Nonspecific laboratory abnormalities in WG include anemia, thrombocytosis, and leukocytosis in 30 to 60% of adults. Marked eosinophilia is rare. Rheumatoid factor is positive in a low titer in two-thirds of patients, whereas ANA is present in 10 to 20% of patients. Serum complement levels are normal or increased. Westergren erythrocyte sedimentation rate and C-reactive protein are elevated in 90% of patients with active and generalized disease (15).

Antineutrophil Cytoplasmic Autoantibodies

The most specific serologic test for WG is autoantibodies directed against cytoplasmic constituents of neutrophils and

monocytes. A cytoplasmic staining pattern on indirect immunofluorescence (cANCA) is characteristic of WG. More specific antibody assays, such as enzyme-linked immunosorbent assay (ELISA), have determined that PR3 is the antigen to which the cANCA in WG is most often directed. Although the cANCA test in WG is not specific for PR3, in patients with vasculitis approximately 90% of cytoplasmic ANCA are PR3-ANCA (4). It should be noted that neither cANCA nor anti-PR3 antibodies are specific for WG, as they are found in other forms of vasculitis, including MPA. Therefore, it is generally recommended that both indirect immunofluorescence ANCA testing and more specific ANCA testing be done in the clinical setting of vasculitis.

The likelihood of obtaining a positive ANCA test in patients with WG varies depending on severity and activity of disease. Circulating cANCA are detected in 90% of patients with active, generalized (sinopulmonary and renal) WG and also in 40 to 70% of those with active, regional (sinopulmonary) disease. In contrast, approximately 30 to 40% of patients in remission still have a positive cANCA (15). This emphasizes the need to treat patients based on their clinical findings rather than just the ANCA test.

Differential Diagnosis

The differential diagnosis for regional WG includes acute infectious processes that lead to sinopulmonary symptoms alone. The differential diagnosis for patients with glomerulonephritis and pulmonary hemorrhage (pulmonary-renal syndrome) includes anti-GBM disease, SLE, HSP, and the other ANCA-associated diseases such as MPA and Churg-Strauss disease. Other rarer causes are listed in Table 44.1. Those with skin involvement, abdominal pain, arthralgias, and glomerulonephritis could have HSP, SLE, or an ANCA-associated disease.

Workup

A routine evaluation should start with a complete blood count, electrolytes, blood urea nitrogen, creatinine, albumin, urinalysis, Westergren sedimentation rate, and chest radiograph. Depending on the clinical indication, indirect immunofluorescence ANCA and ELISA ANCA testing for anti-PR3 and anti-MPO antibodies, ANA, C3, C4, and anti-GBM antibody, should be performed. Consideration should also be given to obtaining computed tomography of the sinuses and orbits.

A renal biopsy is essential for proper diagnosis if hematuria, proteinuria, or azotemia is present. It allows the clinician to classify the glomerulonephritis as immune complex mediated, anti-GBM disease, or pauciimmune. In many centers, the biopsy results return more rapidly than immunologic serologies, thereby allowing a more prompt diagnosis. Moreover, approximately 10% of patients with WG are ANCA negative, so serologic testing cannot be relied on exclusively (4). It

FIGURE 44.2. Segmental necrotizing and crescentic glomerulonephritis. (Periodic acid-Schiff stain $\times 125$.)

should be noted that, unlike a biopsy of the lungs or sinuses, a renal biopsy in a patient with WG rarely shows the presence of granulomas (2,15). A kidney biopsy typically shows a pauciimmune-necrotizing and crescentic glomerulonephritis. Immunofluorescence shows scant immunostaining and few, if any, electron-dense deposits on electron microscopy (21). A renal biopsy documenting the focal, necrotizing, and crescentic glomerulonephritis of WG is shown in Figure 44.2.

In a patient with minimal renal disease, another tissue biopsy site may be needed. In the presence of nodules or infiltrates on chest radiograph or computed tomography, lung biopsy is often diagnostic, with patchy necrosis, granulomatous inflammation, and vasculitis seen. In the setting of pulmonary hemorrhage, surgical lung biopsy is much riskier. Fiberoptic bronchoscopy with bronchoalveolar lavage can confirm the presence of blood and/or hemosiderin-laden macrophages. Stains and cultures can be obtained to rule out infection (15,22).

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS) is a systemic necrotizing vasculitis with hypereosinophilia and extravascular granulomas that occurs almost exclusively in patients with asthma (23). It is also characterized as a pauciimmune small vessel vasculitis, being distinguished from MPA and WG by the presence of granulomatous inflammation and asthma, respectively (24). It is a systemic vasculitis that affects the lungs, skin, peripheral nerves, GI tract, heart, and kidneys (25). Unlike WG, CSS is extremely uncommon in children, with only an occasional case report in the literature and no pediatric case series. As a result, most information presented is adult data used in an effort to prepare pediatricians to recognize the rare patient with this disorder.

It has been postulated that CSS occurs in three clinical phases: a prodromal, allergic phase (asthma and/or allergic rhinitis); an eosinophilic phase (tissue and peripheral eosin-

ophilia); and a vasculitic phase (with multiorgan involvement) (26). Six criteria were developed by the American College of Rheumatology in an effort to standardize the diagnosis of CSS for study purposes. The criteria included asthma, eosinophilia (greater than 10% or absolute eosinophil count greater than 1500), mononeuropathy or polyneuropathy, histologic evidence of a vasculitis, paranasal sinusitis, and nonfixed pulmonary infiltrates on chest x-ray.

Two adult studies have helped characterize this disorder (3,25). Asthma was present at the time of presentation in nearly all cases. Mononeuritis multiplex was present in 44 to 77%; constitutional symptoms (weight loss, fever, and myalgias), sinusitis, and allergic rhinitis all occurred in approximately 60% of cases. Skin involvement occurred in 50 to 70% of cases, with palpable purpura being the most common manifestation. Cardiac involvement occurred at presentation in 12.5 to 28.1%, and existed as pericardial effusion, pericarditis, myocarditis, ischemic cardiomyopathy, and conduction abnormalities. The GI tract was involved in 31 to 38% of patients. Abdominal pain was the most common symptom; more severe involvement included intestinal perforation, GI bleeding, and pancreatitis.

Renal involvement (proteinuria, glomerulonephritis, hypertension, renal insufficiency, and renal infarct) was evident in 26% of cases of CSS in one study. A second study reported that 12.5% of CSS patients had renal involvement that included glomerulonephritis, renal insufficiency, and hematuria. Hypertension was present in 16% of patients (3,25).

Laboratory findings consisted of leukocytosis with eosinophilia, and elevated erythrocyte sedimentation rate was present in 80 to 100% of cases, ANA greater than 1:160 was present in 11 to 15%, rheumatoid factor in 24% of patients, and less than 1% had a positive anti-double-stranded DNA with clinical manifestations of lupus (3,25). ANCA testing was positive in 48% of sera from CSS patients using indirect immunofluorescence and was pANCA in the majority of cases (3). ELISA revealed ANCA specificity toward MPO in 10 of 11 cases (3). In another study, IIF ANCA were negative in eight patients with CSS who were in remission and in 78% who were positive during the acute phase of illness (25). It was also noted that only 50% of patients had a positive ANCA in association with a clinical relapse. Chest x-rays revealed patchy infiltrates in 38 to 75% (3,25).

Histologic findings included necrotizing vasculitis (64%), vascular and perivascular eosinophil infiltrates (55%), and extravascular granulomas (15%) in one study (25). Because extravascular granulomas are only infrequently seen on biopsy specimens, it is recommended that this feature of the disease not be required to make the diagnosis. Renal biopsy specimens have shown segmental proliferative glomerulonephritis in some and necrotizing vasculitis with crescents in others; immunofluorescence has been negative (3,25,27).

Treatment consisted of prednisone alone or usually in accompaniment with cyclophosphamide (CYP). CYP treat-

ment lasted 1.0 to 1.5 years and was most often given orally. Plasma exchange has been studied and does not appear to have additional benefit to that of corticosteroids and CYP (28).

Clinical outcome in adults was favorable. In one study of 32 patients, the patient survival was 94% at 1 year and 90% at 5 years. Four deaths occurred—three directly related to vasculitis (intestinal perforation in two patients and severe cardiac, GI, and renal involvement) and one related to a nosocomial infection. Remissions occurred in all patients, and relapses occurred in 28% of patients; approximately one-half of these relapses occurring in the first year of therapy (25). Long-term prognosis in another study correlated with myocardial involvement, proteinuria greater than 1 g/24 hr, and severe GI tract involvement including GI hemorrhage, intestinal perforation, pancreatitis, or laparotomy (3).

Microscopic Polyangiitis

The distinction between MPA and the other ANCA-associated diseases has been discussed. In brief, it is a nongranulomatous, multisystem, pauciimmune, small vessel vasculitis without upper airway involvement. There is significant overlap with WG in terms of organ system involvement. It is associated with ANCA in more than 80% of patients. pANCA on indirect immunofluorescence is most common and more specifically on MPO. Owing to the small number of ANCA-associated diseases reported in pediatrics, most specifics are derived from adult studies. As previously mentioned, because the Chapel Hill Conference has set stricter diagnostic criteria, future pediatric studies are likely to attempt to more carefully distinguish the various ANCA-associated small vessel vasculitides.

MPA can often mimic cPAN histologically, as both diseases are capable of producing a necrotizing arteritis. The key distinction is in the size of the vessels involved. Because MPA is a small vessel vasculitis, it is capable of affecting arterioles, capillaries, and postcapillary venules. This clinically results in alveolar capillaritis (pulmonary hemorrhage), glomerular capillary inflammation (glomerulonephritis), and inflammation of the dermal postcapillary venules (leukocytoclastic angiitis resulting in purpura). By definition, MPA can affect medium vessels, but cPAN is restricted from affecting vessels smaller than this size (1, reviewed in 4).

A study from Chapel Hill of 107 patients with necrotizing glomerulonephritis who met criteria for MPA was followed prospectively for an average of 2.5 years. Indirect immunofluorescence revealed that 65% were pANCA (+) and 35% cANCA (+) are ANCA positive. Twelve disease-related deaths occurred, and 46 patients reached ESRD. The patients had pulmonary involvement in 36% of cases and cutaneous involvement in 12%. Mortality risk factors were analyzed and revealed that those patients presenting with pulmonary hemorrhage had a relative risk (RR) of

death of 8.6. Other risk factors of statistical significance included increased mortality when cANCA pattern was present (as compared to pANCA; RR, 3.8). A protective effect of CYP treatment was seen when compared to corticosteroids alone (RR, 0.18; $p = .012$). Predictors of need for renal replacement therapy were statistically associated with serum creatinine at the time of study entry and African American race (29). This study thus clearly highlighted the potential morbidity and mortality of this disease.

In another adult study using Chapel Hill criteria, patients with WG ($N = 56$) were compared to those with MPA ($N = 67$). ANCA testing on patients with WG revealed 87% were PR3 (+), 11% MPO (+), and 2% ANCA negative. Those with MPA showed that 39% were PR3 (+), 56% MPO (+), and 5% ANCA negative. Patients with WG were more likely to have upper respiratory and pulmonary disease. Relapses and renal outcomes were similar in both groups (30).

Finally, the French Vasculitis Study Group conducted a recent retrospective study of 85 adults meeting Chapel Hill criteria for MPA. ANCA testing was positive in 75%; 65% were pANCA (+) and 10% were cANCA (+). Constitutional symptoms were prevalent with fever in 55% and anorexia or weight loss in 73% of patients. Renal disease was present in 79%, skin involvement in 62% (purpura in 41%), and mononeuritis multiplex in 58%. Deaths occurred in nearly one-third of patients followed 70 months, most owing to vasculitis or infection (31).

In another study looking at causes of pulmonary renal syndromes in adult patients, serologic testing found that 48 of 88 patients were ANCA positive (PR3—19 patients; MPO—29 patients), 6 patients had exclusively anti-GBM disease, 7 others had both ANCA and anti-GBM antibodies, and 27 patients had neither antibody. The authors noted that only eight of these patients had clinical or histologic evidence to support a diagnosis of WG (32). By Chapel Hill criteria, then, MPA was the most common identifiable cause of pulmonary renal syndrome in adults.

Pediatric reports of this entity are rare. Similar to adults, pediatric patients can present with life-threatening pulmonary hemorrhage as part of the pulmonary renal syndrome. In addition to these organ systems, a recent case report was published of an adolescent female with a pANCA (+) pauciimmune crescentic glomerulonephritis who presented in renal failure with cerebral vasculitis (seizures with multifocal ischemic defects on magnetic resonance imaging). The CNS manifestations of this patient's disease responded to CYP and plasma exchange (33).

In summary, the prognosis of MPA appears similar to WG. Although granulomatous inflammation does not occur, it is often the sinopulmonary symptoms of WG that result in patients seeking medical attention. The relative reduction of these symptoms means patients with MPA may be more apt to present with advanced disease. Because patients with advanced disease tend to have a poor out-

come, a high index of suspicion for MPA (ANCA disease) is needed to minimize long-term morbidity.

Treatment of Antineutrophil Cytoplasmic Autoantibody–Associated Glomerulonephritis and Vasculitis—Wegener Granulomatosis, Microscopic Polyangiitis, and Churg Strauss Disease

The mainstay of treatment for ANCA-associated diseases includes a combination of corticosteroids and cytotoxic agents. Because the dosages and the manner of administration can vary according to the stage of treatment, the treatment section is separated into three parts: acute supportive treatment, induction therapy, and maintenance therapy.

Acute Supportive Treatment

From an immunosuppressive standpoint, most centers treat adults and children with ANCA diseases with either oral prednisone or intravenous (IV) methylprednisolone. Pulse methylprednisolone at a dose of 7 to 15 mg/kg/dose is often given in three successive daily doses followed by daily prednisone at 1 to 2 mg/kg/day (4,28,34–38). CYP is given in one of two ways. Many centers prefer oral CYP to induce a remission and optimally reduce the incidence of relapses (30,39). Others prefer IV CYP, which is as efficacious at inducing a remission as the oral preparation (4,28,34). IV CYP can be given safely with aggressive hydration along with sodium 2-mercaptoethane sulfonate (MESNA) to minimize the risk of hemorrhagic cystitis. In addition, the cumulative dose tends to be much lower with the IV preparation, which should theoretically result in a reduction in dose-related, long-term malignancy risks. In our pediatric cohort of ANCA (+) glomerulonephritis and vasculitis, those children with a history of pulmonary hemorrhage (defined as life-threatening disease) were treated with oral CYP for fear of the consequences of a catastrophic relapse. All others were treated with IV CYP, except for one child who was changed from IV to oral due to lack of response to IV (38).

Other empiric treatments that have been tried but have not been well studied include plasma exchange and IV immunoglobulin (IVIG) (28,36,40). The former treatment has the theoretical advantage of removing a circulating agent that may be causative, whereas the latter may be immunomodulating (41). Additional supportive treatments such as oxygen, assisted ventilation, transfusion, extracorporeal membrane oxygenation, and dialysis have been used as life-saving measures.

Induction Immunosuppressive Therapy

This phase of treatment has been arbitrarily defined as that occurring between 2 weeks and 6 months after diag-

nosis (38). Prednisone is given typically as 1 to 2 mg/kg/day initially divided b.i.d., which is continued for 1 to 3 months before being tapered. Some centers taper to alternate day prednisone at a dose of 1 to 2 mg/kg/q.o.d. after 2 months of treatment, while others slowly reduce the dose of steroids, which are continued on a daily basis. With regard to the CYP dose, those centers giving monthly IV CYP give an initial dose of 500 to 600 mg/m²/dose with a nadir white blood cell count 10 to 14 days later being used to determine the next dose. Dose increases in increments of 250 mg/m²/dose are then used up to a maximum dose of 1000 mg/m²/dose. Oral CYP is given at a starting dose of 2 mg/kg/day (maximum dose of 150 mg). Dosage reductions are made based on the presence of leukopenia/neutropenia on complete blood cell counts, monitored weekly.

Maintenance Immunosuppressive Therapy

This period has been arbitrarily defined as the period that follows the first 6 months of treatment. The optimal duration of treatment remains debatable. Many adult centers are now stopping corticosteroids 3 to 4 months into therapy and discontinuing all treatment as early as 6 months (42). Other centers use the 6-month cutoff as a time to transition patients to a less toxic regimen and substitute azathioprine (AZA) for CYP at this point. Rottem et al. chose to treat children with oral CYP for 1 year after a remission was achieved before reducing the dosage by 25 mg every 2 months as tolerated (8). Their median treatment time with oral CYP was 28 months. In our cohort of children with ANCA-associated vasculitis and glomerulonephritis, we chose to transition patients to AZA after an approximate 6-month treatment period with IV CYP. A select group of patients who had either a poor response to IV CYP or life-threatening disease at presentation were treated instead with oral CYP, which was continued for 1 year. Those treated with oral CYP were changed at 1 year to either AZA or methotrexate (MTX) in an effort to provide sufficient immunosuppressive therapy while avoiding long-term use of CYP (38).

Newer Therapeutic Regimens

MTX has been used as a substitute for CYP during the induction stage of WG treatment of children and adults (9,43). This agent appears to be reasonably effective (71% remission rate) if selectively used in patients with non-life-threatening forms of WG and when used in conjunction with corticosteroids. MTX dosages in WG range from 0.15 to 0.30 mg/kg/wk in adults, to as high as 0.6 mg/kg/wk in children (9,11). Although AZA has been proven to be inferior to CYP during the induction phase of treatment, it may have its greatest role in “maintaining” a remission state, as has been discussed (2,38). Its main advantage is that it is far less toxic than CYP and is usually well tolerated.

Mycophenolate mofetil (MMF) is a newer antiproliferative immunosuppressive medication that possesses a relatively favorable toxicity profile and a lymphocyte selective mode of action, through inhibition of IMPDH (*inosine monophosphate dehydrogenase*). In a study of 11 adults with ANCA-associated systemic vasculitis (WG = 9, MPA = 2), MMF was substituted for CYP during the maintenance phase of treatment and used with corticosteroids to maintain a remission in 10 of 11 patients followed for 15 months (44). No pediatric reports of MMF usage in WG exist at this time. Certainly, larger studies are needed during the maintenance phase to determine whether MMF will prove efficacious.

Treatment Summary

At the present time, our typical approach to a patient with ANCA (+) vasculitis and glomerulonephritis is to treat with prednisone (1 to 2 mg/kg/day; maximum, 80 mg) for 1 to 2 months before tapering to alternate day dosing schedule. In addition, CYP is given for 6 to 12 months before changing over to AZA. The decision on the duration of CYP is related to the severity of disease at presentation, with patients with non-life-threatening disease typically receiving monthly IV CYP for 6 months in conjunction with corticosteroids. If in remission, the patient is then transitioned to AZA at 2 mg/kg/day while steroids continue to be tapered slowly. Those patients with pulmonary hemorrhage (life-threatening disease) are treated with oral CYP for 1 year in conjunction with corticosteroids. At that point, AZA is again substituted for CYP if the patient is in remission. *Remission* is defined as lack of symptoms, stable renal function, benign urinalysis (except for some proteinuria), and a stable erythrocyte sedimentation rate. A repeat renal biopsy looking for histologic confirmation of inactive disease is usually performed before transitioning a patient off of CYP.

Trimethoprim/sulfamethoxazole has become a mainstay of WG treatment, as it can be used as prophylaxis for *Pneumocystis carinii* pneumonia, which occurred in approximately 4% of adult WG patients from the NIH (11). An additional advantage is its efficacy in reducing respiratory relapses in adults with WG, a fact that may be secondary to treatment of nasal carriage of *Staphylococcus aureus*, which was associated with serious sinopulmonary infections in the early NIH studies (2,45).

