge-edge mitral repair.

been reduced. In later patients, implantation of a second clip was permitted if satisfactory reduction in regurgitation could not be achieved through optimal positioning of the first clip. Of 92 patients for whom registry data are available, 82 were able to have one or more clips implanted.[35] A favorable result with 2+ mitral regurgitation or less was achieved at discharge in 68 of 82 patients (83%), with a mean core laboratory echocardiographic mitral regurgitation grade reduced from 3.7 at baseline to 1.6 at discharge and 2.1 at 30-day follow-up. The 30-day major adverse event rate was 5%. In follow-up, 17 patients have undergone elective surgery (12 via valve repair rather than replacement) owing to clip detachment from one leaflet, ongoing mitral regurgitation, or in conjunction with other cardiac surgery. There was clinical improvement (class I or II) in 72% of the nonoperated patients compared with baseline. A pivotal noninferiority trial randomizing patients with similar entry criteria to either the Evalve clip or surgical mitral valve repair has begun recently.

The Edwards MOBIUS device also emulates the surgical Alfieri stitch. A deflectable 16F device is delivered across the mitral orifice via a transseptal approach under transesophageal echocardiographic guidance. Suction through a catheter lumen is used to pull the edge of the anterior or posterior mitral leaflet against the catheter, and a needle and suture are passed through the leaflet (Fig. 46-8). The device then is rotated, and the procedure is repeated against the other mitral leaflet, with tensioning and cutting of the suture to maintain the edge-to-edge approximation. A potential advantage of this approach versus Evalve is that use of a suture rather than a clip device leaves less hardware on the mitral leaflet and theoretically may be less likely to inhibit future repair. The first clinical case was completed in mid-2005 with reduction in mitral regurgitation from 4+ to 2+ prior to scheduled surgical repair. Further device development and pilot experience are anticipated.

The main challenge to edge-to-edge repair is the fact that the surgical precedent is seldom used in a stand-alone setting (i.e., without concomitant annuloplasty). The percutaneous procedure thus would be limited clinically to patients with poor leaflet coaptation in the absence of left ventricular or annular dilatation or as a secondary procedure for residual mitral regurgitation following percutaneous annuloplasty (as is done surgically). Lastly, an edge-to-edge device may have a role as an adjunct to surgical valve repair. In particular, the Alfieri suture has been shown to be useful in treating systolic anterior motion (SAM) of the mitral valve following mitral valve repair.[36] The ability to place a device via catheter may obviate the morbidity associated with reoperation for unremitting SAM.

CONCLUSION

While the percutaneous treatment of mitral stenosis has an established record, definitive catheter-based therapies for mitral regurgitation are largely in preclinical development. It is clear, however, that a number of percutaneous approaches to mitral annuloplasty and edge-to-edge repair have been developed. Interventional cardiologists, and in particular a subset devoted to structural heart disease, have carried out the majority of clinical work in this field. However, close collaboration between cardiologists and surgeons has been integral to the development of transcatheter mitral valve interventions,[16] with one or more cardiac surgeons having been involved in virtually every one of

the projects described herein and in the clinical evaluation of this promising set of devices. The success of percutaneous treatments for mitral regurgitation will depend on close collaboration among cardiologists, cardiac surgeons, and engineers.

The clinical trial landscape is also still under active discussion. If these percutaneous techniques are to be seen as an alternative to traditional surgical methodologies in low- to medium-risk patients, the new techniques will need to demonstrate similar hemodynamic effect, safety, and durability to the current highly refined surgical techniques.[14] On the other hand, it may be that the first and best applications of these percutaneous techniques are in patients at the margins of current surgical indications—patients with mild to moderate mitral regurgitation in the setting of advanced heart failure (who may not meet current surgical indications and are at higher risk for surgical mitral valve repair). In such patients, the appropriate comparison may be exercise capacity with the device with maximal medical therapy versus maximal medical therapy alone.

CHAPTER 47

Tricuspid Valve Disease

Richard J. Shemin

The tricuspid valve is composed of three leaflets (i.e., anterior, posterior, and septal) attached to a fibrous annulus. The leaflets usually attach via chordae tendineae to three papillary muscles that are an integral part of the right ventricular wall. Surrounding structures of surgical importance are the coronary sinus, the atrioventricular node, and the right coronary artery (RCA) (Fig. 47-1A).

The tricuspid valve may malfunction due to structural malformation secondary to other cardiac pathology or due to hardware through the valve [e.g., pacemaker or automatic internal cardiac defibrillation (AICD) wires]. Congenital abnormalities such as atrial septal defect (ASD), ventricular septal defect (VSD), and Ebstein disease lead to malfunction and tricuspid regurgitation (TR). Cases of isolated tricuspid disease associated with systemic lupus erythematosus, cor pulmonale, inferior myocardial infarction, scleroderma, or methysergide intake are noteworthy but rarely encountered in surgical practice.[1–12]

ETIOLOGY

The most common presentation of TR is secondary to cardiac valvular pathology (mostly mitral valve disease) on the left side of the heart. As pulmonary hypertension develops, leading to right ventricular dilatation, the tricuspid valve annulus will dilate. The circumference of the annulus lengthens primarily along the attachments of the anterior and posterior leaflets. The septal leaflet is fixed between the fibrous trigones, preventing lengthening (Fig. 47-1B). As the annular and ventricular dilatation progresses, the chordal papillary muscle complex becomes functionally shortened. This combination prevents leaflet apposition, resulting in valvular incompetence.[13–18]

Eisenmenger syndrome and primary pulmonary hypertension lead to the same pathophysiology of progressive right ventricular dilatation, tricuspid annular enlargement, and valvular incompetence. A right ventricular infarction produces either disruption of the papillary muscle or a severe regional wall motion abnormality that prevents normal leaflet apposition by a tethering effect on the leaflets, leading to regurgitation. Marfan syndrome and other variations of myxomatous disease affecting the mitral and tricuspid valves can lead to prolapsing leaflets, elongation of chordae, or chordal rupture, producing valvular incompetence. Blunt or penetrating chest trauma may disrupt the structural components of the tricuspid valve. Dilated cardiomyopathy in the late stages of biventricular failure and pulmonary hypertension produces TR.[19–22] Infectious endocarditis can destroy leaflet tissue, mostly in drug addicts with staphylococcal infection.[23–26]

The carcinoid syndrome leads to either focal or diffuse deposits of fibrous tissue on the endocardium of valve cusps, cardiac chambers, intima of the great vessels, and coronary sinus. The white fibrous carcinoid plaques, if present on the ventricular side of the tricuspid valve cusps, adhere the leaflet tissue to the right ventricular wall, preventing leaflet coaptation.[27–29] Rheumatic disease of the tricuspid valve is always associated with mitral valve involvement, and the deformity of the tricuspid tissue results in a tricuspid valve stenosis as well as regurgitation.[30]

CLINICAL PRESENTATION AND PATHOPHYSIOLOGY

Tricuspid Regurgitation

Patients with TR have the presenting symptoms of fatigue and weakness related to a reduction in cardiac output. Right-sided heart failure leads to ascites, congestive hepatosplenomegaly, pulsatile liver, pleural effusions, and peripheral edema. In the late stages, these patients are wasted with cachexia, cyanosis, and jaundice. Atrial fibrillation is common. Impressive jugular venous distention with an *s* wave or fused *c* and *v* waves,

Figure 47-1. (A) View of the tricuspid valve and labeled structures of surgical importance. (B) Direction of progressive tricuspid valve annular dilatation.

followed by a prominent *y* descent, is present. During inspiration, this finding is accentuated because of the physiologic increase in venous return. The cardiac oscillatory examination is notable for an S_3 that increases with inspiration and decreases with a Valsalva maneuver, increased P_2 if pulmonary hypertension has developed, and a parasternal pansystolic murmur increasing with inspiration.

The chest x-ray demonstrates cardiomegaly, increased right atrial and ventricular size, a prominent azygous vein, possible pleural effusion, and upward diaphragmatic displacement owing to ascites. Echocardiography best assesses the degree of regurgitation, structural abnormalities of the valve, pulmonary artery pressures (PAPs), and right ventricular function both preoperatively and intraoperatively. A shift in the atrial septum to the left and paradoxical septal motion are consistent with right ventricular diastolic overload. Pulsed Doppler and color-flow studies help to identify systolic right ventricular to right atrial flow with inferior vena cava and hepatic vein flow reversal. Contrast-enhanced echocardiography can be useful, with a rapid saline bolus injection producing microcavities that are visible on echo, demonstrating to-and-fro motion across the valve orifice and reversal into the inferior vena cava and hepatic veins. Possible ASD or patent foramen ovale should be sought. Endocarditic lesions and vegetations are clearly visible on echo; the valve may be destroyed, and septic pulmonary emboli are a common feature. The tricuspid valve in carcinoid syndrome is thickened with retracted leaflets fixed in a semiopen position throughout the cardiac cycle.[31–42]

Cardiac catheterization will document increased right atrial and right ventricular end-diastolic pressure.[43] The right atrial pressure tracing has an absent *x* descent, prominent *v* wave, and "ventricularization" of the right atrial tracing, and the degree of pulmonary artery hypertension is documented. Pulmonary artery pressures of over 60 mm Hg usually are due to left-sided lesions leading to secondary TR. A right ventriculogram has been used but is unnecessary with current echocardiographic evaluation.

Tricuspid Stenosis

Tricuspid stenosis (TS) is most commonly rheumatic. It is extremely rare to have isolated tricuspid stenosis because some degree of TR will be present.[44–47] Mitral valve disease coexists with occasional involvement of the aortic valve. The third world and especially the Indian subcontinent still have a significant prevalence of rheumatic tricuspid valvular disease. The anatomic features are similar to those of mitral stenosis, with fusion and shortening of the chordae and leaflet thickening. Fusion along the free edges and calcific deposits on the valve are found late in the disease. The preponderance of cases are in young women.

The diastolic gradient between the right atrium and right ventricle is significantly elevated even at 2 to 5 mm Hg mean pressure. As the right atrial pressure increases, venous congestion leads to distention of the jugular veins, ascites, pleural effusion, and peripheral edema. The right atrial wall thickens, and the atrial chamber dilates.

If the patient remains in normal sinus rhythm, the right atrial tracing and jugular venous pulse have prominent *a* waves that accentuate with inspiration. The cardiac murmur

is mid-diastolic, increases with inspiration, is heard maximally along the left sternoid border, and may have an opening snap.

Clinical features are consistent with reduced cardiac output producing the symptoms of fatigue and malaise. Significant liver engorgement produces right upper quadrant tenderness with a palpable liver with a presystolic pulse. Ascites produces increased abdominal girth. Significant peripheral edema or anasarca can develop. Severe TS may mask or reduce the pulmonary congestion of mitral stenosis owing to reduced blood flow to the left side of the heart. The low output state of the patient is prominent.

The chest x-ray demonstrates cardiomegaly with an increase in the right atria and pulmonary artery size. The electrocardiogram (ECG) will demonstrate increased P-wave amplitude if the patient is in normal sinus rhythm. Echocardiography reveals the diagnostic features of diastolic doming of the thickened tricuspid valve leaflets, reduced leaflet mobility, and a reduced orifice of flow. The Doppler flow pattern across the tricuspid valve has a prolonged slope of antegrade flow.

The patient's ability to tolerate stenotic lesions of the tricuspid valve is dictated to a large degree by the natural history of the mitral or aortic valve disease. In patients with predominant TR, the negative consequences of right ventricular volume overload develop slowly. Acute TR due to traumatic rupture or complete excision of the tricuspid valve as the treatment for infective endocarditis can be well tolerated for years if the PAP is not elevated. Functional tricuspid incompetence is progressive. Surgical treatment of left-sided valvular lesions is not always adequate to resolve or prevent progressive TR. This is particularly true when pulmonary hypertension persists.

SURGICAL DECISIONS

The cardiologist and the cardiac surgeon face the decision as to when to intervene and when to surgically repair or replace the tricuspid valve. The choice of reparative technique to use for a durable result must be evaluated, as well as which type of valve, mechanical or bioprosthesis, to employ to maximize durability and minimize complications (i.e., thrombosis and thromboembolism). The surgical literature can be misleading due to case-selection bias and the various time frames of retrospective reviews. This is particularly true during the era that cage-ball and single-disk mechanical valves were in use.

SURGICAL EXPOSURE

Tricuspid valve annuloplasty performed with either mitral and/or aortic valve operations is accomplished either through a full or partial lower sternotomy approach or less invasive right mini thoracotomy exposure. Bicaval venous cannulation with caval snares is essential to isolate the right atrium. The cannula can be placed conventionally via the right atrium or less invasively via the femoral vein, and a superior vena cava cannula can be inserted via the internal jugular vein.

Left-sided valve repair or replacement (mitral and/or aortic) is performed under blood cardioplegic arrest with antegrade and/or retrograde administration, moderate systemic hypothermia, and topical cold saline surface cooling. The mitral valve can be exposed through a left atrial incision posterior to the intra-atrial septum or through a transseptal incision (Fig. 47-2).The transseptal incision is particularly useful when a prior aortic valve prosthesis is in place or in reoperations. After unclamping the aorta and completing de-airing maneuvers, attention can be turned to the tricuspid valve during rewarming and return of a cardiac rhythm. During tricuspid valve suturing, misplacement of a suture adversely affecting the cardiac conduction system can be assessed immediately and corrected. In a reoperative setting, approaching the tricuspid valve through a right mini thoracotomy has the advantage of avoiding adhesions and possible injury to the right ventricle during repeat sternotomy. If the operation will include the mitral valve, exposure can be simplified by using a right atrial incision and transseptal approach. If atrial fibrillation is present, a Maze procedure using the Cox-Maze III technique or ablation of atrial tissue using an energy source can be added to the technical maneuvers.

ANNULOPLASTY TECHNIQUES

Techniques to deal with a dilated tricuspid valve annulus with normal leaflets and chordal structures include plication of the posterior leaflet's annulus (bicuspidization), partial purse-string reduction of the anterior and posterior leaflet annulus (DeVega-style techniques), and rigid or flexible rings or bands placed to reduce the annular size and achieve leaflet coaptation. Preoperative and intraoperative echocardiograms are valuable assessment tools to help the surgeon understand the structure and function of the valve.[34–42]

The degree of pulmonary hypertension, right ventricular dilatation, and systolic function, coupled with the size of the right atrium, must be factored into the surgical decision making. The classical technique of inserting a finger via a purse-string suture into the right atrium to palpate the tricuspid valve and withdrawing the fingertip 2 to 3 cm from the valve orifice trying to access the force of the regurgitant jet is of less importance in the current era of cardiac surgery than previously. The intraoperative transesophageal echocardiogram (TEE) allows the surgeon to access the tricuspid regurgitation and look for reversal of flow in the inferior cava. The TEE assessment after the repair ensures leaving the operating room with confidence that the repair is functioning satisfactorily.[48–63]

Minimal right atrial enlargement and + 1 to + 2 regurgitation usually will resolve after surgery on left-sided

Figure 47-2. (A) The superior and inferior venae cavae are cannulated, an oblique atriotomy incision is made, and stay sutures are placed on the right atrial wall to aid exposure. For transatrial exposure of the mitral valve, an incision is placed in the fossa ovale and extended superiorly through the interatrial septum. The superior aspect of the septal incision is extended if necessary into the dome of the left atrium behind the aorta. (B) Stay sutures in the interatrial septum are used for retraction. Use of retractors is avoided to prevent injury to the AV node. The mitral prosthesis is implanted in an antianatomic orientation. (C) The interatrial septum is closed primarily or by using a pericardial patch with a continuous 4-0 Prolene suture.

valve lesions, especially if the pulmonary hypertension resolves. Recent literature has documented the variability in the resolution of TR after dealing effectively with the left-sided valvular lesions.

The pathologic process of functional TR requires an understanding that the tricuspid annulus is a component of both the tricuspid valve and the right ventricle. For the tricuspid valve to leak, the tricuspid annulus and hence, the right ventricle have to be dilated. If the tricuspid annulus and the right ventricle are not dilated, there is a very low probability that TR can occur. Dilation of the tricuspid annulus occurs in the anterior and posterior directions (Fig. 47-1B) corresponding to the free wall of the right ventricle. In addition to tricuspid dilatation, the degree of TR is also directly related to three important factors: the preload, the afterload, and right ventricular function. Thus, TR is difficult to assess accurately because these factors can interfere with the severity of TR under different conditions. Significant TR may not be detected echocardiographically despite considerable annular dilatation in the tricuspid valve. An understanding of these important fundamental concepts would seem to contradict current

practice regarding the management of secondary TR, which focuses on assessment of the severity of TR and advocates treatment of the primary lesion alone (i.e., mitral valve disease). Treatment of the mitral valve lesion alone only decreases the afterload. It does not correct tricuspid dilatation, nor does it affect preload or right ventricular function. Once the tricuspid annulus is dilated, its size cannot return to normal spontaneously, and it may, in fact, continue to dilate further. This may explain why some patients require a second operation for TR years after the initial mitral valve surgery.

Since tricuspid annular dilatation seems to be the underlying mechanism regarding nonorganic TR, Dreyfus and colleagues postulated that it may be a more reliable indicator of tricuspid valve pathology than the degree of TR. Moreover, successful treatment of secondary tricuspid valve pathology may necessitate the correction of tricuspid annular dilatation in addition to mitral valve surgery. Over a 12-year period, these authors performed tricuspid valve repair (TVR) for secondary tricuspid valve dilatation irrespective of the severity of TR because secondary tricuspid dilatation may or not be accompanied by TR. Tricuspid dilatation can be measured objectively, whereas TR can vary according to the preload, afterload, and right ventricular function.

Dreyfus and colleagues performed a prospective study of over 300 patients designed to determine whether surgical repair of the tricuspid valve based on tricuspid dilatation alone rather than TR could lead to potential benefits. Tricuspid annuloplasty was performed only if the tricuspid annular diameter was greater than twice the normal size ($\geqslant$70 mm) regardless of the grade of regurgitation. Patients in group 1 (163 patients, 52.4%) received mitral valve repair (MVR) alone. Patients in group 2 (148 patients, 47.6%) received MVR plus tricuspid annuloplasty. Tricuspid regurgitation increased by more than two grades in 48% of the patients in group 1 and in only 2% of the patients in group 2 ($p < .001$).

The authors concluded that modeling annuloplasty of the tricuspid valve based on tricuspid dilatation improved functional status irrespective of the grade of regurgitation. Considerable tricuspid dilatation can be present even in the absence of substantial TR. Tricuspid dilatation is an ongoing disease process that will, with time, lead to severe TR.[109]

More aggressive use of tricuspid annuloplasty appears to help improve the early postoperative course and prevent residual or progressive TR. Increasingly functional mitral regurgitation (MR) and TR coexist. Matsunaga and Duran analyzed TR in a group of patients who underwent successful revascularization and MVR for functional ischemic mitral regurgitation. They concluded that functional TR is frequently associated with functional ischemic MR. After MVR, close to 50% of patients have TR. The incidence of postoperative TR increases with time. Preoperative tricuspid annulus dilatation might be a predictor of late TR.[110]

Special note should be taken in assessing the foramen ovale for patency. These lesions always should be sutured closed, reducing the possibility of arterial desaturation from right-to-left shunting or paradoxical embolization.

Bicuspidization

After the caval snares are tightened, the right atrium is opened via an oblique incision. Exposure and assessment of all aspects of the tricuspid valve structure should be performed prior to choosing the technique of annuloplasty. Suture plication to deal with mild dilatation of the annulus is accomplished by placing pledgeted mattress sutures from the center of the posterior leaflet to the commissure between the septal and posterior leaflets. A second suture often is necessary to further reduce the annulus, ensuring proper leaflet coaptation while providing an adequate orifice for flow. An annuloplasty ring can be inserted to further support the annular reduction (Fig. 47-3).

DeVega Technique

The DeVega technique also can be employed for mild to moderate annular dilatation.[52] The technique employs a 2-0 Prolene or Dacron polyester suture placed at the junction of the annulus and right ventricular free wall, running from the anteroseptal commissure to the posteroseptal commissure. The second limb of the suture is placed through a pledget and run parallel and close to the first suture line in the same clockwise direction, placing it through a second pledget at the posteroseptal commissure. The suture is tightened, producing a purse-string effect and reducing the length of the anterior and posterior annulus to provide adequate leaflet coaptation and orifice of flow (Fig. 47-4).

The judgment regarding the degree of annular reduction has varied from the guideline of being able to insert two and one-half to three fingerbreadths snugly through the valve orifice to using the ring annuloplasty sizers designed for the tricuspid valve. An annuloplasty sizer, chosen by measuring the intertrigonal distance, can be used as a template while tying the purse-string suture to achieve the proper degree of reduction. The DeVega and suture plication techniques should be reserved for mild annular reductions and situations in which the structural integrity of the annulus is not absolutely necessary for long-term success (i.e., functional TR expected to resolve over time). In these situations, the annuloplasty provides a competent tricuspid valve during the early postoperative course while the heart remodels after surgical treatment of the left-sided valvular lesions.[63–65]

Rings and Bands

Significant degrees of annular reduction requiring durability are best accomplished with rigid rings (e.g., Carpentier-Edwards and MC3), flexible rings (e.g., Duran), or flexible

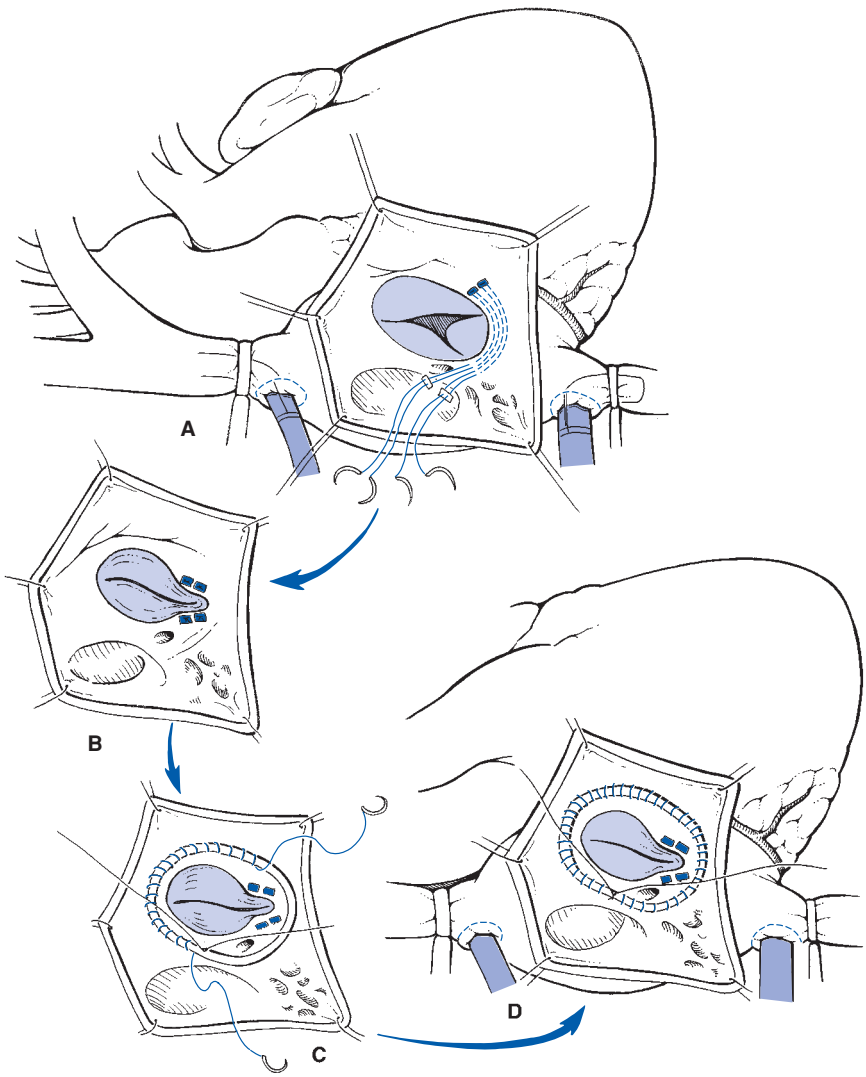

Figure 47-3. (A) Tricuspid valve bicuspidization is accomplished by plicating the annulus along the posterior leaflet. Two concentric, pledgeted 2-0 Ethibond sutures are used. (B) The sutures are tied, obliterating the posterior leaflet, effectively creating a bicuspid AV valve. Saline is injected into the right ventricle to test the competency of the repair. (C) As an option to support the bicuspidization repair, a flexible ring may be placed. Prior to ring implantation, measuring the intertrigonal distance determines the annular size. As an option, the ring can be inserted using a continuous 4-0 Prolene suture. Care is taken to avoid the AV node. As another option, the ring can be implanted above the coronary sinus.

bands (e.g., Cosgrove annuloplasty system). The length of the base of the septal leaflet (i.e., the intertrigonal distance) determines the size of the ring or band. These devices avoid suture placement in the region of the atrioventricular (AV) node (apex of the triangle of Koch) to avoid postoperative conduction problems. The mattress sutures are placed circumferentially, with wider bites on the annulus and smaller corresponding bites through the fabric of the ring or band, producing the annular plication mostly along the length of the posterior leaflet. The result allows the tricuspid valve orifice to be occluded primarily by the leaflet tissue of the anterior and septal leaflets. Overly aggressive annular reduction can lead to ring dehiscence owing to excessive tension on the tenuous tricuspid valve tissue[66–75] (Fig. 47-5).

A recent review of a 790-patient series for the durability and risk factors for failure of a repair was reported by McCarthy and colleagues. The authors reported that TR 1 week after annuloplasty was 3+ or 4+ in 14% of patients. Regurgitation severity remained stable over time with the Carpentier-Edwards ring ($P = .7$), increased slowly with the Cosgrove-Edwards band ($P = .05$), and rose more rapidly with the DeVega ($P = .002$) and Peri-Guard ($P = .0009$) procedures. Risk factors for worsening regurgitation included higher preoperative regurgitation grade, poor left ventricular function, permanent pacemaker, and repair type other than ring annuloplasty. Right ventricular systolic pressure, ring size, preoperative New York Heart Association (NYHA) functional class, and concomitant surgery were not risk factors. Tricuspid reoperation was rare (3% at 8 years), and hospital mortality after reoperation was 37%. The authors concluded that tricuspid valve annuloplasty did not consistently eliminate functional regurgitation, and over time, regurgitation increased importantly after Peri-Guard and DeVega annuloplasties. Therefore, these repair techniques should be abandoned, and transtricuspid pacing leads should be replaced with epicardial leads.[111]

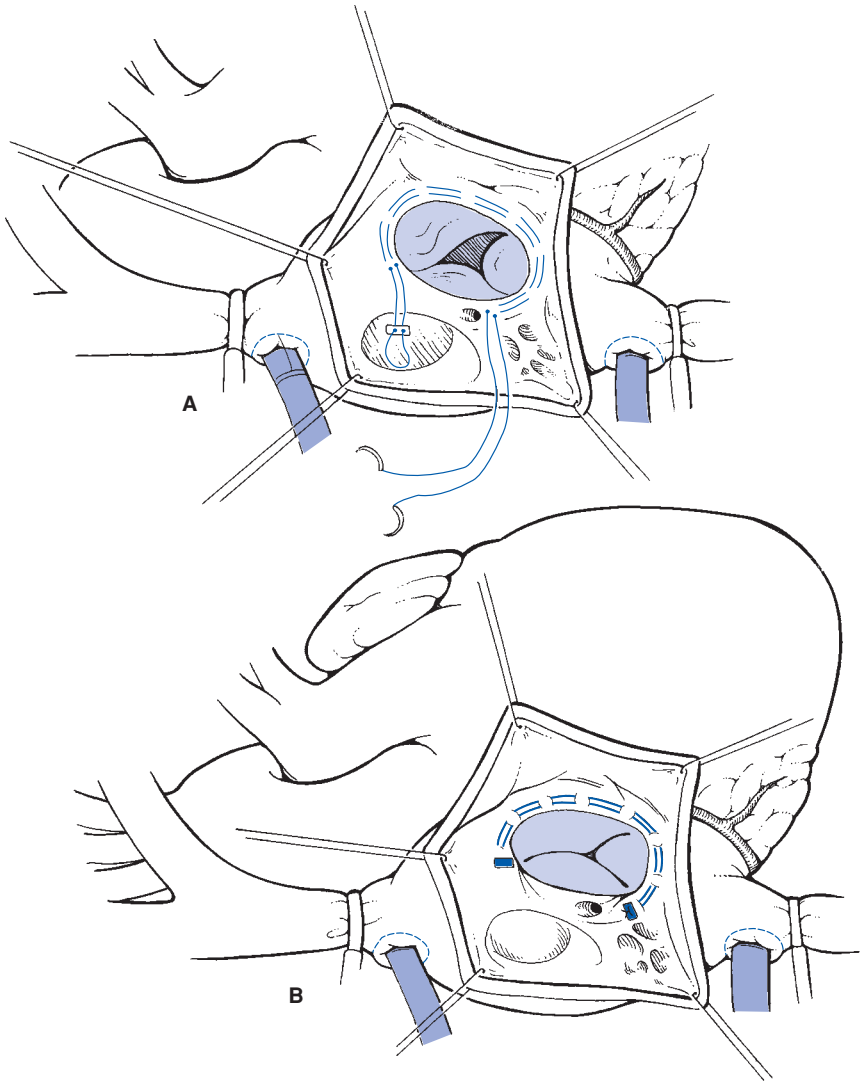

Figure 47-4. (A) A modified DeVega annuloplasty technique is shown. A single pledgeted 2-0 Prolene suture is placed. Care is taken to avoid the area of the AV node. (B) The suture is tied, completing the annuloplasty. Injecting saline into the right ventricle using a bulb syringe tests valve competency.

INTRAOPERATIVE ASSESSMENT OF THE REPAIR

Assessment of tricuspid valve competence after the annuloplasty requires filling the right ventricle with saline and observing leaflet coaptation. This assessment is best performed with the heart beating and the pulmonary artery clamped to allow right ventricular volume to generate enough intracavitary pressure to close the tricuspid valve tightly. If the result appears inadequate, downsizing the ring or ring replacement should be performed. Final assessment is by TEE examination after completely weaning from cardiopulmonary bypass with appropriate volume and afterload adjustment.

TRICUSPID VALVE REPLACEMENT

The technique for secure fixation of a tricuspid valve is with pledgeted mattress sutures using an everting suture technique for mechanical valves and either a supra-annular or an intra-annular technique for bioprostheses. The tricuspid valve leaflets are left in place, preserving the subvalvular structures and helping to avoid injury to the conduction system (Fig. 47-6). If there is concern that the anterior leaflet could billow and obstruct the right ventricular outflow tract, the central portion of the leaflet can be excised and still preserve the chordal attachments.

Tricuspid valve replacement with a homograft is more complicated. The homograft tissue is a mitral valve.[76–79] Sizing is performed by measuring the intratrigonal distances. Fixation of the papillary muscles is either intracavity (right ventricle) or through the wall of the right ventricle. This requires judgment and experience to gauge proper chordal length. The annulus is run with a monofilament suture line. An annuloplasty ring is inserted to prevent dilatation and to ensure adequate leaflet coaptation. Special care is necessary in suture placement to avoid conduction disturbances. Suture placement and tying with the heart beating provide

Figure 47-5. (A) The Carpentier-Edwards ring annuloplasty is shown. A sizer measuring the intertrigonal distance was used to determine the ring size. Multiple interrupted, pledgeted 2-0 Ethibond sutures are placed at the atrioannular junction. All sutures are inserted prior to seating the ring. (B) The valve is seated, and the sutures are tied.

immediate detection of rhythm disturbances. Similar to mitral valve replacement, leaflet and chordal preservation should be performed, or Gore-Tex suture should used as artificial chordae to maintain annular papillary muscle continuity.

A recent report documented the use of a stentless porcine valve in endocarditis in which the commissural posts were anchored to the right ventricular septal, anterior, and posterior walls. Orientation is critical to be sure that the right ventricular outflow tract is straddled by two of the commisural posts.[112]

Carpentier techniques for MVR can be applied to the tricuspid valve. Traumatic disruptions, occasionally endocarditis with healed lesions and perforations, or the rare myxomatous valve can be repaired. Pericardial patching of perforations, partial leaflet resections of the anterior (limited) or posterior (extensive) leaflets, and ring annuloplasty are standard techniques to produce competent valves and avoid replacement.[80–82]

ENDOCARDITIS

Tricuspid valve excision is possible if pulmonary pressures are not elevated and the degree of infection is extensive.[83–91] Blood flows passively through the right side of the heart to the lungs. After eradication of the infection, a second-stage procedure with valve replacement can be performed months to years later. In patients with tricuspid valve endocarditis due to drug addiction, the second-stage valve insertion should be performed preferably after controlling the drug dependence or hopefully curing the accompanying addiction. Late survival and reinfection are correlated directly with continued drug use. Patients with less severe endocarditis can have one-stage procedures with prosthetic replacement or localized leaflet excision and repair.[92,93] Homograft tissue often is versatile for partial or total tricuspid valve repair or replacement but has the limitations of availability, technical difficulty, and limited follow-up. The stentless aortic porcine valve is a novel option.[112]

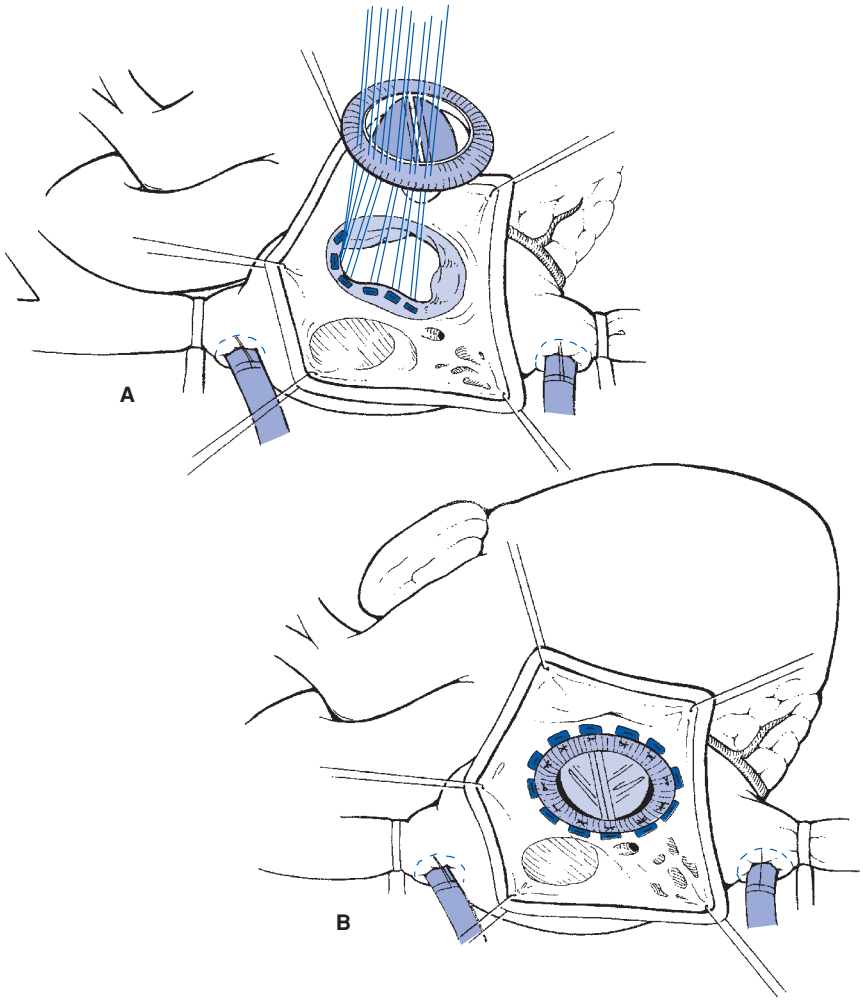

Figure 47-6. (A) Tricuspid valve replacement is performed with a St. Jude Medical valve. The native leaflets are left in situ, and the pledgeted 2-0 Ethibond sutures are passed through the annulus and the edges of the leaflets. (B) The valve is seated, and the sutures are tied. The subvalvular apparatus is visualized to ensure that there is no impingement of the prosthetic valve leaflets. The valve can be rotated if necessary to prevent leaflet contact with tissue.

PROSTHETIC VALVE CHOICE

The choice of prosthesis follows an algorithm similar to that used for valve replacement in other cardiac valve positions. The patient's age, anticoagulation considerations, whether the patient is a young woman during her childbearing years, and social issues must be considered. The previously reported poor results with mechanical valves in the tricuspid position were due to valve thrombosis. Most of these reports were during the era of cage-ball and tilting-disk prostheses.[94] More recent reports with the St. Jude bileaflet valve have provided encouraging data, allowing the surgeon to recommend a mechanical valve with confidence to younger patients who do not have a contraindication to anticoagulation.[95–101] This strategy will avoid the not uncommon situation in the past in which patients received a bioprothesis on the right side and a mechanical prosthesis on the left. Bioprostheses, both porcine and of pericardial tissue, have functioned well in the tricuspid position.[102–105] The data demonstrate a longer duration of freedom from structural valve dysfunction or re-replacement for a bioprosthetic valve in the tricuspid compared with the mitral valve position.[106]

Table 47-1 summarizes multiple reports from the literature. The reports either compare bioprosthetic and mechanical valves in the tricuspid position or present follow-up of bioprosthetic valves alone. The bioprostheses, either porcine or pericardial valves, have excellent freedom from degeneration and re-replacement for structural valve degeneration. In 1984, Cohen and colleagues reported on six simultaneously implanted and then explanted valves from the mitral and tricuspid positions. Degenerative changes were less extensive for the bioprosthetic valves in the tricuspid position than in the mitral position. However, thrombus formation and pannus formation (interpreted as organized thrombotic material) were observed more frequently in the tricuspid position.[106]

Nakano's review of the Carpentier-Edwards pericardial xenograft reported a freedom from structural degeneration of 100% at 9 years, but nonstructural dysfunction was 72.8%. The cause of nonstructural dysfunction was pannus formation on the ventricular side of the cusps. This finding is often subclinical. Echocardiographic follow-up revealed a 35% incidence of this anatomic finding in patients with at least 5 years of follow-up.[104] Guerra reported similar changes

in simultaneously explanted porcine valves. The tricuspid position had less structural tissue degeneration and calcification than the mitral position. The report described the presence of pannus formation on the ventricular side of the cusps in tricuspid porcine valves. The pannus interfered with cuspal pliability and function.[107]

Nakano's 2001 report of bioprosthetic tricuspid valves reported an 18-year freedom from reoperation of 63%.[103] The freedom from structural deterioration was 96%, and nonstructural dysfunction was 77%. Reoperation replacing previously placed bioprosthetic valves occurred in 12 of 58 survivors. In 6 of the 12 patients, the primary indication for reoperation was tricuspid dysfunction, and 7 of the 12 had pannus formation on the ventricular side of the cusps (Fig. 47-7). This rate of degeneration and the subclinically high incidence of pannus formation, often eventually leading to reoperation, are major concerns. Tricuspid bioprosthetic valves require echocardiographic follow-up. Possible anticoagulation of bioprosthetic valves in the tricuspid position can reduce the incidence of pannus formation. The reported data in the literature categorize this pannus formation as nonstructural degeneration; therefore, clinical surgeons should be aware of future reports following this potentially serious clinical problem.

In the tricuspid position it is always possible to place large bioprosthetic or mechanical valves. Prostheses with more than a 27 mm internal diameter do not have clinically significant gradients. Therefore, hemodynamic performance is rarely an issue for tricuspid valve replacement. The data demonstrate excellent results with modern bileaflet mechanical valves. Series comparing bioprosthetic and mechanical valves have been consistent in demonstrating equality during the period of follow-up. The development of thrombus on a bileaflet valve can be treated successfully with thrombolysis.

A recent review by Filsoufi and a meta-analysis of biologic or mechanical prostheses in the tricuspid position both conclude that there is no survival benefit of a bioprothesis over a mechanical valve[113-115] (see Fig. 47-7A,B). Some patients with mitral valve disease and TR undergoing surgery do not require surgical treatment of the tricuspid valve. Guidelines to identify these patients are poorly developed. Experience has shown that careful observation of the patient preoperatively is quite valuable. Absence of tricuspid valve regurgitation during periods of good medical control, absence of TR by transesophageal echocardiography (TEE) at the time of operation, minimal elevation of pulmonary vascular resistance, and absence of right atrial enlargement are helpful findings that permit the surgeon to replace the mitral valve confidently without performing an annuloplasty or replacement of the tricuspid valve. If left unrepaired, reassessment of the tricuspid valve by TEE after weaning from cardiopulmonary bypass is essential.

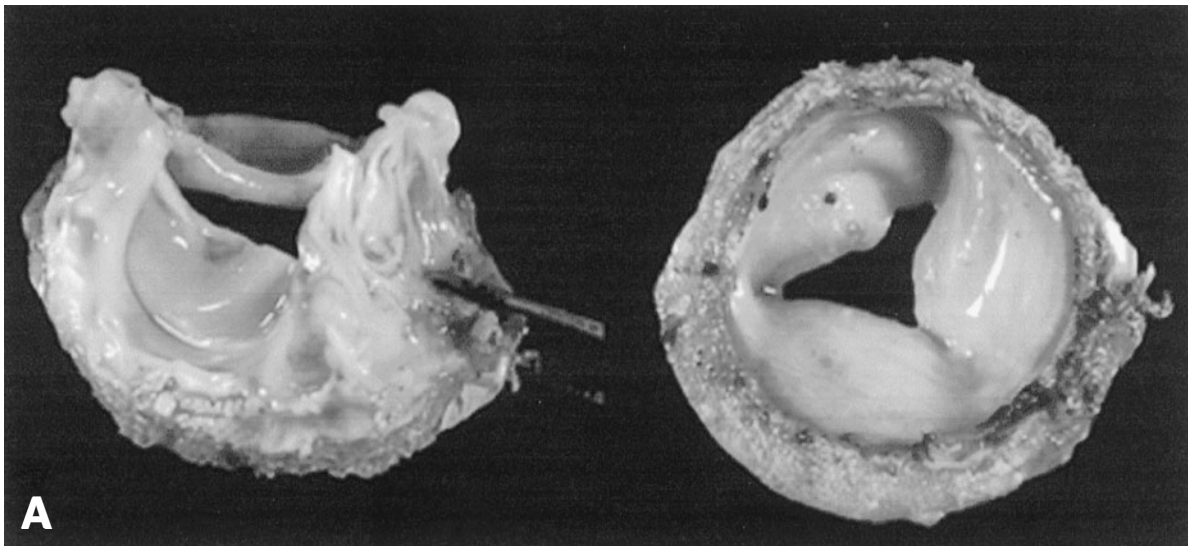
Temporary right ventricular dysfunction due to RCA air embolism often requires a brief return to cardiopulmonary bypass, repeat of air maneuvers, elevation of the blood pressure, TEE evaluation for residual intracavity air, and a search for the characteristic echogenic brightness in the myocardial distribution of the RCA confirming the suspicion of air embolism. Treatment should include 10 to 15 minutes of cardiopulmonary bypass support and reweaning from cardiopulmonary bypass, with inotropic support for right ventricular dysfunction and reassessment of the TR and cardiac function. If TR persists and elevated right atrial pressures greater than left atrial pressures are encountered with an underfilled, well-contracting left ventricle, tricuspid repair should be performed. A patent foramen ovale with interatrial shunting needs to be identified and closed surgically. Hemodynamically, when right atrial pressure is greater than left atrial pressure, the foramen may open, leading to systemic desaturation from a right-to-left shunt.

CONCLUSION

Clinical experience has demonstrated that up to 20% of patients undergoing mitral valve replacement receive a tricuspid annuloplasty, but less than 2% require replacement. The surgeon's clinical judgment and experience guide the approach to tricuspid valve surgery and ultimately lead to variability in reported clinical data. The accuracy of the judgments can be guided by assessment of the risk factors for persistent or progressive tricuspid valve regurgitation. They are related to unresolved or recurrent mitral valve pathology; the degree of preoperative tricuspid regurgitation or the misjudgment of its severity; failure of the pulmonary hypertension and pulmonary vascular resistance to resolve, resulting in persistent impairment in right ventricular function (often with right ventricular dilatation); and failure to recognize organic tricuspid valve disease.

Patients undergoing a tricuspid valve annuloplasty during a mitral valve replacement have more advanced disease than those having mitral valve replacement alone. This is evidenced by the elevation in operative mortality (approximately 12 versus 3%) and the progressive increased hazard of late death (5-year survival of 80 versus 70%) despite good valve function. However, these patients achieved good functional results (class 1–2). It is unknown what the survival and functional result would have been if tricuspid repair had not been performed in these patients, but one presumes that it would have been worse.

The durability of simple annuloplasty techniques such as bicuspidization and the DeVega technique has been good when employed only for mild to moderate degrees of functional TR with successful resolution of pulmonary hypertension after the mitral valve operation. Extensive experience with the tricuspid annuloplasty using the Duran, Carpentier-Edwards, or Cosgrove rings or bands resulted in an 85% freedom from moderate to severe TR at 6 years. The subsequent requirement for tricuspid reoperation is very low. Inadequate resolution of the mitral disease and persistent pulmonary hypertension



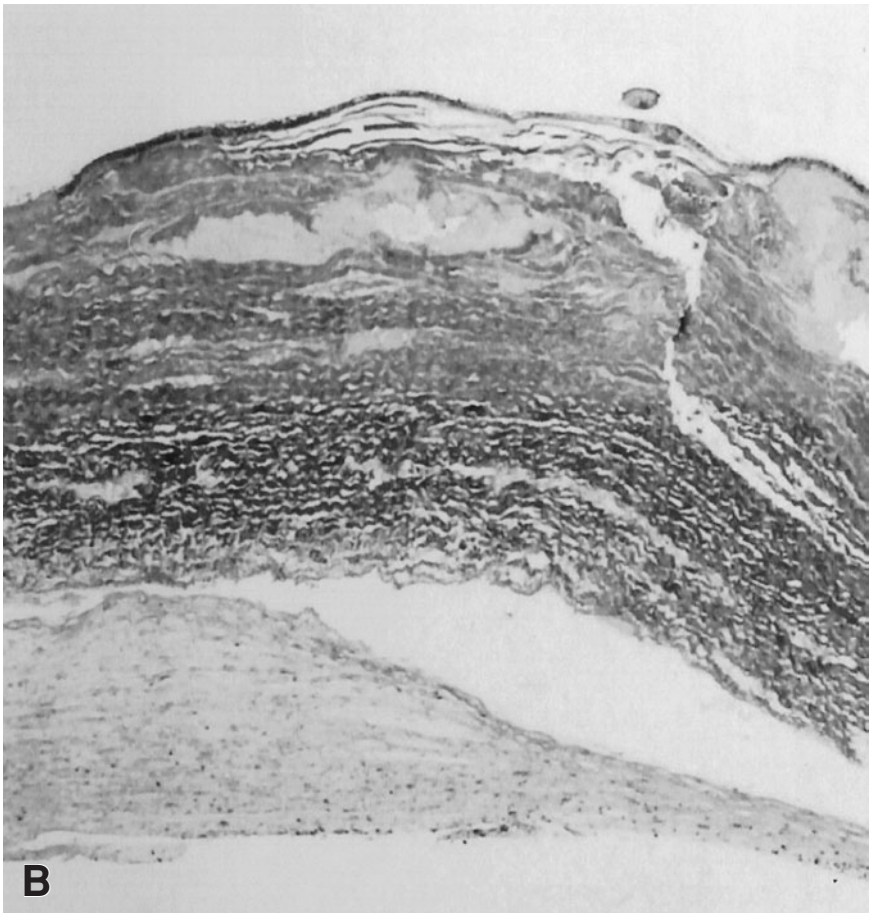


Figure 47-7. (A) Fibrous pannus observed 8 years after implantation of a Carpentier-Edwards pericardial valve. (B) Photomicrograph of a pericardial leaflet. The bottom of the leaflet has pannus, a dense fibrous tissue on the ventricular side. with right ventricular dilatation and dysfunction are the major predictors of poor late results.

Patients requiring tricuspid and mitral valve replacement have operative mortalities from 5 to 10% by current standards. Actuarial survival rates are 55% at 10 years (Fig. 47-8A,B). Advanced right ventricular failure or arrhythmia causes late death. Patients who need valve replacement for endocarditis comprise a unique subgroup with the additional risk for death owing to sepsis, reinfection, and the complications related to drug addiction.

Complete heart block can occur immediately postoperatively owing to damage to the conduction system during mitral and tricuspid valve surgery. This complication can be minimized intraoperatively by performing the tricuspid valve procedure on the perfused beating heart, as described earlier. Late heart block remains a persistent risk with a 25% actuarial incidence at 10 years for patients with mitral and tricuspid prostheses.[108] Late development of heart block rarely occurs after mitral valve replacement and tricuspid annuloplasty (Fig. 47-8A, B). The presence of two rigid prosthetic sewing rings can produce ongoing trauma and lead to AV node dysfunction over time.

The surgical treatment of tricuspid valve disease presents the surgeon with challenges requiring clinical and intraoperative judgment. Following the guidelines presented in this chapter for when to repair or replace the tricuspid valve should lead to optimal clinical outcome. The data support the safe use of mechanical bileaflet prostheses. A lingering concern is the pannus formation on the ventricular side of bioprosthetic cusps. This observation should be followed closely as future clinical series are reported.

CHAPTER 48

Multiple Valve Disease

Hartzell V. Schaff • Rakesh M. Suri

Pathologic changes in the cardiac valves requiring surgical correction of more than one valve can result from rheumatic heart disease, degenerative valve diseases, infective endocarditis, and a number of miscellaneous causes. Further, valve dysfunction may be primary, i.e., a direct result of a disease process, or secondary, i.e., caused by cardiac enlargement and/or pulmonary hypertension. Surgical management is influenced both by the underlying cause of valve dysfunction and, when valves are involved secondarily, by the anticipated response to replacement or repair of the primary valve lesion. In addition, the consequences of various combinations of diseased valves on left and right ventricular geometry and function frequently are different from the remodeling as a result of single-valve disease. This chapter addresses pathophysiologic considerations in multivalvular heart disease, surgical techniques, and management of commonly encountered etiologies.

Repair of multiple lesions was necessary even in the early development of operative management of valvular heart disease (Table 48-1). The first triple-valve replacement during a single operation was reported in 1960, and simultaneous replacement of all four valves was reported in 1992.[1]

Experience from clinical practice indicates that multiple valve disease requiring surgical correction occurs in a few common combinations. As seen in Table 48-2, multiple procedures account for approximately 15% of all operations on cardiac valves; 80% of these operations involve the aortic and mitral positions. Replacement of the mitral and tricuspid valves (with or without aortic replacement) accounts for 20% of operations. Only rarely is the combination of aortic and tricuspid disease encountered.

PATHOPHYSIOLOGY OF MULTIPLE VALVE DISEASE

Valvular regurgitation may result from the pathologic process affecting the valve directly or may be secondary to alterations in ventricular morphology caused by other valve lesions; this secondary or functional regurgitation affects the atrioventricular valves. In some patients, secondary valvular regurgitation may be expected to improve with repair or replacement of the primarily diseased valve. In other patients, the secondary disease process may have advanced to the stage that valve function will not improve following correction of the primary lesion, and thus simultaneous surgical correction should be considered.

Primary Aortic Valve Disease with Secondary Mitral Regurgitation

Isolated aortic valve lesions can cause secondary regurgitation of the mitral valve and, rarely, of the tricuspid valve. Severe aortic valve stenosis with or without left ventricular dilatation frequently is associated with some degree of mitral valve regurgitation. In one series, 67% of patients with severe aortic valve stenosis had associated mitral valve leakage.[2]

When the mitral valve is structurally normal, its regurgitation would be expected to improve with relief of left ventricular outflow obstruction[3]; mild mitral valve regurgitation would be expected to resolve almost completely following aortic valve replacement. Improvement in mitral valve regurgitation results from both decreased intraventricular pressure and ventricular remodeling.[4] If mitral valve regurgitation is severe, some degree of persistent regurgitation is expected following aortic valve replacement, and mitral valve annuloplasty may be required. In contrast, with aortic valve stenosis and mitral valve regurgitation associated with a structurally abnormal mitral valve, repair or replacement of the mitral valve usually is necessary. A recent report alleges that moderate mitral regurgitation has an adverse impact on survival in elderly patients undergoing aortic valve replacement and suggests that those with intrinsic mitral valve disease should be considered for concurrent correction.[5]

Table 48–1.

History of Multiple Valve Operations

Event	Year	Institution
Staged mitral then tricuspid commissurotomy	1952	Doctor's Hospital, Philadelphia, PA[178]
Simultaneous mitral and tricuspid commissurotomy	1953	Cleveland, OH[179]
Simultaneous mitral commissurotomy and aortic valvuloplasty using cardiopulmonary bypass	1956	University of Minnesota, Minneapolis, MN[180]
Simultaneous mitral and aortic valve replacement	1961	St. Francis General Hospital, Pittsburgh, PA[140]
Simultaneous triple-valve replacement	1963	University of Oregon, Portland, OR
Simultaneous quadruple valve replacement	1992	Mayo Clinic, Rochester, MN[137]

Source: Modified with permission from Acker M, Hargrove WC, Stephenson LW: Multiple valve replacement. Cardiol Clin 1985; 3:425.

Thus determination of the morphology and pathophysiologic severity of each valve lesion is critically important in planning surgical management, and preoperative and intraoperative echocardiographic studies are necessary in all patients suspected of having multiple valve disease. Often, transthoracic echocardiography can define the etiology of mitral and tricuspid valvular regurgitation. When valve regurgitation is entirely secondary, the mitral valve leaflets will appear thin and freely mobile, without prolapsing segments. Mitral (and tricuspid) valve regurgitation secondary to rheumatic disease is readily identified when leaflets are thickened and chordae are shortened; fibrosis of these structures restricts leaflet mobility. Leaflet prolapse with or without ruptured chordae tendineae also may cause atrioventricular valve regurgitation.

Transesophageal echocardiography images the heart from a retrocardiac position, which avoids interference from

Table 48–2.

Prevalence of Multiple Cardiac Valve Replacement According to Institution

	University of Alabama	Mayo Clinic	Texas Heart Institute	University of Oregon	Percentage of all valve surgery (11,026 cases)	Percentage of multiple valve surgery (1662 cases)
Years involved	1967–1976	1963–1972	1962–1974	1960–1980		
Total number of all valve operations	2555	2166	4170	2135		
All multiple valve procedures	383 (15%)	437 (20%)	541 (13%)	301 (14%)	15 (1662)	100
M-A	298 (11.6%)	320 (14.7%)	459 (11%)	253 (11.8%)	12 (1330)	80
M-A-T	40 (1.6%)	55 (2.5%)	55 (2.5%)	48 (2.2%)	2 (198)	12
M-T	41 (1.6%)	58 (2.5%)	26 (0.6%)	—	1.5 (125)	8
A-T	4 (0.1%)	4 (0.2%)	1 (0.02%)	—	0.1 (9)	5

interposed ribs, lungs, and subcutaneous tissue. A high-frequency (5-MHz) transducer is employed, which yields better resolution than that of images obtained with routine transthoracic imaging with 2.25- to 3.5-MHz transducers.[6] Thus transesophageal echocardiography provides the best image of the mitral and tricuspid valves and may be obtained preoperatively. Intraoperative transesophageal Doppler echocardiography should be employed in all patients having valve repair or replacement, and the technique is especially important for assessment of response of mitral regurgitation to relief of left ventricular outflow obstruction.[7] In some cases, preoperative left ventriculography may help to quantify left atrioventricular valve leakage. Right ventricular angiocardiography also can be useful in determining the degree of tricuspid valve dysfunction, but it is rarely employed in current practice.[8]

Tricuspid Valve Regurgitation Secondary to Other Valvular Disease

Secondary tricuspid valve regurgitation commonly is associated with rheumatic mitral valve stenosis, and the exact cause is unknown.[9,10] Some authors believe that secondary tricuspid valve regurgitation is a result of pulmonary artery hypertension and right ventricular dilatation.[11] As with the mitral valve, tricuspid valve annular dilatation is asymmetric. Most enlargement occurs in the annulus subtended by the free wall of the right ventricle, and there is little dilation of the annulus adjacent to the septal leaflet of the tricuspid valve.[12,13]

Although pulmonary artery hypertension with secondary enlargement of the right ventricle and tricuspid valve annulus may be an important contributing factor in secondary tricuspid regurgitation, it is not the sole mechanism. For example, congenital heart lesions such as tetralogy of Fallot produce systemic pressure in the right ventricle, yet severe tricuspid valve regurgitation rarely is seen in these patients. Similarly, important tricuspid valve regurgitation is uncommon in children with ventricular septal defects who have enlargement of the right ventricle associated with variable degrees of pulmonary hypertension.

Furthermore, clinical experience suggests that other mechanisms must play a role in development of secondary tricuspid valve regurgitation. Patients who have had mitral valve replacement for rheumatic mitral valve stenosis may develop regurgitation of their native tricuspid valve years after initial operation, and many patients have only modest elevation of pulmonary artery pressure.[14,15]

It is useful to classify secondary mitral and tricuspid valve regurgitation as mild, moderate, and severe.[13] Usually, patients with mild tricuspid valve regurgitation do not have clinical signs and symptoms of right-sided heart failure. Also, mild tricuspid regurgitation demonstrated by preoperative echocardiography may appear even less severe in the operating room under general anesthesia. In most instances, mild secondary tricuspid regurgitation does not require intervention.

Patients with echocardiographic evidence of significant regurgitation who do not have symptoms or have their symptoms controlled by medical treatment can be classified as having moderate tricuspid regurgitation. These patients usually are managed with a DeVega suture annuloplasty or a partial-ring annuloplasty.[16] Patients with severe secondary tricuspid regurgitation and clinical evidence of right-sided heart failure (i.e., pulsatile liver, distended neck veins, and peripheral edema with or without ascites) are managed by concomitant ring annuloplasty or tricuspid valve replacement.

The degree of pulmonary hypertension may influence surgical management of secondary tricuspid valve regurgitation. Kaul and colleagues[17] grouped 86 patients with functional tricuspid regurgitation in association with rheumatic mitral valve disease according to the degree of pulmonary hypertension. One group had severe pulmonary hypertension (mean pulmonary pressure 78 mm Hg), and a second group had moderate pulmonary hypertension (mean pulmonary artery pressure 41 mm Hg). Patients with moderate pulmonary hypertension preoperatively had more advanced right-sided heart failure and right ventricular dilatation, and many of these patients continued to have tricuspid valve regurgitation following mitral valve surgery without tricuspid valve surgery. The patients with severe pulmonary hypertension all showed regression of tricuspid regurgitation, and 28% had complete resolution following mitral valve surgery without operation on the tricuspid valve.

Excluding hospital mortality, about 40% of patients undergoing tricuspid valve surgery have premature death.[8] It is also important to understand that mild to moderate (2+) regurgitation is a risk factor for late failure of tricuspid valve repair, and severe (4+) regurgitation preoperatively is a predictor of early residual regurgitation.[18] Finally, there is recent evidence to suggest that remodeling annuloplasty in the setting of of tricuspid annular dilatation (≥70 mm) at the time of mitral repair significantly decreases the risk of subsequent functional deterioration as compared with those not having annular correction.[19]

VALVE SELECTION FOR MULTIPLE VALVE REPLACEMENT

When multiple valve replacement is confined to the left ventricle, replacement valves should be chosen from the same class with respect to the need for anticoagulation and projected longevity. There are no theoretical or practical advantages to use of a tissue valve and a mechanical valve for mitral and aortic valve replacement, and studies show no reduction in the risk of thromboembolism, valve-related morbidity, or late death.[20,21] In addition, a lower reoperation rate is reported for patients with two mechanical valves in the left ventricle compared with patients with one mechanical and one tissue valve.[20]

For tricuspid valve replacement, alone or in conjunction with other valve procedures, use of a bioprosthesis may

have advantages in regard to minimizing risk of valve thrombosis.[22,23] Furthermore, there are few hemodynamic considerations in selecting a tricuspid prosthesis; the greater hemodynamic efficiency of mechanical valves compared with bioprostheses rarely is an issue in atrioventricular valve replacement, especially the tricuspid valve, in which the annulus diameter in adults is often 33 mm or more. In vitro studies demonstrate only minimal hemodynamic improvement with atrioventricular valves larger than 25 mm.[24]

SURGICAL METHODS

Aortic and Mitral Valve Replacement

Cannulation

Arterial inflow is established by cannulation of the distal ascending aorta near the pericardial reflection just to the left of the origin of the innominate artery (Fig. 48-1*A*). Venous cannulation is simplified by using a two-stage cannula in the right atrium for venous return. Individual cannulation of the superior and inferior venae cavae is reserved for operations that require right atrial or ventricular incisions (Fig. 48-2*A*).

Cardiopulmonary bypass is commenced at 2.4 L/m^2 per minute, and systemic hypothermia is induced according to the requirements of the operation. We prefer maintaining the systemic temperature near normal (35 to 37°C) for most operations, including multiple valve procedures. Provisions for intraoperative autotransfusion are used routinely, and antifibrinolytic drugs such as aprotinin or epsilon-aminocaproic acid (Amicar) may be useful, especially in reoperations, where pericardial adhesions may worsen bleeding.[25]

Cardioplegia

If the aortic valve is competent, myocardial protection during aortic cross-clamping is achieved by initial infusion of cold (4 to 8°C) blood cardioplegia through a tack vent placed in the aorta proximal to the clamp. The volume of cardioplegia needed to achieve diastolic arrest and uniform hypothermia depends on the heart size and the presence of aortic valve regurgitation. Generally, the initial volume of cardioplegia required for hearts with multiple valve disease is higher than that required for coronary revascularization because of myocardial hypertrophy. For patients without cardiac enlargement, we infuse approximately 10 mL/kg of body weight, whereas 15 mL/kg of body weight is used for patients with significant degrees of myocardial hypertrophy. Repeat infusions of 400 mL of cardioplegia are given directly into the coronary ostia at 20-minute intervals during aortic occlusion. We use custom-designed, soft-tipped coronary perfusion catheters to minimize the potential for trauma to the coronary ostia during intubation and infusion.[26]

If aortic valve regurgitation is moderate or severe, cardioplegia is infused directly into the coronary ostia. Initial aortotomy is facilitated by emptying the heart using suction on an aortic tack vent and temporarily reducing the cardiopulmonary bypass flow rate to maximize venous return. Some surgeons prefer retrograde infusion of cardioplegia,[27] and if this method is used, even larger volumes are necessary because of nonnutritive flow through the coronary venous system and variation in coronary venous anatomy.[28,29]

Procedure

After cardioplegia, the aortic valve is inspected through an oblique aortotomy extended into the noncoronary aortic sinus (see Fig. 48-1*B*). Aortic valve regurgitation caused by cuspal perforation or prolapse of a congenitally bicuspid valve often can be repaired,[30] but the decision for or against aortic valve repair should take into consideration whether or not a mitral valve prosthesis will be needed. For example, even though aortic valve repair might seem technically possible, prosthetic replacement may be the best option for a patient who requires mitral valve replacement and will be maintained on warfarin for long-term anticoagulation.

Severe calcification of the valve, whether it is bicuspid or tricuspid, necessitates replacement,[31] and the cusps therefore are excised and annular calcium débrided carefully. The aortic annulus then is calibrated; experience has shown that subsequent replacement of the mitral valve usually reduces the aortic annular diameter by shortening the circumference that is in continuity with the attachment of the anterior mitral valve leaflet. Therefore, we routinely identify (but do not break the sterile packaging of) two aortic prostheses: One corresponds to the calibrated dimension, and the other is the next size smaller. Final selection of the aortic prosthesis is made after mitral valve replacement or repair.

Although exposed first, the aortic valve usually is replaced after mitral valve repair or insertion of the mitral valve prosthesis. Sutures placed in the portion of the aortic valve annulus that is continuous with the anterior leaflet of the mitral valve pull the anterior leaflet superiorly toward the left ventricular outflow area and thus hinder exposure of this area as viewed through the left atriotomy.

If the aortic annulus is small, it can be enlarged with a patch of pericardium.[32] This technique increases annular diameter by 2 to 4 mm or more, and only rarely are more radical techniques necessary.[33–35] Another maneuver to accommodate as large a prosthesis as possible is to place the necessary sutures for the mitral valve repair or replacement but not secure the mitral prosthesis until the aortic valve is implanted. This eliminates downsizing of the aortic prosthesis but does not compromise insertion of sutures in the superior portion of the mitral valve annulus.

After removal of the aortic valve, the right atrial cannula is repositioned, and the mitral valve is exposed through an incision posterior to the interatrial groove (see Fig. 48-1*B*). The presence or absence of thrombi in the left atrium is noted, and the mitral valve is inspected. When there is rheumatic disease of the aortic valve, the mitral valve almost always will be involved to some extent. If aortic valve replacement is necessary, the surgeon should have a low threshold for replacing a diseased mitral valve because scarring and

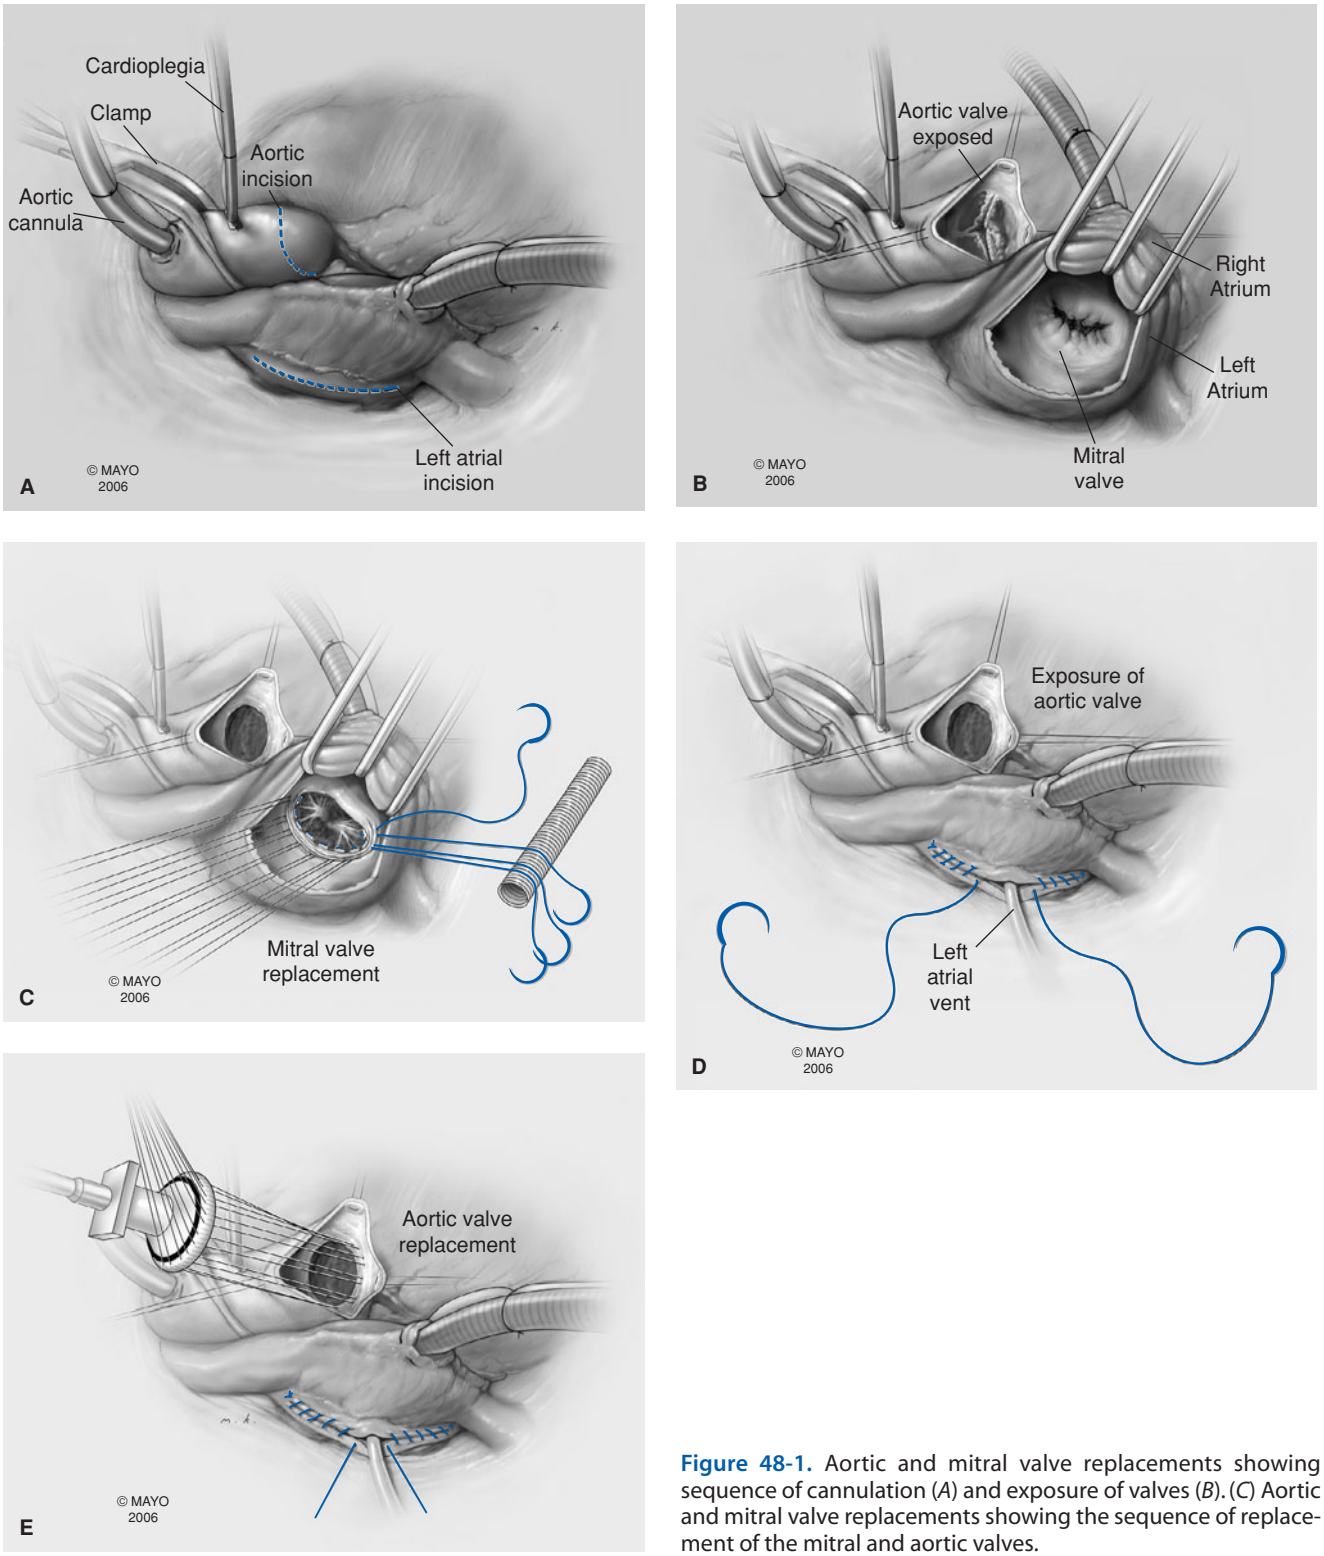

Figure 48-1. Aortic and mitral valve replacements showing sequence of cannulation (*A*) and exposure of valves (*B*). (*C*) Aortic and mitral valve replacements showing the sequence of replacement of the mitral and aortic valves.

fibrosis of the rheumatic process are progressive, and mitral valve repair (commissurotomy for stenosis or leaflet repair and annuloplasty for regurgitation) is less durable than repair for degenerative disease.[36–38] In contrast, when aortic valve replacement is necessary because of calcification of a bicuspid valve or because of senescent calcification, repair of mitral valve regurgitation owing to degenerative causes can be expected to give predictably good long-term results. Repair of the mitral valve is described in Chap. 37.

In preparation for replacement, the anterior leaflet of the mitral valve is excised, and when possible, a portion of the posterior leaflet with its chordal attachments is preserved

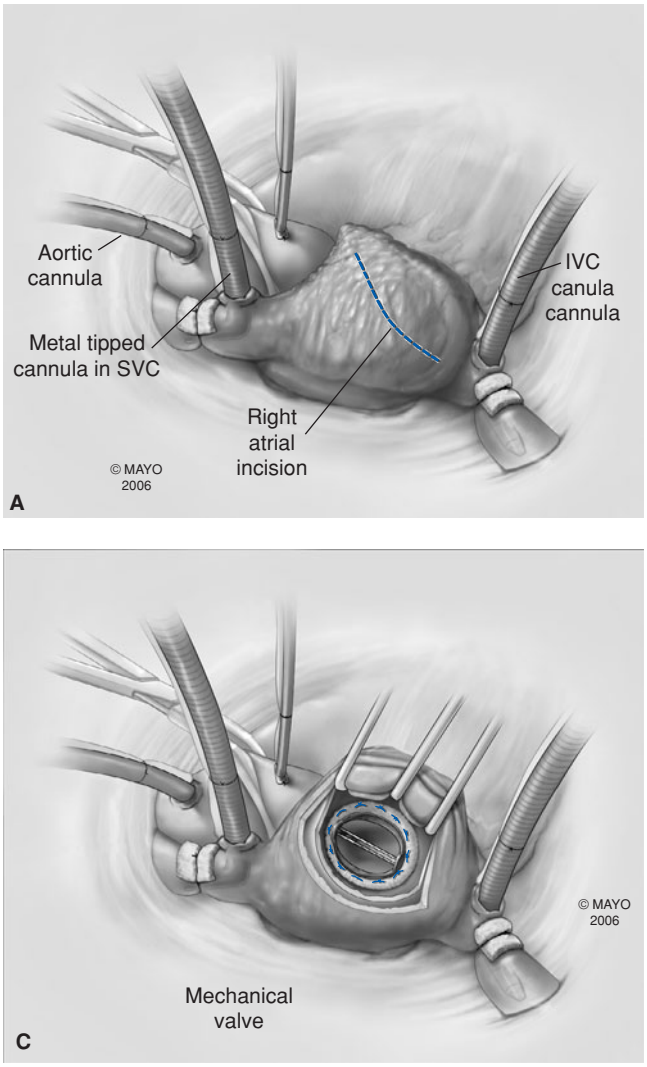

Figure 48-2. Combined mitral valve and tricuspid valve operation. The panels illustrate cannulation (*A*) and transseptal incision (*B*). (*C*) Combined mital valve and tricuspid valve operation: mitral replacement. (Superior vena cava snare not shown.)

to maintain left ventricular papillary muscle–annular continuity.[39–41] Some surgeons make a special effort to preserve the anterior leaflet and its chordal attachments, believing that this has a further beneficial effect on ventricular performance.[42] The mitral prosthesis is implanted using interrupted mattress sutures of 2-0 braided polyester reinforced with felt pledgets, which can be situated on the atrial or ventricular side of the valve annulus (see Fig. 48-1*C*). The leaflets of mechanical valves should be tested for free mobility following valve seating.

When atrial fibrillation is present preoperatively, we obliterate the left atrial appendage by oversewing its orifice from within the left atrium or by ligating it externally. The left atriotomy is closed from each end with running polypropylene sutures. Vent tubing is inserted through the partially closed left atriotomy and left in place while the aortic valve is being replaced (see Fig. 48-1*D*).

After appropriate exposure, the aortic prosthesis is sewn in place with interrupted 2-0 polyester mattress sutures backed with felt pledgets, and the aortotomy is closed, usually with two layers of 4-0 polypropylene. Any remaining air is evacuated from the heart with the usual maneuvers, and a tack vent in the ascending aorta is placed on suction as the aortic clamp is removed. The vent is removed from the left atrium, and closure of the left atriotomy is secured.

In patients with annuloaortic ectasia, the mitral valve sometimes can be visualized and replaced through the enlarged aortic annulus.[43]

Aortic Valve Replacement and Mitral Valve Repair

Intraoperative transesophageal echocardiography is useful in assessing the degree of mitral regurgitation and, importantly, in identifying the cause of valve leakage. When mitral valve regurgitation is only moderate and leaflet morphology is normal, we expect mitral valve function to improve following relief of severe aortic stenosis. In all other instances, the valve should be inspected directly to determine the need for repair or replacement.

Sternotomy, cannulation, and assessment of the aortic valve proceed as described previously. When there is no

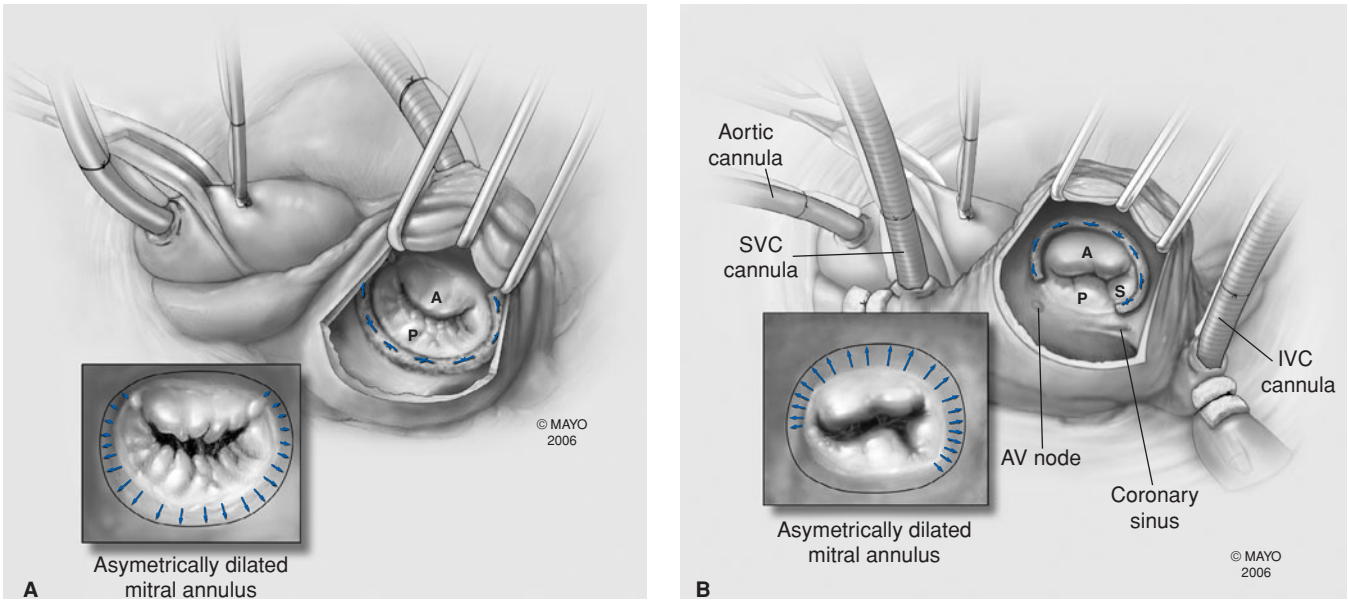

Figure 48-3. Mitral valve repair (*A*) and tricuspid valve repair (*B*) using a partial-ring annuloplasty. (Superior and inferior venae cavae snares not shown.)

indication of tricuspid valve disease and no other right atrial procedures are planned, venous return is obtained through a single two-staged cannula (Fig. 48-3*A*). Specific techniques of mitral valve repair depend on operative findings.[44] Localized prolapse of a portion of the posterior leaflet with or without ruptured chordae usually is managed by triangular excision of that segment and repair with continuous 4-0 polypropylene suture.[45] Ruptured chordae to the anterior leaflet are replaced with 4-0 or 5-0 polytetrafluoroethylene (PTFE) sutures inserted into papillary muscle and through the free edge of the prolapsing leaflet.[46]

Almost all leaflet repairs are supplemented with a posterior annuloplasty. Interrupted 2-0 braided polyester mattress sutures are placed along the posterior circumference of the annulus ending at the right and left fibrous trigones (see Fig. 48-3*A*). Sutures then are spaced evenly through a flexible 6.0- to 6.5-cm-long partial ring; this standard length can be obtained by using a flexible 63-mm posterior annuloplasty band.[47,45] Following annuloplasty, competence of the mitral valve is tested by filling the ventricle with saline or blood; the atrium then is closed, and the aortic valve prosthesis is sewn into place.

Mitral Valve Replacement and Tricuspid Valve Replacement or Repair

In most instances, tricuspid valve regurgitation is caused by annular dilatation.[48] The severity of tricuspid valve leakage can be determined by transesophageal echocardiography prior to bypass and by digital exploration of the right atrium just prior to venous cannulation. Under general anesthesia, changes in blood volume and cardiac output can cause significant fluctuation in the amount of regurgitation, and most often the severity of tricuspid valve leakage is lessened in the immediate prebypass period.

The patient's clinical condition must be correlated with echocardiographic findings and intraoperative assessment of the tricuspid valve. Patients with an enlarged, pulsatile liver, peripheral edema, and jugular venous distension are likely to require tricuspid valvuloplasty following mitral valve replacement or repair. Patients without the stigmata of right-sided heart failure usually have less severe valve leakage, and tricuspid valve function may improve without direct repair or replacement after left-sided valvular lesions are corrected.

The decision for repair or replacement of functional tricuspid valve regurgitation at the time of mitral valve replacement is important because the risk of subsequent reoperation is high. In our earlier experience, operative mortality was 25% in patients who required later reoperation for tricuspid valve regurgitation. Further, tricuspid regurgitation progresses in 10 to 15% of patients after replacement of rheumatic mitral valves.[49] Therefore, we maintain a liberal policy for annuloplasty or prosthetic replacement at initial operation.[50]

Procedure

For operations on the tricuspid valve, insertion of a Swan-Ganz catheter is optional; if one is used, the catheter is withdrawn from the right heart chambers during inspection and assessment of the tricuspid valve. We prefer direct cannulation of the inferior and superior venae cavae.[51] After commencement of cardiopulmonary bypass and cardioplegia, the cavae are snared around the venous cannulae, and the interatrial septum and tricuspid valve are exposed through a right atriotomy (see Fig. 48-2*A*). A decision for repair or replacement of the tricuspid valve is made, and the necessary prosthesis is identified.

When the tricupspid valve is also addressed, we tend to expose the mitral valve through an incision in the interatrial

septum, which crosses the fossa ovalis and can be extended superiorly (see Fig. 48-2*B*). Care should be taken during retraction to avoid tearing the septum inferiorly toward the coronary sinus and triangle of Koch. Alternatively, the mitral valve can be exposed through a standard left atriotomy posterior to the interatrial groove.

After repair or replacement of the mitral valve (see Fig. 48-2*C*), the septal or left atrial incision is closed, and the tricuspid valve is repaired or replaced. For tricuspid valve repair, we use either the DeVega method or ring annuloplasty.[11,16,52,53] Both techniques are based on the observation that the anterior and posterior valve portions of the tricuspid valve annulus are more prone to dilatation than the septal leaflet portion of the annulus, as described previously. When ring annuloplasty is indicated, we prefer a flexible device such as the Cosgrove-Edwards prosthesis[54] or a partial Duran ring (see Fig. 48-3*B*). The use of a partial ring avoids placement of sutures in the annulus near the penetrating bundle of His and reduces risk of injury to conduction tissue.

Tricuspid Valve Replacement and Pulmonary Valve Replacement for Carcinoid Heart Disease

If there is no involvement of the mitral and aortic valves,[55] tricuspid and pulmonary valve replacement usually can be performed without the need for aortic occlusion and cardioplegic arrest. It is important to exclude the presence of a patent foramen ovale to eliminate the risk of air entering the left atrium, and if a defect in the atrial septum is identified, it is closed using a brief period of aortic occlusion. In the past, our strategy for patients with carcinoid heart disease was to replace the tricuspid valve and excise the diseased pulmonary valve.

Subsequent experience has suggested that right ventricular function is better preserved with a competent pulmonary valve, so we now favor pulmonary valve replacement rather than valvectomy.[56] Tricuspid valve replacement always is indicated, and it is usually necessary only to remove the anterior leaflet. A recent review of 200 patients with carcinoid heart disease at our institution demonstrated that prognosis has improved in the current era and that valve replacement surgery was independently associated with prolonged survival.[57]

Carcinoid disease produces fibrosis and retraction of the leaflets, so anchoring sutures (interrupted mattress sutures of 2-0 braided polyester backed with felt pledgets) can be inserted into the remaining septal and posterior leaflets. We prefer to position the pledgets on the ventricular side of the valve annulus. If exposure is difficult, a brief period of aortic clamping and cardioplegic arrest is used during placement of sutures in the posterior and septal leaflets; the aortic cross-clamp is removed, and the heart is allowed to beat rhythmically. The remaining sutures are placed, and all sutures are secured with observation of the electrocardiogram. If atrioventricular block develops, the sutures in the area of the penetrating bundle of His are removed and reinserted in a more superficial location.

Pulmonary valve replacement is performed through a longitudinal incision across the valve annulus onto the outflow portion of the right ventricle. We prefer to insert the prosthetic valve using a continuous 3-0 polypropylene suture, anchoring the sewing ring to the native valve annulus for approximately two-thirds of the valve annulus and then anteriorly to a pericardial patch that is used routinely to augment the valve annulus and to facilitate closure of the pulmonary artery and right ventricle.

Triple-Valve Replacement

Operative preparation is similar to that described previously. Usually left-sided valvular lesions are corrected prior to tricuspid valve procedures. Again, if there is aortic valve regurgitation, the aortotomy is performed first, and cardioplegia is administered; simultaneously, we snare the cavae and open the right atrium. After excision of the aortic valve and calibration of the annulus, the interatrial septum is incised, and the mitral valve is repaired or replaced. Next, the aortic valve is implanted, and after closure of the aortotomy and septotomy, the tricuspid valvuloplasty or prosthetic replacement can be performed without aortic cross-clamping.[58]

RHEUMATIC HEART DISEASE AFFECTING MULTIPLE VALVES

As shown in Table 48-3, rheumatic valvulitis is a common cause of multiple valve disease. Autopsy studies show that almost all patients with rheumatic heart disease have some involvement of the mitral valve, although it is not always evident clinically.[59] The percentages of multiple valve involvement in two autopsy studies of patients with rheumatic heart disease are shown in Table 48-4.

Forty-seven percent of those studied had involvement of more than one valve. Mitral and aortic valve disease was the most common combination and was present in 34% of patients; the second most common combination was mitral, aortic, and tricuspid valve disease (9%). A recent report has suggested that all four valves might be involved with the rheumatic process.[60]

Long-term follow-up of children with rheumatic heart disease suggests that approximately 50% of patients have multivalvular involvement.[61,62] In a study of patients undergoing mitral valvotomy for rheumatic mitral stenosis (Table 48-5), 13% had clinical evidence of other rheumatic valve stenosis or regurgitation. Most of these patients had associated rheumatic aortic disease.[63]

Rheumatic heart disease can cause valve stenosis, regurgitation, or a combination of lesions. The percentages of 290 patients with specific valvular lesions from four studies of multiple valve disease are shown in Table 48-6. Mixed lesions producing stenosis and regurgitation were encountered most commonly in both aortic and mitral valves.

Rheumatic Mitral Stenosis with Rheumatic Aortic Regurgitation

Approximately 10% of patients with rheumatic mitral valve stenosis also have rheumatic aortic regurgitation.[64] Clinical and laboratory characteristics of patients with mitral stenosis and aortic regurgitation are summarized in Table 48-7.

Diagnosis, signs, and symptoms

PHYSICAL FINDINGS: An early blowing diastolic murmur is present along the left sternal border in about 75% of patients with rheumatic mitral stenosis.[65,66] This murmur can mimic a Graham Steell murmur of pulmonary valve regurgitation; however, this diastolic murmur usually originates from the aortic valve and represents mild aortic regurgitation.[67] In patients with aortic regurgitation, a late diastolic murmur can be either the murmur of mitral stenosis or the Austin Flint murmur caused by a regurgitant jet directed toward the anterior mitral leaflet.[68] Exercise or amyl nitrite inhalation intensifies the murmur of organic mitral stenosis while diminishing the murmur of aortic regurgitation and the Austin Flint murmur.[66] Doppler echocardiography differentiates mild aortic regurgitation and pulmonic regurgitation.[69] Occasionally, the murmur and peripheral signs of aortic regurgitation are absent because of mitral stenosis.[65,70]

ELECTROCARDIOGRAPHY: Electrocardiographic and roentgenographic evidence of eccentric left ventricular hypertrophy in patients with mitral stenosis is an important clue to associated aortic valve regurgitation. Also, atrial fibrillation early in the course of aortic regurgitation may be associated with mitral stenosis.[66,71]

ECHOCARDIOGRAPHY: Left ventricular hypertrophy and volume overload detected by echocardiography suggest severe aortic valve regurgitation because these findings normally are not associated with mitral stenosis.[66] Diastolic fluttering

of the anterior leaflet of the mitral valve and the ventricular septum is an additional finding suggesting aortic valve regurgitation in patients with mitral stenosis.[66,72] In the presence of aortic valve regurgitation, the Doppler determination of mitral valve area is overestimated when pressure half-time measurements are used.[73]

CATHETERIZATION DATA: With current echocardiographic methods, cardiac catheterization to determine the severity of valvular heart disease is rarely indicated; however, hemodynamic profiles of such patients have been studied thoroughly. Characteristically, the left ventricular diastolic pressure is elevated in about 35% of patients with mitral stenosis and aortic regurgitation. This can cause the transmitral gradient at rest to be small even when significant stenosis of the mitral valve is present.[43,74] In patients with isolated aortic valve regurgitation, the left ventricular diastolic pressure is elevated more frequently than in patients with concomitant mitral stenosis and aortic regurgitation.[48] Aortography may underestimate the severity of aortic regurgitation in patients with associated mitral stenosis because low cardiac output and low stroke volume produce a concomitant reduction in regurgitant volume.[40]

Pathophysiology

In patients with mitral valve stenosis and aortic valve regurgitation, decreased cardiac output minimizes the classic signs of aortic regurgitation (i.e., waterhammer pulse, head bobbing, or visibly pulsating capillaries). Also, concomitant mitral stenosis reduces left ventricular volume overload, which is a characteristic of isolated aortic regurgitation.[74] The underfilling of the left ventricle characteristic of mitral stenosis is offset by overfilling secondary to aortic valve regurgitation. Pulmonary artery hypertension characteristic of mitral stenosis usually is present.

Operative decision making

Patients with rheumatic mitral stenosis and rheumatic aortic regurgitation of more than a mild degree usually require replacement of both valves. Aortic valve repair is possible using techniques such as cuspal extension with glutaraldehyde-treated bovine or autologous pericardium[75] or the

Trussler technique.[76] Although early results with cuspal extension have been good, inexorable progression of valve fibrosis may necessitate later prosthetic replacement for many patients.[77]

Preoperative transthoracic and intraoperative transesophageal echocardiography aids in assessing function of the aortic valve in patients requiring surgery for mitral stenosis. At operation, the degree of ventricular filling and amount of aortic root distension with infusion of cardioplegia are clues to important aortic valve regurgitation. As stated previously, if mitral valve replacement is necessary, serious consideration should be given to replacement of the aortic valve when there is moderate or worse leakage owing to rheumatic valvulitis.

Great care should be exercised to avoid ventricular distention if ventricular fibrillation occurs prior to aortic clamping. If ventricular fibrillation develops, distension of the heart can be prevented by inserting a left ventricular vent and by compressing the heart manually. Also, even mild or moderate degrees of aortic regurgitation can complicate cardioplegia delivery through the proximal aorta.

Rheumatic Mitral Stenosis with Rheumatic Aortic Stenosis

Diagnosis, signs, and symptoms

PHYSICAL FINDINGS: When rheumatic valve disease produces the combination of mitral valve stenosis and aortic stenosis, the signs and symptoms of both lesions can be present; however, those of mitral stenosis (e.g., dyspnea) tend to predominate, and the signs and symptoms of aortic stenosis (e.g., syncope and angina) occur less frequently. Table 48-8 outlines the clinical characteristics of patients in four studies of combined mitral and aortic stenosis. Dyspnea, the most frequently observed symptom, was present in 95% of patients, and angina and syncope were observed in 29% and 25% of patients, respectively. Mitral valve stenosis even may mask the signs and symptoms of aortic stenosis, making the

clinical recognition of aortic stenosis difficult in patients with combined disease.[78]

In addition, auscultatory findings may be confusing if the elevated end-diastolic pressure caused by aortic stenosis minimizes the opening snap of mitral stenosis.[78–80] Clinical signs of aortic stenosis, i.e., delayed carotid upstroke, systolic thrill, and ejection murmur, may be less prominent in patients with coexisting mitral valve stenosis than in those with isolated aortic valve stenosis.[79] Some clinical features raising suspicion of multiple valve involvement in patients with mitral stenosis or aortic stenosis are shown in Tables 48-9 and 48-10.

Radiographic findings in patients with combined rheumatic mitral and aortic valve stenosis are summarized in Table 48-11. Left atrial enlargement is observed in 85% of patients, and dilatation of the proximal ascending aorta, common in patients with congenitally bicuspid valves, is

relatively infrequent (22%). Calcification of the mitral or aortic valves is identified in approximately 35% of patients.

ELECTROCARDIOGRAPHY: Atrial fibrillation is not common in patients with isolated aortic valve stenosis but is observed in 52% of patients with combined disease (Table 48-12). Approximately one-third of patients will exhibit electrocardiographic evidence of left ventricular hypertrophy, and right ventricular hypertrophy occurs in 18% of patients. Atrial enlargement manifested by P-mitrale is observed in 32% of patients.

ECHOCARDIOGRAPHY: Echocardiography provides definitive information on valve structure, function, and hemodynamics. In patients with combined mitral and aortic stenosis, estimation or measurement of valve area may be more reliable than the pressure gradient because cardiac output may be low, and atrial fibrillation produces variable stroke volume from one cardiac cycle to the next. Severity of mitral valve stenosis is determined by directly measuring the mitral valve orifice on the short-axis view of two-dimensional echocardiography. This method is reliable and reproducible, and there is excellent correlation between mitral valve area measured from a two-dimensional echocardiogram and the area measured directly from a pathologic specimen.[81]

Pathophysiology

In contrast to isolated mitral stenosis, in which ventricular function frequently is preserved, the combination of mitral and aortic stenosis is associated with ventricular hypertrophy and diastolic dysfunction. The pressure load from the aortic stenosis causes a concentric hypertrophy with a small, noncompliant ventricular cavity.[71] Mitral stenosis compromises the ventricle's ability to maintain cardiac output (in contrast to isolated aortic stenosis, in which cardiac output is maintained).[80,82] The decrease in cardiac output minimizes the signs and symptoms of aortic stenosis and may make the diagnosis

of aortic stenosis difficult.[83] Other hemodynamic parameters are similar to those of isolated mitral stenosis, e.g., elevation of left atrial and pulmonary arterial pressures.[82,84]

Operative decision making

Although mitral valve stenosis sometimes can be treated effectively with valvuloplasty, commissurotomy for rheumatic aortic stenosis is indicated rarely. Thus, for patients with both aortic and mitral valve stenoses caused by rheumatic heart disease, we favor prosthetic replacement with mechanical prostheses if patients can manage long-term anticoagulation. If aortic valve stenosis is only mild and the decision is made not to replace the aortic valve at the time of mitral valve replacement, then the patient should be followed carefully because over 50% will develop moderate to severe disease by 15 years postoperatively.[85] The combination of aortic stenosis and mitral stenosis may present unique problems for the surgeon. First, concentric hypertrophy of the left ventricle may displace the mitral valve orifice anteriorly, producing poor exposure through a standard atriotomy; several maneuvers and alternative incisions are described for patients in whom mitral valve exposure is difficult.[83,86–90] Also, the small left ventricular cavity may impinge on struts of a stent-mounted bioprosthesis. There is also the potential for left ventricular outflow obstruction from high-profile prostheses in the mitral position in patients with aortic and mitral valve stenoses and small left ventricular cavity size.

Rheumatic Mitral Regurgitation with Rheumatic Aortic Regurgitation

Diagnosis, signs, and symptoms

PHYSICAL FINDINGS: When mitral regurgitation and aortic regurgitation are both present, the cardinal signs of either lesion may be masked by the other,[71] and when the clinical features of aortic regurgitation predominate, it may be difficult to determine whether coexisting mitral regurgitation requires surgical treatment.[71] The clinical characteristics of patients with combined mitral and aortic regurgitation are summarized in Table 48-13. Dyspnea and congestive heart failure are most common, whereas angina, syncope, and evidence of emboli occur less frequently.

Mitral valve regurgitation produces a characteristic systolic blowing murmur and also may be associated with a diastolic flow murmur. Aortic valve regurgitation produces a characteristic diastolic murmur and also may cause a systolic flow murmur. The combination of two simultaneous murmurs during both diastole and systole may confuse clinical diagnosis. Most patients have a long, pansystolic murmur heard best at the apex, often with a diastolic rumble and decreased intensity of aortic closure. In general, when aortic regurgitation is the dominant lesion, the early diastolic rumble is prominent; when mitral regurgitation prevails, the aortic diastolic murmur is less intense.[91–93] However, the severity of the two lesions does not always correlate with the relative intensity of murmurs.[71] Additionally, a prominent S_3 gallop can be heard, whereas an S_4 is unusual.[94]

Combined aortic and mitral regurgitation also results in significant left ventricular enlargement,[92] which is evident on both electrocardiogram[71,91] and chest x-ray.[71,91,93,94] Characteristic electrocardiographic findings are summarized in Table 48-14. On chest x-ray, nearly all patients have cardiomegaly and left atrial enlargement.[71,91] Calcification of the mitral or aortic valve is relatively uncommon.[71]

ECHOCARDIOGRAPHY: Mitral valve motion and diastolic orifice configuration may be altered in aortic regurgitation with a decrease in the opening amplitude of the anterior leaflet and an abnormal mitral orifice configuration with diastolic

leaflet oscillation.[94] The mitral valve orifice image is deformed because restriction in anterior leaflet excursion is most pronounced in the center of the leaflet, where peak vertical separation normally occurs. This restriction causes the anterior leaflet to appear flattened rather than convex anteriorly, and in severe cases, it actually may be concave toward the left ventricular outflow tract.[94]

CATHETERIZATION DATA: Most patients have elevated right atrial and pulmonary arterial capillary wedge pressure. There is usually a prominent *v* wave in the pulmonary capillary wedge tracing. Approximately 75% of patients have an elevated left ventricular end-diastolic pressure.[64,71]

Pathophysiology

The combination of mitral and aortic valve regurgitation produces severe volume overload of the left ventricle. The reduction of impedance to ejection allows the ventricle to empty further, reducing ventricular wall tension with a resulting increase in the velocity of shortening.[95] Chronic volume overload increases stroke volume and distension of the left ventricle so that a larger stroke volume can be achieved with less myocardial fiber shortening than in normal hearts.[71] Patients who respond to increased volume load by left ventricular dilatation appear to tolerate surgical correction better than patients with left ventricular hypertrophy owing to an increased pressure load.[71]

Patients with aortic valve regurgitation have augmented stroke volume to maintain an adequate cardiac output, but when mitral regurgitation coexists, part of the augmented stroke regurgitates into the left atrium and pulmonary veins. For this reason, when aortic regurgitation is severe, concomitant mitral regurgitation greatly reduces systemic cardiac output and can produce severe pulmonary congestion.[96]

Operative decision making

As stated previously, aortic valves involved with rheumatic disease usually require replacement. When the mitral valve also has rheumatic involvement, we replace the mitral valve at the time of aortic valve operation. After the aortic valve is excised, the mitral valve is inspected visually if it is suspected of being diseased or if the degree of regurgitation is severe.

MYXOMATOUS AND PROLAPSING VALVE DISEASE AFFECTING MULTIPLE VALVES

Myxomatous degeneration is the most common etiology of mitral regurgitation requiring surgical correction in North America, and myxomatous aortic valve disease with annular dilatation is perhaps the most common cause of aortic regurgitation.[97–99] Most cases of isolated mitral or aortic valve prolapse are not associated with known connective tissue disorders. However, the coexistence of both mitral and aortic valvular prolapse together frequently can be seen in patients with connective tissue diseases such as Marfan syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, and others.[96]

Aortic valve regurgitation in patients with Marfan syndrome is caused by progressive enlargement of the sinus portion of the aorta and the aortic valve annulus, i.e., annuloaortic ectasia.[100,101] The principal causes of mitral regurgitation in patients with Marfan syndrome are mitral annular dilatation, floppy or prolapsing leaflets, and mitral annular calcification.[101] The pathologic lesion in Marfan syndrome is cystic medial necrosis, which is characterized by degeneration of elastic fibers and infrequent cysts.[101] Alterations in the synthesis and cellular secretion of fibrillin are responsible for the phenotypic characteristics of many patients with Marfan syndrome.[102] Some patients have myxomatous cardiovascular lesions and annuloaortic ectasia without the other clinical characteristics of Marfan syndrome.

Two-dimensional echocardiographic studies show that the frequency of aortic valve prolapse in patients with mitral valve prolapse varies between 3% and 24%[103,104] (Table 48-15). In one necropsy study, the frequency of mitral regurgitation in Marfan patients with aortic aneurysms (most with aortic regurgitation) was 54% (7 of 13).[101] About 17% of patients who undergo surgery for myxomatous aortic valve require surgical correction of mitral regurgitation (Table 48-16).

Although multiple valve involvement with myxomatous degeneration usually manifests as mitral regurgitation in combination with aortic regurgitation, in some cases, all four valves may be involved.[107] It is not clear whether the underlying pathology of isolated mitral valve prolapse is the same as the cardiovascular lesions that occur in Marfan syndrome and other multiple-floppy-valve syndromes.[108,109]

Table 48–15.

Incidence of Echocardiographic Evidence of Aortic Valve Prolapse in Patients with Mitral Valve Prolapse

	Ogawa[104]	Rippe[103]	Mardelli[186]	Total
Number of patients with MVP	50	400	75	525
Aortic valve prolapse	24% (12)	3% (11)	20% (15)	7% (38/525)
Aortic regurgitation	16% (8)	1% (4)	—	3% (12/450)
Aortic and mitral valve replacement	2% (1)	—	—	2% (1/50)

MVP = mitral valve prolapse.
Number of patients in parentheses.

Diagnosis, Signs, and Symptoms

Signs and symptoms of aortic and mitral valve regurgitation are reviewed in the section on rheumatic valvular disease. In addition to complete evaluation of the aortic and mitral valves and proximal aorta, patients with Marfan syndrome should have assessment of the descending aorta for aneurysm or chronic dissection.

Operative Decision Making

If annuloaortic ectasia is not present, patients with mitral and aortic valve regurgitation caused by myxomatous degeneration are candidates for repair of both valves. The aortic valve is inspected initially, and the decision for repair or prosthetic replacement is made depending on cuspal morphology. If tissue is sturdy and there is little prolapse or prolapse is limited to one cusp, repair can be undertaken with commissural narrowing and cusp resuspension. Often, aortic valve regurgitation is central, and simply narrowing the annulus by commissural plication restores valvular competence. Outcome of repair of both mitral and aortic valves has been good in terms of patient survival and freedom from valve-related complications, but reoperation is necessary in 35% of patients 10 years after the initial procedure; patients with most severe aortic valve regurgitation have an increased risk of late reoperation.[110] If tissue is attenuated, or if multiple cusps have severe prolapse, the valve is replaced.

In most instances, patients with Marfan syndrome and aortic regurgitation require composite replacement of the aortic valve and ascending aorta.[111] Occasionally, moderate aortic regurgitation can be repaired at the time of aortic replacement by suspending the aortic valve inside a tube graft or remodeling the sinus portion of the aorta.[112] Even if the aortic valve is replaced with a composite graft and mechanical valve, the surgeon should favor repair of associated mitral regurgitation.[113] Gillinov and colleagues reported that valvuloplasty is possible in approximately 80% of patients with mitral regurgitation and Marfan syndrome and that 5 years postoperatively, 88% of patients are free of significant mitral valve insufficiency.[114]

Myxomatous Mitral Regurgitation with Tricuspid Regurgitation

Myxomatous degeneration also may involve the tricuspid valve, and presentation of mitral and tricuspid valve regurgitation owing to degenerative disease is not uncommon. In

Table 48–16.

Frequency of Mitral Valve Procedures in Patients Undergoing Aortic Valve Repair or Replacement for Myxomatous Degeneration, Prolapse, or Root Dilation

	David[187]	Gott[188]	Shigenobu[97]	Agozzino[100]	Bellitti[99]	Total
All aortic surgery	18	270	13	69	25	395
Number requiring concomitant mitral surgery	3 (17%)	36 (13%)	5 (38%)	16 (23%)	3 (12%)	73 (16%)

one study, 54% of patients with mitral valve prolapse also had tricuspid valve prolapse; however, most of these patients did not have significant regurgitation.[96] As with tricuspid regurgitation associated with rheumatic mitral disease, preoperative and intraoperative echocardiography is important in evaluating tricuspid disease in patients with myxomatous mitral regurgitation. In contrast to rheumatic disease, myxomatous mitral and tricuspid regurgitation almost always lends itself to valve repair.

SENILE CALCIFIC AORTIC VALVE DISEASE WITH MULTIPLE VALVE INVOLVEMENT

Unlike aortic stenosis caused by rheumatic disease, in which associated mitral valve disease is common, senile calcific aortic stenosis usually presents as an isolated lesion. Although the combination of mitral valve disease and senile calcific aortic stenosis is uncommon, senile aortic calcification is a frequent cause of aortic valve stenosis.[98] The incidence of senile calcific aortic disease has increased steadily in the last 20 years. Therefore, although mitral valve disease associated with calcific aortic stenosis is less common than that seen with rheumatic disease of the aortic valve, as the incidence of calcific aortic stenosis increases, so does the likelihood of encountering patients with disease of both valves.

Patterns of Multiple Valve Involvement with Calcific Aortic Stenosis

Calcific aortic stenosis with infective endocarditis of the mitral valve

Stenotic aortic valves frequently are sites of infective endocarditis. As discussed in the section on endocarditis, the mitral valve may become involved with infective endocarditis by common abscess, by verrucous extension, or from a jet lesion, and infection may cause mitral valve aneurysm, perforation, and/or chordae disruption.[115] Management of these patients usually requires aortic valve replacement and assessment of the mitral valve at the time of operation. Vegetations of the mitral valve sometimes can be removed and perforations patched if the remaining tissue is sturdy and appears healthy.

Calcific aortic stenosis with functional mitral valve disease

Senile calcification of the aortic valve may lead to mixed stenosis and regurgitation,[98] and the volume load from regurgitation may lead to left ventricular dilatation and secondary mitral regurgitation of an otherwise normal mitral valve.[98] Mitral regurgitation secondary to aortic valvular disease is discussed in the section on pathophysiology of multiple valve disease.

Calcific aortic stenosis with calcification of the mitral valve

Degenerative calcification is an age-related process usually affecting the aortic and mitral valves. In a study of patients older than 75 years of age, one-third had degenerative aortic or mitral calcification.[96] About 25 to 50% of patients with calcific aortic stenosis have calcification of the mitral valve annulus. Generally, patients with associated mitral annular calcification are older, have more severe aortic stenosis, and are more often female when compared with patients with aortic stenosis without mitral annular calcification.[106] Mills reported 17 patients undergoing mitral valve replacement for valvular disease related to severe annular calcification. Four of these patients also had concomitant aortic valve replacement.[116] Mitral annular calcification may exist in the setting of rheumatic or myxomatous disease.[117] These patients may have increased incidence of conduction defects,[118] aortic outflow murmurs, coronary artery disease,[119] and stroke.[120] Mitral repair or replacement is facilitated in some circumstances by removal of the annular calcium bar and pericardial reconstruction.[121]

Diagnosis, Signs, and Symptoms

Physical findings

Auscultatory findings in aortic stenosis and mitral regurgitation consist of two systolic murmurs that can be distinguished by location of maximum intensity and radiation. Characteristically, aortic stenosis produces a crescendo-decrescendo murmur at the base, and mitral regurgitation produces a holosystolic murmur at the apex. Occasionally, a prolonged ejection murmur of aortic stenosis may simulate a holosystolic murmur at the apex, and the murmur of severe mitral regurgitation may radiate toward the base and may take on a crescendo-decrescendo pattern simulating an ejection murmur.[66,69]

Electrocardiography

Atrial fibrillation is uncommon in isolated aortic stenosis, and its presence is a clue to associated mitral valve disease.[66] Both aortic stenosis and mitral regurgitation produce left ventricular hypertrophy and left atrial enlargement.

Echocardiography

Echocardiography is essential to delineate mitral valve morphology, determining whether there is prolapse (from either chordal elongation or rupture), annular dilatation, or other abnormalities and also to assess the severity of aortic valve stenosis. Transesophageal echocardiography (either preoperatively or intraoperatively) is preferred at our institution to evaluate the mitral valve completely and accurately.

INFECTIVE ENDOCARDITIS AFFECTING MULTIPLE VALVES

As with infection of a single valve, multiple valve infective endocarditis may occur in valves that are normal, previously diseased, or prosthetic. Infective endocarditis requiring multiple valvular procedures occurs in about 10 to 25% of all

Table 48–17.

Locations and Combinations of Valvular Infective Endocarditis

	NVE	PVE	Total
Number of patients	131	47	178
Aortic	51% (68)	68% (32)	56% (100)
Mitral	27% (36)	23% (11)	26% (47)

patients having operation and usually involves the mitral and aortic valves[12,117,122–123] (Tables 48-17 and 48-18). Conduction defects on electrocardiogram may be a clue to abscess involvement of both the aortic and mitral annulus.[130]

About 1 to 5% of patients who require surgery for multiple valve endocarditis have biventricular involvement, and most instances of tricuspid valve infections are due to intravenous drug use.[127,131] Patients with multiple valve infective endocarditis more frequently have congestive heart failure as an indication for surgery and are more likely to have intracardiac abscess when compared with patients with single-valve infective endocarditis.[127]

Table 48–18.

Incidence of Multiple Valve Replacement for Native-Valve Infective Endocarditis from 1961–1974 at the Mayo Clinic

	No. of patients	Percent
Valve replacement for IE	138	
Aortic	99	71% (99/138)
Mitral	16	12% (16/138)
Multiple	23	17% (23/138)

IE = infective endocarditis.

Aortic Regurgitant Jet Lesion of the Mitral Valve

Perforation of the anterior leaflet of the mitral valve may occur from the regurgitant jet of aortic valve endocarditis, and the diagnosis can be made from transesophageal echocardiography.[132] Often, the perforation in the mitral valve can be débrided and repaired with a patch of pericardium or prosthetic material.

Prosthetic Valve Endocarditis

Risk of prosthetic valve endocarditis is greatest approximately 4 to 6 weeks postoperatively and decreases to a stable rate by about 1 year after operation.[133,134] *Staphylococcus epidermidis* and *Staphylococcus aureus* account for 20 to 30% of cases, respectively.[135] Transesophageal echocardiography can identify vegetations caused by infection as well as prosthetic valve dysfunction and associated abscess cavities.[135] In general, management of patients with endocarditis affecting multiple valves is similar to management of patients with infection of one valve. There are, however, some special considerations. When aortic valve endocarditis is complicated by abscess formation, infections may extend into the mitral annulus and necessitate concomitant mitral valve replacement; this occurs in approximately 12% of patients with aortic root abscess[136] and is especially prevalent when there is involvement of the aorticomitral junction or subannular interventricular septum.[127,136] Surgical reconstruction of the

intervalvular fibrous body during simultaneous aortic and mitral valve replacement is a technically challenging operation reserved for situations where extirpation of endocarditis results in aortomitral discontinuity. The improved survival and durability of this technique in the recent era have been described by David and colleagues.[137]

Tricuspid Valve with Left-Sided Valve Replacement

When the tricuspid valve is excised at the time of left-sided valve replacement, there remains a question of whether the tricuspid valve needs to be replaced. Simple excision of the tricuspid valve seems appropriate only in the absence of pulmonary hypertension and left-sided failure. A prosthetic left-sided valve is intrinsically stenotic, and many patients with tricuspid valve endocarditis can have pulmonary hypertension secondary to septic pulmonary emboli. Silverman found that patients who had tricuspid valve excision alone with left-sided valve replacement required perioperative inotropic support, and management of their postoperative congestive heart failure was more difficult than that of the patients who had tricuspid valve replacement.[127]

Results

Early mortality following surgery for multiple valve endocarditis is in the range of 20 to 30%, and Table 48-19 compares New York Heart Association (NYHA) class-matched groups that had multiple valve procedures for infective endocarditis and for other reasons.

CARCINOID HEART DISEASE AFFECTING MULTIPLE VALVES

Valvular heart disease develops in about 50% of patients with carcinoid tumors; patients with primary carcinoid tumor in the small intestine are more likely to have carcinoid heart disease than those with carcinoid tumors in other locations.[1] In most cases, the tricuspid and pulmonary valves are involved. We have offered valvular surgery to patients with severe symptoms of right-sided heart failure caused by carcinoid heart disease whose systemic carcinoid symptoms are controlled by octreotide and/or hepatic dearterialization.[138] Patients who are being considered for complete resection of hepatic metastases after control of the primary tumor are also candidates for extirpation of cardiac disease and valve replacement. A recent review of 200 patients with carcinoid heart disease from our institution revealed that survival has improved over the past decade. Multivariate analysis indicated that valve replacement surgery was associated with a risk reduction of 0.48.[57]

Diagnosis, Signs, and Symptoms

Jugular venous distension with *v* waves (from tricuspid regurgitation) and *a* waves (from tricuspid stenosis) can be evident. Right ventricular enlargement can produce a pericardial lift. Most patients have murmurs from the tricuspid and pulmonary valves.[138] Patients often demonstrate ascites and liver enlargement as a result of either right-sided heart failure or hepatic metastases or both. Therefore, these findings are not necessarily indicative of severe tricuspid valve regurgitation.

The electrocardiogram of patients with carcinoid heart disease often shows low voltage (85%), right bundle-branch block (42%), and evidence of right atrial enlargement (35%).[1,138] The chest x-ray characteristically shows cardiomegaly (69%), pleural effusions (58%), and pleural thickening (35%).[138]

Echocardiography

Echocardiographic findings of carcinoid heart disease include thickening and reduced motion of the tricuspid valve leaflets; the pulmonic valve cusps may be thickened and retracted. Fusion of the pulmonary valve commissures results in a stiff fibrotic ring that may cause a stricture in the

Table 48–19.

Comparison of Early Outcome Between Patients Having Multiple Valve Surgery for Infective Endocarditis and Patients Having Multiple Valve Surgery for other Reasons[8,108]

	Class II	Class III	Class IV
Multiple valve procedures for infective endocarditis	20% (15)	33% (3)	20% (5)
Multiple valve procedures for other causes	16% (25)	12% (25)	36% (25)

Operative mortality is expressed as percentage, and numbers of patients are in parentheses.

Table 48–20.

A Comparison of Venous Drainage, Presence of Liver Metastases, and Carcinoid Plaque Location in Relation to Location of Primary Carcinoid Tumor[136]

Tumor location	Venous drainage	Liver metastases	Plaque location
Gut	Portal	Yes	Right-sided
Ovary	Systemic	No	Right-sided
Bronchial	Pulmonary	No	Left-sided.

entire pulmonary orifice. Pulmonary regurgitation and stenosis both may be present.[139]

Invasive Studies

Cardiac catheterization is not necessary unless ischemic symptoms or a history of myocardial infarction suggests coronary artery disease.

Pathophysiology

Carcinoid heart disease results from deposition of plaques on the endocardium of the valves and atria; this usually occurs on the right side of the heart. However, plaques can develop on the mitral and aortic valves when there is carcinoid tumor in the lungs or in the presence of intracardiac shunting that bypasses the lungs. Valves are damaged by exposure to circulating substances released from carcinoid tumors such as serotonin and bradykinin. Both these components are inactivated by the lungs and the liver; the relationship between tumor location and the location of cardiac lesions is summarized in Table 48-20.[140]

The plaques usually deposit on the downstream side of the cardiac valves, causing adherence of the leaflet to the underlying structures and producing functional regurgitation. Carcinoid plaque deposition also may constrict the valve annulus and produce stenosis.[1]

The dominant functional lesion of carcinoid heart disease is tricuspid valve regurgitation; the valve is fixed in a semiopen position so that some degree of stenosis is present. Fibrosis and plaque deposition also affect the pulmonary valve, causing mixed stenosis and regurgitation, which increases the degree of tricuspid regurgitation.[1]

Operative Decision Making

Timing of operation

The primary indications for surgery are increasing symptoms of congestive failure with objective evidence of valvular disease.[141] Again, it should be noted that some of the signs of right-sided heart failure, such as peripheral edema, ascites, and hepatomegaly, can be caused by the primary disease. Another indication for operation may be progressive right ventricular enlargement in the absence of symptoms. In a small series of carcinoid patients, right ventricular size and function did not correlate with operative or late mortality.[138] Currently, we employ exercise testing to provide an objective assessment of the functional status and a guideline to the timing of cardiac surgery. If the primary cause for debilitation is right-sided heart failure, it is reasonable to offer valve replacement even though the prognosis may be guarded.[141]

Tricuspid valve operation

The tricuspid valve always requires replacement, and in our earlier experience, we used mechanical prostheses because of the possibility of carcinoid plaque formation on a bioprosthesis. However, review of our patients and those reported previously shows little difference in patient survival with mechanical or tissue valves. Bioprostheses are selected for patients who have liver dysfunction that would complicate anticoagulation with Coumadin and for patients who will undergo subsequent hepatic resection or hepatic artery embolization.

Pulmonary valve options

As stated previously, we now advise valve replacement rather than excision when the pulmonary valve is involved.

Management of the carcinoid syndrome during and early after operation is critically important, and this has been simplified greatly by treatment with long-acting octreotide; this is supplemented intraoperatively with intravenous administration of short-acting octreotide when there is evidence of flushing and vasodilatation.[142] Preoperative steroids and antihistamines also can be used to prevent adverse effects from tumor-released mediators.[142,143] We usually give octreotide, 500 μg intravenously, prior to induction of anesthesia, with additional intravenous doses given as needed at the onset and termination of cardiopulmonary bypass. Postoperatively, octreotide is continued, and the dose is adjusted according to the severity of the flushing and vasodilatation.

Table 48–21.

Rare Causes of Multiple Valve Disease Requiring Surgery

Disease	Valves replaced or repaired
Methysergide/ergotamine toxicity [96]	Aortic and mitral
Radiation injury[136, 189]	Mitral and tricuspid
Q-fever endocarditis[190]	Aortic and mitral
Ectodermal anhydrotic dysplasia[191]	Aortic and mitral
Maroteaux-Lamy syndrome (mucopoly-saccharidosis type VI)[192]	Aortic and mitral
Werner syndrome (adult progeria)[193]	Aortic and mitral
Blunt trauma[194]	Mitral and tricuspid
Lymphoma[195]	Aortic and mitral
Relapsing polychondritis[196]	Aortic and mitral
Systemic lupus erythematosus[197]	Mitral and tricuspid
Secondary hyperparathyroidism[198]	Aortic and mitral
Urticarial vasculitis syndrome (HUVS) with Jaccoud hands deformity[199]	Aortic and mitral

Aprotinin, a kallikrein inhibitor, may mitigate the effects of substances released by carcinoid tumors during anesthesia and reduce intraoperative and postoperative bleeding.[142]

RARE CAUSES OF MULTIPLE VALVE DISEASE

Table 48-21 lists some rare causes of multiple heart valve disease that require surgical correction.

RESULTS OF MULTIPLE VALVE SURGERY

Long- and Short-Term Mortality

Survival following multiple valve surgery has improved along with refinements in myocardial protection; for example, mortality for multiple valve operations performed using normothermic ischemic arrest was approximately 40%[144]; the use of cardioplegic arrest reduced operative risk by three-quarters.[71,144,145] In recent reports,[146] operative mortality (30-day mortality or hospital mortality) ranges from about 6 to 17% (Table 48-22, part A). The 5-year actuarial survival is 60 to 88% (see Table 48-22, part B), and the 10-year actuarial survival is 43 to 81% (see Table 48-22, part C). Risk factors identified for morbidity and mortality following multiple valve surgery include advanced NYHA class,[147–149] advanced age,[147–150,151] current or prior myocardial revascularization,[150] ejection fraction,[147] presence of coronary artery disease,[147,148] aortic stenosis,[152] elevated pulmonary artery pressure,[150] tricuspid regurgitation,[152] and diabetes mellitus.[150]

Clearly, operative mortality is influenced by patient selection,[149] and comparisons between studies are of limited value.[149] Causes of death following multiple valve surgery are low cardiac output,[23,149,152,153–155] myocardial infarction,[154] technical failure,[155] multiple-organ failure,[23] ventricular rupture,[101,150,153] and mechanical obstruction of the prosthetic leaflet.[101,154]

Comparisons of late survival between patients having multiple valve versus single-valve replacement are inconsistent. Some studies show poorer survival[148] after multiple valve replacement, and others report no significant difference in survival.[23,145,148,155–160] The discrepancy in these results may be because the majority of deaths in many reports are secondary to progression of coronary artery disease and noncardiac causes rather than valve-related issues.[145,148] The presence of coronary artery disease and concomitant coronary artery surgery increases mortality following multiple valve surgery.[150,161,162]

Some causes of early death following multiple valve surgery are perhaps less common today owing to changes in practice. In a necropsy study from 1963 to 1985 of patients who died early following double-valve replacement, prosthetic valve dysfunction secondary to mechanical interference was evident in almost 50%, and ventricular rupture had occurred in 15% of patients.[101] Most of these patients received Starr-Edwards caged-ball prosthetic valves. Mechanical failure of low-profile tilting-disk prostheses that are in current use is rare, and early valve-related death with this type of prosthesis is very unusual.[23,148,149,163] The current practice of preserving the posterior leaflet and chordal attachments of the mitral valve during prosthetic replacement may decrease the chance of ventricular disruption.[164]

Thromboembolism

Thromboembolic rates following multiple valve replacement are shown in Table 48-22, part D, and range from 1 to 7% per patient-year for double-valve replacement. Ten years postoperatively, freedom from thromboembolic events ranges from 77 to 89% (see Table 48-22, part E). Although the data presented in Table 48-22, part D, along with other sources,[165] do not indicate significant differences between single and multiple valve replacement, some reports suggest that both mechanical[166] and bioprosthetic[167] valves have an increased

Comparisons to isolated aortic and mitral valve procedures from the same series are included when available. If statistical analysis between the results of multiple and single valve procedures was reported, the p values are included. If a series was limited to a single valve type, it is listed.

**Includes some patients with concomitant tricuspid procedures.*

†dR INR 1.75 = 2.75.

‡INR 4 = 6.

ξ Results reported graphically.

DVR = double valve replacement; AVR = isolated aortic valve replacement; MVR = isolated mitral valve replacement; N.S. = not statistically significant; SJM = St. Jude Medical; C-E = Carpentier-Edwards; B-S = Björk-Shiley; MP = Mitroflow pericardial; MIPB = Medtronic intact porcine bioprosthesis.

risk of thromboembolism in the mitral position. This risk is present early (90 days after operation) in patients undergoing multiple valve replacement that includes a bioprosthetic mitral valve.[167]

Anticoagulation-Related Hemorrhage

Rates of anticoagulant-related hemorrhage following multiple valve replacement, as with single-valve surgery, depend on target international normalization ratio (INR).[168] Risks of hemorrhage are reported to be 0.1 to 4.5% per patient-year following multiple valve surgery (see Table 48-22, part F). Alvarez reported a significantly higher rate of anticoagulant-related hemorrhage following multiple valve replacement than following single-valve replacement.[152]

Prosthetic Valve Infective Endocarditis

Rates of infective endocarditis following multiple valve surgery range from 0.2 to 2.5% per patient-year, as shown in Table 48-22, part G. In comparison with isolated valve surgery, Alvarez reports that prosthesis infection is more frequent following double valve replacement than following either isolated aortic ($p < .05$) or mitral valve replacement ($p < .001$).[152]

Table 48–23.

Results of Triple Valve Surgery by Author

	Coll[209]	Gersh[22]	Galloway[146]	Brown[166]	Mullany[51]	Kara[171]
Years studied	1970–1984	1962–1984	1976–1985		1965–1984	1972–1983
Number of patients	37	91	61	40	109	107
Type of procedure	Triple valve replacement	Triple valve replacement	Triple valve procedure	Triple valve replacement	Double valve replacement with tricuspid repair	Triple valve procedure
Valve type		Various (mostly S-E)	Various	Various	Various (60% S-E)	S-E, Björk, or St. Jude
Operative mortality	5%	24%	23%		21%	20%
Actuarial 5-year survival	75%	55%	62%	78%	70%	53%
Thromboembolism rate		12.3% pt-y		32% at 5 years combined with hemorrhage	4.5% pt-y	
Prosthetic infective endocardit is rate		6%			3%	
Hemorrhage rate		22%		17%		
Significant risk factors		Age, NYHA Class IV			Age, NYHA Class IV	Higher NYHA class, emergent operation, tricuspid replacement

S-E = Starr-Edwards; NYHA = New York Heart Association functional class.

Valve Performance

Rates of bioprosthetic structural deterioration relate to valve position; tissue valves appear to fail earlier in the mitral position than in the aortic position. When multiple valve replacements include the mitral valve, the rates of deterioration are similar[169] or even worse than[165] isolated mitral valve replacement (see Table 48-22, part H).

COMPARISON OF BIOPROSTHETIC VALVES TO MECHANICAL VALVES

Comparisons of outcomes of patients with two or more mechanical prostheses with those of patients with two or more bioprostheses show similar rates of thromboembolism,[20,170] but freedom from operation favors those with multiple mechanical valves.[20,170,171] As might be expected, anticoagulation-related hemorrhage is less in patients with two bioprosthetic valves,[170,172] but there is no clear advantage of one prosthesis over the other in terms of early and late mortality.[20,170,172]

Results of Tricuspid Valve Procedures with Other Valve Procedures

Results of mitral and tricuspid valve surgeries

Reported operative mortality following mitral valve replacement and tricuspid valve repair or replacement is approximately 12 to 15%,[173] and 65% to 75% of patients are alive 5 years postoperatively.[150,173] Outlook for patients with lesser

degrees of tricuspid regurgitation at the time of mitral valve replacement is good; 5-year actuarial survival for patients with tricuspid regurgitation who do not have tricuspid valve repair or replacement is 80 to 84%, and 10-year survival is 62 to 77%.[174]

Triple-valve replacement

The operative mortality following triple-valve replacement is higher than that for double-valve replacement and ranges from 5 to 25%.[22,150] As with double-valve replacement, advanced age and higher NYHA class are associated risk factors for early mortality.[22,175] Causes of perioperative death are similar to those following double-valve replacement and include low cardiac output, multiorgan failure, hemorrhage, and dysrhythmia.[22]

Five-year actuarial survival after triple-valve replacement is 53 to 78%, and 10- and 15-year survivals are 40% and 25%, respectively (Table 48-23).

Considering only perioperative survivors of triple-valve replacement, late survival is comparable with that of patients undergoing isolated valve replacement.[22,176] Reports of thromboembolic rates following triple-valve replacement range from 5 to 12% per patient-year (see Table 48-23).

Double-valve replacement and tricuspid annuloplasty

Operative mortality for patients undergoing double-valve replacement with tricuspid valve repair is about 25%,[51] and the 10- and 15-year survival rates are 35% and 27%, generally comparable with those of patients having triple-valve replacement.[51] Rates of thromboembolism in this group are reported to be 5% per patient-year.[51]

Other Results

The operative mortality for double re-replacement is about 10 to 20%.[148,177] Incidence of postoperative ventricular arrhythmias is higher in patients having combined valve surgery than in those having single-valve surgery.[178] Hemolysis may be more common with multiple valve disease or following multiple valve replacement.[179,180]

The incidence of perivalvular leak following multiple valve surgery is about 4% per patient-year and may be more frequent following multiple valve surgery than following single-valve surgery.[154,156]

When multiple valve surgery is combined with myocardial revascularization, the morbidity and mortality are 12 to 24%.[161,181] Early death in this group of patients is associated with prolonged perfusion time, the need for postoperative inotropic support, and high blood loss.[181]

CONCLUSION

The challenges of multiple valve replacement and repair include not only the technical maneuvers of operation but also the identification of associated valve lesions and correct judgment in surgical management. Echocardiography is the essential tool in preoperative diagnosis, and surgeons should become as familiar and facile with interpretation of ultrasound assessment of cardiac valves as with analysis of coronary angiograms. Finally, the various etiologies of multiple valve disease occur in certain combinations, and understanding the pathophysiology and pathologic anatomy is necessary to select the best procedure and to optimize early and late operative results.

CHAPTER 49

Reoperative Valve Surgery

James P. Greelish • Rashid M. Ahmad • Jorge M. Balaguer • Michael R. Petracek • John G. Byrne

The number of patients undergoing reoperation for valvular heart disease is increasing and will continue to increase as the general population ages.[1] These reoperations most commonly involve structural deterioration of a bioprosthesis and progression of native-valve disease after nonvalve surgery. In fact, structural failure of a biologic valve should be considered part of the natural evolution of tissue valves and should be fully appreciated by both the surgeon and the patient prior to implantation.[2] Reoperations are technically more difficult than primary operations because of adhesions around the heart with an associated risk of reentry, the presence of more advanced cardiac pathology, and the existence of more frequent comorbidities such as pulmonary hypertension. Perhaps most important, reoperative replacement operations often are performed in functionally compromised patients who tolerate complications poorly or who have little reserve.[3] As a consequence of these and other factors, reoperative valve surgery historically has been associated with a considerably higher operative mortality than primary valve surgery, particularly in patients who have had multiple prior replacements.[4] In the modern era, however, with use of alternative surgical approaches and advanced perioperative care, there has been significant improvement in outcomes.[5–9]

Reductions in operative risk and postoperative morbidity after reoperative valve surgery have been made in the past few years through advances in myocardial protection, as well as alternative perfusion strategies such as the proper use of deep hypothermic cardiac arrest.[10] In addition, use of peripheral cannulation techniques to institute cardiopulmonary bypass has become a relatively standard practice in reoperative cases.[11–13] Early institution of cardiopulmonary bypass prior to reentry is known to prevent injury to the distended right ventricle or patent coronary artery bypass grafts during reoperative sternotomy. In addition, this technique reduces myocardial oxygen consumption by decreasing myocardial distension.[4]

Successful replacement of the degenerate cardiac valve usually results in gratifying symptomatic and hemodynamic improvement. Maintenance of this improved state, however, depends on persistence of prosthetic valve function. In this regard, improvements in valve design have mitigated but not eliminated primary bioprosthetic failure.[14–16] As such, the risk of re-replacement for bioprosthetic failure remains a significant factor to be considered in the selection of valve type for implantation.[17]

MECHANICAL VERSUS BIOLOGIC VALVES

The most appropriate valve substitute for an individual patient remains a source of much controversy. This choice should be adapted to each individual patient depending on age, life expectancy, valve size, and cardiac as well as noncardiac comorbidities.[18] Some studies comparing the long-term outcome between biologic and mechanical aortic valve prostheses have yielded similar results with regard to overall valve-related complications.[19–23] However, most recent large studies have documented that anticoagulant-related bleeding with mechanical valves must be balanced against life expectation and the risk of biologic valve re-replacement.[24–27] Bioprosthetic valves are known to undergo a time-dependent process of structural deterioration that results in a freedom of reoperation of 80% at 15 years.[20] Consequently, structural degeneration of a bioprosthesis is the most frequent indication for reoperation in patients with tissue valves.[19,28]

Despite this, recently improved durability of tissue valves, as well as the availability of stentless valves and homografts, has led to surgeons placing bioprostheses in progressively younger age groups.[18,29–32] Contributing to this trend, many patients do not accept the risk of anticoagulant-related hemorrhage associated with mechanical valves: major events 0.5% per patient-year and minor events 2 to 4% per patient-year.[33]

Mechanical prostheses usually are selected for younger recipients because of their proven durability over time. However, the risk of anticoagulant-related bleeding, as well as thromboembolic events (TEs), in these valves is not trivial and depends on valve design, structural materials, and host-related interactions.[33] In a 12-year comparison of Bjork-Shiley versus porcine valves, Bloomfield and colleagues documented severe bleeding complications in 18.6% versus 7.1%, respectively.[34] Moreover, while endocarditis, dehiscence, perivalvular leak, and pannus formation are associated with both biologic and mechanical valves, acute prosthetic thrombosis is exclusively a complication of mechanical valves.[35,36] In considering mechanical valve durability, these associated risks cannot be ignored and must be weighed against the anticipated rate of tissue-valve failure and the need for reoperation.

RISK FACTORS IN REOPERATIVE VALVE SURGERY (TABLE 49-1)

In evaluating patients for reoperative valve surgery, certain factors are associated with added risk. For example, Husebye and colleagues, in a review of their 20-year experience[17] with reoperative valve surgery, found specific issues to carry higher risk. Overall operative mortality was 7% ($n = 14$ patients) for the second and 14% ($n = 69$ patients) for the third reoperation. Operative mortality for the first reoperation ($n = 530$ patients) was 5.9% in the aortic position and 19.6% in the mitral position. In the aortic position, operative mortality was 2.4% for New York Heart Association (NYHA) class I, 1.6% for NYHA class II, 6.3% for NYHA class III, and 20.8% for NYHA class IV, emphasizing the significance of early referral. Regarding the urgency of surgery, the mortality for elective mitral valve reoperations was 1.4%; for urgent procedures, 8%; and for emergency procedures, 37.5%. Based on these findings, the authors have recommended that referral for reoperation be made when valve dysfunction is first noted, i.e., prior to a significant decrement in myocardial function.[17] Similarly, Jones and colleagues reviewed their experience with first heart valve reoperations in 671 patients between 1969 and 1998.[6] Their overall operative mortality for first-time heart valve reoperation was 8.6%, similar to the results published by Lytle[37] (10.9%), Cohn[4] (10.1%), Akins[38] (7.3%), Pansini[2] (9.6%), and Tyers[39] (11.0%). In the Jones and colleagues series, mortality increased from 3.0% for reoperation on a new valve site to 10.6% for prosthetic valve dysfunction or periprosthetic leak; mortality was highest (29.4%) for associated endocarditis or valve thrombosis. Concomitant coronary artery bypass grafting carried a higher associated mortality (15.4%) than when it was not required (8.2%). Among the 336 patients requiring re-replacement of prosthetic valves, mortality was 26.1% for re-replacement of a mechanical valve compared with 8.6% for re-replacement of a tissue valve. The authors concluded through multivariable analysis that significant predictors of mortality were year of reoperation, patient age, indication, concomitant coronary artery bypass grafting, and the replacement of a mechanical valve rather than a tissue valve.[6]

REOPERATIVE AORTIC VALVE SURGERY

Historical Points

Historically, aortic valve surgery typically involved the placement of a mechanical valve. In the past, there were only a few generally accepted indications to use a bioprosthesis for

Table 49–1.

Risk Factors for Reoperative Valve Surgery

Advanced age
Impaired ejection fraction (EF), congestive heart failure (CHF), or advanced preoperative functional class (NYHA)
Urgency of operation or unstable status preoperatively
Preoperative shock
Concomitant coronary artery bypass graft (CABG) or the presence of previous bypass grafts
Prosthetic valve endocarditis
Surgery for perivalvular leaks, valve thrombosis, or prosthetic dysfunction
Renal dysfunction
Chronic abstructive pulmonary disease (COPD)

primary, isolated aortic valve replacement: (1) the presence of well-established contraindications to continuous anticoagulation, (2) the inability to monitor prothrombin levels adequately, and (3) patients whose survival was limited and more dependent on non-valve–related issues.[18,28] In recent years, however, the use of biologic valves in the aortic position has become more common.[25,26]

As mentioned earlier, reoperations are technically demanding, and many patients present in a poor functional state that further increases their mortality, in some series up to 19%.[34,40,41] Generally speaking, optimal planning for reoperation prior to deterioration to NYHA class III–IV levels and before unfavorable comorbid conditions have arisen is imperative to ensure good outcomes.[42] Following these guidelines in the modern era, elective re-replacement of malfunctioning aortic bioprostheses can be performed with results similar to those of the primary operation.[18,24,43] The Mayo Clinic, for example, recently reviewed its experience with 162 reoperative aortic valve replacements (AVRs). Early mortality for reoperative AVR was not statistically different from that for primary AVR.[44] In light of recent lower operative mortality in reoperative valve surgery, a more conservative approach toward issues such as "prophylactic" AVR in patients with asymptomatic mild to moderate aortic stenosis at the time of coronary artery bypass grafting (CABG) also may be more appropriate.[45]

In evaluating the reoperative patient, the presence of concomitant coronary artery disease and pulmonary hypertension has been shown consistently to be independent risk factors.[18] Patients with these risk factors therefore need careful surveillance once the probability of bioprosthetic dysfunction begins increasing (i.e., 6 to 10 years after implantation).[16] Regarding valve surveillance and timing of reoperation, the following variables are relevant to the clinical management of patients with an aortic bioprosthesis: a history of endocarditis prior to the first operation, perioperative infectious complications, coronary artery disease acquired after the first operation, an increase in pulmonary artery pressure, and a decrease in left ventricular function during the interoperative interval.[18] Proper timing of the reoperation therefore is paramount because duration of clinical signs with a dysfunctional aortic bioprosthesis may be misleading. This is further supported by the fact that the need for emergency reoperation is the most ominous risk factor and consistently yields a high early mortality rate of 25 to 44%.[46]

Approaches and Techniques

Conventional resternotomy

The evolution of cardiac surgery through the last few decades has led to the popularization of various surgical approaches. Thoracotomy, for example, once was used extensively to gain access to mediastinal structures. Then median sternotomy became the standard approach. In reoperative cases, however, repeating the sternotomy carries definite risks. Prior to proceeding with a resternotomy, the relationship between certain anterior mediastinal structures (e.g., the right ventricle and the aorta) and the posterior aspect of the sternum must be assessed carefully.[47] This generally can be visualized on chest radiograph or more accurately with a computed tomographic (CT) scan. Recently, it has been shown that multidetector computed tomographic (MDCT) scanning, in combination with retrospective electrocardiographic gating, can be used as a noninvasive way to assess not only the heart's location in relation to the sternum but also graft location and patency.[48–50]

Exposure of the femoral vessels and preparation for emergency femoral-femoral cardiopulmonary bypass should be considered prior to resternotomy. In cases of heightened concern for right ventricle–graft injury or in cases in which a left internal mammary artery (LIMA) graft is patent, the surgeon should consider the use of cardiopulmonary bypass prior to chest reentry. Sternal wires from the previous operation should be undone carefully but left in place as a safeguard during initial sternal division. An oscillating (not reciprocating) bone saw can be used to divide the anterior sternal table. Most authors recommend dividing the posterior table using a combination of scissors and anterolateral rake retraction.[50–52] Following this, bilateral pleural spaces should be entered inferiorly, followed by careful dissection of other mediastinal structures. The pericardial dissection plane can be developed by starting at the cardiophrenic angle and advancing slowly cephalad and laterally on the surface of the right side of the heart. Cephalad dissection should start with freeing the innominate vein prior to spreading the retractor to avoid its injury. Further dissection then is carried down to the superior vena cava, being careful to note the location of the right phrenic nerve. An area of consistently dense adhesions is the right atrial appendage, and caution should be used here. In addition, great care should be taken to avoid "deadventializing" the aorta. The area where the aorta apposes the pulmonary artery is another site of potential injury.

Repairing small ventricular or atrial lacerations should not be attempted before releasing the tension of the surrounding adhesions. Repair of great vessel injuries or severe right ventricle injuries is best done under cardiopulmonary bypass.[51] Active hemorrhage during a second sternotomy usually is due to adherence of the heart or great vessels to the posterior sternum. Prevention of this ominous complication by interposition of pericardium or other mediastinal tissue at the time of the first operation has been suggested but has debatable relevance.[50] The incidence of resternotomy hemorrhage is between 2% and 6% per patient reoperation.[53–55] In a report of 552 patients who had undergone reoperative prosthetic valve surgery, 23 patients (4%) had complications related directly to sternal opening.[17] Of these, 5 patients had entry into the right atrium, 7 patients had lacerated right ventricles, 9 patients had injuries to the aorta, and 2 patients had a previously placed coronary artery graft divided. Nineteen of the 23 complications occurred during a first reoperation. Overall, there were 2 operative deaths related to resternotomy. The first death involved division of a

previously placed coronary artery graft during reentry. The second death was due to laceration of the aorta with subsequent exsanguination.[17] Of note, prior use of a right internal mammary artery (RIMA) graft can be particularly challenging because it frequently crosses the midline, and extreme caution must be used in first dissecting out this vessel.

Macanus and colleagues reviewed their experience with 100 patients undergoing repeat median sternotomy.[54] Eighty-one patients had one repeat sternotomy, whereas the others had undergone multiple sternotomies. All had had a previous valve procedure and were reoperated on for progressive rheumatic valvular disease or for complications related to the prosthesis. Complications included operative hemorrhage in 8 patients, postoperative hemorrhage in 2, seroma in 4, and dehiscence, wound infection, and hematoma in 1 patient each. There was one operative death directly related to resternotomy hemorrhage.[54] When major hemorrhage does occur on sternal entry, attempts at resternotomy should be abandoned, and the chest should be reapproximated by pushing toward the midline. The patient should be heparinized immediately while obtaining femoral arterial and venous cannulation. Blood loss from the resternotomy should be aspirated with cardiotomy suction and returned to the pump. Once bypass has been established, core cooling should be commenced with anticipation of the need for circulatory arrest. Once cool, flow rates can be reduced, and the remaining sternal division can be completed, followed by direct repair of the underlying injury.[50] Anticipating the possibility of this scenario, we frequently expose peripheral cannulation sites prior to beginning a resternotomy. In cases of heightened concern for right ventricle or graft injury, or in patients with a patent LIMA to left anterior descending (LAD) artery graft, cardiopulmonary bypass and cardiac decompression may be initiated *prior* to sternal reentry. After safe sternal entry, the patient may be weaned from bypass for further dissection of adhesions to avoid prolonged pump times.

Minimally invasive reoperative AVR

Reoperative procedures are challenging owing to diffuse mediastinal and pericardial adhesions. A large incision that increases the operative exposure also has been associated with a higher risk of injury to cardiac structures and coronary artery bypass grafts and results in greater bleeding with its associated transfusion requirements.[56–59] A smaller incision with a limited sternotomy, on the other hand, reduces the area of pericardiolysis, thus mitigating these effects. The intact lower sternum that remains also preserves the integrity of the caudal chest wall, thereby enhancing sternal stability and promoting earlier extubation.[60,61] *Minimally invasive* valve procedures gradually have become more accepted as new technologies and instrumentation have been developed.[60] Reoperative procedures in which there is risk for graft injury are an area where minimally invasive strategies may be of direct benefit.[62,63] Our surgical approach in reoperative AVR is shown in Fig. 49-1.[60] In our series of patients, peripheral cannulation sites were exposed

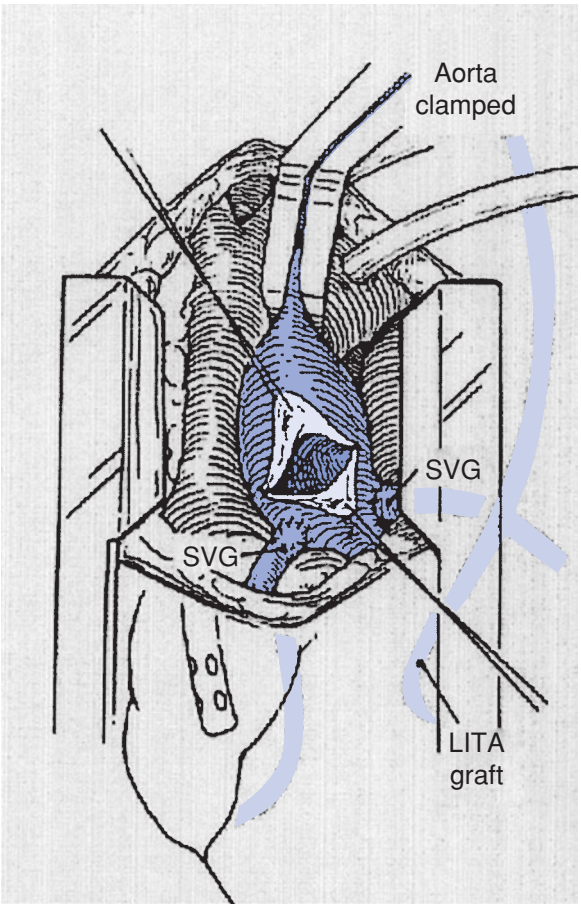

Figure 49-1. Partial upper resternotomy for reoperative AVR. The previous sternotomy incision is exposed to the third or fourth intercostal space depending on the position of the aortic valve, as documented by TEE. After dissection of the ascending aorta, paying particular attention to the position of coronary artery bypass grafts and their proximal anastomoses, cannulation is carried out. In this figure, the ascending aorta and innominate vein are cannulated. Frequently, however, other cannulation sites are required owing to space limitations in the chest. The ascending aorta is cross-clamped, and the aortic valve re-replacement is conducted in a standard fashion. (*Used with permission from Byrne JG, Karavas AN, Adams DH, et al: Partial upper re-sternotomy for aortic valve replacement or re-replacement after previous cardiac surgery. Eur J Cardiothorac Surg 2000; 18(3):282.*

or cannulated prior to beginning the partial upper resternotomy. An external defibrillator was placed on the patient prior to draping for anticipated defibrillation as necessary. Transesophageal echocardiography (TEE) was used in every patient. A partial upper resternotomy was carried out to the third or fourth intercostal space depending on the estimated position of the aortic valve as documented by chest x-ray (CXR)/TEE and then was "T'd to the right."[64] The oscillating saw was used to divide the anterior sternal table, whereas the straight Mayo scissors, under direct visualization, was used to divide the posterior sternal table. In the setting of a patent LIMA-LAD graft or other anterior coronary artery bypass grafts, patients were placed on cardiopulmonary bypass prior to partial resternotomy. Mediastinal dissection was limited to only the ascending aorta as was necessary for

clamping and aortotomy. The right atrium was dissected only if it was cannulated. Although intrathoracic cannulation was preferred, we frequently used peripheral cannulation to avoid clutter in the chest. Retrograde cardioplegia, if necessary, was delivered via a transjugular coronary sinus catheter or with right atrial placement under TEE guidance. Vacuum assistance of venous drainage was used in the majority of patients. Once on cardiopulmonary bypass, all patients were systemically cooled to 20 to 25°C. Patients with patent LIMA-LAD grafts were cooled routinely to 20°C for additional myocardial protection and in so doing avoided the need and potential hazard of dissecting out the LIMA for clamping in an attempt to avoid cardioplegia washout. If flow from the patent LIMA-LAD graft led to significant blood flow out of the coronary ostium and obscured the operative field, pump flows were turned down temporarily to allow visualization. Venting was accomplished by placing a pediatric vent through the aortic annulus. The aortic valve surgery then was performed based on patient indications. While closing the aortotomy, intracardiac air was removed by insufflating the lungs and decreasing flows on cardiopulmonary bypass. Carbon dioxide was used and flooded the operative field. Patients also were tilted from side to side to help with deairing, and the ascending aortic vent was left open until separation from cardiopulmonary bypass. Temporary epicardial pacing wires were placed on the anterior surface of the right ventricle while the heart was decompressed and before the aortic cross-clamp was removed. Two 32F right-angled submammary chest tubes then were placed through the right pleural space, one angled medially into the mediastinum and one angled posterior into the pleural space. Decannulation and closure then were performed in the standard manner.

With our increasing experience in minimally invasive reoperative AVR, we have refined our technique as an alternative to conventional full resternotomy.[60] In so doing, we have ascertained the technical details of the partial upper resternotomy approach (Table 49-2). By following these guidelines, we have yet to convert any patient to a full resternotomy. Lateral CXR and/or TEE is helpful in locating the level of the aortic valve and determining the proximity of the aorta to the posterior aspect of the sternum.[64] If necessary, additional information can be obtained with CT scanning or magnetic resonance imaging (MRI) preoperatively. Also,

Table 49–2.

Thirteen Technical Details for Successful Aortic Valve Replacement After Previous Cardiac Surgery by Use of Partial Upper Resternotomy

1. Routine exposure of peripheral cannulation sites prior to partial upper resternotomy
2. Placement of Zoll (Zoll, Inc., Burlington, MA) defibrillator pads prior to prepping
3. Use of intraoperative transesophageal echocardiography for air removal and inspection of valve
4. In patients with patent left internal mammary artery to left anterior descending coronary artery (LIMA-LAD) graft, peripheral cannulation and cardiopulmonary bypass (CPB) established prior to partial upper resternotomy
5. Mediastinal dissection limited to ascending aorta for clamping and aortotomy and atrium (RA), only if RA is cannulated
6. Use of peripheral cannulation to avoid clutter in the chest
7. Use of vacuum assistance on CPB
8. Use of retrograde cardioplegia (CP) delivered by transjugular retrograde CP catheter in addition to antegrade CP
9. Use of aprotinin unless absolute contraindication
10. Cooling to at least 25°C in all patients primarily for myocardial protection; if a patent LIMA-LAD graft is present, cooling to 20°C without isolation and clamping LIMA graft
11. If visualization is poor due to LIMA-LAD collaterals flowing from coronary ostia, temporary low flows on CPB to improve visualization
12. Venting with a pediatric vent placed through the aortic annulus
13. Placement of temporary pacing wires on the right ventricular free wall before aortic clamp removal

extension of the sternal incision laterally on both sides through the intercostal spaces helps to later reapproximate the sternum. We have tried to limit mediastinal and pericardial dissection primarily to the aorta, believing that this is the principal reason for decreased bleeding and transfusion requirements postoperatively.[60,63,65,66] The right ventricle, which often is attached to the sternum, does not need to be dissected. Also, injuries to patent but atherosclerotic vein grafts can be reduced with this "no touch" technique.[67]

Arterial and venous cannulation sites can vary considerably, reflecting the individual choice of the operating surgeon and the sufficiency of intrathoracic space. Possible cannulation sites, other than standard ones, include the axillary artery, inominate vein, and percutaneous femoral vein.[68,69] Innominate vein or percutaneous femoral vein cannulation, as well as the use of TEE to place the retrograde cardioplegia catheter, has been extremely helpful in minimizing dissection of the right atrium. At present, we consider this approach to be useful for isolated, elective reoperative aortic valve surgery.[60]

Reoperative AVR after homograft/root/allograft

AVR with homografts and autografts was performed increasingly because of excellent freedom from thromboembolism, resistance to infection, and reasonable hemodynamic performance.[29] While improved durability of current tissue valves has slowed this trend, autografts and, to a lesser degree, homografts remain popular in younger patients owing to durability and, in the case of autografts, the potential for growth.[32,70] Consequently, many patients will require aortic valve re-replacement for structural degeneration of their homograft or autograft valve.[71] It is expected that about one-third of patients younger than 40 years of age will require aortic valve re-replacement within 12 years of homograft placement. This is due primarily to calcification and structural valve degeneration. As such, the issue of homograft or autograft durability is particularly pertinent in this subgroup of younger patients who are expected to live beyond 15 years from time of operation.[70]

The incidence of patients with homografts or autografts in need of a second valve operation is expected to increase owing to the aforementioned recent popularity and availability of these conduits. Also, there is varied opinion as to the optimal surgical method of primary homograft AVR, with increased rates of aortic insufficiency in patients with the subcoronary implantation technique. Importantly, the selected technique of primary homograft operation may have relevance at reoperation because calcification or aneurysmal dilatation of the homograft may pose surgical challenges at reoperation. Despite these challenges, Sundt and others[31,72,73] have documented the feasibility of aortic valve re-replacement after full-root replacement with a homograft. In our own series of 18 patients, full-root, mini-root, and subcoronary techniques all were amenable to valve re-replacement.[29]

How to best approach the reoperative root scenario and which valve to reimplant, however, have been debated. At one extreme, Hasnet and colleagues documented the results of 144 patients who underwent a *second* aortic homograft replacement with a hospital mortality rate of only 3.5%.[71] Although Kumar and colleagues, in a multivariate analysis of reoperative aortic valve surgery, did not show that a previous homograft added significant risk,[74] the technical aspects of reoperative AVR in this patient population consistently have been found to be challenging owing to the heavy calcific degeneration that invariably occurs. With this in mind, and owing to the typical absence of the need for a second root operation, we and others[75] believe that a more simplified approach to reoperative aortic valve surgery in patients with previously placed homografts may be optimal. Our approach has been to perform aortic valve re-replacement using a mechanical valve or, less commonly, a stented xenograft while reserving a second homograft and root operation for specific indications such as endocarditis, associated root pathology, or a very young patient with contraindications to a mechanical valve.

Homograft re-replacement nonetheless is performed but is much less common, and hospital mortality varies widely across many centers, ranging between 2.5% and 50%.[31,72,73] David and colleagues, for example, recently reviewed their experience with root operations in 165 patients who previously had undergone cardiac surgery. Of these, 28 had a previous root operation. Overall, 12 operative (7%) and 20 late deaths (12%) occurred.[76] Variations in sample size, valve selection, surgical techniques, and patient factors, as well as the experience of the surgeons, may account for these wide differences.

REOPERATIVE MITRAL VALVE SURGERY

Historical Points

Fundamental to a flawless surgical procedure is excellent and consistent exposure of the mitral valve.[77] Historically, the mitral valve has been exposed through a variety of surgical approaches, including median sternotomy, right thoracotomy, left thoracotomy, and transverse sternotomy.[78] The median sternotomy and right thoracotomy will be discussed in detail below; however, a brief description of the other approaches is warranted.

The *left* thoracotomy has been used in recent years to gain access to the mitral valve in situations in which a right thoracotomy is precluded (e.g., mastectomy/radiation or pleurodesis). This incision is made through the fourth intercostal space, and the left pleural cavity is entered in the standard fashion.[78] Surgery is performed under fibrillatory arrest or with beating-heart technique. Of importance, the mitral valve orientation is noted to be upside down with this approach, with the posterior annulus found anteriorly.[79] Thompson and colleagues recently reported their experience with the beating-heart left thoracotomy approach for reoperative mitral valve surgery. Of the 125 patients undergoing this technique, 86% were in NYHA class III or IV, and 28%

had undergone two or more sternotomies. Thirty-day mortality was 6.4% with low complication rates.[80] While occasionally useful, this approach provides limited access to the other cardiac chambers as well as poor visibility. This left-sided approach is rarely needed and typically reserved for patients in whom reoperative sternotomy or right thoracotomy is considered unacceptable. A bilateral anterior thoracotomy (i.e., transverse sternotomy) carried out through the fourth intercostal space also has been described.[78,81] Rarely used today, this incision transects the sternum transversely, requiring ligation of both internal mammary arteries.

Regardless of the actual approach, once cardiopulmonary bypass has been established and the heart exposed, there are several incisions that can be employed to view the underlying mitral valve. The standard left atriotomy begins with blunt dissection of the interatrial groove (i.e., Waterston's groove), allowing the right atrium to be retracted medially and anteriorly (Fig. 49-2) The right superior pulmonary vein at its junction with the left atrium then is exposed, and the left atrium is opened at the midpoint between the right superior pulmonary vein insertion and the interatrial groove. This incision is extended longitudinally both superiorly and inferiorly to give enough exposure of the mitral valve. Care must be taken to avoid inadvertent injury to the posterior wall of the left atrium, and when closing, one must avoid including the posterior wall of the right pulmonary vein. The right atrial transeptal approach has become more popular in recent years, especially in reoperative valve surgery. After opening the right atrium, the interatrial septum is incised starting at the fossa ovalis and moving vertically upward for a few centimeters (Figs. 49-3 and 49-4). This technique is especially helpful in reoperative surgery because it minimizes the amount of dissection required. Superior biatrial atriotomy, left ventriculotomy, and aortotomy all have been well described[15,59,77,78,82,83] as approaches to the mitral valve; each one has varying advantages and disadvantages.

Approaches and Techniques

Resternotomy

Resternotomy is still the most common approach in reoperative mitral valve surgery. In many cases, this incision provides full and adequate exposure. This is especially true when concomitant procedures are necessary. However, reoperative median sternotomy has known risks, including injury to or embolism from prior grafts, sternal dehiscence, excessive hemorrhage, and inadvertent cardiac injury.[84] Patients with valvular heart disease may be especially prone to these complications because atrial dilatation can result in significant cardiomegaly, atrial thinning, and adherence of the heart to the posterior sternum. As discussed previously, patients undergoing prosthetic valve reoperation have a 4% incidence of complications directly related to sternal reentry that can result directly in intraoperative death.[17,37] Resternotomy also

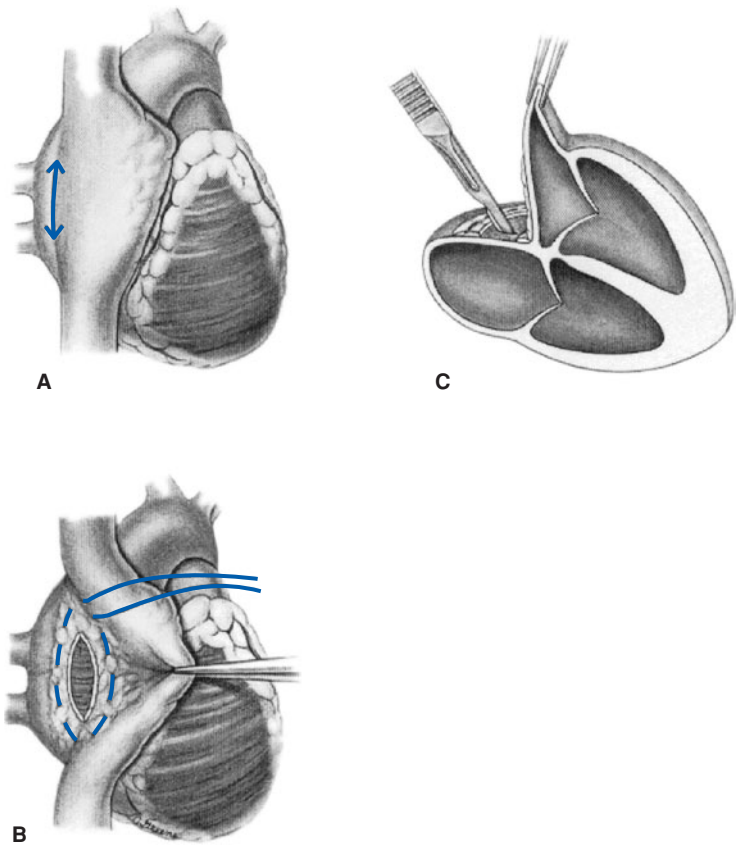

Figure 49-2. Sondergaard's groove approach. The left atrium enlarges to the right, increasing visualization from the right thoracotomy approach. The interatrial groove (Sondergaard's groove) is dissected approximately 1 cm deep, down to the left atrial wall. The purse-string suture is placed in the nondissected area. This prevents tearing of the dissected left atrial wall when the suture is tied down. Sagittal view shows location of the mitral valve in relation to the atriotomy. Figure 49-3. Atrial incision through the fossa ovalis. When the right atrium is incised, an incision is made in the atrial septum through the fossa ovalis. Retraction sutures on both the right atrium and the atrial septum of 2-0 silk then are used to elevate the septum and to keep the left atrium open. The mitral valve then will be exposed (*inset*). (*Used with permission from Byrne JG, Mitchell ME, Adams DH, et al: Minimally invasive direct access mitral valve surgery. Semin Thorac Cardiovasc Surg 1999; 11(3):212.*)

has been noted to be particularly hazardous in the presence of patent internal mammary grafts. Injury to a patent LIMA graft has an associated mortality rate approaching 50%.[50,64] Furthermore, manipulation of patent but diseased saphenous vein grafts can result in embolization into the native coronary circulation with resulting morbidity and mortality.[85,86] Patients with previous aortic valve replacements can have difficult exposure of the mitral valve owing to anterior fixation and probably are best served by an anterolateral thoracotomy approach. In general, in the setting of reoperative surgery, the resternotomy is likely to be the most dangerous part of the operation.[87] In this situation, we also have employed techniques that avoid resternotomy, such as right thoracotomy.

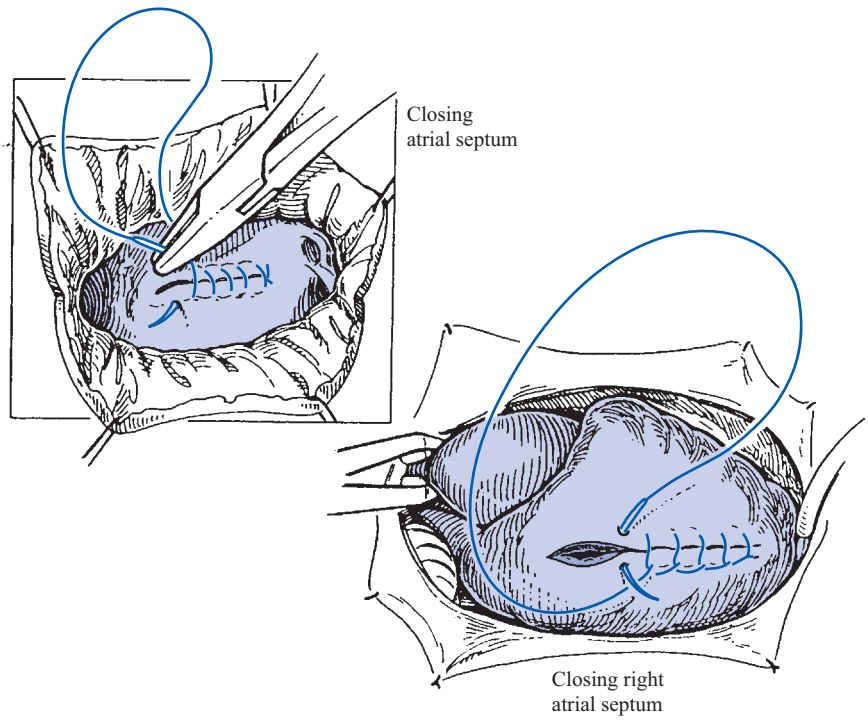

Figure 49-4. Closure. In the transeptal approach, the atrial septum is approximated with running 4-0 Prolene sutures and is left open until the aortic cross-clamp is removed and the air is evacuated. The left ventricle should be filled with fluid before removal of the cross-clamp to help dislodgment of intraventricular air. Once the cross-clamp has been removed, air is evacuated vigorously from the left atrium through the septum or the left atrium itself, and the sutures are tied. The right atrium is then closed with running 4-0 Prolene sutures in two layers. TEE has been very important in helping to monitor the clearing of air from the intracardiac structures. We consider it mandatory in the minimally invasive technique, in which access to the entire cardiac structure is limited. (*Used with permission from Byrne JG, Mitchell ME, Adams DH, et al: Minimally invasive direct access mitral valve surgery. Semin Thorac Cardiovasc Surg 1999; 11(3):212.)*

Right thoracotomy

The right anterolateral thoracotomy approach was one of the first surgical approaches to the mitral valve, and it has become a safe alternative to resternotomy for mitral valve replacement[10,50,88–89] (see Fig. 49-3). This approach provides excellent exposure of the valves (mitral and tricuspid) with minimal need for dissection within the pericardium. In our recent experience with this approach,[87,93–96] all patients had double-lumen endotracheal tubes placed, and operations were performed in the right lateral thoracotomy position. We routinely prepared and draped the right groin to allow femoral cannulation, if necessary. Preoperative and intraoperative Doppler TEE was performed in all patients, as well as standard intraoperative cardiac monitoring and thermodilution Swan-Ganz catheterization. A right thoracotomy was made, and the chest was entered through the bed of the fourth or fifth rib. Adhesions of the right lung to the chest wall or pericardium were divided by electrocautery. The pericardium was entered anterior to the phrenic nerve. Arterial cannulation was performed via the ascending aorta with the use of a flexible aortic cannula or, alternatively, through the groin. Bicaval venous cannulation was carried out with a 28F (DLP) cannula in the superior vena cava and a 32F (USCI) flexible cannula in the inferior vena cava. Patients then were cooled to 20 to 25°C. Fibrillatory arrest occurred spontaneously in the majority of patients. If care is used to avoid left ventricular ejection by keeping the left ventricle empty (i.e., maintaining laminar, nonpulsatile arterial line tracing), a beating-heart technique also may be used. In the absence of aortic insufficiency, aortic cross-clamping usually was not required. Regurgitant flow through the aortic valve occasionally required temporary low pump flow at appropriate temperatures to avoid cerebral injury. The mitral valve then was approached through the left atrium directly by dissection of the intra-atrial (Sundergaard's) groove (see Fig. 49-2) or through the right atrium via the atrial septum (see Fig. 49-4). As the valve procedure was completed, rewarming was initiated (Fig. 49-5). Carbon dioxide (CO_2) can flood into the field and be infused directly into the left atrium and left ventricle to reduce the time spent de-airing. In addition, perfusing blood via a cannula (e.g., the left ventricular vent) positioned across the mitral valve and into the left ventricle will serve to displace residual air. An aortic root vent kept on suction in the ascending aorta is used to remove any ejected air. Patients then were placed in the Trendelenburg position and de-airing ascertained under 2D TEE guidance. When core temperatures reached 37°C, the patient was weaned from cardiopulmonary bypass. Temporary atrial and ventricular pacing wires were placed and exteriorized through the chest wall. Closure then was routine. At the conclusion of the procedure, patients were returned to the supine position and reintubated with a single-lumen endotracheal tube for postoperative ventilation. The use of a small right anterior thoracotomy, femorofemoral bypass, and deep hypothermia has increased since our initial report in 1989.[97] Reduced blood use and decreased risk of LIMA or cardiac structural injury

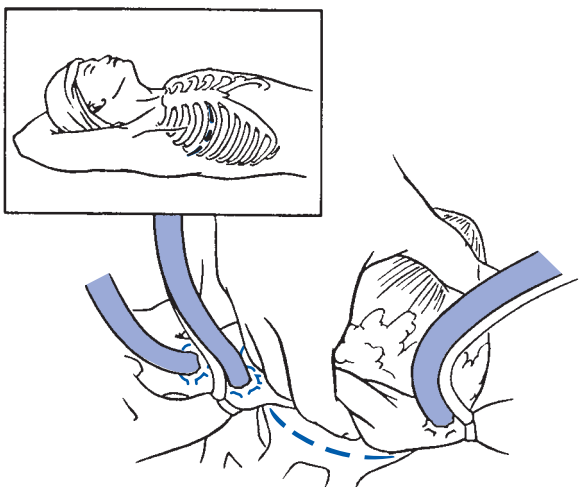

Figure 49-5. Right anterolateral thoracotomy through the fourth intercostal space and standard left atriotomy. (*Used with permission from Balasundaram SG, Duran C: Surgical approaches to the mitral valve. J Card Surg 1990; 5(3):163.*)

during sternal reentry make it a desirable approach for many complicated mitral reoperations. Deep hypothermia (~20°C) and low-flow femorofemoral bypass perfusion, without the necessity of aortic cross-clamping, provide adequate myocardial protection.[98] Cardiopulmonary bypass times, blood loss, blood product usage, and LIMA injury rates have been lower in reoperative patients undergoing right thoracotomy than in those with resternotomy.[37,80,83,90,98,99]

Certain issues must be considered before the right thoracotomy approach is entertained. Patients who require simultaneous coronary artery bypass grafting generally will require a median sternotomy, although isolated right-sided grafting may be performed with a thoracotomy. Simultaneous replacement of the aortic valve is difficult from a thoracotomy approach and generally should be performed through a resternotomy. Significant aortic insufficiency can make effective perfusion on cardiopulmonary bypass difficult because, after opening the left atrium, blood will be returned to the pump via the cardiotomy suction. Unless the ascending aorta is clamped, effective end-organ perfusion will not be achieved. Also, in the setting of aortic insufficiency (AI), exposure of the mitral valve may be difficult owing to this regurgitant flow into the surgical field. Left ventricular distension and myocardial stretch injury also can occur with fibrillatory arrest in patients with and occasionally without AI. Patients with greater than minimal aortic insufficiency therefore should either be excluded from a right thoracotomy approach or expected to require aortic cross-clamping either with traditional clamping or rarely with balloon occlusion. Significant right pleural disease, especially scarring in the right hemithorax, previously has been a relative contraindication to a right thoracotomy, although our series includes two patients with a previous right thoracotomy who did not represent an overwhelming challenge.[84]

Holman and colleagues[100] reported their experience in 84 patients undergoing reoperative mitral valve surgery via right thoracotomy. Myocardial management included ventricular fibrillation in 10 patients, a beating-heart procedure in 58 patients, and hypothermic blood cardioplegia in 16 patients. The mean duration of cardiopulmonary bypass was 63 ± 56 minutes. There were no perioperative strokes, and the operative risk for patients who received cardioplegic arrest was significantly greater than in the other two groups ($p = .007$). The authors concluded that procedures on the beating or fibrillating heart were feasible in most patients and are at least as safe as surgery using cardioplegic arrest.[100]

Minimally invasive/port access right-sided techniques

A final approach to the reoperative mitral valve is with minimally invasive or port access techniques. From January 2000 to July 2005, 517 patients underwent a simplified port access mitral valve procedure performed by one author (MRP) at St. Thomas Hospital in Nashville, TN. Of these 517 patients, 110 (21%) had a previous sternotomy, with 58 (11%) having a previous mitral valve procedure. All 110 operations were done with a 5-cm anterolateral thoracotomy incision through the fourth or fifth interspace under hypothermic fibrillatory arrest. Standard single-lumen endotracheal intubation was used. Cardiopulmonary bypass was instituted via femoral cannulation and vacuum-assisted venous return. Twenty-three patients (21%) had an ejection fraction of less than 30%, and 7 (6%) had an ejection frcation of less than 20%. There were no operative deaths. Skin-to-skin operative times averaged 3 hours and 18 minutes. Thirty-two percent of the patients were discharged in 5 days or less and 68% in 7 days or less (Dr. Michael R. Petracek, personal series, unpublished data). By not cross-clamping, the need for cardioplegia is eliminated, and there is minimal myocardial ischemia. The only dissection is at Waterston's groove; therefore, bleeding is decreased.

Some authors have noted that the distance to the mitral valve with the right thoracotomy approach at times can be limiting. Broaching this issue, Chitwood and colleagues recently reported use of a minithoracotomy aided by the voice-activated robotic camera AESOP.[101] Vleissus also reported 22 patients who underwent a "minimally invasive" right thoracotomy approach to the atrioventricular valves.[69] The procedures performed included mitral valve repair ($n = 12$), mitral valve replacement ($n = 5$), prosthetic mitral valve re-replacement ($n = 4$), repair of a perivalvular leak ($n = 3$), tricuspid valve repair ($n = 5$), and closure of an atrial septal defect ($n = 7$). Mean bypass time was 109 minutes with a mean fibrillatory time of 62 minutes. Operative mortality in this group was 0%, and none of the patients experienced a wound complication. At follow-up, all reoperative patients thought that their recovery from this approach was more rapid and less painful than their original sternotomy.[102] Burfeind and colleagues recently reviewed Duke University's experience with the port access technique.[103] In their series of 60 patients, a 6-cm right anterolateral thoracotomy was used with standard port access technique. Forty-five percent of patients underwent cardiac arrest with the endoclamp technique, whereas ventricular fibrillation was used in 55% of patients. Femoral cannulation was used in all patients. When compared with concurrent cohorts of patients undergoing reoperative sternotomy or right anterolateral thoracotomy, patients undergoing the port access technique had lower mortality and decreased transfusion requirements but significantly longer cardiopulmonary bypass times. While similar results have been found by other groups, one should be mindful of the potential hazards of the port access technique, namely, endoclamp migration.[104–107]

Additional techniques of reoperative mitral surgery

A less common indication for reoperative mitral valve surgery but one that can be challenging is periprosthetic leak. The incidence of perivalular leak for both mechanical and biologic valves is about 0 to 1.5% per patient-year. Of note, perivalvular leak is slightly more common with mechanical than with tissue valves-possibly owing to differences in suture technique for each and sewing ring characteristics. The regurgitant flow across the perivalvular area frequently leads to hemolysis and, through denuding of the endocardium, endocarditis. The antibacteriocidic Silzone coating on St. Jude prostheses has been shown recently to have a particular predilection for this complication.[108]

In evaluating patients with a periprosthetic leak, an assessment of valve function is important. If the valve itself is competent, direct repair of the leak avoids the hazards of valve replacement. While pledgeted suturing may be attempted for smaller leaks, fibrotic tethering of surrounding tissue and the size of the defect may require a bovine or autologous pericardial patch. In cases of significant dehiscence or associated valvular dysfunction, removal of the valve is necessary. Replacement in this situation, however, is prone to leak recurrence because the annulus is partially intact, often calcified, and otherwise less than ideal for suture placement. In these cases, a bovine pericardial skirt can be fashioned and sewn to the sewing ring of the valve. Annular sutures then are placed in a typical fashion through the sewing ring, and the valve is seated. A running suture then can be used to sew this skirt to the left atrium (Fig. 49-6).

An additional risk of reoperative mitral valve replacement is atrioventricular disruption. Care must be used in removing the original valve sewing ring because it is frequently "socked in," and inadvertent removal of excessive annular tissue may occur. Any evidence of disruption of the posterior annulus necessitates patch repair with pericardium (autologous or bovine) prior to placement of annular sutures.[109] When faced with less than ideal annular tissue, and in an attempt to ensure stability, bites must not be overly aggressive in depth. Left circumflex injury can occur and will lead to significant morbidity and mortality (Fig. 49-7). When removal of the old sewing ring will result in severe annular disruption, the ring may be left in place and used as a "neoannulus" for suturing.

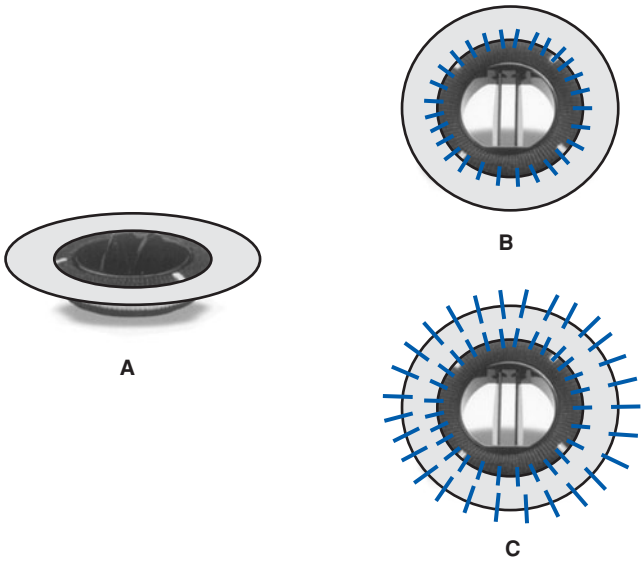

Figure 49-6. Pericardial skirt. Bovine pericardium can be fashioned as a skirt (*A*) and sewn to the sewing ring of the mitral prosthesis (*B*). Standard annular valve sutures are then taken through the sewing ring, the valve is seated, and the skirt is sewn to the left atrium with running technique (*C*). (Carbomedics mechanical valve shown.)