Outcome of Antineutrophil Cytoplasmic Autoantibody-Associated Vasculitis and Glomerulonephritis

Despite high remission rates in childhood WG (87%), relapses were frequent (53%) (7). In addition, morbidity from either the disease or its treatment was extremely high (87%). Nasal deformity was common (48%), as was sub-

glottic stenosis (35%), which necessitated subglottic dilatation in two patients and tracheostomy in six others. Renal insufficiency was present in approximately one-third of patients. Treatment-induced morbidity included cystitis (50%) and infertility (28%). Steroid side effects included cataracts and aseptic necrosis. Infections requiring hospitalization and IV antibiotics occurred in 43% of patients. The frequency of infections correlated with the degree of immunosuppression. The lowest rate occurred while off immunosuppression and increased twofold with steroids alone and increased twelvefold during combined steroid and CYP therapy (8). Although no malignancies were reported, longer-term follow-up is clearly needed. Two pediatric deaths were reported (8.7%), occurring 2.2 and 15 years after disease onset. Adult studies have reported a marked increase in bladder carcinomas (11- to 33-fold increased risk) after successful treatment of WG with CYP for at least 1 year (11,30,46). The risk of bladder carcinoma is higher in patients having had hemorrhagic cystitis, again making a case for the use of IV CYP in whom this complication can be largely eliminated by using IV hydration and MESNA.

Outcomes from other more recent studies have been slightly better, but patient selection criteria and treatment protocols have been modified. Of those pediatric cases with ANCA-associated vasculitis and glomerulonephritis, a cumulative incidence of ESRD of 30% has occurred in 20 patients from six clinical reports (9,35,38,47–49). Because these reports are of children with coexisting glomerulonephritis, all patients had renal disease at presentation. Those developing ESRD typically presented with very advanced disease. Seven of these patients were reported from a single center, and a lower incidence of ESRD (14%) was found. Of the remaining 13 patients, the incidence of ESRD was 38%.

Until recently, children with ANCA (+) glomerulonephritis were believed to have an ESRD risk of 30%. This figure was corroborated by a large recent retrospective series of 31 pediatric patients with ANCA (+) glomerulonephritis conducted by members of the Japanese Society for Pediatric Nephrology. All patients were ANCA (+) and had renal biopsy-proven pauciimmune necrotizing and crescentic glomerulonephritis. Ten had renal-limited, necrotizing crescentic glomerulonephritis, and 21 (68%) were classified as MPA. Twenty-six patients (84%) received treatment with corticosteroids and CYP, and five patients with corticosteroids alone; 84% of patients achieved remission, and 39% of responders relapsed in a median of 24 months. Nine of 31 patients (29%) progressed to ESRD; an additional 6 (19.4%) had reduced renal function, whereas nearly one-half (48.4%) had normal renal function at a median follow-up of 42 months. Life-table analysis showed 75% renal survival at 39 months. Patients who subsequently developed ESRD (N = 9) had significantly higher average peak serum creatinine levels and more chronic pathologic lesions at diagnosis compared with patients with favorable renal outcome (N = 15) (50).

With regard to renal transplantation, disease recurrence has occurred and is estimated to be approximately 17%, with the time to relapse at an average of 31 months (51). Disease recurrence has been successfully treated with CYP (52). The presence of a positive ANCA test, however, is not a contraindication to transplantation, which has occurred as early as 6 months after the development of ESRD (53).

Conclusions

WG and other forms of ANCA-associated small vessel vasculitis continue to be diagnosed in the pediatric population. The renal prognosis is difficult to estimate when comparing patients with WG who have mild if any renal disease at presentation versus those who present to pediatric nephrology units with advanced renal failure. The largest report of children with WG, in which only 9% presented with renal disease, estimated that 14% went on to ESRD (8). This is contrasted to published reports of children presenting with renal disease to a pediatric nephrology center, where the incidence of ESRD ranges from 14 to 60%, with the largest series reporting 29%. The speed with which the children are diagnosed and treated is likely to affect both the short- and long-term outcomes. The long-term outcome can be further improved by finding less toxic treatment regimens capable of achieving disease remission with fewer side effects. Long-term follow-up of these patients is necessary, for even those in sustained remission have the potential to relapse.

POLYARTERITIS NODOSA

cPAN is a necrotizing vasculitis of medium-sized vessels without involvement of arterioles, capillaries, and venules. These medium-sized vessels are defined as main visceral arteries, such as the coronary, hepatic, mesenteric, and renal arteries. Focal-necrotizing injury to the vessel wall leads to aneurysm formation. The clinical features are tissue infarction, hemorrhage, and organ dysfunction (54). It is important that cPAN be distinguished from MPA, a disease with which it is often confused. The confusion dates back to the early descriptions of polyarteritis nodosa when it was believed to occur as two types: polyarteritis with extraglomerular vasculitis (cPAN) and that with glomerulonephritis, which they named *microscopic polyarteritis* (55). These two types of PAN were redefined by the Chapel Hill Consensus Conference. In short, cPAN is a medium vessel vasculitis, which is limited to medium vessels. This distinguishes cPAN from patients with MPA whose necrotizing vasculitis is usually limited to small vessels but can overlap into the medium vessels (1). This means a patient presenting with a systemic vasculitis whose renal involvement is manifested as glomerulonephritis cannot be classified as cPAN.

Unlike patients with MPA, cPAN is typically ANCA negative (56). It has been associated with hepatitis B infection in

adults and children (57–59). Classic PAN is a multisystem disease that can lead to GI, nervous system, musculoskeletal system, cutaneous, and renal involvement. Cutaneous features include livedo reticularis or inflammatory nodules, with or without gangrene. Musculoskeletal symptoms consist of severe myalgias and/or arthritis/arthralgias. Nervous system involvement includes both peripheral neuropathy (mononeuritis multiplex) and encephalopathy. GI symptoms include abdominal pain and blood in the stool. Renovascular hypertension occurs in approximately one-third of adults; renal involvement is usually flank pain and hematuria and, more rarely, retroperitoneal hemorrhage from aneurysmal rupture (54,60,61). Hypertension and renal involvement were present in 65% of patients in one pediatric study, but this study predated Chapel Hill criteria and ANCA testing and almost certainly included a mixture of pediatric patients now classified as having cPAN and MPA (57).

Renal involvement in cPAN, as defined by Chapel Hill criteria, was analyzed in an adult patient cohort from Kuwait. Chronic renal failure with (38%) or without proteinuria (31%) was frequently seen. Less frequently seen were nephrotic syndrome (6%) and rapidly progressive renal failure (6%) (62). A recent pediatric case report of severe renal impairment in a child with cPAN demonstrated the need to use histology to discern necrotizing glomerulonephritis versus necrotizing arteritis of the renal vascular bed (56). Either form of vasculitis is capable of inducing renal failure; the latter form, although less common, occurs through renal ischemia.

The diagnosis of cPAN is often made with the aid of a kidney biopsy, in which a necrotizing vasculitis without a crescentic or necrotizing glomerulonephritis is seen. Angiography of vessels involving the kidney or intestinal vessels often shows aneurysms. The high-resolution technique of selective renal angiography is often required to detect very small peripheral aneurysms (63). The interlobar and arcuate arteries are most commonly involved, with the main renal artery occurring on rare occasions (54). Although aneurysms in the medium-sized renal arteries are seen in cPAN, they are not specific for this entity as they can be seen in TA, Kawasaki disease (KD), WG, MPA, and Churg-Strauss disease (54). Aneurysms of the renal vessels can be seen on an arteriogram done in a child presenting with hypertension who was diagnosed with cPAN (Fig. 44.3).

Treatment consists of corticosteroids and usually an alkylating agent such as CYP or AZA (54,56,59). Plasma exchange has not proven beneficial in this disease (64). The prognosis of this disease has been examined in adults, and it was found that patients with more than 1 g of protein excretion in 24 hours, renal insufficiency, cardiomyopathy, CNS involvement, or severe GI involvement had a worse prognosis (65). Prognosis in children appears to be improving with more aggressive immunosuppressive treatment. A recent series of 11 children from Saudi Arabia reported 100% survival. All of these patients were treated with steroids, and nine children also received cytotoxic agents (66).

FIGURE 44.3. Renal arteriogram of a 5-year-old child presenting with hypertension. Selective injection of left renal artery showed small aneurysms arising from the interlobar and interlobular arteries (arrows). This study aided in the diagnosis of classic polyarteritis nodosa in this child.

This is contrasted to earlier reports in which cytotoxic immunosuppressive treatment was used more sparingly and mortality was as high as 16% (57,67).

KAWASAKI DISEASE

Tomisaku Kawasaki's initial report in English of 50 Japanese children with an illness characterized by fever, rash, conjunctival injection, swelling of the hands and feet, and cervical lymphadenopathy appeared in 1974 (68). This illness would later become known as *Kawasaki disease* or *mucocutaneous lymph node syndrome*. Coronary artery vasculitis is the most important feature of this disease. KD is the second most common form of vasculitis in childhood, behind HSP (69). This disease occurs worldwide but is much more common in Japan where the finest epidemiologic studies exist. This disease is 1.3 times more common in males than females (70). In Japan, KD incidence rates peak at 3 to 5 months of age in females, with two peaks occurring in males—at 3 to 5 months and a second peak at 9 to 11 months of age. This recent survey also revealed that 82% of cases occurred in children younger than 4 years of age (70). It is also the most common cause of acquired heart disease in children in the United States, the United Kingdom, and Japan (69,71). An infectious etiology is suspected but is as yet unproven.

The diagnostic criteria for KD includes six signs and symptoms: fever of 5 days or more; bilateral nonpurulent, conjunctival injection; mucous membrane changes of the upper respiratory tract (injected pharynx, injected, fissured lips, and strawberry tongue); peripheral extremity changes (peripheral edema and erythema, and periungual desquamation); polymorphous rash; and cervical lymphadenopathy (at least one node more than 1.5 cm in diameter) (72). Typical cases have fever of 5 days or more and four of the five criteria without any other known disease process. Atypical cases are characterized by coronary aneurysms and at least four other criteria (73).

KD is a systemic medium vessel vasculitis, and its primary morbidity involves the coronary arteries, in which coronary artery aneurysms have been reported to occur in 20 to 25% of untreated children (74). Renovascular involvement also occurs, albeit less commonly, and typically involves the interlobar arteries of the kidney (75). Recently, a previously normotensive child was reported to develop renovascular hypertension 6 months after an episode of KD. Arteriography revealed unilateral ostial stenosis of the main renal artery (76).

Renal parenchymal involvement has also been noted in KD. Veiga et al. reported a child with acute renal failure associated with biopsy-proven acute interstitial nephritis during the acute phase of illness (77). Nardi et al. performed ultrasonography in 7 children with KD. They found a correlation between enlarged, echogenic kidneys with increased corticomedullary differentiation in affected children and abnormal renal function, hematuria, proteinuria, and pyuria (78). Lande et al. reported a patient with KD who presented with acute renal failure requiring 1 week of hemodialysis before renal function normalized (79).

Laboratory findings in KD include leukocytosis, thrombocytosis, sterile pyuria, and pleocytosis of the cerebrospinal fluid. ANCAs and antiendothelial cell antibodies have been reported to be present in KD (80,81). Two subsequent studies using control patients with nonspecific febrile illnesses revealed that neither ANCA nor antiendothelial cell antibodies were of diagnostic value when attempting to distinguish early KD from other childhood illnesses and, therefore, were unlikely to be involved in the pathogenesis of KD (82,83). Because of the high incidence of coronary aneurysms in KD, echocardiography and ECG are recommended for all patients at the time of diagnosis (69).

After diagnosis of KD is made, the standard of care is IVIG and high-dose aspirin, which have been shown to reduce the risk of coronary aneurysms to less than 5% (84,85). A single dose of 2 g/kg of IVIG is superior to lower doses (400 mg/kg/dose) given on 4 consecutive days (85). IVIG treatment is ideally administered within the first 10 days of illness (85,86). It should be noted that IVIG can be given beyond this 10-day window, and failure to respond to single-dose IVIG may necessitate administration of a second dose later if the patient remains symptomatic (87). Aspirin

dosing is recommended at 30 to 50 mg/kg/day in four divided doses until fever resolves, then 2 to 5 mg/kg/day for a minimum of 6 weeks (69). The role of corticosteroids in KD is controversial but, in general, their use is discouraged.

Long-term outcome of KD largely depends on the presence of coronary artery aneurysms. Follow-up echocardiography is recommended at 10 to 14 days and again in 6 to 8 weeks in an effort to closely monitor for the development of aneurysms or follow up the status of previously diagnosed aneurysms. It is recommended to discontinue aspirin in those without aneurysms 6 weeks into the illness. Most mild coronary artery aneurysms (3 to 4 mm) regress within 2 years, but those who have giant aneurysms (greater than 8 mm) are unlikely to resolve. Persistent aneurysms are prone to stenosis, which can lead to thrombosis, myocardial infarction, or death (69). Indeed, KD is the most common cause of myocardial infarction in childhood (54).

The overall prognosis for KD, however, is quite good. Those with giant aneurysms require the closest follow-up, but it is recommended that all children with KD receive lifelong follow-up (69).

TAKAYASU'S ARTERITIS

TA is the most common large vessel vasculitis in the pediatric age group. It is a granulomatous inflammatory condition that usually begins in the subclavian vessels and progressively involves the carotids, aorta, and possibly the renal arteries. It is known as the *pulseless disease*, owing to its involvement with the aortic arch and subclavian vessels resulting in arterial narrowing and decreased brachial pulses (54,88). Six diagnostic criteria have been established and include age of onset of 40 years or less, claudication of an extremity, decreased brachial pulse, greater than 10 mm Hg difference in systolic blood pressure between arms, bruit over the subclavian artery, and narrowing or occlusion of the aorta, its primary branches or major arteries of the extremities not caused by atherosclerosis, fibromuscular dysplasia, or other causes (89). The diagnosis is most likely when three of these six criteria are met.

Hypertension is the most common renal manifestation and can be attributed to coarctation of the aorta and, less often, renal artery stenosis (90,91). Another renal manifestation is ischemic kidney disease (92). TA occurs predominantly in females. The female to male ratio is 9:1, with most cases being diagnosed between 10 and 20 years of age (54). It is more frequently seen in the Japanese population but does occur worldwide. The pathogenesis of this disorder is poorly understood.

Clinical features are divided into a prepulseless phase and a pulseless phase. Constitutional symptoms (fever, malaise, headache, myalgias, arthralgias, and weight loss) occur during the prepulseless phase. As arterial involvement advances, end-organ–ischemic symptoms occur (93). Adult patients

present with symptoms of claudication, abdominal pain, and/or ischemic changes to the hands. Pediatric patients more often present with symptoms attributed to hypertension and its complications, namely hypertensive encephalopathy and congestive heart failure (93). Other features of TA include dermatologic manifestations (erythema nodosum and pyoderma gangrenosum of the lower extremities in some cases) and symptoms attributable to compromised cerebral blood flow (dizziness, headaches, syncope, and stroke). Hemoptysis, shortness of breath, and pulmonary hypertension can occur due to pulmonary arterial involvement, and angina can occur due to compromised coronary blood flow attributable to either aortic or coronary arteritis. Signs of disease at presentation include hypertension in approximately 50% of cases, asymmetrical pulses, and bruits over the subclavian, brachial, and abdominal vessels (94,95).

Laboratory findings include anemia, elevated erythrocyte sedimentation rate, and elevated C-reactive protein (93,95). Serologic markers, including ANA and ANCA, are typically negative. Arteriography often shows involvement of the aortic arch, its branches, and/or the distal aorta and its branches (95) (Fig. 44.4).

Treatment of TA has consisted of corticosteroids initially in most settings. Steroid-resistant cases have been treated with CYP (96). More recently, MTX has been used in conjunction with corticosteroids and resulted in a higher remission rate and lower maintenance steroid dosage compared to historical con-

FIGURE 44.4. Aortogram obtained at cardiac catheterization in a child with Takayasu's arteritis. The small arrow indicates the catheter within the descending aorta. The large arrow indicates an abrupt tapering of the descending aorta with extensive collateral vessels. (Courtesy of Dr. Thomas J. Forbes, Pediatric Cardiology, Children's Hospital of Michigan, Detroit, Michigan.)

trols (97). Strategies to manage severe hypertension in childhood TA have included the use of vasodilators, beta blockers, and diuretics. Angiotensin-converting enzyme inhibitors have been used but must be used with great caution in those with renovascular involvement due to the risk of precipitating acute renal failure (90). Percutaneous transluminal angioplasty for treatment of stenosis of the descending thoracic and/or abdominal aorta has been used with moderate success (98). The long-term prognosis of TA is generally quite good, with 5-year survival rates of approximately 95% (95,97).

DRUG-ASSOCIATED VASCULITIS

Several drugs have been associated with ANCA positive vasculitis, with hydralazine and propylthiouracil (PTU) being the two most commonly reported (99). In one study, the authors analyzed the 30 patients with the highest titers of anti-MPO antibodies from a pool of 250 patients with ANCA-positive vasculitis and anti-MPO antibodies. Of these 30 patients, 10 patients (33%) were exposed to hydralazine and 3 patients (10%) to PTU. An additional 17% were exposed to other agents such as penicillamine, allopurinol, or sulfasalazine (99).

Patients in the hydralazine group had multisystem disease with renal, sinopulmonary, and dermatologic manifestations. Nine of ten patients had glomerulonephritis, and all five biopsied patients had pauciimmune necrotizing and crescentic glomerulonephritis. Pulmonary abnormalities included pulmonary infiltrates (five patients), hemoptysis (four patients), and alveolar hemorrhage with granulomatous changes in one patient with hemoptysis. Dermatologic manifestations were noted in three patients, with leukocytoclastic vasculitis in two; ear, nose, and throat findings occurred in two patients as well (99). In all ten patients, hydralazine was discontinued and corticosteroids were administered. CYP was also added to the treatment regimen in eight of these patients. Although two patients died, the remainder did well.

PTU exposure was noted in three patients, with only one developing renal involvement—a pauciimmune necrotizing glomerulonephritis. Dermatologic involvement included leukocytoclastic vasculitis in two patients. Treatment consisted of withdrawal of PTU and a combination of topical and systemic corticosteroids, with CYP usage in one patient. The authors concluded that a causal link between exposure to hydralazine or PTU and the development of an ANCA-positive vasculitis was likely.

Another study of childhood-onset Graves disease found that 16 of 25 patients (64%) treated with PTU had a positive ANCA when compared to 6% of untreated patients and none of ten patients treated with methimazole (100). These authors concluded that PTU induces MPO antibody production but speculated that other factors such as patient race and severity of Graves disease may be important cofactors as well. They suggested that methimazole should be considered as first-line therapy for Graves disease.

There is one report of two children on PTU who subsequently developed pauciimmune-necrotizing and crescentic glomerulonephritis associated with ANCA (+) serology. Both patients had hyperthyroidism and were exposed to PTU for 34 months and 1 month, respectively. Indirect immunofluorescence demonstrated pANCA, and ELISA demonstrated antibodies to MPO (101). Both patients were treated with corticosteroids and CYP, with one patient improving and the other developing ESRD.

A recent report of seven children from Japan described an additional cohort of children with PTU-associated ANCA (+) glomerulonephritis. All patients were positive for MPO-ANCA, and had biopsy-proven pauciimmune-necrotizing and crescentic glomerulonephritis. They were a mean age of 14 years and were exposed to PTU for a mean of 37 months (102). Treatment consisted of corticosteroids in all patients, with CYP added in two. Only one of seven patients presented with rapidly progressive glomerulonephritis. Nearly 5-year mean follow-up showed that renal function was normal in all patients; as such, the authors concluded that PTU-associated ANCA (+) glomerulonephritis has a better prognosis than nondrug-induced ANCA (+) glomerulonephritis, such as WG and MPA.

In light of the previously mentioned reports, it behooves the caregiver to take a detailed medication exposure history in all patients with vasculitis. Although hydralazine and PTU are the most commonly associated agents, isolated reports of a number of other medications associated with vasculitis currently exist (penicillamine, allopurinol, and minocycline), and additional medications are likely to be added to this list in the future (103–105).

CONCLUSION

Renal vasculitis should be considered in all patients presenting with glomerulonephritis, especially in those with other systemic symptoms. Those patients with renal-limited disease may be more difficult to diagnose. Serologic tests and renal biopsy optimize the clinician's chances at achieving an early diagnosis. Early diagnosis and aggressive treatment afford the patient with the best chance at a favorable outcome. Continued research into the pathogenesis of these disorders and the development of more specific therapies should lead to better long-term results in this challenging patient population.