The benefits of preservation of the subvalvular apparatus have been clearly demonstrated during first-time mitral valve replacement.[110] Aside from improved contractile function, disruption of the posterior mitral annulus is avoided. David and colleagues found that preservation of the subvalvular apparatus is also important in reoperative patients.[111] Of 513 reoperative mitral valve replacements, preservation of the posterior subvalvular apparatus was accomplished in 103 (21%) patients, with anterior and posterior preservation occurring in 31 patients (6%). Gore-Tex neochordal construction was performed in 135 reoperative mitral valve replacement patients (26%). Perioperative mortality occurred in 3.6% of redo patients with a preserved subvalvular apparatus (native tissue and/or Gore-Tex reconstruction) versus 13.3% of redo patients without preservation ($p < .001$). Attempts at preservation of the subvalvular apparatus in reoperative patients therefore should be made.

REOPERATIVE TRICUSPID VALVE SURGERY

The need for reoperative tricuspid valve surgery most frequently occurs in high-risk patients. In a recent series of tricuspid valve replacements (TVR) by Filsoufi and colleagues,[112] 72% ($n = 58$) were reoperations. The overall operative mortality in this group was 22% ($n = 18$). Risk factors for mortality included urgent/emergent status, age greater than 50 years, functional etiology, and elevated pulmonary artery pressure. Of the 60 survivors, 26 (43%) died during follow-up. The authors concluded that patients requiring TVR are at high risk, frequently at end-stage functional class. As such, serious consideration of the risks should occur prior to embarking on such procedures.

Tricuspid valve endocarditis is most commonly the result of seeding of the tricuspid valve leaflets during sustained bacteremia.[114] Continued sepsis despite antibiotic therapy, heart failure owing to tricuspid insufficiency, and recurrent multiple pulmonary emboli are indications to intervene surgically in tricuspid valve endocarditis. Complete excision of the tricuspid valve (without subsequent replacement) was first advocated by Arbulu and colleagues.[115] From an infectious disease standpoint, this surgical approach has the obvious advantage of complete extirpation of the infected tissue and avoids placement of any prosthetic material. Although it is tolerated initially, the extirpation procedure inevitably leads to late-onset right-sided failure in the majority of patients.[115,116,117] In a 20-year follow-up of the originally reported series of 55 patients with intractable right-sided endocarditis who underwent tricuspid valvectomy without replacement, 2 patients (4%) died in the

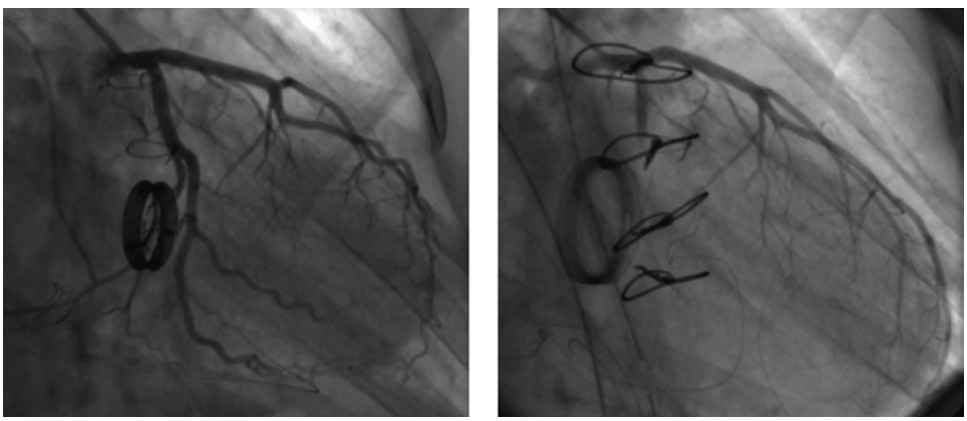

Figure 49-7. Left circumflex artery injury. Preoperative (*left*) and postoperative (*right*) angiograms demonstrating excessive depth of annular sutures leading to left circumflex occlusion.

Table 49–3.

Technical Considerations for Reoperative Valve Surgery
Consider reoperation prior to decline in functional status (NYHA class). Assess RV/aortic proximity to sternum preoperatively with CXR or CT scan
Consider alternate approaches (especially with patent bypass grafts) Right thoracotomy for reoperative MVR Mini-sternotomy for reoperative AVR
Consider alternate cannulation techniques to gain safe entry, e.g., groin, axillary
Address the LIMA-LAD graft if present Dissect it out and clamp it, or Cool and ignore it
Consider ease of implantation in valve choice, e.g., mechanical in homograft
Use "no-touch" technique of bypass grafts
Use a conservative myocardial protection strategy Antegrade and retrograde Systemic cooling Glutamate-aspartate Warm induction/final dose ("hot shot")
If using hypothermic fibrillatory arrest, beware of AI leading to LV distension and/or obscuring operative field
Place external defibrillator pads
Consider the use of antifibrinolytic agents, e.g., aprotinin, amicar

postoperative period owing to right-sided failure. Six patients (11%) required prosthetic valve insertion 2 days to 13 years later for medically refractory right-sided heart failure. Of those who underwent reoperation ($n = 6$), 4 (66%) died. As such, severe hepatic congestion and the need for reoperative valve replacement have made this approach (without replacement) untenable to some practitioners. An alternative treatment option is to perform valvectomy followed by delayed valve replacement 3 to 9 months later.[118,119]

THE HYBRID APPROACH

Recently, hybrid approaches that combine percutaneous intervention (PCI) and valve surgery have been advocated for high-risk reoperative patients. In Byrne's[117] series of 26 patients undergoing initial PCI of culprit lesions followed by valve surgery (*staged hybrid* approach), almost half (46%) the patients underwent reoperation. In this way, surgical time and complexity were minimized. As a consequence, a marked reduction in mortality was observed (3.8%) compared with the predicted mortality calculated by STS algorithms (22%, range 3.5 to 63.5%). These results and those of other similar reports have led to popularization of the hybrid approach to reoperative valve surgery, as well as prompting the creation of hybrid operating rooms (combined catheter laboratory and operating room) throughout the United States.

CONCLUSION

The most common indication for valve re-replacement is structural valve degeneration of a bioprosthesis.[4] After 8 to 10 years of follow-up, biologic valves begin to deteriorate structurally, especially in young patients and in the mitral position, which exposes the valve to higher pressure gradients than seen by the aortic valve. Close follow-up therefore should be encouraged in these patients to avoid missing early degeneration. When patients have been allowed to degenerate into higher NYHA classes, the mortality of reoperative surgery is affected directly (see Table 49-3).

CHAPTER 50

Valvular and Ischemic Heart Disease

Martin LeBoutillier, III • Verdi J. DiSesa

In recent years, there has been a great deal of progress in coronary artery surgery, nonsurgical treatment of coronary artery disease, and the surgical treatment of valvular heart disease. As thoroughly described in previous chapters, surgery on the beating heart has become commonplace. Interventional therapies for coronary artery obstruction have extended to multivessel disease and continue to change the number and the nature of patients referred for bypass surgery. The options for treatment of valvular disease have continued to expand with advances in techniques for repair of aortic and mitral valves, as well as increases in the choices of valve type for replacement. Other areas of rapidly growing interest are surgical treatment of atrial arrhythmias and the surgical approach to the failing ventricle in dilated ischemic cardiomyopathy. Some of these topics will be discussed in subsequent chapters. All are issues that the surgeon must consider when planning strategy for the treatment of the patient with combined valvular and coronary artery disease. More patients are now presenting with increasingly complex pathology. It is less often that the surgeon sees a patient with simple aortic stenosis and proximal coronary artery disease. Rather, that patient now may have been managed with more aggressive medical therapy or even catheter interventions, and is referred at an older age and is sicker, with more diffuse disease, arrhythmias, and worsening ventricular function. As a result those patients who present for surgery have a higher-risk profile than was previously the case, and require a more flexible and thoughtful approach.

The interaction between the pathophysiologies of valvular heart disease and coronary artery disease is complex. Valvular heart disease alters ventricular function. Coronary artery disease may have an additional impact because of its potential to affect ventricular morphology and physiology. In addition to decreases in contractile strength, regional myocardial infarction may lead to distortion of ventricular shape with resulting effects not only on ventricular function, but also on mitral valve performance. In patients with valvular heart disease, coronary obstructions may be symptomatic or asymptomatic, but the decision to intervene surgically is often made regardless of the presence of symptoms and in order to have a positive effect on the pathophysiology of both diseases.

Under most circumstances, surgeons attempt to treat both valvular and coronary artery diseases simultaneously. At the least, this makes for a longer and more complicated operation with longer myocardial ischemia times. Because of this, combined coronary artery and valve operations usually have a higher risk for early and late mortality than operations for valvular heart disease alone (Fig. 50-1). The increased complexity increases the need for careful preoperative assessment of myocardial function and an understanding of the impact of the changing afterload and preload associated with valve surgery on ventricular function. Therefore, in adult patients with combined valvular and ischemic heart disease, the assessment of intrinsic left ventricular function assumes paramount importance. Clinical signs and symptoms of left ventricular failure should be sought. In addition to history, physical examination, and routine lab tests, preoperative echocardiography is mandatory. Transesophageal echocardiography allows for accurate planning when operative repair is considered. It is also important to distinguish heart failure due to valvular disease from reversible or irreversible myocardial dysfunction due to coronary ischemia. Dobutamine stress echocardiography may be useful in eliciting ventricular size and shape changes that occur under stress and any resultant exacerbation of underlying valve pathology. At cardiac catheterization, left ventricular end-diastolic pressure and pulmonary pressures give additional information about left and right ventricular function and supplement noninvasive evaluation of valve function and coronary anatomy. In centers where it is available, positron emission tomography (PET) scans help detect areas of viable myocardium with reversible ischemia and ischemic dysfunction, as distinguished from

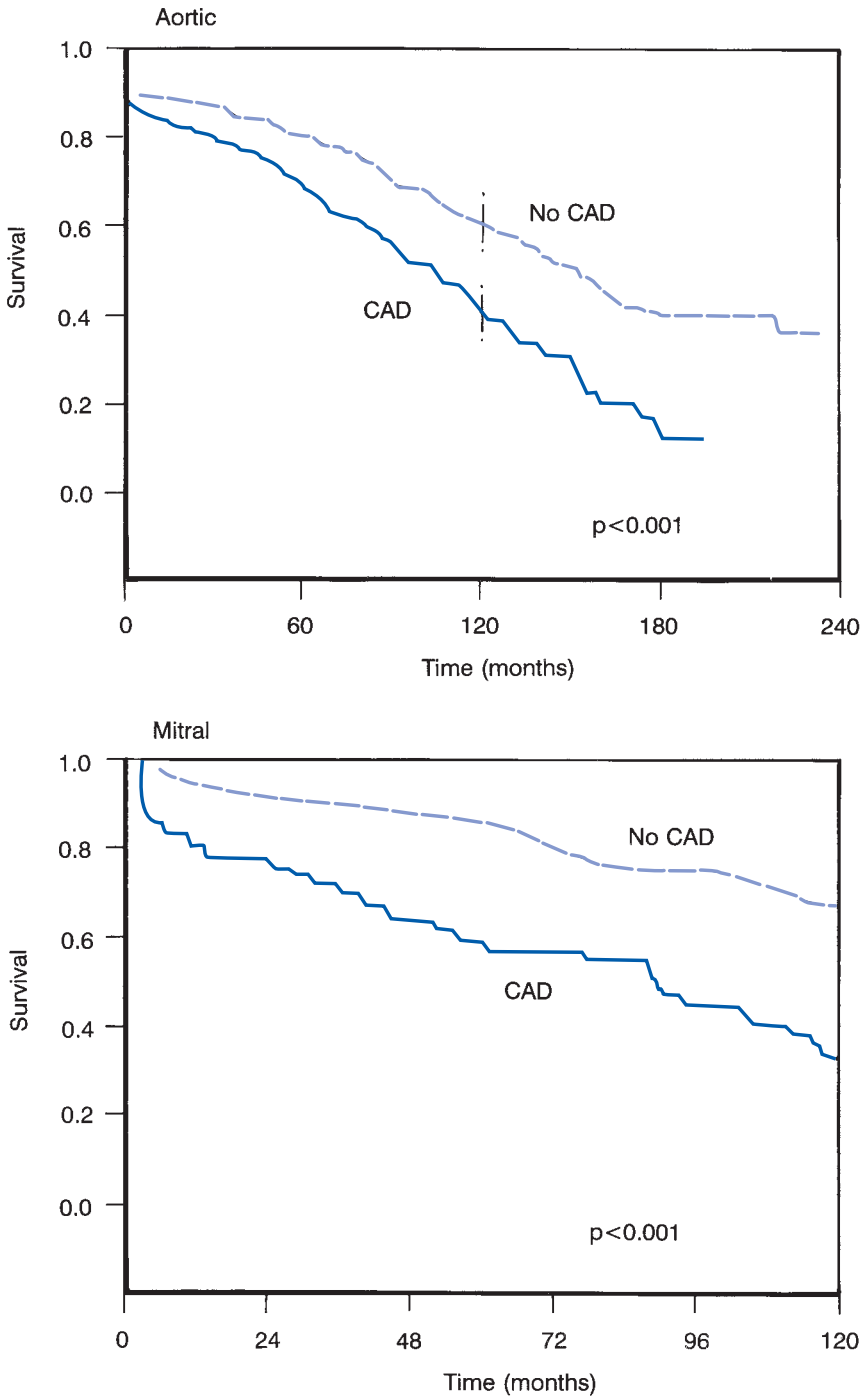

Figure 50-1. Survival after aortic or mitral valve replacement in patients with and without coronary artery disease (CAD). In both cases, long-term survival is significantly worse in patients with coronary disease. (*Adapted with permission from Jones EL, Weintraub WS, Craver JM, et al: Interaction of age and coronary disease after valve replacement: Implications for valve selection. Ann Thorac Surg 1994; 58:378.*)

irreversibly scarred muscle. These assessments are important prior to embarking on combined valve and coronary artery surgery, for they are crucial in estimating operative risk and planning the operative approach.

The assessment of valve pathology is covered in detail in previous chapters on isolated valvular heart disease. As has been noted earlier, coronary angiography is not necessarily required in all patients with valvular pathology who are about to undergo valve surgery. However, given the prevalence of coronary artery disease in aging Western populations, a high index of suspicion leads to the generalized use of coronary angiography in all patients over 40 years of age, and in select younger patients as well.

With present technology and techniques, myocardial revascularization can be added to any valve operation. For the most part, all that is needed is a rational approach, more time, and good myocardial protection. Because of the wide pathophysiologic spectrum of valvular and coronary artery diseases, several frequently encountered valve and coronary artery combinations are considered in this chapter, including (1) aortic stenosis with coronary artery disease (CAD), (2) aortic regurgitation plus CAD, (3) mitral regurgitation plus

CAD, (4) mitral stenosis plus CAD, (5) aortic stenosis and mitral regurgitation plus CAD, and (6) aortic regurgitation and mitral regurgitation plus CAD. Of course, patients may have combined lesions of stenosis and insufficiency, but to avoid unproductive complexity, and because one lesion usually dominates, the somewhat arbitrary categorization noted above will be maintained during the ensuing discussion. For each entity, the clinical presentation, the pathophysiology of the disease state and its correction, the operative and management approach, and short- and long-term results are discussed.

AORTIC STENOSIS AND CORONARY ARTERY DISEASE

Aortic stenosis is one of the more frequently encountered valvular lesions in adult populations. Since degenerative calcific aortic stenosis is most common in patients in their 60s, 70s, and 80s,[1,2] and since congenitally bicuspid valves that become stenotic are more frequent in men who are susceptible to CAD at an earlier age,[3] it is not surprising that the combination of aortic stenosis and CAD is encountered frequently. This disease combination is usually gratifying to treat because the response to surgical relief of aortic stenosis and coronary artery obstructions is significant, immediate, and relatively durable.

Clinical Presentation

Patients with aortic stenosis are asymptomatic initially, but eventually present with angina pectoris, congestive heart failure, syncope, or some combination of these. When significant coronary artery obstructions are present in addition to valvular obstruction, angina pectoris is almost always present. However, angina pectoris can occur in the absence of significant coronary artery obstructions. It is relatively easy to identify symptoms of myocardial ischemia or congestive heart failure in these patients. Neurologic symptoms may be more difficult to elicit, and careful questioning regarding transient symptomatology is required. Symptoms suggestive of carotid artery obstruction should be sought. Specific studies of the carotid arteries may be necessary, especially since the murmur of aortic stenosis may radiate into the carotids and obscure the detection of bruits.

Prominent findings on physical examination include the typical crescendo/decrescendo systolic murmur heard in the aortic area. Signs of congestive heart failure with rales and edema may be present. The electrocardiogram may show left ventricular strain. If the patient suffered recent or old myocardial infarction, electrocardiographic abnormalities typical of infarction also may be present. The echocardiogram typically shows calcified and immobile aortic valve leaflets producing a constricted aortic orifice with the resultant hypertrophied left ventricle. All patients with angina pectoris and all patients with aortic valve disease who are over 40 years of age should have coronary angiography to define coronary anatomy. Right- and left-sided heart catheterization should be performed simultaneously so that complete evaluation of myocardial performance, including measurement of left ventricular end-diastolic pressure and the pulmonary artery pressure, can be obtained. The transaortic valvular gradient also can be determined at catheterization.

The preoperative evaluation of patients with aortic stenosis, coronary artery disease, and poor ventricular function is complicated. Patients with poor ventricular function often generate relatively low transaortic valve gradients. This renders the calculation of valve area and the assessment of critical aortic stenosis less accurate. The morphology of the valve with immobile leaflets and heavy calcification as seen on echocardiography is often an important confirmatory sign that critical aortic stenosis is present. Even in the presence of a small gradient, if echocardiographic signs of significant valve stenosis are present, and if left ventricular intracavitary pressure exceeds 120 mm Hg in systole, mortality rates are acceptable, and response to valve replacement surgery is usually good. A poorly contractile, thinned-out ventricle with low transvalvular gradient and low intracavitary systolic pressure usually suggests that the operation is of high risk and may be of limited or no benefit. A poorly contractile ventricle with normal or increased wall thickness may recover contractile force if a substantial amount of reversibly ischemic myocardium is present and if the degree of aortic stenosis is significant. In addition to ventricular function, other important determinants of the risks and advisability of surgery include patient age, presence of previous cardiac operations, and overall organ function, especially renal function.

The optimal management of a patient with coronary artery disease and mild or moderate aortic stenosis presently remains a matter of some controversy. The dilemma is whether to subject a patient to the lifelong limitations of a valve replacement procedure which may not be necessary, or the prospect of a repeat cardiac operation, perhaps in only a few years, should the aortic stenosis progress.

There is now evidence that favors valve replacement in patients with moderate aortic stenosis who are referred for surgical myocardial revascularization.[4–6] In one study,[4] survival rates at both 1 year and 8 years were superior for patients who underwent valve replacement for moderate aortic stenosis (gradient >30 mm Hg or gradient <40 mm Hg with valve area between 1.0 and 1.5 cm^2). One-year survival was 90% in those having valve replacement compared to 85% in patients having coronary artery bypass graft (CABG) alone. Similarly, 8-year survival (55% versus 39%) was statistically significantly better ($p < .001$).

The rate of progression of aortic stenosis may also provide an indication for valve replacement even without hemodynamically critical disease.[6] For slow progression (<3 mm Hg per year), isolated CABG is preferred for patients with valve gradients <50 mm Hg. In contrast, rapid progression (more than 10 mm Hg per year) favors valve replacement at the time of CABG surgery. One possible exception is in octogenarians with valve gradients <25 mm Hg. Of course, other

individual patient characteristics (life expectancy and other significant comorbidity) may influence the decision as to whether to replace the aortic valve at the time of revascularization surgery.

Pathophysiology

Aortic stenosis produces high ventricular afterload, which ultimately is the source of all the symptoms and signs of aortic stenosis. Most patients with aortic stenosis have hypertrophied and thick-walled left ventricles. Contractile function is initially good, and ejection fraction may be maintained. In later stages of the disease, the ventricle begins to fail with enlargement and global diminution of contractile function. At any stage of the disease, the presence of critical coronary artery obstruction can cause regional wall motion abnormalities. Significant three-vessel CAD of long-standing duration may itself lead to global ventricular dysfunction.

In patients with critical aortic stenosis and good ventricular function, the increased left ventricular afterload is immediately reduced by valve replacement. Since most patients with aortic stenosis have hypertrophied and thick-walled ventricles, intraoperative subendocardial ischemia is more difficult to avoid during aortic cross-clamping. Although revascularization should not decrease left ventricular contractility and may increase it, some myocardial stunning with a temporary decrease in global and regional left ventricular contractility inevitably results from the surgical procedure.[7–10] This, of course, assumes more important pathophysiologic significance in patients with poor ventricular function preoperatively.

Postoperatively, patients may have dramatic improvement in symptoms. Relief of left ventricular outflow obstruction immediately leads to enhanced cardiac output and perfusion of vital organs. In addition, left ventricular function improves both immediately and over time after relief of outflow obstruction and as remodeling ensues. Correction of myocardial ischemia can lead to recruitment of formerly hibernating myocardium[10] with further enhancement of ventricular function.[3]

Operative Management

Monitoring for surgery of the aortic valve and coronary arteries includes catheters and measurements that have become standard for most cardiac surgical operations. These include arterial lines (usually in the radial artery for blood pressure and blood gases) and a pulmonary artery catheter for measurement of pulmonary artery pressures, and cardiac output by thermodilution, with optical sensors for continuous estimation of mixed venous oxygen saturation. While the pulmonary artery catheter has a balloon at its tip, occlusion wedge pressure is rarely measured in the perioperative period because of the danger of pulmonary artery rupture. Particularly useful information is provided by continuous measurement of mixed venous oxygen saturation.

The perfusion setup is standard and similar to that for isolated coronary artery bypass (Fig. 50-2). A single aortic cannula is ordinarily placed in the distal ascending aorta. A single two-stage venous cannula is placed via the right atrial appendage with its tip positioned in the inferior vena cava. After establishment of cardiopulmonary bypass, the patient is usually cooled to 32 to 34°C, during which time a left ventricular vent is positioned via the right superior pulmonary vein. With the heart well emptied, the aortic cross-clamp is applied during a temporary reduction in pump flow. Thereafter, the heart is arrested with cold (4°C) potassium blood cardioplegia and topical irrigation is applied with iced saline solution. After the aorta is opened, the endocardium is intermittently irrigated with iced saline solution to enhance myocardial cooling.

A combination of antegrade and retrograde cardioplegia is optimal. The initial dose of cardioplegia usually is given both ways, half antegrade and half retrograde. Approximately 15 mL/kg is given as the initial dose. Subsequent doses of cardioplegia are given retrograde throughout the operation. This is particularly convenient because retrograde cardioplegia can be given even after the aortic root is opened without significantly disrupting the flow of the operation. Cardioplegia may also be given antegrade via radial and vein grafts after they are attached. This is especially important if a graft has been placed in the right coronary system, as retrograde cardioplegia may not fully protect the right ventricle.

The left internal mammary artery is almost always used to graft the left anterior descending artery when it has a significant obstruction. In general, reversed greater saphenous veins and radial arteries are used for other bypass grafts. The reasoning behind the choice of valve prosthesis is nearly identical to that used in the treatment of isolated valvular heart disease. Any type of prosthesis may be used. However, several issues must be considered. The indications for all types of tissue valves are stronger, as these patients' life expectancies are often shorter. However, these sicker patients may not tolerate well the longer clamp times necessary for the more complex implantation of nonstented tissue valves.

The multiple steps in the combined operation follow a logical sequence. After establishment of cardiopulmonary bypass and insertion of the left ventricular vent, the aorta is clamped and the heart arrested with antegrade and retrograde cold blood cardioplegia and topical hypothermia with iced saline. The first step in the operation is performance of the distal radial artery and saphenous vein bypass grafts. When these are complete, the ventricles may be wrapped in a cooling pad, after which the aorta is opened and aortic valve replacement is carried out using the prosthesis of choice. The aorta is closed completely at this point. The distal anastomosis of the internal mammary artery graft is then made. Following completion of this, air is evacuated from the heart and the aortic cross-clamp is released. A partially occluding clamp is applied to the aorta, and proximal anastomoses are performed when necessary. Alternatively, the proximal anastomoses can be performed with the aortic cross-clamp still in place. While this prolongs the ischemia time, it avoids

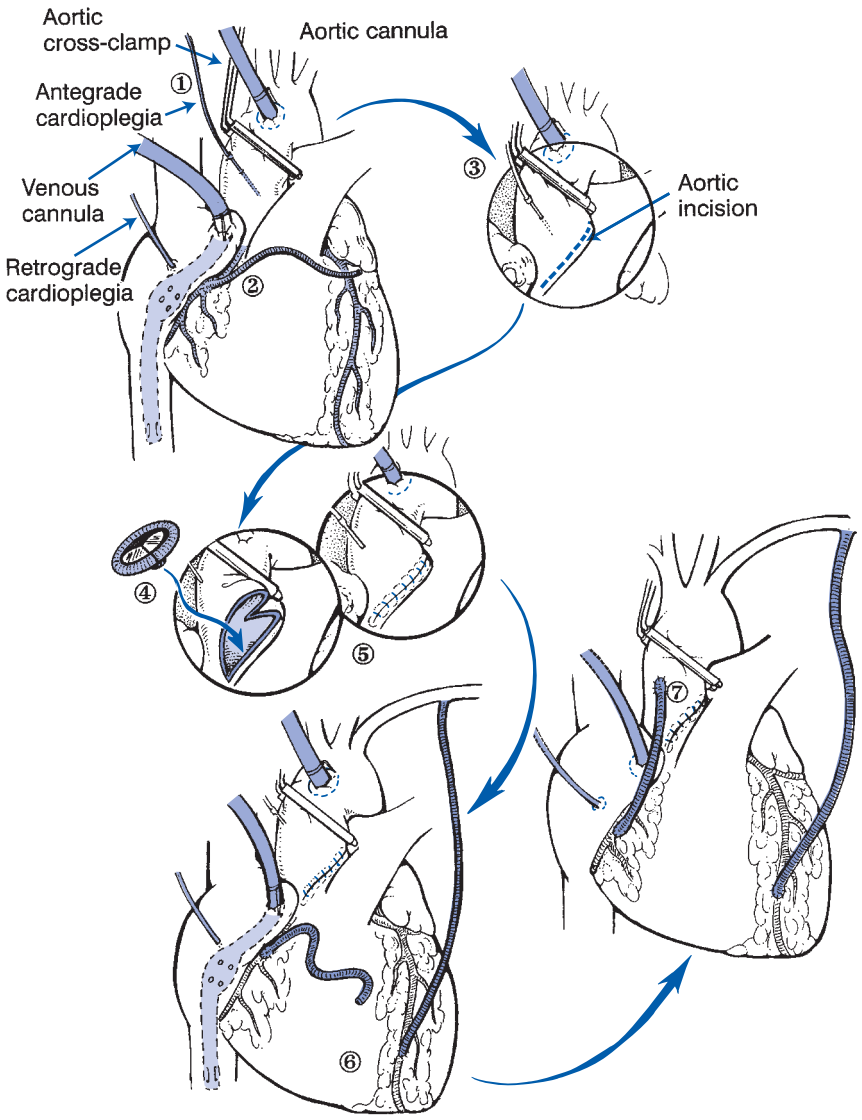

Figure 50-2. Operative sequence for aortic valve replacement and coronary artery bypass grafting. (1) The aorta is cross-clamped and cardioplegia administered antegrade and retrograde. (2) Distal graft anastomoses are performed. (3) The aortotomy is made with an oblique incision into the noncoronary sinus of Valsalva. (4) Aortic valve replacement is carried out using the prosthesis of choice. (5) The aortotomy is closed. (6) The distal mammary artery anastomosis is performed. (7) The proximal graft anastomoses are done. In this case, the proximal anastomoses are done with the aortic cross-clamp in place.

application of a second clamp to the aorta with the potential for disruption of atheromatous debris or injury to the aortic suture line. This consideration is particularly important in patients undergoing reoperations, since the presence of previous bypass grafts can make application of a partially occluding clamp on the aorta difficult. Coordinated sinus rhythm is established after temporary atrial and ventricular pacing wires are positioned. After de-airing is confirmed by transesophageal echocardiography, the left ventricular vent is removed. Of note, atrial-ventricular sequential activation is particularly important to optimize hemodynamic performance in patients with aortic stenosis, because as much as 30% of the cardiac output may be derived from atrial kick as a result of the hypertrophied and noncompliant ventricle that is typical of the patient with aortic stenosis.

Weaning from cardiopulmonary bypass is performed gradually with stepwise diminution of pump flow and increased left ventricular filling. Simultaneous monitoring of the appearance of the heart, pulmonary artery and systemic blood pressures, and mixed venous oxygen saturation is done during weaning. In patients with hypertrophied ventricles, it may be important to keep the left ventricle filled to prevent excessive left ventricular outflow tract obstruction in systole and to provide adequate preload in the noncompliant heart.

In patients with particularly severe ventricular dysfunction who do not wean from bypass, the intra-aortic balloon pump may be used. Two to three attempts to wean from cardiopulmonary bypass using inotropic drugs should be made over a period of 20 to 30 minutes. If weaning from cardiopulmonary bypass is not successful at this point, an intra-aortic balloon pump should be inserted. In some patients, a ventricular assist device is required. Persistent attempts to wean from bypass without mechanical support may be counterproductive because complications from prolonged cardiopulmonary bypass may ensue beyond 30 minutes of elapsed time. As the hypertrophied heart recovers following the ischemic insult, inotropic and mechanical support often

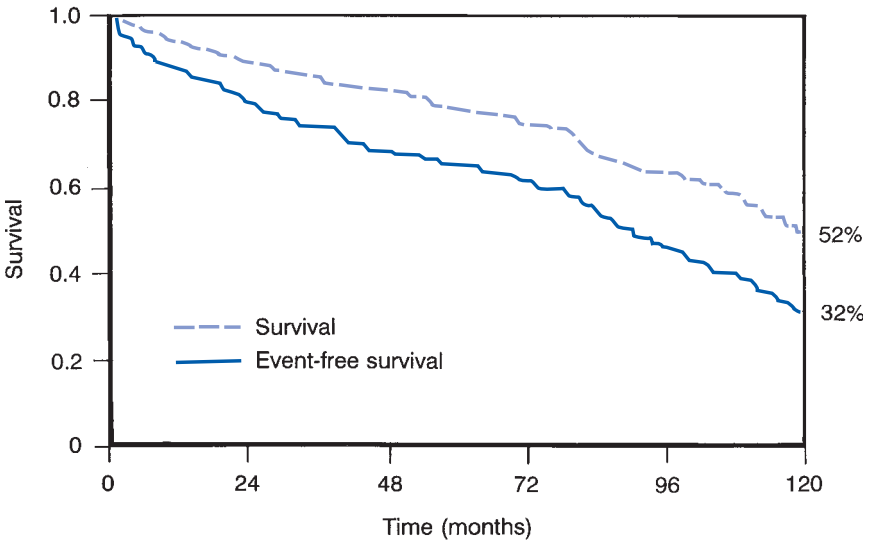

Figure 50-3. Long-term survival and event-free survival after aortic valve replacement and coronary artery bypass grafting in 471 patients. (*Adapted with permission from Lytle BW, Cosgrove DM, Gill CC, et al: Aortic valve replacement combined with myocardial revascularization. J Thorac Cardiovasc Surg 1988; 95:402.*)

can be weaned rapidly. In patients with more impaired ventricular function, weaning, of necessity, occurs more gradually and may take days.

Results

Early hospital mortality after aortic valve replacement and CABG ranges from approximately 2 to 10%.[3,11] Higher mortality is observed in patients with more severe symptoms of heart failure and impaired ventricular function preoperatively. The most frequent causes of operative death are low-output cardiac failure, myocardial infarction, and arrhythmia. Incremental risk factors for hospital death include patient age, functional class, and several measures of ventricular function. In a number of studies, late survival has ranged from 60 to 80% at 5 years and from 50 to 75% at 8 years postoperatively (Fig. 50-3).[12–17] By multivariate analysis, variables leading to reduced late survival include older age, cardiac enlargement, and more severe preoperative clinical symptoms. The use of a mechanical prosthesis at valve replacement has been associated with lower long-term survival and lower long-term event-free survival (Fig. 50-4). As discussed earlier, choice of valve type is a complex issue in combined valve–coronary artery surgery. This is a decision that cannot be made without consultation with the patient. A frank discussion of the advantages and drawbacks of each approach continues to be an important component of the preoperative evaluation and planning for this type of surgery.

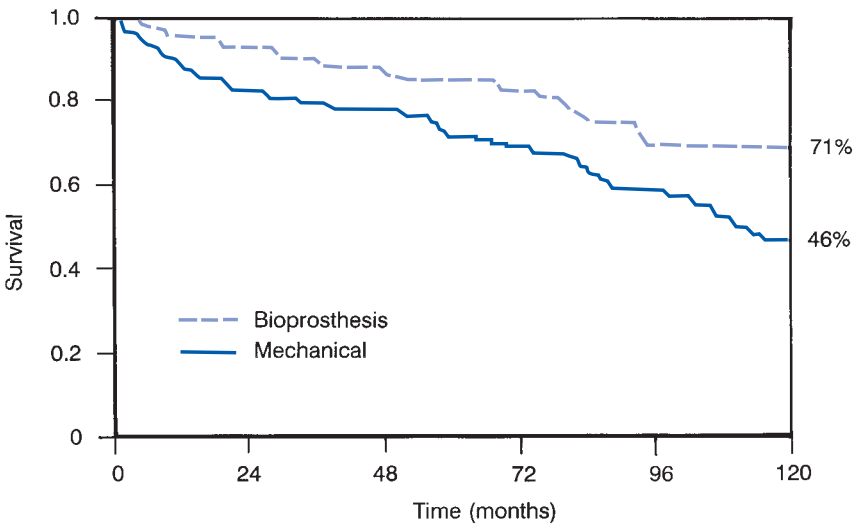

Figure 50-4. Long-term survival advantage for patients undergoing aortic valve replacement and coronary artery bypass grafting using a bioprosthesis (n = 218) versus a mechanical valve (n = 253). *(Adapted with permission from Lytle BW, Cosgrove DM, Gill CC, et al: Aortic valve replacement combined with myocardial revascularization. J Thorac Cardiovasc Surg 1988; 95:402.)*

AORTIC REGURGITATION AND CORONARY ARTERY DISEASE

Significant aortic regurgitation occurs less often in older populations, and is also less often encountered with CAD. Most series of patients undergoing aortic valve replacement and CABG include a relatively small number (10 to 25%) of patients with aortic insufficiency.[3,11–14] While the operative management of patients with aortic regurgitation and CABG is similar to that previously described, aortic insufficiency produces different pathophysiology that has implications for perioperative management, and the presence of an incompetent aortic valve introduces subtle nuances to the intraoperative management of these patients.

Clinical Presentation

Patients with aortic regurgitation and coronary artery disease usually present in one of three ways. The aortic regurgitation may be asymptomatic and detected incidentally during evaluation for symptomatic coronary disease. Second, the patient may be asymptomatic, yet a routine physical examination reveals a murmur of aortic insufficiency that leads to cardiac evaluation and detection of coronary disease. Finally, patients may present relatively late in the course of valvular heart disease with congestive heart failure due to decompensation of the volume-overloaded left ventricle or ischemic damage or both. Patients therefore may present with no symptoms and essentially normal physiology, a classic ischemic syndrome, or congestive heart failure. The physical signs also will depend on the nature of the presentation. In general, all patients with aortic insufficiency have an audible early diastolic blowing murmur. In late stages of the disease, signs of congestive heart failure, including rales and peripheral edema, may be present.

The preoperative evaluation of a patient with aortic insufficiency and CAD is no different from that previously described for patients with aortic stenosis and ischemic heart disease. Echocardiography is particularly useful in detecting aortic regurgitation because the murmur is sometimes subtle and difficult to detect. In addition, echocardiography gives important information regarding both ventricular contractile function and ventricular size. Since many patients with aortic regurgitation are asymptomatic, careful evaluation for changes in ventricular size or function is important because the presence of these changes may constitute an indication to proceed with surgical intervention in the absence of symptoms.

Pathophysiology

Aortic regurgitation increases left ventricular preload and causes left ventricular dilatation. Dilatation does not occur acutely, and patients with acute aortic insufficiency are often severely symptomatic due to a sudden increase in left ventricular end-diastolic pressure and decrease in net forward cardiac output. Left ventricular dysfunction due to CAD also can produce left ventricular dilatation. Valve replacement relieves some of the preload but does not immediately result in improved left ventricular contractility. Revascularization may produce improved contractility by recruitment of hibernating myocardium.[7,10] This operation does not increase left ventricular afterload.

The indications for surgery in aortic regurgitation continue to be somewhat controversial, and are reviewed in depth in the section on aortic valve disease. The evaluation of valvular pathology proceeds along similar lines as those described above, with emphasis on echocardiographic results. However, this evaluation is somewhat more difficult when CAD is also present, because there might be an impact on ventricular function that revascularization may or may not improve. Nevertheless, except in advanced stages of diffuse three-vessel coronary artery disease, myocardial abnormalities due to coronary artery obstructions are usually regional and can be distinguished from global dysfunction due to volume overload from the insufficient valve. Making this distinction is of paramount importance in the preoperative assessment and risk stratification of these patients. Again, decisions about timing of aortic valve surgery in the presence of CAD are different than in cases of isolated valvular disease, with emphasis on fixing the valve earlier in the course of the disease.

Operative Management

The operation is conducted in a fashion similar to that described for aortic stenosis and CAD. However, in the presence of aortic insufficiency, antegrade cardioplegia in the aortic root cannot be given because the cardioplegia solution leaks into the left ventricle. In general, retrograde cardioplegia is used under these circumstances, with doses of antegrade cardioplegia given into the coronary ostia with hand-held catheters after the aorta has been opened.

Considerations in weaning from cardiopulmonary bypass are somewhat different from those described for aortic stenosis. Patients with aortic regurgitation are more likely to have dilated ventricles that tolerate increases in afterload poorly. Therefore, successful perioperative management of these patients requires careful attention to adjustments in preload and afterload. In patients with volume-overloaded ventricles due to aortic insufficiency, vasodilators may be an important component of postoperative management. Drugs such as milrinone and dobutamine have a role because they provide both inotropic support and ventricular unloading. The mechanical ventricular unloading device—the intra-aortic balloon pump—also may be used. It is rare that mechanical circulatory assistance with a ventricular assist device is required. Its use should be reserved for younger patients without comorbid conditions in whom prompt improvement in ventricular function is anticipated.

Results

Early results after operation for aortic regurgitation and CAD include an expected hospital mortality rate of less than 10%.[3,11] Incremental risk factors for hospital death are similar to those described previously, with advanced age and poor ventricular function having the greatest impact. Late survival after this operation is similar to that for aortic stenosis and CAD (see Fig. 50-3).[12–17] Despite the impression that patients with aortic insufficiency and CAD do not do as well as those with aortic stenosis, aortic insufficiency has not been an independent risk factor for early or late mortality.[3] Interestingly, recovery of ventricular ejection fraction does have a favorable impact on late mortality. When ventricular dilatation and diminution in ventricular systolic function occur in the setting of aortic regurgitation, these often are irreversible changes. While some improvement of function can occur with elimination of the volume overload and with revascularization in patients with combined valvular and coronary artery diseases, there may be less recovery of ejection fraction in patients with aortic insufficiency compared with aortic stenosis. Failure of recovery of ventricular function in this setting may have an impact on long-term survival, but not one so great as to render aortic insufficiency an independent risk factor for late death.

MITRAL REGURGITATION AND CORONARY ARTERY DISEASE

Successful management of patients with mitral regurgitation and CAD remains one of the greater challenges in adult cardiac surgery. This group of patients tends to be sicker, and their surgical care is accomplished at higher risk.[1,18–21] This is almost certainly because of the complex interaction between the left ventricle and the mitral valve. Normal valve function depends on normal function of the entire mitral apparatus, which includes the ventricular wall and the papillary muscles. Similarly, normal ventricular function depends on competence of the mitral valve. Therefore, there is unique potential for CAD and mitral valve disease to interact, making the patient sicker, the pathophysiology more complicated, and the surgical management more difficult.

In patients with preserved ventricular function, the pathophysiology and management strategies are not significantly different from those for treatment of isolated mitral regurgitation or CAD. Of course, the operation is more complex and longer, and therefore, as has been described previously, a carefully conceived operative plan with special attention to myocardial preservation is important. However, the more interesting problems are in those patients with mitral insufficiency and CAD who do not have normal hearts, and in fact, most patients with this disease combination do not have normal ventricular function.

Clinical Presentation

The spectrum of clinical presentation ranges from patients who are asymptomatic to those who are moribund in cardiogenic shock. The patient may have no signs or symptoms of heart disease, or may have predominant symptoms of failure, ischemia, or both. Finally, patients may present with acute syndromes often related to myocardial infarction and the sudden development of mitral insufficiency. These patients are extremely ill when they present in congestive heart failure and cardiogenic shock. Management of these patients is the most difficult.

Findings on physical examination obviously relate to the nature of the presentation, and can range from signs of mild mitral insufficiency to severe congestive failure or cardiogenic shock. An electrocardiogram may show evidence of ischemic heart disease. All patients should undergo echocardiography. The echocardiogram is particularly useful because it gives information both about the valve and about ventricular geometry and function. Transesophageal echocardiography is especially useful in the evaluation of mitral function. Assessments of mitral valve leaflet structure and function, chordal anatomy, and functioning of the papillary muscles and adjacent ventricular wall via transesophageal echocardiography are invaluable. All these data are important in planning the operative approach to the mitral valve and assessing the risk of surgery. Cardiac catheterization is performed in these patients for the same reasons outlined for patients with aortic valve disease. Any patient with angina pectoris or a positive stress test and any patient with mitral insufficiency over the age of 40 should have coronary angiography before surgery. As noted previously, cardiac catheterization also provides information about hemodynamics that is important in planning the operation.

Pathophysiology

Mitral regurgitation increases left ventricular preload and decreases afterload at the expense of cardiac output. Ischemic damage causes ventricular dilatation with decreased contractility and an increase in left ventricular filling pressures. These lesions combined cause synergistic decompensation and can produce pulmonary hypertension and secondary tricuspid regurgitation. Cardiac output may be very low, especially in patients with acute mitral insufficiency. Mitral insufficiency may occur in association with CAD, but often the CAD is the cause of mitral insufficiency. The pathophysiology of primary mitral insufficiency can be due to involvement of the valve leaflets, the annulus, the subvalvular apparatus, or some combination of all of the above. A detailed understanding of the pathophysiology of primary mitral insufficiency is important for planning the operative approach.

When CAD is the cause of mitral insufficiency by its effect on regional and global ventricular function, the pathophysiology is more complicated. Global ventricular

dysfunction from CAD can produce ventricular dilatation with mitral annular dilatation and subsequent mitral insufficiency. The jet of mitral regurgitation is usually central and often can be managed with annuloplasty. Alternatively, regional wall motion abnormalities involving the papillary muscle and the adjacent ventricular wall can produce dynamic changes that produce insufficiency of the mitral valve. These abnormalities are now becoming better understood and are discussed more completely in Chapter 41.

Correction of mitral insufficiency either by valve repair or valve replacement produces an instantaneous increase in left ventricular afterload. The ventricle no longer has the low-impedance left atrial chamber in which to eject blood and must overcome systemic afterload in systole. Even when myocardial ischemia is reversible, recruitment of hibernating myocardium may take time. These factors in combination with the sudden increase in left ventricular afterload are responsible for the difficulty and increased risk of managing this entity. Secondary right ventricular failure may be present or ensue because pulmonary hypertension does not decrease immediately after mitral valve repair or replacement, and CAD also may affect right ventricular function.

Symptomatic mitral insufficiency and symptomatic CAD are the usual indicators for combined surgery. As noted, patients with acute illnesses may be in extremis. Ventricular dysfunction is not per se a contraindication to surgery, especially if it is due to reversible ischemia. Patients with global irreversible cardiomyopathy and mitral insufficiency should not be operated on because the ventricle tolerates the increase in afterload poorly and results are unsatisfactory. Estimation of the viability of the myocardium and demonstration of reversible ischemia using thallium or PET scanning therefore are important.

Finally, with the left atrial enlargement that is common, patients often present with chronic or recent-onset atrial fibrillation. This further acts to reduce cardiac output and may also benefit from ablation therapy at the time of surgery.

Operative Management

One important preoperative decision in patients with mitral regurgitation and CAD is whether there is, in fact, any need for valve surgery. Since mitral regurgitation in the presence of CAD may be functional and due to reversible myocardial ischemia, revascularization alone may improve mitral regurgitation. It is important, therefore, to distinguish organic from functional mitral insufficiency. Intraoperative transesophageal echocardiography is an essential tool for assessment of mitral valve function in this setting.[22] Patients with no preoperative congestive heart failure, absent or only transient murmurs of mitral insufficiency, normal pulmonary pressures in the operating room, and trace to mild mitral insufficiency by transesophageal echocardiography after induction of anesthesia probably do not need mitral valve surgery at all.[23] Many of these patients will appear to have more mitral regurgitation and higher pulmonary pressures at catheterization or when they are ischemic than when they are under anesthesia. Clearly, however, those with moderate to severe insufficiency will need to have the valve regurgitation addressed.[24] Several recent studies suggest that the quality of modern surgical results justifies a more aggressive approach to valve repair in patients with moderate mitral insufficiency and CAD.[25–28] Some patients with ventricular enlargement and annular dilation secondary to CAD and/or mitral insufficiency may be managed with annuloplasty alone. Patients with organic mitral valve disease such as leaflet prolapse, chordal rupture, or chordal elongation need primary repair. Restricted leaflet motion is frequently a complication of ischemic changes in ventricular shape. Standard leaflet resection techniques for posterior flail segments are indicated. In sicker patients, and those with restricted leaflet motion or more complex lesions (severe myxomatous degeneration), an edge-to-edge leaflet approximation (the "Alfieri stitch") may be appropriate.[29] This is especially true in patients with extensive calcification of the posterior annulus or severely restricted posterior leaflet motion.[30] As noted elsewhere, results of mitral repair and CABG are superior to those of mitral valve replacement, which should be avoided except in the setting of acute, severe mitral insufficiency due to papillary muscle rupture.[31]

Anesthetic considerations are similar to those described previously, although it must be recognized that these patients are in general sicker than patients with aortic valve disease, and in some cases are among the sickest patients treated. Monitoring includes a radial artery line and a pulmonary artery catheter. As suggested earlier, transesophageal echocardiography is particularly important in this group of patients. Setup for cardiopulmonary bypass is similar to that described earlier. However, both venae cavae are cannulated for venous return (Fig. 50-5). This is usually accomplished by introducing the cannulas through purse-strings in the superior vena cava and low in the right atrium. After clamping the aorta, cardioplegia is administered antegrade and then retrograde. Subsequent doses of cardioplegia are given retrograde. As with aortic disease, special attention must be paid to protecting the right ventricle during periods of prolonged retrograde cardioplegia.

The most common incision is in the wall of the left atrium anterior to the right pulmonary veins. Preparative dissection of the interatrial groove usually facilitates exposure using this incision. Another choice for exposure of the mitral valve is the transseptal approach. This allows for direct visual insertion of the retrograde cardioplegia catheter through a purse-string, and affords an excellent view of the mitral valve, especially if the left atrium is not enlarged, without excessive stretching of the right atrium or the cavae. If necessary, the incision can be carried up into the dome of the left atrium for even greater exposure. Other incisions are discussed in the section on mitral valve disease. Choice of coronary artery grafts is similar to that for aortic disease.

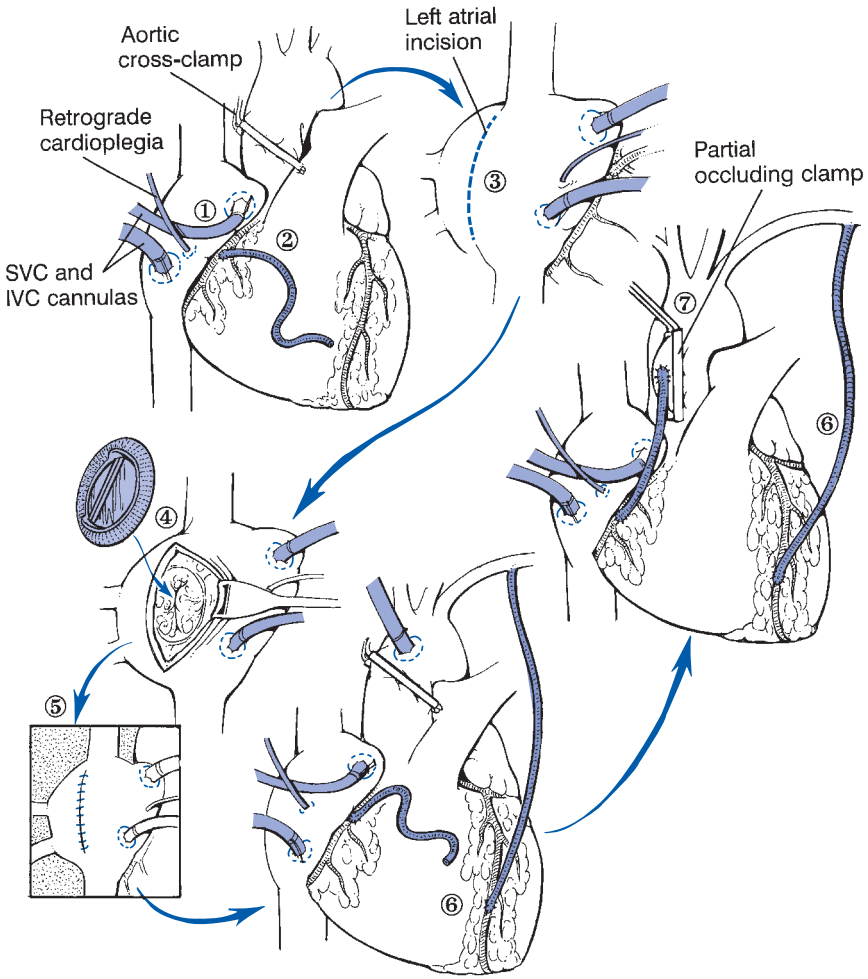

Figure 50-5. Operative sequence for mitral valve replacement and coronary artery bypass grafting. (1) Cannulation and cross-clamping of the aorta with antegrade and retrograde cardioplegia. (2) Distal vein graft anastomoses are performed. (3) Left atriotomy is performed after dissection in the interatrial groove. (4) Mitral valve repair or replacement with the prosthesis of choice. (5) Closure of left atriotomy. (6) Distal anastomosis using the mammary artery is performed. (7) Proximal graft anastomosis is done. In this case, the cross-clamp has been removed and a partially occluding aortic clamp used.

The first choice in surgery for mitral insufficiency is valve repair. When valve repair is impossible, valve replacement follows the same guidelines set forth in Chapter 43. However, in patients with this disease combination and an abbreviated life expectancy, a stronger rationale for use of a tissue prosthesis may exist.[32] Regardless of the type of prosthesis, an effort should be made to retain continuity between the papillary muscles and the mitral annulus. The attachments to the posterior leaflet usually can be retained in their entirety without interfering with prosthesis function. The anterior leaflet must be resected either in whole or in part to avoid left ventricular outflow tract obstruction or interference with mechanical valve function. However, major chordal attachments may still be preserved and incorporated into the annular suture line. Regardless, standard practice is to retain continuity between the mitral annulus and the subvalvular apparatus whenever the mitral valve is replaced. Short- and long-term ventricular function appear to be better when this is done. Obviously, in this clinical setting, in which ventricular function has a significant impact on short- and long-term results, all steps should be taken to ensure optimal myocardial performance postoperatively.

Patients with papillary muscle rupture due to infarction are usually extremely sick. Valve replacement is almost always required. Some surgeons have reported success with reimplantation of the papillary muscle. This strategy is risky in these sick patients because the operation must be both expeditious and effective. Multiple attempts to achieve mitral valve competence are tolerated poorly. A reimplanted, infarcted papillary muscle does not necessarily restore mitral valve competence and also may be subject to late breakdown.

As in combined aortic valve and coronary artery surgery, distal graft anastomoses are performed first (see Fig. 50-5). At this point, after the atrium has been opened, it may be prudent to undertake an arrhythmia ablation procedure in selected patients. Radiofrequency or cryoablation probes can be used to create a lesion set within the left and right atria, as described elsewhere in this text (see Chapter 58). The left atrial appendage may be oversewn. Valve repair or replacement is then carried out, followed by performance of the mammary artery anastomosis. Proximal graft anastomoses can be done either after release of the cross-clamp and application of a partially occluding clamp or with the cross-clamp in place. Weaning from cardiopulmonary bypass is similar to that in patients with aortic insufficiency and CAD. Again, in this group of patients, afterload reduction using drugs or the intra-aortic balloon pump may be required. Inotropic drugs with

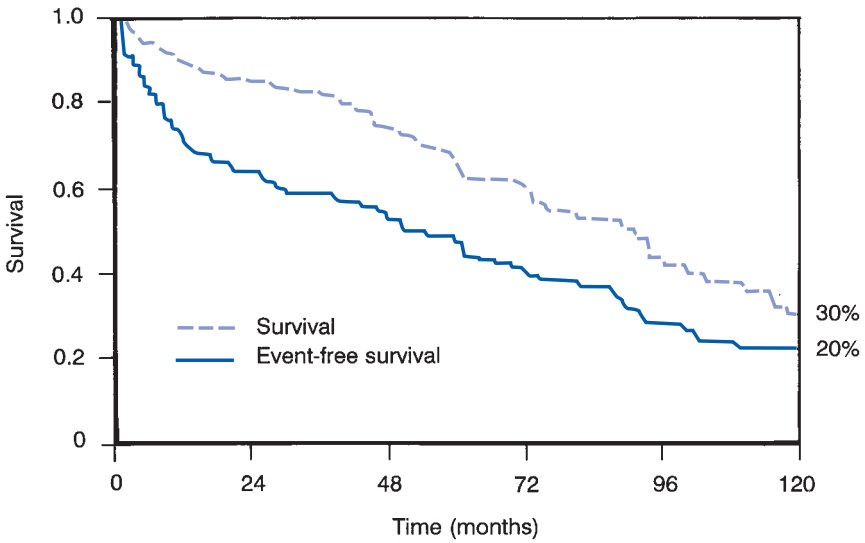

Figure 50-6. Survival and event-free survival after mitral valve replacement combined with coronary artery bypass grafting in 278 patients. (*Adapted with permission from Lytle BW, Cosgrove DM, Gill CC, et al: Mitral valve replacement combined with myocardial revascularization: Early and late results for 300 patients, 1970 to 1983. Circulation 1985; 71:1179.*)

afterload-reducing capabilities such as dobutamine and milrinone may be indicated. The surgeon should have a low threshold for adding a drug such as milrinone to epinephrine because this combination has some theoretical advantages as a result of positive inotropic and unloading effects, as well as a reduction in pulmonary artery pressures. Alternatively dobutamine, which has both central inotropic and peripheral afterload-reducing effects, may be a first-choice drug. Since some of these patients are particularly sick, little time should be wasted in futile attempts to wean from cardiopulmonary bypass on medications and without the intra-aortic balloon. There should be a low threshold for insertion of the intra-aortic balloon in patients whose hemodynamics may be quite tenuous for hours to days after surgery, especially when the operation is an emergency.

Another consideration for a select subset of patients with this disease is the incorporation of ventricular remodeling into the operation. A large body of work is now emerging indicating that patients with anterior infarctions and dilated cardiomyopathy, mitral insufficiency, and CAD will benefit from exclusion of the infarcted area and remodeling of the left ventricle with return to elliptical shape.[33] This can be performed safely, along with mitral repair and coronary revascularization, in carefully selected patients. The result can be a dramatic increase in ejection fraction with greatly improved postoperative function.

Strict attention must be paid to right ventricular function in this group of patients, although right ventricular failure is more common in the setting of mitral stenosis. Right ventricular failure must be anticipated and correctly diagnosed and managed. The presence of a falling systemic blood pressure and cardiac output with falling pulmonary artery pressure and/or pulmonary capillary wedge pressure should prompt a search for right ventricular failure, which is manifested by a rising central venous pressure. Failure to recognize this and inappropriate administration of fluid can lead to irreversible right ventricular failure.

Results

Hospital mortality for this group of patients is higher than for most other forms of acquired heart disease. Early mortality rates range from 3% in good-risk patients to 60% in the sickest patients.[15–21,34] The higher mortality is seen in patients with acute ischemic mitral valve disease and severe ventricular dysfunction who require emergency surgery. Incremental risk factors for early death include age, functional class, ventricular function, pulmonary pressures, and cardiogenic shock. Late survival in patients with this entity is 55 to 85% at 5 years and 30 to 45% at 10 years (Fig. 50-6).[15–21,35]

In general, patients who survive surgery have good relief of symptoms. Significant risk factors for late death include preoperative functional class, left ventricular function, and an ischemic as opposed to a degenerative etiology for mitral insufficiency (Fig. 50-7).

MITRAL STENOSIS AND CORONARY ARTERY DISEASE

Patients with mitral stenosis and CAD usually have good left ventricular function and often are a relatively easy group of patients to take care of because the mitral stenosis protects the left ventricle from hemodynamic loads. CAD may cause left ventricular dysfunction, but this is unusual. A more usual concern is right ventricular dysfunction postoperatively, since in patients with mitral stenosis, pulmonary hypertension, with its potential to produce right ventricular failure and tricuspid insufficiency, is often encountered.

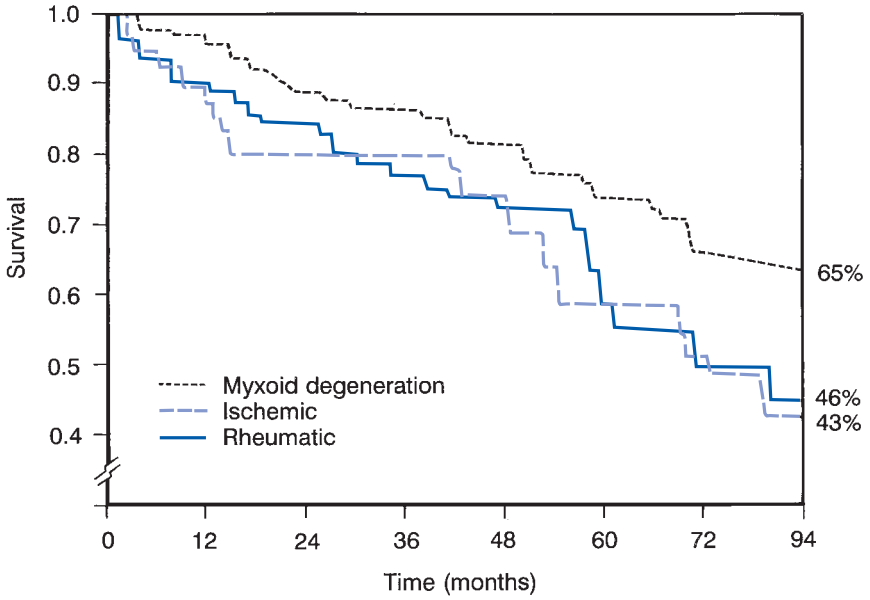

Figure 50-7. Survival after mitral valve replacement and coronary artery bypass grafting based on the etiology of mitral valve disease. A survival advantage for patients with myxoid degeneration of the mitral valve is demonstrated. (*Adapted with permission from Lytle BW, Cosgrove DM, Gill CC, et al: Mitral valve replacement combined with myocardial revascularization: Early and late results for 300 patients, 1970 to 1983. Circulation 1985; 71:1179.*)

Clinical Presentation

As implied earlier, mitral stenosis is usually the dominant lesion in patients with mitral stenosis and CAD. Therefore, symptoms usually are due to the valvular lesion. Patients may have congestive heart failure with shortness of breath, orthopnea, and fatigue. Atrial fibrillation is a common presenting symptom with mitral stenosis. Patients with mitral stenosis and CAD infrequently have angina as a presenting symptom. The electrocardiogram may show evidence of right ventricular strain and hypertrophy. Transesophageal echocardiography confirms the diagnosis of mitral stenosis and usually shows a small left ventricle with preserved contractile function. The right ventricle may be enlarged and hypertrophied. Cardiac catheterization further confirms the diagnosis by showing a gradient across the mitral valve. Other important information gleaned from invasive catheterization includes a measurement of the pulmonary artery pressures and central venous pressure. The degree of pulmonary hypertension is a marker of the severity and duration of mitral stenosis and alerts the surgeon to the potential for right ventricular failure postoperatively. An elevated central venous pressure is a potential sign that right ventricular decompensation has already occurred. Coronary angiography should be done in all patients with angina pectoris, and as noted before, in any patient over age 40 in whom mitral valve surgery is anticipated.

Pathophysiology

Unlike the other entities described, mitral stenosis and CAD do not have significantly synergistic pathologic effects on the heart. CAD usually has more profound effects on the left ventricle, which remains protected in patients with mitral stenosis until late in the disease. The right ventricle is the chamber most vulnerable to the effects of long-standing mitral stenosis, as noted. However, even with right ventricular hypertension, the potential impact of CAD on right ventricular function in adults is usually insignificant. In the rare patient with diffuse CAD and ischemic cardiomyopathy, the risk of surgery is enhanced because of global ventricular dysfunction.

The indications for surgery, not surprisingly, are usually determined by the severity of the mitral stenosis. Patients with significant heart failure and low cardiac output from mitral stenosis whose calculated valve area is less than 1 cm^2 should have a mitral valve operation and associated bypass grafting if significant CAD is present. A rare patient may have significant CAD and mild mitral stenosis detected incidentally. These patients may be managed with CABG and mitral commissurotomy if this is technically feasible.

Operative Management

Monitoring, perfusion setup, and operative sequence are identical to those described for treatment of mitral regurgitation and CAD. Transesophageal echocardiography is useful to assess both the feasibility of mitral commissurotomy (or more extensive mitral repair) and the results of valvuloplasty. In most patients with mitral stenosis, valve replacement is required because irreversible damage to the leaflets and subvalvular apparatus is usually extensive. A mechanical prosthesis is used most often because the majority of patients have chronic atrial fibrillation from left atrial enlargement, and long-term anticoagulation is indicated. However, the potential benefits of an ablation procedure (as discussed above) within the left and right atria also may have an impact on prosthetic choice.

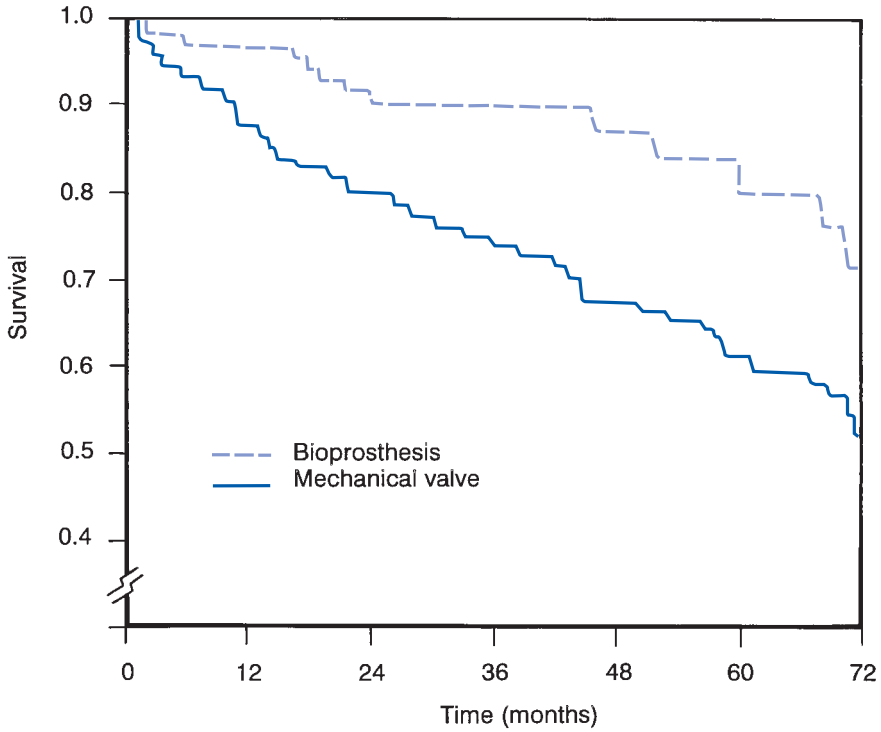

Figure 50-8. Comparative survival after mitral valve replacement and coronary artery bypass grafting for patients having mitral valve replacement with a bioprosthesis (n = 82) or mechanical valve (n = 100). *(Adapted with permission from Lytle BW, Cosgrove DM, Gill CC, et al: Mitral valve replacement combined with myocardial revascularization: Early and late results for 300 patients, 1970 to 1983. Circulation 1985; 71:1179.)*

Transesophageal echocardiography is often important in monitoring both right and left ventricular function postoperatively. The early differentiation between left and right ventricular failure is facilitated by the use of this modality during weaning from cardiopulmonary bypass. If inotropic drugs are required, their selection should be based in part on the consideration that pulmonary hypertension and right ventricular failure might be an important component of the clinical syndrome. Drugs such as isoproterenol, dobutamine, and especially milrinone (the latter often in combination with norepinephrine) may be indicated for their combined beneficial effects on right ventricular contractility and pulmonary vascular resistance. Judicious use of inotropic drugs and careful administration of fluid should result in optimal cardiac output. The intra-aortic balloon is almost never useful in these patients because right ventricular problems predominate, and the intra-aortic balloon has little direct effect on right ventricular function. Temporary support with a right ventricular assist device may be employed because mitral valve replacement can lead to dramatic decreases in pulmonary artery pressures and subsequent recovery of right ventricular function.

Results

Early mortality after combined surgery for mitral stenosis and CAD is approximately 8%.[12–14,15–18,27] This is not significantly different from results of surgery in lower-risk patients with mitral regurgitation and CAD. Long-term probability of survival is approximately 50% at 7 years and in one series was not significantly different from that for patients with ischemic mitral insufficiency.[15–17,19–21,35] Interestingly, long-term survival of patients with myxoid degeneration of the mitral valve and CAD (65%) was significantly better than survival of the patients with rheumatic or ischemic mitral valve disease and CAD in at least one series (see Fig. 50-7).[19] As implied, rheumatic valve pathology is a risk factor for late death, as is poor preoperative left ventricular function and the presence of ventricular arrhythmias. Interestingly, the use of a bioprosthesis without anticoagulants confers both a survival advantage and an event-free survival advantage in these patients (Fig. 50-8). These data lend support to the hypothesis that biologic valves may be appropriate for mitral replacement in older patients and in those with CAD, whose expected life span may be shorter than the expected durability of the replacement device.[32]

AORTIC STENOSIS, MITRAL REGURGITATION, AND CORONARY ARTERY DISEASE

Patients with aortic stenosis, mitral regurgitation, and CAD often present with aortic stenosis as the predominant lesion. It is important to note that functional mitral regurgitation may improve after relief of aortic stenosis with concomitant reduction in left ventricular systolic pressure. If the mitral valve is not intrinsically diseased, it may not require surgery.

Clinical Presentation

Patients with these diseases often present identically to patients with aortic stenosis and CAD, but may do so earlier because of the combined valvular lesions. Angina, congestive heart failure, and syncope may be presenting symptoms alone or together. It is relatively uncommon for symptoms due to mitral insufficiency to be predominant. Echocardiography is an extremely important tool in this disease combination. Careful evaluation of the mitral valve, often using transesophageal echocardiography, is necessary to determine the degree of intrinsic mitral valve disease, since improvement in mitral insufficiency is expected after aortic valve replacement and relief of left ventricular obstruction. It is critical to determine whether or not anatomic abnormalities of the mitral valve are present that might not reverse with aortic surgery alone. Of course, cardiac catheterization is required, as it is for the other disease entities described.

Pathophysiology

Aortic stenosis increases left ventricular afterload and the potential amount of mitral regurgitation. The left ventricle may be better preserved in this setting than in patients with isolated mitral insufficiency and CAD. Also as noted, the mitral valve may not be structurally diseased. Because of earlier presentation, pulmonary hypertension and subsequent right ventricular failure and tricuspid valve incompetence are usually not prominent features. Because relief of outflow obstruction helps left ventricular function immediately, these patients often do quite well.

The indications for surgery are usually the same as for aortic stenosis and CAD. Critical aortic stenosis, when documented, requires valve replacement; if significant CAD is present, coronary artery bypass grafts are also done. Mitral valve repair is almost always necessary and possible when mitral insufficiency is moderate to severe and/or anatomic abnormalities of the valve are detected. If absolutely necessary, valve replacement may be performed. End-stage ventricular dysfunction with ventricular dilatation and myocardial thinning is the primary cardiac contraindication to surgery.

Operative Management

Anesthesia and perfusion setup are identical to those described for mitral valve and coronary artery surgery. In this entity, intraoperative transesophageal echocardiographic monitoring plays an important role because the intraoperative assessment of mitral valve function before and after bypass is critical. The choice of valves for aortic replacement is the same as described previously. In most situations, however, bioprosthetic valves should be considered, especially if the mitral valve is to be repaired.

Under almost all circumstances in which anatomic abnormalities of the mitral valve are detected or in which mitral insufficiency is severe, mitral valve repair should be considered. Annuloplasty may be all that is required if the mitral insufficiency is due to annular dilatation and there is a symmetric central jet of regurgitation. More complex disease may require more extensive repair or even replacement of the mitral valve. When the decision is made not to operate on the mitral valve, transesophageal echocardiography is done to assess residual mitral valve dysfunction following aortic valve replacement and coronary artery bypass surgery. If moderate or severe mitral regurgitation remains, the valve is repaired or replaced. This is technically more difficult after the aortic valve has been replaced, since the prosthesis in the aortic position hinders exposure of the mitral valve. Therefore, every effort must be made to assess mitral valvular morphology and function before starting cardiopulmonary bypass.

As in the other entities described, distal graft anastomoses are performed first (Fig. 50-9). After these grafts are completed, the aorta is opened and the aortic valve is resected. Replacement of the aortic valve, however, is deferred until after the mitral valve operation. However, it is important to resect the aortic valve before replacing the mitral valve to improve exposure of the latter. In addition, sutures used for mitral valve repair or replacement, if placed first, may become disrupted during resection or débridement of the aortic valve and annulus. After resection of the aortic valve, the atrium is opened and the mitral operation is performed. The atrium is closed with a vent across the mitral valve. The aortic valve is then replaced and the aorta is closed. The internal mammary artery graft is done last. Proximal graft anastomoses can be done with the aortic cross-clamp in place or after removal of the cross-clamp and placement of a partially occluding clamp, as described previously.

As noted, this group of patients may have preserved ventricular function, and weaning from cardiopulmonary bypass may be relatively easy. Inotropic drugs and the intra-aortic balloon can be used as indicated.

Results

Early hospital mortality is 12 to 16%.[36,37] Not surprisingly, predictors of early death include severe mitral regurgitation, lower ejection fraction with more severe symptoms of heart failure, and the presence of triple-vessel CAD. Late survival is approximately 60% at 72 months (Fig. 50-10). Multivariate predictors of late mortality include advanced symptoms of heart failure and increased severity of mitral insufficiency.

AORTIC AND MITRAL REGURGITATION AND CORONARY ARTERY DISEASE

Not many patients have regurgitation of both the aortic and mitral valves and CAD. These patients usually have rheumatic heart disease and present early in the course of the disease. Aortic regurgitation may be the primary valve pathology in a patient with significant CAD. Patients may

(*Adapted with permission from Akins CW, Buckley MJ, Daggett WM, et al: Myocardial revascularization with combined aortic and mitral valve replacements. J Thorac Cardiovasc Surg 1985; 90:272.*)

have mitral disease secondary to left ventricular dilatation from ischemia as well as from aortic regurgitation. Organic mitral valve disease may not be present. Assessment of left ventricular contractility may be difficult because of the alterations in preload and afterload produced by this combination of lesions. In addition, the presence of reversible ischemia may obscure accurate assessment of ventricular function. Therefore, assessment of myocardial viability is important.

Clinical Presentation

Most patients with this combination of cardiac lesions present with congestive heart failure. It is unusual to see a patient with angina as the primary symptom who also has significant insufficiency of both the aortic and mitral valves. Typical murmurs of aortic and mitral insufficiency are present, and the patient may have other signs of chronic congestive heart failure, including rales and peripheral edema. If myocardial infarction is a significant component of the pathophysiology and presentation of the disease, evidence of it may be seen on electrocardiogram and echocardiogram. On echocardiography, patients may have regional wall motion abnormalities if infarction has occurred, as well as global ventricular dilatation and dysfunction from the combined valvular lesions. Cardiac catheterization defines the coronary anatomy and helps define the severity of the valvular insufficiency and ventricular dysfunction. Accurate assessment of true left ventricular function is difficult in this entity. Mitral insufficiency may abnormally inflate visual measurements of ejection fraction because the ventricle can eject into the low-pressure pulmonary venous circuit. The misleading ejection fraction combined with the multiple volume overloads of leaking aortic and mitral valves and the potential contribution of dysfunctional myocardium from ischemia make it very difficult to get an accurate perception of preoperative left ventricular function. Thallium or PET scans may be useful to assess which areas of dysfunctional myocardium may be viable and potentially recruitable after revascularization.

Pathophysiology

Symptoms and signs of left ventricular failure develop as the left ventricle dilates. In patients with rheumatic disease with both valves intrinsically damaged, ischemic disease may be minimal. In the more common setting of patients with aortic regurgitation and severe ischemia, mitral regurgitation is likely to be secondary to both of these processes, and valve repair should be possible. Correction of aortic regurgitation reduces preload, whereas correction of mitral insufficiency increases afterload. The dilated myopathic ventricle may not have sufficient reserves to maintain adequate output under these circumstances. Higher postoperative preload may need to be maintained while afterload is reduced. Any additional contractility as a result of revascularization, given a smaller left ventricle, should further improve output. Hence, forward flow should improve if ventricular contractility is maintained or increased. However, because of the multiple, uncontrollable variables that inhibit preoperative assessment of ventricular function, prediction of expected improvement from this operation is difficult.

This consideration is extremely important. Patients with severe and irreversible ischemic myocardial disease and poor ventricular function will not do well with operative treatment of this entity. Therefore, preoperative assessments of myocardial viability and reversible ischemia are important. It is also important to assess whether organic mitral valve disease is present. The best results in these patients are in those in whom no mitral operation, or at most annuloplasty, is required.

Operative Management

Details of the operative technique are similar to those described previously. Because of the presence of aortic insufficiency, retrograde cardioplegia must be used in conjunction with hand-held antegrade ostial cannulas as necessary. Transesophageal echocardiography is required in the operating room for the assessment of mitral valve function. Residual 1+ to 2+ mitral regurgitation may be acceptable in certain patients because relief of aortic regurgitation can be expected to reduce ventricular size, which may lead to improvement of mitral regurgitation with time. Similarly, myocardial revascularization also may lead to ultimate improvement in ventricular and mitral valve function.

In weaning from cardiopulmonary bypass, afterload reduction is extremely important because of the large preoperative volume overload of the heart. Drugs that reduce ventricular afterload, including vasodilators and inotropic drugs such as milrinone, may be particularly appropriate. The intra-aortic balloon pump may be needed.

Results

Early hospital mortality in this group of patients may be high, and if myocardial failure is severe, overall mortality rates exceed the range already noted for double-valve and coronary artery surgery.[36,37] Important determinants of risk in these patients are the familiar ones. In several series, predictors of hospital death and late events included severe mitral regurgitation, lower ejection fraction, more severe symptoms of congestive heart failure, and severe triple-vessel CAD.

SUMMARY

This chapter has reviewed the management of patients with valvular and ischemic heart disease. The discussion has focused on management of disease of the aortic and mitral valves, since these are the valves most frequently affected in adults who present with these combined diseases.

Rather than concentrate on the details of the technical aspects of valve implantation or coronary artery grafting, the discussion has focused on the particular problems for surgical management that the combined pathophysiology of valvular and ischemic heart disease produces. As has been noted often during the discussion, there is usually an interaction between valve function, myocardial perfusion, and ventricular performance. Dysfunction of the aortic and mitral valves has secondary effects on ventricular function, and the addition of CAD can make this interaction more complex. Therefore, the pathophysiology of these disease states can be complicated. In order to manage these entities successfully, this pathophysiology must be understood so that accurate estimates of risk and reasonable expectations for results can be achieved.

In almost every case, ventricular function and severity of mitral incompetence are important short- and long-term risk factors. Also, functional mitral insufficiency in the absence of anatomic abnormalities of the mitral valve may resolve after aortic and/or coronary artery surgery, and therefore an operation on the mitral valve may not be required. Finally, data from several sources suggest that patients with both coronary artery and valvular heart disease should be considered for a tissue prosthesis because of reduced life expectancy and the benefits of avoiding long-term anticoagulation.

In addition, the complex interaction between ventricular function, valvular function, and coronary ischemia requires that the operation be well planned with attention paid to expeditious surgery with short myocardial ischemia times and good myocardial preservation. Much of the discussion in this chapter, therefore, has focused on the operative plan and the development of a rational approach to intraoperative and postoperative management of these patients.

CHAPTER 51

Aortic Dissection

T. Brett Reece • G. Randall Green • Irving L. Kron

Thoracic aortic dissection occurs as blood flow is redirected from the aorta (true lumen) through an intimal tear into the media of the aortic wall (false lumen). A dissection plane that separates the intima from the overlying adventitia along a variable length of the aorta is created within the media. The acute form of aortic dissection is often rapidly lethal, while those surviving the initial event go on to develop a chronic dissection with more protean manifestations. The purpose of this chapter is to review the etiology and pathogenesis of aortic dissection, examine current diagnostic algorithms, and provide detailed descriptions of contemporary surgical techniques for treatment. Additional information regarding follow-up and the subsequent management of these patients is presented to provide a comprehensive understanding of a clinical entity that has challenged physicians and surgeons for centuries.

HISTORY

Sennertus is credited with the first description of the dissection process, but the earliest detailed descriptions of the clinical entity appeared in the 17th and 18th centuries, during which time Maunoir named the process aortic "dissection."[1,2] Laennec defined the propensity of the chronically dissected aorta to become aneurysmal.[3] Aortic dissection was exclusively a postmortem diagnosis until the first part of the 20th century, but in 1935 Gurin attempted surgical intervention with the first aortic fenestration procedure to treat malperfusion syndrome.[4] In 1949, Abbott and Paulin advanced surgical treatment by theoretically preventing aortic rupture by wrapping the aorta with cellophane.[5] Other attempts at surgical treatment over the years met with limited clinical success, though certain concepts regarding surgical management are still in use today. With the advent of cardiopulmonary bypass, De Bakey and Cooley forever altered the natural history of aortic dissection by successfully performing primary surgical repair using techniques not remarkably different from contemporary procedures.[6–8] Investigators such as Wheat made substantial contributions by defining physiologically based medical management algorithms to complement surgical correction.[9] There is still considerable controversy regarding surgical versus medical treatment of certain forms of acute thoracic aortic dissection.

CLASSIFICATION

The classification systems used for aortic dissection are based on the location and extent of dissection. The particular type is then subclassified based on the timing of dissection. Acute dissection has traditionally been used to describe presentation within the first 2 weeks, while the term chronic is reserved for those patients presenting at greater than 2 months following the initial event. The more recently added subacute designation is sometimes used to describe the period between 2 weeks and 2 months.

Two classification systems are most frequently used in clinical practice: the De Bakey and the Stanford systems (Fig. 51-1). The De Bakey system differentiates patients based on the location and extent of aortic dissection.[10] The advantage of this system is that four different groups of patients with different forms of aortic dissection emerge and provide the greatest opportunity for subsequent comparative research. In contrast, the Stanford system proposed by Daily and associates is a functional classification system.[11] All dissections that involve the ascending aorta are grouped together as type A, regardless of where the primary tear occurs. Proponents of the simpler Stanford system contend that the clinical behavior of patients with aortic dissection is essentially determined by involvement of the ascending aorta. Critics, however, suggest that individual patients in the type A classification may be quite different from one another depending on the distal extent of dissection. Drawing clinical conclusions from such a potentially heterogeneous patient

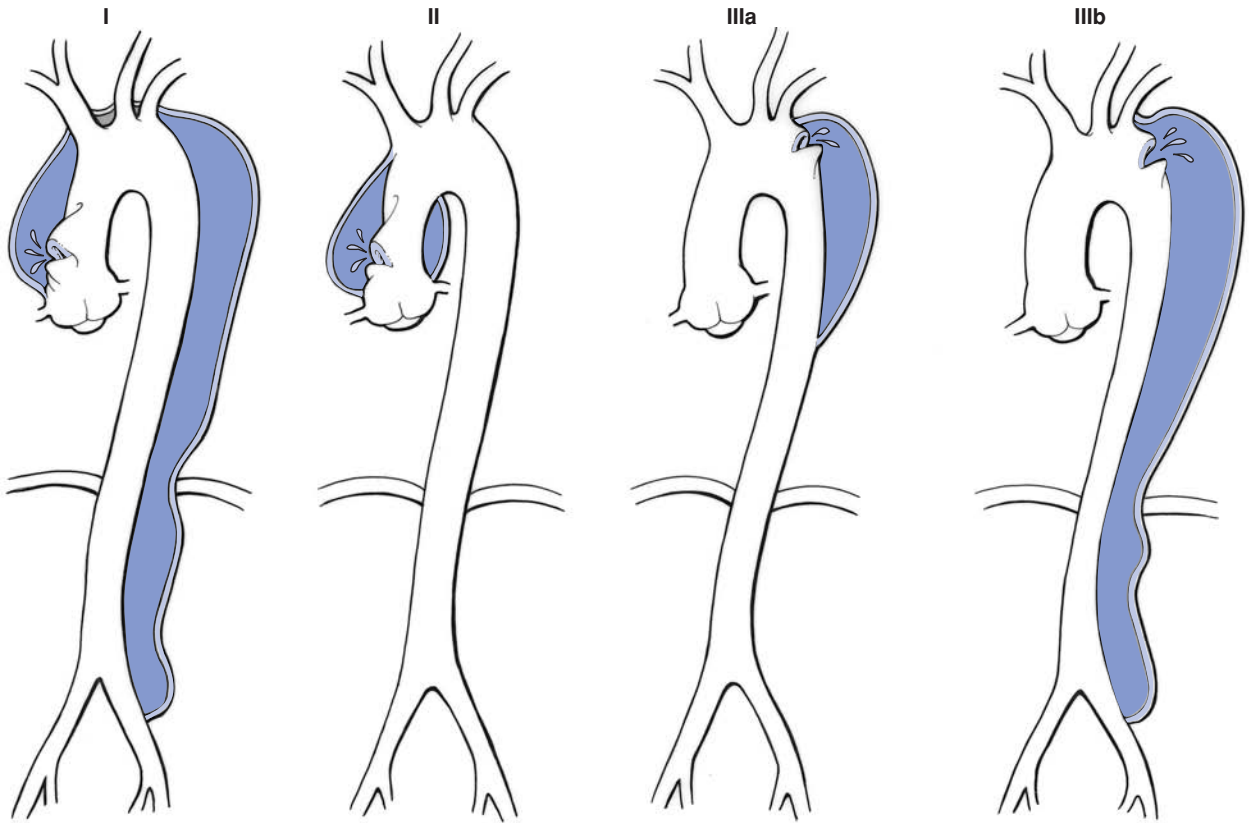

Figure 51-1. Classification of aortic dissection. De Bakey type I and Stanford type A include dissections that involve the proximal aorta, arch, and descending thoracic aorta. De Bakey type II only involves the ascending aorta; this dissection is included in the Stanford type A. De Bakey type II and Stanford type B include dissections that originate in the descending thoracic and thoracoabdominal aorta regardless of any retrograde involvement of the arch. These are subdivided into subtypes a and b, depending on abdominal aortic involvement.

population has inherent limitations. The Stanford system will be used throughout this chapter.

INCIDENCE

Aortic dissection is the most frequently diagnosed lethal condition of the aorta. Dissection occurs nearly three times as frequently as rupture of an abdominal aortic aneurysm in the United States.[12] There is an estimated worldwide prevalence of 0.5 to 2.95 per 100,000 per year; the prevalence ranges from 0.2 to 0.8 per 100,000 per year in the U.S., resulting in roughly 2000 new cases per year. These figures are, however, only an estimate. In one autopsy series, the antemortem diagnosis was made in only 15% of patients, revealing that many immediately fatal events go undiagnosed.[13] Clinically, type A dissections occur with an overall greater frequency (Table 51-1).

ETIOLOGY AND PATHOGENESIS

There are several hypotheses regarding the etiology of the intimal disruption (primary tear) that permits aortic blood flow to create a cleavage plane within the media of the aortic wall. This was originally viewed as a consequence of a biochemical abnormality within the media upon which normal mechanical forces in the aorta acted to create an intimal tear. The link between the abnormal media, termed cystic medial necrosis or degeneration, and the primary tear has not been scientifically established. In fact, medial degeneration is found in only a minority of patients with acute aortic dissection and most are children.[14] This theory has lost support over the years.

Alternatively, there are data supporting a relationship between aortic dissections and intramural hematoma. Advocates of this theory suggest that bleeding from vasa vasorum into the media creates a mass, which results in localized areas of increased stress in the intima during diastole. These areas then permit intimal disruption. In fact, between 10% and 20% of patients thought to have acute aortic dissection are found to have intramural hematoma, suggesting that it may be a precursor to dissection.[15] Penetrating atherosclerotic ulcers have been implicated as the source of intimal disruption in certain cases, yet support for the concept has waned over the years. The pattern of atherosclerotic involvement of the thoracic aorta resulting in penetrating ulcer and the frequency of dissection throughout the aorta do not support this theory.

Table 51–1.

Clinical Characteristics of Patients Presenting with Acute Type A and B Thoracic Aortic Dissections

	Type A	Type B
Frequency	60–75%	25–40%
Sex (M:F)	1.7–2.6:1	2.3–3:1
Age (y)	50–56	60–70
Hypertension	++	+++
Connective tissue disorder	++	+
Pain		
Retrosternal	+++	+,–
Interscapular	+,–	+++
Syncope	++	+–
Cerebrovascular accident	+	–
Congestive heart failure	+	–
Aortic valve regurgitation	++	+,–
Myocardial infarction	+	–
Pericardial effusion	+,–	+++
Pleural effusion	+,–	+,–
Abdominal pain	+,–	+,–
Peripheral pulse deficit	Upper and lower extremities	Lower extremities

While no single disorder is responsible for aortic dissection, several risk factors have been identified that can damage the aortic wall and lead to dissection (Table 51-2). These include direct mechanical forces on the aortic wall (i.e., hypertension, hypervolemia, and derangements of aortic flow) and forces that affect the composition of the aortic wall (i.e., connective tissue disorders or direct chemical destruction). Hypertension is the mechanical force most often associated with dissection and is found in greater than 75% of cases. Although the role of increased strain on the aortic wall is intuitive, the mechanism by which hypertension actually leads to dissection is unclear. Similarly, hypervolemia, high cardiac output, and an abnormal hormonal milieu certainly contribute to the increased incidence of dissection in pregnancy, but the mechanism is unclear. Atherosclerosis is not a risk factor for aortic dissection except in preexisting aneurysms or in the case of atherosclerotic ulceration, which may lead to dissection in the descending thoracic aorta. Iatrogenic trauma to the aortic intima may result in dissection. Catheterization procedures, aortic root and femoral artery cannulation for cardiopulmonary bypass, aortic cross-clamping, surgical procedures performed on the aorta (aortic valve replacement and aorto-coronary bypass grafting), and placement of intra-aortic balloon pumps have all been reported to result in dissection. Aortic transection as a result of trauma rarely results in excessive dissection and deserves differentiation from the process of aortic dissection. This process is usually limited to the aortic isthmus, and in addition to the risk of rupture may present as a circular prolapse of the intima and media, producing aortic obstruction referred to as "pseudo-coarctation" (Fig. 51-2).

Table 51–2.

Risk Factors for Type A and B Thoracic Aortic Dissection

Hypertension
Connective tissue disorders
Ehlers-Danlos syndrome
Marfan disease
Turner syndrome
Cystic medial disease of aorta
Aortitis
Iatrogenic
Atherosclerosis
Thoracic aortic aneurysm
Bicuspid aortic valve
Trauma
Pharmacologic
Coarctation of the aorta
Hypervolemia (pregnancy)
Congenital aortic stenosis
Polycystic kidney disease
Pheochromocytoma
Sheehan syndrome
Cushing syndrome

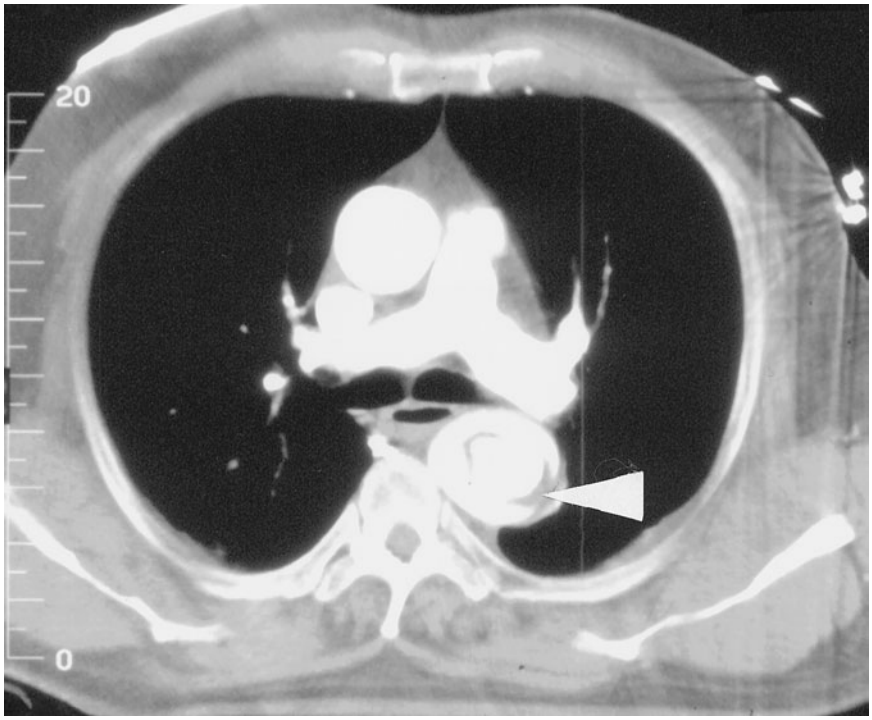

Figure 51-2. Axial image of CT arteriogram showing a nearly circumferential dissection flap (arrowhead) as a result of acute traumatic aortic dissection.

Once a cleavage plane exists in the media, the aortic wall floating within the lumen is termed the dissection flap and is composed of the aortic intima and partial-thickness media. The primary tear is usually greater than 50% of the circumference of the aorta, but the full circumference is rarely involved. The primary tear in type A dissection is usually located on the right anterior aspect of the ascending aorta and follows a somewhat predictable course, spiraling around the arch and into the descending thoracic and abdominal aorta on the left and posteriorly. The dissection may propagate in a retrograde fashion for a variable distance as well to involve the coronary ostia; this occurs in roughly 11% of all dissections.[15] Myocardial ischemia and rupture into the pericardium are the cause of death in as many as 80% of deaths from acute dissection. Often the distal false lumen communicates with the true lumen through one or more fenestrations within the dissection flap. The false lumen may also end blindly in as many as 4 to 12% of patients, in which case blood in the false lumen frequently becomes thrombotic. The false lumen may also penetrate the adventitia causing rupture and death. Regardless of whether the true and false lumens communicate, perfusion of aortic side branches may be compromised by the dissection, resulting in end-organ ischemia (Fig. 51-3). If these acute complications are avoided, the weakened outer aortic wall, composed of partial media and the adventitia, may dilate over time resulting in aneurysm formation. This evolving dilatation is the reason for operation in the majority of chronic dissections regardless of type.

The adventitia provides most of the tensile strength of the aortic wall with little contribution from the media. The media is composed of concentrically arranged smooth muscle interposed with connective tissue proteins such as collagen, elastin, and fibrillin within the ground substance. Abnormal constituents of the media, as in certain connective tissue disorders such as Marfan disease and Ehlers-Danlos syndrome, are associated with aortic dissection. Marfan syndrome is an autosomal dominant inherited disorder in which a point mutation in the fibrillin-1 gene located on the long arm of chromosome 15 results in an abnormal media. The incidence of Marfan syndrome is approximately 1 per 5000 live births. There are, however, many incomplete forms of the disease and as many as 25% may be sporadic, in which no known fibrillin abnormalities are observed. Type IV Ehlers-Danlos syndrome is a connective tissue disorder of the pro(1(III) chain of type III collagen with an incidence of 1 in 5000. The structurally abnormal media is susceptible to dissection. Of note, there are also familial aggregations of dissection without discernible biochemical or genetic abnormalities.

ACUTE AORTIC DISSECTION

Clinical Presentation

Signs and symptoms

As many as 40% of patients suffering acute aortic dissection die immediately. Those surviving the initial event may be stabilized with medical management, and it is these patients in whom subsequent therapeutic intervention for aortic dissection has altered the natural history of the disease. The

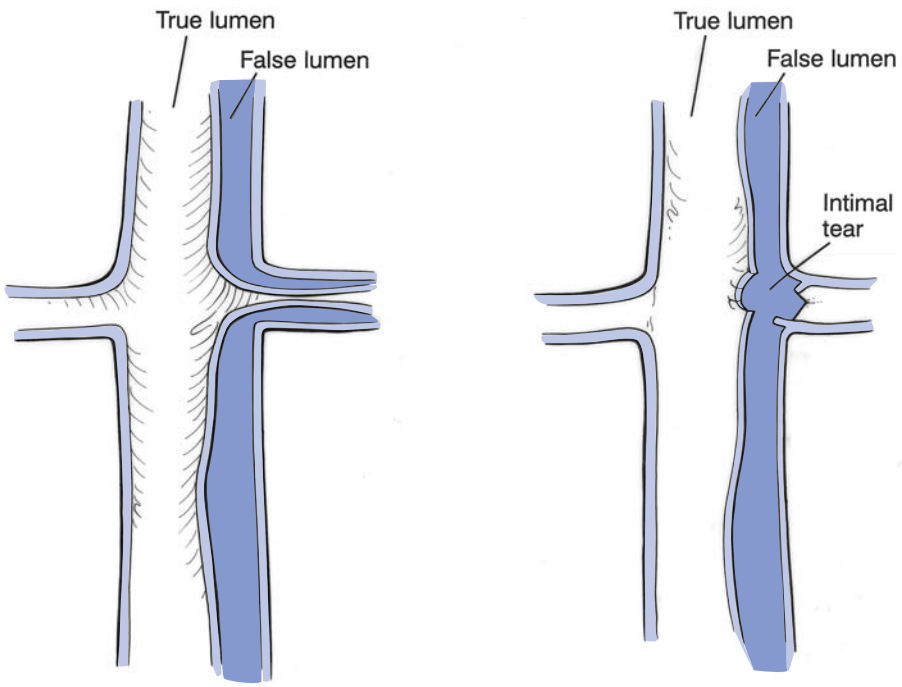

Figure 51-3. Diagram of aortic dissection. (A) An intact dissection membrane compresses the true lumen and causes malperfusion of a branch artery. (B) Rupture of the dissection membrane that may or may not restore blood flow to the branch.

clinical outcome is eventually determined by dissection type and timing of presentation, patient-related factors, and the quality and experience of the individuals and institution providing care.

The initial evaluation of a stable patient with suspected aortic dissection includes a detailed history and physical examination focusing on those elements likely to rule in the diagnosis. Most importantly, the diagnosis of aortic dissection requires a high level of suspicion. Up to 30% of patients ultimately diagnosed with acute dissection are first thought to have another diagnosis. Aortic dissection should always be considered in the setting of severe, unrelenting chest pain, which is present in most patients. Patients usually have no previous episodes of similar pain, which often causes anxiety. Pain is usually located in the mid-sternum for ascending aortic dissection, and in the interscapular region for descending thoracic aortic dissection (see Table 51-1). The location of maximum pain tends to change as the dissection extends in an antegrade or retrograde direction. Such "migratory pain" should arouse clinical suspicion. The character of the pain is often described as "ripping" or "tearing." The pain is constant with greatest intensity at the onset. Although painless dissection has been described, it usually occurs in the setting of an existing aneurysm in patients in whom the pain of a new dissection may not be differentiated from chronic aneurysm pain. Patients may also present with signs or symptoms related to malperfusion of the brain, limbs, or visceral organs. These findings confuse the true diagnosis, as the obvious signs of ischemia distract the historian from a less apparent initial episode of pain.

Elements of the past medical history such as primary hypertension, presence of aneurysmal disease of the aorta, or familial connective tissue disorders are useful as risk factors to help establish the diagnosis. Illicit drug use is an increasingly important predisposition to ascertain during the initial evaluation. The differential diagnosis of chest pain as a result of aortic dissection includes diagnoses such as myocardial ischemia, aortic aneurysm, acute aortic regurgitation, pericarditis, musculoskeletal pain, and pulmonary embolus. It is essential to consider aortic dissection in each case, as specific therapy (e.g., thrombolytic therapy for acute myocardial infarction) may impact the survivability of acute dissection.

Patients suffering acute dissection appear ill. Tachycardia is usually accompanied by hypertension in the setting of baseline essential hypertension and increased catecholamine levels from pain and anxiety. Hypotension and tachycardia may result from aortic rupture, pericardial tamponade, acute aortic valve regurgitation, or even acute myocardial ischemia with involvement of the coronary ostia. An abnormal peripheral vascular examination is present in a minority of patients with acute aortic dissection, but when present an abnormal pulse exam may indicate the type of dissection. Absence of pulses in the upper extremity suggests ascending aortic involvement, whereas pulse deficits in the lower extremities speak to involvement of the distal aorta. These findings are subject to change as the dissection progresses or reentry into the true lumen occurs. Auscultation of the heart may reveal a diastolic murmur consistent with acute aortic regurgitation or an S_3 indicating left heart volume overload. Physical exam findings such as jugular venous distension and a pulsus paradoxus are signs of pericardial tamponade that should be identified in any unstable patient to initiate the correct diagnostic and treatment algorithms. Unilateral loss of breath sounds, usually the left, may indicate hemothorax as a result of aortic leak or rupture with hemothorax. Alternatively, a pleural effusion may exist secondary to pleural

inflammation related to the dissection. This finding requires additional evaluation prior to treatment.

A complete central and peripheral neurologic exam is critical in that abnormalities are present in up to 40% of acute type A dissections. Involvement of the brachiocephalic vessels with loss of brain perfusion may result in transient syncope or stroke. Syncope may also result from rupture into the pericardium and is an ominous sign. Stroke rarely improves with restoration of blood flow and may even cause hemorrhage and brain death, yet surgery is indicated in such patients. Fortunately, stroke is a presenting feature in fewer than 5% of patients with acute type A dissection. Loss of perfusion to intercostals or lumbar arteries may result in spinal cord ischemia and paraplegia. Peripheral nerve ischemia as a result of malperfusion may yield findings similar to spinal cord malperfusion and should be discerned, as these patients often improve with restoration of blood flow. Acute aortic dissection may also cause superior vena cava syndrome, vocal cord paralysis, hematemesis, Horner syndrome, hemoptysis, and airway compression as a result of local compression and mass effect.

Diagnostic studies

Routine diagnostic studies including blood tests, chest x-ray, and electrocardiogram (ECG) should be obtained, but are often not sufficient to establish the diagnosis of acute aortic dissection. ECG often reveals no ischemic changes. Obvious ischemic changes are present in up to 20% of acute type A dissections, while only nonspecific repolarization abnormalities are present in nearly one-third of patients with coronary ostial involvement. The ECG may also reveal left ventricular hypertrophy in those patients with long-standing hypertension. The chest x-ray is abnormal in 60 to 90% of patients with acute dissection (Fig. 51-4). Although most patients have at least one, if not several abnormal findings, a normal chest x-ray does not rule out the diagnosis. Blood should be drawn and sent for complete blood count, serum and electrolytes, creatine kinase with myocardial isoenzymes, and troponin, and a blood type and screen are obtained. These tests obtained at the time of initial observation are usually unremarkable. There is frequently a mild to moderate leukocytosis. Anemia may result from sequestration of blood or hemolysis. Liver function tests, serum creatinine, myoglobin, and lactic acid may all be abnormal in the setting of certain malperfusion syndromes.

Diagnostic imaging

Diagnostic imaging is essential to clarify the anatomy of an acute aortic dissection, regardless of clinical certainty of diagnosis or the acuity of the patient. The diagnosis should be made rapidly with minimal distress for the patient. Two imaging modalities currently meet these criteria and are used to diagnose acute aortic dissection: computed tomography (CT) and echocardiography. Magnetic resonance imaging (MRI) and aortography, with or without intravascular ultrasound, are used to diagnose acute aortic dissection but are second-line modalities for various reasons. The benefits, disadvantages, and diagnostic accuracy of each are useful when choosing the most appropriate study for a particular clinical situation (Table 51-3). Each test provides disruption, reentry points, whether there is flow or thrombus in the false lumen, status of the aortic valve, presence and nature of myocardial ischemia, and brachiocephalic and aortic branch vessel involvement. Specific data may be necessary for operative planning and subsequent management to define the imaging study most appropriate for a particular patient.

Helical CT scanning is widely available and is now the most frequently utilized test to diagnose acute aortic dissection. It requires intravenous contrast medium that may limit its use in certain clinical situations, but generates images familiar to most practitioners and has a high sensitivity and specificity. This technique can be performed quickly, fulfilling

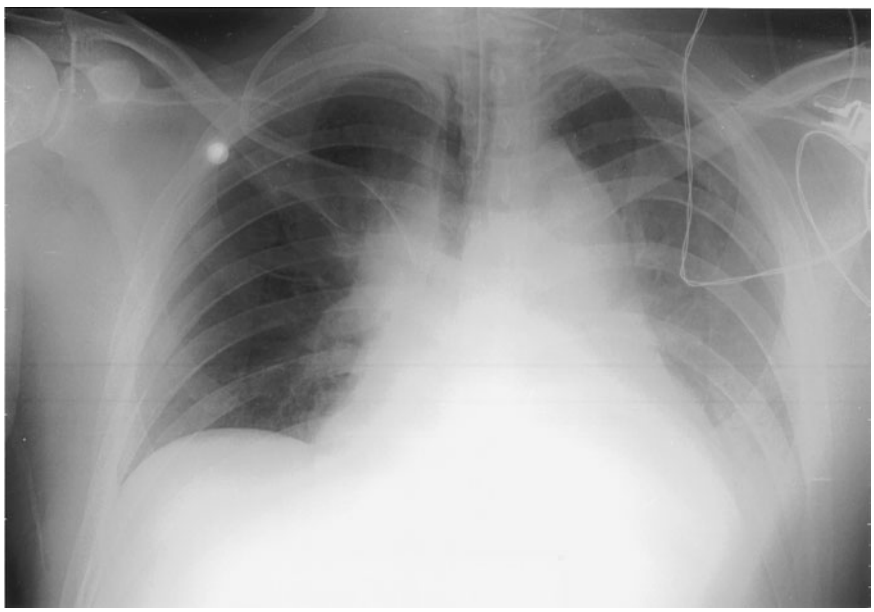

Figure 51-4. Plain chest x-ray exhibiting many features of acute type A dissection, such as a widened mediastinum, rightward tracheal displacement, irregular aortic contour with loss of the aortic knob, an indistinct aortopulmonary window, and a left pleural effusion.

Table 51–3.

Sensitivity and Specificity of Various Imaging Modalities Useful for the Diagnosis of Thoracic Aortic Dissection

Imaging study	Sensitivity	Specificity
Aortography	80–90%	88–93%
Computed tomography	90–100%	90–100%
Intravascular ultrasound	94–100%	97–100%
Echocardiography		
Transthoracic	60–80%	80–96%
Transesophageal	90–99%	85–98%
Magnetic resonance imaging	98–100%	98–100%

the requirements for use in the early management of acute dissection. Additional structures such as the pleural and pericardial spaces are imaged. When performed and formatted as an arteriogram, aortic branch vessels may also be evaluated; involvement of the brachiocephalic vessels is identified with nearly 96% accuracy. The diagnosis of dissection requires two or more channels separated by a dissection flap (Fig. 51-5). Transaxial two-dimensional images can be reconstructed to display three-dimensional images of the aorta that not only aid in diagnosis, but also are useful for operative planning.

Transesophageal echocardiography (TEE) is currently the second most frequently utilized study for making the diagnosis of acute aortic dissection. It is widely available, requires no intravenous contrast or radiation, and generates dynamic images of the aorta from which the diagnosis can be made (Fig. 51-6). It requires operator expertise both to acquire the necessary images and to conduct the examination safely. Although the safest setting in which to perform TEE is the operating room under general anesthesia, it can be performed in a monitored setting using topical anesthesia and light sedation. Patient comfort is paramount in this situation, as rupture has been reported during difficult studies and a complete examination of the entire aorta is necessary to exclude the diagnosis of acute dissection. Absolute contraindications to TEE include esophageal abnormalities such as varices, stricture, or tumor. A full stomach or recent meal are relative contraindications, but

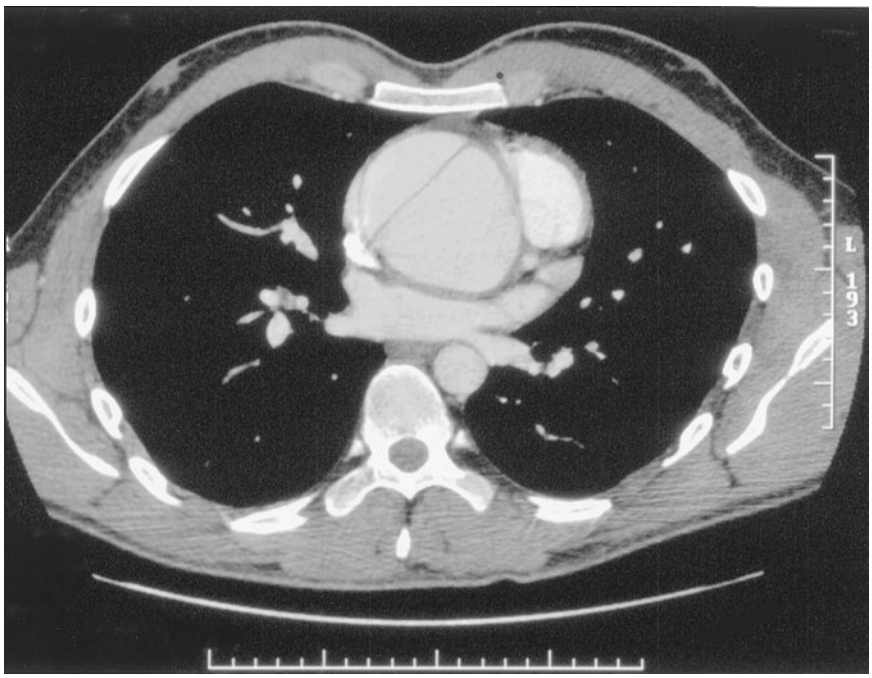

Figure 51-5. Axial image of CT arteriogram of acute type A dissection showing a dissection flap in the mid-ascending aorta.

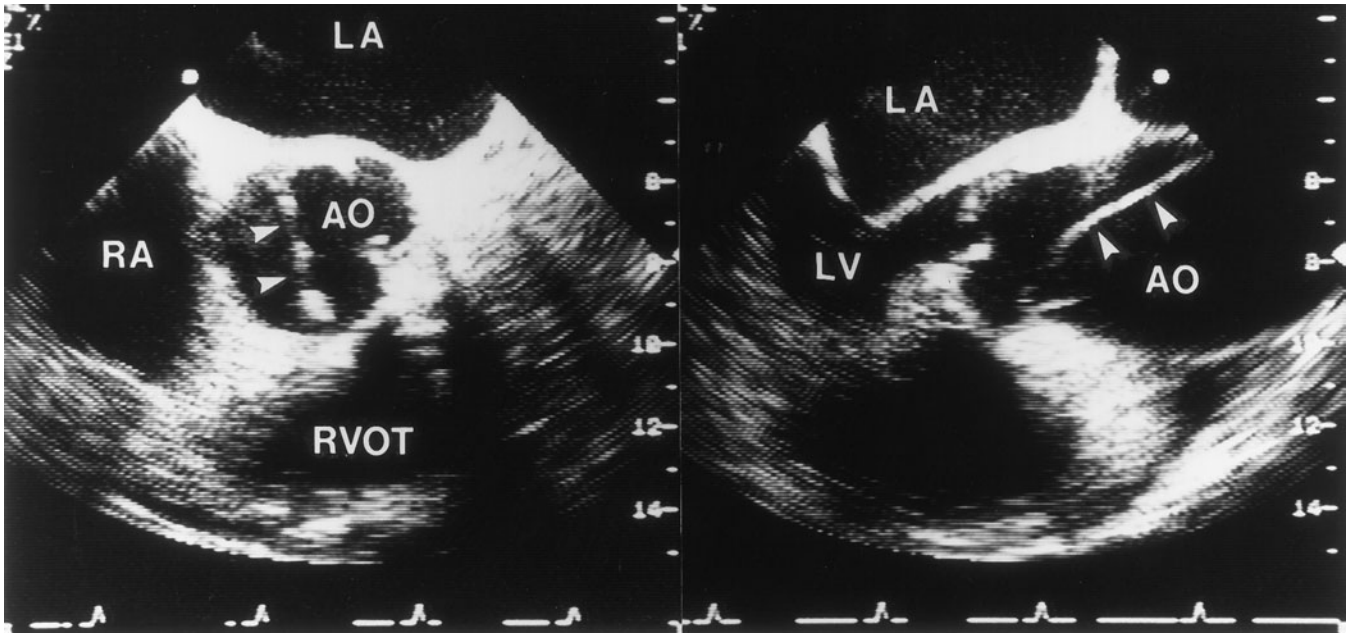

Figure 51-6. Transesophageal echocardiogram showing the dissection membrane (arrows) in the short (left panel) and long (right panel) views of a type A dissection.

recognition of these conditions permits safe examination with few complications in the vast majority of patients. Criteria for making the diagnosis of acute aortic dissection include visualization of an echogenic surface separating two distinct lumens, repeatedly, in more than one view, and that can be differentiated from normal surrounding cardiac structures. The true lumen is identified by expansion during systole and collapse in diastole. Communication of the false lumen is found by identifying distal tears in the flap and flow in the false lumen with the addition of color Doppler; the absence of flow indicates false lumen thrombosis. TEE additionally may provide high-quality images of the aortic valve and pericardial space. The coronary ostia are directly evaluated and regional left ventricular function may be assessed to identify myocardial ischemia indirectly. Color flow Doppler reliably quantifies aortic regurgitation and may be used to assess for additional valvular abnormalities. The pericardium and pleural space are also visualized and therefore effusions may be identified.

Transthoracic echocardiography provides images of the ascending aorta and sections of the aortic arch that may yield the diagnosis, but with much less sensitivity than transesophageal imaging. As such, transthoracic imaging may prove useful, but is generally insufficient to reliably establish the diagnosis. Transthoracic evaluation is additionally limited by patient-related factors including body habitus, emphysema, and mechanical ventilation. A negative transthoracic study should be complemented by a transesophageal study, which provides greater detail of the entire aorta.

Aortography was the first study used to diagnose acute dissection in 1939 and until recently was considered the gold standard for diagnosis. It is an invasive test requiring nephrotoxic contrast media in which the aorta is visualized in multiple two-dimensional projections. The diagnosis of dissection depends on visualization of the intimal flap, two distinct lumens, or compression of the true lumen by flow through an adjacent false lumen (Fig. 51-7). Indirect signs of dissection include the presence of branch vessel abnormalities

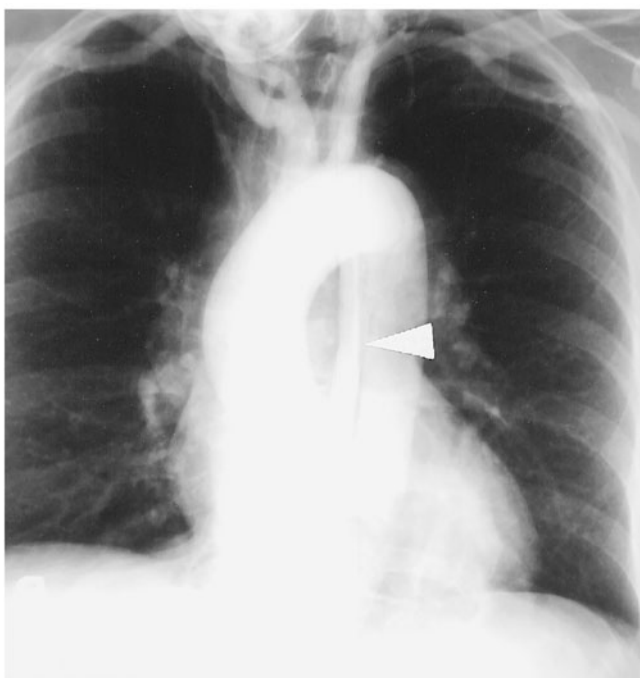

Figure 51-7. Aortogram of acute type B dissection illustrating differential contrast enhancement of the true and false lumens in the descending thoracic aorta. The intimal flap (arrowhead) can be seen separating the two lumens.

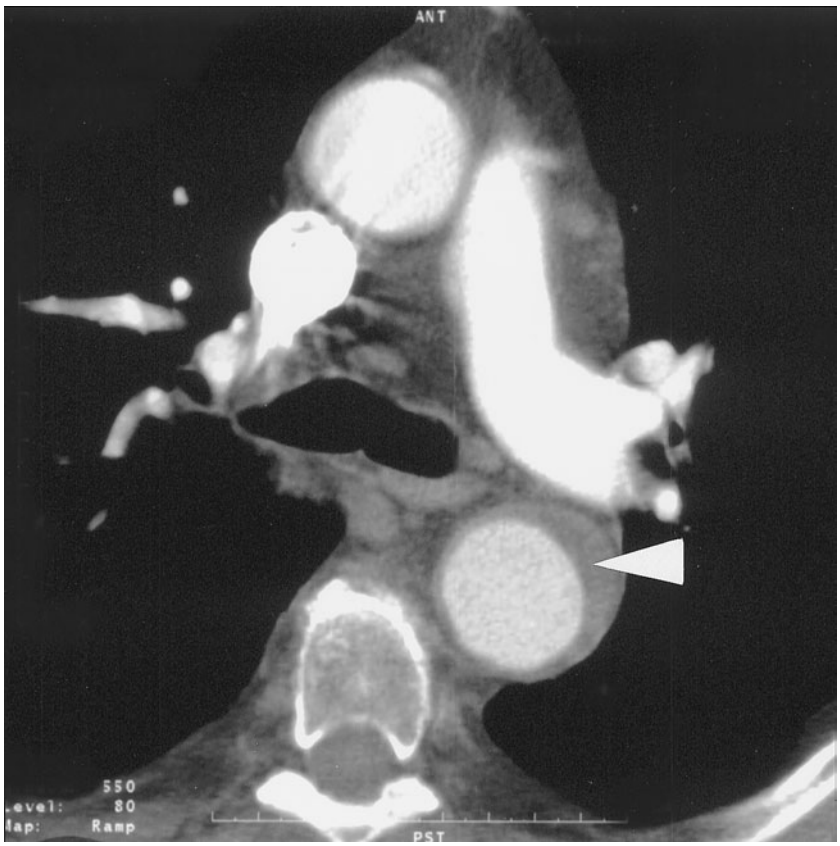

Figure 51-8. Axial image from a CT arte-riogram showing an intramural hematoma of the descending thoracic aorta (arrowhead).

and abnormal intimal contour on injection of the false lumen. The status of the aortic valve may be evaluated and coronary angiography in the setting of type A dissections is possible only with this diagnostic test. However, coronary angiography is not recommended given that the coronary ostia are involved in 10 to 20% of acute type A dissections and are easily evaluated at the time of surgery. Coronary atherosclerosis is present in 25% of all patients with acute aortic dissection, but even in those patients repair of the dissection should take precedence. Aortography is sometimes useful in acute type B dissections with evidence of mesenteric ischemia or oliguria, and in type A dissection with signs of malperfusion because catheter-based intervention may be possible. Aortography can have a high false-negative rate secondary to thrombosis of one lumen or when contrast equally opacifies each lumen, impairing distinction of a separate true and false lumen.[13,16] The diagnosis of intramural hematoma may also be difficult given the absence of intimal disruption, while penetrating atherosclerotic ulcer is usually easily visualized. Visualization of the dissection variants is best with either CT scanning or MRI (Figs. 51-8 and 51-9). One major limitation to the use of aortography in the acute setting is the need for skilled personnel. The time required to assemble this team varies with each institution, rendering aortography less useful when compared to other immediately available diagnostic tests. Aortography also requires arterial access, which can be painful and precipitate rupture or dissection extension.

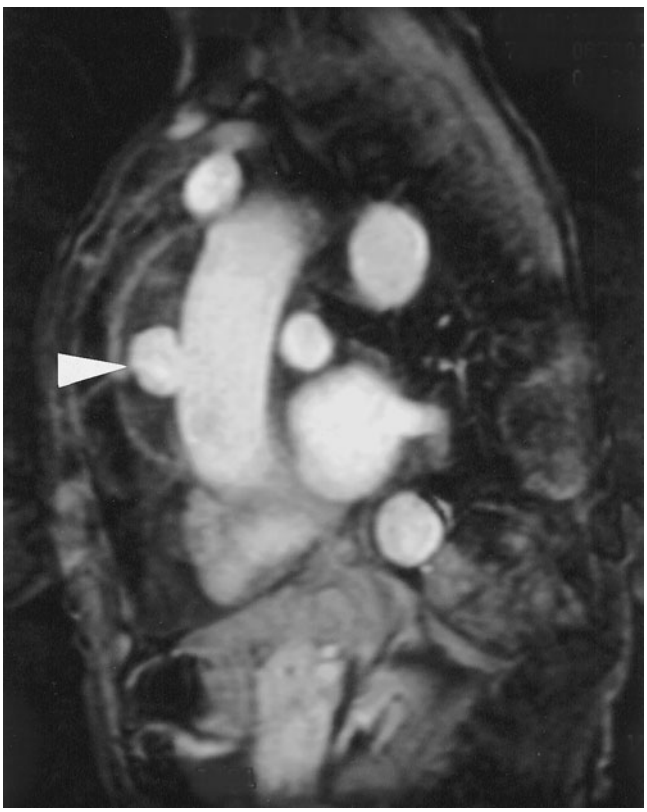

Figure 51-9. Sagittal contrast-enhanced MRI of penetrating atherosclerotic ulcer of the ascending aorta (arrowhead).

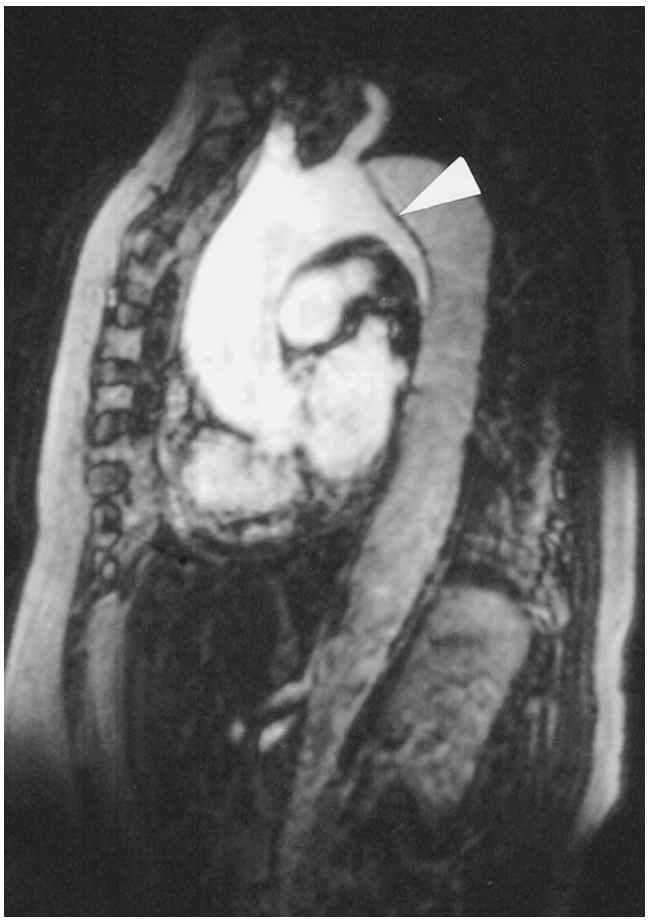

Figure 51-10. Sagittal contrast-enhanced magnetic resonance image of a chronic type B dissection. The dissection flap (arrowhead) is clearly identified and the false lumen appears to extend the entire length of the thoracic and abdominal aorta (darker posterior lumen).

Intravascular ultrasound is a catheter-based imaging tool that provides dynamic imaging of the aortic wall and an intimal flap in patients with aortic dissection. It is particularly useful in delineating the proximal and distal extent of dissection and for identifying the true and false lumens in questionable cases during aortography. High-resolution images of the normal three-layered aortic wall are differentiated to identify the abnormally thin wall adjacent to the false lumen. Because the aortic wall itself is imaged, intramural hematoma and penetrating atherosclerotic ulcers may also be identified. Currently, as an isolated imaging study, it is time consuming and requires skilled personnel, as with aortography, and generally is not useful as an initial study in the acute setting. It may be most useful in combination with aortography when the initial imaging studies are negative, yet there remains a high clinical suspicion of dissection.

MRI and the newer contrast-enhanced magnetic resonance angiography generate superior images, reliably demonstrating aortic dissection (Fig. 51-10). In fact, some consider this the gold standard imaging study given the published diagnostic accuracy. Dissection is identified as an intraluminal membrane separating two or more channels (Fig. 51-11). MRI provides detailed images of the entire aorta, the pericardium, and pleural spaces similarly to those obtained with CT. Cine imaging may also be used to evaluate left ventricular function, the status of the aortic valve, and flow in aortic branch vessels, as well as flow in the false lumen. It is, however, not widely available and the presence of ferromagnetic metal contraindicates its use. Another disadvantage of MRI is that artifact is identified in up to 64% of studies, which underscores the need for expert radiologic interpretation of the images. These factors account for its infrequent use in the acute setting.

Diagnostic strategy

The evaluation of suspected acute aortic dissection begins with a determination of the clinical likelihood that the diagnosis is correct and an evaluation of the hemodynamic stability of the patient. The unstable patient should undergo ECG to rule out acute coronary syndrome and be transferred immediately to the operating room. Medical management may be initiated as soon as the diagnosis is suspected. It is our practice to intubate and mechanically ventilate such patients while essential monitoring lines are placed. A transesophageal echocardiogram is then performed. If TEE fails to reveal acute aortic dissection, a hemodynamically unstable patient will then have a protected airway and invasive monitoring lines for subsequent evaluation of alternative diagnoses and continued resuscitation. If, however, acute dissection is suspected despite a negative TEE, CT arteriogram or aortography (potentially with intravascular ultrasound) is the next study of choice.

Clinically and hemodynamically stable patients permit a more detailed history and physical examination with imaging decisions tailored to specific aspects of the presentation. At the University of Virginia, such patients are first evaluated with a CT arteriogram. A CT scanner is located in the emergency department and these data may be obtained in less than 15 minutes. If that study is negative yet the diagnosis is still entertained, TEE is performed. In a recent review, an average of 1.8 imaging studies was used to correctly diagnose acute aortic dissection.[13] Although TTE is a relatively insensitive study (especially in the descending thoracic aorta), patients with suspected acute type A dissection may first undergo that study. If positive, subsequent confirmation using TEE may be performed in the operating room to expedite surgical management; if negative, either CT scanning or TEE performed in the intensive care unit is appropriate.

Natural History

Fifty percent of patients suffering acute type A aortic dissection are dead within 48 hours.[17] A conventional wisdom has evolved that acute type A dissection carries a "1% per hour" mortality. Newer data, however, reveal a different prognosis such that medical management may be considered in certain

Figure 51-11. Axial (A) and sagittal (B) contrast-enhanced magnetic resonance images of a chronic type A dissection.

high-risk groups. In one such study, type A dissection was managed medically in 28% of patients for various reasons with a 58% in-hospital mortality.[18] Regardless, this relatively high mortality demonstrates that patients surviving acute type A dissection must be quickly and aggressively diagnosed and managed.

The natural history of acute type B dissection is difficult to determine, primarily because early autopsy series failed to analyze these patients as a distinct group. As a result, most of the studies estimate a 50% mortality for untreated acute type B dissection. More contemporary data from Elefteriades and associates, however, reveal a 9% initial hospital mortality for acute type B dissection, with 66% of the remaining patients having no specific aortic complications requiring surgery.[19] These data are obviously influenced by modern medical treatment but speak to a more benign clinical course when compared to type A dissection.

Initial Medical Management

Recognizing the natural history of patients with aortic dissection dictates that management occurs as part of the initial diagnostic evaluation. The initial patient encounter therefore focuses as much on making the diagnosis as in identifying factors that require immediate treatment. The site of this initial evaluation and resuscitation is determined primarily by the hemodynamic stability of the patient. The unstable patient belongs in the operating room, whereas a more detailed diagnostic approach from which management follows on an urgent basis can be undertaken in stable patients. Therefore, the hypotensive patient who may be hypovolemic as a result of blood loss into the thorax or pericardium undergoes the aforementioned evaluation and resuscitation on transfer to the operating room. It is preferable to avoid procedures such as TEE or central line placement on an awake patient outside the operating room because hypertension resulting from patient discomfort may precipitate aortic rupture or propagation of dissection.

In the stable patient, blood pressure is measured in both arms and immediately treated to achieve a target systolic blood pressure between 90 and 110 mm Hg. Blood pressure control in hypertensive patients with pain should first be treated with narcotic analgesics. In general, the goals of hypertension management in acute aortic dissection are twofold.[9] First, aortic wall stress is lowered by decreasing the systolic blood pressure, which reduces the possibility of rupture. Second, shear stress on the aorta is decreased by minimizing the rate of rise of aortic pressure to decrease the likelihood of dissection propagation, so-called anti-impulse therapy. The drugs most commonly used for these purposes are sodium nitroprusside and esmolol. Sodium nitroprusside is a direct arterial vasodilator with a short onset and duration of action, which make it ideal to rapidly achieve the target systolic blood pressure. The rate of rise of aortic pressure, however, is increased when sodium nitroprusside is used alone. Esmolol is added to decrease the inotropic state of the myocardium and to decrease the heart rate. This drug is a $beta_1$-selective blocking agent with a short half-life that can easily be titrated to achieve the target blood pressure. Loading doses for esmolol and sodium nitroprusside should be avoided to prevent hypotension. Alternative $beta_1$-blocking drugs such as propranolol or metoprolol, and the combined alpha and beta-blocker labetalol are appropriate in the subacute phase. Alternatively, calcium channel blockers may be necessary to reduce systolic blood pressure in those patients with a contraindication to beta-blocker use. There are, however, no compelling data supporting their efficacy in acute dissection.

Operative Indications

The goals of surgery in acute type A dissection are to prevent aortic rupture into the pericardium or pleural space and to avoid involvement of the coronary ostia or aortic valve

Table 51–4.

Operative Indications for Acute and Chronic Type A and B Thoracic Aortic Dissection

Dissection type	Operative indication
Acute	
Type A	Presence
Type B	Rupture
	Malperfusion
	Progressive dissection
	Failure of medical management
Chronic	
Type A	Symptoms related to dissection (congestive heart failure, angina, aortic regurgitation, stroke, pain)
	Malperfusion
	Aneurysm
Type B	Symptoms related to dissection
	Malperfusion
	Aneurysm

(Table 51-4). The presence of ascending aortic involvement is, therefore, an indication for operative management in all but the highest-risk patients. The difficulty arises in determining which patients are high risk and which additional factors should affect the management algorithm. Patient age, for example, is not regarded as an absolute contraindication to surgery. This fact should perhaps be considered, however, given the few reported survivors of operative treatment for acute type A dissection who are greater than 80 years of age. Neurologic status at the time of presentation can also affect the decision to operate. While most agree that obtunded or comatose patients are unlikely to improve with surgical repair, complications such as stroke or paraplegia at the time of presentation are not contraindications to surgical correction. The status of the dissection should not be a factor; thrombosis of either lumen occurs, but these patients remain at risk for lethal complications and surgery is indicated. Similarly, patients with subacute type A dissection who present or are referred longer than 2 weeks following the event require operation. Scholl and colleagues demonstrated that these patients have avoided the early complications of dissection and may safely undergo elective operation rather than emergency repair.[20]

The goals of surgical management of complicated acute type B dissection are the prevention of free rupture and continued perfusion of end organs in the absence of symptoms. The advent of endovascular intervention has provided another option for the type B dissection; however, indications for these procedures are identical to the indications

for open intervention. The most frequent causes of death in acute type B dissection are aortic rupture and visceral malperfusion. These, however, occur much less frequently with medical management than do complications of acute type A dissection treated nonoperatively. Between 70 and 80% of patients with acute type B dissection survive the acute and subacute phases with medical management alone. Such success with medical management has traditionally relegated surgical treatment for acute type B dissections to the complications of medical management of progression of disease (see Table 51-4). The indications for repair include contained or free aortic rupture, acute aortic expansion, malperfusion syndrome, pain or progression of dissection despite maximal medical management, and failure of medical management to control hypertension. Although medical management of acute type B dissection is the rule in most centers, some centers advocate immediate surgical intervention in selected patients with uncomplicated acute type B dissection. Factors that may favor early operation in acute type B dissection are the presence of Marfan syndrome, a large false aneurysm, arch involvement, and presumed medical compliance issues.[21] As in acute type A dissection, acute paralysis does not contraindicate surgery because patients can have remarkable improvement following revascularization.

There is some debate regarding the treatment of patients diagnosed with intramural hematoma and penetrating atherosclerotic ulcer. Recent data regarding the natural history of these dissection variants have made the issue less confusing. Intramural hematoma may lead to acute rupture in up to 35% of patients, whereas regression or no change in the hematoma is seen in the majority of medically managed patients surviving the initial period. Similarly, patients with penetrating atherosclerotic ulcer were found to have a 42% rate of acute rupture.[22] As a result of these relatively high acute rupture rates, the Yale group currently recommends early operative intervention for intramural hematoma and penetrating ulcer involving the ascending aorta. In the descending aorta, medical management with anti-impulse therapy and a low threshold for operative intervention result in the lowest mortality. These patients require continuous observation and repeat diagnostic imaging after 3 to 5 days in the hospital to monitor the lesion.

Operative Technique

Anesthesia and monitoring

Anesthesia used during the repair of aortic dissections is often narcotic-based with inhalational agents for maintenance. Single-lumen endotracheal tubes are used for procedures performed through a median sternotomy, while double-lumen endotracheal tubes are useful but not mandatory for procedures performed through a left thoracotomy. Monitoring lines often include central venous access with a pulmonary artery catheter and one or more arterial pressure monitoring lines specific to the operation performed. One or two radial arterial lines and at least one femoral line are required to ensure adequate perfusion of the upper and lower body. All patients require a TEE probe for various reasons. Core body temperature is monitored in the bladder using a Foley catheter and in the esophagus using a nasopharyngeal probe. A wide skin preparation to include the axillary and femoral arteries is essential to provide all possible cannulation options.

Neurologic monitoring is available, but its utility remains controversial. Advocates of both cerebral and spinal cord monitoring argue that these monitors are able to detect injury to neurons prior to irreversible cellular injury.[23] Thus, this warning allows for detection of imminent injury and subsequent evasion of injury. Opponents argue that there is a significant learning curve and that the injury has already occurred once these monitors can identify ischemic neurologic changes. Depending on the location of the dissection and the resultant location of the vascular control can dictate the type of monitoring desired. Manipulation of the ascending aorta and arch can affect cerebral perfusion. In these cases, transcranial Doppler or near-infrared spectroscopy have been utilized. Intraoperative transcranial Doppler monitoring is utilized to identify malpositioned cannulas or to document need for adjustment of retrograde perfusion.[24] Opponents of transcranial Doppler argue difficulty with low baseline flow in patients and poor signal with thick temporal bones, which confounds interpretation of the results and the response to them. Continuous noninvasive near-infrared spectroscopy can be utilized to monitor cerebral oxygenation, a marker of cerebral blood flow. Although the role of noninvasive near-infrared spectroscopy in aortic dissection has not been elucidated, advocates extrapolate use from studies on carotid endarterectomy and coronary bypass.[25,26] Noninvasive near-infrared spectroscopy can be utilized for identification of regional oxygenation changes during the case, which may be particularly useful during normothermic periods of these cases.[23] Somatosensory evoked potentials are argued to be useful in identifying neurologic injury ranging anywhere from the peripheral nerve to the brain. These studies may even identify ischemic cerebral injury during hypothermic circulatory arrest earlier than electroencephalography.[27] Somatosensory evoked potentials can also be useful in the detection of spinal cord ischemia and guide the identification of crucial spinal cord vasculature requiring reimplantation. The use of somatosensory evoked potentials at some centers has led to reduced intraoperative and postoperative paraplegia.[28] Neurologic monitoring remains a relatively new technology that is operator-dependent, but probably is useful in experienced hands.

Hemostasis

Surgical procedures for aortic dissection can be associated with significant blood loss. Strict blood conservation is an

important aspect of the operation and at least one cell-saver device should be available. Packed red blood cells, platelets, and fresh frozen plasma should be in the operating room at the start of the operation. Coagulopathy as a result of the preoperative status of the patient, cardiopulmonary bypass, and deep hypothermic circulatory arrest contribute to excessive blood loss. Improvements in vascular graft material have all but eliminated this as a reason for intra- and postoperative blood loss. Antifibrinolytic drugs such as ε-aminocaproic acid and aprotinin are useful hemostatic adjuncts. Aprotinin is particularly useful when used in either the full or one-half Hammersmith regimen, and is most effective when administered prior to the operation. In patients in whom deep hypothermic circulatory arrest is used, aprotinin is administered in our practice only after the period of circulatory arrest. Until recent reports on the magnitude of renal and thrombotic complications with its use, aprotinin was a mainstay of hemostasis for these cases. Although its use is now considered controversial, some surgeons would still consider its use in dissection repair due to the relative coagulopathy in these cases compared to more straightforward cases on cardiopulmonary bypass.[29] Currently, the role of aprotinin is unclear even within our practice. Patients will often require transfusion of fresh frozen plasma, platelets, and possibly cryoprecipitate. Fibrin glues and hemostatic materials such as Surgicel and Gelfoam are useful as systemic coagulopathy is corrected.

Cardiopulmonary bypass

There are various options for arterial and venous cannulation sites based on the type of dissection. Arterial cannulation of the uninvolved distal aortic arch is preferable in acute type A dissection. Cannulation of the true lumen of the dissected ascending aorta is possible. The true lumen can be safely accessed using the Seldinger technique over a long wire introduced and guided by TEE.[30] Alternative sites include the right subclavian and the innominate artery for antegrade perfusion, or either femoral artery with retrograde aortic perfusion. Access of the axillary is described both using direct cannulation of the vessel or by cannulation of a silo graft sewn to the artery, with a low risk of complications including stroke.[31–33] However, direct axillary cannulation appears to cause more morbidity than side arm cannulation, including further dissection, brachial plexus injury, and limb ischemia.[34] The aortic dissection often involves the innominate artery, making access to the true lumen of this vessel more hazardous. In any case of retrograde aortic perfusion, it is essential to monitor proximal perfusion with a functioning radial arterial catheter.

There is debate over which femoral artery to cannulate in the setting of lower extremity malperfusion with a pulse deficit. Dissection of the abdominal aorta often leaves the left femoral artery originating from the false lumen, and therefore cannulation of the right femoral artery will most often perfuse the true lumen. Perfusion of the false lumen can cause retrograde dissection and malperfusion of aortic branch vessels arising from the true lumen. In that event, cardiopulmonary bypass should be stopped for aortic cannulation through an alternative site to achieve whole body perfusion. If the chest has been opened, direct cannulation of the ascending aorta is often successful when guided by TEE. An alternative cannulation technique is through the left ventricular apex and aortic valve. The cannula is then held in position with an ascending aortic tourniquet. Fortunately, there are usually multiple reentry tears throughout the dissection flap which permit perfusion of both lumens regardless of the lumen cannulated.

Venous cannulation is most often accomplished through the right atrium using a two-stage venous cannula, while bicaval cannulation is reserved for certain cases in which retrograde cerebral perfusion is preferred during circulatory arrest. A left ventricular vent is necessary in the setting of aortic valve incompetence and is easily placed through the right superior pulmonary vein or rarely through the left ventricular apex wall. Cardioplegia is administered retrograde through a coronary sinus catheter with additional protection via direct cannulation of the undissected coronary ostia.

The formerly popular "clamp and sew" technique used for repair of acute type B dissection has largely been replaced by the use of partial left heart bypass. Arterial cannulation sites for this technique include the distal thoracic aorta for limited dissections of the proximal descending thoracic aorta or the femoral artery for those extending into the abdomen. Venous drainage of oxygenated blood is through the left inferior pulmonary vein or the left atrium via the appendage when accessible. This technique does not require an oxygenator or pump suction and therefore the dose of heparin (100 U/kg) is less than with full cardiopulmonary bypass.

Cerebral protection

Surgical repair of aortic dissection involving the arch requires disruption of adequate blood flow to the brain during a period of circulatory arrest. Cerebral protection during that period is paramount and may be achieved through either deep hypothermia with cessation of electrical activity or some form of continued cerebral perfusion. Deep hypothermia during circulatory arrest was the first method used to perform operations on the aortic arch and remains an effective method for shorter procedures. Generally, periods of circulatory arrest up to 14 minutes are acceptable at 25°C, and periods up to 31 minutes appear to result in only transient neurologic sequelae at 15°C in a small number of patients.[35] Specifically, the risk of transient neurologic dysfunction on cognitive testing following a period of circulatory arrest is roughly 10% at less than 30 minutes, but increases to 15% at 40 minutes, 30% at 50 minutes, and 60% at 60 minutes.[36]

It is critical to correctly estimate brain temperature to ensure expected outcome. Nasopharyngeal and tympanic temperatures are measured to estimate brain temperature but are imperfect. For that reason, some groups use electroencephalographic silence to determine the appropriate point at which to discontinue cooling and perfusion. Slow systemic

cooling on cardiopulmonary bypass (20 to 25 minutes) while maintaining a maximal temperature gradient between perfusate and patient of less than 10°C is ideal. The head is then packed in ice to maintain a low brain temperature. While cooler temperatures increase the safe interval of circulatory arrest, cooling to lower than 15°C may result in a form of nonischemic brain injury and is therefore not recommended. Methylprednisolone and thiopental administration during cooling are adjunctive measures thought by some to decrease cerebral metabolic requirements during the period of circulatory arrest, but we currently do not use either. Reinstitution of cardiopulmonary bypass with systemic rewarming following repair proceeds without exceeding a 10°C temperature gradient to at least 37°C, as core body temperature often falls briefly after cessation of active warming and separation from cardiopulmonary bypass. Furosemide and mannitol are administered to initiate diuresis and to promote free radical scavenging following circulatory arrest.

Continued cerebral perfusion during the period of circulatory arrest is an alternative technique for cerebral protection, especially for circulatory arrest times >20 minutes. Cerebral blood flow may be delivered in either a retrograde or antegrade fashion. The technique for retrograde cerebral perfusion depends on the venous cannulation strategy. If bicaval cannulation is required, reversing flow through the superior vena caval cannula with a proximally placed tourniquet is simple and effective. Dual-stage venous cannulation requires placement of a retrograde coronary sinus catheter into the superior vena cava through a purse-string suture. Retrograde cerebral perfusion has the added benefit of flushing atherosclerotic material and air from the brachiocephalic vessels. A flow rate necessary to produce a superior vena caval pressure of 15 to 25 mm Hg is considered optimal. Selective antegrade cerebral perfusion has recently gained popularity. Once the aortic arch is open, the innominate artery and the left common carotid artery are encircled with vessel occluders and each lumen is cannulated with a retrograde coronary sinus cannula. With the left subclavian artery occluded, flow rates are slowly increased to achieve perfusion pressures of 50 to 70 mm Hg at the desired circulatory arrest temperature. These cannulas are then removed just prior to completing the anastomosis of the brachiocephalic vessels to the vascular graft, at which time cardiopulmonary bypass may be reinstituted.

Techniques for type A dissection

The exposure for procedures performed on the ascending aorta and the proximal arch is through a median sternotomy. This can be modified with supraclavicular, cervical, or trapdoor incisions to gain exposure to brachiocephalic vessels or the descending thoracic aorta. When dissecting the distal arch, it is important to identify and protect both the left vagus nerve with its recurrent branch and the left phrenic nerve. Replacement of the ascending aorta in type A dissections is best performed by an open distal anastomosis technique if the arch is involved (30%) or if arch involvement is unknown. The open distal anastomotic technique requires clamping the mid-ascending aorta and cardiac arrest via administration of antegrade and/or retrograde cardioplegic solution. The dissected ascending aorta proximal to the clamp is then opened. Evaluation and surgical correction of the aortic valve is ideally performed at this time while systemic cooling continues. If dissection does not involve the aortic root, the aorta is transected 5 to 10 mm distal to the sinotubular ridge. If dissection involves the sinotubular ridge, the proximal aorta is reconstructed by reuniting the dissected aortic layers between one or two strips of Teflon felt using either 3-0 or 4-0 polypropylene suture. Safi and associates use a technique of interrupted pledgeted horizontal mattress sutures as compared to the felt sandwich technique. In their experience, this provides superior stabilization and decreases the potential for subsequent aortic stenosis. There has also been a great deal of enthusiasm for reuniting the dissected layers using gelatin-resorcinol-formalin glue or the newer BioGlue (CryoLife International, Kennesaw, Ga). There are, however, concerns regarding each of the commercially available types of glue. Excessive application of these adhesives has been reported to lead to redissection of the vessel, anastomotic pseudoaneurysm formation, and potential infectious complications.[37–40] Most reviews focus on the tissue toxicity of the formalin component in these adhesives as the source of the reported complications.[41]

Once the temperature reaches 18 to 20°C, perfusion is discontinued during a brief period of circulatory arrest. The aortic clamp is released and the intima of the aortic arch is inspected and repaired accordingly (Fig. 51-12). If the intima is intact, the distal anastomosis is performed and the graft is

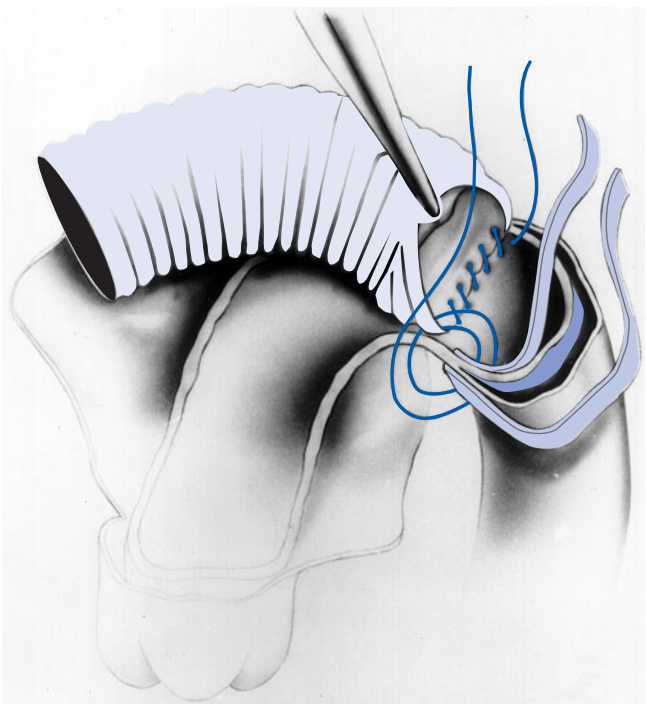

Figure 51-12. The false lumen of the distal aorta is closed and the aortic wall is reconstructed with inside and outside felt strips.

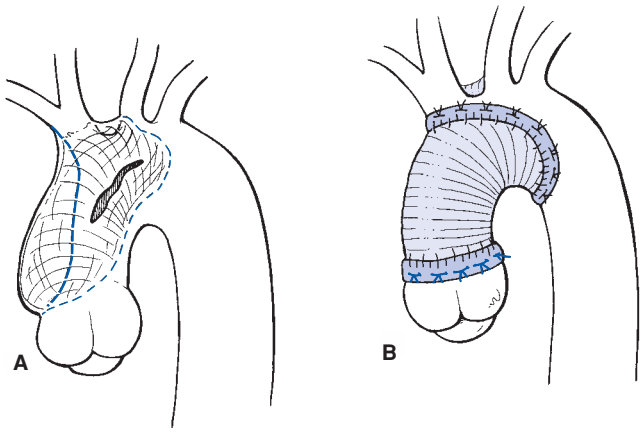

Figure 51-13. (A) The type A dissection extends into the proximal aortic arch. (B) The distal dissected aortic wall is reconstructed with inside and outside felt strips to replace part of the arch and ascending aorta.

cannulated, de-aired, and clamped for resumption of cardiopulmonary bypass with systemic warming. If the intima of the arch is violated, then a hemiarch reconstruction is performed (Fig. 51-13). We have only rarely found it necessary to perform a complete arch resection for an acute dissection. If a complex aortic root procedure is required, it is often useful to repair the aortic root with one vascular graft and use a separate graft to create the distal aortic anastomosis. The two grafts are then measured, cut, and anastomosed to provide the correct length and orientation for aortic replacement.

If the ascending aorta cannot be cross-clamped, the patient is cooled to 20°C with subsequent circulatory arrest. The distal aortic reconstruction is performed first in this circumstance, at which time the graft is cannulated and proximally clamped with resumption of cardiopulmonary bypass and systemic rewarming. Cannulation of the graft for antegrade systemic perfusion and rewarming is associated with improved neurologic outcome compared to retrograde perfusion and should be performed whenever possible. Newly available vascular grafts include 7- to 8-mm Dacron sidearm grafts for easy cannulation to facilitate this technique. Because a cross-clamp is not applied, the left ventricle must be decompressed once fibrillation starts during systemic cooling (approximately 20°C) to prevent distension and irreversible myocardial injury. Proximal ascending aortic repair is completed during the period of rewarming.

An alternative to the open distal technique is possible when dissection is limited to the ascending aorta or the proximal arch away from the origin of the brachiocephalic vessels. Antegrade arterial perfusion is achieved through distal arch or right subclavian artery cannulation; retrograde perfusion via cannulation of a femoral artery has traditionally provided acceptable results. An aortic cross-clamp is applied tangentially just proximal to the innominate artery. The ascending aorta is resected to include the inferior aspect of the arch. The layers of the dissected aorta proximal to the clamp are then reunited if necessary and the ascending aorta replaced with an appropriately sized, beveled vascular graft. The proximal reconstruction and anastomosis may then be performed and the entire procedure performed without requiring deep hypothermia and circulatory arrest.

Isolated dissection of the aortic arch is rare. Classified as a type A dissection, it requires resection of the arch at the site of intimal disruption and aortic replacement. Surgical management of the brachiocephalic vessels is determined by the integrity of the adjacent intima. If intact, the brachiocephalic vessels are reimplanted as a Carrel patch into a vascular graft after repair (Fig. 51-14). If the dissection involves individual vessels, each may require repair and reimplantation individually into the graft used for arch replacement (Fig. 51-15).

Aortic root dissection often fails to violate the intima of the coronary ostia. Repair of the ascending aorta at the sinotubular junction is therefore sufficient to reunite the aortic root layers and provide uninterrupted coronary blood flow. Minimal disruption of the coronary ostial intima should be repaired primarily with 5-0 or 6-0 polypropylene suture. If, however, the ostium is circumferentially dissected and an aortic root replacement is necessary, an aortic button should be excised and the layers reunited with running 5-0 polypropylene suture, glue, or both. Coronary buttons are then reimplanted into the vascular graft or to a separate 8-mm vascular graft as part of a Cabrol repair (Fig. 51-16). Aortocoronary bypass grafting is performed only when the coronary ostium is not reconstructible and as a last resort.

Acute type A dissection is complicated by aortic valve insufficiency in up to 75% of patients. Fortunately, preservation of the native valve is successful nearly 85% of the time. The mechanism of aortic insufficiency in most cases is the loss of commissural support of the valve leaflets. This is repaired using pledgeted 4-0 polypropylene sutures to reposition each of the commissures at the sinotubular ridge (Fig. 51-17). The dissected aortic root layers are then reunited using 3-0 polypropylene suture and either one or two strips of Teflon felt. Bioglue is placed between the layers prior to suture repair of the sinotubular ridge to buttress the repair and reform the sinuses of Valsalva. Aortic valve preservation must always be performed using intraoperative TEE to assess the valve postoperatively. No more than mild aortic insufficiency should be present. In addition to commissural resuspension, techniques exist to spare the aortic valve and replace the aortic root in acute type A dissection, but the experience is early and the number of patients few. This topic is covered in greater detail in the section on surgical techniques for chronic type A dissection.

If the aortic valve cannot be spared, replacement of the ascending aorta and valve should be performed using a composite valve graft or homograft. The composite valve graft is implanted using horizontal mattress 2-0 Tycron sutures to encircle the annulus and to seat the valved conduit (Fig. 51-18). The previously excised and reconstituted coronary buttons are reimplanted into the vascular graft with running 5-0 polypropylene suture (Fig. 51-19). The left

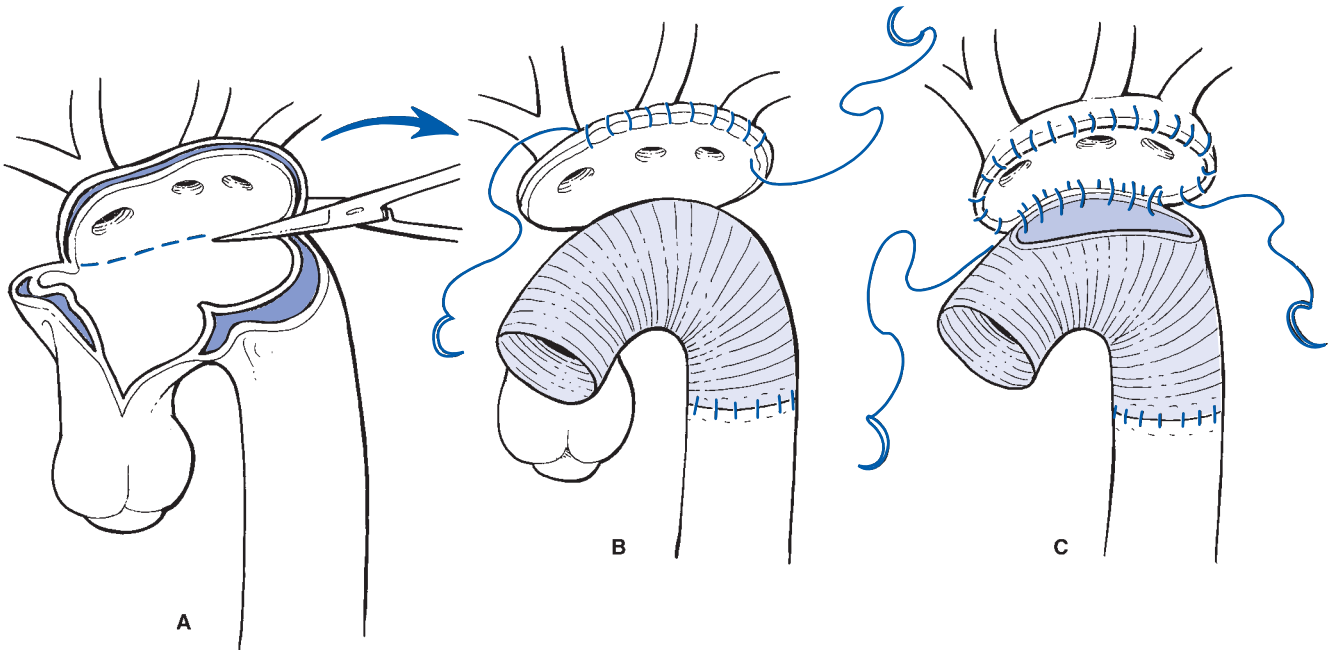

Figure 51-14. Brachiocephalic vessels can be reattached to an arch graft as a unit if the inner cylinder of origin of each vessel remains intact. (A) The arch vessels are excised as a unit from the superior surface of the dissected aortic arch. (B) The separated layers of the brachiocephalic patch are reunited using inner and outer felt strips and continuous suture. (C) A corresponding hole is cut in the aortic graft and the continuous brachiocephalic unit is sutured into place.

coronary button is implanted first, at which time the graft is clamped and placed under pressure to define the proper orientation and position of the right coronary button. The aortic homograft is similarly implanted using horizontal mattress 2-0 Tycron sutures, except that a generous margin of aortic root below the coronary buttons is retained for a second hemostatic suture line of running 4-0 polypropylene. This is an ideal solution for individuals who have a contraindication to anticoagulation or for young females. The Ross procedure (pulmonary autograft) is not applicable in those patients with connective tissue disorders and is not recommended in acute dissection.

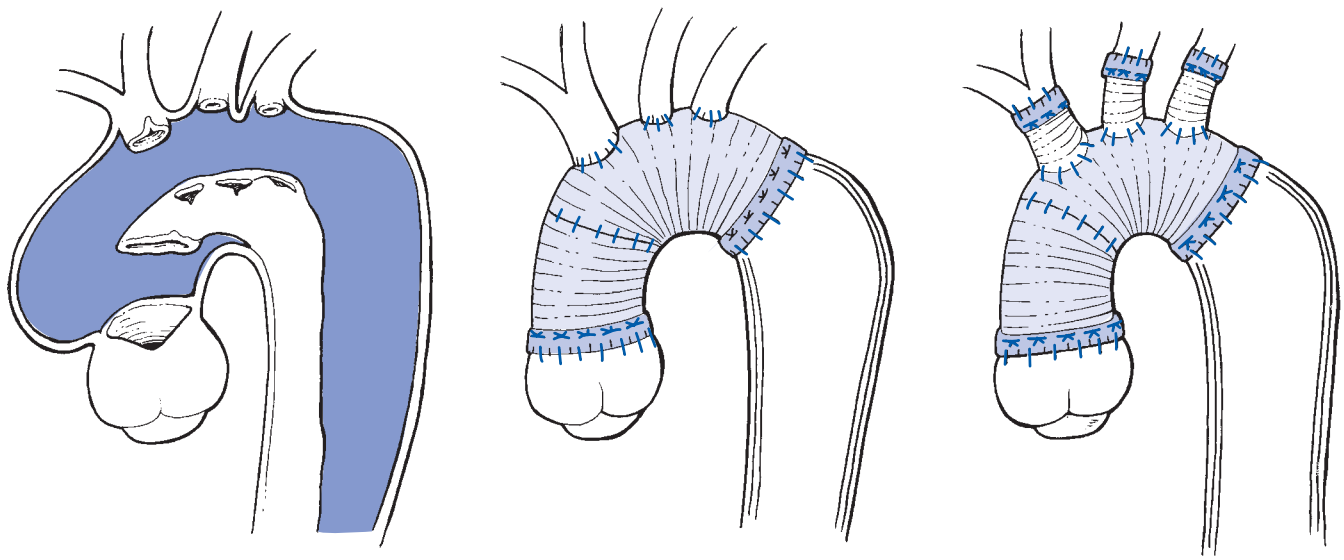

Figure 51-15. The brachiocephalic vessels are separated from the true lumen by the dissected false lumen (left panel). If individual brachiocephalic vessels are also damaged beyond repair, short interposition grafts are added to reconnect each artery to the aortic graft (right panel).

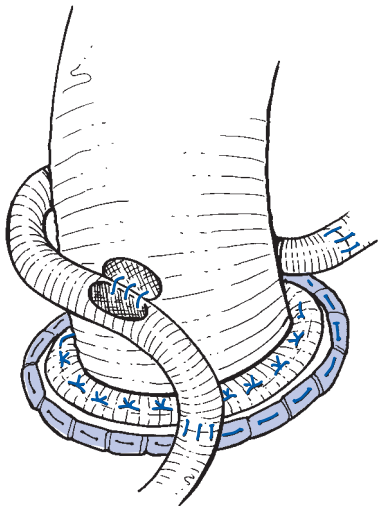

Figure 51-16. Illustration showing the attachment of the coronary ostia to the graft using the Cabrol technique. The ends of a 60-mm Dacron graft are sewn end to end to each coronary ostium. A side-to-side anastomosis is made between the intercoronary tube graft and the aortic graft.

Endovascular stent grafting is currently under investigation as a definitive form of management in acute type B dissection and in conjunction with surgery for acute type A dissection. Long-term data and prospective comparisons to surgery will be necessary before percutaneous management can be recommended as an alternative to surgery.

Techniques for type B dissection

The right lateral decubitus position is optimal for surgical treatment of acute type B dissections requiring operation. The pelvis is canted posteriorly to allow access to both sets of femoral vessels. A posterolateral thoracotomy in the fourth intercostal space provides sufficient access to the aorta; notching the fifth and sixth ribs posteriorly permits visualization of the entire thoracic aorta distally. A thoracoabdominal incision may be required to access the abdominal aorta in the case of visceral malperfusion. This may be performed either through the abdomen or the retroperitoneum. The left hemidiaphragm must be carefully divided in a radial fashion while marking adjacent sites on each side of the division with metal clips. This provides all necessary exposure and facilitates subsequent diaphragm approximation at the end of the case.

The ideal operation for acute type B dissection is replacement of as little of the descending thoracic aorta as is necessary. The extent of replacement rarely exceeds the proximal third and includes the primary tear in most cases. Such a strategy optimizes preservation of intercostal arteries perfusing the spinal cord to combat an incidence of paraplegia that may be as high as 19% following surgery for acute type B dissections.[42] This point is controversial, however, and some groups advocate replacement of the entire thoracic aorta. Any less extensive aortic replacement leaves dissected aorta with the potential for late aneurysmal dilation when there is perfusion of the false lumen. The ideal strategy to minimize spinal cord malperfusion yet resect all involved aorta has not been proven.

Once the thoracic aorta has been exposed, the operation continues with division of the mediastinum between the left subclavian and the left common carotid arteries. The left subclavian artery is encircled with an umbilical tape and Rommell tourniquet. It is essential that the left vagus and recurrent laryngeal nerves are identified and preserved during the course of the dissection. Ultimately, the entire distal arch must be free enough to place an aortic clamp between the left common carotid and left subclavian arteries. Next, the proximal descending thoracic aorta is circumferentially mobilized, dividing intercostal arteries in the segment to be excised. The left inferior pulmonary vein is then dissected and a 4-0 polypropylene purse-string suture placed posteriorly to cannulate for partial left heart bypass. Following the administration of 100 U/kg of intravenous heparin, 14F cannulas are inserted into the left inferior pulmonary vein and either a normal-appearing area of descending thoracic aorta or percutaneously into either femoral artery. Bypass is then initiated with flow rates between 1 and 2 L/min. The left subclavian artery is controlled and vascular clamps are placed on the aorta proximally and distally on the mid-thoracic aorta. Right radial artery pressure is measured to maintain proximal aortic systolic pressure between 100 and 140 mm Hg and mean femoral artery pressure greater than 60 mm Hg.[43] The aorta is then opened longitudinally and bleeding from intercostal arteries is controlled by suture ligation. Transection of the aorta distal to the origin of the left subclavian artery provides a site for the proximal anastomosis. This is performed using 3-0 polypropylene suture and may require external reinforcement with Teflon felt strips.

The graft inclusion technique is another technique in which the posterior aspect of the proximal aorta is not fully transected. The proximal anastomosis is then made to the intact posterior aspect of the aorta. We do not recommend this technique since one cannot be certain of anastomosing all layers of the aorta. The size of the vascular graft is based on the diameter of the distal aorta and beveled to match the aorta proximally. This anastomosis may include the origin of the left subclavian to treat dissection in this vessel. A separate 6- to 8-mm Dacron graft can be used if there is intimal disruption involving the proximal segment of the left subclavian artery. Once the proximal anastomosis is complete, the proximal clamp is released and repositioned on the vascular graft to inspect the anastomosis. Attention is then turned to repairing the distal aorta with Teflon felt or glue. The distal anastomosis is completed, the clamps are released, and partial left heart bypass is terminated. Decannulation is routine except that percutaneously placed femoral artery cannulas 14F or smaller may be removed without direct repair. When cannulas larger than 15F are required, open surgical repair of the femoral arteriotomy is indicated.

Endovascular stent graft placement is another option for type B aortic dissections. These devices are generally

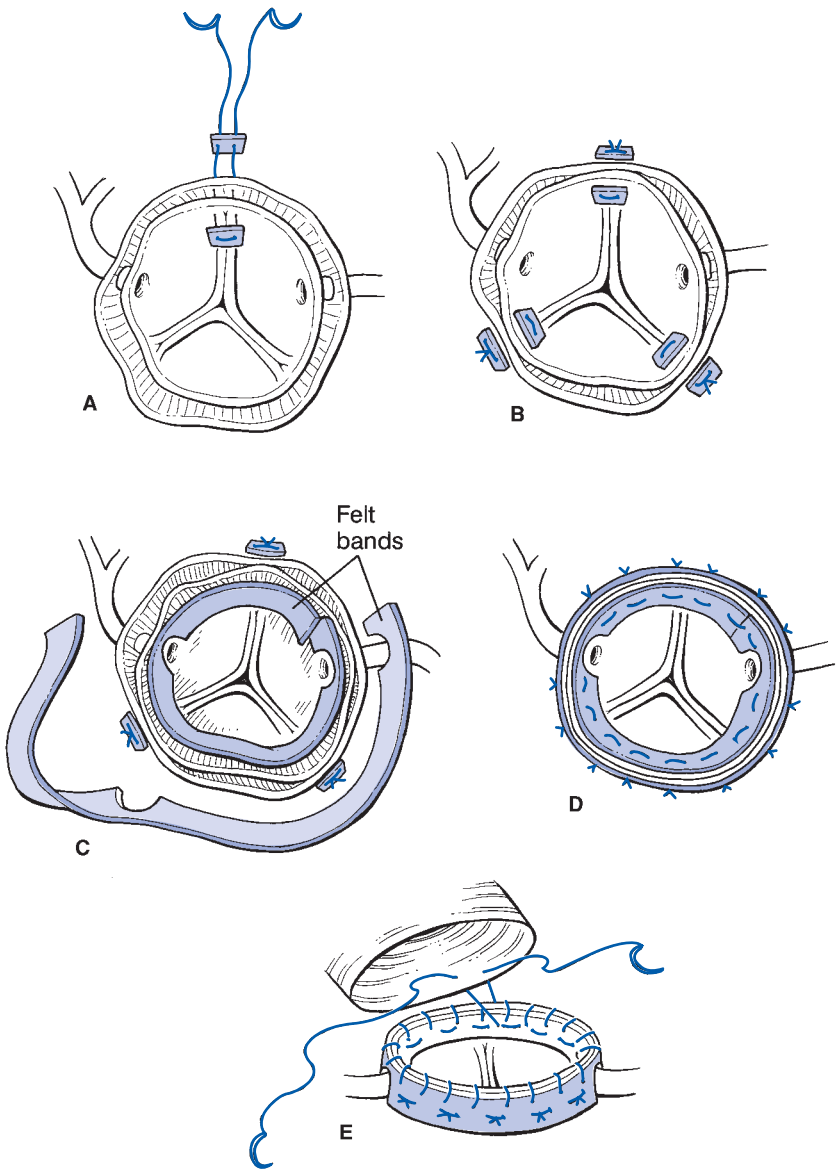

Figure 51-17. Resuspension and preservation of the native aortic valve in a type A dissection. (A) The dissected layers are approximated at each commissure with double pledgeted mattress sutures. (B) The aortic valve commissures are completely resuspended. (C) Thin felt strips (8- to 10-mm wide) are placed inside and outside from the circumference of the aorta. The coronary ostia are not compromised. (D) The aortic walls are sandwiched between the felt strips with a horizontal mattress. (E) A vascular graft is sutured to the reconstructed proximal aorta.

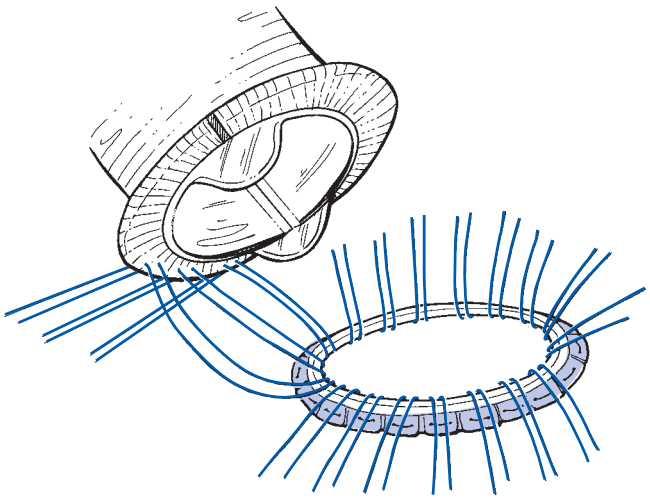

Figure 51-18. Everting 2-0 pledgeted mattress sutures are placed shoulder to shoulder around the aortic annulus to anchor a composite graft containing a St. Jude prosthesis.

introduced through the femoral arteries as access to the thoracic aorta. However, alternative access via the iliac arteries or infrarenal aorta has been described. Fluoroscopy is of course mandatory, but adjuncts like intravascular ultrasound and TEE can be useful in clarifying the true and false lumens as well as the proximal and distal fixation sites of the graft. Important considerations with deployment include graft de-airing, possible aortic blood flow restriction with pharmacologic manipulation, and various deployment strategies, such as partial or rapid deployment. Stent grafts should be oversized 10 to 20% relative to the native aortic diameter to adequately address the dissection. Care must be taken to avoid injury to the proximal aorta during stent graft placement to reduce the risk of retrograde dissection and its inherent morbidity.[44] Due to the curvature of the aorta and the proximal pressure wave, make the landing zone critical for thoracic stent graft placement. In some cases, coverage of the left subclavian artery proximally and retrograde revascularization of the celiac

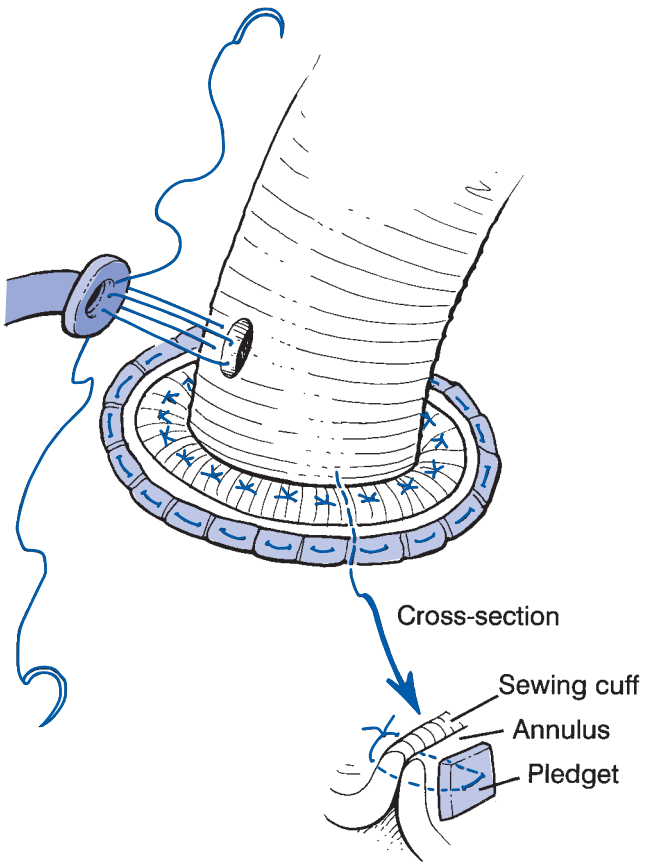

Figure 51-19. The coronary ostia are attached to the graft by the button technique using continuous 5-0 polypropylene suture.

distally may be required to improve the landing zone for the stent graft, thus reducing significant endoleaks.

Rupture of the thoracic aorta prior to or during repair is a catastrophic event often leading to operative death. Successful management requires immediate cannulation of the femoral artery and vein for cardiopulmonary bypass and eventual deep hypothermic circulatory arrest, but only if the ruptured area can be locally controlled. Assisted venous drainage through the femoral vein is often adequate, but direct cannulation of the right ventricle through the pulmonary artery may also be performed. A left atrial vent is placed through the left inferior pulmonary vein once the heart begins to fibrillate; the left ventricle may be vented as well directly through the apex. Once the nasopharyngeal temperature reaches 15°C, the vent is occluded and cardiopulmonary bypass is stopped. The head is placed down and the aorta opened for repair under circulatory arrest. The distal aorta should be clamped to minimize blood loss. Once the proximal anastomosis is performed, the proximal clamp is moved onto the graft and the graft cannulated to resume cardiopulmonary bypass.

Spinal cord ischemia resulting in paraplegia or paraparesis is a recognized complication of acute dissection repair that may be partially preventable and even reversible. The incidence of spinal cord ischemia is between 19 and 36% following repair of acute type B dissection.[42,43] Whereas various strategies exist to prevent spinal cord ischemia during repair of chronic dissection, very few are feasible in the acute setting. Pharmacologic agents such as steroids, free radical scavengers, vasodilators, and adenosine are promising adjuncts to prevent spinal cord ischemia but presently have little to no proven clinical utility. We presently use left atrial to femoral artery bypass and reimplant key intercostal arteries and selectively use cerebrospinal fluid drainage as outlined by Safi and colleagues.[45]

Malperfusion syndrome

Malperfusion of aortic branch vessels may occur from the coronary ostia to the aortic bifurcation and may dominate the presentation of certain patients. Although autopsy series yield a greater percentage of patients with evidence of malperfusion, clinical series reveal that dissection is not infrequently complicated by malperfusion of at least one organ system (Table 51-5).[46,47] Compression of the true lumen by the false lumen is the mechanism by which aortic branch vessel occlusion occurs in the majority of cases. Branch vessels may also be completely sheared off the true lumen and perfused to various degrees by the false lumen. Malperfusion is most often treated with primary surgical repair of the dissection, but catheter-based or open fenestration is reappearing as a potentially more effective treatment.

Percutaneous fenestration, angioplasty, and stenting are relatively new adjuncts to the surgical management of malperfusion syndromes. Renewed interest in these procedures grew from the recognition that hospital mortality of patients presenting with malperfusion was as high as 60%.[48] Surgical fenestration to treat malperfusion, however, reduced the mortality to under 20%.[49,50] Indications for percutaneous fenestration and endovascular stent placement were developed to treat malperfusion syndrome with the goal of improving outcome even further. Direct stenting of

Table 51–5.

Frequency and Location of Malperfusion in Acute Type A and B Thoracic Aortic Dissection

Vascular system	Frequency
Renal	23–75%
Extremities (upper and lower)	25–60%
Mesenteric	10–20%
Coronary	5–11%
Cerebral	3–13%
Spinal	2–9%

obstructed branch vessels and percutaneous fenestration with or without placement of a stent in the true lumen are the procedures most commonly performed. In certain situations, stents may be placed across an existing distal reentry tear to maintain patency and perfusion of the true lumen and the branch vessels. Balloon fenestration may be required to create such a communication between the lumens or to prevent thrombosis of the false lumen from which branch vessels may originate. Early results indicate that this procedure is both safe and effective, with restoration of flow in up to 90% of patients and an average 30-day mortality of 10 to 25%.[51,52] Given that the majority of postoperative mortality in patients with acute dissection and malperfusion is related to the duration of concomitant malperfusion, one strategy is percutaneous reperfusion followed by surgical repair.[53] Percutaneous treatment of malperfusion may also be performed following surgical repair of dissection but with less success in most reports.

The techniques used for surgical treatment of malperfusion depend on the location of the affected branch vessel but are generally quite similar. Malperfusion of the brachiocephalic vessels as a result of acute type A dissection is treated by repairing the dissection proximally if the intima is intact. If the intima is violated or if dissection extends into any brachiocephalic vessel, the artery should be resected from the arch, the layers reunited, and the vessel reimplanted into the arch, perhaps with an interposition vascular graft if necessary. Extra-anatomic bypass to the carotid arteries is an option in unreconstructible cases.

Malperfusion of the intra-abdominal viscera may be apparent at presentation but may also complicate surgical repair of acute type A or B dissections. Again, proximal repair of the dissection is standard treatment, but if this fails or if malperfusion persists despite repair, an additional procedure is necessary. Either open surgical or percutaneous fenestration of the dissection flap is necessary. Percutaneous fenestration is performed by pulling an inflated balloon or a fenestration knife through the dissection flap to create a communication between the two lumens. A surgical fenestration procedure is performed through a midline laparotomy or left flank incision to provide exposure of the infrarenal aorta (Fig. 51-20). Occasionally, fenestration of intra-abdominal aortic branch vessels may be required if the intima is violated beyond the ostia. If the dissection flap cannot be completely excised, the distal vessel layers must be reunited. Consideration should be given to patch angioplasty to prevent narrowing when closing smaller vessels. In the event that perfusion is not reestablished, extra-anatomic bypass may be required.

Obstruction of the terminal aorta or malperfusion of the lower extremities following operative repair is best treated with percutaneous fenestration. Surgical fenestration remains an option if percutaneous techniques fail to reestablish blood flow. In the event that surgical fenestration fails, the best solution is femorofemoral bypass grafting in the setting of unilateral malperfusion, or axillofemoral and femorofemoral bypass grafting if bilateral lower extremity malperfusion exists.

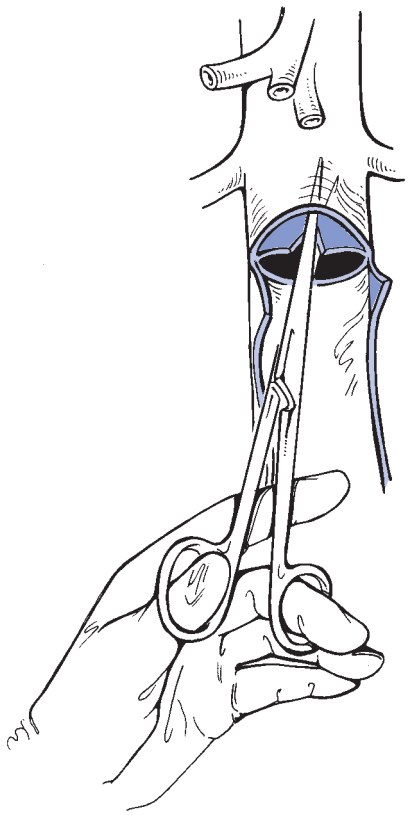

Figure 51-20. Fenestration of the abdominal aorta for visceral malperfusion. A transverse incision is made into the aorta, preferably into nondissected aorta. The proximal dissection membrane is incised and then excised to decompress the false lumen as far proximally as possible. The dissected layers are reconstructed with Teflon felt or glue and the aortotomy is closed directly.