HENOCH-SCHÖNLEIN PURPURA

ROSANNA COPPO
ALESSANDRO AMORE

HISTORY AND DIAGNOSTIC CRITERIA

At the beginning of the nineteenth century, Heberden reported the observation of a child presenting with petechial hemorrhages on the lower limbs, joint and abdominal pain, bloody stools, and gross hematuria (1). The syndrome was named after the description by Schönlein of the clinical entity characterized by purpura and joint pain (2) and by Henoch of the frequent association of gastrointestinal symptoms and renal involvement (3). Henoch-Schönlein purpura (HSP) is a small vessel vasculitis with multiorgan involvement including skin, gastrointestinal tract, joints, and kidneys with variable clinical expression (4,5). The syndrome frequently begins after an infectious episode. The past ambiguous definitions of hypersensitivity angitis, anaphylactoid purpura, or streptococcal rheumatic peliosis indicate the frequent relationship between HSP and either allergy or infections.

The differential diagnosis is sometimes difficult in adults because HSP overlaps other forms of systemic vasculitides, which are more common in adult age. Conversely, in subjects younger than 20 years, palpable purpura and bowel angina are most often due to HSP (5). Skin biopsy may be helpful, as it shows granulocytes in the small arteriole or venule walls (leukocytoclastic vasculitis) and immunoglobulin (Ig) A vascular deposits. The 1994 Consensus Conference on Nomenclature of Systemic Vasculitides defined HSP as a *small vessel vasculitis* (involving capillaries, arterioles, and venules) with IgA-dominant immune deposits, typically involving skin, gut, and glomeruli and associated with arthralgias or arthritis (6).

PATHOGENESIS

The finding of IgA deposits in the vessel wall as well as in the glomerular mesangial area allows a clear-cut distinction between HSP and other systemic vasculitides or collagen diseases with similar multiorgan involvement.

IgA is found in serum and mostly in external secretions. It plays a major role in mucosal immunity. There are two

distinct subclasses of IgA—IgA1 and IgA2—differing with the insertion of 19 amino acids, present in IgA1 and absent in IgA2 subclass (7). Either subclass is synthesized by plasma cells as a 155-kDa protein consisting of two α heavy chains and two κ or λ light chains, or as dimers or polymers of the basic 4-chain Ig structure, with molecular weights multiple of 155 kDa. Dimers are joined by a J chain and can be transported from the basolateral to the luminal surface of secretory epithelia via a specialized glycoprotein receptor, the secretory component. In human serum, IgA is predominantly monomeric, of the IgA1 subclass, and is derived from plasmocytes within the bone marrow and the spleen. Mucosal-derived plasmocytes produce predominantly dimeric IgA containing J chain (8). Glomerular deposits in HSP as well as in primary IgA nephropathy (IgAN) are made of polymeric IgA1, leaving open the possibility of either bone-marrow or mucosal origin, by a somehow disturbed synthetic pathway (9).

HSP and IgAN can be triggered by mucosal infections. Because IgA is the prominent Ig in mucosal secretions acting as a defense against viral and bacterial agents, several authors have tried to identify the eliciting antigen(s). HSP could be secondary to an immune response because eluted mesangial IgA cross-react with the mesangial area of other biopsy samples from different HSP patients (10). The concept of HSP as an antigen-dependent process was further emphasized by the experimental observation that most closely reproduces HSP: a systemic vasculitis with nephritis can be induced by injecting animals with a complement-activating carbohydrate antigen (11,12). Food antigens or infectious organisms have been suspected (13–15), but the possibility of a single eliciting antigen remains unproven (16,17).

The accumulation of IgA immune complexes (ICs) within glomeruli has been considered the major pathogenic mechanism for HSP nephritis as for idiopathic IgAN. High levels of IgA-ICs have been detected during clinically active phases of purpuric rashes or HSP nephritis (18–21). However, IgA-ICs are not detected in all patients with renal involvement, which means that other pathogenic mechanisms may be involved.

FIGURE 45.1. Human immunoglobulin A1 is highly glycosylated, as it contains five short O-linked oligosaccharide chains composed of *N*-acetylgalactosamine acid (GalNAc), galactose (Gal), and neuraminic acid (Neu5Ac). These oligosaccharides are coupled to serine (Ser) or threonine (Thr) residues in the hinge region, connecting the CH1 and CH2 domains.

In HSP patients, and particularly in those with nephritis, circulating IgA molecules react with α -galactosyl residues (21), fibronectin (22) or gluten-derived molecules (17) or mesangial matrix glycoproteins (23), and endothelial cells (24). Hence, it was postulated that these effects were not due to true antigen-antibody reactions but to some kind of affinity of circulating IgA to various molecules, mostly glycoproteins.

Attention has been focused on the carbohydrate moieties of IgA molecules. Human IgA1, the predominant subclass deposited in both HSP nephritis and primary IgAN, is highly glycosylated (7) (Fig. 45.1). In addition to the N-linked oligosaccharides typically present in the carboxyl terminal portion of all classes of Ig heavy chain, IgA1 contains five short O-linked oligosaccharide chains composed of *N*-acetylgalactosamine, galactose, and sialic acid. These oligosaccharides are coupled to serine or threonine residues, which lie in the hinge region connecting the CH1 and CH2 domains, at the junction between the Fab and the Fc portions of the IgA molecule (7).

Several data support an aberrant IgA1 glycosylation, not only in patients with primary IgAN but also in patients with HSP (25–27). A genetic defect leading to an inadequate activity of β 1-3 galactosyltransferase in B cells has been postulated as for primary IgAN (28). An imbalance in lymphocyte function, with a prevalence of T-helper 2 over T-helper 1 T-cell subsets, can lead to altered IgA glycosylation in mice (29). *In vitro* desialylated or degalactosylated IgA show a high tendency for self-aggregation resulting in the formation of macromolecules with a molecular weight similar to IgA-ICs (30). Hence, aberrantly glycosylated IgA can circulate in monomeric form or participate in the formation of self-aggregates or true ICs.

Whether present in ICs or in self-aggregates, such aberrantly glycosylated IgA likely escape clearance by hepatic receptors for asialoglycoproteins (31) because of the lack of galactose and possibly because of the size of the aggregates, which excludes them from the space of Disse. Abnormally glycosylated IgA1 may deposit in glomeruli more readily than normal IgA1 by virtue of enhanced lectin-like reactivity with the fibronectin, laminin, and collagen within the mesangial matrix (23). Finally, mesangial catabolism of aberrantly glycosylated IgA may be diminished. In combination, these factors can lead to the accumulation or a prolonged persistence of IgA deposits in the mesangium.

An enhanced interaction of IgA with Fc α receptors on mesangial cells results in cellular activation and phlogistic mediator synthesis. We demonstrated an increased expression of integrin adhesion molecules (32) and of the inducible form of nitric oxide synthase in mesangial cells (33) after incubation with aggregates of desialylated or degalactosylated IgA. The resultant increase in the production of intraglomerular nitric oxide may lead to peroxidative damage, apoptosis, and sclerosis. The effect can be further enhanced by the concomitant depressed expression of vascular endothelial growth factor induced by aberrantly glycosylated IgA on mesangial cells, leading to an impaired repair process (34). Aggregates of IgA also stimulate the synthesis of a variety of cytokines (e.g., interleukin-6, platelet-derived growth factor, interleukin-1, tumor necrosis factor- α , transforming growth factor- β), vasoactive factors (e.g., prostaglandins, thromboxane, leukotrienes, endothelin, platelet-aggregating factor, nitric oxide), or chemokines (monocyte chemoattractant protein-1; interleukin-8; macrophage inflammatory protein-1; HRANTES) by mesangial cells (35,36).

Complement activation may have a role in the pathogenesis of HSP nephritis. It is of interest that aberrantly glycosylated IgA can activate complement more efficiently than normal IgA (37).

Antineutrophil cytoplasmic antibodies of the IgA isotype [IgA-antineutrophil cytoplasmic antibodies (ANCA)] have been found in adults with HSP, but other reports failed to confirm these findings (38,39). We demonstrated that IgA molecules from children and adults with HSP nephritis show an increased binding to sonicated neutrophil extracts and to purified myeloperoxidase but not to serine protease 3 (26). Of interest, this reactivity was never observed in sera from patients with primary IgAN, even though they have aberrantly glycosylated IgA. This binding is affected by electrical charge and carbohydrate interactions. Both fibronectin and the lectin jacalin, which can bind IgA and the carbohydrate moieties of other glycoproteins, enhance the binding of IgA to myeloperoxidase. These data are consistent with a lectin-like binding of IgA to neutrophil cytoplasmic antigens. We speculate that the aberrant glycosylation of IgA1 in HSP patients explains

several abnormal reactivities and a high affinity for ANCA antigens. These antigens may be released in excess during phlogistic processes, leading to circulating IgA1-ANCA complexes, which, in the presence of increased levels of eosinophilic cationic proteins (40) as well as other phlogistic mediators (41,42), may favor vascular deposition of IgA1. The vascular affinity for circulating IgA-containing immune material leads to purpura and systemic vasculitis.

B cells synthesizing IgA are increased during acute phases of the disease, and abnormalities of T-suppressor activity have been observed during the acute phase (43). Transforming growth factor- β -secreting T cells have been detected in circulation during the phases of clinical activity of HSP, but they resolve during recovery (44). In patients with HSP nephritis, a reduction in Fc γ , C3b, and fibronectin receptor function of mononuclear phagocytes has been reported (45). These abnormalities were transient, probably secondary to saturation of receptors more than a primary event.

Plasma IgE levels are increased in HSP and are significantly higher than in IgAN (46). This increase could be consequent to a prevalence of T-helper 2 lymphocytes. Serum eosinophil cationic proteins are elevated in HSP (40), again suggesting an activation of the IgE-system allergy. Serum C3 and C4 values are within the normal ranges, even though CH50 and properdin levels are often reduced. These data, together with the frequent increase in C3d (19,42) in young patients with active HSP nephritis, suggest C3 activation, possibly via the alternative pathway, balanced by enhanced factor synthesis, thus masking the complement consumption.

Several reports indicate that some HLA class II gene polymorphisms can be a risk factor for HSP. A positive association with DRB1*01 and DRB1*11 (64 vs. 48% in the controls) as well as a negative association with HLA-DRB1*07 was first reported by our group in an Italian cohort (47,70) and confirmed in another study (48). An increase of DQA1*0301 was found in Japanese children (49). An increased frequency of homozygous C4A or C4B null phenotype was observed in whites (50) and in Japanese patients (49). No association of angiotensin-converting enzyme genes, polymorphism and manifestations, or progression of HSP nephritis was found (51). The risk of developing severe gastrointestinal complications is negatively associated with polymorphism of the intracellular adhesion molecule 1, and it has been suggested that it might also reduce the risk of renal involvement (52).

CLINICAL DATA

Epidemiology

HSP is the most frequent vasculitis in childhood. Its annual incidence is approximately 14 cases of 100,000 children (53). HSP is frequent in the first decade of life; however, it rarely affects children younger than 2 years of age. The

median age at onset is 4 to 5 years (54). The sex ratio shows a male preponderance (male to female ratio, 1.4–1.7:1) (55). Renal involvement is more frequent between 6 and 10 years of age (56–58). The geographic distribution of HSP is similar to that of primary IgAN. HSP is common in Europe [particularly in France, Italy, Spain, UK (4), and Finland] and Asia (e.g., Japan, Singapore, and China) (59), whereas it is less common in North America and Africa. The disease may be favored by racial factors, as HSP rarely affects blacks and Indians (60).

Factors Triggering Henoch-Schönlein Purpura

The disease may be triggered by a peculiar event, most often an infectious disease, in approximately two-third of patients (56). *Streptococcus* β , *Yersinia*, *Mycoplasma*, *Toxoplasma*, varicella, measles, rubella, adenovirus, HIV, and several other agents have been recorded among the triggering factors but without direct evidence of causality (44). There is a peak incidence of HSP in winter in North Europe and in June in Italy (58). Some epidemic clusters and familial cases of HSP have been reported (61).

The role of allergic reactions has been questioned, as well as the role of vaccinations (e.g., against smallpox or influenza), drugs (e.g., including ciprofloxacin, vancomycin, minocycline, carbamazepine), or other allergens (44).

Systemic Manifestations

HSP syndrome is characterized by a multiorgan involvement (56,58,62).

Skin

The characteristic skin lesions consist of slightly raised, palpable, purpuric macules that do not disappear on pressure with normal platelet count. They mostly begin with erythematous macules, some of which evolve into slightly raised urticarial papules, which soon become purpuric and eventually take a fawn color as they fade. Individual petechiae often become confluent in large patches. The purpuric rash often has a symmetric distribution over the extensor surfaces of the lower limbs and forearms and the buttock sides (Fig. 45.2). The purpura is present in the ankle area and in the milder cases it can be present only there. It also affects pressure areas (e.g., belt and pants) and occasionally affects earlobes, nose, and genitalia. Sometimes the rash is accompanied by fever and general malaise, with a clinical picture of infectious purpura or allergic reaction. At microscopic examination of skin biopsy, leukocytoclastic vasculitis of dermal vessels is observed with IgA deposits in the vascular wall.

Purpura is concomitant with renal involvement in two-thirds of the cases (58). In 25% of children, purpura pre-

FIGURE 45.2. Purpuric rash of Henoch-Schönlein purpura over the sides of the buttocks. (See Color Plate 45.2.)

cedes and in 8% follows the urinary abnormalities by 3 to 12 months.

The purpura lasts for a few days but often relapses. Subsequent flare-up of purpura occur in 26% of children with severe renal disease (62). Relapses of purpura may be accompanied by macroscopic hematuria and a transient increase in proteinuria, although the extent and duration of purpuric rash are not correlated with the severity of the renal lesions.

Gastrointestinal Tract

Gastrointestinal symptoms are reported in 50 to 70% of patients (4), more frequently in children than in adults (58). The most typical manifestation is diffuse abdominal pain, increasing after meals, referred to as *bowel angina*. Vomiting, hematemesis, and hematochezia or melena is frequent (5). Major abdominal complications, like intussusception, intestinal infarction, and bowel perforation are rare events. The pain is often severe and mimics an acute surgical emergency. Steroid therapy may be useful in relieving bowel-wall edema and pain.

Joints

Transient arthralgia is reported in 50 to 70% of cases (4). They mostly involve lower limb articulations, ankles, and knees, with a picture of oligoarticular synovitis. A periarticular edema may be present. The articular involvement does not lead to joint erosions, deformities, or functional limitations.

Kidney

The selection of HSP patients strongly affects the data concerning the prevalence of renal involvement (4,53,55,59,63). Variations in the prevalence of renal involvement among different series may also depend on the methods of detection of

FIGURE 45.3. Renal involvement detected by urinalysis in unselected cohorts of children with Henoch-Schönlein purpura.

nephritis. The prevalence may increase if serial urinalyses are performed. The percentage of renal involvement among children with HSP increases progressively to 35% at 1 year (64). In unselected cohorts of children, the prevalence of the renal involvement during the course of HSP is approximately 33%, ranging from 20 to 55% (57) (Fig. 45.3).

In cohorts of children with severe renal disease, as in the cohort of the Italian register of renal biopsies in children (65), the prevalence of glomerulonephritis related to HSP is 11.6% of all renal diseases.

The preselection of children investigated also affects the clinical picture. General pediatricians often report a systemic disease with modest and transient urinary abnormalities (66), whereas in pediatric nephrology departments the renal disease is more severe (56,67,68).

The manifestations of glomerulonephritis secondary to HSP include isolated microscopic or macroscopic hematuria, mild or heavy proteinuria with or without nephrotic syndrome, renal failure, and hypertension (57). The most frequent clinical presentation of HSP nephritis in nonselected pediatric series is an isolated microscopic hematuria (66,69). In 80% of cases, it is detected within 4 weeks after the onset of the disease. It is often transient, detectable only by routine urinalysis during the acute phase, followed by a complete recovery. In some patients, proteinuria of variable amount is present (Fig. 45.4). A nephrotic syndrome is more common in referral centers but is rare in unselected series. Renal function is normal in most children but may be impaired in children with nephrotic syndrome. It is most often a moderate renal failure, which rarely requires dialysis. Hypertension is rare at onset of the disease and has been reported in children with minimal urinary abnormalities.

FIGURE 45.4. Clinical presentation of children with nephritis of Henoch-Schönlein purpura. Cumulative data from 666 children (63,69,72,78–80,90).

Other Nonrenal Manifestations

HSP can be complicated by a cerebral vasculitic process resulting in convulsions, encephalopathy, chorea, or blindness (63).

Other rare manifestations include hemorrhage in the calf or subcutaneously, pulmonary-renal syndrome, pancreatitis, adrenal bleeding, or testicular involvement, mimicking torsion (44).

The vasculitic process can affect the ureter (70). In these cases, it is generally associated with loin pain. The ureteral lesions of necrotizing vasculitis may evolve into sclerotic lesions and progress to stenosis, requiring correction (71,72).

LABORATORY DATA

In HSP, as in idiopathic IgAN, serum IgA levels are increased in up to 50 to 70% of patients, but the increase is often limited to the acute initial phase, and when the disease heals, serum IgA returns within normal values, confirming a pivotal role of IgA abnormalities in pathogenesis of HSP. The subclass mostly increased is polymeric IgA1 (44).

IgA-ICs and IgA-fibronectin aggregates have been detected mostly during the acute phase or during clinical relapses (19–22). IgA antibodies to endogenous or exogenous antigens have been reported, including IgA rheumatoid factor (73). High levels of IgA reacting with sonicated neutrophil extracts (IgA-ANCA) and with purified cytoplasmic antigens (myeloperoxidase) have also been detected in children with HSP nephritis (38,26).

Platelet count is in the normal range, and the activity of the clotting factors is normal. Conversely, abnormalities in fibrin-stabilizing factor (factor XIII) have been reported as well as increased von Willebrand factor plasma levels (74), indicating an endothelial damage that favors fibrin deposition and crescent formation.

PATHOLOGY

Light Microscopy Features

HSP nephritis is characterized by mesangial damage with different degrees of hypercellularity (Fig. 45.5), ranging from isolated mesangial proliferation to focal and segmental proliferation and severe crescentic glomerulonephritis.

Light microscopic examination shows a wide range in terms of the type and severity of glomerular involvement from one patient to another and also within the same biopsy, from glomerulus to glomerulus (56). Classifications of HSP nephritis are mostly based on the severity of the proliferative lesions (4,60). Six histologic classes are distinguished according to the presence or absence and the extension of extracapillary proliferation, with subclasses defining the degree of the endocapillary proliferation (Table 45.1). The distribution of histologic grades in an analysis of 270 children showed 50% in class III, with almost even representation of the other classes, but class VI, pseudomembranoproliferative lesions, is far less common (Fig. 45.6).

Adhesions of the tuft to Bowman's capsule can be found in coincidence with segmental proliferative lesions, often with splitting and duplication of glomerular basement membranes. In rare cases, there is a severe mesangial proliferation associated with mesangial interposition in which cells and matrix migrate into the capillary walls, between the basement membrane and endothelial cytoplasm, mimicking a membranoproliferative glomerulonephritis. Polymorphonuclear cells may infiltrate the glomerular tufts, sometimes as severely as in acute post-streptococcal glomerulonephritis. Segmental necrosis of the glomerular tuft is often present at onset. It is not rare to detect intracapillary glomerular thrombi.

It is common to find crescent formation varying in size from a limited segment to circumferential crescents. At onset, crescents are cellular, then evolve into fibrous cres-

FIGURE 45.5. Renal biopsy specimen from a patient with nephritis of Henoch-Schönlein purpura showing expansion of the mesangial matrix and increase in mesangial cellularity (periodic acid-Schiff $\times 250$). (See Color Plate 45.5.)