Postoperative Management

Invasive hemodynamic monitoring is used to ensure adequate end-organ perfusion with a target systolic blood pressure between 90 and 110 mm Hg. Early postoperative blood pressure control begins with adequate analgesia and sedation using narcotics and sedative-hypnotic agents. The patient should, however, be allowed to emerge from general anesthesia briefly for a gross neurologic examination. The patient is then sedated for a period to ensure continued hemodynamic stability and to facilitate hemostasis. Coagulopathy is aggressively treated with blood products and antifibrinolytic agents as necessary and by warming the patient. Hematocrit, platelet count, coagulation studies, and serum electrolytes are obtained and corrected as necessary. An ECG and chest radiograph are used to assess for abnormalities and to serve as baseline studies. A full physical exam including complete peripheral vascular exam is performed upon arrival. Despite adequate repair of the dissection, perfusion of the false lumen may persist and therefore malperfusion syndrome remains possible. If an abdominal malperfusion syndrome is suspected postoperatively, this should be aggressively evaluated with ultrasound and subsequent angiography if positive. A strong clinical suspicion is enough to warrant this

evaluation given the consequences of failed recognition. In the morning, if the patient has been hemodynamically stable without excessive bleeding and the results of a neurologic exam are normal, the patient may be weaned from the ventilator and extubated. Management is routine from that point forward.

Long-Term Management

Surviving the operation for acute dissection represents the beginning of a lifelong requirement for meticulous medical management and continued close observation. It has been estimated that replacement of the ascending aorta for type A dissection obliterates flow in the distal false lumen in fewer than 10% of patients. As a result, the natural history of repaired dissection may involve dilatation and potential rupture of the chronically dissected distal aorta. This was the reason for the late death in nearly 30% of DeBakey's original series in 1982 and is currently the leading cause of late death following surgical repair.[54] Often a multidrug antihypertensive regimen including beta-blocking agents is required to maintain systolic blood pressure below 120 mm Hg. There are some data indicating that blood pressure control within a narrow range may alter the natural history of chronic dissection by diminishing the rate of aneurysmal dilatation. The long-term durability of the aortic valve following supracoronary reconstruction is quite good, with freedom from aortic valve replacement of 80 to 90% at 10 years. Progressive aortic insufficiency of the native valve is, however, possible and should be followed with transthoracic echocardiography in some patients.

Follow-up diagnostic imaging is required to monitor aortic diameter in patients with chronic dissection. Spiral CT arteriogram and MRI are the imaging studies of choice. MRI and ultrasound are useful in patients with renal insufficiency and in those requiring only imaging of the abdominal aorta. Echocardiography is useful for imaging the ascending aorta and provides additional information regarding the aortic valve. It is important to recognize the resolution limitations of each imaging modality and inherent imprecision of comparing different imaging modalities to evaluate changes. In general, measurements should be made at the same anatomic level with respect to reproducible anatomic structures (i.e., the sinotubular ridge, proximal to the innominate or left subclavian arteries, or at the diaphragmatic hiatus). It is important to recognize that the false lumen should be included in measurements of aortic diameter whether it is perfused or not. Three-dimensional reconstruction of spiral CT and MRI scans minimizes the error introduced by aortic eccentricity when comparing imaging studies and has simplified following this patient population. The current recommendations are to obtain a baseline study prior to hospital discharge and at 6-month intervals during the first year. If the aortic diameter remains unchanged at 1 year, studies are obtained yearly. Aortic enlargement of more than 0.5 cm within a 6-month period and greater eccentricity on comparison of three-dimensional reconstruction images are high-risk changes for which the interval is decreased to 3 months if surgery is not indicated.

Results

The operative mortality for repair of acute aortic dissection has fallen since DeBakey's original 40% mortality was reported in 1965. Improved intensive care unit and floor care of these patients, earlier recognition of dissection through improved imaging modalities, development of hemostatic vascular graft material, more effective hemostatic agents, and improvements in the safety of cardiopulmonary bypass are likely responsible. In the last two decades, most centers consistently report an operative mortality for acute type A dissection of between 10 and 20%. The high early mortality in acute dissection parallels the number of patients who present profoundly hypotensive and in shock. The mode of death is stroke, myocardial ischemia/heart failure, or malperfusion in most cases. The operative mortality of patients suffering acute type B dissection is higher than for type A dissection because the indications for surgery have traditions of dissection as previously discussed.[19] Early death following acute dissection occurs as a result of aortic rupture or as a consequence of malperfusion.[8]

The published results for long-term survival following acute type A dissection surgically treated over the last decade are roughly 71 to 89% at 5 years and between 54 and 66% at 10 years.[55–57] Operative repair of acute type B dissection yields 5-year survival of 48% with a 10-year survival of 29%.[58]

CHRONIC AORTIC DISSECTION

Clinical Presentation

Signs and symptoms

Chronic aortic dissection is usually asymptomatic. It may be incidentally discovered following an asymptomatic acute dissection; this most often occurs in patients with a preexisting aortic aneurysm. Some patients eventually require surgical treatment for chronic dissection and most do so as a result of aneurysmal dilatation of a chronically dissected aortic segment. Presenting complaints often include intermittent, dull chest pain or even severe skeletal pain from erosion into the bony thorax with large or rapidly expanding aneurysms. Aortic insufficiency may develop with chronic type A dissection and present with typical features of congestive failure including fatigue, dyspnea, and mild, dull chest pain. Infrequently, chronic dissection may result in paralysis/paraplegia from loss of vital intercostal arteries or even distal embolization of thrombus or atheroma from the false lumen. Malperfusion syndrome is an uncommon presentation for patients with chronic dissection given the likelihood that the true and false lumens communicate.

Diagnostic imaging

Diagnostic imaging of chronic aortic dissection is usually performed for surveillance but may also be necessary in patients with symptoms attributable to dissection and for operative planning. As previously discussed, routine follow-up for acute dissection occurs on a scheduled basis and is usually done with either CT or MRI. We prefer CT scanning for patients with normal renal function and no contrast allergy because CT is usually the original imaging study obtained during the acute dissection. The improved accuracy that comes with comparing similar studies combined with the availability, cost, and patient satisfaction make CT favorable for this purpose. MRI is utilized mostly as a follow-up study for patients with renal insufficiency, but is the study of choice to provide precise anatomic detail for operative planning. TEE is useful to follow chronic type A dissection when there is aortic insufficiency. It can provide cross-sectional images of the ascending aorta, but generating images useful for comparison to previous studies is highly dependent on the skill of the operator. For that reason, we use echocardiography to follow patients with aortic insufficiency, but also obtain a CT scan to assess ascending aortic diameter. Aortography is used primarily for operative planning. Patients older than 50 years and those with risk factors for coronary artery disease routinely undergo coronary arteriography prior to operation and images of the aorta are obtained at that time. Aortography is especially useful to determine the origin of aortic branch vessels for operative planning when noninvasive imaging is inadequate (Fig. 51-21).

Natural History

Chronic type A dissection develops in patients who fail to undergo immediate surgical treatment of the acute dissection. In contrast, chronic type B dissection may occur in patients successfully treated medically for the acute process and in those with repaired type A dissection who have a retained dissected descending thoracic aorta. The natural history of acute dissection rarely involves spontaneous healing. This phenomenon is observed in 4 to 31% of medically treated patients. Many patients with distal communication of the false lumen go on to develop aneurysmal dilatation of the aorta. The natural history of this process has been examined and reveals that there is an annual rate of expansion of 2 to 3 mm per year in communicating dissections, and the rate is 1 mm per year in those not communicating. Despite appropriate medical management and close follow-up, 30 to 40% progress to aneurysmal dilatation at 10 years.[59–62] This number is probably even higher in those patients with connective tissue disorders. In one study of 50 patients over a period of 40 months, 18% had fatal rupture and another 20% underwent surgical repair because of symptoms or aneurysm enlargement, emphasizing the need for diligent follow-up care. Risk factors for rupture of chronic type B dissection in that study included older age, chronic obstructive pulmonary disease, hypertension, and marginally pain. Chronic beta-blocker treatment reduces the rate of aortic dilatation as well as the incidence of dissection-related hospital admissions and procedures.[63]

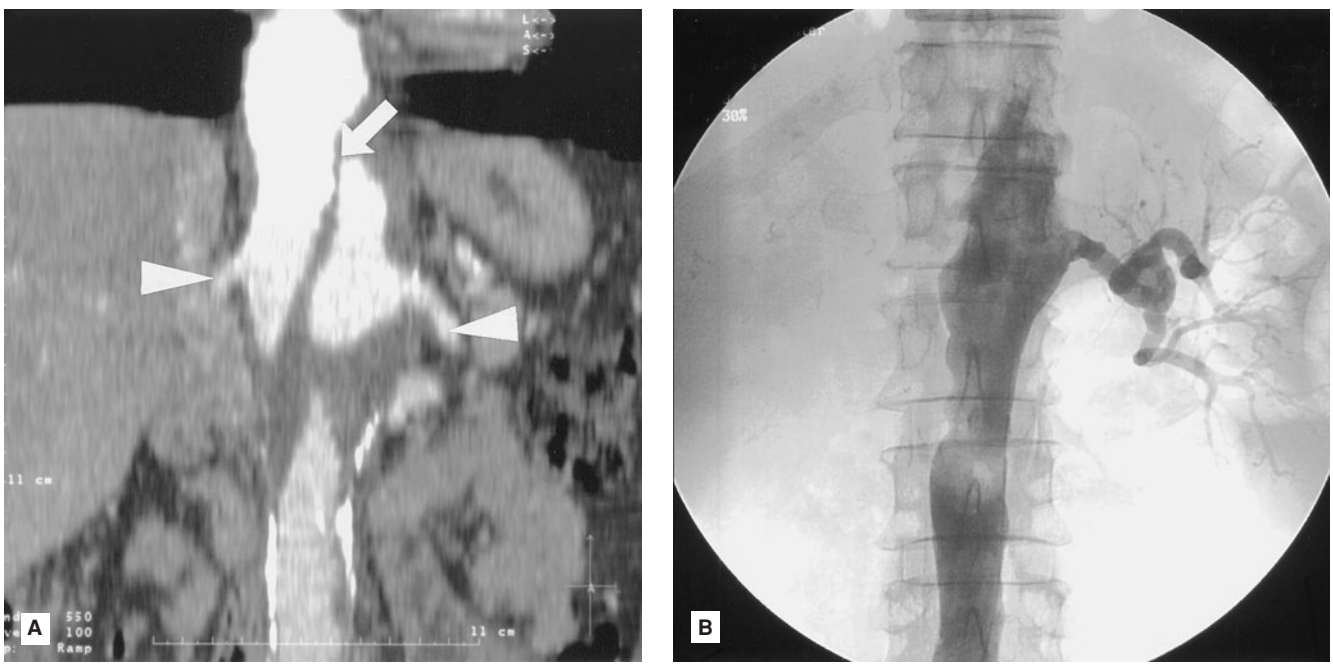

Figure 51-21. Coronal view of contrast-enhanced MRI (A) demonstrating chronic type B dissection with renal arteries (arrowheads) separated by the dissection flap (arrow). Aortogram (B) of the same patient revealing that each renal artery is perfused exclusively by either the true or false lumen. Such tests are often complementary and may influence surgical strategy.

Operative Indications

The operative indications for chronic type A and B dissections are shown in Table 51-4. Chronic type A dissection is rarely symptomatic, yet a minority will present with chest pain as a result of aneurysm expansion or heart failure related to aortic regurgitation. Chronic type B dissection may also present with back pain or infrequently with a malperfusion syndrome. While each of these findings is an indication for intervention, the most common indication for surgical management is aneurysmal dilatation. The Yale group recently reviewed the size criteria indicating operative intervention for thoracic aortic aneurysms.[64] These criteria dictate that replacement should be performed for ascending aortic size greater than 5.5 cm, or 5 cm if a connective tissue disorder is present. Similarly, the two most frequent indications for operative repair of chronic type B dissection are aneurysmal dilatation and malperfusion. In the descending thoracic aorta, replacement is indicated at 6.5 cm, or 6 cm if there is a family history or physical stigmata of a connective tissue disorder. Eccentricity of the aorta was also predictive of rupture, as was rapid expansion (more than 1 cm per year) and continued smoking. Such factors should therefore be considered when deciding to operate based on aneurysm size alone.[65]

Operative Technique

General considerations

The purpose of operation in chronic aortic dissection is to replace all segments of dissected aorta at risk for rupture and to prevent the possibility of subsequent malperfusion syndrome. The conduct of the operation including surgical approach, monitoring lines required, anesthetic technique, and cardiopulmonary bypass is similar to that described for acute dissection. Greater emphasis is placed on methods of cerebral and spinal cord protection and various technical differences exist for aortic valve preservation and to avoid postoperative malperfusion.

Cerebral and spinal cord protection

The incidence of paraplegia following repair of thoracoabdominal aneurysms resulting from aortic dissection is reportedly as high as 10%. Both mechanical and pharmacologic interventions have been advocated over the last decade to reduce this risk. It appears that partial left heart bypass alone as previously described is sufficient for patients with aneurysmal dilatation of the thoracic aorta above the level of T9 and results in a paraplegia rate between 5 and 8%.[66] Aneurysms involving the distal aortic arch require full cardiopulmonary bypass and deep hypothermic circulatory arrest for spinal cord protection. In such cases and in the case of the more extensive thoracoabdominal aneurysms, additional measures have variably reduced paraplegia rates lower than those observed with cord hypothermia alone. Drainage of cerebrospinal fluid as described by Safi and associates is routinely used in our practice for aneurysms extending lower than T9. Reimplanting intercostals and lumbar arteries between T9 and L1 is also important.[67] The aortic cross-clamp is moved progressively distal to perfuse branches as they are implanted. Preoperative identification of the anterior spinal artery origin has been suggested, but the combination of distal perfusion, cerebrospinal fluid drainage, and reimplanting large intercostal and lumbar arteries has provided adequate success at our institution. Additional techniques used for spinal cord protection include measurement of sensory and motor evoked potentials, regional epidural cooling, and the use of a variety of pharmacologic agents for cellular protection.

Techniques for type A dissection

Chronic type A dissection, with or without aneurysmal enlargement, is treated using similar operative techniques described for acute dissection. The particular operation performed depends on the specific pathology involving the aortic root, status of the aortic valve, distal extent of dissection, and brachiocephalic vessel involvement. The pathology of each of these components can be very different in a chronic dissection as compared to the acute process. These differences underlie the need for surgical techniques appropriate to each unique abnormality. In general, the ascending aorta is replaced using a vascular graft to include the entire diseased segment as in acute dissection, but surgical treatment of the aortic valve and creation of the distal anastomosis differ.

Whereas the aortic valve can be repaired in most cases of acute type A dissection by simple commissural resuspension, the rate of aortic valve replacement is much higher in patients with chronic dissection. Preservation of the aortic valve is complicated by morphologic changes in the valvular apparatus such as leaflet elongation and annuloaortic ectasia, which render the valve irreparable in as many as 50%. More severe grades of preoperative aortic regurgitation portend a lower probability of valve preservation. In patients in whom the aortic valve cannot be preserved with simple commissural reattachment, three options exist to treat aortic insufficiency: composite valve-graft replacement, aortic valve replacement with separate ascending aortic replacement, and finally valve-sparing aortic root repair. The technical aspects of composite valve-graft repair were covered under acute type A dissection. Separate aortic valve and ascending aortic replacement are appropriate when there is an operative indication to repair the ascending aorta in the setting of a normal aortic root and structural aortic valve disease. Note that this operation is not appropriate for patients with connective tissue disease. In this situation aortic root replacement is required.

There are several methods for aortic valve preservation when aortic root replacement is indicated. One such technique is performed by reimplanting the valve commissures into an appropriately sized vascular graft, which is secured to the left ventricular outflow tract using multiple horizontal mattress sutures.[68] A more elegant yet time-consuming

technique requires resection of the sinuses of Valsalva leaving a 5-mm rim of aorta circumferentially around the leaflets. Scallops are then created in the vascular graft to resuspend the commissures and remodel the aortic root. David and colleagues advocate Teflon felt reinforcement of the aortic annulus to prevent late annular dilatation and recurrent aortic insufficiency. The midterm outcome of such operations revealed a freedom from reoperation of 97 to 99% at 5 years and a 5-year survival for the aortic dissection subgroup of 84%.[69] Cochran and associates devised a similar technique to recreate the sinuses of Valsalva, which may be more important than previously recognized and contribute to improved long-term valve durability.[70] Such data in patients with chronic dissection are lacking. These techniques appear appropriate for patients with Marfan syndrome and in those with congenitally bicuspid aortic valves.

Treatment of the distal aorta in chronic type A dissection is somewhat controversial. Some advocate obliteration of flow in the false lumen with distal aortic repair, whereas others purposely maintain flow into both the true and false lumen using distal resection of the intimal flap. Those who reunite the chronically dissected aortic layers to perfuse only the true lumen maintain that false lumen perfusion continues through distal reentry tears in over 50%. There is a theoretical concern that important side branches arise exclusively from the false lumen and perfusion may be interrupted with this technique. Our practice at the University of Virginia is to resect the distal chronic dissection flap to obviate such concerns. The distal anastomosis is therefore made to the outer wall of the aorta, which has a great deal of structural integrity. Malperfusion of the brachiocephalic vessels as a result of chronic type A dissection is treated with resection of the dissection flap from the arch. Infrequently, the chronic dissection flap extends into more distal branch vessels and may present as transient ischemic attacks or stroke. In such cases it is often necessary to resect the dissection flap into the branch vessel or reunite the layers distally prior to reimplantation.

Infrequently, chronic type A dissection results in extensive aneurysmal dilatation of the aorta extending from the ascending aorta through the arch and into the descending thoracic aorta. Surgical treatment of such extensive disease has traditionally been performed as a staged procedure in which the ascending aorta and arch are replaced first through a sternotomy. The second stage of the so-called elephant trunk procedure is performed 6 weeks later through a left thoracotomy for replacement of the descending aorta using a second vascular graft. Originally described by Borst and associates, this technique has been used extensively with good results.[71] In some cases, the aorta distal to the left subclavian artery may be so large as to preclude the use of a two-stage repair. Kouchoukos and coworkers recently described a single-stage repair performed through a bilateral anterior thoracotomy in which the arch is repaired first during a brief period of circulatory arrest. Right subclavian and femoral artery cannulation for cardiopulmonary bypass provide proximal and distal perfusion during the subsequent ascending and descending aortic replacement. The hospital mortality was 6.2% and there were no adverse neurologic outcomes in the small series.[72]

Techniques for type B dissection

The techniques used for replacement of the descending thoracic aorta are identical to those described for treatment of acute type B dissection. The extent of resection, however, for chronic type B dissection is usually greater, with the goal of removing all dissected aorta at risk for rupture or symptoms. Usually these operations can be performed through the left chest, but more extensive aneurysms or cases of visceral malperfusion require a thoracoabdominal incision or a staged repair similar to the elephant trunk. The proximal anastomosis is ideally made to undissected normal aorta, but infrequently the distal arch is involved, which requires alteration in surgical strategy. Most of the technical controversy regarding repair of chronic type B dissection centers on methods of spinal cord protection during these operations.

As mentioned we prefer the combination of partial left heart bypass and cerebrospinal fluid drainage. Sites for cannulation are the left inferior pulmonary vein and the left femoral artery or descending thoracic aorta. Depending on the location and extent of the aneurysm, the distal arch is mobilized first. The area between the left common carotid and left subclavian artery is circumferentially dissected, and the left subclavian artery is independently controlled. Partial left heart bypass is then initiated. Ideally clamps are placed between the left subclavian and left common carotid arteries and on the aorta distal to the involved segment. If the entire descending thoracic aorta is diseased, the clamp is placed on the mid-thoracic aorta to perform the proximal anastomosis first. The aorta is opened and small intercostal arteries are oversewn. The proximal anastomosis is made to normal aorta whenever possible with running 3-0 polypropylene; 4-0 polypropylene is used if the tissue is fragile. The clamp is moved distally onto the graft to inspect the proximal anastomosis and achieve hemostasis. Several centimeters of the dissection flap is then resected from the lumen of the distal aorta and the distal anastomosis created to the adventitia of the chronic dissection. In more extensive thoracoabdominal disease, the clamp is progressively moved distal as intercostal arteries below T7 to L2 and visceral vessels are reimplanted (Fig. 51-22). Bypass is terminated and the operation completed.

Full cardiopulmonary bypass with deep hypothermic circulatory arrest may be necessary in patients in whom the proximal anastomosis cannot be safely or adequately performed with a clamp in the usual position. Kouchoukas and associates have a large experience in this area and cite a 6.2% 30-day mortality, 1.9% stroke rate, and no paraplegia in the subgroup of patients with aortic dissection.[73] These data strongly support this simple and elegant technique as one of the most efficacious for spinal cord and visceral organ protection in these complicated procedures.

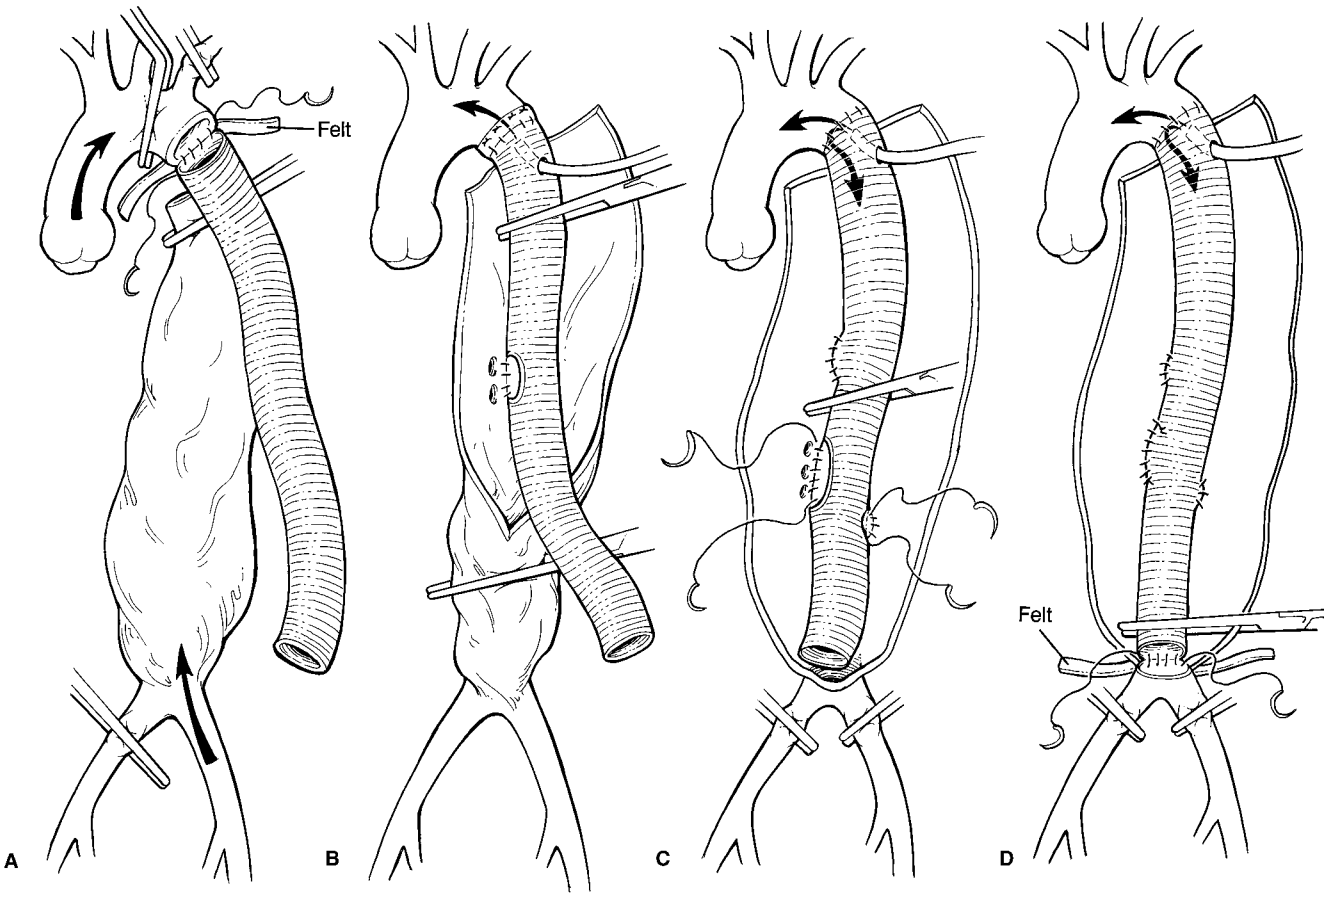

Figure 51-22. Replacement of the thoracoabdominal aorta. (A) A left femoral cannula perfuses the lower body and viscera while the heart continues to eject. The arch is transected near or at the left subclavian and any dissection involving the proximal cuff is repaired. (B) The clamp is moved down and a second arterial cannula is inserted into the proximal graft to perfuse the upper body and heart. The anterior wall of the dissection is incised longitudinally and bleeding intercostals of the upper six pairs are oversewn. A group of lower intercostal arteries above the celiac axis is sutured to the graft. (C) The clamp is moved down and the distal aortic clamp is moved to the left common iliac artery. A patch of aorta containing the celiac, superior mesenteric, and right renal artery is sewn into the graft. The left renal artery is sutured separately to the graft. (D) The proximal clamp is moved below the visceral anastomoses and the distal aortic anastomosis is made to the aortic bifurcation.

Results

The operative mortality for chronic type A dissection is between 4 and 17% and on average is very similar to that reported for chronic type B repair at 11 to 15%.[74,75] The actuarial survival following operation for chronic type A and B dissections is no different at 5 years (59 to 75%) or at 10 years (45%).[58] The stroke rate following repair of chronic type A dissections is 4%. Early neurologic complications occurred in 9%.[75] Regular follow-up of the aortic valve is necessary when the native valve is preserved at the initial operation. This is best performed using transthoracic echocardiography on a yearly basis. Early reports indicated that nearly 20% of patients require reoperation secondary to progressive aortic regurgitation. The most recent data from David and colleagues, however, reveal a 90 ± 4% 5-year freedom from severe or moderate aortic insufficiency in patients with aortic root aneurysm, and 98 ± 2% in patients with ascending aortic aneurysm following valve-sparing surgery.[69]

CONCLUSION

Considerable improvement in the treatment of patients with acute and chronic aortic dissection has occurred over the last 50 years. Continued progress is inevitable and technologies such as endovascular repair may eventually achieve results comparable to surgery. Complex forms of dissection that include aortic root and valvular pathology, however, will require surgical treatment for the foreseeable future. These patients will undoubtedly benefit from the novel basic and clinical research taking place in the areas of spinal cord and cerebral protection, strategies for cardiopulmonary bypass, improved vascular graft technology, and procedures for

preservation of the aortic valve. Such progress may even permit advancement in our greatest remaining clinical challenge, those patients who are hemodynamically unstable following aortic dissection.

CHAPTER 52

Ascending Aortic Aneurysms

Derek R. Brinster • Robert J. Rizzo • Ralph M. Bolman, III

EARLY DESCRIPTIONS AND SURGICAL INTERVENTIONS

Arterial dilations were first described in the ancient *Ebers Papyrus*, a medical scroll written in Egypt in 2000 B.C. The first accurate description of arterial aneurysms is credited to the Greek physician Galen (A.D. 126–c216). This was based on his observation of false aneurysms in gladiators injured during battle in the 2nd century.[1] Antyllus, during the same time period, made the distinction between traumatic aneurysms and those of a degenerative etiology. Antyllus believed that these lesions were due to clot formation and he was the first to attempt surgical treatment of aneurysms with proximal and distal ligation, opening of the aneurysmal sac, and removal of its contents.[2]

In the late 1500s, the great French surgeon Ambroise Paré (1510–1590) described a death by a ruptured thoracic aortic aneurysm and concluded that internal aneurysms were incurable. Paré also proposed that syphilis played a causative role in some aortic aneurysms, but this was not generally accepted until 1895 when Dohle described the microscopic findings of syphilitic aortitis.[1]

The earliest surgical treatment of aneurysms consisted of interruption of arterial flow via either ligation or the stimulation of thrombosis. These procedures met with variable success depending on the position of the aneurysm and the extent of collateral circulation.[2] Arterial ligation was popularized in the 1800s by John Hunter, who demonstrated safe and reproducible means of ligating certain peripheral arteries.[3] Innovative measures used to cause thrombosis of aneurysms included the insertion of long segments of wire[4] with the application of an electric current,[5] and wrapping of aneurysms with cellophane or other irritating materials.[6,7]

In 1888, Rudolph Matas introduced a very different approach. In an operation he referred to as obliterative endoaneurysmorraphy,[8,9] stitches placed from within the aneurysm sac obliterated the arterial openings. This provided more secure closure of large aneurysms that would have been difficult to ligate externally. Recognizing the importance of maintaining arterial continuity for certain aneurysms, he subsequently devised techniques of restorative or reconstructive endoaneurysmorraphy,[10] in which diseased segments of the aneurysm wall were resected and the remaining vessel wall was reconstructed to reestablish flow. The number of aneurysms to which these techniques could be applied, however, was very limited. The broad application of surgical treatment for major arterial aneurysms would have to await the development of satisfactory conduits and the techniques to insert them.

In the early twentieth century, Alexis Carrell and Charles Guthrie made several advances in the treatment of arterial aneurysms by using advanced anastomotic techniques and the use of aortic homografts as replacement conduits. This work later won Carrell the Nobel Prize and provided the basis for modern anastomotic techniques and use of graft replacements.[11]

Evolution of Modern Surgical Techniques

Replacement of the ascending aorta was first attempted without the use of cardiopulmonary bypass by Cooley and DeBakey in 1952 when they reported removal of a sacciform ascending aortic aneurysm by lateral resection and aortorrhaphy.[12] The first modern replacement of the ascending aorta with the use of cardiopulmonary bypass was subsequently reported by Cooley and DeBakey using an aortic allograft in 1956.[13] Mueller and associates combined allograft insertion with aortic valve repair in 1960 in a patient with Marfan syndrome.[14] As the need for conduits grew, attention was shifted to the development of a suitable artificial conduit. The first fabric to be utilized was Vinyon N cloth by Blakemore and Voorhees in New York City in 1954.[15] Dacron was subsequently introduced by DeBakey,[2] who

discovered it in a Houston department store, and it soon became the artificial conduit of choice for aortic replacement. Technical improvements in graft replacements included the impregnation of these polyester grafts with albumin, collagen, or gelatin, which has greatly reduced the blood loss through the grafts.

Replacement of the supracoronary ascending aorta with a synthetic graft and separate mechanical aortic valve replacement was performed by Starr and colleagues in 1963.[16] Wheat and coworkers[17] in 1964 resected the ascending aorta and entire aortic root except for small tongues of aortic tissue surrounding the coronary arteries. They then performed a mechanical valve insertion and fashioned the proximal tube graft to accommodate the coronary arteries, which were left in situ. The first use of a composite valve-graft conduit to replace the aortic root and ascending aorta was done by Bentall and De Bono in 1968.[18] The coronaries were left intact in the aortic wall and the surrounding aortic tissue was sewn to orifices that were created in the tube graft. The remaining aorta was wrapped tightly around the tube graft, creating an inclusion cylinder arrangement. In 1981 Cabrol and colleagues used an 8- to 10-mm Dacron graft to facilitate the restoration of coronary blood flow following aortic root replacement.[19] Variations of these pioneering procedures using modern low-profile mechanical valves and hemostatic collagen- or gelatin-impregnated woven Dacron grafts are commonly performed today.

INCIDENCE AND RISK FACTORS

Aortic aneurysms are the 13th leading cause of mortality in the United States.[20] The incidence of thoracic aortic aneurysms is estimated to be 5.9 cases per 100,000 person-years,[21] and the incidence appears to be increasing as a result of routine screening studies, improved imaging modalities, and increased clinical awareness. Aneurysm disease is the most common indication for surgical therapy on the thoracic aorta and replacement of the ascending aorta accounts for the majority of thoracic aortic procedures.[22] The mean age at the time of diagnosis ranges from 59 to 69 years.[23] Men are typically diagnosed at a younger age and there is a 2:1 to 4:1 male predominance.[23]

Traditional risk factors have included smoking, hypertension, atherosclerosis, and well-defined genetic disorders such as Marfan syndrome and Ehlers-Danlos syndrome.[21,24–27] Subtler forms of inherited metabolic disorders are being elucidated,[28] and perhaps play a role in more instances than was previously suspected. Syphilis, at one time the predominant etiology of ascending aortic aneurysms, has become very uncommon with the development of effective antibiotics. Bicuspid and unicuspid aortic valves are associated with ascending aortic aneurysms and dissections beyond that which can be attributed to simple hemodynamic disturbance, suggesting an underlying abnormality of the aortic wall.[29]

ETIOLOGY AND PATHOPHYSIOLOGY

General

Most of the elasticity and tensile strength of the aorta is derived from its medial layer, which consists of approximately 45 to 55 lamellar units of elastin, collagen, smooth muscle cells, and ground substance. In the ascending aorta, the elastin content is high, consistent with its compliant nature, and diminishes as one proceeds distally into the descending thoracic and abdominal aorta. The media also becomes thinner distally, and in the abdominal aorta the total number of lamellae is reduced by approximately one-half.[30]

The aortic wall is a biologically active environment. Smooth muscle cells synthesize and degrade elastin, collagen, and proteoglycans.[31] In the media of a typical ascending aortic aneurysm there is fragmentation of elastic fibers, and loss of smooth muscle cells[32] or alteration in smooth muscle cell function.[31] The resulting pathologic entity is referred to as cystic medial degeneration or cystic medial necrosis. In advanced forms there is a dramatic loss of elastic fibers and smooth muscle cells with the accumulation of a basophilic amorphous material giving the media a true cystic appearance.[32] Subtler degrees of elastic fiber fragmentation are normal, and the diameter of the ascending aorta typically increases with age.[33] Smoking has been associated with increased concentrations of elastolytic enzymes within the aortic wall, possibly hastening this process.[33,34] The role of atherosclerosis is controversial.

During systole, the ascending aorta expands, converting a portion of the kinetic energy of left ventricular contraction into potential energy in the aortic wall. During diastole the aorta recoils, converting this potential energy once again into the kinetic energy of forward flow.[35] This coupling of the left ventricle and aorta ensures efficient forward flow during both phases of the cardiac cycle. With weakening of the aortic wall and loss of elasticity, dilation ensues. Dilation results in increased wall tension relative to intra-aortic pressure according to the law of Laplace. This amplifies the injurious forces on the aortic wall produced by hypertension and results in progressive dilation. These pathologic changes in the aortic wall can result in inefficient ventricular-aortic coupling, aortic valve incompetence, and the potential for rupture or dissection.

Idiopathic Cystic Medial Degeneration

Cystic medial degeneration is the most common etiology of ascending thoracic aortic aneurysm disease.[36] Elastic fiber fragmentation is a normal process of aging,[33] but is accelerated in some individuals for poorly understood reasons. This results in premature weakening of the aortic wall, aneurysmal dilation, and the potential for rupture or dissection. Many cases that are now considered idiopathic may in the future be described as subtle disorders of metabolism that accelerate aortic wall degeneration in response to common risk factors.

Genetic Disorders

Marfan syndrome

Marfan syndrome is an autosomal dominant connective tissue disorder, with potentially life-threatening cardiovascular manifestations.[37] The estimated frequency is 1 per 10,000 births.[38] This disorder has been traced to the fibrillin gene of chromosome 15,[39–43] with more than 70 different defects identified thus far.[44] It is believed that one-third of cases are secondary to spontaneous mutations.[45] Fibrillin is one of the major structural components of the elastic fiber.[46] The resulting abnormal elastic fibers are prone to disruption and result in histologic findings consistent with cystic medial degeneration of the smooth muscle layer at an early age.[32] Seventy-five to eighty-five percent of patients with Marfan syndrome have dilation of the aortic sinuses and annulus in addition to the ascending aorta. This morphology, referred to as annuloaortic ectasia, is the classic presentation of Marfan syndrome, but can occur in the absence of a known connective tissue disorder. Because of the frequent aortic root involvement, aortic insufficiency is common.[47] In addition, one half of patients with Marfan syndrome also have mitral regurgitation.[21]

Ehlers-danlos syndrome

Ehlers-Danlos syndrome is an inherited disorder of connective tissue with multiple subtypes characterized by various defects in the synthesis of type III collagen.[48] Type IV Ehlers-Danlos may be associated with life-threatening cardiovascular manifestations including ascending aortic rupture without dissection. Type IV Ehlers-Danlos is most commonly a sporadic genetic disorder, but may be inherited as an autosomal dominant trait.[48,49] Spontaneous arterial rupture is the most common cause of death and usually involves the mesenteric vessels.[49] Less commonly, patients develop abdominal or thoracic aortic aneurysms or dissections.[50,51] Surgical treatment is challenging because of the friable nature of the vascular tissue.

Familial aneurysms

Certain families, without phenotypic expression of Marfan syndrome, exhibit strong histories of ascending aortic aneurysm formation and dissection transmitted in an autosomal dominant fashion. In a recent study of 15 such families, 9 demonstrated evidence of linkage to the 5q locus, although the specific gene and product have not been identified.[28] None of the 15 families demonstrated linkage to the fibrillin gene. Further investigation will likely reveal other examples of more subtle inherited or spontaneously occurring disorders of metabolism that result in accelerated deterioration of the aortic wall.

Bicuspid aortic valve disease

Bicuspid aortic valve disease is the most common congenital anomaly and occurs in 0.9 to 2.0% of the population or approximately 4 million people in the United States. There is evidence to suggest an intrinsic smooth muscle abnormality which leads to a higher rate of cystic medial degeneration in those patients with congenital bicuspid valve disease.[52,53] Those patients with bicuspid aortic valve disease and aneurysmal dilation of the ascending aorta should be considered for earlier surgery due to the intrinsic weakness of the aorta.[54]

Atherosclerosis

Atherosclerosis is reported to be the second most common cause of aneurysmal degeneration in the ascending aorta.[21] Atherosclerosis is less commonly seen in ascending aortic aneurysms than in descending thoracic or abdominal aortic aneurysms and it has long been theorized that the development of invasive atheromas results in destruction of elastic fibers and smooth muscle cells in the media, resulting in weakening and dilation.[21] This process was proposed as the primary etiology of descending thoracic and abdominal aortic aneurysms, and the second most common cause of ascending aortic aneurysms.[21,55] These theories are now challenged by the concept that atherosclerosis is a concomitant process that infiltrates a diseased media with altered barriers.[56] This would explain the divergent course of the atherosclerotic abdominal aorta towards obstructive versus aneurysmal disease.

Aneurysms Associated with Aortic Dissection

Patients who survive acute dissection of the ascending aorta often have or will develop an associated aneurysm. This aneurysmal dilation most commonly originates from the false lumen of the aortic dissection. This outer wall of the false lumen consists of only the weak outer media and adventitia. The rate of expansion is higher than in other types of ascending aortic aneurysms, as the barrier to dilation and rupture is only this outer one-third of the media and the adventitia.[21,57] Aortic dissection is discussed in Chapter 51.

Aneurysms Associated with Aortic Valve Disease

Aneurysms of the ascending aorta are frequently associated with bicuspid and unicuspid aortic valves. Although initially thought to be secondary to poststenotic dilation, a primary structural abnormality of the aortic wall appears contributory. Aortic enlargement occurs at an accelerated pace in congenitally stenosed valves compared to trileaflet valves with equivalent degrees of stenosis.[29,58] Aortic dissection occurs in patients with bicuspid aortic valves at a rate 10-fold that of the normal population, a trend that is not found in other forms of aortic stenosis.[24] This strongly implies an inherent weakness in the aortic wall.

Infection

Bacterial (mycotic) aneurysms

Primary bacterial infection of the ascending aortic wall resulting in aneurysm formation is rare. These aneurysms are termed mycotic aneurysms regardless of the infectious

pathogen. This is believed to occur either after an episode of bacterial endocarditis or from an aortic jet lesion causing endothelial trauma.[59] Organisms most commonly isolated from patients with mycotic aneurysms are, in order of decreasing frequency, *Staphylococcus aureus, S. epidermidis, Salmonella*, and *Streptococcus*.[60] Mycotic ascending aortic aneurysms are usually the result of infective valvular endocarditis.[59] Infection of laminar clot within a previously formed aneurysm may also occur after transient bacteremia.[60]

Syphilitic aneurysms

Before the advent of antibiotics, syphilitic aortitis, caused by the spirochete *Treponema pallidum*, was the most common cause of ascending aortic aneurysms. Syphilitic aortitis causes an obliterative endarteritis of the vasa vasorum which results in ischemic injury to the aortic media with subsequent destruction of elastic and muscular elements.[32] The media is replaced by a thickened fibrous tissue, which begins to dilate. This process most commonly involves the ascending aorta and arch,[61] but may involve the root as well. If the regions of the coronary ostia are involved, significant coronary obstruction may occur.[1] Antibiotic therapy does not reverse the vascular pathology and aneurysm formation.

Arteritis

Ascending aortic aneurysms may develop as the result of inflammatory conditions such as Takayasu arteritis, Kawasaki disease, Behçet disease, and giant cell arteritis. Takayasu arteritis most commonly involves the aortic arch and its major branches, but may involve any or all segments of the aorta. Takayasu arteritis usually produces obstructive lesions, but may have a dilative component in 15% of cases.[62] Giant cell arteritis (temporal arteritis) may lead to weakening of the aortic wall and eventual aneurysm formation or dissection.[63,64] In one population-based study temporal arteritis was associated with a greater than 17-fold increase in the risk of developing a thoracic aneurysm.[65] Medial destruction of the aortic wall by these inflammatory pathologies is the etiology of aneurysm formation.

Trauma

Chronic traumatic aneurysms of the aorta are rare and usually involve the descending aorta rather than the ascending aorta. Although the ascending aorta is the site of rupture in 20% of blunt aortic injuries, survival beyond the initial injury is unusual, with the patient usually succumbing to acute cardiac tamponade and other concomitant injuries.[66] This subject is covered in Chapter 57.

Pseudoaneurysms

Pseudoaneurysms are defined as aneurysmal dilations that do not contain all layers of the arterial wall. The wall of a pseudoaneurysm is composed primarily of variable layers of the media, adventitia, thrombus, and surrounding structures.[33] Postoperative pseudoaneurysms may occur at an aortic suture line or at the site of aortic cannulation. Causes include technical error, acute dissection, native tissue degeneration, or deterioration of the graft or suture material.[67,68] The use of modern monofilament suture and low-porosity collagen- or gelatin-impregnated Dacron grafts,[69] as well as the abandonment of the inclusion cylinder technique,[70,71] have lessened the incidence of this complication. Less commonly, pseudoaneurysms of the ascending aorta occur after trauma or infection.

NATURAL HISTORY

General

The aorta functions not only as a conduit delivering blood to the tissues, but also as an important modulator of the entire cardiovascular system.[72] The appropriate application of surgical treatment depends on an understanding of the relative risks of surgery versus the natural history of the disease. The natural history of untreated aneurysms of the thoracic aorta often concludes with patient death because of rupture or dissection. Figure 52-1 shows the estimated actuarial survival curve for 72 patients who were diagnosed with thoracic aneurysms from 1951 to 1980 and were followed nonoperatively. Seventy-four percent of the patients experienced

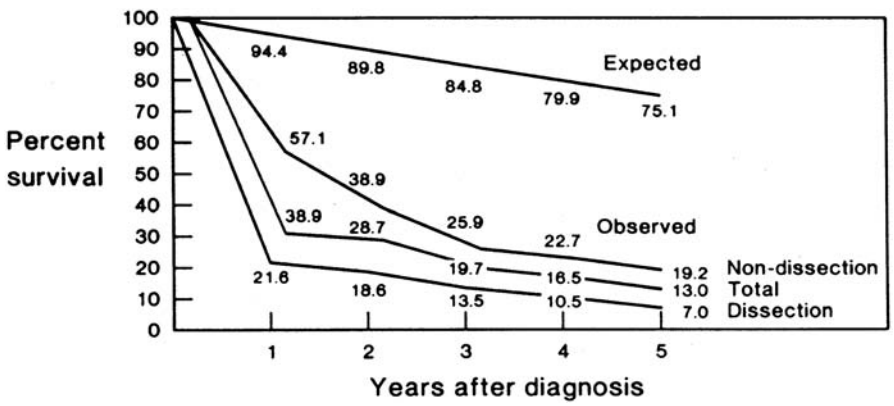

Figure 52-1. Actuarial survival estimates of 72 patients followed nonoperatively with thoracic aneurysms and dissections. *(Reproduced with permission from Bickerstaff et al.[21])*

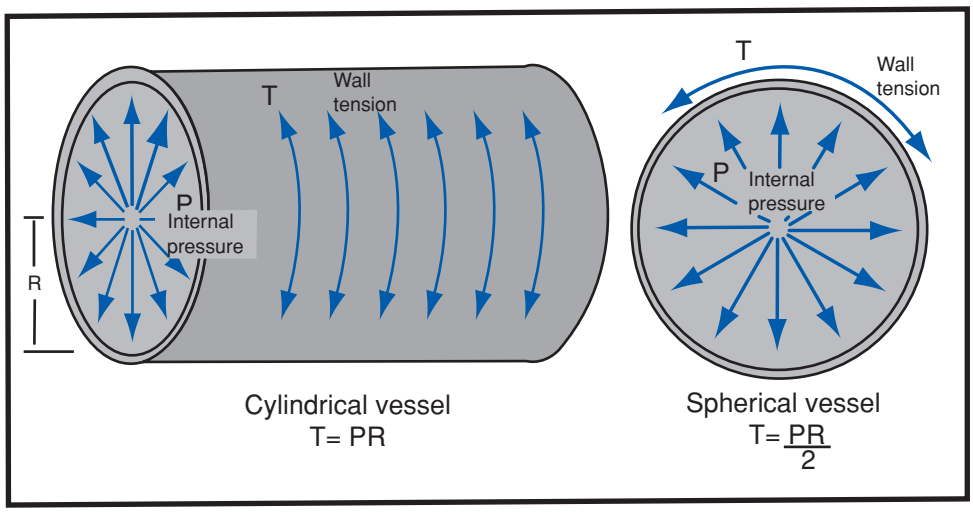

Figure 52-2. The law of Laplace. T = tension; P = pressure; R = radius. *(Illustration from HyperPhysics by Rod Nave, Georgia State University.)*

rupture, and 94% of these patients died.[21] The potential for complications of rupture or dissection is primarily dependent on size and the underlying etiology of the aneurysm.

Size

Based on the law of Laplace, wall tension increases as the radius of an aneurysm increases (tension = pressure x radius; Fig. 52-2). It is therefore intuitive that larger aneurysms have a greater risk of rupture. This was first established for abdominal aortic aneurysms by Szilagyi and associates in 1966.[73] Subsequent natural history studies have confirmed this finding and have found also that larger aneurysms have a higher rate of expansion.[74,75] Coady and coworkers[76] have written extensively on the natural history of thoracic aortic aneurysms. The incidence of acute dissection or rupture according to size in their cohort of patients is shown in Fig. 52-3. Logistic regression analysis revealed a 4.3-fold increased risk of rupture or dissection in an aneurysm 6.0 to 6.9 cm in diameter compared to an aneurysm 4.0 to 4.9 cm in diameter. Growth rates varied from 0.08 cm per year for aneurysms less than 4.0 cm to 0.16 cm per year for aneurysms greater than 8.0 cm in diameter. Mean growth rates as great as 0.42 cm per year have been reported in other series.[77,78] Dapunt and colleagues[57] also noted an increased rate of growth in smokers and patients with a history of hypertension. Davies and associates[79] demonstrated similar results in their evaluation of cumulative risk of negative outcomes based on thoracic aortic aneurysm size on initial presentation (Fig. 52-4).

The Influence of Etiology on Natural History

Marfan syndrome

Although size criteria are perhaps most important, the underlying etiology must be considered. Patients with Marfan syndrome have accelerated aneurysm growth and tend to rupture or dissect at smaller sizes.[79] This is particularly true for those with a family history of early complications.[79] The

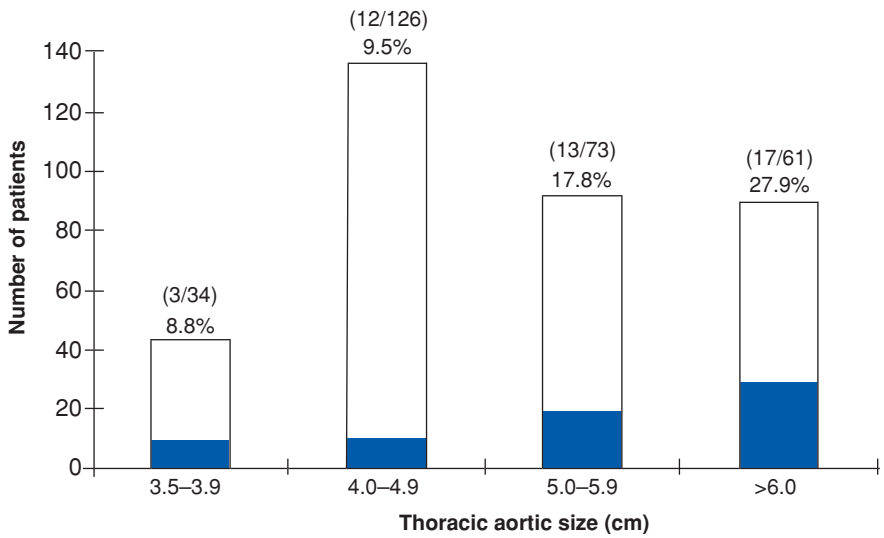

Figure 52-3. The incidence of acute dissection or rupture of thoracic aneurysms according to size. The height of the column corresponds to the total number of patients and the black area to the proportion of patients who suffered complications of dissection or rupture. *(Reproduced with permission from Coady et al.[76])*

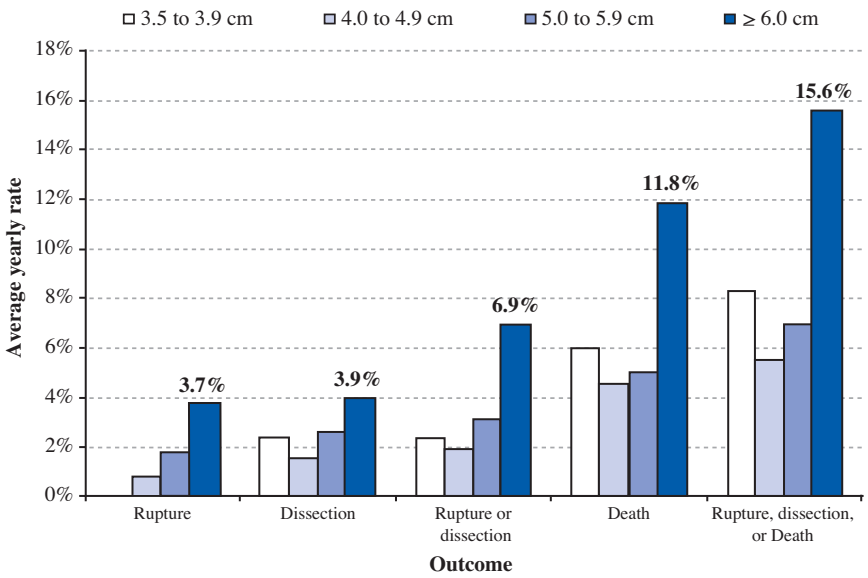

Figure 52-4. Average yearly rates of negative outcomes (rupture, dissection, and death). These estimates represent the average rate during the first 5 years after presentation. *(Reproduced with permission from Davies et al.[79])*

average age of death for untreated patients with Marfan syndrome is 32 years,[80] with complications of the aortic root being responsible for 60 to 80% of these deaths from aortic rupture, acute congestive heart failure from valvular incompetence, or acute aortic dissection.[47,81]

Familial aneurysms

The inheritance of aneurysmal disease without an associated phenotypic syndrome such as Marfan syndrome was first noted for abdominal aortic aneurysms.[82,83] In 1997 familial aggregation of thoracic aneurysms was noted by Biddinger and associates.[84] Coady and coworkers[85] estimated that 19% of their study population fit criteria for familial aneurysms by pedigree analysis. The primary mode of inheritance was autosomal dominant, but X-linked and recessive patterns were also evident in some cases. This subgroup had an annual growth rate almost double the growth rate for the entire population.

Aortic dissection

In chronic dissections, the barrier to rupture is the outer third of the media and the adventitia. Dissections are therefore associated with an accelerated rate of expansion and rupture. Comparisons between dissecting and nondissecting thoracic aneurysms of similar size have revealed as much as a sixfold greater growth rate for dissections.[23]

Syphilitic aneurysms

The average time from the diagnosis of advanced syphilis to cardiovascular symptoms is 10 to 20 years.[1] The average survival from the onset of cardiac symptoms is only six to eight months.[1] Saccular aneurysms, which are common in this disease, may have a more rapid rate of expansion and greater risk of rupture.[86] Dissection is less likely because of the scarring that occurs within the media.[32] Modern studies of growth rates and size at the time of rupture are not feasible because of the rarity of this condition.

CLINICAL PRESENTATION

Signs and Symptoms

A significant number of ascending aortic aneurysms are asymptomatic when diagnosed, being incidentally noted on chest x-ray or other imaging study.[26] Echocardiographic evaluation of aortic insufficiency is also a frequent mode of diagnosis. Between 25 and 75% of patients, however, present with chest pain that results in the diagnosis of an aneurysm.[26,87,88] Pain from the ascending aorta is usually localized to the anterior chest. The pain may be acute in onset signifying impending rupture, or a chronic gnawing pain from compression of the overlying sternum. Occasionally signs of superior vena cava or airway compression are present.[88] Less commonly, aneurysms of the ascending aorta or aortic root can rupture into the right atrium or the superior vena cava, presenting with high-output cardiac failure, or bleed into the lungs with ensuing hemoptysis. Hoarseness resulting from stretch injury of the left recurrent laryngeal nerve suggests involvement of the distal aortic arch or proximal descending thoracic aorta. In contrast, dissection of the ascending aorta presents with severe "tearing" pain in 75% of patients.[25,26]

Physical Examination

In the case of rupture, the patient will present in extremis. In a patient without rupture, the examination is often unremarkable. If the sinotubular ridge or aortic root is dilated, a widened pulse pressure or diastolic murmur signifying aortic

insufficiency may be noted. If dilation is isolated to the ascending aorta, however, the aneurysm can reach large dimensions without producing physical findings. A thorough vascular examination should be carried out to look for any concomitant peripheral vascular disease, carotid disease, or sequelae of distal embolization. Abdominal aortic aneurysms are present in 10 to 20% of patients with atherosclerotic involvement of an ascending aortic aneurysm,[25,89] and this should also be sought on physical examination. In rare cases, aneurysms may cause compression necrosis of the overlying sternum and ribs. Syphilitic aneurysms have been noted to erode through the chest wall and rupture externally.[1]

DIAGNOSTIC STUDIES

Electrocardiogram

With significant aortic insufficiency, left ventricular hypertrophy or strain is evident. Patients with generalized atherosclerosis may show evidence of concomitant coronary artery disease, or previous myocardial injury.

Chest Radiography

Many asymptomatic ascending aortic aneurysms are first detected on chest x-ray. The enlarged ascending aorta produces a convex contour of the right superior mediastinum (Fig. 52-5A). In the lateral view, there is loss of the retrosternal air space (Fig. 52-5B). Aneurysms confined to the aortic root can be obscured by the cardiac silhouette and may not be evident on chest radiograph.[90]

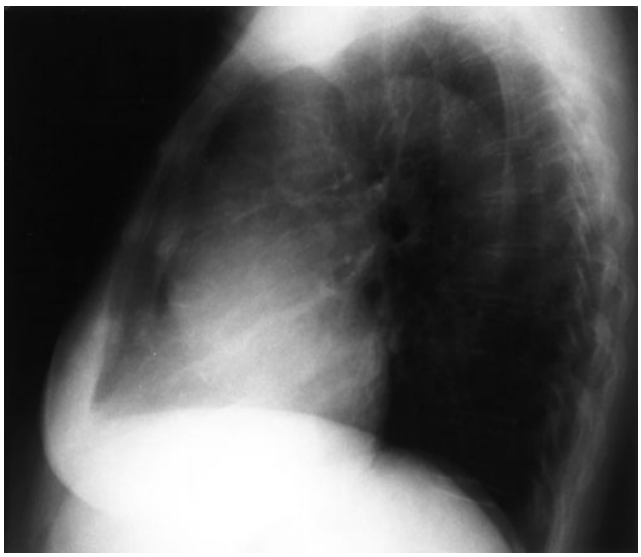
Echocardiography

Transesophageal echocardiography (TEE) is a portable diagnostic tool that can be moved to the patient's bedside. This portability aids in diagnosis of acute aortic pathologies in the emergency department, operating room, and clinical suite. Ascending aortic aneurysms are the most common cause of isolated aortic insufficiency,[91] and therefore aneurysms are frequently detected during evaluation of a regurgitant aortic valve. TEE can accurately detect and differentiate between ascending aortic aneurysms, dissections, and intramural hematoma.[92] Imaging of the distal ascending aorta is obscured by air in the tracheobronchial tree, with up to 40% of its distal extent not well visualized.[93] Transthoracic echocardiography is far less reliable.[87] TEE is an invasive imaging modality and carries a small risk of esophageal perforation, respiratory compromise, and hemodynamic instability, which demands proper patient selection.

Aortography

Aortography provides precise delineation of the aortic lumen, and certain diseases have very characteristic arteriographic patterns. Annuloaortic ectasia has a "pear-shaped" morphology (Fig. 52-6) with prominent dilation

A



B

Figure 52-5. Posteroanterior and lateral chest radiograph of a patient with an ascending aortic aneurysm. New York, McGraw-Hill, 1997; p 1163.)*

of the aortic sinuses and less severe dilation of the ascending aorta tapering to normal caliber at the origin of the innominate artery. Pseudoaneurysms appear as saccular outpouchings with irregular contour.[94] Syphilitic aneurysms involving the aortic root are often associated with coronary ostial stenosis.[32]

One of the beneficial aspects of aortography is accurate demonstration of the relationship of the aneurysm to the arch vessels. Aortography also detects aortic regurgitation and cephalad displacement of the coronary ostia. In

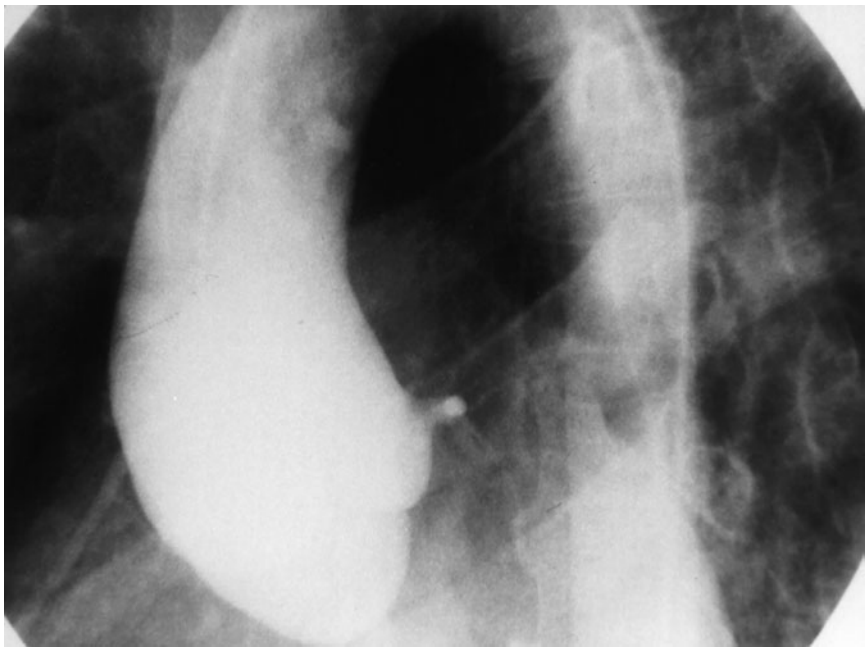


Figure 52-6. Aortic angiogram of a patient with classic annuloaortic ectasia. The aortic root is dilated and the ascending aorta tapers to a normal caliber at the origin of the innominate artery giving the classic "pear-shaped" morphology. *(Reproduced with permission from Downing SW, Kouchokos NT: Ascending aortic aneurysm, in Edmunds LH Jr (ed): Cardiac Surgery in the Adult. New York, McGraw-Hill, 1997; p 1163.)*

patients over the age of 40 or with a pertinent history, the opportunity is afforded to check for coronary disease and left ventricular dysfunction. Disadvantages include contrast and radiation exposure, puncture site complications, underestimation of aneurysm size in the presence of laminar clot, and the likelihood of missing dissections.

Computed Tomography

Contrast-enhanced computed tomography (CT) is the most widely used noninvasive technique for imaging the thoracic aorta. CT scanning provides rapid and precise evaluation of the ascending aorta in regard to size, extent, and location of the disease process (Fig. 52-7). CT scanning detects areas of calcification, and accurately identifies dissections and mural thrombus. When laminar clot is present, CT scanning provides a more accurate assessment of aneurysm size than aortography. However, because structures are visualized in an axial view only, the diameter of a tortuous aorta can be grossly overestimated. Three-dimensional reconstruction of CT scans may prove useful in determining the proximal and distal extent of aortic disease relative to the arch vessels, which can aid the surgeon in operative planning.[88] Ideally, the entire thoracic and abdominal aorta should be examined for evidence of concomitant aneurysm disease in the arterial tree. The main disadvantage of CT scans is the need for contrast solution for optimal resolution, which may be contraindicated in those patients with renal insufficiency or a history of a dye allergy.

The origin of the innominate artery and its relationship to the distal portion of the aneurysm can be appreciated on the sagittal view. *(Images provided courtesy of Kent E. Yucel, MD.)*

Magnetic Resonance Imaging

The benefits of magnetic resonance imaging (MRI) over CT scanning include visualization in the sagittal and coronal planes (Fig. 52-8), enhanced three-dimensional imaging (Fig. 52-9), and the avoidance of contrast and radiation exposure. Cardiac imaging with MRI is evolving, and may provide evaluation of cardiac perfusion, myocardial function, and coronary and valve anatomy with a single modality in the future.[95–97] Contrast-enhanced MR angiography allows more precise measurements of the aorta and its major branches with images comparable to conventional angiography. Currently, however, MRI is expensive, less readily available, and more time consuming than CT scanning. In addition, current MRI monitors are relatively unsuitable for those patients connected to mechanical ventilators or hemodynamic monitoring equipment.

INDICATIONS FOR OPERATION

Symptoms

Emergent operation is indicated in the setting of acute ascending aortic dissection or rupture. Ascending aortic aneurysms rupture into the pericardial space and result in

death from acute cardiac tamponade. Aortic dissections may rupture or may compromise coronary or cerebral circulation. Operative mortality is significant in this setting, but death is certain in the case of rupture and probable in the case of acute dissection if not surgically addressed.

Symptomatic aortic insufficiency or stenosis may be the primary indication for operation. When replacing or repairing a diseased valve a decision must be made regarding the moderately dilated aorta. Michel and colleagues[98] reported that 25% of patients undergoing surgery for aortic insufficiency who had ascending aortic diameters greater than 4 cm required subsequent operation for aortic replacement. Prenger and associates[99] reported a 27% incidence of aortic dissection following aortic valve replacement in patients with aortic diameters greater than 5 cm. Based on these findings it is recommended that aortic diameters of 4 to 5 cm be dealt with at the time of aortic valve surgery. Further incentive for earlier surgery is the improved possibility of native valve preservation.

Size and Growth Rate

Because the diameter of an aneurysm strongly correlates with the risk of rupture or dissection, size has long been used as the criterion for elective surgical intervention. Size of the aneurysm at initial evaluation is the strongest predictor of risk of rupture. Although size criteria for the abdominal aorta have been well established and generally agreed upon, less of a consensus has emerged for the thoracic aorta. Variable growth rates and propensities for rupture in different regions of the thoracic aorta and with different underlying pathologies are perhaps to blame. The average size of rupture of the thoracic aorta reported in the literature is highly variable.[57,100,101] Coady and coworkers[76] report rupture or dissection at a median size of 5.9 cm in the ascending aorta (Fig. 52-10) and 7.2 cm in the descending aorta. Because

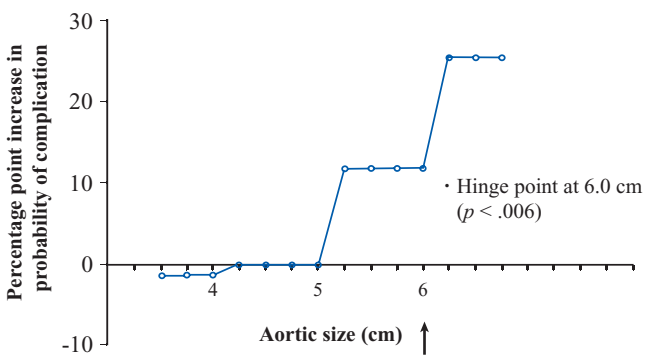

Figure 52-10. Logistic regression analysis of initial aneurysm size for risk of rupture or dissection. The probability of rupture or dissection is 25% higher in patients who present with aneurysms 6.0 cm or larger versus a comparison group with aneurysms 4.0 to 4.9 cm in diameter. Six centimeters appears to be a "hinge point" beyond which the risk of complications greatly increases. *(Reproduced with permission from Coady et al.[108])*

intervention at these diameters would have by definition resulted in rupture or dissection in 50% of patients, preemptive surgical therapy at 5.5 cm and 6.5 cm, respectively, for ascending and descending aneurysms seems appropriate.

As opposed to absolute size criteria, some surgeons prefer the use of ratios of measured to expected size. The expected size is based on the body surface area and age of the patient. The ratio indicating intervention is adjusted based on the underlying etiology. Ergin and colleagues[102] advocate a ratio of 1.5 for the average patient with an asymptomatic incidentally discovered ascending aortic aneurysm. This leads to intervention at a size of only 4.8 to 5.0 cm in an adult less than 40 years of age with a body surface area of 2 m^2. Because the ascending aorta normally increases in size with age, the diameter for intervention would be higher in a patient more than 40 years old.

The rate of expansion is also an important consideration. Reported mean growth rates of thoracic aneurysms vary from 0.10 to 0.42 cm per year.[56,77,79,103–105] The rate of expansion is usually greater in the descending aorta and in conditions with a weakened aortic wall, such as Marfan syndrome or chronic dissection.[76] Growth at a rate of greater than 1.0 cm per year is certainly an accepted indication for surgical intervention,[57] but more often the rate of dilation is used by the surgeon as supplementary information that helps to guide the timing of surgery rather than serve as an absolute indication.

The Influence of Etiology

Patients with Marfan syndrome or with familial aneurysms, particularly when there is a history of early dissection or rupture, should undergo earlier intervention. Gott and associates[106,107] recommend intervention in patients with Marfan syndrome at an ascending aortic diameter of 5.0 to 6.0 cm. Coady and coworkers[108] recommend intervention at 5.0 cm. Ergin and colleagues[102] recommend a ratio of measured diameter to predicted size of 1.3. Patients with chronic dissection should be considered to have similar intervention criteria as those with Marfan syndrome. Patients with bicuspid and unicuspid aortic valves are probably at intermediate risk[109] and Ergin and associates[102] recommend intervention at a ratio of 1.4 in these patients. Pseudoaneurysms are at a high risk of rupture and should be treated when discovered. In summary, the overall assessment of appropriate size of ascending aortic aneurysm to consider surgical repair is based on a paradigm that considers both size and etiology (Table 52-1).

PREOPERATIVE PREPARATION

A careful preoperative evaluation of the patient is important to minimize the risks of surgery. Nearly one-third of patients undergoing surgery for thoracic aortic disease have chronic obstructive pulmonary disease.[89] Patients with suspect pulmonary function should have spirometery and room air

Table 52–1.

Current Guidelines For Surgery

arterial blood gases. Smoking cessation, antibiotic treatment of chronic bronchitis, and chest physiotherapy may prove beneficial in elective situations. Normal renal function should be ensured with the appropriate blood work, and abnormal results should prompt further investigation. Because unaddressed severe carotid disease is a risk factor for stroke during ascending aortic operations,[110] patients over the age of 65 should have duplex imaging of their carotids. Younger patients with peripheral vascular disease, extensive coronary artery disease, carotid bruits, or history suspicious for cerebral ischemia should be investigated as well.[111] Abdominal aortic aneurysms occur in 10 to 20% of patients with ascending aortic aneurysms.[25,89] Patients with "atherosclerotic aneurysms" that extend into the aortic arch have a greater than 50% probability of having distal thoracic or abdominal aortic aneurysms.[89] CT or MRI of the abdominal aorta is indicated if disease is suspected.

CHOICE OF PROCEDURE

The specific procedure that is performed depends on the distal extent of aortic involvement, condition of the aortic root and the aortic valve (Fig. 52-11), underlying pathology, life expectancy of the patient, desired anticoagulation status, and surgeon preference. Specific procedures and their indications are listed in Table 52-2.

Ascending Aortic Aneurysms

Ascending aortic aneurysms with normal sinuses and aortic annulus require only replacement of the ascending aorta from the sinotubular ridge to the origin of the innominate artery with a Dacron tube graft. If the aortic valve is diseased,

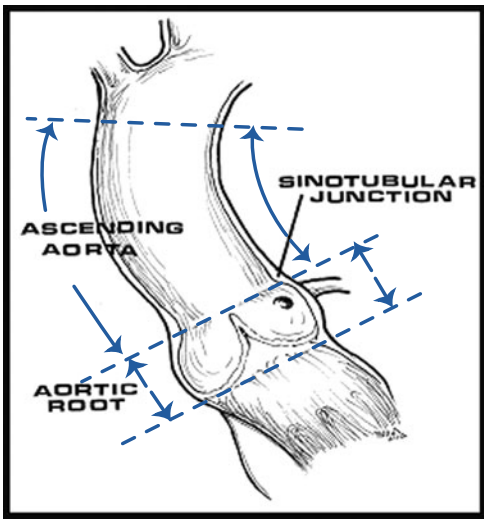

Figure 52-11. Illustration demonstrating the relationship of the aortic root, sinotubular junction, and ascending aorta. *(Illustration provided by R. Bolman, MD.)*

this can be replaced separately. The sinuses in patients with Marfan syndrome should not be preserved because of the frequent need for reoperation (Fig. 52-12).[112,113]

Annuloaortic Ectasia

Composite valve-graft conduit

Patients who have significant dilation of the aortic root in addition to an aneurysm of the ascending aorta or patients with Marfan syndrome should undergo replacement of the ascending aorta and root. This is usually done with a composite graft consisting of a mechanical valve inserted into a collagen- or gelatin-impregnated Dacron graft that comes preassembled. The coronary arteries are reimplanted as buttons.

Aortic allograft

The ascending aorta and root can be replaced with an aortic allograft with coronary reimplantation.[114] Accepted indications include patients with endocarditis, women anticipating pregnancy, young adults with active lifestyles, or patients with any other contraindications to anticoagulation.[115]

Pulmonary autografts (ross procedure)

A pulmonary autograft can be used to replace the aortic root and proximal ascending aorta. More distal replacement of the ascending aorta requires addition of a Dacron graft. The Ross procedure is most commonly performed for congenital surgery because of the proposed growth potential of the autograft. The use of the Ross procedure in adults with aneurysmal disease is more controversial. Potential indications include young adults with active lifestyles and life expectancies exceeding 15 to 20 years, women anticipating pregnancy, or patients with any contraindication to

Table 52–2.

Specific Procedures and Indications

Procedure	Potential indications
Simple tube graft*	Ascending aortic aneurysm with normal aortic root May correct central AI resulting from dilation of the ST junction
Composite valve-graft conduit	Involvement of ascending aorta and the root with aortic valve that cannot be spared
Separate ascending aorta-aortic valve replacement*	Ascending aortic aneurysm with normal root and aortic valve that requires replacement
Aortic allograft	Endocarditis with root destruction or infection of previous composite graft Root replacement for younger patients with active lifestyle or patients with contraindications to warfarin
Pulmonary autograft†	Root replacement for young patients who will benefit from growth potential of autograft Root replacement for younger patients with active lifestyle or patients with contraindications to warfarin
Aortic valve-spring procedure Reimplantation Root remodeling	Diseased ascending aorta and root with grossly normal aortic valves
External wrapping of the ascending aorta	Debilitated patients with limited survival who may not tolerate more extensive procedures

** Sparing the aortic root is contraindicated in Marfan syndrome.*
† The use of a pulmonary autograft is contraindicated in Marfan syndrome AI = aortic insufficiency; ST = sinotubular junction.

warfarin therapy.[115] The Ross procedure is contraindicated in patients with Marfan syndrome or inherited weakness of the aortic wall that may affect durability of the autograft.[115,116]

Valve-sparing procedures

If the aortic valve leaflets are grossly normal and aortic insufficiency is secondary to dilation of the sinotubular ridge or aortic root, then the native valve can often be spared.[117,118] Yacoub and associates have been able to apply valve-sparing techniques in almost 80% of patients operated on for ascending aortic aneurysms.[119] A variety of procedures are used to preserve the aortic valve. Reduction of the diameter of the sinotubular ridge via ascending aorta replacement[120] may be all that is required to correct central insufficiency. If the aortic root is involved, it may be completely replaced by inserting the

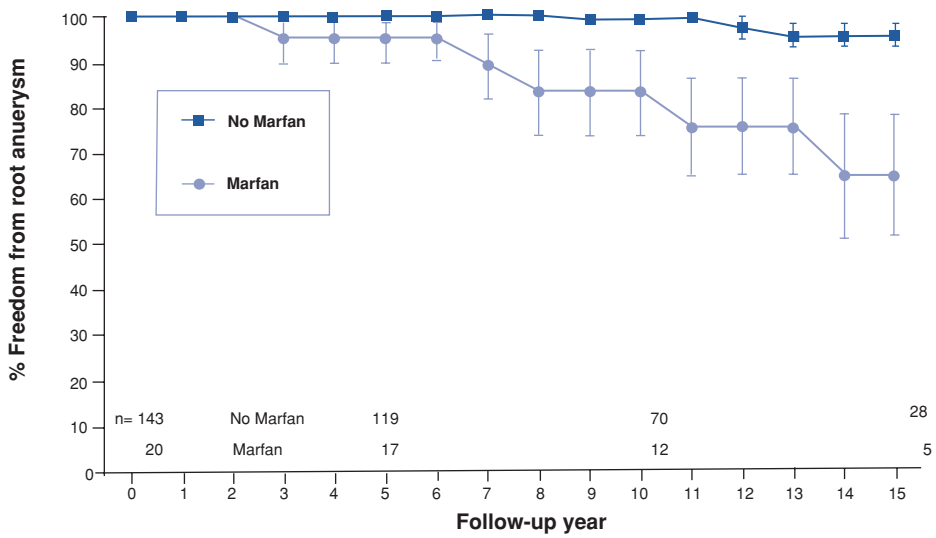

Figure 52-12. Actuarial estimate of freedom from late aortic root aneurysm for patients with and without Marfan syndrome who have undergone ascending aortic operations ($p < .0001$). *(Reproduced with permission from Yun KL, Miller DC: Ascending aortic aneurysm and aortic valve disease: What is the most optimal surgical technique? Semin Thorac Cardiovasc Surg 1997; 9:233.)*

scalloped native valve into a Dacron graft,[121] or dilated sinuses may be individually remodeled with tongues of the proximal Dacron graft.[122] If significant annular dilation is present, an aortic annuloplasty can be performed with the external application of a strip of graft material.[123] The application of valve-sparing procedures to patients with Marfan syndrome is controversial, as the durability of the leaflets is in question.[124] These procedures are discussed in detail in Chapter 37.

Alternative procedures

In older patients who are at high risk, or who have limited life expectancy, external wrapping of the aorta or separate valve and ascending aorta replacement may be appropriate without addressing the aortic root.[103,113,125]

Management of Associated Conditions

Coronary artery disease

Twenty-five percent of patients undergoing surgery for ascending aortic aneurysms will have concomitant coronary artery disease.[89] These patients should have appropriate bypass grafting performed at the time of ascending aneurysm surgery.

Mitral valve disease

Mitral valve disease is frequently encountered in patients with aortic aneurysms. This is particularly true for patients with Marfan syndrome, in whom the incidence approaches 30%.[48] Patients who have evidence of moderate to severe mitral regurgitation should undergo mitral valve repair or replacement at the time of aortic replacement.[68,126] Gilinov and associates[127] reported results of mitral valve repair in patients with Marfan syndrome, many of whom also had simultaneous replacement of the aortic root. They observed an 88% actuarial rate of freedom from significant mitral regurgitation at 5 years.

OPERATIVE TECHNIQUE

General

Monitoring and anesthesia

Venous access consists of two large-bore peripheral lines and a central line. We monitor filling pressures and cardiac output with a pulmonary artery catheter. A radial artery line provides blood pressure monitoring and determination of activated clotting times. Systemic temperature is monitored with nasopharyngeal and bladder probes. Transesophageal echocardiographic assessment of myocardial and valvular function is routine. Anesthesia is maintained with isoflurane and intravenous fentanyl.

Incision

A median sternotomy is the preferred incision. Extension into the left fourth or fifth interspace facilitates exposure of the distal aortic arch or descending aorta when required.

Perfusion

Cannulation is performed following heparinization (350 U/kg) and confirmation of an activated clotting time greater than 450 seconds. If the distal ascending aorta is not involved, this region or the proximal arch is cannulated. The aortic cannulation site must allow enough room proximally for the cross-clamp and a sufficient cuff of aortic tissue to sew to, while still allowing all diseased aorta to be resected. Epiaortic ultrasound assists in finding safe areas for clamping and cannulation. If the arch is involved and circulatory arrest will be required, either the right axillary artery, the femoral artery, or the aneurysm itself is cannulated. Before retrograde perfusion of the femoral artery is considered, however, TEE assessment of the descending aorta is performed. Venous cannulation is performed with a 21F or 24F two-stage cannula in the right atrial appendage. The superior and inferior vena cava are cannulated separately if circulatory arrest or mitral valve procedures will be required. This bicaval cannulation allows for retrograde cerebral perfusion and a transseptal approach to the mitral valve. The superior vena cava cannula should be placed above the azygos vein for retrograde cerebral perfusion. Flow during retrograde cerebral perfusion should be approximately 200 to 300 mL/min to maintain a jugular venous pressure of 20 to 25 mm Hg. Carbon dioxide insufflation into the pericardial well is routinely used for any procedure that requires opening the left heart.

Right axillary cannulation provides the benefit of allowing one arterial perfusion site for the entire operation and permitting a method for cerebral perfusion by the use of selective antegrade cerebral perfusion (SACP). Using this method, a low flow of approximately 10 mL/kg through the right axillary artery is initiated at the time of systemic circulatory arrest. A snare or clamp is placed on the innominate artery and cerebral perfusion is via the right carotid and right vertebral artery (Fig. 52-13).

The cardiopulmonary bypass circuit is primed with lactated Ringer solution and 25 g of mannitol. No glucose is added to the prime to prevent exacerbation of neurologic injury.[128] The cannulas are attached, and low-flow cardiopulmonary bypass is initiated. A left ventricular vent is inserted via the right superior pulmonary vein and a balloon-tipped catheter is inserted into the coronary sinus for retrograde cardioplegia delivery. Cardiopulmonary bypass flow is increased to 2.2 to 2.5 L/min/m^2 and moderate systemic hypothermia (28°C) and hemodilution (hematocrit 15 to 25%) are established.

Myocardial protection

Cold blood hyperkalemic cardioplegia (4°C) is given antegrade into the aortic root at a rate of 300 mL/min for 2 minutes and then retrograde at a rate of 200 mL/min for an additional 2 minutes. A cooling jacket may be used to facilitate this process. If the aortic valve is grossly incompetent, and prompt arrest is not achieved with retrograde cardioplegia, the aorta is opened and the coronary ostia are cannulated directly. During the procedure, retrograde cardioplegia is administered every 20 minutes.

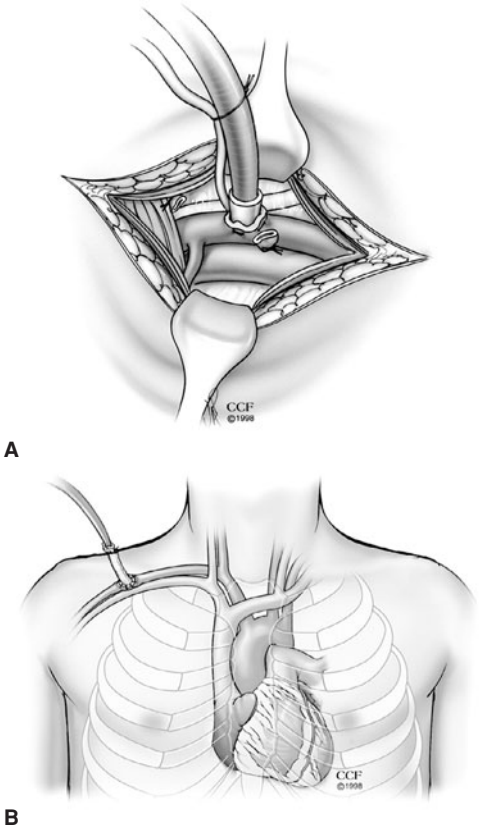

Figure 52-13. (A) Direct cannulation of axillary artery with right-angle arterial cannula (note division of crossing vein). (B) Cannulation of axillary artery with a side graft. A straight arterial cannula is inserted into graft. *(Reprinted with permission from Sabik JF, Nemeh H, Lytle BW, et al: Cannulation of the axillary artery with a side graft reduces morbidity. Ann Thorac Surg 2004; 77:1315.)*

Choice of graft

Woven double velour Dacron grafts impregnated with collagen or gelatin are relatively impervious to blood and have excellent handling characteristics. If root replacement is required, prefabricated composite grafts with mechanical valves are available. Bioprosthetic valves can be inserted into a Dacron graft if desired. The indications for pulmonary autograft or aortic allograft use have been previously discussed.

Specific Operative Techniques

Replacement of the ascending aorta

After cardiopulmonary bypass is established the aorta is clamped just proximal to the innominate artery, and the heart is arrested with cold blood cardioplegia. The aorta is transected below the clamp leaving a sufficient cuff for subsequent anastomosis (Fig. 52-14A). The proximal aorta is then transected just above the commissures. An appropriately sized Dacron graft is selected and sewn to the distal aorta with a continuous 3-0 or 4-0 polypropylene suture, incorporating a strip of felt (Fig. 52-14B). If required, the aortic valve is replaced at this time (Figs. 52-14C and 52-14D). The proximal anastomosis is performed in the same fashion after the graft is cut to the appropriate length (Figs. 52-14E and 52-14F). The graft is de-aired and the patient is weaned from cardiopulmonary bypass. After decannulation and protamine administration, suture line hemostasis is ensured.

Replacement of the ascending aorta and aortic root with a composite valve-graft conduit

The Bentall operation has been considered the gold standard for treatment of combined ascending aortic aneurysm disease and aortic valve pathology.[129] After establishing cardiopulmonary bypass, the aorta is clamped proximal to the innominate artery and the heart is arrested with cold blood cardioplegia. The aorta is transected beneath the clamp, ensuring an adequate cuff of aortic tissue. Proximally the aortic root is excised leaving only buttons of aortic tissue surrounding each of the coronary arteries (Fig. 52-15A). The coronaries are mobilized for 1 to 2 cm to prevent tension during reimplantation. A composite graft is selected based on the size of the aortic annulus. The sewing ring of the composite graft is sutured to the annulus with 2-0 pledgeted polyester mattress sutures placed immediately adjacent to each other (Fig 52-15B). The adjacent placement of sutures and the selection of a conduit that snugly fits within the annulus help to ensure hemostasis. A second suture line with a 4-0 running polypropylene suture can be used to approximate the aortic remnant to the newly secured valved conduit sewing ring to aid in hemostasis. Openings for coronary reimplantation are made in the appropriate position in the Dacron graft with an ophthalmic cautery (Fig. 52-15C). First the left and then the right coronary arteries are attached using 4-0 or 5-0 polypropylene suture in continuous fashion incorporating a thin strip of felt (Fig. 52-15D). The distal anastomosis is then performed with a continuous 3-0 or 4-0 polypropylene suture also incorporating a strip of felt. The graft is vented with a needle and the left atrium and ventricle are de-aired. After the patient is decannulated and protamine has been administered, suture line hemostasis is scrutinized.

Replacement of the ascending aorta and aortic root with an allograft or autograft

The muscular tissue at the base of the conduit is sutured to the aortic annulus with a continuous or interrupted 4-0 polypropylene or braided synthetic suture. The suture line is reinforced with a strip of Dacron or pericardium. Coronary ostia are created and coronary buttons are inserted with a continuous 4-0 or 5-0 polypropylene suture. Extension with a Dacron tube graft may be required to successfully replace the entire diseased aorta.