TABLE 45.1. CLASSIFICATION OF HENOCHE-SCHÖNLEIN NEPHRITIS LESIONS ACCORDING TO EMANCIPATOR

Class I: minimal glomerular lesions and absence of crescents
Class II: no crescents
IIa: pure mesangial proliferation
IIb: focal-segmental endocapillary proliferation
IIc: diffuse endocapillary proliferation
Class III: presence of extracapillary cellular proliferation in less than 50% of glomeruli
IIIa: in association with focal and segmental endocapillary proliferation
IIIb: with diffuse endocapillary proliferation
Class IV: florid extracapillary proliferation in 50–75% of glomeruli
IVa: in association with focal and segmental endocapillary proliferation
IVb: with diffuse endocapillary proliferation
Class V: extracapillary proliferation in more than 75% of glomeruli
Va: in association with focal and segmental endocapillary proliferation
Vb: with diffuse endocapillary proliferation
Class VI: pseudomembranoproliferative glomerulonephritis

Adapted from Emancipator SN. IgA nephropathy and Henoch-Schönlein purpura. In: Jennette JC, Olson JL, Schwartz MM, et al., eds. *Hepinstall's pathology of the kidney*. Philadelphia: Lippincott-Raven publishers, 1998.

cents, generating segmental scars or global sclerosis. The most common histologic feature is a predominance of small crescents. In children with severe renal symptoms, extracapillary proliferation is detected in more than one-half of the cases (59,62). In these cases, crescents often involve less than 50% of glomeruli (class III). Some biopsies show periglomerular inflammatory infiltrates, mostly associated with crescents (15% of the children) (62).

Hyalin change or accumulation of fibrinoid material or necrosis with inflammatory infiltration and clear findings of vasculitis are present in approximately 10% of children. Blood vessels may show medial hypertrophy and intimal fibroelastosis. Necrosis of the capillary tuft has been reported in 8% of children, coincident with extracapillary proliferation.

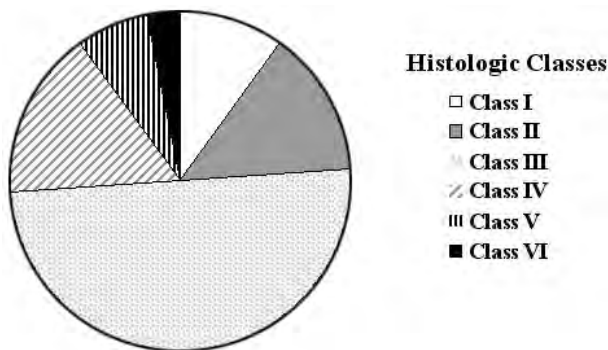

FIGURE 45.6. Distribution of histologic grades in Henoch-Schönlein purpura nephritis. Cumulative data from 270 renal biopsies (59,81,106).

FIGURE 45.7. Immunopathology of Henoch-Schönlein nephritis. Mesangial deposits of IgA (antiimmunoglobulin A $\times 250$). (See Color Plate 45.7.)

The renal biopsies from children with HSP nephritis show degenerative tubular alterations with flattening, vacuolization, desquamation, and focal loss of the brush-border microvilli in the cortex (60). Tubular cylinders and blood casts are detected in 30% of patients.

Immunohistochemistry

Mesangial IgA granular deposits are the hallmark of the disease, which, in contrast with the frequent focal and segmental proliferative changes, is always diffuse as in primary IgAN (Fig. 45.7). IgA1 is the dominant subclass with equal distribution of light chains. The J chain is detectable, indicating that IgA in deposits is dimeric, but it is not identical to secretory IgA because the secretory component is absent. Extensive subendothelial deposits are associated with the most severe histologic forms with endocapillary proliferation or crescents.

C3 is codeposited in 75 to 85% of the cases similarly to idiopathic IgAN. The membrane attack complex C5-C9 and the alternative complement pathway components are always detected. Early classical pathway complement components C1q and C4 are present only rarely and stain with low intensity (60). IgG and IgM codeposits are present in 40% of the cases. Fibrin or fibrinogen deposits are found in 60 to 70% of patients, both in mesangial and in parietal areas, often coincident with mesangial proliferation, suggesting a role of the clotting cascade activation. Glomerular fibrin-related deposits are much more frequently present in HSP nephritis than in IgAN (55) and are often related to active phases with extracapillary proliferation. Deposits of IgA and C3 can be found in arterioles or cortical peritubular capillaries in children with severe glomerular changes.

Electron Microscopy

Electron-dense deposits are detectable in a setting of mesangial matrix expansion and variable degree of cellular hyperplasia (60). The deposits, initially paramesangial and small, become larger and of nonuniform density, in strict connection with the mesangial matrix. Most deposits have a mesangial localization with parietal extensions (in 60% of the cases) and are purely mesangial in 30% of cases. The parietal, paramesangial electron-dense material is generally subendothelial, more rarely subepithelial. Sometimes, electron-dense deposits, hump-like with garland shape or fluffy aspects, are detectable. In other cases, deposits show with a woolly aspect in the external rara lamina, placed in the periphery of the capillary loops and delimited by a thick layer of new basement membrane. As a possible consequence of the membrane reactivity to immune deposits, the presence of parietal deposits modifies the capillary basal membrane profile because of the widening of the rara internal and external lamina, with neofomed layers.

Follow-Up Renal Biopsies

Studies of serial biopsies in children with HSP showed a good correlation between the histologic changes, clinical data, and outcome (75). When patients undergo clinical resolution, mesangial proliferation disappears and crescents regress, while others evolve into segmental synechiae. IgA deposits substantially decrease and sometimes completely disappear. Conversely, when repeat biopsies are performed in patients with persistently active or progressing nephritis, the proliferation continues to be severe, and evolution into fibrotic lesions is detected. The importance of careful clinical monitoring during the follow-up of children with HSP nephritis must be stressed also on the basis of the good correlation between clinical and histologic data reported by this study.

Nonrenal Lesions

The typical lesion of HSP, either in skin, gut, or in kidney vessels, is leukocytoclastic vasculitis with fragmentation of leukocyte nuclei in and around arterioles, capillaries, and venules, surrounded by infiltrating neutrophils and monocyte cells in the presence of nuclear residues (nuclear dust) in the wall of arterioles. Fibrin deposits and arteriolar and venular necrosis can be found. Deposits of IgA and C3 are present in the dermal capillaries in purpuric lesions and uninvolved skin and are considered a valid diagnostic criterion, with 100% specificity in combination with leukocytoclastic vasculitis. IgG and IgM can be codeposited in approximately 20% of the cases, whereas C1q and C4 are absent. Similar deposits have been reported in superficial derma capillaries of IgAN patients. In dermatitis herpetiformis, IgA deposits are found as well, but they are located

on the top of the derma papilla. In systemic lupus erythematosus, the dermal-epidermal junction is mostly positive for IgG, C1q, and C4.

The diagnosis may be difficult in the rare cases in which skin eruption entirely consists of urticaria lesions without purpura. Hypersensitivity vasculitis is sometimes overlapping, but the dermal IgA vascular deposits are specific for HSP lesions.

Correlations between Clinical and Pathologic Data

In the Italian HSP series of 74 children (58,62), patients with minimal proteinuria had a higher prevalence of class I and II lesions (92%), without crescents. In cases with significant proteinuria, more severe renal lesions were frequently found. Extracapillary proliferation was also often found in children with nonnephrotic proteinuria (33% of class III and IV). Gross hematuria at presentation was associated with crescent formations in the 22% of the children. The clinical feature mostly predictive for severe histologic lesions is the onset with renal function impairment, as 62% of children with severe acute nephritic syndrome and severe kidney function impairment had crescents, and other authors reported similar findings (76).

CLINICAL COURSE AND PROGNOSIS

HSP nephritis accounts for 5% of children with end-stage renal failure in Europe (4,56). The clinical course and long-term outcome vary according to the cohorts examined, particularly when unselected cohorts are compared with children followed by pediatric nephrology units. In unselected series, HSP is a mild disease, with renal involvement in a minority of cases, mostly presenting with isolated hematuria or minimal proteinuria and with long-term sequelae concerning no more than 1% of patients (80). Reports of series of children admitted into general pediatric hospitals indicate a prevalence of urinary sediment abnormalities of 20 to 28%, generally lasting for more than 1 month (73,77–80). With a follow-up of more than 10 years, a progression to end-stage renal failure is observed in approximately 2 to 3% of the children with initial signs of renal involvement (81).

The remission rates reported by tertiary reference centers are below 50%, with poor outcome in 10 to 25% of children (56,68). In cohorts of children with a severe disease, long-term prognosis is poorer, as 15 to 30% of them progress to renal failure with wide variability depending on the duration of follow-up (57). In a long-term follow-up study, a late progression was observed after 25 years in 25% of children, not only in cases with persistently active renal disease but also in others having experienced clinical improvement after the acute phase (68). These authors reported persistent urinary

FIGURE 45.8. Long-term renal outcome of patients with Henoch-Schönlein nephritis. Mean 5-year follow-up of 57 children with severe Henoch-Schönlein nephritis, warranting renal biopsy. CFR chronic renal failure; GFR, glomerular filtration rate. (Adapted from Coppo R, Mazzucco G, Cagnoli L, for the Italian Group of Renal Immunopathology. Long-term prognosis of Henoch-Schönlein nephritis in adults and in children. *Nephrol Dial Transplant* 1997;12:2277-2283.)

abnormalities in 15% of children with a nephritic onset or persistent heavy proteinuria, 40% of those with a nephritic presentation and 50% of those with mixed nephritic-nephrotic syndrome at onset. Some of these patients ended in chronic renal failure. It is clear that renal function may deteriorate during the follow-up even in patients who apparently completely recovered 2 years after onset (68), perhaps due to sequences of glomerular hypertension.

The presence and extent of extracapillary proliferation is certainly important to identify children with potentially progressive renal disease. There is a close relationship between the extent of crescents and long-term sequela in patients with class IV and V, with extensive glomerular involvement by crescents in more than 50% and more than 75% of glomeruli, respectively. In a Japanese series, 33% of class IV and 83% of class V ended with chronic renal failure (59). In the Italian multicenter study (62), after 1 to 20 (mean, 5) years, one-third of the children who had had a renal biopsy were in remission (Fig. 45.8). In 40% of the cases, only minimal or moderate proteinuria was left. Chronic renal failure or end-stage renal disease occurred in 12% of children. The delay between onset and end-stage renal failure varied from a few days to 20 years, with an average of 10 years. When comparing children and adults with a HSP nephritis, the outcomes were substantially similar, with loss of renal function in 26% of adults and in 27% of children after 10 years (62).

Children at Risk for Progression

It is of paramount importance to identify children with potentially progressive renal disease. As reported above, the clinical presentation is, in general terms, indicative of the long-term outcome (69). In some reports, nephrotic syndrome or renal

FIGURE 45.9. Risk factors for progression of renal disease in Henoch-Schönlein purpura nephritis. Cumulative data of 77 children (63,69,72,78,79,90).

insufficiency at onset were risk factors (44%) for renal failure after two decades of follow-up (68) (Fig. 45.9).

Conversely, in the Italian cohort (62), no significant prognostic factor was found, including renal function impairment at presentation or hypertension. Mild proteinuria or, at the opposite, nephrotic-range levels, were associated with high frequency of remission or functional deterioration. However, children with mild proteinuria also frequently displayed severe histologic lesions with extracapillary proliferation, and nephrotic and nonnephrotic children had similar outcomes.

The percentage of glomeruli involved by extracapillary proliferation, the extent of Bowman's space occupied by individual crescents, the fresh or fibrous crescent ratio and are important risk factors (67). The predictive value of mild extracapillary proliferation was low when crescents involved less than 50% of glomeruli (class III) (renal failure in 18% of children with crescents on renal biopsy), also because some cases without crescents experienced an unfavorable outcome (23% of cases).

Renal Transplantation in Children with Henoch-Schönlein Purpura Nephritis

Recurrence of IgA mesangial deposits may occur after renal transplantation, even though the recurrence of clinical symptoms of HSP is rare. The actuarial risk for histologic or immunofluorescent recurrence is 35% at 5 years, with graft loss in 11% (82,83). In most patients, no clinical manifestations or minimal hematuria accompany histologic recurrence in grafted kidneys (84). Recurrence is not prevented by triple therapy, including cyclosporine, and is more frequent in rapidly progressive cases. Delaying transplantation of 1 year after the last systemic signs was not effective in decreasing the rate of recurrence (82). The recurrence rate appears to be increased in recipients of living-related grafts, suggesting a role for genetic factors. This is controversial, however, and the issue of using living donors for renal transplantation in HSP is still debated (85,86).

THERAPY

Mild cases do not require treatment, provided urine monitoring is ensured to detect anomalies mostly during the first 2 to 3 months after onset of the purpuric rash.

The abdominal pain is generally controlled by small doses of steroids, which favor a rapid resolution. Patients with recurrent necrotizing purpura or severe abdominal pain have been successfully treated by intravenous Ig infusions (87).

Because in most cases the purpuric rash precedes by days or weeks the detection of urinary abnormalities, attempts have been made to prevent the development of the nephropathy by giving prednisone (1 to 2.5 mg/kg/day for 1 to 3 weeks). A beneficial effect was not observed in retrospective studies, which compared treated versus untreated patients. However, the treatment was often reserved to the more active cases, thus introducing a selection bias, which may have influenced the outcome (88,89). Conversely, a prospective trial (albeit not strictly randomized) suggested a protective effect of a 2-week course of prednisone (90). The prevention consisted in avoiding the appearance of microscopic hematuria, which is not associated with a high risk for progression to renal failure.

Once the nephritis has developed, it is possible either to treat or to wait for a spontaneous remission. Based on observations dating decades ago, oral corticosteroids were believed to be ineffective for treating HSP nephritis. Indeed, retrospective analyses failed to demonstrate any benefit of prednisone in children with HSP nephritis (91). However, again a selection bias favoring treatment of more severe cases was likely, because the severity of the disease was a major determinant in the decision to treat. More recently, a 1-year treatment with oral prednisone and azathioprine in patients with moderately severe renal involvement gave positive results in comparison with historical, untreated cases (92,56). However, as the historical group included particularly severe cases, no recommendation for treatment of moderately severe HSP nephritis is presently possible (93).

Tonsillectomy has been proposed for HSP nephritis, as for primary IgAN, with the aim of limiting the mucosal immune response. The overall analysis does not support the recommendation for this intervention in HSP nephritis (94).

There is a need for an efficient treatment for children with severe endocapillary and extracapillary proliferation and clinical presentation of nephrotic or nephritic syndrome with impaired renal function. An aggressive therapeutic regimen resulted in a favorable clinical outcome in 11 of 12 children with 60 to 90% glomeruli with crescent formation. This regimen consisted in a triple therapy of three methylprednisolone pulses followed by a 6-month course of prednisone, dipyridamole, and cyclophosphamide for 3 months (95). More than 60% of these patients experienced a complete remission. Similar positive results have been reported using high-dose steroids in association with oral cyclophosphamide (96).

A larger French series confirmed that methylprednisolone pulses followed by a 3-month course of oral prednisone and, in some patients, with a 2-month course of oral cyclophosphamide, resulted in clinical recovery in 71% of children with nephritic syndrome or crescentic involvement in greater than 50% of the glomeruli, versus 40% in a historical group of untreated children (97). Similarly, in children with greater than 50% glomeruli involved with crescents, good results were reported with oral prednisone for 4 months in association with a 2-month course of cyclophosphamide and heparin or warfarin for 4 months (98). A combination of prednisone, azathioprine, or cyclophosphamide also gave positive results (99).

Our group (100), and more recently others (101), successfully treated children with rapidly progressive HSP nephritis with plasma exchanges, corticosteroids, and cytotoxic drugs. In our series, even though some cases experienced a complete remission, most had subsequent relapses and, despite a new cycle of plasma exchanges, renal function did not improve, and patients progressed to end-stage renal failure. The progression was delayed by 1 to 4 years. In the Japanese series, 60% of the treated patients had a complete remission of renal disease after 10 years. A German series showed that aggressive treatment including PE may delay the rate of progression in the majority of patients with severe crescentic HSP nephritis, but the treatment was unable to definitely prevent the progression to end-stage renal failure (102).

The analysis of uncontrolled studies with a combination of corticosteroids (e.g., either intravenous pulses or oral), immunosuppressive drugs (e.g., cyclophosphamide or azathioprine) sometimes in association with anticoagulation (e.g., warfarin or dipyridamole) in children with nephrotic range proteinuria, or major extracapillary proliferation on biopsy allows us to conclude that aggressive therapeutic regimens are effective in decreasing the rapidity of progression to chronic renal failure. However, these treatments should be started early during the course of the disease before the crescents become fibrotic. At this late stage, the treatments are ineffective.

In patients with heavy proteinuria, favorable results with decrease in proteinuria and improvement of histologic index of renal activity have been reported using intravenous Ig infusions (103,104). However, a rebound was noticed shortly after the therapeutic cycles, which somehow banished the positive results obtained (103). On the contrary, Ig infusion may be useful in cases with severe recurrent purpuric rash and mild urinary symptoms.

RELATIONSHIP BETWEEN HENOCH-SCHÖNLEIN PURPURA AND PRIMARY IMMUNOGLOBULIN A NEPHROPATHY

The main reason for which a relationship between HSP and IgA nephropathy has been suggested is that these two conditions are indistinguishable by renal histopathology. Further-

more, other features are in favor of an unifying concept. Occasional patients with IgA nephropathy have extrarenal symptoms. A few patients may present with IgA nephropathy and develop a purpuric rash months or years later. In the following years, some patients with HSP may develop episodes of macroscopic hematuria suggestive of IgA nephropathy, in the following years. The occurrence of both diseases in the same family is not uncommon. In a French national survey on 40 families with two or more members affected by primary IgAN, five had members presenting with complete HSP syndrome, confirming a possible genetic link between the two diseases (105). Most patients with HSP nephritis who undergo renal transplantation have a recurrence of IgA deposits in the graft in the absence of extrarenal symptoms, as do patients with IgA nephropathy. Last, a male preponderance is seen in both diseases, and the high prevalence of both conditions is observed in the same geographic areas (e.g., Europe, Asia).

HSP and primary IgAN share similar disturbances in the IgA system. Both diseases present with high levels of serum IgA, as well as high levels of circulating IgA-ICs, IgA1-IC, and IgA-fibronectin aggregates, as discussed above, even though the levels in acute phases of HSP are generally higher than in primary IgAN (20,22). Both diseases have aberrantly glycosylated IgA in circulation.

SYSTEMIC LUPUS ERYTHEMATOSUS

PATRICK NIAUDET
RÉMI SALOMON

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease characterized by highly diverse clinical manifestations and the presence in the serum of antibodies reacting with different cell nuclei components. The skin, joints, lungs, heart, kidneys, nervous system, and other organs are involved. The role of autoantibodies in the pathogenesis of the disease is subject to debate. Certain autoantibodies, such as those reacting with cell surface determinants or circulating proteins, are directly responsible for specific clinical manifestations of the disease. The clinical course of the disease is characterized by flares, periods of chronic disease, and periods of remissions.

The American Association of Rheumatology developed diagnostic criteria of SLE (1,2) to establish with certainty the diagnosis of SLE and to distinguish it from other rheumatic diseases (Table 46.1). When four of these criteria are present, the sensitivity of the diagnosis of SLE is 95% and the specificity is 96%. Some patients with the disease may not satisfy the criteria initially but may develop other manifestations later and then develop the full criteria for the diagnosis of SLE. For example, some patients may have isolated nephritis, such as membranous nephropathy, without serologic evidence of SLE at first.

The prevalence of SLE is approximately 40 per 100,000 in Europe and North America (3). SLE is three times more frequent in blacks than in whites but is exceptional in blacks from Africa (4,5). In a recent survey of pediatric lupus in the United Kingdom, the relative risk was 6.7 in Asian populations and 6.1 in black populations compared with the white population (6). The frequency of the principal risk factors for SLE does not differ in blacks compared to whites (7). In more than 80% of cases, SLE affects females after puberty. The female to male ratio increases from 2:1 in prepubertal children to 4.5:1.0 in adolescents and 8:1 in adults (8). In children, most cases of lupus occur after age 5, with a peak incidence in late childhood and adolescence (9). Twenty percent of SLE cases begin in childhood.

The presentation of the disease in children varies both in terms of the gravity of symptoms and the diversity of clinical manifestations. However, the disease is often more acute

and severe, affecting multiple organs in children compared to adults (10–13). In addition to the organ damage, SLE has a major detrimental impact on growth and psychological development. It is important to promote a multidisciplinary approach to SLE to assure better individual treatment of patients.

PATHOGENESIS

The etiology of the SLE remains unknown, despite the progress that has been made during the recent years in understanding the pathogenic mechanisms of the disease. SLE is characterized by the development of autoantibodies directed against a variety of self-components, and, contrary to other autoimmune diseases, there are no stigma of organ-specific autoimmunity.

Genetic Factors

The evidence for a genetic susceptibility to SLE in humans is based on familial aggregation. The prevalence of SLE is estimated to be 2.6 to 3.5% in first-degree relatives of SLE probands compared with 0.3 to 0.4% in relatives of matched controls. Moreover, an increase in concordance rate is observed in monozygotic twins (24 to 56%) compared to dizygotic twins (2 to 5%). The risk of developing the disease in siblings of SLE patients is 10 to 40 times higher than that in the general population. A French analysis of 125 families that included at least two individuals with SLE demonstrated a nonmendelian inheritance, suggesting a complex multifactorial inheritance pattern with several genes interacting together in a single individual (14). Population-based studies have shown associations of SLE with numerous polymorphic alleles of several major histocompatibility complex class II genes and of various complement components (C1q, C2, C4). Further association with Fc γ on chromosome 1q23, mannose binding ligand, interleukin-6 and -10, and tumor necrosis factor has been demonstrated. Genetic linkage studies have identified 60 susceptibility loci with varying degrees

TABLE 46.1. THE 1982 REVISED AMERICAN ASSOCIATION OF RHEUMATOLOGY CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

Malar rash
Discoid rash
Photosensitivity
Oral ulcers
Arthritis
Serositis (pleuritis or pericarditis)
Proteinuria >0.5 g/d or red blood cell casts
Psychosis or seizures
Hemolytic anemia or leukopenia (<4000/mm ³) or lymphopenia (<1500/mm ³) or thrombopenia (<100,000/mm ³)
Antinuclear antibodies
Anti-double-stranded DNA antibodies or anti-Sm antibodies or false-positive TPI/VDRL or positive lupus erythematosus cell test

TPI, *Treponema pallidum* immobilization.

of evidence for linkage in humans. Seven of these met or exceeded the threshold for significant linkage at 1q22-23, 1q41, 2q37, 4p16, 6p21-11, 16q13, and 17p13. An interaction between 16q12 and 1q23 loci has been demonstrated in a cohort of 115 multiethnic families. This interaction is more pronounced in nonwhites (15). Recently, a polymorphism in a gene encoding an immunoreceptor named *programmed cell death 1* (PD-1) has been associated with development of lupus in Europeans and Mexicans (16). Because lupus is a multifactorial disease with multigenic inheritance, it is highly likely that many more polymorphisms with subtle functional impact will be described. Studies in various mouse models suggest that lupus may be mediated by a multitude of genetic

abnormalities that impact on specific checkpoints, starting with a loss of immunologic tolerance to nuclear antigens and progressing to a pathogenic autoimmunity and to organ targeting. Several studies suggest that increased liberation or disturbed clearance of nuclear DNA-protein complexes after cell death may initiate the disease. DNase1-deficient mice, generated by gene targeting, exhibit a phenotype very similar to classic human SLE (17). Moreover, mutations responsible for a loss of function of this enzyme have been found in patients with SLE (18). Table 46.2 shows several gene variants that have been associated with SLE in humans and in mice (16–27).

Environmental and Infectious Factors

Based on twin concordance studies, the induction of SLE requires more than genetic factors. Environmental, hormonal, toxic, and infectious factors have been proposed. The high degree of homology between a small peptide sequence of the Epstein-Barr virus (EBV) nuclear antigen-2 and the SmD1 ribonucleoprotein, a target of autoantibodies in SLE patients, suggests that antibodies elicited by the viral antigen may cross-react with SmD1. EBV-specific immune responses may play a role in the production of SmD1 autoantibodies in SLE patients (28). Seroconversion against EBV was observed in 99% of children with SLE as compared to only 70% of their controls. Thus, EBV may be a causative factor in SLE (29). Photosensitivity is a common feature of SLE, and the disease is aggravated by sun exposure in 40 to 70% of patients. Ultraviolet light induces apoptosis of keratinocytes, which may, in turn, develop

TABLE 46.2. MOUSE AND HUMAN GENES THAT CAUSE LUPUS

Categories	Mouse with null mutation	Patients with systemic lupus erythematosus (SLE)	References
Regulatory machinery			
Activation threshold of lymphocytes			
PD-1	Autoimmune cardiomyopathy	A polymorphism in intron 1 is more frequent in patients than in control (12 vs. 5%)	16,19
Lyn	Autoreactive antibodies and severe glomerulonephritis	Lyn is significantly decreased in B cells at the messenger RNA and protein levels	20,21
Deletion of autoreactive T cells			
P21	Anti-double-stranded DNA, glomerulonephritis	Reduced expression of p21 in lymphocytes	22,23
Scavenger machinery			
C1q	High autoantibody titers, 25% had glomerulonephritis with great numbers of glomerular apoptotic bodies	C1q deficiency is strongly associated with SLE	24,25
DNase1	Antinuclear autoimmunity and glomerulonephritis	Heterozygous nonsense mutation and decreased DNase1 activity in serum of patients	17,18
Serum amyloid P (SAP)	Antinuclear autoimmunity and severe glomerulonephritis	Low levels of SAP-DNA complexes in serum of patients	26,27

small surface blebs containing lupus autoantigens such as the Ro particle (30). Similarly, drugs (e.g., chlorpromazine) (31) and environmental toxins (e.g., silica dust) are capable of inducing apoptosis.

Hormonal Factors

The female predominance in SLE is particularly strong during childbearing ages, suggesting that hormonal differences may contribute to the increased risk of the disease (32,33). Reduced androgen levels and increased estradiol and prolactin levels have been reported in SLE patients. Moreover, whereas administration of androgens leads to improvement, estrogen and prolactin exacerbate disease severity. On the other hand, a population-based study of 240 female SLE patients found little evidence that estrogen- or prolactin-related exposures were associated with an increased risk of lupus (34).

Role of T and B Lymphocytes

In SLE, autoantibodies, immune complexes, and autoreactive T cells may cause tissue damage. The loss of self-tolerance in the periphery appears to be critical in the pathogenesis of SLE (35). Self-antigen can trigger autoimmunity by several ways. The level of autoantigens may be increased by an impaired clearance of immune complexes or of apoptotic cells. Defects in the complement system or lymphocyte Fc receptor alterations may enhance the level of available autoantigen (36–38). Perturbations of the cytokine network could activate antigen-presenting cells and thereby reduce the signaling threshold to a given concentration of autoantigen in self-reactive peripheral T or B cells (39). Alterations in these different regulatory pathways have been described in lupus-prone natural and knockout mouse models (Table 46.2). Moreover, polymorphisms or mutations of several genes implicated in these processes have been reported in lupus patients.

The production of autoantibodies against components of the cell nucleus is a hallmark of SLE. The most prominent of these autoantibodies is directed against double-stranded (ds) DNA and histones. There is growing evidence that the nucleosome, the fundamental unit of chromatin, composed of histones and dsDNA, is a major autoantigen that drives a T-cell-dependent autoimmune response. The implication of the nucleosome in the pathogenesis of SLE seems to be related closely to an abnormal regulation of apoptosis and an impaired clearance of apoptotic products. High levels of these products and particularly of nucleosomes themselves have been observed in lupus patients in comparison to controls (40).

Dendritic cells are key regulators of the immune system. These professional antigen-presenting cells induce the activation of naïve T cells and stimulate growth and proliferation of B cells. The serum of patients induces monocytes to

differentiate into dendritic cells able to capture dying allogeneic cells and present their antigens to autologous CD4⁺ T cells leading to proliferation. Furthermore, this capacity to induce dendritic cell differentiation is correlated with disease activity (41), and the capacity is abolished by blocking interferon-gamma, suggesting that this cytokine is the major mediator of monocyte to dendritic cell differentiation. One scenario proposes that dendritic cells might capture apoptotic cells and nucleosomes present in the blood of SLE patients. Subsequent presentation of autoantigens by these dendritic cells to CD4⁺ T cells could initiate the expansion of autoreactive T cells, followed by differentiation of autoantibody-producing B cells.

Complement Deficiency

Activation of the complement system is implicated in the defense against microbes and in the adaptive immune response and inflammation. The complement system plays a paradoxical role in the development and expression of SLE. While the activation of complement is involved in tissue damage, inherited deficiencies of components of the classic pathway are strongly associated with the development of SLE. Lupus develops in many patients with complete deficiencies in C1q (90%) and C4 (75%), suggesting that these molecules have a protective role against the development of the disease (42). The protective role of C1q has been confirmed by the observation of severe lupus nephritis in C1q-deficient mice.

CLINICAL MANIFESTATIONS

Lupus is often acute in onset and includes general symptoms of fever and fatigue associated with cutaneous and articular symptoms (11,43). SLE may also begin with an isolated symptom such as a hemolytic anemia, a nephritic syndrome with hematuria, chorea, or pericarditis. The performance of systematic serologic tests permits the linkage of these manifestations to SLE (44).

General symptoms, particularly weight loss, anorexia, and asthenia, are virtually constant in SLE. Episodic fever is frequent during acute phase of the disease or during infection. Pulmonary or urinary tract infections are frequent during the course of SLE. Opportunistic infections may be life threatening. A number of factors may favor a relapse of the disease, including exposure to ultraviolet light (45), infection (46), stress (47), surgery, or pregnancy.

Joints and Muscles

Arthralgia is the most common manifestation of SLE, observed in 80% of cases during the evolution of the disease (48). Both large and small articulations, especially of the hands, are affected, causing moderate pain and articular swelling. The damage of periarticular tissues is often more

pronounced than synovial damage, especially in the form of tendinitis. Arthritis is very rarely deforming, and synovial fluid contains relatively few cells. Myalgia is less frequent. Avascular osteonecrosis, which often affects femoral heads, may occur in the absence of treatment with corticosteroids.

Skin

The most classic skin lesion of SLE is the butterfly rash over the cheeks and nose, which is present in one-third of cases. The rash often appears after sun exposure. Maculopapular eruptions on the upper portion of the trunk as well as any areas exposed to light are the most common. Papular lesions and squamous lesions on the trunk, face, and palms of the hands can be observed in the less severe cutaneous forms of the disease, often linked to the presence of anti-Ro antibodies. Raynaud's phenomena of the extremities causes painful white marble-like lesions, leg ulcers, and periungual or finger-pad erythema. Urticarial eruptions and pigmentation anomalies are sometimes observed. Cutaneous photosensitivity is noted, especially in white patients. Mucosal lesions, particularly in the form of oral ulcerations, are common. Alopecia is observed in some children, especially those with active forms of the disease.

Lungs

Pulmonary involvement occurs in more than 75% of children. Pleuritis, observed in 40% of children, is often asymptomatic or may be present as thoracic pain. The pleural fluid is an exudate, containing a large number of neutrophils and lymphocytes. The levels of C3 and C4 in the fluid are diminished, and the level of antinuclear antibodies (ANA) is elevated. Anomalies in diaphragmatic function have been reported and can be responsible for dyspnea. Pulmonary damage may be manifested as an acute pneumonitis with thoracic pain, dyspnea, and fever. Poorly defined opacities can be observed on x-ray. Histologically, these lesions consist of infiltrates of lymphocytes and plasma cells. Chronic fibrosing alveolitis has been described. Pulmonary arterial hypertension is a rare but a severe problem that may be secondary to repeated pulmonary embolism (49). Acute pulmonary hemorrhage during the acute phase of the disease or during infections may be life threatening.

Heart

Pericarditis is frequent in SLE and is often diagnosed on echocardiography. Myocarditis with congestive heart failure is rare. Endocarditis of Liebman-Sachs, which often affects the mitral valve and is associated with antiphospholipid (APL) antibodies, is rare (50).

Nervous System

Neuropsychiatric symptoms are present in 30 to 45% of children with SLE. (51,52). These symptoms can either be a

direct result of SLE or secondary to arterial hypertension, renal insufficiency, infectious complication, hemostasis abnormalities, or various treatments, particularly corticosteroids (53). Mood disorders or behavior disturbances are often difficult to interpret in this chronic disease. Headache is the most frequent neurologic manifestation of SLE and is often accompanied by localized or generalized seizures. Symptoms suggestive of a cerebral tumor have been described. Chorea is frequent in children, sometimes in association with APL antibodies. Cranial nerve palsies have been described, particularly ptoses and hemiparesis. Psychiatric symptoms consist of difficulties with attention or memory, disorientation, behavioral problems, depression, or psychotic states with hallucinations and delirium (54,55). These symptoms can occur in an acute, transitory manner, during a flare of the disease, or may be more prolonged. They are often linked to ischemic cerebral vascular lesions that can be visualized by magnetic resonance imaging. Damage to the large arteries is rare. The role of antineuronal antibodies that are found in up to one-half of patients in the pathophysiology of these lesions is uncertain. Thrombotic phenomena secondary to the antiphospholipid antibodies may also play a role in the pathogenesis of neurologic manifestations (56). Behavioral problems and a decrease in academic achievement are often noted in children with SLE. These problems could be linked to the disease itself, to treatment with corticosteroids, or to the psychological response to a serious chronic illness. If these problems are secondary to SLE, the symptoms can respond favorably to an increase in corticosteroid doses.

Eye

Both the retina and the cornea can be affected by SLE. Keratoconjunctivitis sicca is the most common ocular manifestation. The retinal lesions consist of white, cotton-like exudative lesions of the optic nerve, papillary edema, or thrombosis of the central retinal artery.

Hematopoietic System

Hematologic manifestations are common in SLE. Inflammatory cervical or diffuse adenopathies occur in children with SLE. Anemia, observed in more than one-half of cases, is usually normochromic and normocytic, and its degree reflects the activity of the disease. Hemolytic anemia is present, and is often, in less than 10% of cases, accompanied by reticulocytosis, a positive Coombs' test, an increase in free bilirubin levels, and a decrease in haptoglobin levels. Aplastic anemia has been reported and responds to treatment with corticosteroids. Leukopenia, noted in more than 50% of cases, is partially responsible for an increased sensitivity to infections. Neutropenia may be linked to medullary suppression, hypersplenism, or antineutrophil antibodies. Lymphopenia affects both T and B lymphocytes. Thrombopenia, noted in 10 to 25% of cases, is accompanied by an

increase in megakaryocytes in the marrow, indicating peripheral destruction of platelets. The acute, severe forms of thrombocytopenia are often observed during an acute phase of the disease and are responsive to treatment with corticosteroids, while more chronic forms are less symptomatic and less responsive.

Antiphospholipid Antibodies

APL antibodies may be directed against epitopes on oxidized phospholipids complexed with a glycoprotein, beta 2-glycoprotein I, or against the glycoprotein itself. The principal APL antibodies include anticardiolipin antibodies, beta 2-glycoprotein I antibodies, and the lupus anticoagulant. These APL antibodies are responsible for thrombosis *in vivo*. Conversely, they prolong phospholipid-dependent coagulation tests *in vitro* (57). Patients with SLE have a high incidence of APL antibodies with a consequent high risk of thrombosis.

A patient with the APL syndrome must meet at least one of the two clinical criteria (e.g., vascular thrombosis or complications of pregnancy) and at least one of two laboratory criteria (e.g., anticardiolipin antibodies or lupus anticoagulant antibodies). Patients with APL antibodies develop arterial or venous thromboses, thrombocytopenia, and the experience of repeated abortions. Primary APL syndrome occurs in patients without clinical evidence of another autoimmune disease, whereas secondary APL occurs in association with autoimmune or other diseases. The prevalence of APL antibodies is 1 to 5% among apparently healthy subjects in the young and increases with age. Among patients with SLE, the prevalence of APL is much higher, ranging from 12 to 30% for anticardiolipin antibodies and 15 to 34% for lupus anticoagulant antibodies (58). The APL syndrome develops in 50 to 70% of patients with SLE and APL antibodies within 20 years of the initial diagnosis.

Patients with primary and secondary APL syndrome have similar consequences of APL antibodies. The clinical hallmark of the APL syndrome is the presence of vascular thrombosis. Venous thromboses are more frequent than arterial thrombosis. Involvement of the small vessels, particularly in the kidneys, can mimic the hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura. APL syndrome may also occur as a more chronic process, resulting in progressive loss of organ function (59).

In a cross-sectional cohort study in 59 consecutive SLE patients, 13 thrombotic events occurred in 10 of the 59 patients (17%). There was a direct relationship between the presence of a lupus anticoagulant and a thrombotic event (60). Similar findings were reported in a retrospective study in 36 children with lupus nephritis. No difference in the incidence of APL positivity was detected between the eight children who experienced thrombotic complications and the others (61).

Altered fibrinolysis, secondary to an increase of the inhibitor of the plasminogen activator and a decrease of protein S, has also been described in patients with SLE. Other more rare circulating anticoagulants have been observed. They are true *in vivo* anticoagulants, including antifactor VIII, antifactor XI, and antifactor XII.

Endocrine Manifestation

An autoimmune thyroiditis, including antithyroid and antimicrosome antibodies, may be responsible for symptoms of hypothyroidism and, less often, hyperthyroidism. A recent study found a high frequency of antithyroid antibodies in children with SLE, but most often without clinical manifestations. Diabetes mellitus is often secondary to high doses of corticosteroids, but it may be secondary to SLE with the presence of antiinsulin receptor antibodies. Hormonal contraception may promote lupus activity and thromboses, particularly in patients with APL antibodies. Therefore, it is important that appropriate contraception is adapted when necessary, and patients must be informed of the risks of future pregnancy, which would need specialized monitoring (62).

Gastrointestinal Manifestations

Gastrointestinal manifestations are often secondary to the side effects of treatments. Gastritis and peptic ulcers may be secondary to the use of nonsteroidal antiinflammatory agents or corticosteroids. Oral ulcers are frequent during the course of SLE, and patients may complain of dysphagia. Esophageal reflux or ulceration may occur. Abdominal pain is a frequent complaint in patients with SLE, and it may be related to serositis, peritonitis, intestinal vasculitis, intraabdominal thrombosis, small intestinal bacterial overgrowth, or pancreatitis (63). Vascular lesions can cause intestinal ischemia or perforations. Clinical manifestations linked to these gastrointestinal lesions can be masked by corticosteroids. Pancreatitis may be directly related to SLE or secondary to corticosteroid therapy.

Hepatomegaly is frequent but rarely accompanied by significant liver dysfunction. The presence of liver abnormalities with ANA is more likely to be due to chronic active hepatitis, also called *lupoid hepatitis*, than to SLE.

RENAL DISEASE IN SYSTEMIC LUPUS ERYTHEMATOSUS

Pathogenesis of Lupus Nephritis

Genetic or acquired susceptibility factors are probably associated with the onset of renal disease. Numerous mouse models have improved our understanding of the pathogenesis of lupus nephritis.

Nucleosome plays a central role in the pathogenesis of SLE. There is increasing evidence that increased apoptosis and impaired clearance of apoptotic cells facilitate the emergence of anti-DNA antibodies and immune complexes. Nucleosomes are also important for triggering tissue lesions, including glomerular lesions. There are at least two mechanisms that explain how autoantibodies mediate tissue damage: (a) deposition of preformed immune complexes in the kidney or *in situ* formation of these complexes via the interaction between nucleosome already deposited in the glomerulus and anti-dsDNA or (b) cross-reactivity of antibodies with glomerular basement membrane components. α -Actinin has recently been identified as a cross-reactive target bound by nephritogenic anti-dsDNA in a lupus mouse model (64). α -Actinin is an actin-bundling protein expressed in podocytes, monocytes, capillaries, and larger vessels. Mutations of the gene encoding the isoform α -actinin-4 have been identified in familial focal and segmental glomerulosclerosis. α -Actinin may also be a target for anti-dsDNA in humans. Other cell-surface and matrix receptors on various cell types, including mesangial cells, fibroblasts, and monocytes, could bind nucleosomes in the kidney.