Open technique for distal anastomosis

The distal aortic anastomosis may need to be sewn under circulatory arrest as an open technique if clamping of the distal

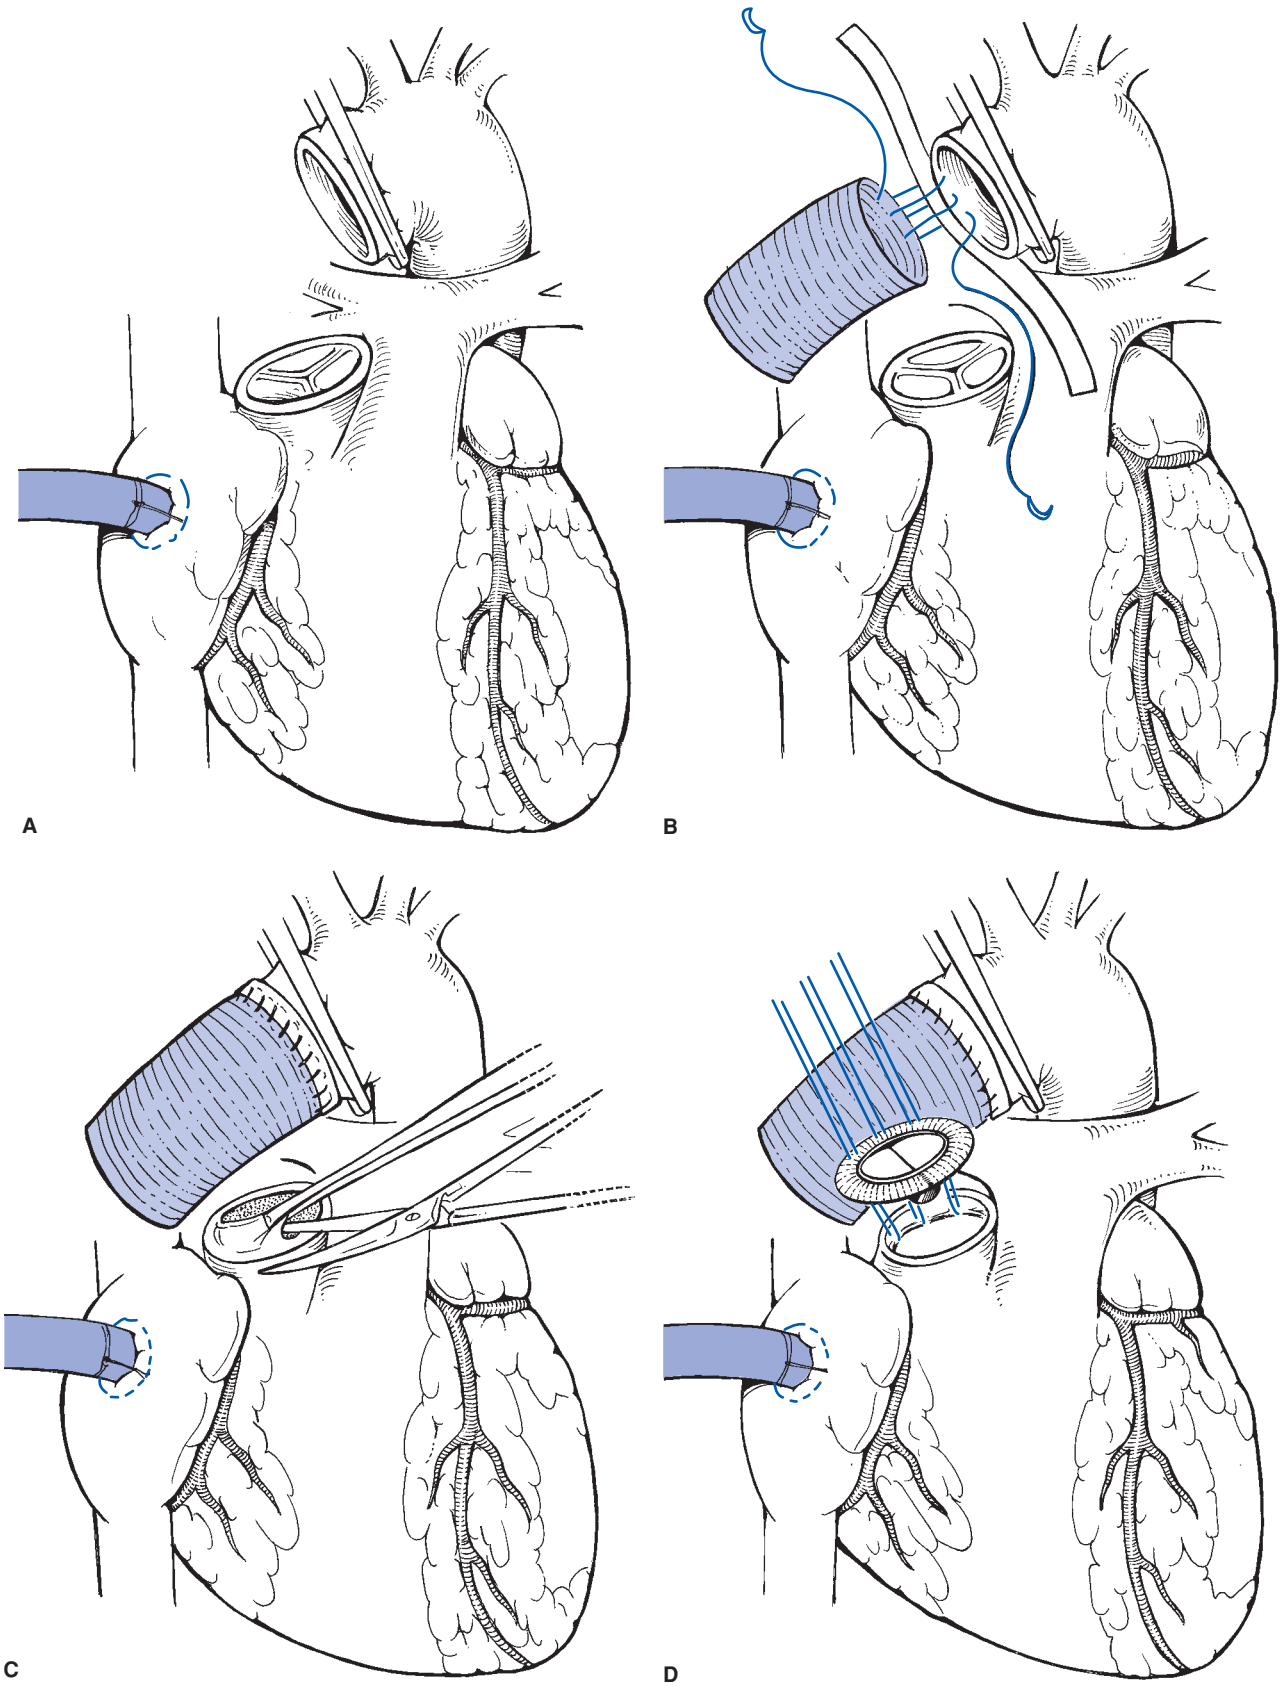

Figure 52-14. Illustration of simple aortic tube graft placement with separate replacement of the aortic valve. (A) The aorta is clamped proximal to the innominate artery (the aortic perfusion cannula is not shown) and the diseased aorta is resected down to just above the aortic valve commissures. (B) A Dacron graft is sewn to the distal aorta with a 3-0 or 4-0 polypropylene suture reinforced with a strip of Teflon felt. (C) If aortic valve replacement is indicated, the diseased valve is excised. (D) The valve is replaced with the valve of the surgeon's choice. *(Continued)*

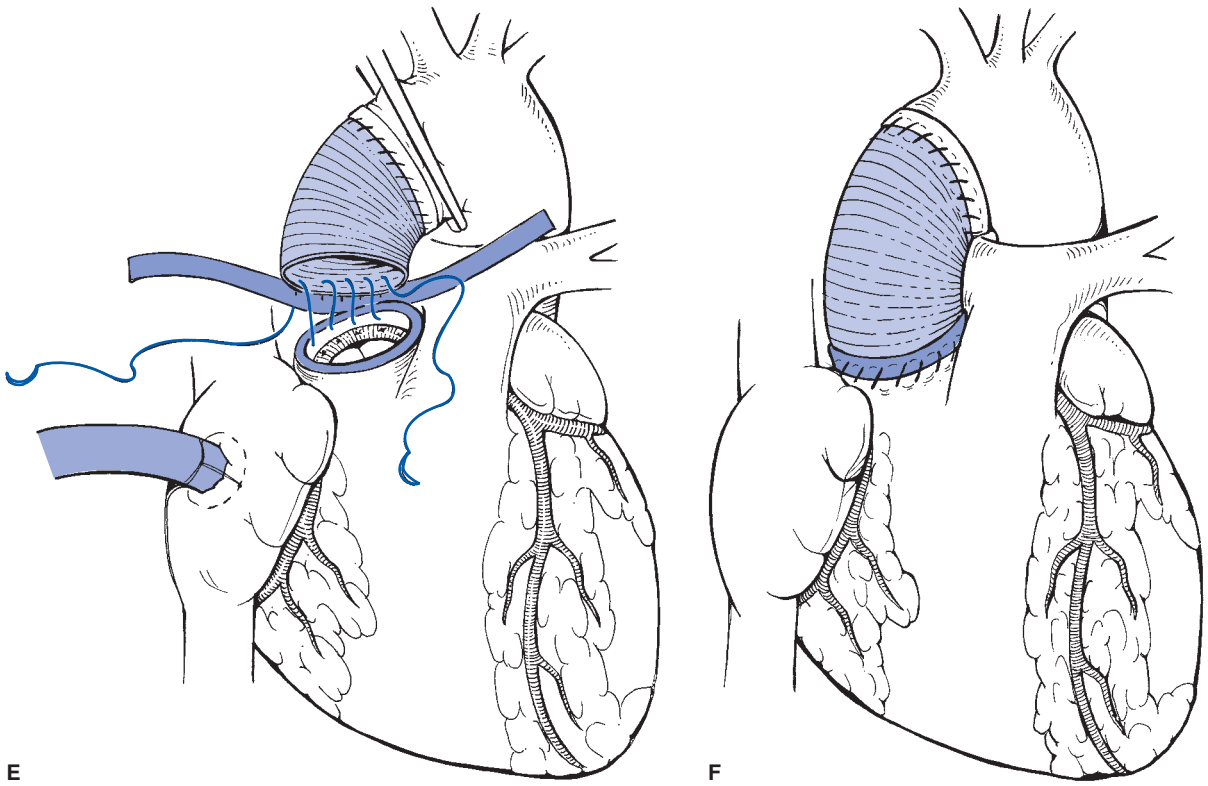

Figure 52-14. (*Continued*) (E, F) The graft is sewn to the proximal aorta with 3-0 or 4-0 polypropylene reinforcing the aortic tissue with a strip of Teflon felt. *(Reproduced with permission from Downing SW, Kouchokos NT: Ascending aortic aneurysm, in Edmunds LH Jr (ed): Cardiac Surgery in the Adult. New York, McGraw-Hill, 1997; p 1163.)*

ascending aorta is not safe, or if partial or complete arch replacement is indicated. Clamping may be dangerous because of atherosclerotic disease or clot, or may not be possible because of the distal extent of the aneurysm. Cardiopulmonary bypass is initiated with right axillary artery cannulation, femoral artery cannulation, or direct cannulation of the ascending aneurysm, depending on the indication for circulatory arrest. The typical cardiopulmonary bypass setup for a case requiring circulatory arrest and retrograde cerebral perfusion is shown in Fig. 52-16. Central nervous system protection is enhanced by maintaining the blood glucose below 200 mg/dL, as well as by the administration of methylprednisolone (7 mg/kg) and thiopental (7 to 15 mg/kg). Mannitol (0.3 to 0.4 g/kg) and furosemide (100 mg) are given for renal preservation. Once the nasopharyngeal temperature reaches 15°C and the electroencephalogram has been isoelectric for 5 minutes, the patient is placed in Trendelenburg position and the circulation arrested. Approximately 25% of the patient's volume is drained into the venous reservoir.

The aorta is divided distally in a region dictated by the distal extent of disease. If the aneurysm ends at the takeoff of the innominate artery, the aorta can be transected here and the graft sewn, leaving the arch intact. If the aneurysm extends to the proximal undersurface of the arch, the distal end of the graft is beveled to conform to the resected surface of the arch (Fig. 52-16B). If the arch in the region of the origin of the brachiocephalic vessels is involved, then the aorta is divided distal to the origin of the left subclavian artery. The distal anastomosis is performed with a running 3-0 polypropylene suture reinforced with a felt strip. An elliptical portion of the graft is then excised that corresponds to a single island of aortic tissue that has been fashioned around the origin of the brachiocephalic vessels. This anastomosis is performed with felt-enforced running 3-0 polypropylene sutures as well. During this anastomosis, either selective antegrade cerebral perfusion (SACP) or slow retrograde perfusion of the superior vena cava is performed to remove any air or particulate debris (see Fig. 52-16B). Additionally, SACP may be used for the majority of the systemic circulatory arrest period with retrograde perfusion used at the end of circulatory arrest to allow a washout of any debris in the arch vessels. Antegrade perfusion is then initiated via direct cannulation of the graft, insertion of a cannula into a previously placed 8-mm side graft, or reinstitution of full antegrade perfusion through the original right axillary cannula (Fig. 52-16C). Femoral perfusion is not resumed in order to prevent cerebral embolization of distal aortic debris that may have occurred during previous manipulations.

The patient is rewarmed, and any additional procedures that are required such as coronary revascularization or mitral valve interventions are performed now that cerebral

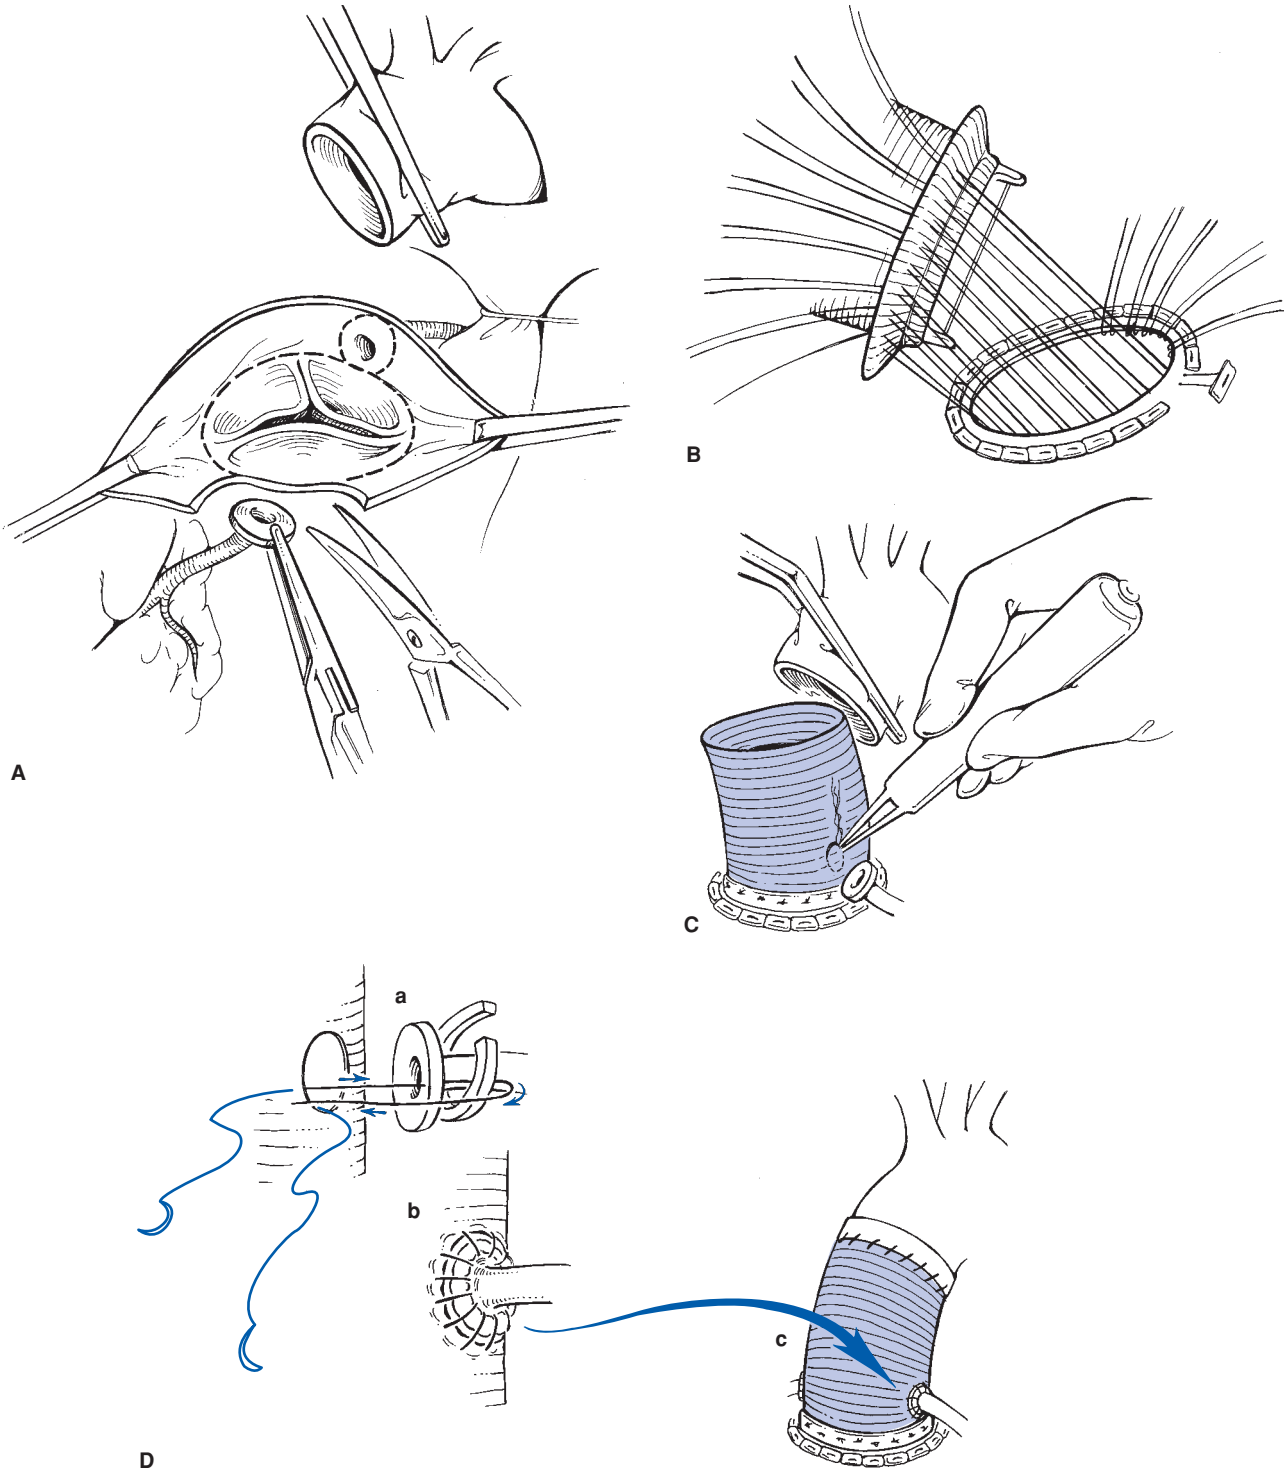

Figure 52-15. Illustration of insertion of a composite valve-graft conduit with coronary artery reimplantation. (A) A full-thickness button of aortic wall adjacent to each coronary ostium is fashioned. The aortic valve and sinuses are then excised. (B) Pledgeted 2-0 braided polyester sutures are placed in the supra-annular position and immediately adjacent to one another to ensure a watertight closure. The sutures are placed in the upper half of the sewing ring, helping to seat the valve deep within the aortic annulus. Note that no knots or suture material are exposed to the bloodstream. (C) Ophthalmic cautery is used to create an orifice in the graft in the appropriate position for left coronary reimplantation. (D) The left coronary anastomosis is performed first with a continuous 4-0 or 5-0 polypropylene suture incorporating a thin strip of felt. The right coronary anastomosis is then performed in a similar fashion. *(Reproduced with permission from Downing SW, Kouchokos NT: Ascending aortic aneurysm, in Edmunds LH Jr (ed): Cardiac Surgery in the Adult. New York, McGraw-Hill, 1997; p 1163.)*

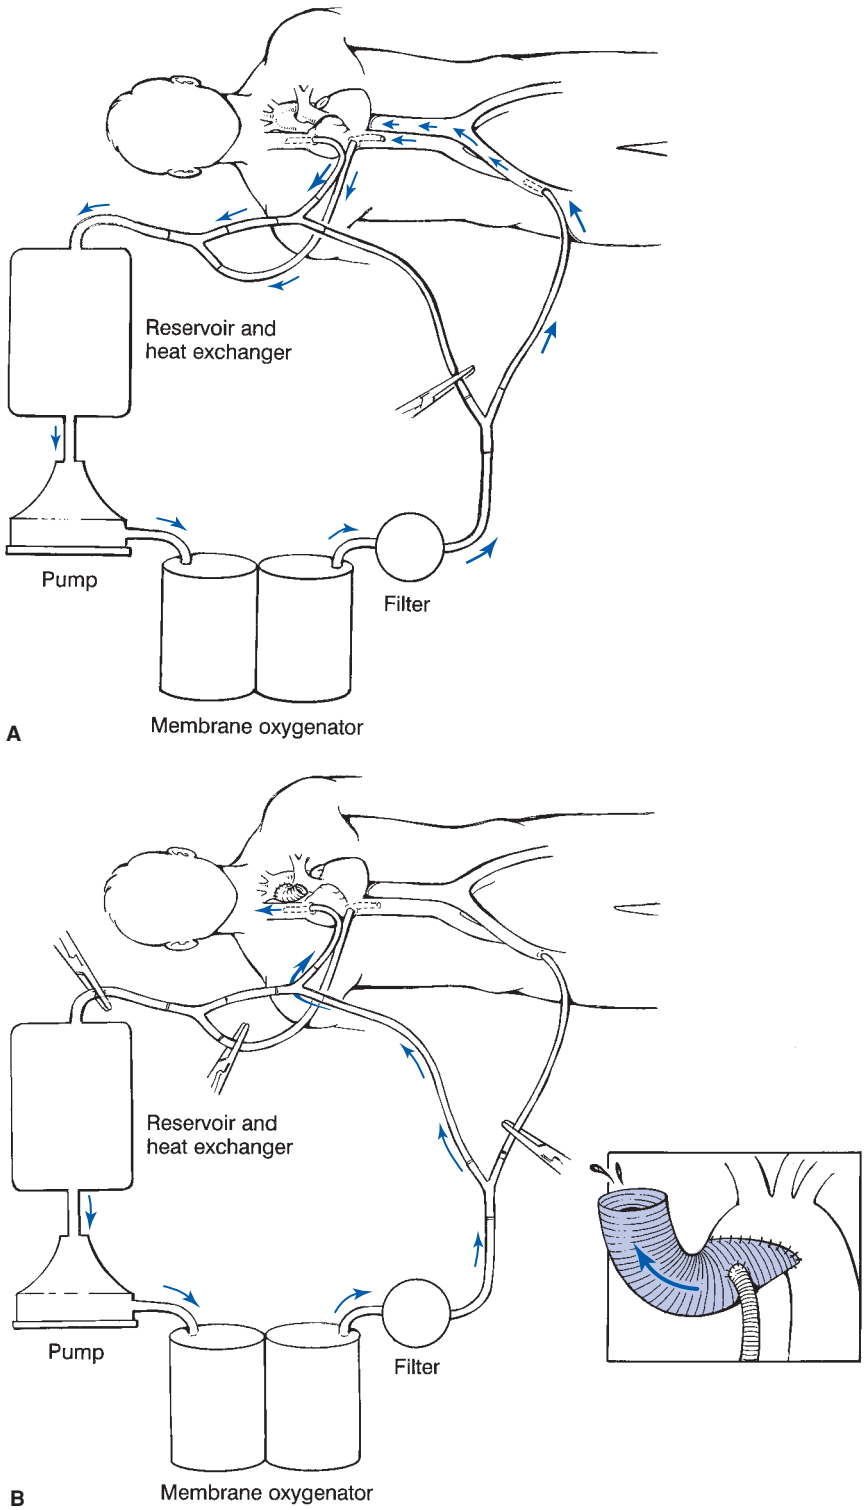

Figure 52-16. Schematic representation of the cardiopulmonary bypass circuit used for circulatory arrest when a portion or all of the aortic arch is to be replaced, or when it is unsafe to clamp the ascending aorta. (A) Cardiopulmonary bypass is established using two vena cava cannulas and a femoral artery cannula. A shunt connecting the venous and arterial lines is clamped. (B) The arterial and inferior vena caval lines are clamped and the shunt is opened, allowing retrograde cerebral perfusion of cold oxygenated blood through the superior vena cava cannula. Air and atherosclerotic debris are evacuated from the brachiocephalic arteries (inset). A separate 8-mm Dacron graft is sewn to the side of the Dacron graft to allow antegrade reperfusion of the brain once the distal anastomosis is done.

circulation has been restored. The proximal graft is sewn to the ascending aorta just above the sinotubular ridge or the aortic annulus in the case of composite graft placement. Thorough de-airing is performed and the patient is weaned from cardiopulmonary bypass. After protamine, suture lines are inspected closely.

Cabrol technique for reestablishing coronary flow

Avoidance of tension at the site of coronary reimplantation after aortic root replacement is essential to prevent postoperative bleeding and pseudoaneurysm formation. In the Cabrol technique, a single 6- to 8-mm Dacron graft is anastomosed end to end to the coronary arteries and

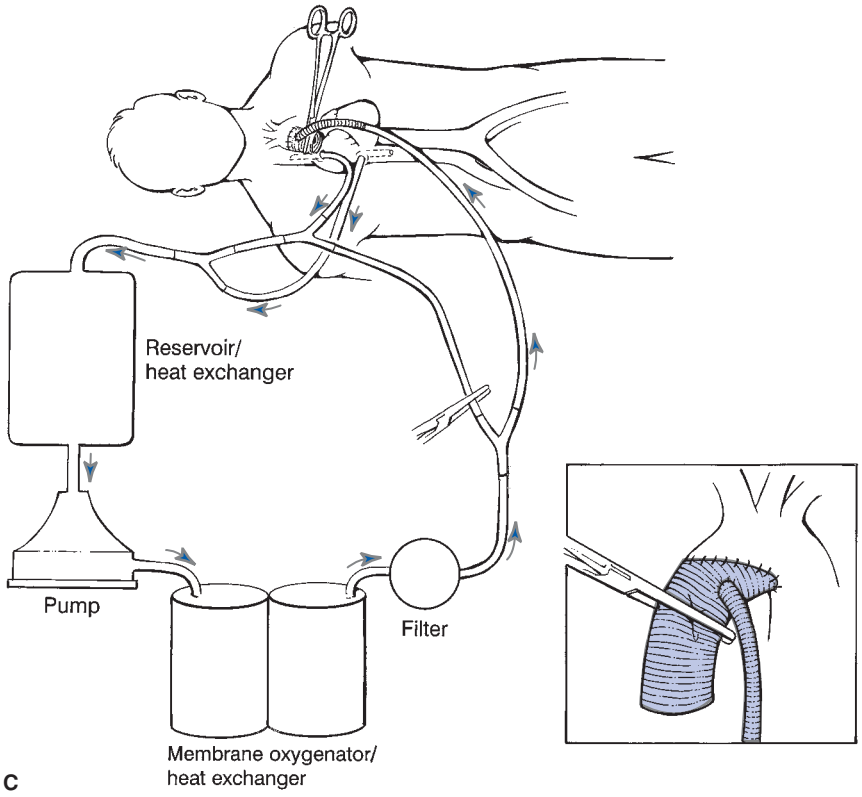

Figure 52-16. (*Continued*) (C) Cardiopulmonary bypass is reestablished in an antegrade fashion. The femoral arterial cannula is removed and the shunt is occluded. *(Reproduced with permission from Downing SW, Kouchokos NT: Ascending aortic aneurysm, in Edmunds LH Jr (ed): Cardiac Surgery in the Adult. New York, McGraw-Hill, 1997; p 1163.)*

then the mid-segment of the coronary graft is anastomosed side to side to the aortic graft (Fig. 52-17). This technique is often required when the coronary ostia are low or when there is scarring from a previous operation preventing adequate mobilization. Oversizing of the Cabrol side arm above 8 mm should be avoided to avoid potential stasis and risk of postoperative thrombosis. Tension on the left coronary anastomosis is more common, and a small Dacron interposition graft may be required on this side in isolation in certain cases.

Reoperation on the ascending aorta and aortic root

Reoperative surgery on the ascending aorta and aortic root can be particularly challenging but is becoming more frequent. Because of improved outcomes,[68,71,110,130,131] the criteria for treatment of ascending aortic disease have been liberalized to include more elderly patients and more patients who have had previous cardiac surgery.[132,133] Increasing use of allografts, pulmonary autografts, and valve-preserving techniques may also result in an increased need for subsequent reintervention as these patients age. Indications for reoperation include aortic insufficiency, development of aneurysms or dissections in remaining segments of the thoracic aorta, false aneurysms, prosthetic valve malfunction or infection, or degeneration of biologic prostheses.[132]

To maximize safety, preemptive peripheral exposure or cannulation is required either through right axillary artery/femoral venous cannulation or through femoral artery/femoral venous cannulation. In the case of large pseudoaneurysms or grafts tethered to the posterior sternal wall, significant blood loss may be unavoidable upon entry. In such situations it is necessary to go on "pump-sucker bypass" until structures are dissected out and bleeding is controlled. Fifty percent of patients undergoing reoperation have significant aortic insufficiency, making myocardial preservation more challenging. In such cases, the perfusate temperature must not be reduced until exposure is sufficient to allow either clamping of the aorta or venting in order to prevent fibrillation and distension of the left ventricle and direct antegrade perfusion and retrograde perfusion of cardioplegia must be administered. Reimplantation of coronary buttons in the case of root replacement is often not possible without use of a modified Cabrol technique or an interposition graft.

Management of Complications

Bleeding

Woven Dacron grafts impregnated with collagen or gelatin are relatively impervious to blood and have reduced blood loss following replacement of the ascending aorta. Anastomotic bleeding is lessened with the use of Teflon pledgets at the aortic and coronary anastomoses. When composite valve-graft insertion is indicated, choosing a valve size that snugly fits the annulus and placing mattress stitches immediately adjacent to each other are helpful. Tension must be avoided at the sites of coronary reimplantation, as this is a frequent site of bleeding. The modified Cabrol method or an

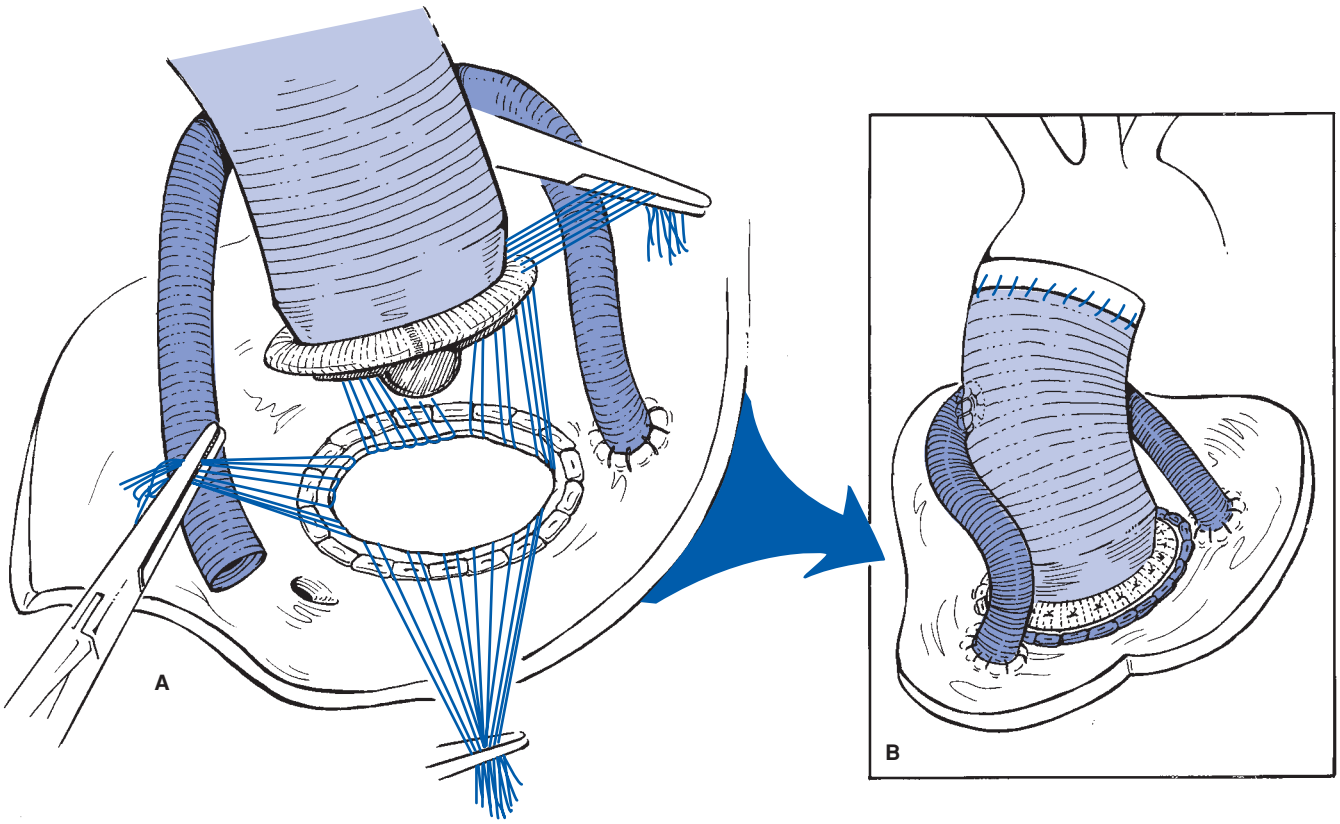

Figure 52-17. Classic Cabrol technique for coronary reimplantation. (A) An 8- to 10-mm Dacron tube graft is anastomosed end-to-end to the aortic tissue surrounding the left and right coronary ostia. (B) An opening is made in the mid-portion of the coronary graft and in an appropriate position in the aortic graft and an anastomosis is formed. The modified Cabrol technique involves the formation of individual coronary buttons allowing the small-caliber Dacron graft to be sewn to the full thickness of the aortic tissue surrounding the coronary ostia. *(Reproduced with permission from Downing SW, Kouchokos NT: Ascending aortic aneurysm, in Edmunds LH Jr (ed): Cardiac Surgery in the Adult. New York, McGraw-Hill, 1997; p 1163.)*

interposition graft should be used when any tension is present. The inclusion technique of graft insertion is associated with an increased incidence of bleeding and pseudoaneurysm formation and has largely been abandoned.[68,134,135] All coronary and aortic anastomoses should be sewn to the full thickness of the aorta, and wrapping of the graft with residual aorta is not indicated. After the administration of protamine, all anastomoses must be evaluated closely.

Suspected coagulopathy should be documented by laboratory tests and treated accordingly. In cases of refractory coagulopathy, the anastomosis can be wrapped tightly with a small segment of Dacron to reduce tension on the suture line and reduce needle hole bleeding. Homologous blood donation can be avoided in a significant number of patients with the use of blood conservation techniques such as Cell Savers, autologous blood donation, plateletpheresis, the reinfusion of chest tube drainage, and the use of antifibrinolytics.[71]

Stroke

Neurologic injury following proximal aortic surgery remains a significant cause of morbidity and mortality.[136] Embolization of atherosclerotic debris or thrombus from the ascending aorta and arch produces focal neurologic deficits. Diffuse injury can be attributed to microemboli of air or cellular debris, insufficient or uneven cooling, and a prolonged circulatory arrest period. After circulatory arrest periods exceeding 40 minutes the incidence of stroke greatly increases.[137] Profound hypothermia may itself be injurious to the central nervous system without associated circulatory arrest.[137]

Stroke due to embolization is diminished when the aorta is evaluated via epiaortic ultrasound or other imaging modality to detect atherosclerotic plaques and thrombus. This allows appropriate adjustments to be made in clamping and cannulation strategies.[138] The utility of retrograde cerebral perfusion as an adjunct to hypothermic circulatory arrest is controversial, but some groups report an increase in the safe period of circulatory arrest.[139–141] Laboratory evidence suggests that the primary benefits of retrograde cerebral perfusion are flushing of embolic material and perhaps more homogeneous cooling, rather than effective nutrient delivery, which is far superior with antegrade circulation.[142] Resumption of antegrade circulation through the graft once

the distal aortic anastomosis is complete, rather than retrograde via the femoral vessels, after a period of circulatory arrest avoids embolization of distal aortic debris. Patients with severe carotid artery occlusive disease are at increased risk of stroke during ascending aortic procedures,[110] and patients older than 65, those with peripheral vascular disease, or those with pertinent histories should be evaluated.

Pulmonary dysfunction

Cardiopulmonary bypass is known to cause alterations in pulmonary function as evidenced by changes in alveolar-arterial oxygen gradients, pulmonary vascular resistance, pulmonary compliance, and intrapulmonary shunting. Usually these changes are subclinical, but a full-blown adult respiratory distress–like syndrome is reported in 0.5 to 1.7% of patients following cardiopulmonary bypass.[143] The specific cause is the subject of much investigation and debate, but it is generally accepted that exposure of blood elements to the foreign surface of the cardiopulmonary circuit results in the activation of inflammatory cells and the complement cascade resulting in pulmonary injury.[143] The duration of cardiopulmonary bypass, urgency of the procedure, and general condition of the patient may roughly correlate with the occurrence and severity of pulmonary dysfunction, but it can be unpredictable.[144]

Treatment is supportive, with early diagnosis and treatment of any subsequent pulmonary infections. Preventive measures may include preoperative optimization of pulmonary function, minimization of pump time, judicious use of blood products, heparin-coated bypass circuits,[145,146] and leukocyte depletion.[147,148]

Postoperative coronary insufficiency

Coronary insufficiency is uncommon in the postoperative period, but may occur following root replacement and coronary reimplantation. Ischemia may be due to kinking of a Dacron or saphenous vein interposition graft. Coronaries implanted under tension, or aortic suture lines, may bleed resulting in compression from an expanding hematoma. Suspicion of coronary insufficiency must be promptly evaluated with angiography and/or reoperation.

RESULTS OF OPERATION

Perioperative Morbidity

The primary causes of significant morbidity in the early postoperative period are neurologic injury and bleeding. Stroke has been reported in 1.8 to 5.9% of patients in various series.[71,89,131,149–151] Antegrade reperfusion following completion of the distal aortic anastomosis[71] and the use of retrograde cerebral perfusion[138,139] may lower the risk of stroke in patients requiring circulatory arrest. Postoperative bleeding requiring reoperation ranges from 2.4 to 11.1%.[68,71,131,149–152] The use of the exclusion technique of graft insertion and blood-impervious grafts has resulted in lower bleeding rates in more recent series. Ten to eighteen percent of patients require prolonged mechanical ventilation,[71,151] and 18 to 25% require prolonged (more than 6 hours) inotropic support.[68,151] Postoperative myocardial infarction, reported in up to 2.5%, may be related to technical problems with coronary reimplantation.[71,131,149]

Perioperative Mortality

Contemporary surgical series on ascending aortic disease using modern grafting techniques and methods of cerebral and myocardial protection report hospital mortality rates of 1.7 to 17.1%.[44,71,102,130,131,152–155] Comparison of outcomes is difficult, however, because of heterogeneity of patients. Some series do not include dissection,[131] and the proportion of emergent operations, reoperations, and arch replacements is highly variable. The most common cause of early death is clearly cardiac failure. Other frequent causes of early death include stroke, bleeding, and pulmonary insufficiency.[68,89,130,149–151]

Risk Factors for Hospital Mortality

Emergent operation after the onset of acute dissection or rupture is the clearest risk factor for early death.[89,102,149] Risk of death following elective intervention is increased by increasing New York Heart Association classification,[130,149,156] increasing age,[89,102,150,151,156] prolonged cardiopulmonary bypass time,[68,149,150] dissection,[130] previous cardiac surgery,[89,151] and need for concomitant coronary revascularization.[149,151] Major risk factors are shown in Table 52-3.

Table 52–3.

Independent Predictors of Early Mortality

Risk factor	*p* Value (range)
Emergent operation	000–.0017
New York Heart Association functional class	.0001–.015
Age	.01–.045
Cardiopulmonary bypass time	<.001–.018
Dissection	<.001–.04
Concomitant coronary artery bypass graft	.001–.0014
Previous cardiac operation	<.001–.0068
Arch replacement	<.001
Reoperation for bleed	.0009–.032

Only risk factors found to be predictive on multivariate analysis are reported. Some of the reported risk factors were not significant in some series. Data are from the following references: 41,61,80,119,137,138,139,141,142,143.

Late Mortality

Reported actuarial survival, like early mortality, is variable and dependent on the patient cohort. Survival rates are 81 to 95% at 1 year,[89,149] 73 to 92% at 5 years,[89,102,130,149] 60 to 73% at 8 to 10 years,[102,130,151] and 48 to 67% at 12 to 14 years.[68,130,157] Predictors of late mortality include elevated New York Heart Association class,[68,151] requirement for arch reconstruction,[151] Marfan syndrome,[68] and extent of distal disease.[89,149] The most common cause of late death is cardiac, but distal aortic disease accounted for 32% of late deaths in one series.[89]

Reoperation

Reoperations may be required because of pseudoaneurysm formation, valve thrombosis or endocarditis, progression of disease in the native valve or remaining aortic segments, or degeneration of a bioprosthesis. Reported mortality for reoperative ascending aortic surgery varies between 6 and 22%, but has been reported as low as 3% for elective reoperations[133] and as high as 100% for emergent reoperations.[158] Predictors of poor outcome have included emergent reoperation, requirement for arch replacement, preoperative functional class III/IV, and duration of cardiopulmonary bypass.[132,133] Freedom from reoperation is 86 to 90% at 9 to 10 years.[130,151] Predictors of late reoperation have included Marfan syndrome (Fig. 52-18), the inclusion cylinder technique (Fig. 52-19),[68,159] and chronic dissection. Surveillance of patients who have undergone previous aortic surgery to minimize the need for urgent reoperations and appropriate resection of all diseased aortic tissue at the time of original operation will improve outcomes. In one series it was estimated that nearly 60% of redo aortic cases were required because of inadequate repair during previous operations.[132] Since the majority of these inadequate repairs involve residual aneurysm disease remaining at the distal ascending aorta or in the arch, some surgeons have advocated the routine use of hypothermic circulatory arrest (HCA) with the removal of the aortic cross-clamp to ensure complete resection of all diseased aorta.[160] Other groups have stressed the increased incidence of transient neurologic complications with the routine use of HCA and limit HCA to only those patients with aneurysms of the arch.[161,162]

Thromboembolism

Major thromboembolic events following replacement of the aortic root with a composite graft are currently uncommon. Unlike simple aortic valve replacement, suture material and pledgets are excluded from the bloodstream. Freedom from thromboembolism was 82 to 83% at 10 to 12 years in two older series.[68,150] The incidence in more recent series is considerably lower.[71] Gott and associates[130] reported an incidence of only 0.42 thromboembolic events per 100 patient years.

Prosthetic Valve Endocarditis

Prosthetic valve endocarditis is not reported in some series, but was the most common late complication occurring after root replacement reported by Gott and colleagues.[130] The actuarial freedom from endocarditis in 270 patients was 88% at 14 years.

Results of Operation in Patients with Marfan Syndrome

Gott and associates[106] reviewed the experience of 10 surgical centers with regard to root replacement in 675 patients with Marfan syndrome from 1968 to 1996. The 30-day mortality was 3.3%, but was only 1.5% for elective repair. Emergency surgery resulted in a 30-day mortality of nearly 12%. The survival rate was 93% at 1 year, 84% at 5 years, 75% at 10 years, and 59% at 20 years. Complications related to the residual thoracic aorta and arrhythmias were the leading causes of death. The most frequent late complication was thromboembolism. Advanced New York Heart Association class at the time of original operation was the only predictor of late death. This very complete multicenter review demonstrates that root replacement in Marfan syndrome can be performed with a low mortality and good long-term survival. Kaplan-Meier survival analysis is shown in Fig. 52-20.

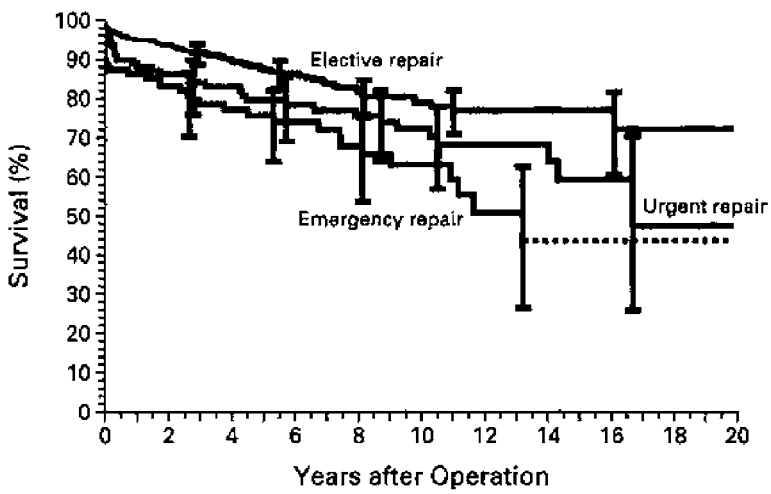
LONG-TERM SURVEILLANCE AFTER ASCENDING AORTIC OPERATIONS

All patients who have undergone thoracic aortic surgery must have long-term follow-up. Residual aortic tissue is often not normal and patients are prone to subsequent development of dissections or aneurysms. Pseudoaneurysms are frequently asymptomatic in the early stages and may initially present as periprosthetic hematomas.[163] A significant proportion of patients will require reoperation, and emergent operation is associated with a very high mortality. Periodic CT or MRI is ideal for assessing progression of disease in the residual aorta and for discovering the development of complications. Patients at increased risk of reoperation, such as those with Marfan syndrome, familial aneurysms, or dissections, require more vigilant follow-up.

THE INFECTED AORTIC GRAFT

Incidence

Graft infections are reported in 0.9 to 1.9% of patients following surgery of the thoracic aorta[164,165] and are associated with a mortality rate ranging from 25 to 75%.[165,166] Most graft infections become evident in the first month after operation[166,167] but may occur years after graft insertion.[168]



No. at Risk											
Elective repair	455	381	294	204	141	97	64	42	17	4	1
Urgent repair	117	88	74	62	53	41	23	16	8	4	3
Emergency repair	103	73	57	41	31	21	10	4	3	2	0

Risk Factors

The risk of infection with any graft is increased with breaks in sterile technique and postoperative infectious complications. In one series 55% of patients had previous significant infectious complications, including wound infection, line sepsis, pneumonia, empyema, or septicemia.[168] The ascending aortic graft may be particularly vulnerable because of proximity to the wound and poor natural tissue coverage. The major infectious agents are *Staphylococcus aureus, S. epidermidis*, and less commonly *Pseudomonas*.[166–168] Infections may also be polymicrobial, fungal, or indeterminate.

Diagnosis

The majority of patients present with clinical signs of infection such as fever, chills, and elevated white blood cell count.[167–169] CT or MRI may demonstrate fluid collections or air in the periprosthetic space, but these are nonspecific findings, particularly in the early postoperative period. Confirmation of infection may require CT-guided aspiration of suspicious fluid collections. Associated pseudoaneurysms are detected by aortography or transesophageal echocardiography. Nuclear imaging techniques are endorsed by some,[170] but can be nonspecific for infection versus normal postoperative inflammation.[168]

Treatment

The traditional treatment of infected ascending aortic grafts, originally described by Hargrove and Edmunds in 1984,[165] includes removal of the infected prosthetic material, aggressive tissue débridement, local irrigation, systemic antibiotic therapy, replacement of the infected conduit, and utilization of autologous tissue to surround the new conduit and obliterate dead space. Most surgeons prefer replacement of the infected graft with a cryopreserved homograft, as it may be more resistant to subsequent infection.[171–173] The ideal autogenous tissue filler is the greater omentum because of its physical properties and its proposed ability to help combat infection.[174] In some cases small pseudoaneurysms have been resected and the graft locally repaired,[168] although this is controversial. Mortality rates remain substantial despite these aggressive measures.[168]

CHAPTER 53

Aneurysms of the Aortic Arch

David Spielvogel • Manu N. Mathur • Randall B. Griepp

The unique considerations in approaching aortic arch (AA) surgery concern cerebral protection. The question of how best to protect the brain while providing surgical access to the cerebral vessels is still a subject of controversy and research. The issues of concern in brain protection involve both minimizing global ischemia during the mandatory arrest of the circulation during AA surgery and preventing embolization of air and atheromatous debris from the often very diseased arch during the repair. Thus, cerebral protection methods are a major focus of discussion in this chapter, which describes in considerable detail the history and rationale for the use of hypothermic circulatory arrest, selective antegrade perfusion, and retrograde cerebral perfusion for prevention of global ischemia. It also discusses use of axillary artery cannulation and of a branched graft technique to minimize possible embolic damage.

SURGICAL INDICATIONS

There are urgent and elective indications for AA surgery. Urgent indications include rupture of an atherosclerotic aneurysm, rupture of the false lumen of a type A aortic dissection, type A dissection with extensive intimal tears in the arch, and mycotic arch aneurysms. Elective indications include arch aneurysms greater than 6 cm, saccular aneurysms with rapid enlargement (>1 cm/y) or symptoms (pain or hoarseness). Smaller aneurysms of 5 cm should be considered for repair in patients with Marfan syndrome or a family history of rupture or dissection.

PREOPERATIVE EVALUATION

Medical history and routine laboratory studies are important in evaluating possible symptoms due to the aneurysm and identifying comorbidities in these often elderly patients. A family history of a ruptured aneurysm is not uncommon, and aids in the decision to recommend surgery.[1] Comorbidities may influence and alter the operative approach, allow anticipation and possibly prevention of intraoperative or postoperative complications, or may contraindicate operation altogether.

Evaluation of an AA aneurysm requires a contrast-enhanced computed tomographic (CT) scan of the entire aorta. With new multidetector CT scans, the entire aorta can be imaged rapidly with reduced contrast and three-dimensional reconstructions. However, with advances in magnetic resonance imaging (MRI), equally detailed images can be obtained, and MRI is becoming the preferred modality for imaging by some surgeons.[2] Disadvantages of MRI are the duration of the examination and the cost; however, in patients with renal dysfunction, MRI is preferable, as the contrast agents are not nephrotoxic. Angiograms are not routinely required to visualize the lesion. Usually coronary angiography is indicated and visualization of the brachiocephalic vessels can be done with very little additional risk.

Cardiac Status and Management of Coronary Artery Disease

All patients require a preoperative echocardiogram to assess left ventricular function (LVF) and to exclude significant valvular heart disease. In patients with aneurysms of the ascending aorta in whom a Bentall procedure may be required, coronary arteriography is carried out to delineate the anatomy of the proximal coronary arteries. All patients over the age of 40 require routine coronary arteriography. Younger patients with coronary risk factors such as abnormal electrocardiogram, history of angina or smoking, or strong family history should also undergo coronary angiography.

If significant coronary artery disease (CAD) is present, coronary artery bypass surgery (CABS) or angioplasty is considered. If amenable to angioplasty, this is done with bare-metal stents several weeks before aneurysm surgery to prevent

possible stent thrombosis, since thrombotic complications have been observed when surgery involving administration of heparin and protamine is carried out sooner after angioplasty[3] or with discontinuation of antiplatelet therapy for drug-eluting stents.[4] If the aneurysm can be resected by a median sternotomy, or if the coronary arteries that require bypass are easily accessible through a left thoracotomy, coronary artery bypass grafting (CABG) can be done at the time of aneurysm repair. If the aneurysm is very extensive, or if access to the relevant coronary arteries will be difficult through an incision that is optimal for aneurysm resection, CABS is undertaken in a separate procedure several weeks prior to aneurysm repair.

If severe respiratory dysfunction is suspected on the basis of pulmonary function tests, or if there is a history of limited exercise tolerance, pulmonary consultation is requested. Active pulmonary infection is treated prior to surgery. Patients are urged to stop smoking for at least a month before operation and may require pulmonary rehabilitation. Pulmonary dysfunction increases operative risk and prolongs recovery, but chronic lung disease is not necessarily a contraindication to surgery unless oxygen dependence or significant carbon dioxide retention are present.

Cerebral Vessels and Prevention of Stroke

A carotid and vertebral duplex ultrasound is requested if there is a history of transient ischemic attacks or strokes, or if carotid bruits are present. In patients identified as having an aberrant left vertebral artery exiting the arch directly, documentation of the size and patency of the right vertebral artery is essential to guide operative strategy in complete arch replacement. Since emboli are likely to arise from the diseased aorta in the presence of an arch aneurysm, a history of a focal cerebral insult is not a contraindication to surgery. In patients with such a history, a CT scan of the brain is carried out preoperatively; this enables detection of silent fresh cerebral infarcts, which necessitate postponement of surgery in most instances. The preoperative CT scan is also invaluable for identification of old and new lesions, and may be helpful in determining prognosis if focal neurologic symptoms occur postoperatively. Rather than attempt to identify those patients most at risk for intraoperative and postoperative cerebral embolization because of extensive friable atherosclerotic debris in the ascending aorta and arch, we assume that all patients with arch aneurysms have a very high risk of embolization and take all possible steps to minimize their occurrence. Reasonably accurate preoperative identification of those patients at highest risk is possible using transesophageal echocardiography (TEE), high-resolution CT angiography, and even better visualization of the ascending aorta and arch is possible using epiaortic ultrasound intraoperatively (12-MHz probe).[5–7]

Cannulation Sites

For arterial cannulation in the management of arch aneurysms, we use the right axillary artery almost exclusively.[8] The axillary artery is usually soft and rarely involved in the generalized atherosclerotic process or dissected in a type A dissection. Its use avoids retrograde perfusion through a diseased abdominal and descending thoracic aorta and hence retrograde embolization. Axillary cannulation reduces the turbulent flow patterns in the arch and intraluminal atherosclerotic debris associated with ascending aortic cannulation.[9–12] In aortic dissection surgery the risk of malperfusion is lower than with other cannulation techniques and its use has been associated with improved outcomes.[13,14] Another advantage of axillary artery cannulation is its usefulness for selective antegrade cerebral perfusion during arch reconstruction.

The femoral vessels are still commonly used for cannulation. However, these are often calcified and atherosclerotic, and associated with the inherent risk of local dissection, retrograde dissection, and cerebral embolization. Cannulation can also be carried out in the ascending aorta using intraoperative epiaortic ultrasound to select a site free of atheroma in a segment of aorta adjacent to or even included in the anticipated resection; the perfusion cannula can subsequently be moved to the graft during the procedure. Despite the accuracy of epiaortic ultrasound, we are still concerned about using the aorta as a cannulation site and prefer to use the right axillary artery. Our preference is direct axillary cannulation with a right angle wire-reinforced arterial cannula (Edwards Lifesciences, Irvine, CA). The cannula is inserted through a transverse arteriotomy. In a few patients the right arm is potentially ischemic, therefore the period of cannulation should be limited and the cannula removed and the artery repaired prior to protamine administration. Many surgeons prefer the side branch technique with an 8 or 10 mm graft attached to the artery with a 5-0 polypropylene suture through a longitudinal arteriotomy.[11] In patients with very small axillary arteries, transsecting the artery and sewing a 6 mm graft end to end, and then cannulating the graft with a smaller straight femoral arterial cannula works well, avoiding less desirable cannulation sites.

ANESTHESIA AND MONITORING

In general, anesthesia for repair of AA aneurysms is no different from that for conventional open heart surgery, which relies primarily on the use of high doses of narcotics. Routine hemodynamic monitoring includes a Swan-Ganz catheter, a jugular venous bulb catheter if possible, and left radial and femoral arterial catheters. Transesophageal echocardiography is used to monitor LVF and distention, to confirm adequate flow in the arch and arch vessels, and to guard against malperfusion. Although we do not rely on electroencephalographic (EEG) surveillance, it is still used by some surgeons to determine maximum cerebral metabolic suppression in conjunction with hypothermic circulatory arrest, and to assess adequacy of cerebral protection.

Cerebral oximetry confirms the adequacy of cerebral perfusion and oxygenation. The baseline and trend may be more important than the actual number when assessing cerebral blood flow. With individual catheters for selective cerebral perfusion, acute changes may indicate catheter migration

(into the right subclavian artery), catheter obstruction, or dislodgment.[15,16] Any asymmetrical decline should prompt a thorough assessment to determine sufficient cerebral flow. If unilateral selective cerebral perfusion from the right axillary is used for cerebral protection, cerebral oximetry of the contralateral hemisphere may indicate the need for an additional catheter in the left common carotid artery in patients without sufficient collaterals.[17,18] Cerebral oximetry may not detect cerebral embolic events.[19] Transcranial Doppler is more sensitive in detecting embolic events and confirming cerebral blood flow, but is more operator-dependent and may not be available in emergent situations (CPB).[20]

We no longer administer barbiturates because at the doses recommended to enhance cerebral protection, they significantly depress myocardial function, and also because there are conflicting laboratory data with regard to their effectiveness in the presence of hypothermia.[21] We give 2 g of methylprednisolone at the beginning of the case before the start of perfusion, where use of hypothermic circulatory arrest (HCA) is anticipated. If HCA exceeds 30 minutes, we continue to administer steroids for 48 hours postoperatively (125 mg every 6 hours for 24 hours, then 125 mg every 12 hours for 24 hours).

In patients in whom a thoracotomy is utilized, use of a double-lumen tube that permits selective ventilation of the right lung is helpful if substantial dissection and mobilization of the descending thoracic aorta is necessary before institution of cardiopulmonary bypass (CPB).

Perfusion

The routine perfusion protocol for intracardiac operations is also utilized for repair of arch aneurysms. When initiating cardiopulmonary bypass via the axillary artery, perfusion is begun, while slowly watching for retrograde dissection and adequacy of flow. Transesophageal echocardiography is helpful in cases of dissection to avoid malperfusion. With right axillary artery cannulation, the site of arterial perfusion is constant and allows retrograde flushing of the brachiocephalic vessels. For distal aortic arch reconstruction, a Y connector in the arterial line enables a second antegrade perfusion catheter to be used if needed. Distal arch descending aneurysms require transfer of the perfusion cannula from the femoral artery to the proximal graft following deep HCA.

Although some controversy exists about whether pH during cooling should be maintained according to alpha-stat or pH-stat principles, we continue to utilize values uncorrected for temperature, the alpha-stat approach. The continued use of alpha-stat management for selective cerebral perfusion in adult patients may be beneficial by preserving cerebral autoregulation, maintaining metabolic suppression, and reducing the risk of cerebral embolization.[22] In patients with previous strokes, experimental studies reveal the damaged brain's susceptibility to ischemia during selective cerebral perfusion.[23] The use of pH-stat management may be marginally beneficial in this subset of patients.[24] However, further studies are necessary.

Currently our technique for selective cerebral perfusion (SCP) is alpha-stat management, a perfusate temperature between 15 and 20°C, a hematocrit of 25 to 30%, and flows of 10 mL/kg/min with a mean arterial pressure (MAP) of 40 to 60 mm Hg. Overperfusion has been shown to be as detrimental as underperfusion in a canine model.[25]

We rely on a long duration of cooling, a low esophageal temperature, a high jugular venous oxygen saturation, and topical hypothermia to ensure adequate cerebral protection during HCA.

OPERATIVE TECHNIQUES

Incision

In >90% of AA cases, an extended median sternotomy is used. This incision gives access to the ascending aorta, the arch, and the proximal descending thoracic aorta as far as 5 cm beyond the origin of the left subclavian artery. The conventional median sternotomy is extended along the border of the sternocleidomastoid muscle on the left side of the neck. The strap muscles of the left side of the neck may be incised, and the innominate vein is mobilized and preserved but can be divided if necessary.

If the anticipated surgical procedure involves both intracardiac pathology and/or extensive resection of the ascending aorta and the arch, as well as resection of aorta beyond the proximal descending thoracic aorta, some surgeons advocate a thoracosternotomy or bilateral thoracotomy incision.[26–29] This incision is a bilateral anterior thoracotomy in the third or fourth intercostal space joined by dividing the sternum. It gives excellent exposure to the entire ascending aorta, arch, and most of the descending aorta. However, it may have a deleterious effect on pulmonary function, and puts both phrenic nerves at risk. We have preferred to carry out the repair in this situation in two stages using the elephant trunk approach,[30–32] and to reserve the thoracosternotomy incision for some reoperations and patients requiring emergent correction of simultaneous cardiac and aortic arch/descending aortic pathology. In patients with a lesion primarily in the descending aorta that extends no farther proximally than the distal arch, a left lateral thoracotomy in the fourth or fifth intercostal space is the incision of choice; this can be extended inferiorly across the costochondral site if necessary.

Cooling and Rewarming

We lower the perfusate temperature to 10°C, and monitor both bladder and esophageal (or tympanic) temperatures. After HCA, we utilize a period of hypothermic reperfusion, since our laboratory data have shown that this may be beneficial.[33] During rewarming, we never raise blood temperature above 37°C, and we avoid creating a gradient exceeding 10°C between blood and esophagus. Warming is discontinued when the patient reaches an esophageal (or tympanic) temperature higher than 35°C, and a bladder temperature of 30 to 32°C. We prefer the patient to rewarm gradually in the intensive care unit following closure.

Graft and Suture Materials

We use collagen-impregnated grafts. We excise the aneurysmal portion of the aorta completely and carry out a full-thickness anastomosis to the remaining normal aorta. We use Teflon felt on the outside of the aortic wall for reinforcement, and place the graft within the cuff of the aorta. Although some surgeons feel that reinforcing anastomoses with Teflon felt is not necessary, pseudoaneurysms are extremely rare with this technique.[34] Most anastomoses are carried out using 3-0 polypropylene, but 2-0 polypropylene is used for suturing one large graft to another because the lifetime integrity of a graft-to-graft anastomosis depends on the sutures.

Myocardial Protection

We use antegrade blood for cardioplegia if the coronary ostia are readily accessible, supplemented with retrograde perfusion. Otherwise, 60 mEq of potassium is infused into the pump over 1 to 2 minutes just prior to circulatory arrest; this effectively converts ventricular fibrillation to asystole. For the remainder of the procedure, we rely on total body hypothermia—supplemented with antegrade and retrograde blood cardioplegia and topical cooling—for myocardial protection.

Prevention of Paraplegia

Although the possible development of paraplegia is not a major concern with most operations involving the AA, it is a consideration with procedures involving the descending thoracic and thoracoabdominal aorta. In these patients, some protection of the spinal cord is afforded by the use of total body hypothermia, but additional safeguards are warranted including cerebrospinal fluid drainage and when indicated, distal perfusion. During operations for resection of the distal arch plus a significant portion of the descending aorta, we routinely monitor somatosensory evoked potentials (SSEPs). Motor evoked potentials (MEPs) have recently been introduced and may provide superior monitoring of anterior cord integrity.[35,36] Intercostal vessels are sacrificed gradually prior to institution of CPB: each vessel is clamped initially, and the vessel is sacrificed only if no changes in MEPs and SSEPs are seen for more than 10 minutes after their temporary occlusion.[37,38] MEP and SSEP monitoring is continued until the patient exits the operating room, confirming the return of signals and spinal cord integrity. Mean arterial pressure is maintained in the range of 80 to 100 mm Hg, or possibly a higher level determined by intraoperative evoked potential changes. Thereafter, function of the lower extremities is assessed clinically on an hourly basis, for a total of 72 hours of postoperative monitoring. If deterioration in motor function of the lower extremities is seen, blood pressure is increased, and intrathecal pressure is decreased by withdrawal of cerebrospinal fluid. These maneuvers to increase spinal cord perfusion pressure have proven successful in reversing the manifestations of late-onset paraparesis in the majority of our patients,[38] and also have been effective in the hands of others.[39–41]

Prevention of End-Organ Ischemia

End-organ complications are rare with our techniques due to the use of deep hypothermia. As antegrade selective cerebral perfusion has gained popularity, surgeons are performing arch surgery at moderate hypothermia (20 to 28°C). Caution needs to be taken at these temperatures, since end organs are more vulnerable to ischemia. In order to limit lower body ischemia, thoracoabdominal perfusion during antegrade cerebral perfusion has been recommended via the femoral artery while clamping the proximal descending aorta, or by antegrade perfusion through an endoluminal balloon cannula placed in the descending aorta or side-arm graft placed to the arch graft.[42,43]

Control of Hemorrhage

Most current aortic surgery is carried out using antifibrinolytic agents to inhibit bleeding. We routinely use epsilon-aminocaproic acid, but others have reported that tranexamic acid is as effective. Aprotinin remains controversial but its use is increasing. Some surgeons have observed an untoward incidence of renal dysfunction and intravascular thrombosis when using this protease inhibitor in conjunction with HCA,[44,45] but others feel that the drug is safe if adequate doses of heparin are used concurrently. The demonstration of benefit associated with use of aprotinin with HCA has not been consistent.[46,47] Severe allergic reactions to aprotinin have been reported.[48] In simple cases involving only a short interval of hypothermia, such as ascending aortic and hemiarch replacement, blood and clotting factors are usually not required. If an interval of HCA longer than 30 minutes or duration of perfusion exceeding 3 hours is anticipated, 2 to 4 units of fresh frozen plasma and 5 to 10 units of platelets are brought to the operating room at the end of perfusion. These are infused if any question arises concerning the adequacy of hemostasis after protamine is given. Rarely in reoperative aortic surgery, acute dissections, and in patients with preoperative coagulopathy is mediastinal packing required to control bleeding. Alternatively, a Cabrol fistula is created in the superior mediastinum to shunt shed blood into the right atrium.[49] If this fails activated recombinant factor VIIa is indicated as rescue therapy for patients with refractory nonsurgical postoperative hemorrhage.[50,51]

Use of Glue

European surgeons have enthusiastically used gelatin resorcinol formaldehyde (GRF) and other biological glues, predominantly in strengthening aortic tissue after aortic dissection. Excellent results have been reported with the use of these glues in acute type A dissection.[52] Recently, however, there has been concern that the formaldehyde component of the GRF glue may be toxic to the aortic media and cause tissue necrosis, leading to late redissection and pseudoaneurysm formation.[53,54] We have not found GRF glue to be necessary. Due to the concerns about GRF glue, Bioglue (CryoLife, Inc., Kennesaw, GA) composed of bovine serum

albumin and glutaraldehyde gained popularity as an agent to strengthen friable tissues, particularly in acute aortic dissection.[55] It has been widely used as a sealant along suture lines. Recent evidence suggests that it should be used with caution, as it has been shown to leak through needle holes and embolize. Equally worrisome are the reports of localized tissue toxicity.[56–59] In most scenarios we find glues unnecessary.

Treatment of Infected Grafts and Mycotic Aneurysms

In patients in whom a previously inserted graft has become infected, or if a mycotic aneurysm is suspected, our initial strategy is to treat the patient for several days with specific intravenous antibiotics when the organism is known, and with broad-spectrum antibiotics otherwise. At the time of surgery, the entire infected aneurysm or graft is removed and replaced with a new graft. Often the organism causing the infection can be cultured from the resected specimen. Intravenous antibiotics are continued for at least 6 weeks, and if a suitable agent can be found, oral antibiotic therapy is instituted for an additional 3 to 6 months. In cases of a frankly purulent operating field, the chest may be left open, mediastinal washout occurs within 24 to 48 hours, and then pectoralis major or omentum may be brought into the wound and wrapped around the implanted prosthetic graft. A vacuum-assisted closure dressing is applied and the mediastinum closed when signs of sepsis have resolved. Others report the successful use of cryopreserved homografts in this setting.[26,27] C-reactive protein is a useful biochemical marker to help guide the length of antibiotic therapy and determine resolution of inflammation.[60–62]

CEREBRAL PROTECTION TECHNIQUES

Hypothermic Circulatory Arrest

Historical and theoretical considerations

Hypothermic circulatory arrest was first introduced in the early days of open heart surgery as an alternative to extracorporeal circulation. In the 1960s, isolated case reports described the use of HCA in repair of AA aneurysms.[63,64] The merit of HCA as a technique for correction of complex congenital heart lesions in infants was advocated by Barrat-Boyes and associates.[65] This prompted renewed interest in its use in adults with aneurysms of the AA. The first series of such cases was reported by Griepp and colleagues.[66]

Since that time, the efficacy of HCA in protecting the brain in adults with aortic aneurysms has been widely accepted. However, increasing utilization of HCA also revealed some of its limitations and raised concerns about its safety, especially when longer durations are required. A combination of hypothermia and circulatory arrest with selective antegrade cerebral perfusion may allow one to take optimal advantage of the benefits of both cerebral protection strategies.

The basis for the initial enthusiasm for the use of hypothermia to protect the brain during circulatory arrest was a series of investigations in adult dogs that documented profound inhibition of cerebral metabolism with lowering of brain temperature.[67] Using a ratio of normothermic metabolic rate and hypothermic metabolic rate at various temperatures, Michenfelder and Milde postulated that complete arrest of the cerebral circulation for as long as 30 minutes at 18°C would not result in any permanent neurologic injury, and in subsequent experiments they provided evidence indicating that periods of HCA as long as 60 minutes should be safe.[68]

Subsequent laboratory investigations in puppies[69] and piglets,[70] however, showed that suppression of cerebral metabolic function by hypothermia is less complete than that predicted by the formula proposed by Michenfelder. In puppies, cerebral metabolic rate is reduced only to 40% of control levels at 18°C, and HCA for 60 minutes at 18°C results in detectable early behavioral dysfunction following surgery and in quantitative EEG changes.[69,71] More prolonged HCA at 20°C in young piglets produces unequivocal behavioral sequelae as well as histologic evidence of cerebral damage.[72] HCA for even short intervals is followed by severe cerebral vasoconstriction that may last for hours. During this period, normal levels of cerebral metabolism are maintained by means of increased oxygen extraction, and the animals are vulnerable to hypoxic insults.[71,73–75] A period of cold reperfusion has been shown to reduce intracranial pressure during the recovery phase following HCA.[33] In this and other experimental studies, high intracranial pressure correlates with delayed neurologic recovery and subsequent cerebral histopathologic abnormalities. Oxygen saturation data also imply that cerebral blood flow several hours postoperatively is better following cold reperfusion, suggesting improved recovery from HCA.

In a review of 200 adults who underwent HCA during operations on the thoracic aorta, our group found that 19% of the patients had temporary neurologic dysfunction (TND) postoperatively, with varying degrees of obtundation, confusion, agitation, or transient parkinsonism. Occurrence of these symptoms correlated significantly with age and duration of HCA; the interval of HCA averaged 47 minutes in patients with symptoms of TND, and was 33 minutes in those without symptoms. Duration of HCA did not correlate with mortality or with permanent neurologic injury, which was usually focal, and was significantly more frequent in older patients and in those with obvious atheromatous debris in the arch or descending aorta at the time of operation.

More sensitive neuropsychologic testing after deep hypothermic circulatory arrest showed that HCA duration of more than 25 minutes and advanced age were significant predictors of poor performance in examinations of memory and fine motor function.[76] Impairment of memory function may be related to injury of the hippocampus, which is particularly sensitive to ischemic injury because of its high metabolic rate.[77] Patients with impaired neurocognitive function several weeks postoperatively were significantly more likely to have manifested TND immediately postoperatively.

Therefore, TND is a reflection of subtle brain injury, possibly as a result of inadequate cerebral protection. Based on these findings, a duration of circulatory arrest exceeding 25 minutes must be considered a risk factor for long-term albeit subtle deficits in cognitive function.

Past projections of the theoretical safe duration of circulatory arrest based on rates of oxygen consumption at various brain temperatures are now considered to have been misleading. McCullough and associates[78] recalculated Q_{10} for the adult human brain based on direct measurements of cerebral metabolic rate for oxygen ($CMRO_2$) during HCA. Q_{10} describes the temperature-dependent decrease in cerebral metabolism. The Q_{10} for $CMRO_2$ is defined as the ratio of two $CMRO_2$ measurements differing by 10°C. These data predict that the safe period of arrest at 15°C is about 30 minutes, and that at 10°C it is 40 minutes. Beyond this limit, cerebral cellular anoxia occurs. These observations support the use of truly profound hypothermia before a period of circulatory arrest to achieve maximum cerebral metabolic suppression, particularly if arrest time will exceed 30 minutes. Intracranial temperatures should be protected from rising during HCA by packing the head in ice.[72,73,79,80]

Use of corticosteroids

High-dose methylprednisolone given at 2 and 8 hours before CPB reduces the change in cerebrovascular resistance and improves cerebral blood flow, cerebral arteriovenous oxygen difference, and oxygen metabolism following deep hypothermic circulatory arrest, and may serve as a neuroprotective agent.[81] Additionally, in 4-week-old piglets, pretreatment with corticosteroids 4 hours prior to CPB—compared to steroids in the CPB prime—reduced total body edema and cerebral vascular leakage, with improved immunohistochemical indices of neuroprotection.[82] The beneficial effect of corticosteroid pretreatment requires alterations in de novo protein synthesis at the level of the mRNA,[83] and inhibition of adhesion molecule expression in the endothelial cells, which impacts on the trafficking of leukocytes into the injured areas.[84] Other benefits of methylprednisolone given 8 hours prior to CPB and HCA were improved pulmonary compliance and alveolar-arterial gradient, and decreased pulmonary vascular resistance.[85] Consistently, benefits are more apparent when steroids are given several hours prior to the institution of CPB; this has influenced our current practice.

Clinical implementation

In patients with AA aneurysms, we no longer utilize EEG or auditory or sensory evoked potentials to guide the efficacy of cerebral cooling. Based on laboratory studies, we prefer to cool with the perfusate lowered to 10°C to an esophageal temperature of 13 to 15°C for a minimum of 30 to 40 minutes. The head is packed in ice to prevent rewarming during the period of circulatory arrest. Animal studies continue to support this practice.[72,73,79,80] We use jugular venous saturations (>95%) to indicate adequate cerebral cooling and maximal metabolic suppression, since continuing oxygen extraction is an accurate reflection of significant ongoing cerebral metabolic activity. An association between low preoperative cerebral venous saturation and poor recovery of cerebral function following circulatory arrest was noted in some of our experimental animals[69] and also has been observed clinically by others.[86]

Careful rewarming following HCA, maintaining a gradient of no more than 10°C, reduces the likelihood that oxygen demand will exceed oxygen supply during the interval of inappropriate cerebral vasoconstriction following HCA.[71,73–75,87] Avoidance of high perfusate temperatures is essential.[88] Careful hemostasis and maintenance of normal hemodynamics during the postbypass period are also important, since the vulnerable period of cerebral recovery during which increased oxygen extraction is relied upon to support adequate cerebral metabolism may extend up to 8 hours postoperatively.

Based on careful laboratory studies and clinical review, optimal cerebral protection and minimizing embolization may best be achieved by liberal use of axillary cannulation; avoiding manipulation of atherosclerotic vessels before HCA; using the above-mentioned safeguards during institution of HCA and rewarming; restricting HCA to less than 25 minutes; and, when more complex arch repairs are required, using hypothermic antegrade SCP.[89,90] Use of SCP has been demonstrated to reduce temporary neurologic dysfunction associated with prolonged periods of HCA.[91]

Selective Cerebral Perfusion

Historical and theoretical considerations

The earliest attempts to repair aneurysms of the AA were carried out by DeBakey and associates[92] using normothermic cerebral perfusion involving several pumps and cannulation of both subclavian and both carotid arteries. The problems associated with controlling pressure and flow in these separate vascular beds to ensure relatively uniform perfusion, as well as the poor outcome of the patient led to early abandonment of this technique. Interest waned, but the technique was revisited by several surgeons in the late 1980s, spurred by the realization that HCA may not be safe for the long durations required for repair of more complex and extensive aneurysms. It was recognized that combining selective cerebral perfusion with hypothermia allowed use of much lower flow rates, and that hypothermic SCP afforded better cerebral protection from global ischemia than HCA alone or HCA and retrograde cerebral perfusion.[93–95]

The resurgence of interest in selective hypothermic cerebral perfusion was pioneered by several surgeons. Bachet's group fashioned the term "cold cerebroplegia" to describe perfusion of the innominate and left carotid arteries with blood between 6 and 12°C (flow 250 to 350 mL/min) in 54 patients with arch aneurysms. Mortality was 3%, and only one episode of severe neurologic injury occurred, with a 4% incidence of transient focal lesions.[96] Matsuda and colleagues[97] operated on 34 patients with AA aneurysms using SCP at 16 to 20°C, with a mortality of 9%, a 3% incidence of stroke, and a TND incidence of 5%. His technique

required cannulation of the brachiocephalic and left carotid arteries with a two-pump system, and bilateral temporal artery and continuous internal jugular venous saturation monitoring. The authors pointed out that hypothermic cardiopulmonary bypass may not carry a higher risk of coagulopathy. Kazui and coworkers[98,99] have since championed this technique, first describing its use in 1986. Between 1990 and 1999, 220 patients underwent total arch replacement with SCP and open distal anastomosis, with an in-hospital mortality of 12.7% and permanent neurologic dysfunction of 3.3%. Multivariate analysis showed in-hospital mortality was determined by renal failure, long CPB time, and shock, and permanent neurologic deficit was associated with old cerebrovascular accident and long CPB duration. Kazui and colleagues, perfusing two arteries with flows of 10 mL/kg/min at 22°C—considered 50% of physiologic levels based on experimental studies—found that selective cerebral perfusion time had no significant impact on outcome.[100] In a multicenter study Di Eusanio and colleagues definitively demonstrated the efficacy of selective antegrade cerebral perfusion (with 15F retrograde coronary sinus perfusion cannulas) in reducing temporary and permanent neurologic dysfunction. In 588 patients undergoing both partial and full AA replacement, the risk of permanent and temporary neurological injury was 3.8 and 5.6%, respectively. Overall mortality was 8.7%.[101]

The presence of clot or atheroma in the aorta is a determinant of stroke during operation for aneurysm of the AA. Atherosclerotic lesions often develop at the origin of the brachiocephalic vessels. Complete resection and branch grafting should reduce the rate of neurologic injury. In Dr. Kazui's latest 50 patients with atherosclerotic AA aneurysms,[102] the mortality was 2%, permanent neurologic injury 4%, and TND occurred in 4% (adverse outcome 6%), with a history of cerebrovascular disease a risk factor for permanent neurologic dysfunction. The Kazui technique (Fig. 53-1) and sequence of reconstruction are as follows: systemic cooling of the patient to 22°C is followed by circulatory arrest and SCP to 22°C via two malleable cannulas (Fuji System, Tokyo, Japan), one in the innominate and one in the left common carotid artery. The left subclavian artery is clamped, distal anastomosis to the

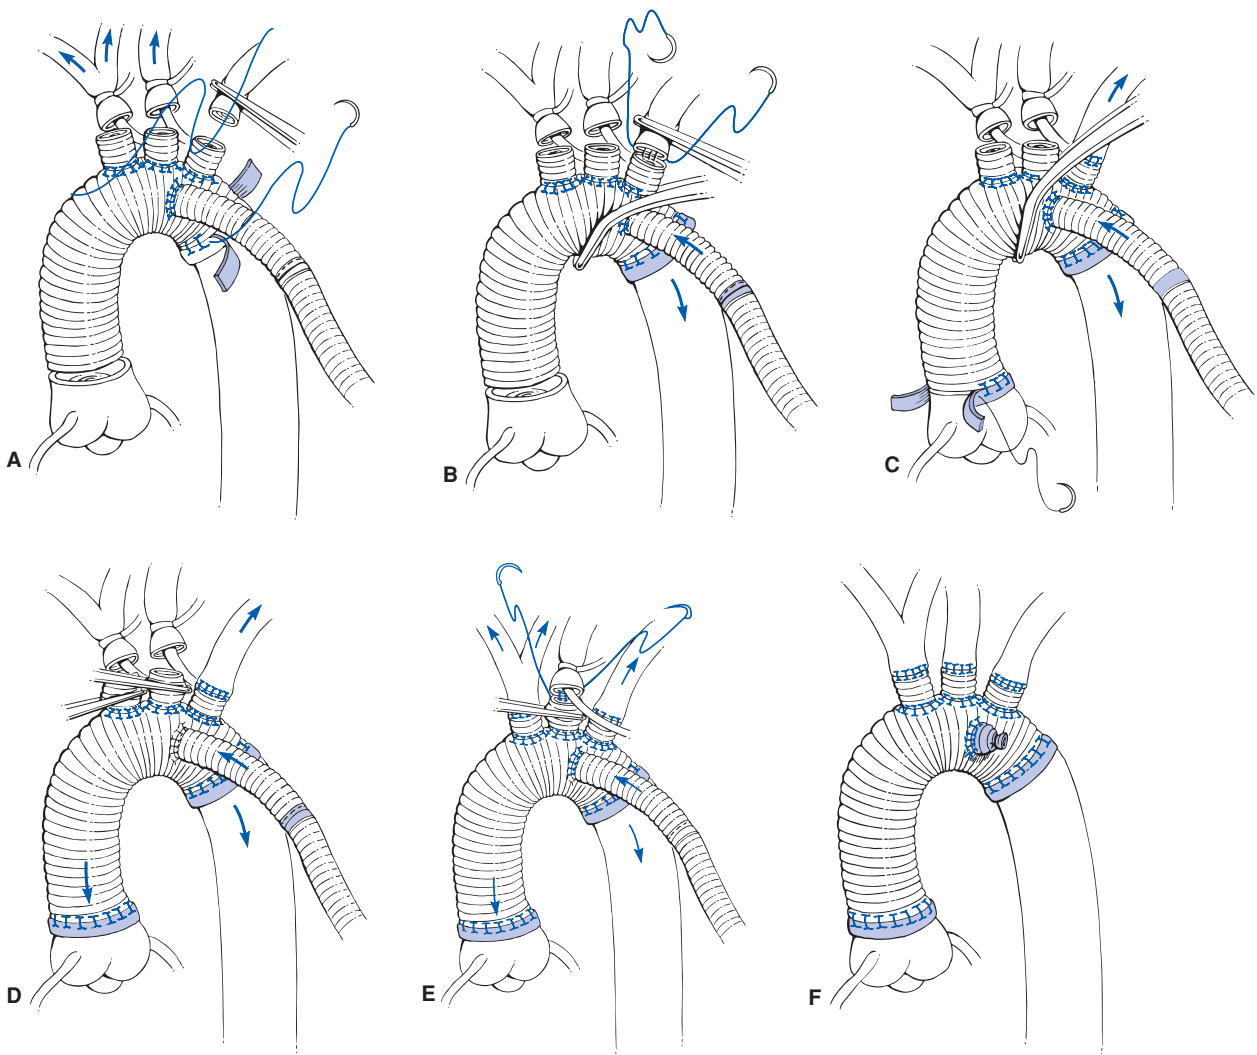

Figure 53-1. (A through F) Dr. Kazui's technique for total arch replacement with a four-branch graft.

descending aorta is performed, and lower body perfusion is achieved via the fourth side arm of the four-branch graft. Left subclavian anastomosis is followed by perfusion, measurement, and construction of the proximal anastomosis, and then the innominate artery and left common carotid artery anastomoses, with full perfusion restored. Permanent neurologic injury is again an independent risk factor for in-hospital mortality. This technique allows one to perform the transsection of the brachiocephalic vessels distal to their origins and free of macroscopic atherosclerotic disease to avoid dislodgment and embolization of debris. Newly designed malleable cannulas allow superior visibility and simultaneous pressure monitoring (personal communication).

Jacobs and associates[103] performed 50 arch replacements with selective antegrade cerebral perfusion and moderate hypothermia to 28 to 30°C. EEG monitoring guided reconstruction techniques, pump flows, and perfusion pressures. Overall adverse outcome was 6%, TND rate 4%, and pulmonary complications occurred in 25%. Antegrade cerebral perfusion time ranged from 75 to 235 minutes, with a mean of 165 minutes. No correlation between long SCP duration and neurologic injury was noted.

In patients with extensive aneurysmal disease involving the ascending aorta, arch, and varying amounts of the descending thoracic aorta, a single-stage reconstruction can be performed with the "arch first" technique via bilateral anterior thoracotomies as described by Rokkas and Kouchoukos.[26] This technique employs an interval of HCA followed by SCP of the upper body while the aortic reconstruction is completed. The use of brachiocephalic artery perfusion allows unhurried completion of AA repairs. In the recent series of 46 patients, the hospital mortality was 6.5% but no patient sustained a permanent neurologic event. Transient neurologic dysfunction occurred in 13% of patients.[28] Currently, the interval of deep HCA is shortened further with unilateral cerebral perfusion from the right axillary artery and individual branch grafting of the brachiocephalic vessels. The mean circulatory arrest time was 8.8 minutes in the initial 12 patients.[29]

Using right brachial cannulation for unilateral SCP, Kucuker and associates[104] reported a permanent stroke rate of 2.2% for 181 patients undergoing ascending and hemiarch replacement (90 patients) or total arch replacement (91 patients). No mention of temporary neurologic dysfunction was made. The patients were cooled to 26°C, and when flow was decreased to 500 to 600 mL/min (8 to 10 mL/kg/min) the innominate, left common carotid, and occasionally the left subclavian artery were clamped. Arch replacement was performed under continued low-flow perfusion. Mean SCP time was 36 ± 27 minutes (range 17 to 80 minutes). Hospital mortality occurred in 12 patients (6.6%) with five deaths in acute dissections. To ensure contralateral cerebral flow, transcranial Doppler allowed continuous noninvasive monitoring of the middle cerebral artery. In the rare case of inadequate left hemispheric perfusion an additional catheter can be placed into the left common carotid artery.[16,18] This was unnecessary in this series of patients. A separate cohort of patients undergoing neurocognitive testing revealed no postoperative deficits.[105] Still, a certain level of caution related to left hemispheric ischemia is prudent based on anatomic studies. Merkkola and colleagues found 14% of autopsy specimens with insufficient collateral circulation of at least 0.5 mm in the circle of Willis[105a]. These findings confirm the continued necessity for hypothermic perfusion. The preceding paragraphs have indicated that there is no consensus regarding the optimal temperature to implement selective cerebral perfusion. Our laboratory studies suggest that SCP at 10 to 15°C after deep HCA provides better global cerebral protection and thus we use SCP at about 15°C.[106]

Clinical implementation

In our current era of AA reconstruction, cerebral injury is most often related to the risk of embolization.[107–109] With liberal use of direct axillary artery cannulation,[110] HCA, and grafting to individual brachiocephalic vessels,[29,102,111,112] followed by SCP, lengthy periods of circulatory arrest are no longer necessary. Laboratory studies have shown that a short period of deep HCA to reduce the risk of embolization will not compromise the superior cerebral protection provided by SCP.[113] Diseased origins of the brachiocephalic vessels in the arch are avoided, and the arch repair can proceed in an unhurried fashion.

Our approach is as follows: After cooling, and during a brief period of HCA, the individual brachiocephalic arteries are dissected free and anastomosed to a ready-made trifurcated graft (Hemashield, Boston Scientific, Natick, MA), beginning either with the left subclavian or the innominate artery. The trifurcated graft is clamped, and perfusion selectively restored to the upper body. Occasionally, when the left subclavian artery is displaced lateral and cephalad, a preoperative left subclavian to left carotid bypass is performed. A bifurcated graft is sewn to the left common carotid and innominate arteries (Fig. 53-2). Typically, flows between 600 and 1000 mL/min are required to maintain a mean pressure of 40 to 60 mm Hg, while allowing the perfusate temperature to drift upward. At the end of the arch reconstruction, the branch graft is sewn to the ascending aortic graft without interrupting flow.

Retrograde Cerebral Perfusion

The limitations of HCA, the success of retrograde cardioplegia, and isolated encouraging reports of the possible efficacy of retrograde cerebral perfusion (RCP) in mitigating the effects of massive air embolism[114] contributed to widespread interest in and enthusiasm for RCP in the early 1990s.[115] The mechanisms whereby RCP may accomplish neuroprotection include: (1) flushing embolic material from the cerebral circulation,[116] (2) providing cerebral flow sufficient to support cerebral metabolism,[117] and (3) maintaining cerebral hypothermia.[118] There is, however, evidence that RCP may worsen neurologic outcome by inducing cerebral edema.

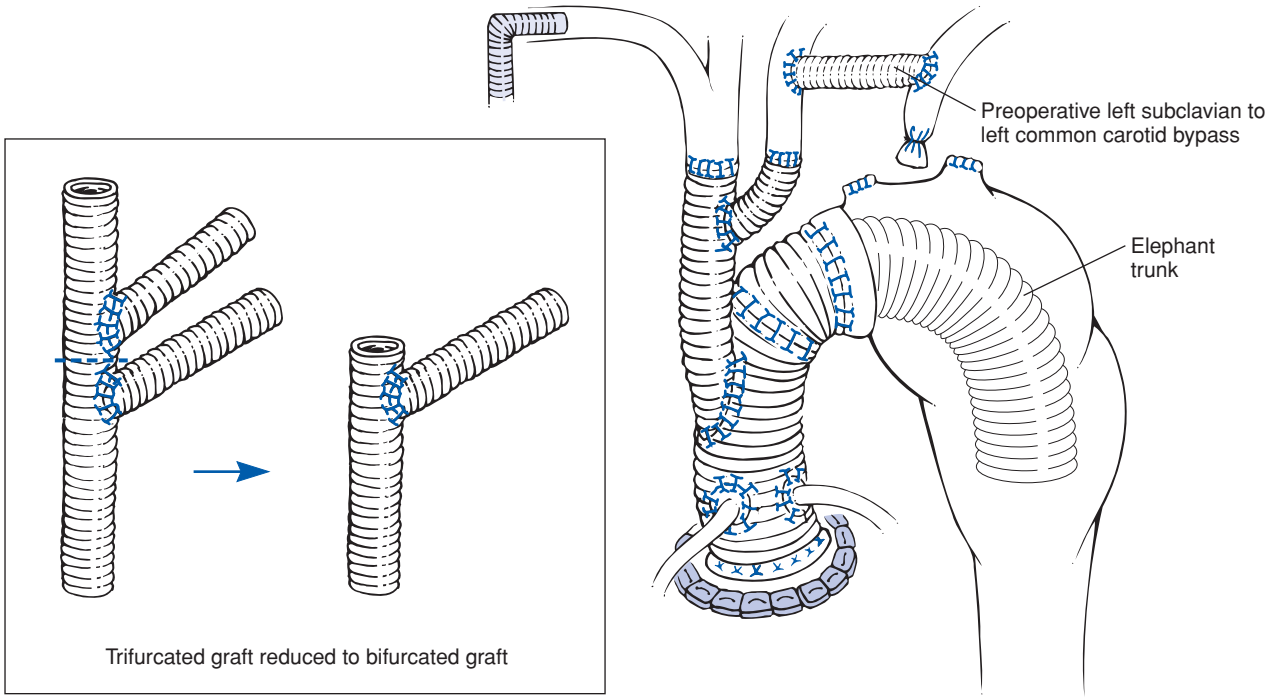

Figure 53-2. A preoperative left subclavian artery to left common carotid artery bypass is done when the left subclavian artery is markedly displaced laterally and cephalad.