Inherited deficiencies of the early components of the complement classic pathway are the strongest susceptibility genes for the development of SLE in humans. C1q-deficient mice have been generated by homologous recombination (24). The presence of multiple apoptotic bodies in the altered glomeruli suggests a critical role for C1q in the clearance of apoptotic cells. This finding is consistent with the report that C1q binds to apoptotic keratinocyte (65). Apoptotic cells are believed to be a major source of the autoantigens of the SLE, and impairment of their removal by complement may explain the link between hereditary complement deficiency and the development of SLE.

Another study on the lupus-prone New Zealand black and New Zealand white mouse has shown that the γ chain of the T-lymphocyte receptor is mandatory for the initiation of the inflammatory cascade in the kidney. Indeed, when the New Zealand black and New Zealand white mice were backcrossed with Fc γ R-deficient mice, glomeruli were not affected despite the deposition of immune complexes and C3 (66). In humans, decreased binding affinity of the Fc γ RIIIA-158F allele may result in ineffective clearance of antigen-antibody complexes, resulting in an increased susceptibility to immune-complex-mediated nephritis (67). Of interest, another polymorphism in the gene coding for the Fc γ RIIIA receptor represents a significant risk factor for SLE but has no clear effect on susceptibility for lupus nephritis (68).

Clinical Findings

Clinical symptoms of renal involvement are noted in 40 to 80% of patients, appearing most often during the first years (8). Renal involvement is variable, with some patients

showing minimal urinary anomalies and others having nephritic syndrome with rapidly progressive renal failure. Proteinuria is the most frequent symptom. Proteinuria is frequently abundant, accompanied by a nephrotic syndrome. Microscopic hematuria is frequently associated with proteinuria and is rarely seen in isolation. The urinary sediment contains granular and red blood cell casts. Patients with severe nephritis are often hypertensive and have reduced renal function. Up to 50% of children with lupus nephritis have a decreased glomerular filtration rate (GFR). Signs of renal tubular dysfunction may be observed and are related to immune deposits along the tubular basement membranes and to interstitial cellular infiltrates. Increased excretion of β_2 -microglobulin is frequently found. Renal tubular acidosis with hyperkalemia has been reported.

Histologic Classification

Most nephrologists believe that the presence of urinary abnormalities or impairment of renal function is an indication for renal biopsy, especially to guide the initial treatment (69). There is no correlation between symptoms and the class of glomerular lesions (focal or diffuse proliferative glomerulonephritis with varying degrees of severity or membranous glomerulonephritis). The type of histologic lesion is most important in deciding the best therapy and in determining prognosis. A renal biopsy may be indicated in a patient with glomerular disease in which there are no extrarenal manifestations of SLE. It is more difficult to decide whether to perform a renal biopsy in patients with no clinical evidence of renal disease. Indeed, glomerular lesions may be found in this setting, most often with mesangial deposits and mild mesangial proliferation. Although the clinical evidence of renal involvement is present in only 40 to 75% of SLE patients, renal biopsy studies show nearly universal histologic changes. The majority of clinically asymptomatic patients will show moderate histologic damage, but some may have more severe histologic lesions, such as focal and segmental glomerulonephritis, or, very rarely, diffuse proliferative glomerulonephritis.

Histologic anomalies are present in virtually all SLE patients, and immune deposits are almost always found on immunofluorescence examination or by electron microscopy. There is a wide diversity of glomerular damage in SLE. Moreover, tubulointerstitial and vascular lesions can be observed in addition to glomerular lesions. Numerous classifications have been proposed based primarily on the histologic damage observed by light microscopy. One such system was developed by the International Study of Kidney Disease in Children. The classification of the World Health Organization is now widely accepted (Table 46.3) (70,71). An adequate renal specimen, containing at least ten glomeruli, must be obtained for light microscopy analysis. Immunofluorescence examination is also mandatory. Electron microscopy may aid the classification but is not necessary for diagnosing

TABLE 46.3. WORLD HEALTH ORGANIZATION CLASSIFICATION OF LUPUS NEPHRITIS

I. Normal glomeruli
A. No deposit
B. Normal by light microscopy but deposits by immunofluorescence or electron microscopy
II. Mesangiopathic glomerulonephritis
A. Mesangial widening and/or mild hypercellularity
B. Moderate hypercellularity
III. Focal and segmental glomerulonephritis (with mesangial alterations)
A. With active necrotizing lesions
B. With active and sclerosing lesions
C. With sclerosing lesions
IV. Diffuse proliferative glomerulonephritis (with severe mesangial and endocapillary proliferation and subendothelial deposits)
A. Without segmental lesions
B. With active necrotizing lesions

lupus nephritis. The study of renal biopsies has allowed for the definition of several histopathologic aspects of lupus nephritis (Fig. 46.1). Furthermore, biopsies have permitted clinicopathologic correlations with the natural outcome of the disease. Of importance, the histologic categories of the biopsies guide therapeutic decisions (72,73).

The World Health Organization classification of lupus nephritis includes six classes:

In class I, the glomeruli appear normal on light microscopy. Immunofluorescence and electron microscopic examinations are negative or show slight mesangial deposits. In these cases, patients generally show no clinical or biologic signs of renal damage. Class I is rarely observed on biopsy specimens of SLE patients and is present only in patients without clinical manifestation of renal disease.

In class II, there is a hypertrophy of the mesangial matrix, with a proliferation of mesangial cells. This is called a *mesangial proliferative lupus glomerulonephritis* and is observed in 20% of patients. Immunofluorescence and electron microscopy examination show mesangial deposits, whereas the glomerular walls are normal. Urine examination can be normal or may reveal a microscopic hematuria and moderate proteinuria. The prognosis is excellent except in cases of transformation to a more severe form (74).

Class III is observed in 10 to 20% of patients. These lesions appear as focal lupus glomerulonephritis in which the proportion of glomeruli presenting focal lesions is less than 50%. Class III can range from focal proliferative and necrotic lesions affecting a limited proportion of glomeruli to more

diffuse lesions affecting a higher proportion of glomeruli. In the latter cases, tubulointerstitial lesions are often present in addition to glomerular lesions. Immunofluorescence and electron microscopy examination reveal diffuse mesangial deposits and focal deposits along the glomerular capillary walls.

When less than 20% of glomeruli are affected by small segmental lesions, patients usually have mild renal symptoms with low-grade proteinuria without nephrotic syndrome and normal GFR. The long-term prognosis is favorable, with probably less than 5% risk of progression to end-stage renal failure after 5 years (75). Conversely, when cellular proliferation, necrosis, and large subendothelial deposits involve more than 40% of the glomeruli, the clinical symptoms are more severe with active urine sediment, nephrotic syndrome, hypertension, and moderate renal insufficiency in some patients. The prognosis is the same as for diffuse proliferative glomerulonephritis (72,75).

Class IV corresponds to diffuse proliferative lupus glomerulonephritis, the most common and severe form of lupus nephritis, in which more than 50% of glomeruli present a marked hypercellularity. Hypercellularity may affect a segment of the glomerulus or may be global, involving more than one-half of the glomerular tuft. In addition, active lesions are often seen including necrotic lesions, karyorrhexis, hematoxylic bodies, leukocytic infiltrates, wire loops, and hyaline thrombi. The proportion of glomeruli with epithelial crescents is an important factor in determining the prognosis of this type of glomerulonephritis. Tubulointerstitial lesions with mononuclear cell infiltrates are common. Immunofluorescence and electron microscopy examination show diffuse mesangial and extensive subendothelial immune deposits. Deposits are also found frequently along the tubular basement membranes and the capillary walls. The clinical symptoms are often severe: hematuria with casts, nephrotic syndrome, hypertension, and moderate or severe renal insufficiency. Patients with class IV glomerulonephritis are at high risk of progression to end-stage renal disease if adequate therapy is not undertaken.

Class V corresponds to membranous lupus glomerulonephritis, characterized by a thickening of the glomeruli capillary walls and the presence of global or segmental continuous subepithelial immune deposits separated by "spikes." There is little or no cellular proliferation, and mesangial deposits are almost constant in SLE. In some patients, the membranous lesions are associated with lesions of class II, III, or IV. The latter category resembles clinically diffuse proliferative glomerulonephritis. Membranous glomerulonephritis may precede other manifestations of lupus. Moderate proteinuria is accompanied by hematuria in 50% of patients. Nephrotic syndrome often develops. Moderate renal failure and hypertension are observed in 25% of patients.

Class VI corresponds to an advanced stage of lupus nephritis where most glomeruli are sclerotic but without evidence of active glomerular lesions.

By immunofluorescence, the composition of deposits is remarkable no matter where they are located. In these

FIGURE 46.1. Class I: Normal glomerulus by light microscopy (*right-hand side*) but mesangial immune deposits by immunofluorescence (*left-hand side*) study. Class II: Purely mesangial hypercellularity and mesangial matrix expansion in glomerulus by light microscopy, with mesangial immune deposits by immunofluorescence study. Class III: Segmental endo- and extracapillary proliferation involving 50% of all glomeruli by light microscopy with mesangial and some subendothelial immune deposits by immunofluorescence study. Class IV: Global endo- and extracapillary proliferation and subendothelial deposits by light microscopy and numerous immune deposits by immunofluorescence study. Class V: Membranous glomerulonephritis, with subepithelial deposits by light microscopy, clearly defined by immunofluorescence study. (See Color Plate 46.1.)

deposits, IgG is dominant, mostly IgG1 and IgG3. IgA and IgM are also present, as well as early complement components, C4 and C1q, along with C3. Such positivity for all three Ig classes and C3, C4, and C1q is called *full house* and is found only in lupus nephritis. Fibrin deposits are also found, particularly in class IV biopsies.

Activity and Chronicity Indexes

Pirani et al. and Morel-Maroger et al. introduced the concept of histologic signs of activity and chronicity (76,77).

Later, Austin et al. introduced the activity and the chronicity indices, which may help to define the prognosis (78). Active histologic lesions include cellular crescents, endocapillary proliferation, fibrinoid necrosis, karyorrhexis, thrombi, wire loops with subendothelial immune deposits, glomerular leucocyte infiltration, and interstitial mononuclear cell infiltration (Table 46.4). These active lesions are each graded 0 to 3 (with both necrosis and cellular crescents graded 0 to 6) to give an activity index graded 0 to 24. Active lesions are potentially reversible with the treatment. Recent studies have shown that glomerular capillary

Tubular atrophy

wall necrosis is associated with poor outcome, especially when these lesions affect a high percentage of glomeruli (79). Extramembranous deposits are not considered as active lesions. Conversely, irreversible lesions, including glomerular sclerosis, fibrous crescents, tubular fibrosis, and interstitial fibrosis, permit the definition of chronicity index. These lesions do not respond to treatment. If the activity and the chronicity indices are important to decide the best therapy for individual patients, their prognostic significance is still debated. The National Institutes of Health group found that an activity index greater than 12 of 24 or an elevated chronicity index were indicative of a poor renal prognosis (78). A chronicity index less than 2 was associated with a 10-year renal survival rate of 100%, whereas a chronicity index between 2 and 4 was associated with a 10-year renal survival rate of only 70%. The renal survival rate at 10 years was only 35% in patients with a chronicity index greater than 4. However, a more recent study including unselected patients with lupus nephritis found that activity and chronicity indices were not well correlated with renal outcome (80).

Repeat Renal Biopsies

Repeat biopsies have shown that transformations from one class to another are possible, either via aggravation or amelioration of the histologic lesions. A mesangiopathic glomerulonephritis can transform into focal and segmental glomerulonephritis or diffuse proliferative glomerulonephritis. These, in turn, are susceptible to improvement under treatment. In contrast, transformation is rare in cases of membranous glomerulonephritis. Repeat renal biopsies

allow for the evaluation of the efficiency of treatment and are useful in considering therapeutic changes, particularly in cases of worsening clinical symptoms (e.g., proteinuria, renal insufficiency). In some cases, clinical aggravation may be secondary to sclerotic lesions, for which treatment is ineffective. Sclerotic lesions are especially seen in patients who have had insufficient treatment for an active nephropathy. In other cases, clinical deterioration may be related to active histologic lesions, which require a more aggressive treatment. Also, deterioration of renal function may be related to nephrotoxic treatments, such as nonsteroidal antiinflammatory drugs, cyclosporine, or antibiotics, rather than to SLE itself. Hill et al. recently reported that a repeat renal biopsy at 6 months after a change of treatment carries great prognostic significance (81).

Prognostic Factors in Patients with Severe Lupus Nephritis

Some patients with diffuse proliferative glomerulonephritis are at higher risk of progression, particularly those with extensive crescent formation and necrotizing glomerular lesions (82–87). In addition to these histologic signs of severity, other factors may be of prognostic significance, including age, gender, race, hypertension, initial serum creatinine concentration, the delay between onset of renal disease and treatment, the occurrence of exacerbations of the nephropathy, and the response to therapy after the first year (78,84,88–92). Thus, despite numerous controlled and uncontrolled therapeutic studies, there is still no general agreement on the best course of therapy in these patients.

An analysis of these prognostic factors is important in proposing the most effective and safest therapy for individual patients. Several studies have shown that lupus nephritis has a worse prognosis in men compared to women. Renal survival in black Americans with diffuse proliferative glomerulonephritis is poorer compared to white patients (93). Renal survival rate in black patients was 58% at 5 years, compared to 95% in white patients who retained renal function after pulse cyclophosphamide therapy. Several possible reasons for the significance of race in the poorer prognosis in lupus nephritis have been proposed and include socioeconomic effects, different HLA phenotypes, and inherited susceptibility for progression to renal failure.

Levey et al. identified several risk factors for progression to renal failure in 86 patients with severe class III or class IV lupus glomerulonephritis who were treated with prednisone and oral cyclophosphamide (94). An elevation of serum creatinine was the only initial feature predictive of progression to renal failure. Of interest, the same authors found that the subsequent clinical course in response to therapy supplemented prognosis based on initial serum creatinine. The risk of progression to renal failure was higher in those patients who did not show resolution of renal abnormalities within 48 weeks of follow-up. Patients with

normal initial serum creatinine and patients with resolution of initial serum creatinine elevations to normal had a similar and much lower risk of progression to renal failure. Other authors have also reported the poor prognostic significance of elevated serum creatinine at presentation (78,84,89,95,96). However, these findings were not confirmed in several studies with longer periods of follow-up (72,83,92,97).

Esdaile et al. studied the impact of the delay between the onset of renal disease, the renal biopsy, and initiation of therapy (98). They found that the duration of renal disease before renal biopsy was a statistically significant predictor for renal failure or death due to renal disease. The most likely explanation for these findings is that early treatment of renal disease is associated with better outcome. There was a significant increase in serum creatinine, in urinary protein excretion, and in activity and chronicity indexes on renal biopsy in those patients in whom the treatment was delayed. Lim et al. found that chronicity index, male gender, and initial renal insufficiency were prognostic factors for diffuse proliferative lupus nephritis (99). Similarly, Conlon et al. analyzed, retrospectively, a cohort of 43 patients, one-half of which progressed to end-stage renal disease and were treated with IV cyclophosphamide. Elevated serum creatinine and a high degree of interstitial fibrosis on renal biopsy before treatment were associated with a worse renal prognosis (100).

Moroni et al. studied the prognostic significance of renal flares, defined as a rapid increase of serum creatinine or proteinuria, in a retrospective study of 70 patients with lupus nephritis (92). Patients with renal flares had a higher probability of having a persistent doubling of serum creatinine compared to those who had no renal flares. The relative risk of having a persistent doubling of serum creatinine was 27 times higher in patients with rapid increases in serum creatinine. This outcome was more frequent in patients who did not respond rapidly to therapy. These data support the need for aggressive treatment of lupus nephritis exacerbations.

Several reports have claimed a poorer prognosis of lupus nephritis in children as compared to adults. However, Cameron et al. reported a renal survival rate of 85% at 5 years and 82% at 10 years in a series of 80 patients with onset of disease under the age of 20 years (101). Platt et al. found 5- and 10-year survival rates of 85 and 81%, respectively, in a series of 70 patients (9). A few reports in recent years have identified the risk factors for renal failure in children with lupus nephritis. Yang et al. retrospectively evaluated the clinical course, histopathology, and prognosis of 167 children (102). Patients with persistent hypertension, anemia, increased serum creatinine concentration at the time of biopsy, and low titer of CH50 were more prone to develop renal failure. The overall renal and patient 5-year survival rates were 87.7% and 91.1%, respectively. McCurdy et al. reported on a group of 71 children, of whom 22% progressed to end-

stage renal failure (96). They also found that persistent hypertension, anemia, abnormalities of the urinalysis, and elevated serum creatinine levels were associated with progression to renal failure. Emre et al. found that the prognosis of lupus nephritis in children is primarily dependent on the histopathologic lesions. Moreover, the severity of the clinical renal disease at admission and the presence of persistent hypertension were the main poor prognostic factors (103). Baqi et al. analyzed the risk factors for renal failure in 56 children with lupus nephritis (104). Univariate analysis revealed that an elevated serum creatinine level, a decreased C3 complement level, hypertension, and class IV lupus nephritis were associated with the rate of progression to renal failure. Multivariate analysis showed that progression to renal failure was independently associated with class IV lupus nephritis, hypertension at presentation, and low C3 complement level in association with elevated serum creatinine levels. These three reports, as well as other studies in adults, found that hypertension was virtually always a significant risk factor for renal failure. Therefore, children with hypertension should be treated appropriately with antihypertensive drugs, as control of blood pressure may be as important as antiinflammatory treatment.

Prognostic Factors in Patients with Membranous Lupus Nephritis

Patients with pure membranous nephropathy without mesangial hypercellularity have a good prognosis with a 5-year renal survival close to 85% (105,106). Conversely, Sloan et al. found that when membranous nephropathy was associated with segmental endocapillary proliferation or necrosis in less than 50% of glomeruli, the 5-year renal survival was 72% and only 49% when more than 50% of glomeruli were affected (106). Therefore, associated glomerular inflammation and necrosis are important prognostic factors in membranous lupus nephritis. Elevation of initial serum creatinine or worsening renal function and severe nephrotic syndrome are also risk factors for poor renal outcome.

LABORATORY INVESTIGATIONS

SLE is characterized by a large variety of autoantibodies, of which some, such as anti-DNA antibodies, are found almost exclusively in patients suffering from this disease (107). Such autoantibodies associate with the corresponding antigen and form immune complexes, which activate the classic complement pathway. These immune complexes can be detected in the circulation or are deposited in different tissues where they are detectable by immunofluorescence techniques.

The detection of ANA by indirect immunofluorescence is a simple and sensitive test in which the serum is incubated with a tissue section. ANA are present in significant

titer in 95% of patients with SLE, and the diagnosis is unlikely in their absence (108). The pattern of fluorescence gives an indication of the specificity of the antibodies. A homogenous or diffuse aspect of fluorescence is related to the presence of antidesoxyribonucleoprotein antibodies and is strongly associated with SLE. The same antibodies are responsible for the formation of Hargraves cells (lupus erythematosus cells). After the reaction of the antibodies with the nucleus of leukocytes, the chromatin pattern is altered, and the DNA forms a large mass with the antibodies and complement that is then ingested by a phagocyte. A peripheral aspect of the fluorescence points to the presence of antinative DNA antibodies, characteristic of active SLE. A speckled aspect of the fluorescence is related to the presence of antibodies reacting with various nuclear antigens, such as anti-Sm or antiribonucleoprotein antibodies. Such a pattern of fluorescence may be observed in SLE or mixed connective tissue disease but is more frequently associated with scleroderma. The nucleolar pattern is observed in only 25% of patients with SLE.

The presence of ANA is not unique to SLE because they can be detected in other rheumatologic disorders such as chronic juvenile arthritis, scleroderma or mixed connective tissue disease, autoimmune hepatitis, thyroiditis, or after taking certain medications. ANA titers should be determined, as low levels can be found in up to 2% of the general population. High levels of ANA are highly suggestive of SLE. A small number of patients with SLE do not have ANA, but more than one-half of these do have anti-SSA antibodies. Anti-SSA antibodies cannot be detected by indirect immunofluorescence tests. Clinically, patients with anti-SSA antibodies generally have photosensitivity, arthralgia, and serous effusions.