Initial laboratory results and clinical reports regarding RCP were encouraging. However, upon closer examination, many of the studies that reported improved outcomes with RCP used historical controls and short durations of RCP that are well within the limits defined as safe for HCA alone. There were also some disturbing studies, using various techniques in several different animal species, reporting that no flow to the brain during RCP could be demonstrated.[119,120] In other experimental studies, the most effective conditions for retrograde flow were under circumstances—including clamping of the inferior vena cava and use of high perfusion pressures—that resulted in disturbingly high rates of fluid sequestration, significant cerebral edema, and mild cerebral histopathology; these sequelae were seen even after relatively short intervals of RCP.[116] Studies in our laboratory in which cerebral blood flow was quantitated not only by collecting AA return, but also by counting the number of microspheres trapped in the brain, have demonstrated conclusively that too little capillary flow occurs during RCP (even with occlusion of the inferior vena cava) to confer any meaningful metabolic benefit, even during deep hypothermia.[121] Other laboratory studies using intravital microscopy to directly visualize the cerebral capillary blood flow concluded that RCP does not provide adequate cerebral capillary blood flow to prevent ischemia, but may induce brain edema.[122] A recent animal study showed that intermittent pressure augmentation during moderate hypothermic RCP efficiently dilated the cerebral vessels, allowing an adequate blood supply without injury to the brain, providing similar neuroprotection as antegrade SCP.[123]

The relationship between the use of RCP and mortality rates is unclear. In some studies, RCP duration was not found to be a predictor of death,[124–126] whereas in others it was.[115,127] Clinical outcome studies comparing RCP and HCA have also yielded mixed results, with some having mortality rates comparable to those with use of other cerebral protection methods,[115,128,129] and others reporting reduced mortality rates with RCP.[130–132] In three studies that included SCP patients, RCP patients had similar mortality rates.[133–135]

The literature examining the relationship between RCP and neurologic morbidity is also mixed. In some series, RCP duration was not found to be a predictor of neurologic morbidity,[125,126] whereas in others it was.[115,127] RCP has been found to be associated with neurologic morbidity rates that are either similar to those associated with HCA,[129,136] or lower.[128,130–132,137] When patients with SCP were included, RCP patients had similar outcomes in three studies[133–135] and worse outcome in one.[137]

In our own earlier[138] and more recent[139] clinical studies, we have been unable to demonstrate any benefit of RCP in our patients. Experimental data from our laboratory suggest that RCP, especially at high pressures, although successful in removing some emboli, may aggravate cerebral injury.[116] In our recent clinical study,[139] we were unable to demonstrate a decrease in the incidence of stroke with RCP. This may be explained by a greater prevalence of patients

with clot or atheroma in the RCP group, but it nevertheless is also possible that RCP may not be effective in preventing stroke. Mortality was higher in the RCP group, and temporary neurologic dysfunction was higher with RCP than with SCP. Furthermore, RCP resulted in no reduction of transient neurologic dysfunction compared with HCA alone,[139] reinforcing the notion that RCP probably has no nutritive value for brain tissue. The induction of cerebral edema documented in our animal studies of RCP[116] cannot easily be demonstrated in the clinical situation, but may be another reason for our repeated observation of delayed neurologic recovery postoperatively in patients treated with RCP. Recently, we studied neuropsychologic dysfunction after RCP; we found that RCP was of no benefit, and probably had a negative impact on cognitive outcome.[140] Other investigators believe that neurocognitive outcome depends on the duration of RCP, and if RCP is less than 60 minutes, it is comparable with outcomes of patients undergoing CABG, whereas prolonged RCP >60 minutes is associated with neurocognitive impairment.[141]

We believe that the major benefit of RCP is in providing continued cerebral cooling by venoarterial and venovenous anastomoses during arrest of antegrade circulation, which helps to protect the brain, especially in those patients in whom systemic cooling is not as thorough and prolonged as it should be. We continue to believe that a major benefit of RCP in the studies of others—usually with a historical control group and with a duration of RCP short enough that good results would be anticipated with use of HCA alone—can be explained largely by the enhanced cooling brought about by continuous bathing of the brain with cold blood during RCP. The effective cooling achieved during RCP may make a difference, especially if the initial cooling interval is short and the head is not packed in ice. Several experimental studies reinforce this view.[118] We no longer routinely use RCP. We believe that an upward drift in temperature during HCA can more safely be prevented by thorough initial cooling and packing the head in ice.

Clinical implementation

Although we do not routinely use RCP for cerebral protection, many surgeons do occasionally use a short period of retrograde perfusion in patients who have a high risk of embolization because of clot or atheroma in the aorta, recognized either preoperatively or intraoperatively. Clinicians apply RCP very briefly at the end of a period of HCA solely for the purpose of flushing out potentially embolic debris.

Retrograde perfusion is always employed in conjunction with profound systemic hypothermia. To initiate retrograde perfusion, blood is infused into either one or both venae cavae at a flow rate to maintain the superior vena cava pressure between 15 and 20 mm Hg. Given the rich network of collaterals between the superior vena cava and inferior vena cava, it probably makes no difference whether inflow is into the superior vena cava, into the inferior vena cava, or into both venae cavae. Cardiac distention is avoided by choking both venae cavae. When whole-body retrograde perfusion is carried out in this fashion, the initial flow rate is usually 800 to 1000 mL/min, but once the venous capacitance vessels have been filled, a flow of 100 to 500 mL/min is usually sufficient to maintain superior vena cava pressure at 15 to 20 mm Hg.

REPRESENTATIVE PROCEDURES

Aortic arch reconstruction requires different approaches, techniques, and operative strategies, depending on the arch pathology and the involvement of the aorta proximal and distal to the arch. Thus, we describe seven different situations and our approach to reconstruction of the arch in each of these.

Case 1: Bentall Procedure and Hemiarch Replacement

The patient has Marfan syndrome and an aortic root aneurysm associated with severe aortic regurgitation and a dilated ascending aorta and proximal arch (Fig. 53-3).

A median sternotomy is performed. Cardiopulmonary bypass is initiated via the right axillary artery and a two-stage right atrial cannula. Cooling is begun, and when the heart fibrillates, a ventricular vent is placed via the right superior pulmonary veins. The ascending aorta is cross-clamped and opened. Cardioplegia is infused into both coronary ostia, and this is supplemented with topical cooling and retrograde blood cardioplegia. Perfusate temperature is maintained at 10°C until the esophageal temperature reaches 20°C, and is maintained at that level while the Bentall procedure is being performed. After aortic valve removal, a composite prosthesis is sutured to the aortic annulus utilizing interrupted pledgeted sutures. Coronary buttons 1 to 1.5 cm in diameter are fashioned. The remainder of the aorta proximal to the clamp is excised. The coronary buttons are mobilized. A corresponding opening is made in the posterior aspect of the graft with ophthalmic electrocautery and the left coronary button is anastomosed to the graft with 4-0 polypropylene. A thin strip of Teflon felt buttressing is used to reinforce the button. As the coronary button anastomosis is being carried out, jugular venous samples are drawn every 5 minutes and the perfusate temperature is lowered to 10°C.

When the jugular oxygen saturation is above 95% and the esophageal temperature is between 13 and 15°C, the head is placed downward after being packed in ice, perfusion is discontinued, and the cross-clamp is removed. The distal ascending aorta and proximal arch are mobilized and excised, leaving a beveled aortic cuff extending from the base of the innominate artery on the right to 1 cm proximal to the ligamentum arteriosum and the recurrent laryngeal nerve on the left. The composite Dacron graft is beveled and anastomosed to the aorta with a continuous 3-0 polypropylene suture (Fig. 53-3B). Care is taken to place a 1 cm cuff of Teflon felt outside the aorta and to invaginate the graft

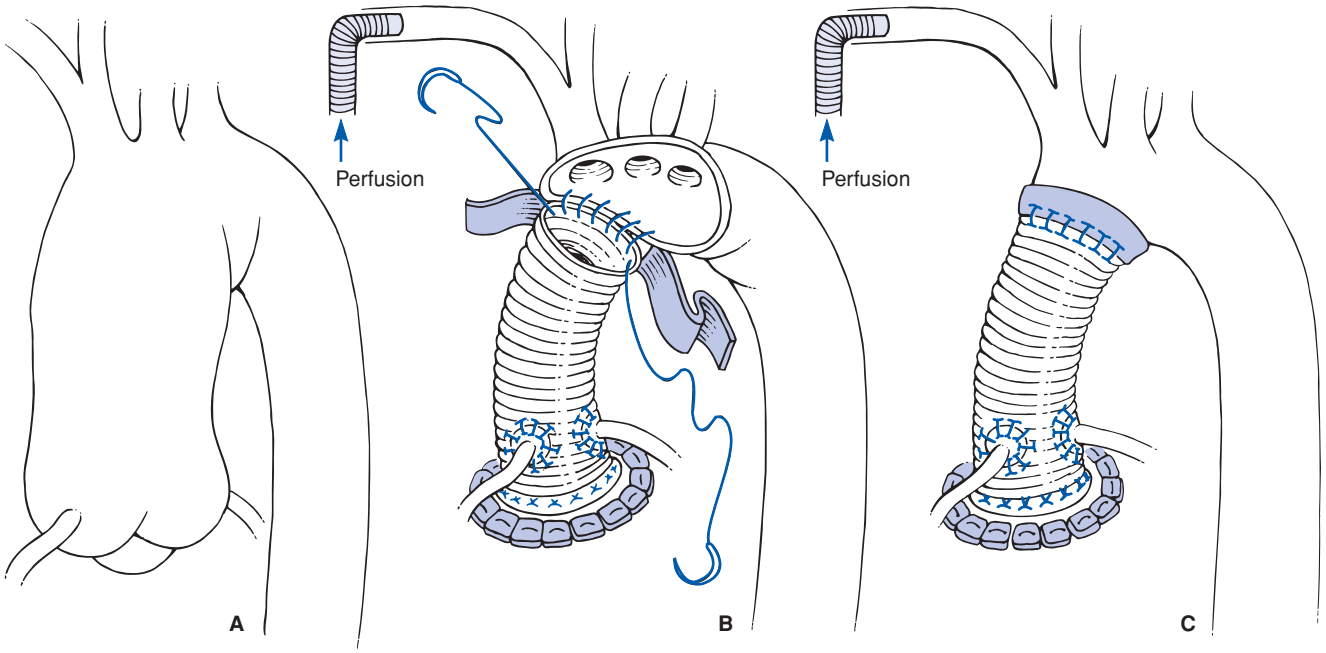

Figure 53-3. (A) Ascending aortic aneurysm extending into the underside of the aortic arch. (B) Bentall reconstruction of the aortic root with open resection of the hemiarch. Perfusion is via the right axillary artery. (C) Completed repair and full systemic perfusion.

within the aorta. The last few loops of the suture line are left loose; the head is placed in steep Trendelenburg position, and perfusion through the axillary artery cannula is restarted at a rate of 500 mL/min to flush all air from the aorta. Once all the air is evacuated, the suture line is tied and cold perfusion is commenced for several minutes, followed by rewarming (Fig. 53-3C). The location for implantation of the right coronary button is marked. The distal ascending aortic graft is cross-clamped and a separate opening is made in the anterior aspect of the graft. The right coronary artery button is reimplanted with running 5-0 polypropylene reinforced with a thin strip of Teflon felt. Prior to tightening the suture line the heart is de-aired. The cross-clamp is removed. A gradient of 10°C or less between the perfusate temperature and esophageal temperature is maintained at all times. Circulatory arrest time is usually less than 20 minutes. Approximately 50 to 60 minutes of warming is necessary to raise the esophageal temperature to 35°C and the bladder temperature to 30 to 32°C; at this time, the patient is weaned from cardiopulmonary bypass.

Case 2: Total Arch Replacement for Nonatherosclerotic Pathology

The patient is a young male with an acute type A aortic dissection referred for emergency surgery. In the past, the operation we describe here has been our standard operation for total arch replacement.[142,143] We now use this technique in rare cases in which the arch is free of atherosclerotic debris, and where an unexpected finding such as an arch tear in aortic dissection requires total arch replacement.

Intraoperative TEE confirms a type A dissection involving the ascending aorta, arch, and descending aorta (Fig. 53-4). However, the location of the intimal tear is not clearly visualized. Flow is present in both the true and false lumens, and there is minimal aortic regurgitation (AR) and no pericardial blood or tamponade.

The right axillary artery is prepared for cannulation. A median sternotomy is performed. Cannulation is carried out via the right axillary artery and the right atrium. Cardiopulmonary bypass with cooling is commenced. When the heart fibrillates, a left ventricular vent is placed via the right superior pulmonary vein. The aorta is cross-clamped and the proximal aorta is opened. Cardioplegia is infused into both coronary ostia and this is supplemented with topical cooling. Careful inspection of the ascending aorta reveals no intimal tear. Perfusate temperature is maintained at 10°C until the esophageal temperature reaches 20°C, and this temperature is maintained while the proximal aortic reconstruction is performed.

The minimal AR is dealt with by resuspending each commissure with pledgeted horizontal mattress sutures. The root is reconstructed by using a 4-0 polypropylene weave to suture a Teflon strip on the outside and a pericardial strip on the inside of the dissected aortic layer. A Dacron graft is anastomosed with 3-0 polypropylene to invaginate the graft within the aortic sandwich. During aortic reconstruction, cooling is continued, and when the esophageal temperature reaches 13 to 15°C, and the jugular venous oxygen saturation is above 95%, the head is placed downward after being packed in ice, perfusion is discontinued, and the cross-clamp is removed. The aorta is opened

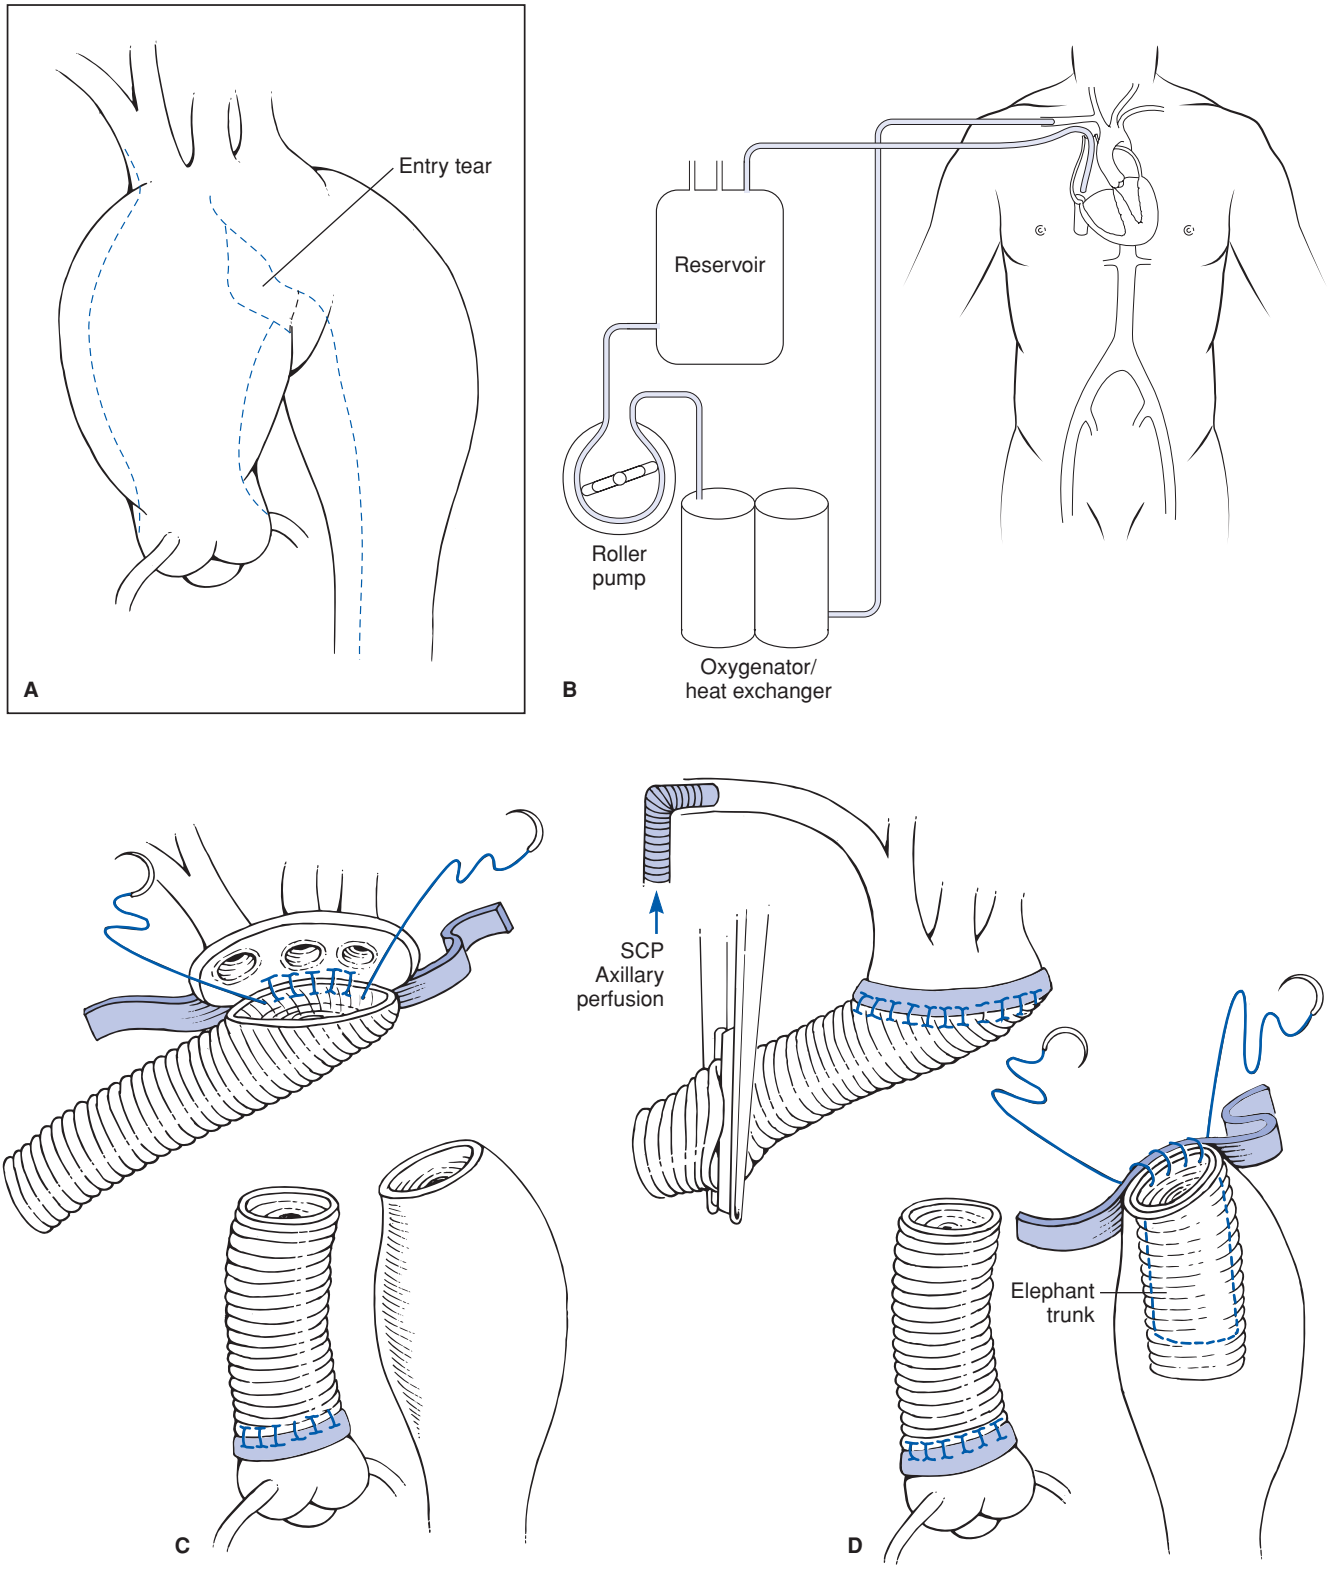

Figure 53-4. (A) Acute type A aortic dissection with the entry point located in the aortic arch. (B) Cardiopulmonary bypass via the right axillary artery. (C) Separate graft anastomosis to the brachiocephalic vessels. (D) Selective cerebral perfusion (SCP) and elephant trunk construction.

into the arch to search for the intimal tear, which is found in the arch opposite the arch vessels. The arch is mobilized and excised, leaving an island of aortic tissue containing the three head vessels. A 16 mm Hemashield (Boston Scientific, Natick, MA) graft is then beveled and sutured to the island of aortic tissue with Teflon reinforcement on the outside, once again invaginating the graft within the aorta, so that the dissected layers are sandwiched between the Teflon on the outside and the graft on the inside. The period of circulatory arrest is usually less than 30 minutes. Antegrade perfusion is then slowly restarted via the right axillary artery, and after careful de-airing, the beveled graft is clamped so that antegrade cerebral perfusion can be instituted at flows between 600 and 1000 mL/min to maintain a proximal perfusion pressure of 40 to 60 mm Hg (Fig. 53-4D).

Attention is now directed to the descending aorta just distal to the left subclavian artery. The aorta is incised circumferentially, Teflon felt is placed outside the aorta, and to facilitate the distal anastomosis, a small elephant trunk is constructed by invaginating the main arch portion of the graft. On completion of the suture line, the graft is everted, trimmed, and anastomosed to the ascending aortic graft with 3-0 polypropylene. The 16 mm arch graft is then beveled, and a longitudinal opening is made in the ascending aortic portion of the graft. The two grafts are anastomosed to each other with 3-0 polypropylene.

The heart is de-aired, the clamp on the beveled graft is removed, and perfusion to the heart and lower body is resumed. After rewarming, the patient is weaned from cardiopulmonary bypass in the standard fashion.

Case 3: Total Aortic Arch Replacement for Atherosclerotic and Calcified Aneurysms

Our technique for total arch replacement in elderly patients or in patients with atherosclerotic and calcified aneurysms has evolved to our current "no-touch" technique (Fig. 53-5). A trifurcated graft is anastomosed to the arch vessels during hypothermic circulatory arrest in order to reduce the risk of embolization; cerebral ischemia is minimized by permitting antegrade cerebral perfusion as arch reconstruction is completed.[144,145]

A median sternotomy is performed with extension of the incision superiorly along the medial border of the left sternocleidomastoid muscle. The recurrent laryngeal nerve is preserved as the AA and its branches are exposed. A no-touch technique of dissection is utilized: the patient is dissected away from the aneurysm.

Cardiopulmonary bypass is initiated using the right axillary artery and the right atrium, with a perfusate temperature lowered to 10°C. Examination of the AA with transesophageal echo confirms retrograde flow in the arch, and monitors for dissection or malperfusion. Cardioplegia is given after cross-clamp application, and is supplemented with topical hypothermia. If the ascending aorta is calcified or severely atherosclerotic, no attempt at cross-clamping is made. The patient is cooled and the heart vented. Just prior to circulatory arrest, 60 mEq of potassium chloride is added to the pump prime over 2 minutes to produce diastolic cardiac arrest. Alternatively, the heart is protected with retrograde blood cardioplegia.

Even in patients with severe atherosclerotic disease of the AA, the arch vessels just beyond their origins are

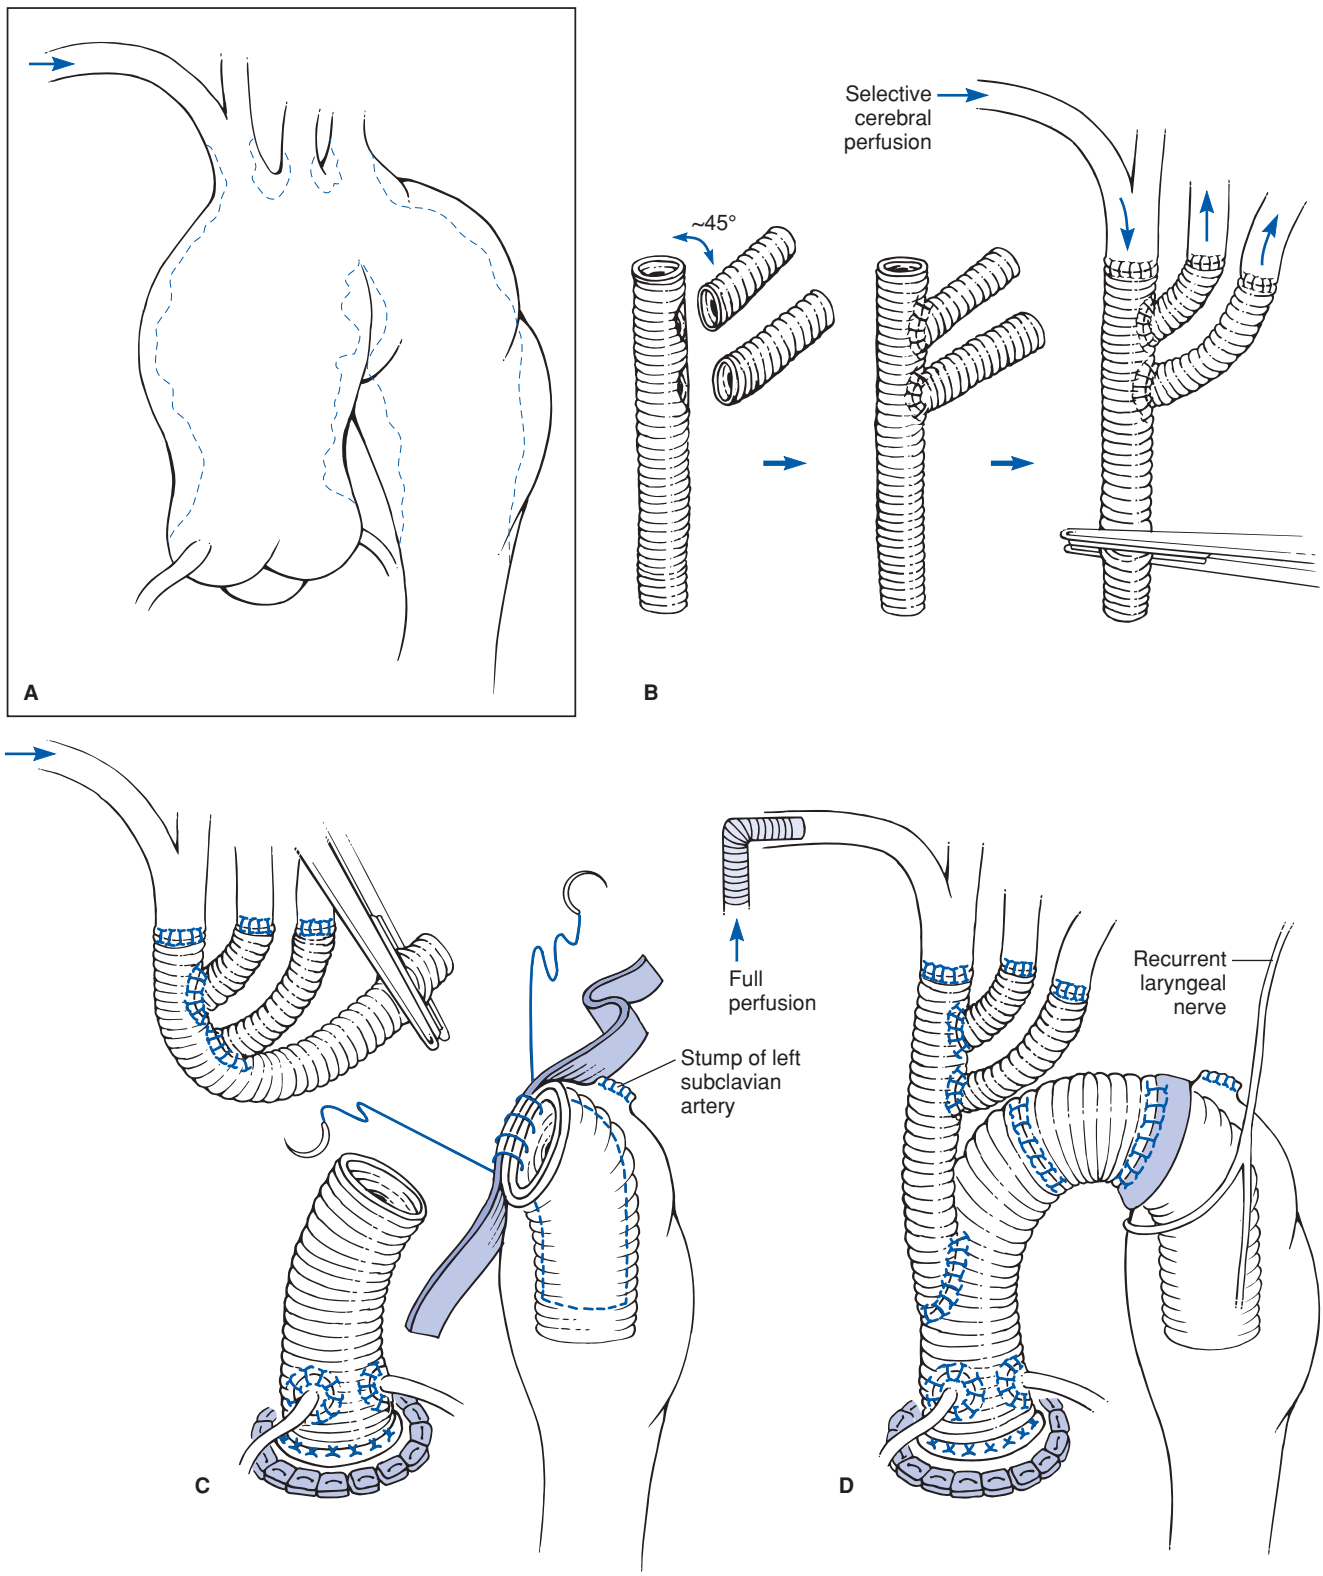

Figure 53-5. (A) Atherosclerotic ascending and arch aneurysm. (B) Fabrication of the trifurcated graft. (C) Selective cerebral perfusion and construction of the elephant trunk. (D) Completed repair.

usually spared. This location is ideal for subsequent anastomoses. After carefully sizing the innominate, left carotid, and left subclavian arteries, a trifurcated graft is constructed as illustrated (see Fig. 53-5B). Completion of this phase usually coincides with adequate core cooling. The head is packed in ice to prevent rewarming during the ischemic period. When the esophageal temperature reaches 13 to 15°C, and jugular bulb oxygen saturation is above 95%, maximum cerebral metabolic suppression is achieved. The patient is placed in the Trendelenburg position to prevent air trapping during the period of circulatory arrest. The arterial line is clamped during deep HCA.

At the beginning of circulatory arrest, the innominate artery is transsected just distal to its origin or at the level where atherosclerosis is minimal. The large limb of the trifurcated graft is trimmed and anastomosis is carried out with 5-0 polypropylene suture. The common carotid and the left subclavian artery anastomoses are constructed in a similar fashion. Each anastomosis takes 6 to 10 minutes, depending on the exposure. Reversing the order of the anastomoses may provide better access to the left subclavian artery in some patients. The trifurcation graft is carefully de-aired, and the proximal portion is clamped, restoring perfusion to the head and upper extremities. Perfusion pressures are maintained at 40 to 60 mm Hg, requiring flows between 600 and 1000 mL/min. Perfusate blood temperature is allowed to drift upward. No active rewarming is done. The AA is reconstructed in a variety of ways depending on the pathology.

For ascending and arch disease with aortic valve involvement, a Bentall or valve-sparing procedure precedes arch reconstruction. If the aortic valve is spared, arch repair begins at the proximal descending thoracic aorta with a suitable cuff of aortic tissue preserving the recurrent laryngeal nerve. If aneurysmal disease involves distal aortic segments, an elephant trunk[30,111,146] may be constructed in either the distal or the more proximal aortic arch, or in the distal ascending aorta where the aortic caliber permits. This maneuver, as described by Kuki,[146] avoids potential nerve injury. The anastomosis is constructed with running 3-0 polypropylene, reinforced with a strip of Teflon felt, taking great care to place the Dacron graft within the native aorta and the felt on the outside. The everted graft is then stretched and measured to the appropriate length and sutured to the sinotubular junction or to the graft previously used for aortic root reconstruction. Graft-to-graft anastomoses are constructed with 3-0 polypropylene. At this point, the Dacron graft is distended with cardioplegic solution to facilitate choosing the ideal site for anastomosing the trifurcated graft to the ascending portion of the aortic graft. An elliptical opening is made and the trifurcation graft is beveled and trimmed. Cerebral and upper extremity perfusion are not interrupted. On completion of this anastomosis, the patient is placed in the Trendelenburg position, and the cross-clamp is removed, restoring full myocardial and systemic perfusion. The patient is now rewarmed. With a blood temperature of approximately 30°C, the ascending aortic graft is vented, and the heart is defibrillated. Cardiopulmonary bypass is discontinued once the patient's esophageal temperature is 35°C.

Case 4: Total Arch Replacement with an Aberrant Left Vertebral Artery

On occasion the left vertebral artery (LVA) will exit the AA directly (Fig. 53-6). This poses a small challenge during arch reconstruction with branch grafts.[147] This anomaly is recognized on CT angiography and prompts a duplex ultrasound evaluation of the right vertebral artery (RVA) to ensure patency and antegrade flow. With a patent normal sized RVA, the LVA can be temporarily occluded during selective cerebral perfusion and reimplanted during patient rewarming. Three options have been used: direct reimplantation of the LVA into the left common carotid artery, attachment of a portion of reverse saphenous vein to the vertebral artery, and anastomosis to the arch graft or the left subclavian limb of the trifurcated graft. This last technique is essential if any question of the integrity of the RVA exists. A very small LVA (<2 mm) with a patent RVA may be ligated. Follow-up imaging studies have confirmed continued patency.

Case 5: Thoracosternotomy for Arch Reconstruction

For patients with prior ascending aortic replacement presenting with arch and proximal descending aortic pathology (Fig. 53-7), or patients with arch and proximal descending aortic disease alone, an alternative approach can facilitate a one-stage repair.[27,28] A bilateral anterior thoracotomy can be used. Both internal mammary arteries are ligated. Exposure of the transverse AA and proximal descending thoracic aorta is outstanding. For brachiocephalic artery reconstruction, either a large Carrell patch to a separate graft or a trifurcated graft or a four-branch graft to the individual vessels can be used, depending on the degree of atherosclerotic disease and/or scarring from previous surgery. Patients tolerate the incision, and adequate exposure of the phrenic and recurrent laryngeal nerves allows careful preservation. The only drawback involves sternal union, and therefore secure stabilization of the sternal tables at the end of the procedure is imperative. Arterial perfusion is the same, through the right axillary artery. Venting of the left ventricle during systemic cooling and cardiac fibrillation can be carried out either via the right superior pulmonary vein or via a small separate thoracotomy overlying the left ventricular apex.

Case 6: Arch Replacement Following a Previous Bentall Procedure for Extensive Thoracic Aortic Aneurysmal Disease

Replacement of the AA following a previous surgical procedure involving the ascending aorta can be challenging.

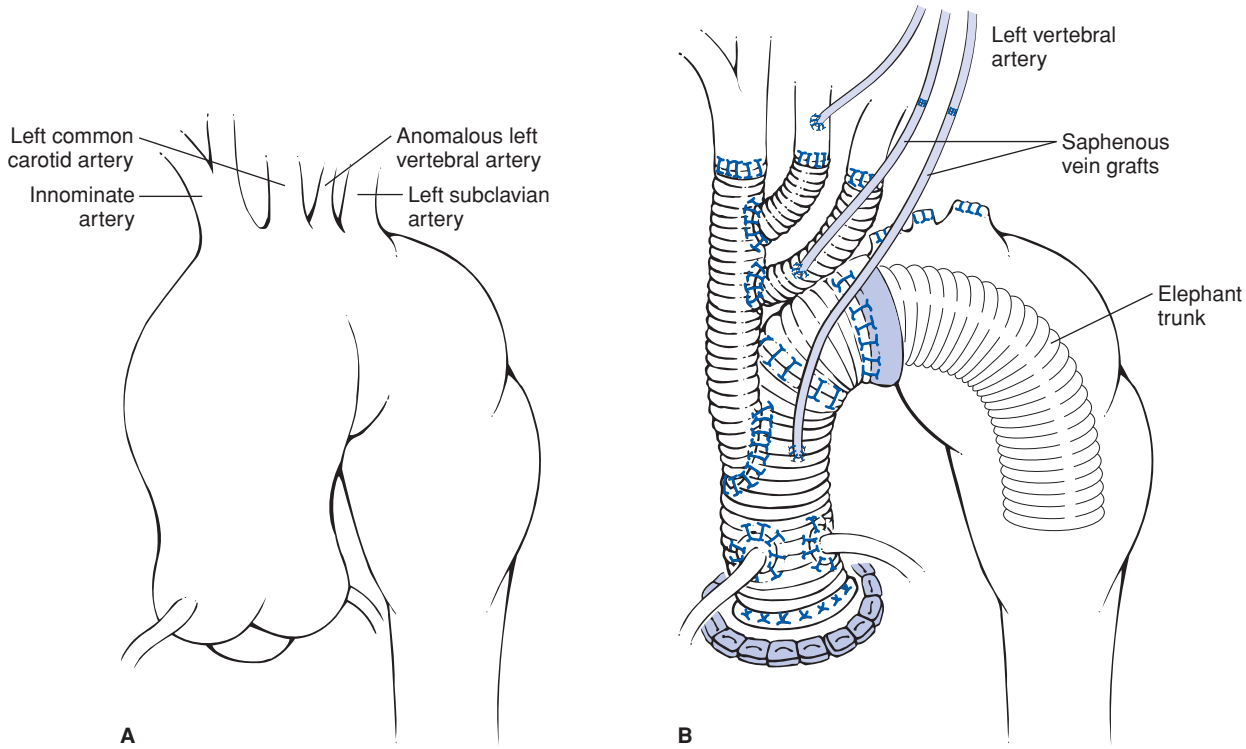

Figure 53-6. (A) Anomalous left vertebral artery exiting the aortic arch directly. (B) Three techniques for reconstruction.

A simple approach will facilitate repair and avoid many of the pitfalls of other techniques (Fig. 53-8). The arch is exposed through the previous sternotomy and the brachiocephalic vessels are dissected free, mobilizing the innominate vein. Extensive dissection of the previous graft risks injury to the pulmonary artery. The right atrium and right superior pulmonary vein are exposed. Cannulation is via the right axillary artery and right atrium. A coronary sinus retrograde catheter is an important adjunct for myocardial protection. Cardiopulmonary bypass is begun and the patient is cooled. The left ventricle is vented. After adequate cooling and circulatory arrest a trifurcated graft is placed to the brachiocephalic vessels as previously described, followed by SCP. To facilitate the procedure all of the arch vessel stumps are oversewn with 3-0 polypropylene. The elephant trunk is constructed proximal to the origin of the innominate artery and left long to traverse the arch into the proximal descending aorta. If the reason for re-operation is residual chronic aortic dissection, a small caveat can avoid disaster. The elephant trunk should not be longer than the distal fenestration allowing equal perfusion of the true and false lumens. On occasion the false lumen is partially filled with thrombus. In this situation the elephant trunk should be directed into the true lumen to avoid embolization from the false lumen. Part of the graft is everted back into the mediastinum and trimmed as short as possible, leaving perhaps two or three rings. This is anastomosed to the previous Bentall graft with 2-0 or 3-0 polypropylene. The trifurcated graft is then attached to the old Bentall graft through an elliptical opening in the right lateral side. The surgical procedure continues to conclusion. The arch remains pressurized until the second stage repair, with either an open surgical technique or thoracic endograft. Using this technique we have reduced our morbidity and mortality comparable to first-time arch replacement.

Case 7: Descending Thoracic Aortic Aneurysm Involving the Distal Arch

Descending thoracic aortic aneurysms often involve the distal AA, or are associated with a distal arch that is calcified and severely atherosclerotic, making cross-clamping dangerous (Fig. 53-9). If the arch appears severely diseased, one might consider a two-stage reconstruction to isolate the cerebral circulation and reduce the risk of embolic stroke. For lesser degrees of intraluminal disease we use the following technique.

Operation is carried out through a left thoracotomy in the fourth or fifth intercostal space with the incision extended inferiorly across the costochondral plate to improve exposure if necessary. The internal mammary artery is usually preserved. The left femoral artery and vein are dissected out in preparation for cannulation. The descending aorta is gradually mobilized. Intercostal arteries are serially clamped and then sacrificed when no changes in the SSEPs and MEPs develop. Care is taken not to manipulate the distal arch adjacent to the left subclavian artery. Cannulation for CPB is carried out with a long perfusion catheter inserted via

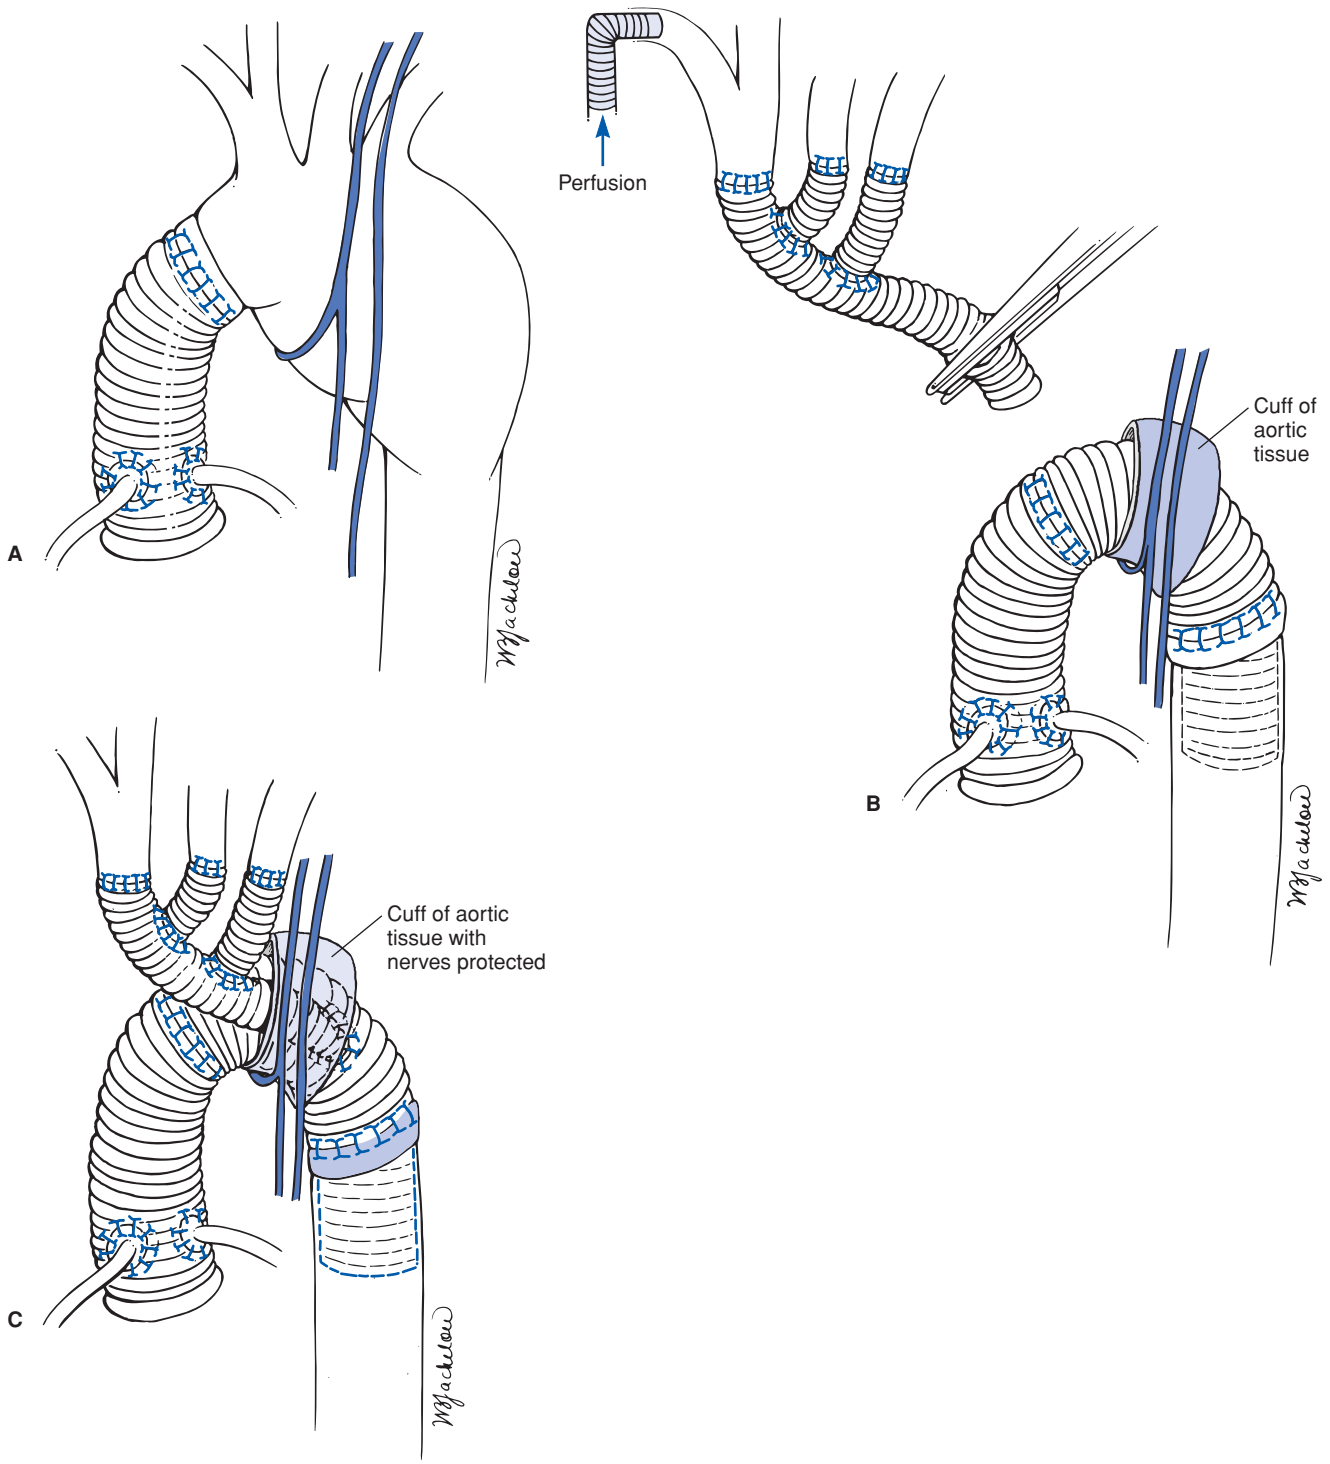

Figure 53-7. (A) Recurrent arch proximal descending aneurysm approached via a thoracosternotomy. (B) Selective cerebral perfusion and arch reconstruction. (C) Completed repair.

the left common femoral vein, and positioned in the right atrium with the aid of a guidewire and TEE monitoring. Occasionally the main pulmonary artery is used for venous inflow. The left common femoral artery is cannulated. Perfusion is begun gradually to avoid a rapid shift in the perfusion patterns in the aorta that might dislodge atheromatous debris. Once perfusion is established, care is exercised to avoid manipulating the descending thoracic aorta, inasmuch as dislodged debris would be carried retrograde toward the arch vessels and the coronary arteries. During cooling and once ventricular fibrillation has occurred, left ventricular distention is closely monitored with TEE and pulmonary

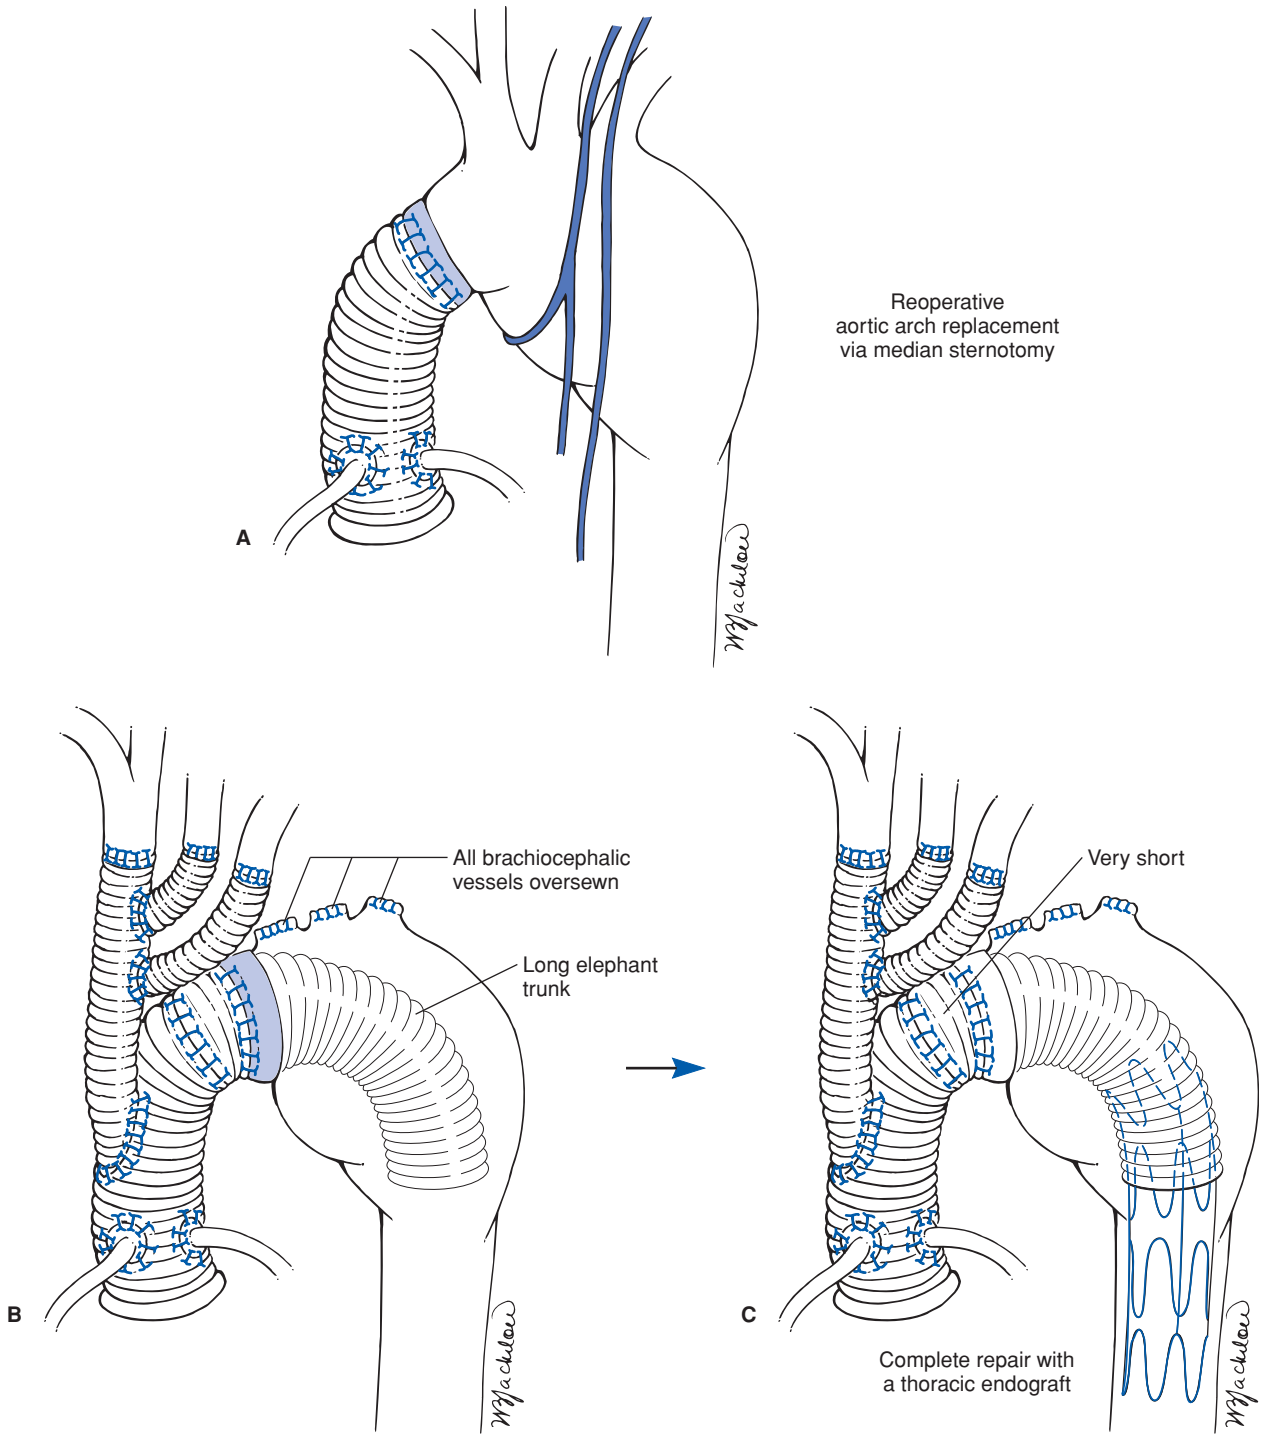

Figure 53-8. (A) Reoperative aortic arch aneurysm approached via median sternotomy. (B) Elephant trunk reconstruction proximal to the innominate artery. (C) Completed repair with a thoracic endograft placed retrograde.

artery pressures. If there is any sign of left ventricular dilatation, a vent is introduced into the left ventricular apex or via the left atrium. After about 30 to 40 minutes of cooling, the esophageal temperature has usually decreased to 13 to 15°C, and the jugular venous saturation exceeds 95%. Cardiopulmonary bypass is discontinued.

The left ventricular vent is clamped, and the descending thoracic aorta is opened. A cuff of the underside of the AA, extending inferiorly to the distal ascending aorta and superiorly to the margin of the left carotid artery, is fashioned. An attempt is made to preserve the recurrent laryngeal nerve. A single side-arm graft is anastomosed to the

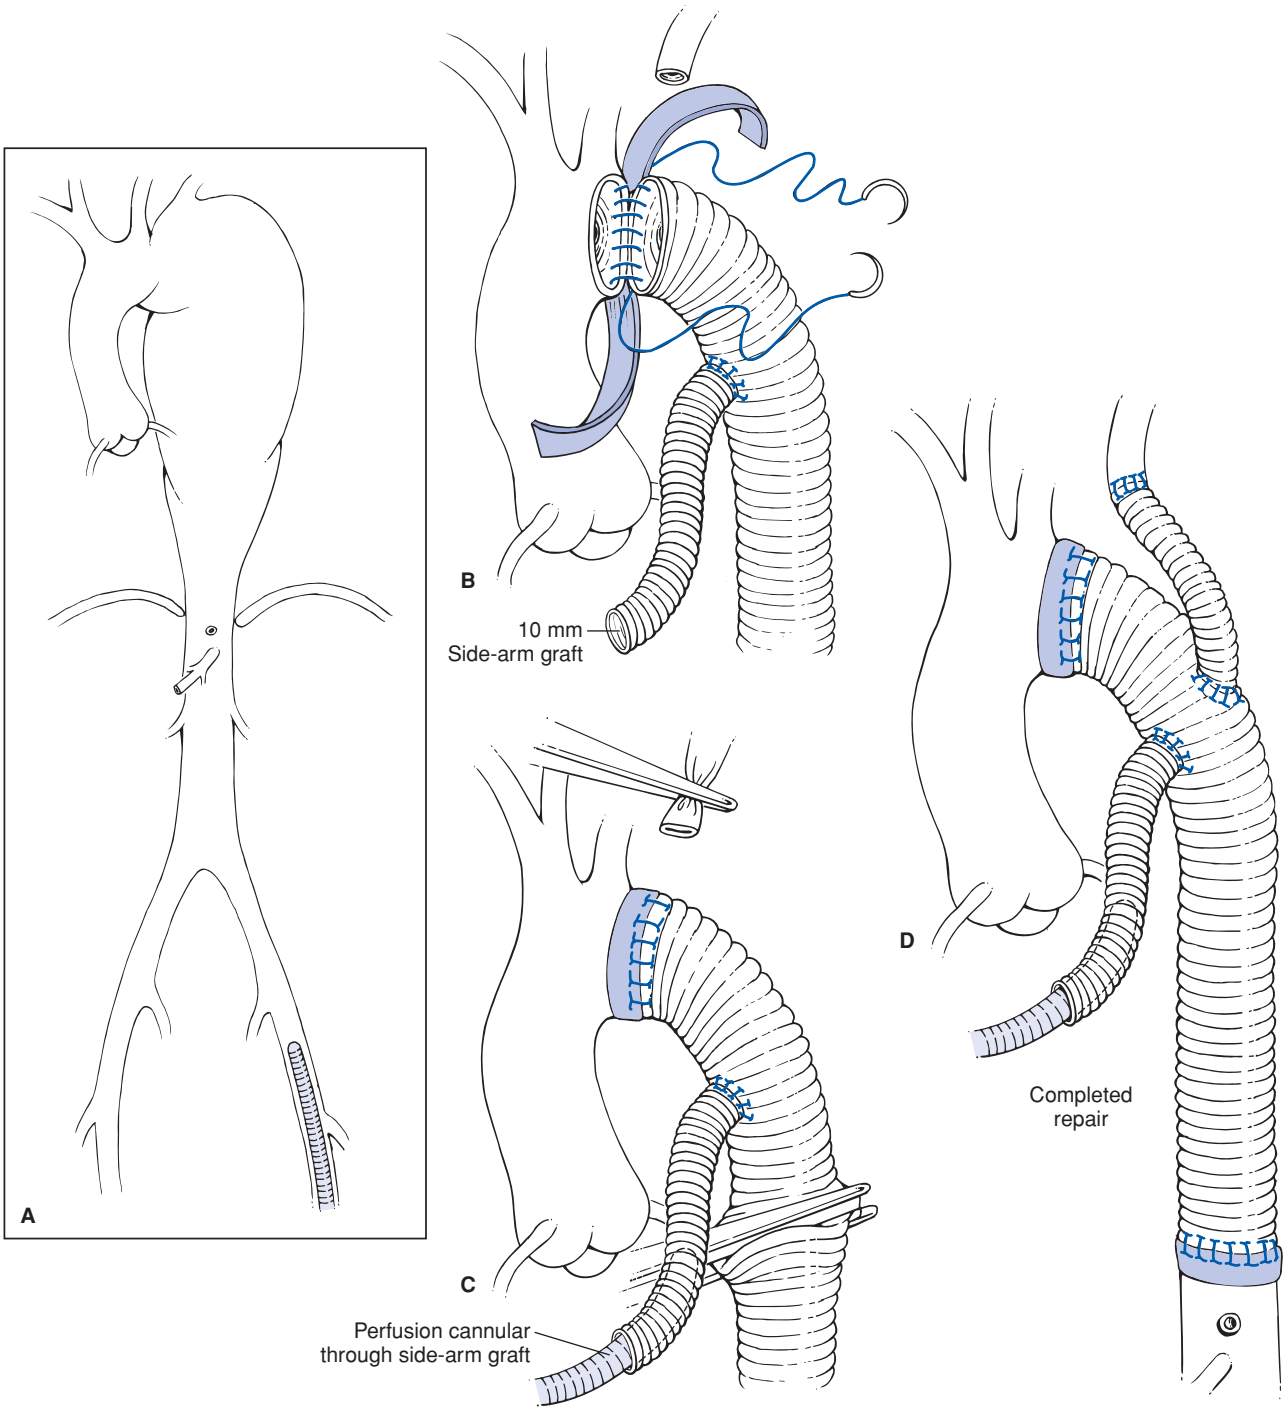

Figure 53-9. (A) Distal arch descending thoracic aortic aneurysm with femoral artery perfusion. (B) Hypothermic circulatory arrest and anastomosis to the distal arch. (C) Selective cerebral perfusion via a side-arm graft. (D) Reattachment of the left subclavian artery and completed repair.

native aorta with a running suture of 3-0 polypropylene. Teflon felt is used, and the graft is invaginated within the aorta. The brachiocephalic vessels are carefully aspirated. To facilitate the de-airing and removal of debris, the left ventricular vent is attached to the cardioplegia line and cold blood is infused at approximately 400 mL/min into the left ventricle out the ascending aorta and arch. This continues for several minutes until the blood returning through the graft is free of air and particulate matter. A perfusion cannula is then placed into the side-arm graft, and antegrade perfusion is begun to the brachiocephalic and coronary arteries. The graft and subclavian artery are clamped. The left ventricular vent is returned to low suction.

Attention is now turned to the distal descending aorta. Perfusion via the femoral artery catheter is used briefly to wash any loose debris in the descending aorta out into the

field. A distal cuff is fashioned, and the graft is anastomosed to it with a running 3-0 polypropylene suture. Teflon felt is utilized. The clamp on the graft is removed, and the flow to the entire body is provided through the perfusion catheter placed in the side-arm graft. Rewarming, defibrillation, and weaning from CPB are carried out in standard fashion. During rewarming, a separate 8 or 10 mm graft is sewn to the left subclavian artery, trimmed to the appropriate length, and anastomosed to the descending graft with a side-biting clamp.

SSEP and MEP monitoring is continued to the conclusion of the operation, and arterial pressures are maintained in the high normal range. The evoked potentials gradually return, but below baseline secondary to systemic hypothermia. An intrathecal catheter is placed preoperatively and is used to drain cerebrospinal fluid in order to keep the cerebrospinal fluid pressure below 12 mm Hg for the first 24 to 48 hours, depending on the extent of resection.

RESULTS

The contemporary experience suggests that HCA/SCP is superior to HCA alone for preventing cerebral injury during aortic arch reconstruction and that SCP/trifurcated graft with axillary artery cannulation may be the optimal technique for reducing adverse outcome.[112,148]

Recently reported series of total AA replacement compare favorably with our results. Safi and associates[31] reported a 30-day mortality of 5.1% in 117 patients undergoing stage I elephant trunk reconstruction, with an adverse outcome rate of 6.8%. Interestingly, 43 (37%) of patients did not return for second-stage repair, and 30.2% died from distal aneurysm rupture in short-term follow-up. Schepens and colleagues[149] reviewed 100 consecutive stage I elephant trunk reconstructions from 1984 to 2001, with an 8% mortality, 12% adverse outcome, and 2% TND. The majority of patients received isolated unilateral or bilateral antegrade cerebral perfusion for cerebral protection.

Ueda[150] described 207 consecutive patients with AA repairs from 1988 to 2000, 50% with atherosclerotic aneurysm, and a 12% mortality. The author re-emphasized the poor long-term outcome of patients with postoperative neurologic injury. Recently, the use of the anterolateral approach to complicated arch repair avoided cerebral dysfunction;[151] this is a technique we have employed with contained ruptures and redo arch replacements. Hilgenberg and Logan[152] reported adverse outcome in 6% of 67 patients, with 16% experiencing TND with acute dissection, which was the only independent risk factor for neurologic dysfunction. Hirotani and colleagues,[153] using a pharmacologic mixture to improve cerebral protection with HCA, performed total arch replacement in 43 patients with a mortality of 10.7% and an adverse outcome rate of 14.7%. The duration of circulatory arrest did not correlate with mortality or postoperative stroke, again illustrating the embolic nature of focal neurologic injury.

Coselli and coworkers,[154] in a series of 227 patients with AA surgery, experienced a 6% early and a 9% late mortality, with a 3% incidence of stroke. The reduction in neurologic injury was attributed to a >50% use of retrograde cerebral perfusion during HCA. Finally, Kazui and associates[102] in their contemporary collection of 50 patients and use of a refined technique of total arch replacement in atherosclerotic aneurysms, achieved outstanding results: 2% mortality, 6% rate of adverse outcome, and 4% incidence of TND. Duration of CPB was the only univariate risk factor for TND, and a history of cerebrovascular accident was correlated with permanent neurologic dysfunction. Di Eusanio and colleagues,[101] in a multicenter study using antegrade cerebral perfusion for total arch replacement in 352 patients, experienced an 8.7% rate of in-hospital mortality, permanent stroke rate of 3.8% (adverse outcome rate of 12.5%), and rate of TND of 5.6%. Independent predictors of adverse outcomes included urgent operation, recent stroke, tamponade, unplanned coronary revascularization, and pump time. Postoperative complications were a 12.1% return for bleeding, myocardial infarction in 2.9%, prolonged ventilation (>5 days) in 17.7%, and renal failure requiring temporary hemodialysis in 4.6%. Numata and coworkers,[17] using right axillary perfusion and a separate cannula in the left common carotid artery for 120 arch replacements, achieved impressive results: 5.8% mortality and 0.8% permanent stroke rate, with 5.8% (7 patients) experiencing TND.

From our prospectively compiled database of patients undergoing aortic surgical procedures, we identified 150 consecutive patients (91 male, 59 female) who underwent nonemergent resection of aneurysms of the transverse arch between September 1999 and December 2005, utilizing hypothermic antegrade cerebral perfusion after an interval of deep hypothermic circulatory arrest provided by direct axillary artery cannulation and a trifurcated graft.

The mean age was 63 ± 14 years (range 20 to 87 years). The most frequent etiology of the aneurysm was chronic dissection, which was present in 56 patients (37.3%). Atherosclerosis occurred in 48 patients (32.0%), and the aneurysms were classified as degenerative in 29 (19.3%). Sixty-eight patients (45.3%) had undergone previous cardiac surgery.

Among the known risk factors for adverse outcome after surgery, chronic obstructive pulmonary disease was present in 23 patients (15.3%), insulin-dependent diabetes in 8 (5.3%), and dialysis-dependent renal failure in 6 patients (4.0%). Among potential risk factors for postoperative neurologic injury, a history of transient ischemic attack was present in 5 patients (3.3%), and 13 patients (8.6%) had experienced a preoperative stroke.

The mean maximal diameter of the aorta was 6.1 cm (range 4.0 to 12 cm). The extent of aortic replacement varied, and a number of patients had concomitant procedures. Lone arch replacement was undertaken in 38 patients

(25.5%). In addition, 74 patients (49.6%) had ascending aortic replacement, 21 (14.1%) had ascending and root replacement, and 4 (2.7%) had resection of the descending aorta. An elephant trunk was placed in 144 patients (96.6%), distal to the left subclavian artery in 87 (58.0%), distal to the left common carotid in 34 (22.7%), between the brachiocephalic and left carotid arteries in 9 (6.0%), and proximal to all arch branches in 18 (12.0%). Coronary artery bypass grafting was performed in 36 patients (24.0%). All arch reconstructions were completed using a single period of HCA followed by SCP utilizing the trifurcated graft technique. Mean duration of HCA was 31.1 ± 6.5 minutes (range 17 to 48 minutes). Mean duration of SCP was 66.6 ± 21.0 minutes (range 21 to 125 minutes). Mean temperature of SCP was 15.8 ± 2.1°C (range 12.0 to 22.1°C). The duration of CPB was 239 ± 53.1 minutes (range 157 to 390 minutes).

Adverse outcomes were seen in 13 patients (8.7%). There were 7 hospital deaths (4.7%) and 6 permanent strokes (4.1%).

The most frequent complication was prolonged intubation (>48 hours), which was necessary in 24 patients (16.0%). TND developed in seven patients (4.7%). No correlation between preoperative neurologic risk factors and postoperative events was found. Return to the operating room for bleeding was required in seven patients (4.7%). Temporary renal support was needed in nine patients (6.0%), but none required permanent dialysis. Median intensive care unit stay was 3 days (range 1 to 108 days) and hospital stay was 10 days (range 4 to 108 days).

Techniques of AA replacement must be an integral part of the neurologic protection scheme. The two facets of neurologic protection, prevention of cerebral injury during global ischemia and avoidance of particulate athero-emboli, are not mutually exclusive. In the current era, with a combination of deep hypothermia and SCP, the prevention of cerebral embolization plays an even greater role in further reducing the risks of arch replacement in an aging population. To this end, two surgical strategies have emerged to balance the neurologic risks: the four-branched graft AA replacement championed by Dr. Kazui and others,[99,101,155] and more recently, the trifurcated graft technique.[112] The benefits are illustrated by shorter durations of deep HCA and the utilization of SCP to restore and maintain cerebral oxygenation while isolating the brachiocephalic vessels during subsequent arch repair. Selective cerebral perfusion can be performed in several different ways: right axillary artery cannulation and a single balloon catheter in the left common carotid artery,[104] direct balloon tip catheter perfusion of the innominate artery and left common carotid arteries,[99,101,155] unilateral brain perfusion from the right axillary artery[29] or the right brachial artery,[104] and even direct bilateral cannulation of the carotid arteries outside the thorax.[156] Our technique avoids instrumentation of the brachiocephalic vessels and ensures bilateral cerebral perfusion, albeit at the expense of lower core brain temperatures and longer deep HCA intervals but well within the accepted safe limits. Recently, a slight modification of the trifurcation graft method has shortened the deep HCA times further (Fig. 53-10). Using the same perfusion technique following a single period of deep HCA, the left subclavian artery is anastomosed to the first limb of the trifurcated graft followed by the innominate artery. Partial SCP at 400 to 500 mL/min is begun with the left common carotid open to back-flush via collaterals. The left common carotid is then gently occluded with a soft clamp, restoring cerebral circulation. Next, under partial SCP the left carotid artery is attached and de-aired. Flows are increased to 10 mL/kg/min. The remaining reconstruction proceeds as usual. The deep HCA time is shortened to ~20 minutes without the need to instrument the vessels. This may become important when residual atherosclerotic disease is present in the individual brachiocephalic vessels or in the event of acute or chronic dissection, when cannulation may be difficult and risk malperfusion. It is possible that perfusion cannulas can become dislodged or displaced during SCP.[15] Lastly, the perfusion cannulas in the limited space of the mediastinum may obscure the operative field during subsequent arch replacement.

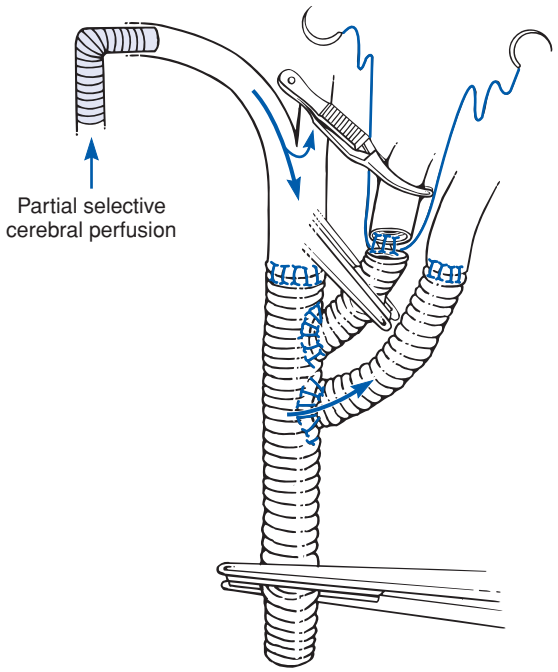

Figure 53-10. Partial selective cerebral perfusion.

LONG-TERM FOLLOW-UP

Aortic arch aneurysms may represent a localized manifestation of an often multilevel disease process of the aorta. Therefore, long-term follow-up of the unresected aorta in postoperative patients is mandatory. All patients with aortic aneurysms are entered into our database (n = 2308) and follow-up program. Patients with small aneurysms require ongoing radiographic imaging at either 6- or 12-month intervals, depending on the location, rate of progression, and

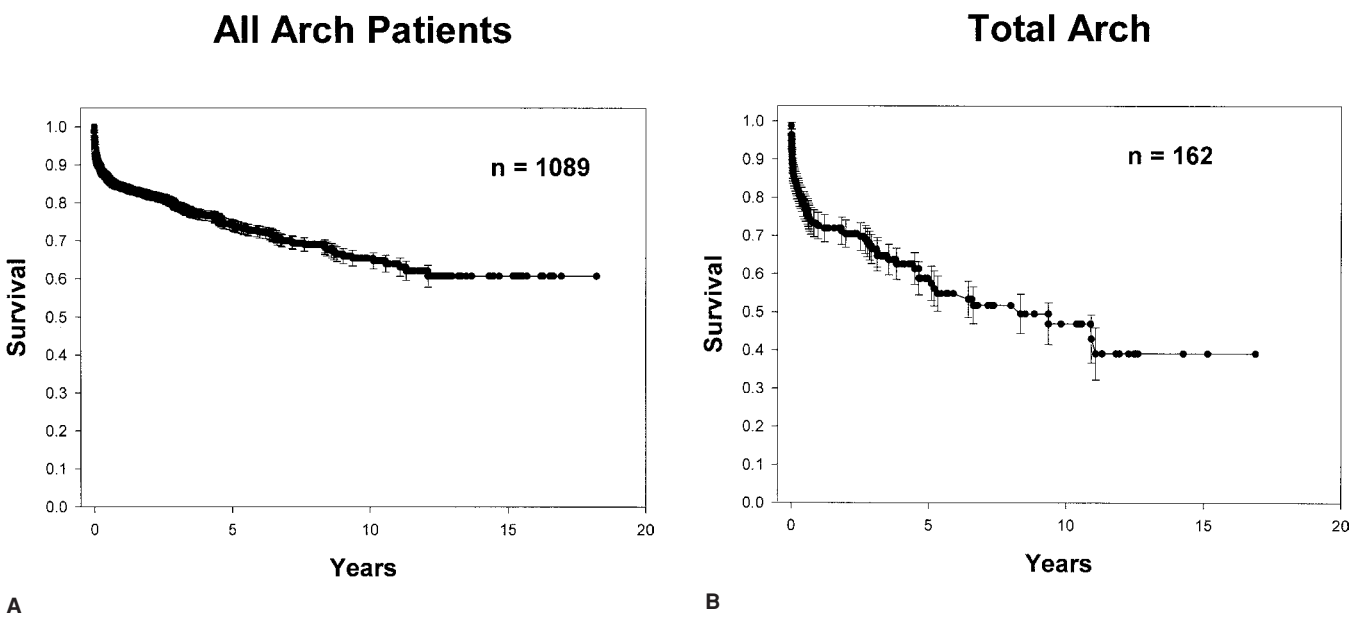

Figure 53-11. Life table analysis of long-term survival following total aortic arch replacement with the trifurcated graft technique.

etiology. Baseline CT scan, MRI, or angiograms obtained in the postoperative period document the integrity of the repair and provide a baseline for later comparison. In those patients with no portion of the unresected aorta dilated to a diameter exceeding 4 cm, the first re-evaluation is scheduled in 1 year. Patients with significant residual dissection or aneurysmal dilatation are followed more closely at 6-month intervals. Medical therapy includes control of hypertension, β-blocker therapy in patients with aortic dissection and Marfan syndrome, and encouragement of cessation of cigarette smoking.

When examining patients undergoing total arch replacement with a trifurcated graft—reflecting more extensive aneurysmal disease—survival at 1 year is 75%; it is 73% at 3 years, and 61% at 5 years (Fig. 53-11). Reduced 1-year survival results from rupture prior to a staged repair, mortality from the second stage surgery, and failure to return for stage two. Long-term results reported in the literature confirm the importance of continued surveillance of patients following total arch replacement. Crawford and colleagues[157] found that 70% of patients with operations involving the AA had significant disease elsewhere in the aorta. Coselli and associates documented that 15% of 227 patients with AA repairs required additional surgery within a mean interval of 17 months.[154] Heinemann and coworkers[158] reoperated on 24% of 82 patients with type A dissection over a 10-year period. Detter and colleagues,[158,159] examining the long-term prognosis of aortic aneurysm in patients with and without Marfan syndrome, found a reoperation rate of 10.7 and 66.7%, respectively, reinforcing the necessity of continued radiographic follow-up, particularly in patients with Marfan syndrome, residual dissection, and AA aneurysms. Late death occurred in 25% of Marfan patients and 14% of nonMarfan patients, with 18% caused by redissection and recurrent aneurysm in the Marfan group. In our series of 162 patients following type A aortic dissection, 17% required reoperations: 23 distal and 4 proximal.[160]

Elective replacement of other aortic segments can be carried out with an acceptable morbidity and mortality, in contrast with the low salvage rate seen in patients presenting with contained ruptures and untreated comorbid disease.

CHAPTER 54

Descending and Thoracoabdominal Aortic Aneurysms

Joseph S. Coselli • Scott A. LeMaire

An aortic aneurysm is a permanent localized dilatation whose diameter is at least 1.5 times larger than the expected normal diameter of that portion of the aorta.[1] Aneurysms of the descending thoracic aorta can involve any portion of the aorta between the left subclavian artery and the diaphragm. Thoracoabdominal aortic aneurysms (TAAAs) are characterized by dilatation of the aorta at the diaphragmatic hiatus—the boundary that separates the descending thoracic and abdominal aortic segments—with varying degrees of extension into the chest and abdomen (Fig. 54-1). Because of the extent of this type of aortic disease and the formidable operative procedures required to treat it, this entity continues to represent a significant clinical challenge to the cardiovascular surgeon. As our population ages and the availability of new diagnostic modalities increases, so do both the number of identified descending thoracic aortic aneurysms (DTAAs) and TAAAs and the number of patients in need of surgical intervention.

PATHOGENESIS

Causes of DTAAs and TAAAs include nonspecific medial degeneration, dissection, connective tissue disorders, aortitis (e.g., Takayasu's arteritis), aortic coarctation, and infection. Traditionally, many thoracic aortic aneurysms were labeled atherosclerotic aneurysms; however, although atherosclerosis and aortic aneurysms share common risk factors and frequently coexist, thoracic aortic aneurysms are primarily the result of age-related medial degeneration, which is characterized by changes in elastin and collagen that reduce aortic integrity and strength. Subsequent aortic enlargement and aneurysm formation provide fertile ground for superimposed intimal atherosclerosis and further degeneration of the aortic wall. The usual histologic changes in the aging aorta include elastin fragmentation, fibrosis with increased collagen, and medial degeneration.[2] As with most aneurysmogenic processes, medial degeneration usually causes diffuse, fusiform aortic dilatation. In some cases, however, medial degeneration produces saccular aneurysms along the descending thoracic aorta. These saccular aneurysms may be superimposed on or coexist with more generalized, fusiform aneurysmal disease of the thoracoabdominal aorta.

Aortic dissection is the progressive separation of the aortic wall layers that usually occurs after a tear forms in the intima and inner media. Propagation of the separation within the layers of the media creates a new channel—the false lumen—that is separated from the original, true lumen by the dissecting membrane. The weakened outer aortic wall is prone to progressive aneurysmal dilatation (Fig. 54-2). Penetrating aortic ulcers and intramural hematomas are two variants of aortic dissection that can occur in the descending and abdominal aortic segments. Penetrating aortic ulcers are disrupted atherosclerotic plaques that can penetrate the aortic wall, leading to formal dissection or rupture. Intramural hematomas are collections of blood within the aortic wall without an intimal tear; accumulation of the hematoma can result in formal dissection.

Connective tissue disorders are genetic diseases characterized by defective components of the extracellular matrix, such as fibrillin in Marfan syndrome and collagen in Ehlers-Danlos syndrome. When the defect occurs in the aortic wall, the resulting weakness often leads to aneurysm formation. In the Marfan aortic wall, fragmentation of elastic fibers and the deposition of extensive amounts of mucopolysaccharides produces abnormal elastic properties that predispose the aorta to dilatation.[3,4] The aorta in Marfan patients is particularly prone to dissection, which is the most common cause of DTAAs and TAAAs in these patients.[5]

Both chronic, nonspecific aortitis and systemic autoimmune disorders, such as Takayasu's arteritis, giant cell arteritis (temporal arteritis), and rheumatoid aortitis, can cause destruction of the aortic media and progressive aneurysm formation. Although Takayasu's arteritis usually causes

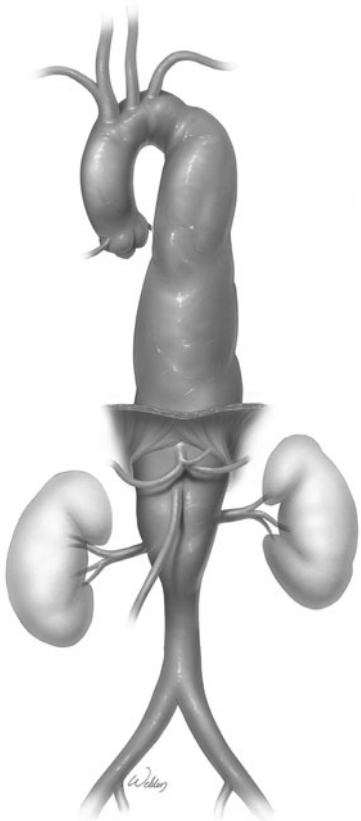

Figure 54-1. Drawing depicting a thoracoabdominal aortic aneurysm.

obstructive lesions related to severe intimal thickening, the associated medial destruction can result in aneurysmal dilatation.

Aneurysms involving the upper descending thoracic aorta can develop in patients with congenital aortic coarctation. These aneurysms occur in the setting of unrepaired coarctation as well as after coarctation repair.[6] The post-repair aneurysms appear to be most common in patients who have had patch graft aortoplasty operations.[7,8] Histologic examination of the aneurysmal tissue has revealed medial degeneration, smooth muscle cell necrosis, and loss and fragmentation of elastic fibers.[9]

Infection can produce a saccular "mycotic" aneurysm in a localized area of the aortic wall that has been damaged by the infectious process. For unknown reasons, such mycotic aneurysms tend to occur along the lesser curvature of the transverse aortic arch or in the upper abdominal aorta adjacent to the origins of the visceral branches. In such cases, only a portion of the aortic circumference is affected; consequently, localized weakening causes a diverticular or saccular outpouching.

Each of the disease processes described above cause aneurysms through progressive degeneration and dilatation of the aortic wall. In contrast, pseudoaneurysms of the thoracic aorta form as the result of chronic leaks through discrete defects in the aortic wall. These leaks are initially contained by surrounding tissue; the accumulation of organized thrombus and the associated fibrosis forms the wall of the

Figure 54-2. Drawing and computed tomography image of a thoracoabdominal aortic aneurysm caused by dilatation of the false lumen in a patient with chronic aortic dissection.

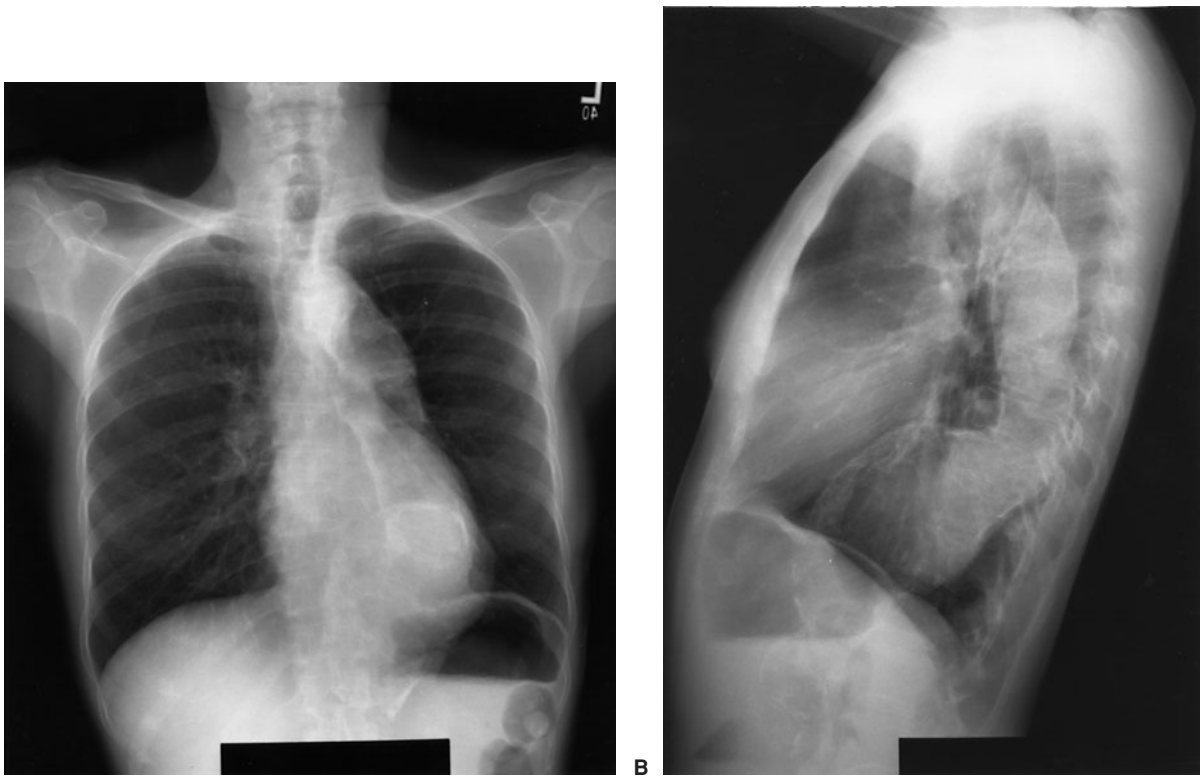

Figure 54-3. Chest radiographs in (A) posteroanterior and (B) lateral projections showing the calcified wall of a thoracoabdominal aortic aneurysm.

pseudoaneurysm. Pseudoaneurysms can develop after surgical or percutaneous interventions performed to repair aortic coarctation, dissection, or aneurysm.[10] Unrepaired blunt and penetrating injuries are the other common cause of aortic pseudoaneurysms. Chronic traumatic pseudoaneurysms typically develop in the proximal descending thoracic aorta after blunt aortic injuries;[9,11] the management of these lesions is covered in detail in a subsequent chapter.

Although the underlying pathologic processes may differ among various types of aortic aneurysms, the ultimate disease process is the same for all: progressive aortic dilatation and eventual rupture. The relationship among pressure gradients, vessel diameter, and vessel wall tension described by the Laplace law—which states that increasing luminal diameter leads to greater wall tension—contributes to the cycle of progressive dilatation.

CLINICAL PRESENTATION AND DIAGNOSIS

At the time of diagnosis, patients with DTAAs and TAAAs are commonly asymptomatic. For example, Panneton and Hollier[12] reported that degenerative TAAAs are asymptomatic in roughly 43% of patients. In asymptomatic patients, DTAAs and TAAAs are often discovered when imaging studies are performed to evaluate unrelated problems. For example, chest radiographs may show widening of the descending thoracic aortic shadow, which may be highlighted by a rim of calcification outlining the dilated aneurysmal aortic wall (Fig. 54-3). Aneurysmal calcium may also be seen in the upper abdomen on standard radiographs.