Antinative dsDNA antibodies are more specific to SLE (109–111). They can be detected in the serum by measuring their capacity to bind radiolabeled native DNA (Farr test) or by an immunoenzymatic technique. Anti-DNA antibodies can also be detected by indirect immunofluorescence on the microorganism *Critidia luciliae*, which have a kinetoplast in their cytoplasm containing native DNA. The Farr assay detects high-avidity antibodies, whereas the immunoenzymatic technique also detects low-avidity antibodies. The enzyme-linked immunosorbent assay is of interest for screening diagnosis. The Farr assay is better correlated to the presence and the severity of the nephritis. Moreover, the Farr assay gives estimation on the level of antibodies, which is used to monitor disease activity. Normal or stable levels are positively correlated to a stability of the disease, whereas an increase often precedes the reappearance or aggravation of clinical manifestations of the disease.

Anti-Sm antibodies are specific to SLE but are only found in 30% of patients and are often associated with a less severe form of the disease (112). Antiribonucleoprotein antibodies, present in 35% of SLE cases, are not specific for SLE. Antierthrocyte antibodies, detected by the Coombs'

test, can be responsible for severe hemolytic anemia. Anti-platelet antibodies are often present, sometimes causing thrombocytopenia. Antilymphocyte antibodies, directed against T lymphocytes, may play a role in the pathogenesis of the disease. Siegert et al. found a correlation between the levels of anti-C1q antibodies and the occurrence of nephritis, the titers of anti-DNA antibodies, and hypocomplementemia (113). The increase of anti-C1q titers was correlated with the development of proliferative glomerulonephritis. Thus, the serial measurements of these antibodies may be useful to predict relapses of nephritis. Because C1q is found in glomerular immune deposits, C1q may act as a planted antigen for anti-C1q antibodies, thus increasing the inflammatory reaction (114).

APL antibodies, including anticardiolipin and the lupus anticoagulant, may be found in SLE and are responsible for an increased risk of thrombotic complications.

Many of these autoantibodies can be responsible for the formation of immune complexes, either in the serum or localized in tissues. Circulating immune complexes can be detected by several tests, but these tests are not useful in the diagnosis or the monitoring of SLE, as many other conditions can be accompanied by circulating immune complexes. Immune complexes deposited in tissues are detected by direct immunofluorescence techniques. Deposits are frequently found in the kidneys. Skin biopsy may show immunoglobulin, principally IgG, and complement fraction deposits at the dermoepidermic junction. This is the lupus band test that is highly suggestive of SLE (115).

Hypocomplementemia is observed in 75% of cases at presentation, particularly in patients with nephritis. Decreased levels of CH50, C1q, and C4 are related to the activation of the classic pathway of the complement system. A permanently low C4 level may also be secondary to null C4 alleles. A deficiency of other complement factors may also be observed. Levels of C4, C1q, and C3 are used to monitor disease activity in conjunction with anti-DNA antibodies. In most patients with nephritis, flares are preceded by a decrease of these complement components. Concentrations of properdin and factor B are also depressed due to the activation of the alternative pathway.

Regular testing of biologic parameters (blood cell count, erythrocyte sedimentation rate, serum albumin, proteinuria, urinary sediment, GFR, anti-DNA antibodies, CH50, C4, and C3) every 3 to 6 months is important during the evolution of the disease. This testing allows for the detection of hematologic or renal involvement as well as a serologic evidence of disease activity before the appearance of clinical manifestations (116).

DRUG-INDUCED LUPUS

Several drugs, particularly those that are metabolized by acetylation in the liver, such as procainamide or hydralazine, can induce a lupus-like syndrome (117,118). The syndrome is

more likely to develop in slow acetylators, which have a genetically determined deficit in hepatic *N*-acetyltransferase (119).

One characteristic of drug-induced lupus is the presence of antihistone antibodies that are found in 95% of such patients. Other autoantibodies, such as anti-DNA antibodies, are rarely found in those with drug-induced lupus. These autoantibodies are formed against a complex between DNA and a histone dimer of H2A and H2B. Of interest, although the drugs responsible for drug-induced lupus are quite heterogeneous, all of these antibodies are directed against the same epitope (120). With hydralazine, the complex is composed of H1 and H3-H4 and DNA.

Procainamide, hydralazine, penicillamine, isoniazid, interferon-alpha, methyl dopa, chlorpromazine, and diltiazem are all likely causes of lupus. Anticonvulsants (e.g., phenytoin, mephenytoin, trimethadione, ethosuximide), quinidine, anti-thyroid drugs, and antimicrobial agents (e.g., sulfonamides, rifampin) may possibly induce lupus. Clinical manifestations associated with drug-induced lupus include fever, cutaneous rash, arthralgia, and serositis, whereas renal, hematologic, or neurologic symptoms are rare. Anti-DNA antibodies are often absent, and the levels of complement fractions are normal.

The differentiation between SLE and lupus syndrome secondary to a medication is not always clear. The principal criterion is the spontaneous recovery from the syndrome within 6 months after withdrawal of the suspected medication.

NEONATAL LUPUS

Neonatal lupus occurs in 1 to 2% of children born to mothers with lupus and is due to passively transferred autoantibodies. The main complication of neonatal lupus is a total and irreversible atrioventricular block secondary to anti-SSA (Ro) and anti-SSB antibodies, which interfere with the development of the conduction system (121). Some infants require insertion of a pacemaker. The incidence of congenital heart block in children from mothers with anti-SSA (Ro) antibodies ranges from 0.2 to 7.5% (122).

Other newborns, particularly girls, may present with erythematous rash that often develops after exposure to ultraviolet light. The rash regresses totally after 6 months. Other manifestations may include anemia, moderate leukopenia and thrombocytopenia, or hepatomegaly with cytolysis (123).

TREATMENT OF LUPUS NEPHRITIS

Therapeutic options for patients with lupus nephritis vary depending on the histologic lesions observed on renal biopsy.

Therapy of Patients with Mild Renal Lesions

Patients with class II mesangial proliferative lupus glomerulonephritis do not need specific therapy, as there is little

probability of progression (74). Nevertheless, careful follow-up of the patient is necessary, as transformation to a more severe renal disease is possible.

Therapy of Patients with Focal and Segmental Glomerulonephritis

Patients with focal and segmental glomerulonephritis who have less than 20% of the glomeruli affected by small segmental lesions have a favorable long-term outcome. These patients may require treatment for extrarenal lesions, but they do not need specific therapy for these renal lesions. Conversely, when cellular proliferation and necrosis involve more than 40% of the glomeruli, the course of the disease is similar to that of diffuse proliferative glomerulonephritis, and the same aggressive therapy is needed (72,75).

Therapy of Patients with Diffuse Proliferative Glomerulonephritis

Patients with active and extensive focal proliferative glomerulonephritis and those with diffuse proliferative glomerulonephritis are at high risk of progression to end-stage renal disease if adequate therapy is not undertaken (124). The therapeutic regimen for class IV lupus nephritis has changed over the years (125). Although there are a large number of reports on this topic, there are only a few randomized studies. Most of these studies do not indicate the long-term outcome after 10 years of follow-up. Pollak et al. showed that high doses of corticosteroids could improve the course of diffuse proliferative glomerulonephritis, whereas low doses were ineffective (126). Most nephrologists treat these patients with prednisone, 1 to 2 mg/kg/day for several months, followed by a slow dose reduction when the disease is controlled. However, high doses of oral prednisone alone may give poor long-term results and are often associated with serious side effects. Many authors have proposed initial therapy with IV methylprednisolone pulses that have potent and rapid antiinflammatory and immunosuppressive effects (127–131). After methylprednisolone pulses, extrarenal symptoms disappear rapidly, and serum creatinine rapidly returns to normal. Furthermore, these pulses frequently permit initiation of oral prednisone at a lower dose, thus reducing the complications of long-term treatment.

Some patients with diffuse proliferative glomerulonephritis are well controlled with corticosteroids alone. However, several studies have shown that renal survival is significantly better when cyclophosphamide or azathioprine is added to corticosteroids (132–136). A metaanalysis of eight trials published between 1971 and 1983 compared the outcome of 113 patients treated by corticosteroids alone with the outcome of 137 other patients who received cyclophosphamide or azathioprine in addition to corticosteroids with a follow-up of 2 to 82 months (137). The

addition of cyclophosphamide or azathioprine lowered the incidence of progression to renal failure by 40% compared to a treatment with corticosteroids alone. There was no difference in terms of mortality between both groups. The metaanalysis could not determine whether cyclophosphamide or azathioprine was superior.

In studies performed at the National Institutes of Health, 111 patients with lupus nephritis were randomized in five groups and received either high-dose prednisone alone or moderate doses of prednisone in association with azathioprine, oral cyclophosphamide, oral cyclophosphamide and azathioprine, or cyclophosphamide given as IV boluses (138). There was no difference in outcome during the first 5 years, but after 5 years, the incidence of renal failure was significantly higher in the group receiving prednisone alone compared to patients given IV cyclophosphamide. There was a trend to a better outcome in patients who received IV cyclophosphamide compared to those given oral cyclophosphamide alone or in combination with azathioprine, although the differences were not statistically significant. Patients receiving azathioprine did better during the first decade than those treated with prednisone alone, but the incidence of renal failure was not statistically different after 10 years in these two groups. The results of these studies have greatly influenced nephrologists in their therapeutic decisions. Many of them use IV cyclophosphamide for the treatment of diffuse proliferative glomerulonephritis (139,140). However, the interpretation of the results of the National Institutes of Health trials should take into account several points. First, among the 111 patients enrolled in the studies, 6 had no renal biopsy, 7 had a mesangiopathic glomerulonephritis, and 16 had pure membranous glomerulonephritis. Second, some of the patients included in the prednisone group were from a historical group. Third, the number of at-risk patients after 10 years was only 8 to 12 in each group. Aggressive therapy, including cytotoxic agents, is indicated in those patients at high risk for progression to renal failure, including an elevated serum creatinine level at the time of renal biopsy, a severe nephrotic syndrome, hematocrit below 25%, crescent formation, severe tubulointerstitial disease, and vascular changes (86).

Cyclophosphamide given as monthly boluses at a starting dose of 750 mg/m² may be less toxic than given orally every day at a dose of 2 mg/kg body weight. The dose of cyclophosphamide given as boluses is increased to 1000 mg/m² if the white blood cell count remains above 3000/mm³ (141). The optimal duration of cyclophosphamide pulse therapy has not been determined. Another National Institutes of Health trial was performed in 65 patients with severe lupus nephritis defined by an impairment of renal function or a high-activity index on renal biopsy (135). Three regimens were compared. The first regimen consisted of 6 monthly pulses of cyclophosphamide, the second of the same regimen followed cyclophosphamide pulses every 3 months for an 2 additional years, and the third of 6 monthly pulses of methylprednisolone without cyclophos-

phamide. Oral prednisone was given to all patients at a starting dose of 0.5 mg/kg/day and then tapered. The probability of doubling serum creatinine after 5 years of follow-up was higher in patients treated with methylprednisolone pulses compared to those receiving cyclophosphamide (48 vs. 25%). The probability of relapse of lupus nephritis was significantly higher in patients receiving cyclophosphamide pulses for 6 months compared to those receiving the long-course cyclophosphamide regimen (55 vs. 10% after 5 years of observation). The conclusions were that cyclophosphamide pulses are more effective than methylprednisolone pulses in preserving renal function and that maintenance cyclophosphamide pulses reduce the risk of relapse. Recent studies have shown that a combination of methylprednisolone pulses and cyclophosphamide pulses are more effective in the long-term follow-up and no more toxic than either therapy alone (131,142).

The data on the efficacy of cyclophosphamide pulses remain scant in children with active lupus nephritis (143). Lehman et al. treated 16 children with cyclophosphamide monthly for 6 months and then every 3 months (144). They reported significant improvement at 1 year in urine protein excretion, hemoglobin levels, C3 and C4, and creatinine clearance despite a significant reduction in prednisone dosage. Baqi et al. compared the results of two treatment modalities in children with class II and class IV lupus nephritis: high-dose pulse methylprednisolone for 10 days, followed by oral prednisone (20 patients) or IV cyclophosphamide given monthly for 6 months and then every 3 months for a period of 3 years with oral prednisone (30 patients) (104). The authors did not find any difference in outcome for the two treatment modalities.

Other authors have reported on the potential to control the disease with shorter courses of therapy. The Euro-Lupus Nephritis Trial performed a randomized trial in 90 adult patients with diffuse proliferative lupus nephritis to compare the efficacy and the toxicity of a high-dose IV cyclophosphamide regimen (6 monthly pulses and 2 quarterly pulses) and a low-dose IV cyclophosphamide regimen (6 fortnightly pulses at a fixed dose of 500 mg) (145). The regimen of low-dose cyclophosphamide followed by azathioprine achieved similar clinical results compared to the high-dose cyclophosphamide regimen. Levey et al. reported the results of the Lupus Nephritis Collaborative Study, in which patients with severe lupus nephritis were treated with oral prednisone at a starting dose of 60 to 80 mg/day and oral cyclophosphamide for 8 weeks (94). Exacerbations were treated using increased doses of corticosteroids. Only 16% of the 31 patients who had normal serum creatinine concentration at the start of the treatment had a rise of serum creatinine at latest follow-up. Only two of them (6.5%) progressed to renal failure. Conversely, 16 of the 55 patients (29%) with elevated initial serum creatinine levels progressed to renal failure during the follow-up period. Patients with severe lupus nephritis and normal initial

serum creatinine may thus achieve excellent outcome without cyclophosphamide pulses, although the duration of follow-up in this study was rather short. Lim et al. suggested that treatment with oral corticosteroid could induce remission in patients who have mild histologic and clinical features and recommended an evaluation of the prognostic factors before the selection of treatment modality (146).

After the observations of the improvement of nephritis in murine lupus with the use of mycophenolate mofetil (MMF) (147–149), several uncontrolled studies in adults and in children confirmed the potential benefits of this drug in lupus nephritis (150–154). A controlled trial involving 42 patients with diffuse proliferative lupus nephritis compared the efficacy and side effects of a regimen of prednisolone and MMF given for 12 months with those of a regimen of prednisolone and cyclophosphamide given for 6 months, followed by prednisolone and azathioprine for 6 months. At 1 year, both groups showed similar rates of complete or partial remissions, relapses, and treatment discontinuations (155). Adverse effects of treatment were more frequent in the group of patients receiving cyclophosphamide. Two other controlled trials comparing MMF and IV cyclophosphamide found no significant differences with a follow-up of 1 to 2 years (156,157). Ongoing trials are being performed in the United States, and long-term follow-up of these patients is important to confirm whether MMF is as efficient as IV cyclophosphamide.

An effective treatment should be associated with control of the extrarenal manifestations of SLE, a normalization of complement levels and anti-DNA antibody titers, as well as a decrease in the activity of the urine sediment, a decrease of proteinuria, and a decrease or stabilization of plasma creatinine. Our current protocol for patients with severe lupus nephritis is to start with 3 methylprednisolone pulses followed by oral prednisone 1.5 mg/kg/day and 6 monthly pulses of cyclophosphamide. In children with milder disease, we may begin the treatment with IV methylprednisolone pulses followed by oral prednisone at moderate doses, 1.0 to 1.5 mg/kg body weight per day before deciding to add cytotoxic agents. A second renal biopsy is performed, and when the disease is controlled, the patient may be maintained on azathioprine or mycophenolate while the prednisone dosage is slowly tapered. This regimen may have a lower risk of neoplasia and gonadal toxicity than prolonged cyclophosphamide therapy (158). There is a risk of flare of SLE if the immunosuppressive treatment is stopped before 2 years or in case of significant proteinuria (159). Therefore, corticosteroids and immunosuppressive drugs should only be stopped after 3 years if the patient shows normal GFR, proteinuria less than 1 g/day, and inactive urine sediment.

Treatment of Relapses

Relapse of the disease may be defined by a worsening of renal symptoms. Some patients may present with an increase in serum creatinine associated with active urinary

sediment and often increased proteinuria (160). The presence of red-cell or white-cell casts is predictive of a renal relapse. In other patients, increase in proteinuria is the only renal symptom. In such cases, serologic abnormalities are important. An elevation in the titer of anti-DNA antibodies and a decrease in the complement levels (C4 and C3) are most often associated with renal flares. These serologic parameters should be checked regularly, as their changes often precede clinical relapse (161,162). In cases with worsening of renal symptoms, repeat renal biopsy may also be of help before deciding a change in the therapy. Patients who show active lesions on repeat renal biopsy may need aggressive treatment. Other patients with increased serum creatinine may have extensive tubulointerstitial lesions with mild glomerular lesions, which do not respond to therapy. Other patients treated initially for diffuse proliferative glomerulonephritis and who responded well to therapy may have an increased proteinuria several months later. A repeat renal biopsy is useful in this situation, as it may show active lesions or pure membranous nephropathy, which require different therapeutic decisions. We believe that a repeat renal biopsy is often needed in patients with renal relapses to decide the best therapy and to avoid unnecessary aggressive treatments. Some authors treat renal exacerbations with methylprednisolone pulses followed by oral prednisone with tapering doses (163).

Treatment of Patients with Membranous Nephropathy

Patients with pure membranous nephropathy, mild proteinuria, and normal renal function have a good prognosis, and there is general agreement that no specific treatment is needed (105,106). The treatment of patients with nephrotic syndrome is controversial. These patients are at risk of thrombotic complications. Moroni et al. performed a trial in which patients were randomly assigned to receive either a 6-month regimen consisting of corticosteroids (3 methylprednisolone pulses followed by oral prednisone 0.5 mg/kg/day during months 1, 3, and 5) and chlorambucil (0.2 mg/kg/day during months 2, 4, and 6) or treatment based on symptoms (164). The probability of surviving without developing renal failure at 10 years was 92% in the treated group versus 60% in the control group. Complete or partial remissions were significantly more frequent in the treated group. Radhakrishnan et al. treated 10 nephrotic patients with cyclosporine for periods up to 43 months (165). Proteinuria decreased to less than 1 g/day in six patients and between 1 and 2 g/day in two patients. Repeat renal biopsies in five patients showed a decrease in the histologic activity index but a rise in the chronicity index. Serum creatinine levels were not significantly increased at the end of the study.

Patients with a worsening of renal function should have a repeat renal biopsy, as patients with membranous nephrop-

athy may develop proliferative glomerulonephritis. In this setting, aggressive treatment must be undertaken rapidly.

Other Therapeutic Approaches

Plasma exchange has been proposed with the goal of removing immune complexes that may be involved in the pathogenesis of lupus nephritis. A randomized controlled trial of 86 patients with severe lupus nephritis compared a standard therapy with prednisone and oral cyclophosphamide to the same treatment with plasma exchanges, three times a week for 4 weeks (166). The mean follow-up was 136 weeks. There were no differences between both groups in terms of patient survival, renal survival, clinical activity of the disease, and complications. However, plasma exchange may not be of help in individual patients (167,168). A multicenter trial of the effects of synchronized plasma exchanges and cyclophosphamide pulses in patients with very severe lupus is currently in progress.

Intravenous immunoglobulins have been reported to be effective in individual patients, including patients with proliferative lupus nephritis (169–171). Cyclosporine has been given to patients who were not well controlled by standard therapy. The treatment was followed by a decrease of proteinuria and an improvement of renal function, and the dose of prednisone could be tapered (172). These results suggest that cyclosporine may be used as a steroid-sparing agent in some patients. Several biologic agents have recently been studied in SLE. LJP-394, which consists of four linked oligonucleotides, has been shown to decrease anti-DNA titers (173). Anti-CD40 ligand monoclonal antibodies improve renal disease in murine lupus (174). However, studies in humans were abandoned because of thrombotic complications (175).