Although DTAAs and TAAAs remain asymptomatic for long periods of time, most ultimately produce a variety of symptoms before they rupture. Degenerative TAAAs produce symptoms in approximately 57% of patients; 9% of patients present with rupture.[12] The most frequent symptom is back pain between the scapulae. When the aneurysm is large in the region of the aortic hiatus, pressure on adjacent structures may cause mid-back and epigastric pain. Other potential signs and symptoms related to compression or erosion of adjacent organs include stridor, wheezing, cough, hemoptysis, dysphagia, and gastrointestinal obstruction or bleeding.[13] Hoarseness results from traction on the vagus nerve as the distal aortic arch expands and causes recurrent laryngeal nerve paralysis. Thoracic or lumbar vertebral body erosion (Fig. 54-4) causes back pain, spinal instability, and neurologic deficits from spinal cord compression; mycotic aneurysms have a peculiar propensity to destroy vertebral bodies. Additionally, neurologic symptoms, including paraplegia, paraparesis, or both, may result from thrombosis of intercostal and spinal arteries. This is most frequently seen with acute aortic dissection, which may occur primarily or be superimposed on medial degenerative fusiform aneurysmal disease. Thoracic aortic aneurysms, like aneurysms in other locations, may produce distal emboli of clot or atheromatous debris that gradually obliterates and thromboses visceral, renal, or lower extremity branches.

Figure 54-4. Computed tomography image of a large thoracoabdominal aortic aneurysm that has caused erosion of the adjacent vertebral body.

DETERMINING APPROPRIATE TREATMENT

Once an aneurysm involving the descending or thoracoabdominal aorta has been discovered, precise determination of the extent and severity of disease is the critical next step toward clarifying the specific diagnosis, determining the appropriate treatment, and when repair is indicated, planning the appropriate intervention.

Determining Extent and Severity of Disease

Aneurysm diameter and changes in diameter are major considerations in treatment planning. Because aneurysms are defined as permanent localized dilatations of an artery to at least 150% of the artery's expected normal diameter, the diagnosis of an aneurysm in the thoracic aorta requires knowledge of its normal diameter.[1] At the level of the mid-descending thoracic aorta, the average aortic diameter is 28 mm for men and 26 mm for women; at the level of the celiac axis, it is 23 mm for men and 20 mm for women; and at the infrarenal aorta, it is 19.5 mm for men and 15.5 mm for women.[14] Normal aortic diameters, however, vary with a person's age, gender, and body surface area. Aortic enlargement with advancing age has been reported in a number of studies.[15–18] Even when adjusted for age and body surface area, mean aortic size is significantly smaller in women than in men; on average, aortic diameter is 2 to 3 mm greater in men than in women. Body surface area is a better predictor of aortic size than is height or weight, particularly in patients less than 50 years of age.[15,19]

In addition to aneurysm diameter, the precise location of the aneurysm needs to be determined to enable the selection of appropriate treatment options. Descending thoracic aortic aneurysms can involve any portion of the aorta between the left subclavian artery and the diaphragm. Thoracoabdominal aneurysms may involve the entire thoracoabdominal aorta from the origin of the left subclavian artery to the aortic bifurcation, or they may involve only portions of the thoracic and abdominal segments. The Crawford classification of TAAAs (Fig. 54-5)

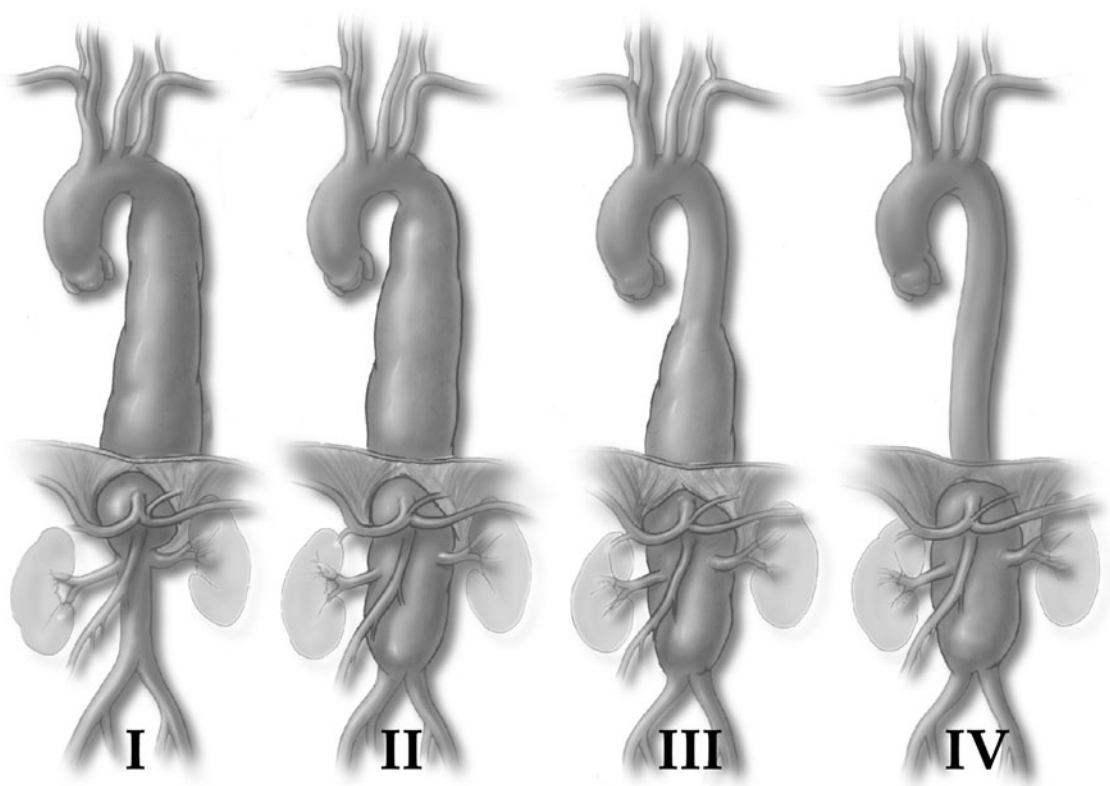

Figure 54-5. The Crawford classification of thoracoabdominal aortic aneurysms.

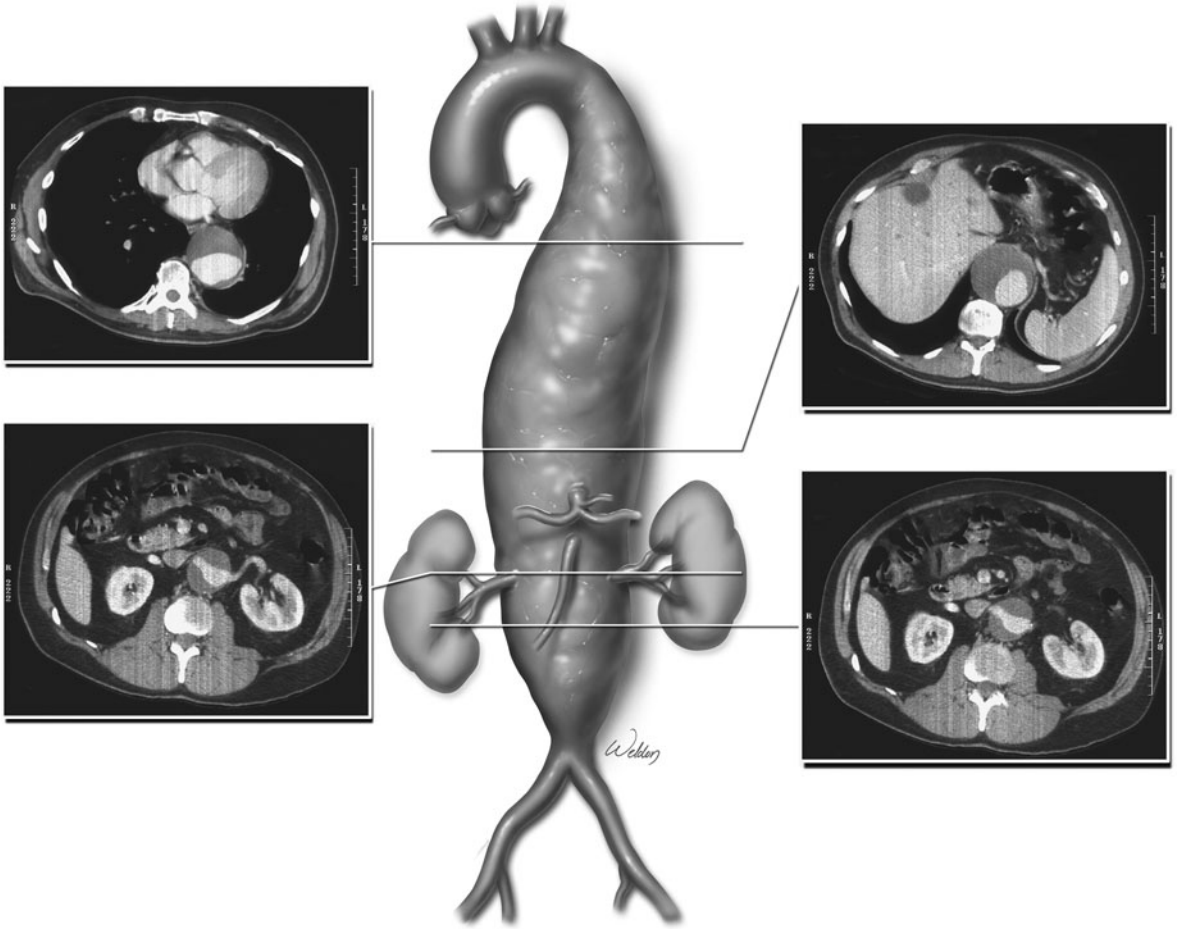

Figure 54-6. Drawing and contrast enhanced computed tomography images of a degenerative extent II thoracoabdominal aortic aneurysm with extensive intraluminal thrombus.

permits standardized reporting of the extent of aortic involvement, thereby allowing appropriate risk stratification, choice of specific treatment modalities based on the extent of the aneurysm, and a type-specific determination of the risks for neurologic deficits and other morbidity and mortality associated with TAAA repair. Extent I aneurysms involve most or all of the descending thoracic aorta and the upper abdominal aorta. Extent II aneurysms involve most or all of the descending thoracic aorta and extend into the infrarenal abdominal aorta. Extent III aneurysms involve the distal half or less of the descending thoracic aorta and varying portions of the abdominal aorta. Extent IV aneurysms involve most or all of the abdominal aorta.

Cross-sectional imaging techniques are the primary means of visualizing the thoracic and abdominal aorta and determining aneurysmal diameter and extent. Computed tomography (CT) scanning and magnetic resonance angiography (MRA) enable clinicians to obtain excellent images without the potential morbidity or cost associated with angiography.[20] CT scanning is widely available and can image the entire thoracic and abdominal aorta, major branch vessels, and virtually all adjacent organs.[21] Computer programs can construct sagittal, coronal, and oblique images, as well as three-dimensional reconstructions, from CT data.[22–24] Contrast-enhanced CT scanning also provides information about the aortic lumen, intraluminal thrombus (Fig. 54-6), presence of aortic dissection (see Fig. 54-2), intramural hematoma, mediastinal or retroperitoneal hematoma, aortic rupture, and periaortic fibrosis associated with inflammatory aneurysms.[25] CT angiography with multiplanar reconstruction is especially useful for planning endovascular procedures. Advantages of CT include being less expensive and somewhat quicker to perform than MRA, and at present, the wider availability of CT expertise. Also, CT can be used with patients who have implanted ferromagnetic prostheses or other devices, which can cause image artifacts or injury in patients undergoing MRA.[26] Advantages of MRA include its use of nontoxic gadolinium instead of a nephrotoxic contrast agent, the fact that it does not expose the patient to ionizing radiation, and its ability to reveal pathology within the aortic wall, including intramural hemorrhage.

Ongoing improvements in noninvasive imaging modalities have substantially reduced the role of catheter aortography in assessing thoracic aortic aneurysms. However, catheter aortography remains useful in situations where noninvasive

methods are not feasible—for example, when artifact or heavy calcification obscures the area of interest.[27] Anterior, posterior, oblique, and lateral views provide detailed information about branch vessels. The risks of aortography include renal toxicity from the large volumes of contrast material required to adequately fill large aneurysms. There is also a risk of embolization from laminated thrombus secondary to manipulation of intraluminal catheters. Angiography can be helpful in patients with suspected renal or visceral ischemia, aortoiliac occlusive disease, horseshoe kidney, or peripheral aneurysms.

Indications for Operation

In asymptomatic patients, the decision to consider surgical repair is based primarily on the diameter of the aneurysm. To prevent fatal rupture, elective operation is recommended when diameter exceeds 5 to 6 cm or when the rate of dilatation exceeds 1 cm per year. In patients with connective tissue disorders, such as Marfan syndrome and related disorders, the threshold for operation is lower for both absolute size and rate of growth.[5] Nonoperative management—which consists of strict blood pressure control, cessation of smoking, and at least yearly surveillance with imaging studies—is appropriate for asymptomatic patients who have small aneurysms. Symptomatic patients, however, are at increased risk of rupture and warrant expeditious evaluation and urgent aneurysm repair, even when the above threshold diameters have not been reached. The onset of new pain in a patient with a known aneurysm is particularly concerning and often heralds significant expansion, leakage, or impending rupture. Malperfusion caused by chronic dissection is also an indication for TAAA repair. Degenerative DTAAs and TAAAs with superimposed acute dissection are especially prone to rupture and are therefore treated with emergent operation.

Open Repair versus Endovascular Repair

An evolving aspect of selecting appropriate treatment in these patients is the choice between performing an open repair, an endovascular repair, or a combined procedure. Two major factors that clinicians consider when deciding between open and endovascular aneurysm repair are the patient's physiologic reserve and vascular anatomy.[28] The open repairs described in this chapter are ideal for directly addressing complex anatomy but require considerable physiologic reserve.

Endovascular repairs—which are covered in detail in a subsequent chapter—are associated with less physiologic strain than are open surgical approaches but may not provide durable repair in patients with complex anatomy. The use of endovascular surgical options for treating DTAAs is rapidly increasing.[29–34] This less invasive approach has been used in patients with aortic dissection and traumatic, mycotic, and ruptured DTAAs.[35–37] Repairing DTAAs with stent grafts is an attractive alternative to standard open procedures in selected patients with compromised cardiac, pulmonary, or renal status, who have undergone previous complex thoracic aortic procedures, or who are very elderly. Recent data show that in general, endovascular repair of the descending thoracic aorta is associated with less early mortality and morbidity than is open repair.[29–32] Appropriate anatomy, however, is critical for successful endovascular repair. Landing zones that have inadequate length, excessive angulation, extensive intraluminal thrombus, or severe vessel calcification will not allow secure endograft fixation, precluding endovascular repair. Furthermore, the long-term durability of these repairs remains unclear, particularly in patients with complex aortic disease, such as chronic aortic dissection or connective tissue disorders. In contrast with endovascular DTAA repair, pure endovascular treatment of thoracoabdominal aortic disease—which often requires the use of fenestrated or branched endografts to maintain branch vessel perfusion while the aneurysm is being excluded—remains rare and purely experimental.[38–42]

Combining open and endovascular procedures capitalizes on the principal benefits of both by creating durable repairs in patients with complex anatomy while minimizing physiologic stress and postoperative complications. Accordingly, combined approaches—commonly called "hybrid" procedures—appear well-suited for patients with limited physiologic reserve (precluding standard open repair) and complex aneurysmal anatomy (precluding standard endovascular repair). For example, in patients with DTAAs that have an insufficient proximal landing zone, an open procedure to reroute the brachiocephalic circulation can convert the aortic arch into a satisfactory landing zone for a stent-graft.[43] Thoracoabdominal aortic aneurysms have also been repaired using hybrid approaches: open visceral bypass grafting to secure organ perfusion is followed by stent-graft coverage of the entire aneurysm, including branch vessel ostia.[44–47] Although hybrid procedures are feasible and appear to be associated with reduced postoperative morbidity and mortality, the durability of these repairs is unclear.

PREOPERATIVE EVALUATION

In each patient, the indications for operation discussed above are weighed against the risks posed by surgical intervention.[48,49] An adequate preoperative assessment of physiologic reserve is critical in evaluating operative risk. With the exception of patients who require emergency operation, patients undergo a thorough preoperative evaluation, with emphasis on cardiac, pulmonary, and renal function.[50]

Cardiac Status

Impaired myocardial contractility and reduced coronary reserve are common among elderly patients undergoing aortic reconstruction. Patients need substantial cardiac reserve in order to tolerate clamping of the thoracic aorta. Given the prevalence of preoperative cardiac disease and the physiologic strain of aortic clamping, it is not surprising that cardiac complications are a major cause of postoperative mortality. Reports indicate that cardiac disease has been responsible for 49% of early deaths and 34% of late deaths after TAAA repair, attesting to the importance of careful preoperative cardiac evaluation.[12,51]

Several imaging techniques are useful for preoperative screening for cardiac disease. Transthoracic echocardiography is noninvasive and can satisfactorily evaluate both valvular and biventricular function. Dipyridamole-thallium myocardial scanning identifies regions of myocardium that are reversibly ischemic, and it is more practical than exercise testing in this generally elderly population, whose exercise capacity is often limited by concurrent lower extremity peripheral vascular disease. In patients with evidence of reversible ischemia on noninvasive studies, and in those with a significant history of angina or an ejection fraction of 30% or less, cardiac catheterization and coronary arteriography are performed. Patients who have asymptomatic aneurysms and severe coronary artery occlusive disease (i.e., significant left main, proximal left anterior descending, or triple-vessel coronary artery stenosis) undergo myocardial revascularization before aneurysm repair. In appropriate patients, percutaneous transluminal angioplasty is carried out before surgery. If clamping proximal to the left subclavian artery is anticipated in patients in whom the left internal thoracic artery has been used as a coronary artery bypass graft, a left-common-carotid-to-subclavian bypass is necessary to prevent cardiac ischemia when the aortic clamp is applied.

Renal Status

Preoperative renal insufficiency has been a major risk factor for early mortality throughout the history of TAAA repair. It was among the predictive variables selected in Svensson and associates'[52] multivariate analysis of Crawford's complete experience with TAAA surgery in 1509 patients treated between 1960 and 1991. The reports by Acher and coworkers[53] and our group[48] confirm that preoperative renal impairment remains an important predictor of early death. Patients with preoperative renal failure who are being treated with an established hemodialysis program appear to have a level of risk similar to that of patients with normal renal function. Patients with severely impaired renal function who are not on chronic hemodialysis frequently require transient temporary hemodialysis early after operation and are clearly at increased risk for postoperative complications.

Although patients are not rejected as surgical candidates on the basis of renal function, careful assessment of renal function aids in predicting perioperative risk and adjusting treatment strategies accordingly. Renal function is assessed preoperatively by measuring serum electrolytes, blood urea nitrogen, and creatinine. Kidney size and perfusion can be evaluated using the imaging studies obtained to assess the aorta. Patients who have poor renal function secondary to severe proximal renal artery occlusive disease are revascularized at operation by either renal arterial endarterectomy, stenting, or bypass grafting, with the expectation that renal function will stabilize or improve.[51,54]

Because of the nephrotoxic effects of vascular contrast agents, surgery is delayed (if possible) for 24 hours or longer after CT scanning or aortography has been performed. This is especially important in patients with preexisting renal impairment. Strategies to reduce the risk of contrast-induced nephropathy include periprocedural administration of acetylcysteine and intravenous hydration.[55,56] If renal insufficiency occurs or is worsened after contrast administration, the surgical procedure is postponed until renal function returns to baseline or is satisfactorily stabilized.

Pulmonary Status

Pulmonary complications are the most common form of postoperative morbidity in patients undergoing DTAA and TAAA repairs. Most patients undergo pulmonary function screening with arterial blood gases and spirometry. Patients with a forced expiratory volume in 1 second >1.0 L and a partial carbon dioxide pressure <45 mm Hg are satisfactory surgical candidates. In suitable patients, borderline pulmonary function frequently is improved by smoking cessation, progressive treatment of bronchitis, weight loss, and a general exercise program that the patient follows for a period of 1 to 3 months before operation. However, surgery is not withheld from patients with symptomatic aortic aneurysms and poor pulmonary function. In such patients, preservation of the left recurrent laryngeal nerve, phrenic nerve, and diaphragmatic function is particularly important.

OPEN SURGICAL REPAIR

Intraoperative Strategies for Organ Protection

Organ ischemia is a major source of the morbidity related to DTAA and TAAA repair. We currently employ a multimodal approach (Table 54-1) in an attempt to maximize organ protection during these operations (Fig. 54-7).[57] The rationale for and details of several important strategies are discussed below.

Table 54–1.

Current Strategy for Spinal Cord and Visceral Protection During Descending and Thoracoabdominal Aortic Aneurysm Repair

All extents
- Moderate heparinization (1 mg/kg)
- Permissive mild hypothermia (32–34°C, nasopharyngeal)
- Aggressive reattachment of segmental arteries, especially between T8 and L1
- Perfusion of renal arteries with 4°C crystalloid solution when possible
- Sequential aortic clamping when possible

Extent I and II thoracoabdominal repairs
- Cerebrospinal fluid drainage
- Left heart bypass during proximal anastomosis
- Selective perfusion of celiac axis and superior mesenteric artery during intercostal and visceral anastomoses

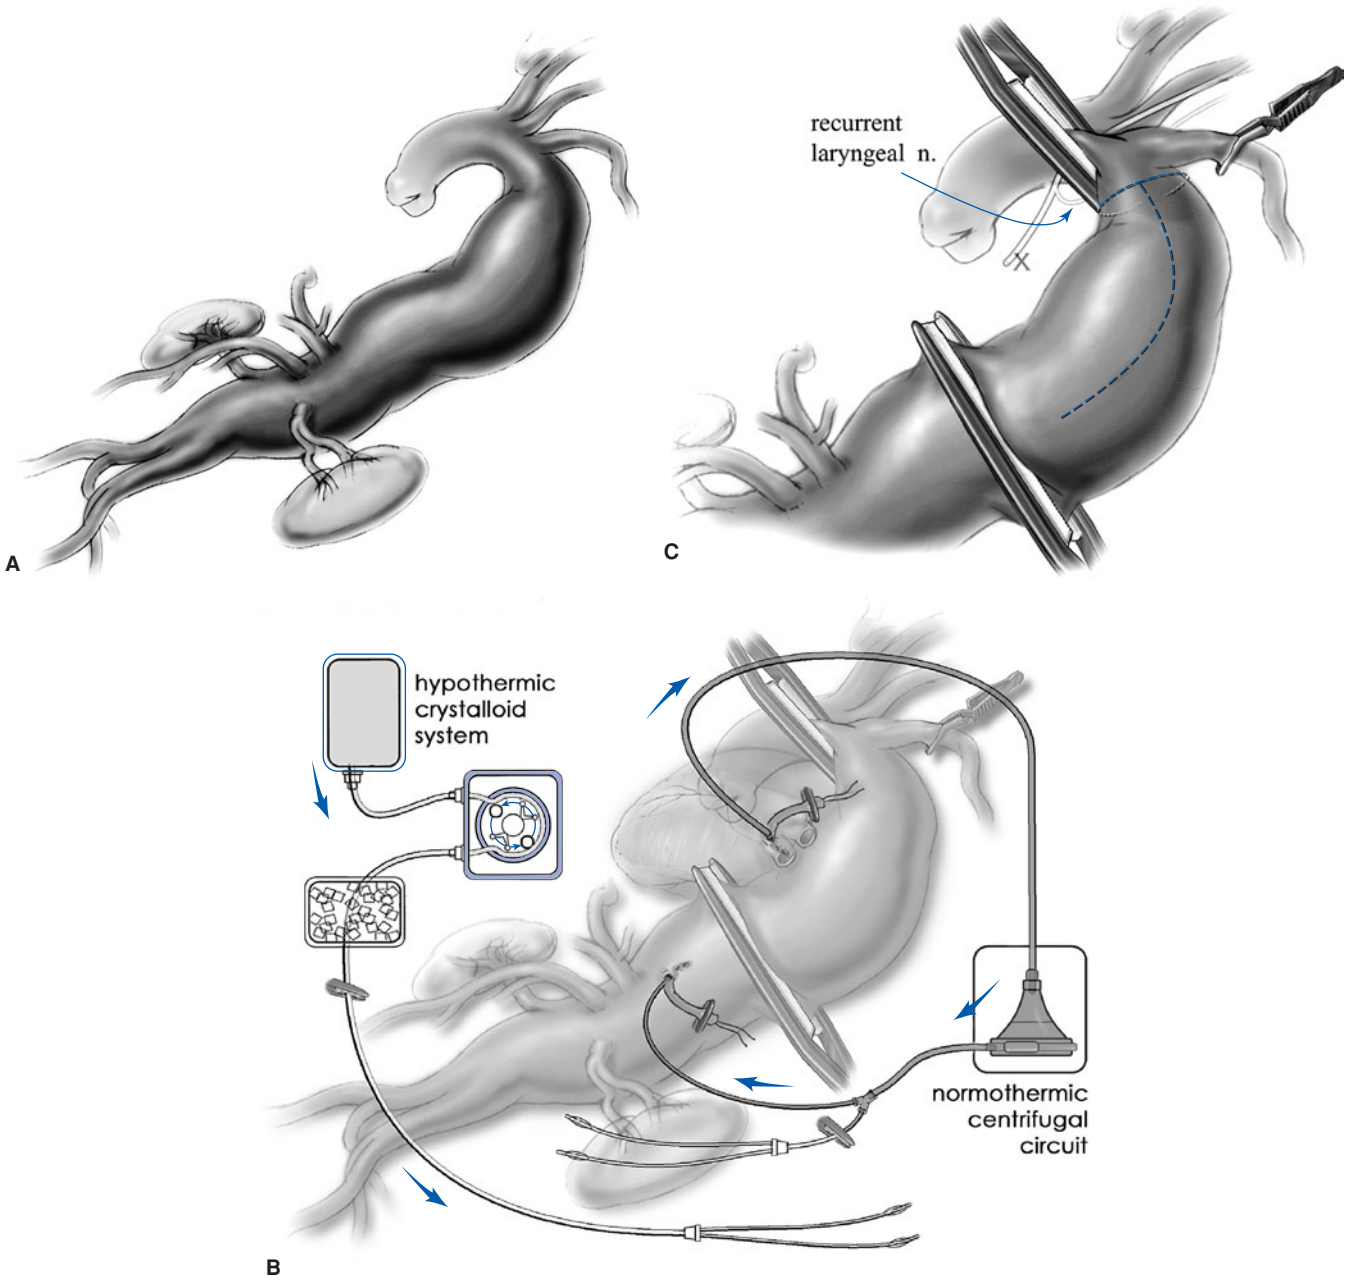

Figure 54-7. Drawings illustrating repair of an extent II thoracoabdominal aortic aneurysm (A) that extends from the left subclavian artery to the aortoiliac bifurcation. (B) The perfusion systems used during the repair are a left heart bypass circuit to provide distal aortic perfusion and a cold renal delivery system to provide selective renal hypothermia. The proximal portion of the aneurysm is isolated between clamps placed on the aortic arch (between the left common carotid and left subclavian arteries), the mid-descending thoracic aorta, and the left subclavian artery. (C) Whenever possible, the phrenic, vagus (indicated by X), and recurrent laryngeal nerves are preserved during the repair. The isolated segment of aorta is opened longitudinally and divided circumferentially a few centimeters beyond the proximal clamp.

Heparin

Heparin (1 mg/kg) is administered intravenously before aortic clamping or the start of left heart bypass (LHB). Potential benefits of heparinization include preserving the microcirculation and preventing embolization. After this small heparin dose is administered, the activated clotting time generally ranges from 220 to 270 seconds. By inhibiting the clotting cascade, the use of heparin may help to reduce the incidence of disseminated intravascular coagulation.

Hypothermia

The benefits of hypothermia during ischemia are well accepted.[58,59] Hypothermia's protective effects are largely

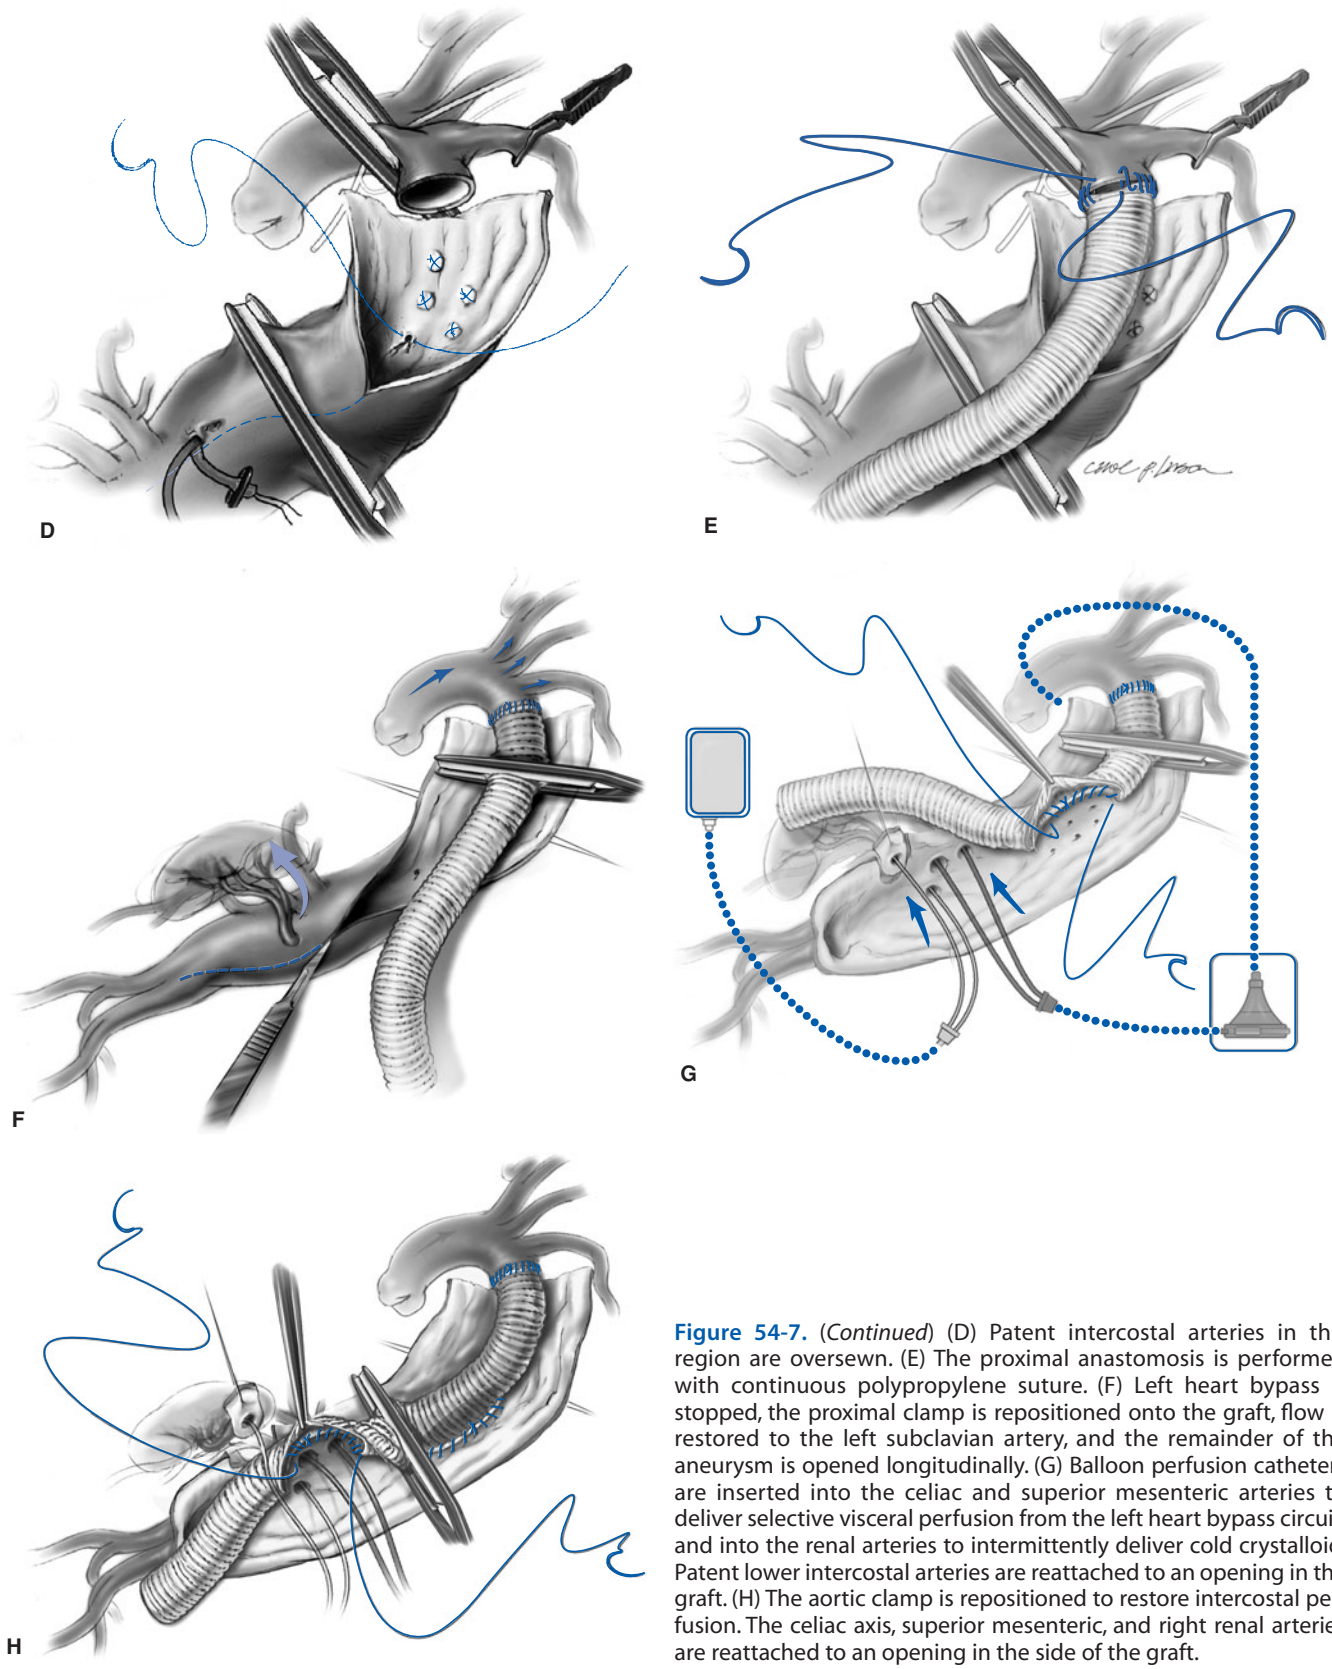

Figure 54-7. (*Continued*) (D) Patent intercostal arteries in this region are oversewn. (E) The proximal anastomosis is performed with continuous polypropylene suture. (F) Left heart bypass is stopped, the proximal clamp is repositioned onto the graft, flow is restored to the left subclavian artery, and the remainder of the aneurysm is opened longitudinally. (G) Balloon perfusion catheters are inserted into the celiac and superior mesenteric arteries to deliver selective visceral perfusion from the left heart bypass circuit, and into the renal arteries to intermittently deliver cold crystalloid. Patent lower intercostal arteries are reattached to an opening in the graft. (H) The aortic clamp is repositioned to restore intercostal perfusion. The celiac axis, superior mesenteric, and right renal arteries are reattached to an opening in the side of the graft.

presumed to be secondary to decreased tissue metabolism and a generalized reduction in energy-requiring processes in the cell. However, the mechanisms may be more complex and involve, for example, membrane stabilization and reduced release of excitatory neurotransmitters.[60,61]

We routinely use mild passive systemic hypothermia during DTAA and TAAA repairs. The patient's temperature is allowed to drift down to a nasopharyngeal temperature of 32 to 33°C. Warm water is used to irrigate the operative field after the aortic repair is completed, thereby reversing the

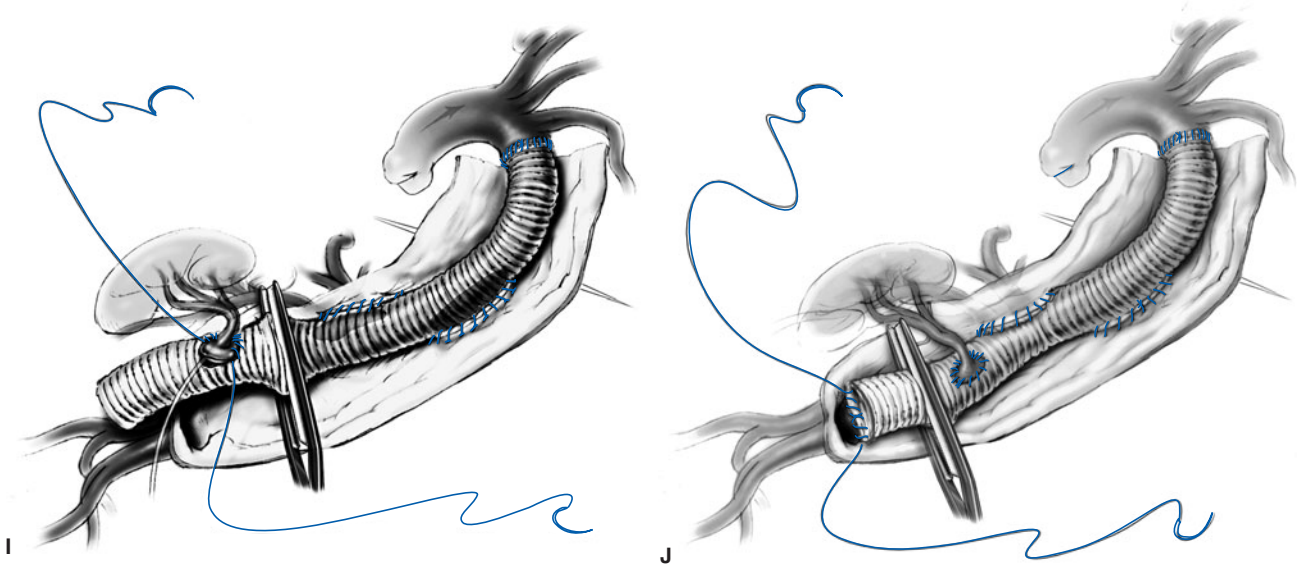

Figure 54-7. (*Continued*) (I) The aortic clamp is repositioned to restore visceral and right renal perfusion. The mobilized left renal artery is reattached. (J) The aortic clamp is repositioned to restore left renal perfusion. The distal anastomosis at the aortoiliac bifurcation completes the repair.

cooling process and initiating slow rewarming of the patient. In patients in whom LHB is used, an in-line heat exchanger in the bypass circuit may be used to rewarm patients and reduce the risk of arrhythmia or coagulopathy, but in our experience this has generally not been necessary.

In addition, whenever possible during TAAA repairs, renal protection is achieved by perfusing the kidneys with cold (4°C) crystalloid (see Fig. 54-7G). We reported on a group of patients who underwent Crawford extent II TAAA repair with LHB and who were randomized either to renal artery perfusion of cold lactated Ringer solution for renal cooling or to normothermic blood perfusion from the LHB circuit.[62] Multivariate analysis confirmed that the use of cold crystalloid perfusion was independently protective against acute renal dysfunction.

Profound systemic hypothermia and regional spinal hypothermia are two alternative methods of employing the protective effects of hypothermia. Kouchoukos and colleagues[63–66] have published several reports showing that hypothermic cardiopulmonary bypass with circulatory arrest can provide safe and substantial protection against paralysis and renal, cardiac, and visceral organ system failure during operations on the thoracic and thoracoabdominal aorta. Despite these protective effects, many clinicians avoid using this approach, principally because of the associated risks of coagulopathy, pulmonary dysfunction, and massive fluid shift.

With regard to regional spinal cord hypothermia, two methods are described in the literature: direct infusion of cold perfusate into the epidural or intrathecal space, and intravascular cold perfusion into isolated thoracic aortic segments (with the expectation that the intercostal vessels will deliver the cold perfusate to the spinal cord). Epidural cooling for regional spinal cord hypothermia is effective in preventing paraplegia after aortic cross-clamping in canine and leporine models.[67–71] Additionally, a series of 337 TAAA repairs reported by Cambria and colleagues[72] showed that, in patients with extent I, II, or III TAAAs, the incidence of spinal cord ischemic injury was reduced from 19.8% to 10.6% after the introduction of epidural cooling at their institution in 1993. A similar technique, cold perfusion into isolated aortic segments, has been tested in animal models to show that cord temperature, and thereby the extent of ischemic spinal cord injury, can be rapidly and effectively reduced by this method.[73,74]

Cerebrospinal fluid drainage

The body of evidence supports using cerebrospinal fluid (CSF) drainage to reduce the risk of ischemic spinal cord injury in TAAA patients, although the mechanisms remain controversial.[75–80] In our study of 145 patients undergoing extent I or II TAAA repair, patients were randomized to CSF drainage or no CSF drainage. Postoperatively, 9 patients (13%) in the control group developed paraplegia or paraparesis, whereas only 2 patients (2.6%) in the CSF drainage group developed such deficits ($p = 0.03$).[81] Additionally, a meta-analysis of eight studies (three randomized controlled trials and five cohort studies) of CSF drainage in TAAA repair found that CSF drainage substantially reduced the incidence of postoperative neurologic impairment ($p < 0.0001$).[82]

Cerebrospinal fluid drainage does carry risks, including intracranial bleeding, perispinal hematoma, and meningitis. Therefore, although we routinely use CSF drainage in patients undergoing Crawford extent I or II TAAA repairs, we do not routinely use CSF drainage during less extensive

repairs, such as DTAA or extent III or IV TAAA repairs, because the risks may outweigh the benefits in these cases.

After induction, an 18-gauge intrathecal catheter is placed through the second or third lumbar space. The catheter permits CSF pressure monitoring and aspiration of fluid throughout the operation and for 2 to 3 days postoperatively. Cerebrospinal fluid is allowed to drain passively from the catheter and is aspirated with a closed collection system as needed to keep the CSF pressure between 8 and 10 mm Hg during the operation, between 10 and 12 mm Hg during the early postoperative period, and between 12 and 15 mm Hg after patients have confirmed that they are able to move their legs.

Segmental artery reattachment

Because of the often tenuous nature of the blood supply to the spinal cord, we take an aggressive approach to reattaching patent segmental arteries. Intimal atherosclerosis, particularly in medial degenerative fusiform aneurysms, obliterates many intercostal and lumbar arteries and complicates matters anatomically. Patent segmental arteries from T7 to L2 are selectively reattached to one or more openings made in the graft (see Fig. 54-7G). Large arteries with little or no back-bleeding are considered particularly important. After intercostal arteries are reattached, the proximal clamp is often moved down the graft to restore intercostal perfusion. When none of these arteries is patent, endarterectomy of the aortic wall and removal of calcified intimal disease can be considered as a means of identifying arteries suitable for reattachment.

Left heart bypass

Disruption of blood flow to the spinal cord and abdominal viscera contributes significantly to the development of ischemic complications. Conversely, maintaining flow through spinal and visceral arteries during all or part of the anatomic repair should reduce the duration of organ ischemia and prevent associated morbidity.[83,84] Borst and associates[85] found that using LHB for distal perfusion during DTAA and TAAA repair effectively unloads the proximal circulation during aortic occlusion and maintains adequate perfusion of distal vital organs, thereby reducing early mortality and renal failure. Furthermore, combined distal perfusion and aggressive reattachment of distal intercostal arteries decreased the risk of spinal cord damage.

Like CSF drainage, LHB appears to provide the greatest benefit to patients undergoing the more extensive repairs. Our own retrospective review of 1250 consecutive repairs of extent I or extent II TAAAs found that LHB (used in 666 cases) reduced the incidence of spinal cord deficits only in patients with extent II repairs,[86] replicating the findings of our previous study of LHB in TAAA repair procedures.[87] In patients undergoing extent I repairs, the incidence of paraplegia was similar in the LHB and no-LHB groups, despite the fact that the LHB group had significantly longer aortic clamp times. This suggests that by providing spinal cord protection, LHB enables the surgeon to spend more time creating secure anastomoses. A propensity score analysis of 387 of our patients who underwent DTAA repair with (n = 46) or without (n = 341) LHB during the construction of the proximal anastomosis found no effect of LHB on postoperative paraplegia and paraparesis rates.[88] Data from series in which LHB and CSF drainage were used together suggest that combining these adjuncts may further reduce rates of spinal cord injury.[89–91]

Because patients with extensive TAAAs (extents I and II) are at greatest risk of developing postoperative paraplegia or paraparesis, we use LHB to provide distal aortic perfusion during the proximal portion of the aortic repair. This is achieved by using temporary bypass from the left atrium to either the femoral artery (most commonly the left) or the distal descending thoracic aorta with a closed-circuit in-line centrifugal pump (see Fig. 54-7B). The left atrial cannula is placed via an opening in the inferior pulmonary vein. Initially, cannulation of the distal descending thoracic aorta (usually at the level of the diaphragm) was used solely as an alternative to femoral artery cannulation in patients with femoral or iliac artery occlusive disease. Because this technique causes few complications and eliminates the need for femoral artery exposure and repair, distal aortic cannulation has become our preferred approach. Careful examination of CT or magnetic resonance images assists selection of an appropriate site for direct aortic cannulation. Areas with intraluminal thrombus are avoided because cannulation could lead to distal embolization. Bypass flows are adjusted to maintain normal proximal arterial and venous filling pressures. Flows between 1500 and 2500 mL/min are generally required. Left heart bypass facilitates rapid adjustment of proximal arterial pressure and cardiac preload, thereby reducing the need for pharmacologic intervention. Because LHB effectively unloads the left ventricle, it is useful in patients with suboptimal cardiac reserve.

Selective visceral perfusion

Distal aortic perfusion can only provide flow to the mesenteric and renal branches during the initial portion of a TAAA repair. However, after the aorta is opened adjacent to the visceral branches, selective visceral perfusion can be delivered through separate balloon perfusion catheters that are placed within the origins of the celiac, superior mesenteric, and renal arteries; these catheters are attached to the LHB circuit using a Y-line off the arterial perfusion line (see Fig. 54-7B). This provides oxygenated blood to the abdominal viscera while the intercostal and visceral branches are reattached to the graft (see Figs. 54-7G and H). With this technique, the total mesenteric and renal ischemic times can be reduced to just a few minutes during even the most complex aortic reconstructions. Reducing hepatic ischemia in this fashion may decrease the risk of postoperative coagulopathy, and reducing bowel ischemia may decrease the risk of bacterial translocation.

Although we continue to use selective perfusion of the celiac and superior mesenteric arteries, we no longer selectively perfuse the renal arteries with blood from the LHB

circuit. Instead, as discussed above, we intermittently infuse cold crystalloid into the renal arteries.[62] Other groups, however, still selectively perfuse the renal arteries. Jacobs and colleagues[92] recently reported the use of distal aortic and selective renal perfusion in 295 patients undergoing TAAA repair. After surgery, only 6% of patients had substantially elevated levels of serum creatinine, which was temporary in all cases. Additionally, only 1% of patients required dialysis, which was also temporary in each case.

Spinal cord monitoring

Motor evoked potential (MEP) monitoring can potentially estimate spinal cord motor neuron function, and thereby motor tract blood supply, during the aortic repair. This monitoring technique involves stimulating the motor cortex or motor neurons and recording the amplitude of the resulting motor response, usually from a peripheral muscle. Monitoring of MEPs, which was approved by the U.S. Food and Drug Administration in 2003 for use in the intraoperative monitoring of spinal cord function in TAAA patients, has generally been found to be more sensitive to spinal cord ischemia and more predictive of adverse neurologic events than is somatosensory evoked potential monitoring.[93–95] The method requires special anesthetic techniques, because complete neuromuscular blockade does not allow the degree of motor activity necessary for myogenic MEP monitoring. This technique is generally used in conjunction with LHB.

The results of several studies suggest that monitoring MEPs to guide the use of spinal perfusion-enhancing measures (e.g., reattaching more segmental arteries, increasing distal and proximal perfusion pressures, and enhancing CSF drainage) improves the outcome of TAAA and DTAA repair. For example, Jacobs and colleagues[96] published excellent results in a series of 184 patients undergoing TAAA repair with a protocol that included LHB, CSF drainage, and MEP monitoring. The authors found that MEP was a sensitive technique for assessing spinal cord ischemia and identifying the segmental arteries that critically contribute to spinal cord perfusion. With this protocol, the incidence of neurologic deficits after TAAA repair was 2.7%. Other series of TAAA and DTAA repairs have found similarly low rates of postoperative paraplegia and paraparesis when MEP is used in this fashion.[95,97]

Incisions and Aortic Exposure

A fundamental principle of surgical DTAA and TAAA repair is the importance of adequate exposure.[98] Exposure is optimized when the patient is placed in a modified right lateral decubitus position with the shoulders placed at 60 to 80° and the hips flexed to 30 to 40° from horizontal. The patient is stabilized in this position with a beanbag. Selective ventilation of the right lung and deflation of the left lung are ideally achieved by using a double-lumen endobronchial tube. Deflating the left lung reduces retraction trauma to the lung, improves exposure, and alleviates the risk of cardiac compression.

Aneurysms limited to the descending thoracic aorta are approached through a full posterolateral thoracotomy (Fig. 54-8A). In most cases, the left pleural space is entered through the sixth intercostal space. When the aneurysm predominantly involves the upper portion of the descending thoracic aorta, using the fifth intercostal space improves access to the distal aortic arch. Exposure of the distal descending thoracic aorta is enhanced by dividing the costal margin.

The thoracoabdominal incision varies in length and level, depending on the anticipated extent of aortic replacement. When the aneurysm extends into the superior aspect of the thorax (as in extents I and II), the upper portion of the thoracoabdominal incision is made through the sixth intercostal space; the upper or lower ribs may be divided posteriorly to achieve additional proximal or distal exposure, respectively, as needed. The posterior portion of the incision is made between the scapula and the spinal processes. With extent III aneurysms, an incision through the seventh or eighth intercostal space is made according to the desired level of exposure. In each of these approaches, the incision is gently curved as it crosses the costal margin to reduce the risk of tissue necrosis at the apex of the lower portion of the musculoskeletal tissue flap (Fig. 54-9A). In contrast, extent IV aneurysms are approached via a straight oblique incision through the ninth or tenth interspace (Fig. 54-9B). The distal extent of the incision is at the level of the umbilicus. The incision is extended toward the pubis if iliac aneurysms also require repair.

Fixed metal retractors attached to the operating table provide consistent static exposure. For TAAA repairs, the diaphragm is divided in a circular fashion to protect the phrenic nerve and to preserve as much diaphragm as possible. A 3- to 4-cm rim of diaphragmatic tissue is left laterally and posteriorly to facilitate closure when the operation is complete. The abdominal aortic segment is exposed via a transperitoneal approach; the retroperitoneum is entered lateral to the left colon. A dissection plane is developed in the retroperitoneum anterior to the psoas muscle and posterior to the left kidney. Dissection within this plane extends directly to the left posterolateral aspect of the abdominal aorta. The left colon, the spleen, the left kidney, and the ureter are retracted anteriorly and to the right. An open abdominal approach permits direct inspection of the bowel, abdominal viscera, and visceral blood supply after aortic reconstruction is completed. An entirely retroperitoneal approach can be used in patients with a "hostile abdomen" (i.e., patients with multiple prior abdominal operations or a history of extensive adhesions, peritonitis, or both).

The crus of the diaphragm is divided, and the left renal artery is identified but not circumferentially dissected or encircled with a tape. Commonly, a large lumbar branch of the left renal vein courses posteriorly around the aorta. This branch may be ligated and divided as needed. If a retroaortic left renal vein is encountered and the aortic repair must extend below the vein, portions of the vessel are isolated with

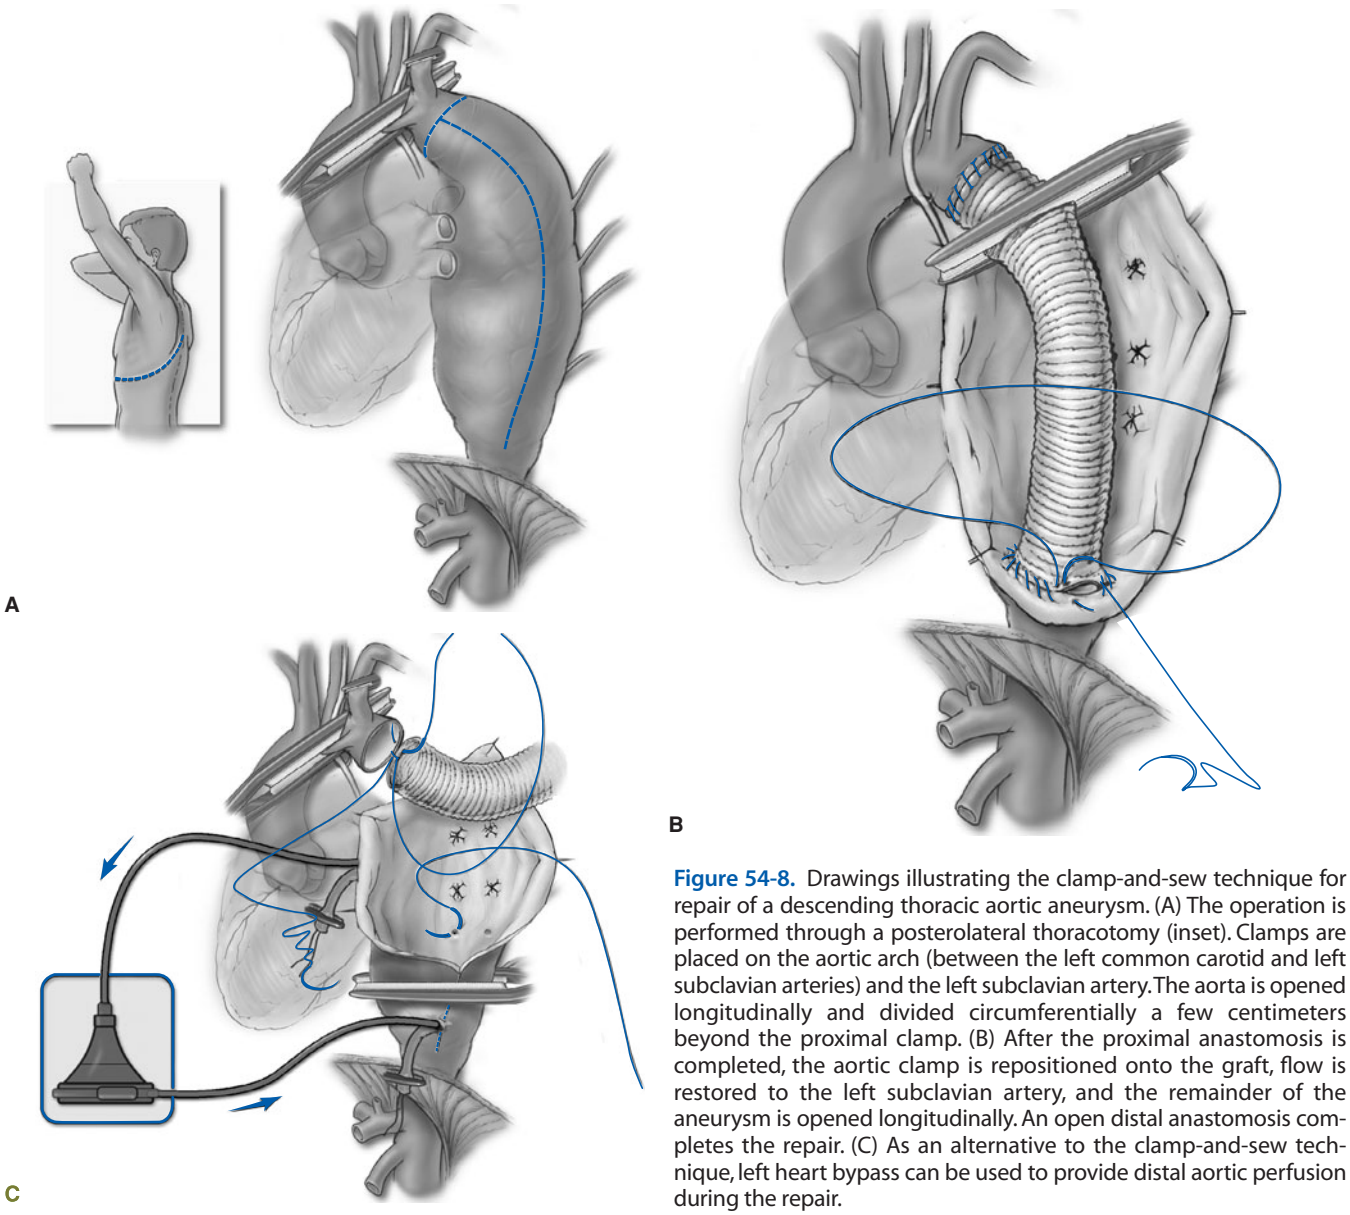

Figure 54-8. Drawings illustrating the clamp-and-sew technique for repair of a descending thoracic aortic aneurysm. (A) The operation is performed through a posterolateral thoracotomy (inset). Clamps are placed on the aortic arch (between the left common carotid and left subclavian arteries) and the left subclavian artery. The aorta is opened longitudinally and divided circumferentially a few centimeters beyond the proximal clamp. (B) After the proximal anastomosis is completed, the aortic clamp is repositioned onto the graft, flow is restored to the left subclavian artery, and the remainder of the aneurysm is opened longitudinally. An open distal anastomosis completes the repair. (C) As an alternative to the clamp-and-sew technique, left heart bypass can be used to provide distal aortic perfusion during the repair.

vascular clamps. Direct reanastomosis or interposition grafting of this retroaortic renal vein is necessary if the left kidney appears congested and has distended collaterals.

Management of the Descending Thoracic Aortic Segment

When the aneurysm encroaches on the left subclavian artery, the distal aortic arch is mobilized gently by dividing the remnant of the ductus arteriosus. The vagus and recurrent laryngeal nerves are identified (see Fig. 54-7C). The vagus nerve may be divided below the recurrent nerve to provide additional mobility, thereby protecting the recurrent nerve from injury. Preserving the recurrent laryngeal nerve is particularly important in patients with chronic obstructive pulmonary disease and reduced pulmonary function. If clamping proximal to the left subclavian artery is anticipated, the left subclavian artery is separately and circumferentially mobilized to enable placement of a bulldog clamp.

After heparin is administered, a clamp is applied to the proximal descending thoracic aorta or the distal transverse aortic arch (between the left common carotid and left subclavian arteries) (see Figs. 54-7B and 54-8A). When LHB is being used, a distal aortic clamp is placed between T4 and T7 (see Fig. 54-7C). After the aorta is opened, patent upper intercostal arteries are oversewn (see Fig. 54-7D). In the setting of chronic dissection, the partition between the true and false lumens is completely removed. The aorta is transected 2 to 3 cm beyond the proximal clamp and separated from the esophagus to allow the surgeon to place full-thickness sutures in the aortic wall without injuring the esophagus. A

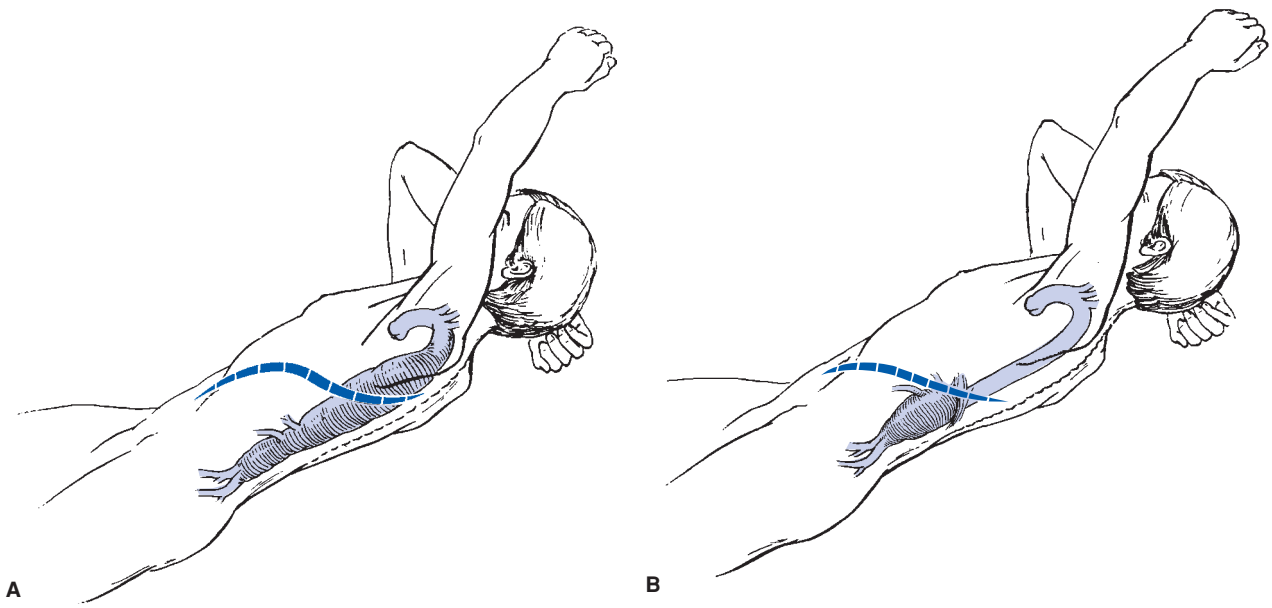

Figure 54-9. Drawings of the typical incisions used in thoracoabdominal aortic aneurysm repairs. (A) A curvilinear incision is used to approach extent I, II, and III thoracoabdominal aneurysms. (B) A straighter, oblique incision is used to approach extent IV thoracoabdominal aortic aneurysms.

22- or 24-mm gelatin-impregnated woven Dacron graft (Vascutek USA, Inc., Ann Arbor, Mich) is used in most patients. The proximal anastomosis is performed with continuous polypropylene suture (see Fig. 54-7E). Most anastomoses are made with 3-0 polypropylene suture; however, in patients with particularly fragile aortic tissues, such as those found in patients with acute aortic dissection or Marfan syndrome, 4-0 polypropylene sutures are commonly used. Felt strips are generally not used; instead, intermittent polypropylene mattress sutures with felt pledgets are used to reinforce selected portions of the anastomoses. The use of surgical adhesives is avoided in these operations.

After the proximal anastomosis is completed, the entire remaining aneurysm is opened longitudinally (see Fig. 54-7F). For repairs that extend to the diaphragm or beyond, patent lower intercostal arteries are selected and reattached to an opening cut in the side of the graft (see Fig. 54-7G). In DTAA repairs, the distal anastomosis is then performed (see Fig. 54-8B). A distal clamp is not used, allowing an "open" anastomosis.

Elephant trunk repairs

A staged operative procedure is preferred in patients presenting with extensive aneurysmal disease involving the ascending aorta, aortic arch, and descending thoracic or thoracoabdominal aorta. When the DTAA or TAAA is not causing symptoms and is not substantially larger than the ascending aorta, the proximal aortic repair is performed first. This allows treatment of valvular and coronary artery occlusive disease during the first operation.

In these patients, the elephant trunk technique described by Borst and colleagues[85] is employed (Fig. 54-10). In this technique, the ascending and transverse aortic arch are replaced first, leaving a segment of graft suspended within the proximal descending thoracic aorta to be used in the second procedure.[99] This technique permits access to the distal graft during the second operation without the need to dissect in and around the distal transverse aortic arch. This reduces the risk of injury to the left recurrent laryngeal nerve, esophagus, and pulmonary artery.

Reversed elephant trunk repairs

Conversely, in patients with similarly extensive aneurysmal disease who present with a DTAA or TAAA that has ruptured, causes symptoms (e.g., back pain), or is considerably larger than the ascending aorta, the DTAA or TAAA is treated during the initial operation, and the ascending aorta and transverse aortic arch are repaired in a second procedure. During this "reversed" elephant-trunk repair (Fig. 54-11), a portion of the proximal end of the aortic graft is inverted down into the lumen during the first operation and is later used to facilitate second-stage repair of the ascending and transverse aortic arch.[100,101]

Repairs requiring hypothermic circulatory arrest

In some cases, the upper descending thoracic aorta cannot be safely clamped because it is too large, or because the aneurysm has ruptured. Hypothermic circulatory arrest is used in these situations.[63–66] Cardiac bypass is usually established using the femoral vessels. A cannula connected to a Y-limb from the venous line is placed in the left atrium via a pulmonary vein; this enhances venous drainage and prevents cardiac distention. After the patient has been cooled to electrocerebral silence, circulatory arrest is initiated, the

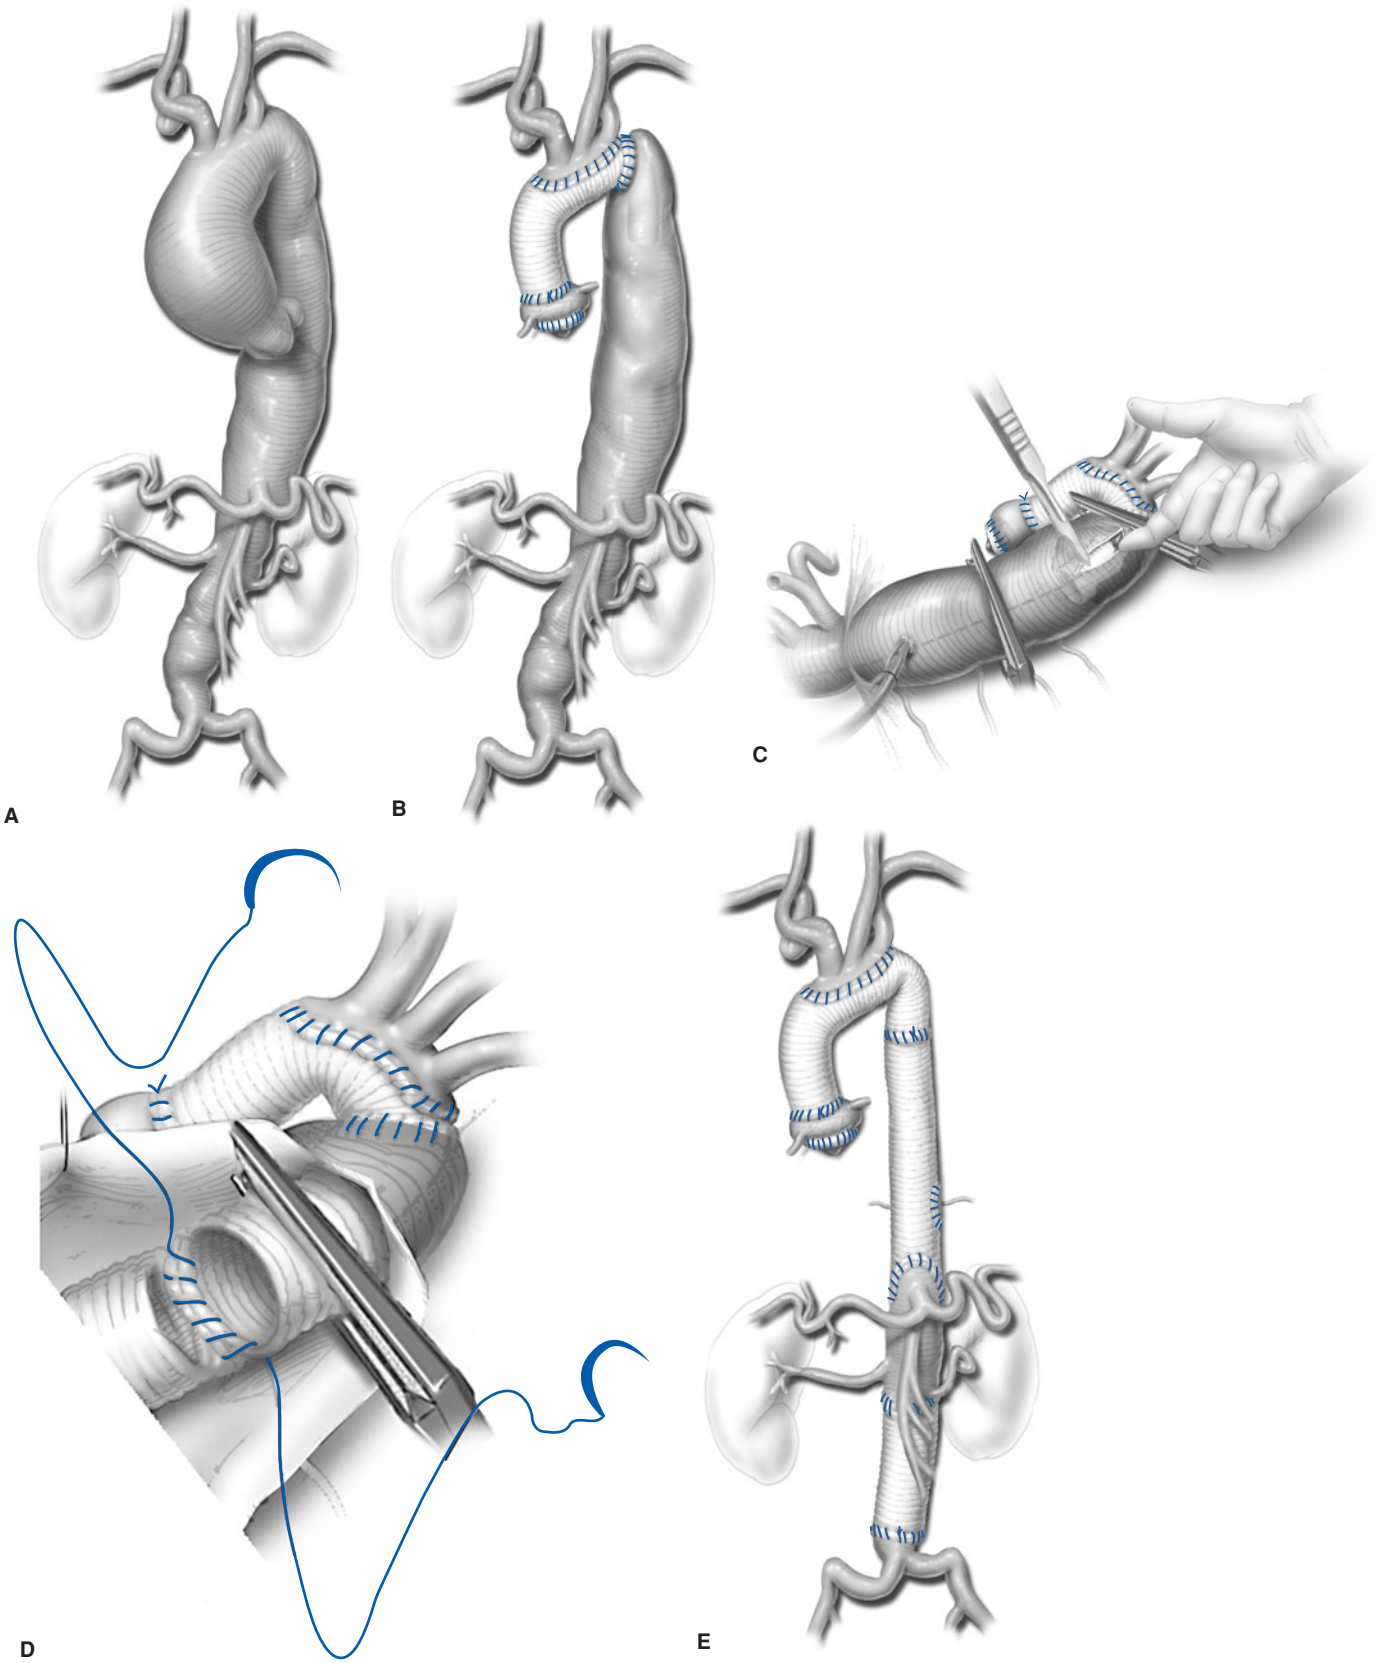

Figure 54-10. Drawings illustrating the two-stage elephant trunk repair of an extensive aneurysm (A) involving the ascending, transverse arch, and entire thoracoabdominal aorta. (B) The first stage includes graft replacement of the ascending aorta and transverse aortic arch. A segment of the graft (the trunk) is left suspended within the aneurysmal descending thoracic aorta. (C) During the second stage, the graft trunk is retrieved and (D) used for the proximal anastomosis. (E) The completed repair includes reattachment patches for a pair of intercostal arteries and the visceral arteries.

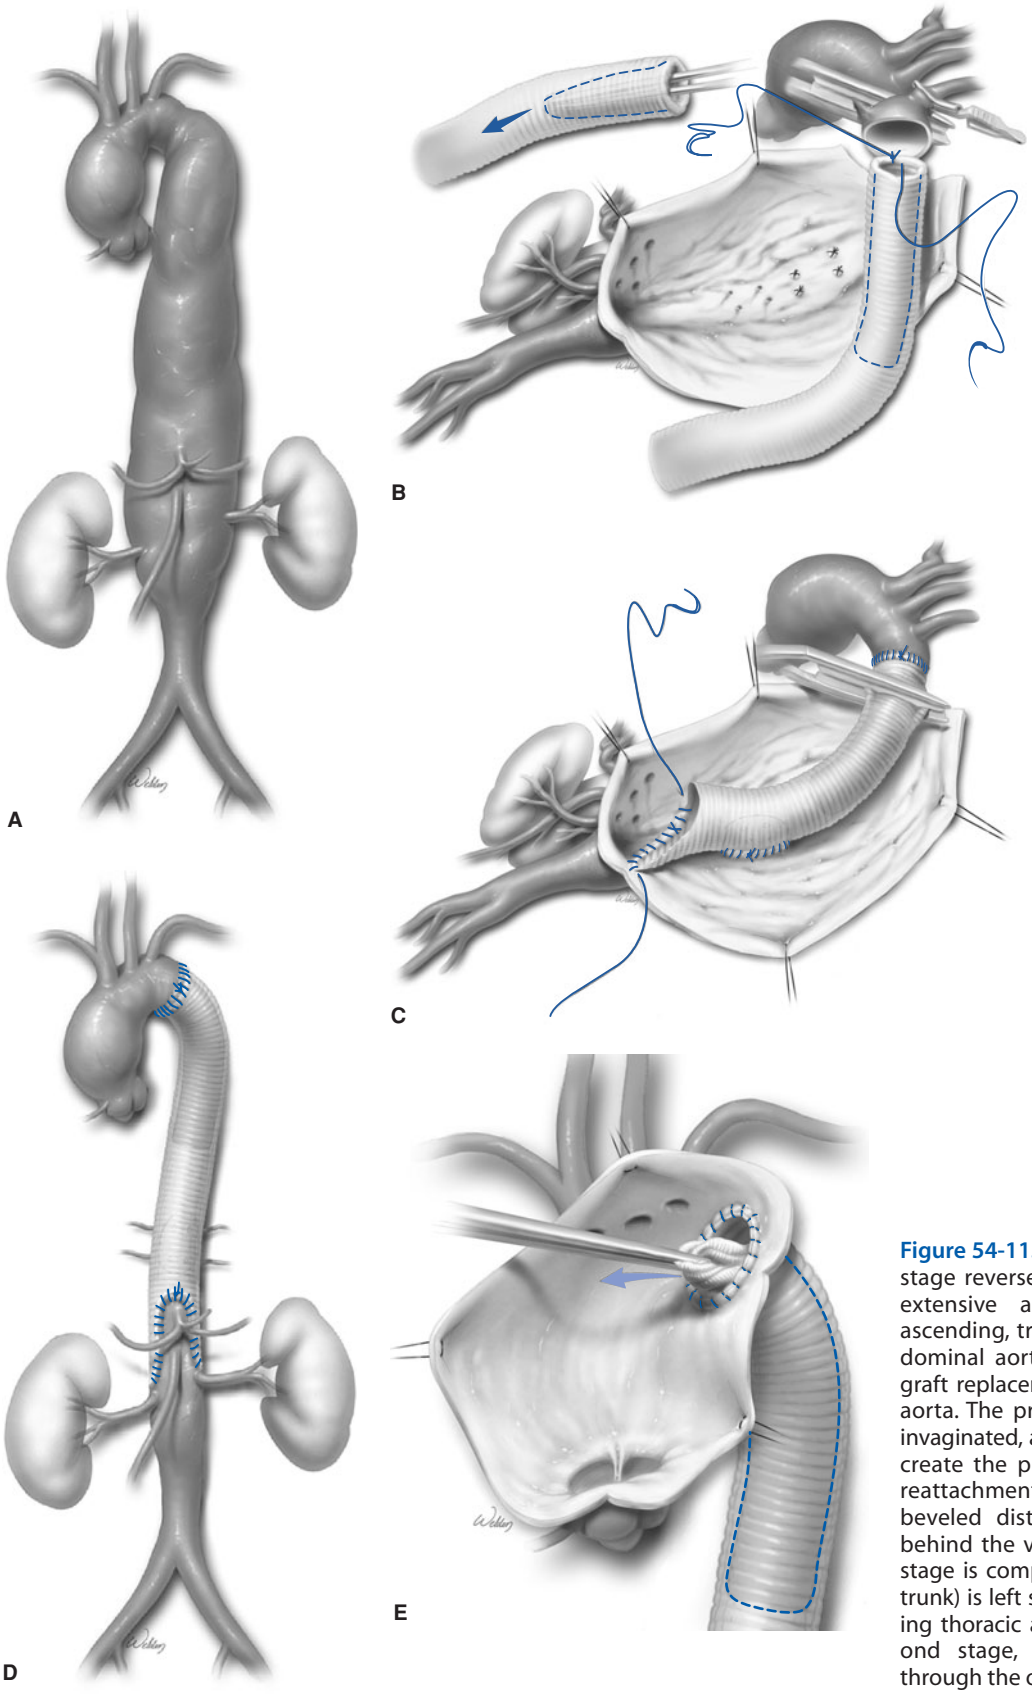

Figure 54-11. Drawings illustrating the two-stage reversed elephant trunk repair of an extensive aneurysm (A) involving the ascending, transverse arch, and thoracoabdominal aorta. (B) The first stage involves graft replacement of the thoracoabdominal aorta. The proximal portion of the graft is invaginated, and the folded edge is used to create the proximal anastomosis. (C) After reattachment of intercostal arteries, a beveled distal anastomosis is performed behind the visceral ostia. (D) After the first stage is completed, a segment of graft (the trunk) is left suspended within the descending thoracic aortic graft. (E) During the second stage, the graft trunk is retrieved through the open aortic arch and

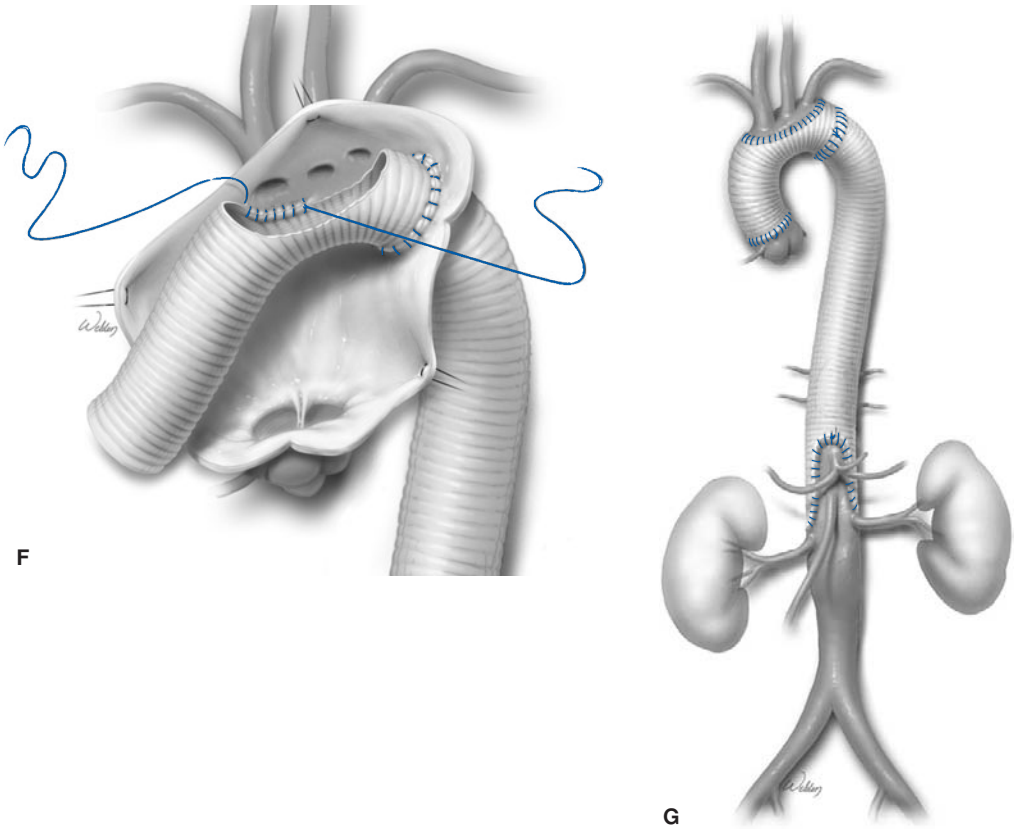

Figure 54-11. (*Continued*) (F) used to replace the arch and ascending aorta, (G) which completes the repair.

aneurysm is opened, and the proximal anastomosis is performed. After completing this anastomosis, a Y-limb from the arterial line is connected to a side branch of the graft. The graft is de-aired and clamped, pump flow to the upper body is resumed, and the remainder of the aortic repair is performed.

Management of the Abdominal Aortic Segment

In patients with TAAAs, after completing the descending thoracic aortic repair, the remainder of the aneurysm is opened longitudinally (see Fig. 54-7F). This incision runs posterior to the left renal artery and continues to the distal extent of the aneurysm. When present, the remaining dissecting membrane is excised. The origins of the visceral and renal branches are identified. Cold saline is intermittently delivered to the renal arteries via balloon catheters (see Fig. 54-7G). In patients receiving LHB, balloon cannulas are also placed in the celiac and superior mesenteric arteries so that selective visceral perfusion can be delivered from the pump circuit. Patent lower intercostal arteries are reattached to an opening in the graft. Subsequently, the celiac, superior mesenteric, and renal arteries are reattached. In extent I repairs, the reattachment of the visceral arteries is often incorporated into a beveled distal anastomosis (see Fig. 54-11C), but in extent II and III repairs, the visceral artery origins are reattached to one or more oval openings in the graft (see Fig. 54-7H). The left renal artery requires attachment to a separate opening in the graft in 30 to 40% of cases (see Fig. 54-7I). Patients with Marfan syndrome are prone to developing aneurysms involving their visceral reattachment patch; a multi-branched graft enables separate bypasses to each of the vessels, thereby minimizing the amount of remaining aortic tissue and reducing the risk of recurrent aneurysms. Multi-branched grafts are also useful in patients with large aneurysms that have caused wide displacement of the celiac, superior mesenteric, and renal arterial ostia (Fig. 54-12). Visceral artery stenosis is encountered in at least 25% of cases and requires endarterectomy (if anatomically suitable), stenting, or interposition bypass grafting.[52,54,102] As the aorta is replaced from the proximal to the distal portion of the aneurysm, the aortic clamp is moved sequentially to lower positions along the graft to restore proximal blood flow. Sequential clamping is occasionally precluded by anatomic facters. When the TAAA extends below the renal arteries, a distal anastomosis is performed near the aortoiliac bifurcation (see Fig. 54-7J).

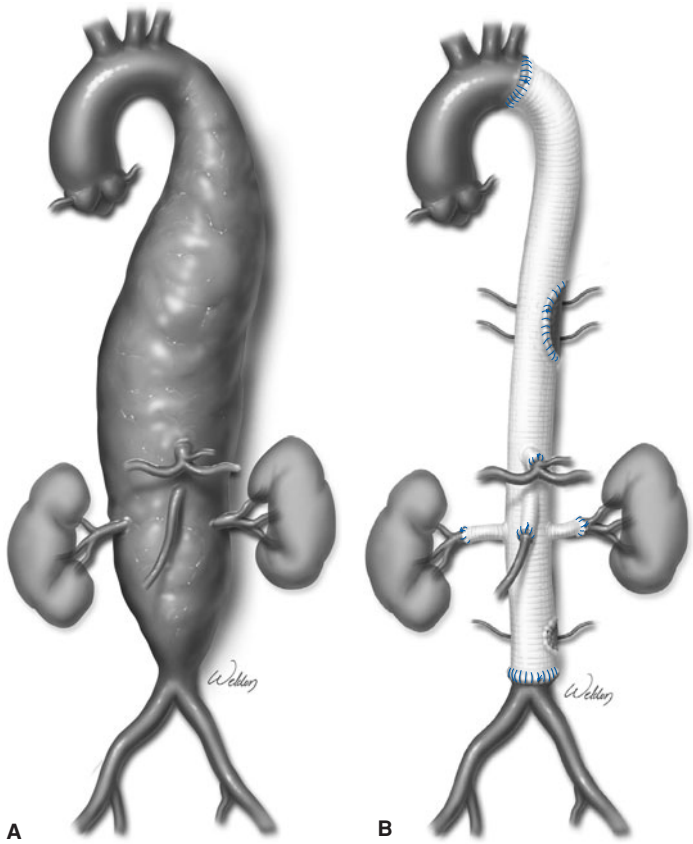

Figure 54-12. Drawings showing (A) a thoracoabdominal aortic aneurysm with wide displacement of the celiac, superior mesenteric, and both renal arterial ostia. (B) The aorta was replaced with a multi-branched graft that facilitated separate reattachment of each of the visceral arteries.

In patients with iliac artery aneurysms, a bifurcation graft is sewn onto the end of the straight graft; the graft's limbs are then anastomosed to the common iliac, external iliac, or common femoral arteries, depending on the extent of disease. Care is taken to preserve circulation to at least one of the internal iliac arteries.

Closure

After aortic unclamping, protamine sulfate is administered to reverse the effects of heparin. It is imperative that adequate hemostasis be achieved and secured at all suture lines. The renal, visceral, and peripheral circulations are assessed. The aneurysm wall is then loosely wrapped around the aortic graft. Two posteriorly located thoracic drainage tubes and a closed-suction retroperitoneal drain are placed before closure. The diaphragm is closed with continuous polypropylene suture; postoperative disruption of the diaphragmatic repair is exceedingly rare.

PERIOPERATIVE COMPLICATIONS

Since 1986, we have performed open surgical repair of 2755 DTAAs or TAAAs. Overall operative mortality was 6.3% (n = 173), which included the 4.7% of patients (n = 130) who died within 30 days of surgery. Complications that are commonly associated with an increased risk of death include paraplegia, renal failure, respiratory failure, cardiac events, and bleeding. The incidence of paraplegia or paraparesis in our series was 3.6% (n = 99), and the incidence of renal failure requiring hemodialysis was 5.1% (n = 140). Return to the operating room for postoperative bleeding was required in 2.5% of patients (n = 69). Early results stratified by the extent of repair are listed in Table 54-2.

Because aortic anastomoses are often extremely fragile during the early postoperative period, even brief episodes of hypertension may disrupt suture lines and cause severe bleeding or pseudoaneurysm formation. Therefore, to protect the integrity of the anastomosis, meticulous blood pressure control is maintained during the first 24 to 48 hours. In most cases, we use nitroprusside and intravenous beta-antagonists to maintain the mean arterial blood pressure between 80 and 90 mm Hg. In patients with severely friable aortic tissue, such as those with Marfan syndrome, we use a target range of 70 to 80 mm Hg. Hypotensive episodes must also be avoided because they can precipitate ischemic complications, including paraplegia and renal failure.