PROGNOSIS AND COMPLICATIONS

Until 30 years ago, the prognosis of patients with lupus nephritis was very poor. Better management of lupus has improved the prognosis with a 10-year survival rate exceeding 80% (176). The disease is often marked by flares and periods of remission. The prognosis of SLE must also take into consideration iatrogenic complications, because they are often linked with flares of the disease, particularly infections, vascular complications, osteonecrosis, or thrombosis.

Infectious complications are a significant cause of death during the course of SLE (177). These are favored by leukopenia and the reduction of the phagocytic functions, functional asplenia, hypocomplementemia, and, more important, by treatment with corticosteroids and immunosuppressive agents (178–180). Some authors have recommended systematic preventive antibiotherapy and antipneumococcal vaccination. Sepsis may be difficult to distinguish from a relapse of lupus. Herpes zoster is very common among the viral

complications (9,181). Early treatment with acyclovir avoids dissemination.

Accelerated atherosclerosis is now recognized as a frequent cause of morbidity and mortality in young adults with lupus, and the process may start during childhood (181–186). Myocardial infarction has been reported in very young patients (187). The pathogenesis is probably multifactorial and includes inflammatory vascular disease, APL antibodies, hypertension, lipid abnormalities associated with the nephrotic syndrome or renal insufficiency, and corticosteroids (188–193). The risk of coronary disease is multiplied nine times during the course of SLE and increases with age and the duration of the disease.

Thrombosis is another common complication of SLE (194). The risk factors include APL antibodies, decreased levels of plasminogen activator, decreased levels of protein S, and in some patients, the additional risks related to the nephrotic syndrome (195–200). Arterial thromboses are observed in lupus patients with APL antibodies and often involve cerebral arteries (201). Venous thromboses are more common (202). Pulmonary embolism is frequent and may be complicated by pulmonary hypertension.

End-stage renal failure occurs in 10 to 20% of patients with severe renal disease after a mean period of 5 years (203,204). While lupus nephritis progresses to renal insufficiency, the activity of SLE often diminishes in terms of other clinical manifestations and biologic symptoms (205). Dialysis can be started and these patients do as well as non-lupus patients with end-stage renal disease. Some patients, however, have a rapid course to renal failure, maintaining clinical and serologic signs of activity. Therapeutic decisions are difficult as aggressive treatments may allow a recovery of renal function and discontinuation of dialysis. On the other hand, these patients are at higher risk of iatrogenic complications, particularly infection, which may be life-threatening (206,207). Clinical and biologic symptoms of the disease most often improve in patients on chronic dialysis, thus allowing stopping of corticosteroids and immunosuppressive therapy. However, clinical manifestations can persist or even appear at this stage.

Renal transplantation is the treatment of choice for those who progress to renal failure. The outcome after renal transplantation in these patients is similar to that of patients with other diseases in adults (208–211) and children (212). However, it is advisable to wait before proposing transplantation until the clinical and serologic activity of lupus has decreased for a few months. Moreover, a period without corticosteroids and immunosuppressive agents may be beneficial to the child. After renal transplantation, the activity of the disease declines, and recurrence in the graft is unusual. The very low rate of recurrence of the disease after transplantation is a strong argument against a direct role of circulating immune complexes in the pathogenesis of the nephropathy.

Ischemic thrombosis of the bone is a rare complication of lupus in children. Several factors may be involved, including

the presence of APL antibodies and corticosteroid therapy. It may affect any bone, but the femoral head and the femoral condyle are more commonly involved (213). Bone mineral density measurements may show osteoporosis, and a recent study found an inverse correlation between bone mineral density and the cumulative dosage of corticosteroid but no significant correlation between bone mineral density and duration or activity of the disease (214).

Growth retardation is a major concern in children treated for several years with corticosteroids, particularly those who need to maintain on daily steroid therapy. Other complications of corticosteroids include cataracts, gastrointestinal hemorrhage, and diabetes mellitus. A cushingoid aspect is frequent and often badly tolerated by adolescent girls. It may explain poor compliance leading to severe relapses.

Side effects of cytotoxic drugs are common. The incidence of hemorrhagic cystitis after IV cyclophosphamide is very low, provided adequate hydration using the IV route is given (141). To minimize the risk of hemorrhagic cystitis, mesna, which binds to cyclophosphamide metabolites in the urine, may be helpful. Nausea and vomiting may be in part prevented by the concomitant use of antiemetic agents such as ondansetron (Zofran). Cyclophosphamide pulses often result in neutropenia with a serious risk of infection, which may be life-threatening (180). Children and their families should be aware of the risk of transient alopecia. Ovarian toxicity is another serious complication (215,216). The risk of amenorrhea depends on the age of the patient at the start of treatment and the total number of pulses (217). When treatment is given for 6 months, the risk of amenorrhea is very low if the patient is younger than 25 years, whereas 25% of patients older than 30 years will develop this complication. When the total number of pulses exceeds 15, the probability of developing amenorrhea is 17% for patients younger than 25 years and nearly 100% for those older than 30 years. Gonadotropin-releasing hormone antagonist may preserve ovarian function (218). There are no published data on long-term gonadal toxicity of cyclophosphamide pulses given to prepubertal girls. The gonadal toxicity of pulse cyclophosphamide in men has not been studied. However, studies in children with idiopathic nephrotic syndrome suggest that this toxicity may occur if the cumulative dosage is higher than 200 mg/kg. Severe infections have been reported in children with lupus nephritis after IV cyclophosphamide (219). It should be noted that no disseminated malignancies have been reported in patients treated with cyclophosphamide pulses, although longer follow-up periods are needed before any definite conclusions may be drawn.

HEMOLYTIC UREMIC SYNDROMES

CHANTAL LOIRAT
C. MARK TAYLOR

DEFINITIONS OF HEMOLYTIC UREMIC SYNDROME AND THROMBOTIC THROMBOCYTOPENIC PURPURA

The syndromes known as *hemolytic uremic syndrome* (HUS) and *thrombotic thrombocytopenic purpura* (TTP) share similar clinical features and pathology. Both are defined by hemolytic anemia with fragmented red cells and thrombocytopenia, an association commonly referred to as *microangiopathic hemolytic anemia* (MAHA). The underlying pathology is thrombotic microangiopathy (TMA), a microvascular occlusive disorder of capillaries, arterioles, and, less frequently, arteries. In TTP, microvascular aggregation of platelets causes ischemic lesions mainly in the brain, less frequently in the kidney and other organs. By contrast, in HUS, platelet-fibrin thrombi mostly affect the kidney. TTP was initially described by Moschcowitz in 1925 (1) and HUS by Gasser et al. in 1955 (2). TTP, which occurs most often in adults, is characterized by the clinical pentad of fever, MAHA, thrombocytopenia, neurologic abnormalities, and variable renal dysfunction. HUS is characterized by the triad of MAHA, thrombocytopenia, and acute renal failure, although brain involvement may complicate the disease. Clearly, the clinical description of both syndromes overlaps. In general, nephrologists call the syndrome they see HUS, whereas hematologists call it TTP.

Both disorders remained mysterious until the 1980s. In 1982, Moake et al. (3) reported that unusually large multimers of von Willebrand factor (VWF) released from endothelial cells were present in the plasma of patients with chronic relapsing TTP and proposed that a failure to process these multimers explained the disorder. In 1985, Karmali et al. (4) demonstrated that HUS in children was associated with enteric infection by *Escherichia coli* that produce verocytotoxin (VT) (Shiga-like toxin). Subsequent investigations clarified the mechanisms of both disorders (5).

VARIOUS TYPES OF HEMOLYTIC UREMIC SYNDROMES IN CHILDREN

Twenty years ago it was recognized that childhood HUS could be divided into two main groups according to the

clinical presentation and outcome. The importance of a prodrome of diarrhea associated with HUS (D+ HUS) was recognized as a distinguishing feature of the main group (6). Its infectious origin was confirmed a few years later (7). D+ HUS represents approximately 90% of cases in children, usually younger than 3 years of age, and is an acquired disease related to the endothelial toxicity of infectious agents, mainly VT-producing *Escherichia coli* (VTEC).

In contrast, HUS not associated with a prodrome of diarrhea (D- HUS) can occur at any age, including the newborn. D- HUS may be familial, with autosomal dominant or, more frequently in children, autosomal recessive transmission. A similar distinction between acquired and intrinsic forms applies in adults (8). In children, various pathogenic mechanisms, corresponding to distinct subgroups of D- HUS, are described (9). A neonatal form is associated with methylmalonic acidemia due to intracellular vitamin B₁₂ deficiency. Some D- HUS cases are associated with abnormalities of the complement regulator factor H (fH) or its gene. Another subgroup of children with HUS, often of neonatal onset and running a recurrent TTP-like course, has been shown to have constitutional deficiency of the VWF-cleaving protease (VWF-cp). In spite of these advances, the pathogenesis in many cases of D- HUS remains unknown.

SOME PROBLEMS OF TERMINOLOGY

The D+ HUS/D- HUS terminology is simple and clinically useful, but it can mislead. Occasionally, some patients with VTEC infection do not have diarrhea (10,11). On the other hand, a diarrheal disease may trigger HUS in a patient with a constitutional predisposition to HUS. Thus, classifying patients only according to the presence or absence of diarrhea can lead to erroneous management.

D+ HUS is commonly referred to as *typical*, and D- HUS as *atypical*. This terminology, although criticized, remains useful for the rough classification of patients.

TABLE 47.1. A CLASSIFICATION OF HEMOLYTIC UREMIC SYNDROME (HUS) IN CHILDREN

Infection-induced HUS	
Enterohemorrhagic <i>Escherichia coli</i> producing verocytotoxin	
Shigella dysenteriae type 1 producing Shiga toxin	
<i>Streptococcus pneumoniae</i> producing neuraminidase	
Human immunodeficiency virus	
Genetic HUS	
Complement abnormalities: factor H deficiency, factor H-gene mutations	
von Willebrand factor–cleaving protease constitutional deficiency	
Defects of vitamin B ₁₂ intracellular metabolism	
Drug-induced HUS	
Calcineurin inhibitors	
Mitomycin C, cytotoxic drugs, gemcitabine	
Ticlopidine, clopidogrel	
Quinine	
HUS superimposed to other pathologies	
<i>De novo</i> posttransplantation HUS	
After bone marrow transplantation	
Systemic lupus erythematosus and antiphospholipid syndrome	
Collagen type III glomerulopathy	
HUS of unknown etiology	
Autosomal recessive HUS of unknown mechanism	
Autosomal dominant HUS of unknown mechanism	
HUS of unknown mechanism without a prodrome of diarrhea	

However, the terms *epidemic* and *sporadic*, implying D+ HUS and D– HUS, are irrelevant. D+ HUS may occur in an outbreak of VTEC infection, but most cases occur in

isolation. Ideally, the classification of the various forms of HUS should rely on etiology and pathogenesis, rather than on overlapping clinical criteria.

In all cases, a thorough inquiry of recent and past history of the patient and the family members is indicated. Unexplained anemia or thrombocytopenia at birth or later, bleeding or thrombotic events, complications of pregnancy, hematuria or proteinuria, and renal disease or unexplained death in family members, particularly in infancy, are important pointers to underlying mechanisms.

In this chapter, we have used an etiologic classification whenever there is good evidence for it. Table 47.1 is an attempt to classify pediatric HUS, to guide the clinician towards a diagnosis. Table 47.2 summarizes the currently recommended investigations.

DIAGNOSIS OF HEMOLYTIC UREMIC SYNDROME

Microangiopathic Hemolytic Anemia

MAHA, a consistent feature of HUS, is a Coombs' test–negative hemolytic anemia in which red cells become fragmented (schizocytes). The hemolysis is intravascular and plasma lactate dehydrogenase is elevated, whereas haptoglobin is very low in the acute phase and during relapse. Haptoglobin is often the last abnormality to normalize in remission, and persistently low haptoglobin

TABLE 47.2. DIAGNOSTIC APPROACH OF THE VARIOUS SUBGROUPS OF HEMOLYTIC UREMIC SYNDROME

Subgroup	Clinical features	Investigations
VT-producing <i>Escherichia coli</i> –induced hemolytic uremic syndrome	Age <3, but not neonatal Prodromic diarrhea Sudden onset	Stool culture on MacConkey's sorbitol medium; serotyping of colonies; VT detection in stools by polymerase chain reaction Detection of immunoglobulin M antibodies in the serum (O157 and other selected serotypes)
<i>Streptococcus pneumoniae</i> infection	Concomitant infection by <i>S. pneumoniae</i>	Erythrocytes polyagglutination detected during attempted blood group determination (false-positive Coombs' test) Confirm by peanut lectin <i>Arachis hypogea</i> test Factor H deficiency, factor H gene mutations Complement C3 may be low due to alternative pathway activation
Complement anomalies	Any age, including neonates Relapsing course Familial, several years apart (siblings or parents)	Total VWF-cp deficiency, without anti-VWF-cp antibodies
VWF-cp deficiency	Severe neonatal hemolytic anemia and thrombocytopenia treated by exchange transfusions Later onset also observed Thrombotic thrombocytopenic purpura–like relapsing course Familial (siblings)	
Inborn errors of vitamin B ₁₂ metabolism	Generally neonatal onset with failure to thrive and neurologic deterioration Also observed in older children without neurologic symptoms	Increased serum and urine methylmalonic acid, low serum homocysteine, high urine homocysteine
Antiphospholipid syndrome	Malignant antiphospholipid syndrome	Measure antiphospholipid and anticardiolipin antibodies and lupus anticoagulant

VWF, von Willebrand factor; VWF-cp, von Willebrand factor–cleaving protease; VT, verocytotoxin.

levels may indicate ongoing chronic hemolysis in some cases. There is no correlation between the severity of anemia and the renal impairment. Often, the reverse is seen, in that children with prolonged anuria exhibit only mild hemolysis. The correction of MAHA by nephrectomy in chronic D- HUS cases suggests that red cell fragmentation occurs in the renal microcirculation, an idea supported 40 years ago by Brain et al. (12).

Thrombocytopenia

Thrombocytopenia associated with MAHA is another common feature of all types of HUS. It is variable in severity. Petechia and surgical bleeding rarely occur unless the platelet count is below $20 \times 10^9/L$. Thrombocytopenia is due to consumption. Plasma fibrinogen and factor V levels are normal, prothrombin and partial thromboplastin times are normal or shortened. Thrombin-antithrombin III complexes, prothrombin fragments, and D-dimers are increased, indicating localized thrombus formation and dissolution, although the overall fibrinolytic activity of plasma is reduced (13,14).

Acute Renal Failure

Sudden anuria is observed in approximately 50% of children with D+ HUS (11,15). Most other children with D+ HUS have oliguria. Rarely, high urine output renal failure occurs. Microscopic hematuria is usual in the acute phase. Urine may be red either because of hematuria or because of hemoglobinuria in severe hemolysis. Proteinuria is also common at the acute phase. By contrast, renal involvement in D- HUS often has an insidious onset with proteinuria, hematuria, and a progressive increase of serum creatinine over a few days or weeks.

FIGURE 47.2. Preglomerular arteriole in glomerular thrombotic microangiopathy, showing the widening and swelling of the endothelial and subendothelial layers, with narrowing of the arteriolar lumen.

Hypertension may be observed transiently in the acute phase of D+ HUS. This may relate to volume overload. Renin-mediated hypertension may also occur in the severe forms of D+ HUS, either early or months or years after the acute phase. In D- HUS, severe renin-dependent

hypertension is frequent, both at onset and in relapse, and generally persists.

PATHOLOGY

Renal biopsies, undertaken more commonly 20 years ago than today, demonstrate three main types of lesions as identified by Habib et al. (16,17).

Glomerular Thrombotic Microangiopathy

Glomerular TMA is characterized by the thickening of glomerular capillary walls, with widening of the subendothelial space, and frequent double contour appearance (Fig. 47.1). Endothelial cells may appear swollen, obstructing the capillary, or detached from the basement membrane. These lesions are observed mainly in glomerular capillaries and preglomerular arterioles (Fig. 47.2), whereas larger arteries are only rarely involved. The mesangial matrix often has a fibrillar appearance. The glomeruli may be

FIGURE 47.5. Cortical necrosis with diffuse glomerular and tubulointerstitial fibrosis.

enlarged, with capillaries distended by red cells and platelet-fibrin thrombi (Fig. 47.3A) that may also be observed in the afferent arterioles (Fig. 47.3B). Immunofluorescence microscopy shows fibrin deposits in the subendothelial spaces and in capillary and arteriole thrombi. This pattern is typical of D+ HUS (15–19).

Arterial Thrombotic Microangiopathy

Arterial TMA involves arterioles and interlobular arteries. Intimal edema and proliferation, necrosis of the arterial wall, luminal narrowing, and thrombosis are observed (Fig. 47.4A). Glomeruli appear ischemic and shrunken, with wrinkling of the basement membranes of the collapsed capillaries (Fig. 47.4B). Arterial TMA is typical of D– HUS and is generally associated with severe hypertension and poor renal prognosis (17,20).

Cortical Necrosis

Cortical necrosis (Fig. 47.5), patchy or rarely diffuse to the whole superficial cortex, is due to acute cortical ischemia after obstruction of the local microcirculation. It is mainly observed in the most severe forms of D+ HUS and is generally associated with prolonged anuria at the acute phase, with a high risk of chronic renal failure.

INFECTION-INDUCED HEMOLYTIC UREMIC SYNDROME

Verocytotoxin-Producing *Escherichia coli* Infection and Hemolytic Uremic Syndrome

HUS is the most severe manifestation of VTEC infection in humans. At least 80% of childhood HUS in developed countries is attributable to this zoonosis, and from the early

1980s, HUS has become a leading cause of pediatric acute renal failure in developed countries.

Verocytotoxin-Producing *Escherichia coli*

Most strains of *E. coli* pose no risk to human health and reside as commensal organisms in the colon. However, in 1977, it was recognized that certain *E. coli* produced a potent exotoxin that caused lysis of vero cells, a primate kidney cell line with epithelial characteristics (21). The toxin, VT-1, was subsequently shown to be homologous to Shiga toxin produced by *Shigella dysenteriae* type 1 (22) and a member of a family of toxins with similar structure. The toxins produced by *E. coli* are referred to by two interchangeable terms, VT or Shiga-like toxin.

VTEC infection was associated with hemorrhagic colitis in 1982 (23) and with childhood HUS 1 year later (4,24). There followed a number of epidemiologic reports that confirmed VTEC as a cause of human disease (5,25–27), and with this came the recognition that other members of the Shiga toxin family, VT-2 and VT-2c, were involved (see later).

In outbreaks of human VTEC infection, the causative strains have frequently been traced to animal sources, predominantly cattle (28,29). Contaminants include meat and bovine products, fruit, vegetables, and surface water. VTEC can survive for long periods in soil and water. However, bacteriologic surveillance of apparently healthy humans, for example, those working in the meat industry, has shown that VTEC excretion is not uncommon, and the strains identified differ from those associated with disease (30). Likewise, the strains of VTEC that colonize animals usually have different properties from those affecting humans, even though they produce the same toxins (31). This suggests that, although the toxin or certain variants of it are necessary for inducing human disease, they are not sufficient by themselves. Other bacterial cofactors are usually needed.

The most important virulence cofactor found in human pathogenic VTEC is the ability to form an attaching and effacing lesion on enterocytes. This is a characteristic of enteropathogenic *E. coli* (EPEC) (32). The genes responsible for this reside in the locus for enterocyte effacement, a 35.6-kB pathogenicity island in the bacterial chromosome that includes the genes for intimin and the translocated intimin receptor, *eaeA* and *tir*, respectively. EPEC inject their own bacterial receptor, the translocated intimin receptor, into the host enterocyte by a type 3 secretion system as outlined in Figure 47.6. This becomes incorporated into the apical membrane of the colonocyte. The *E. coli* can then bind to the host cell via surface expression of the adhesion protein intimin. In so doing, the translocated intimin receptor causes signaling events in the host cell, leading to cytoskeletal changes such as loss of the normal villous structure and a condensation of actin to form a nest-like pedicle beneath the adherent bacterium (33).

Enterohemorrhagic *E. coli* (EHEC) can be considered as those that combine both VT production and the adhesion properties of EPEC. Unlike *S. dysenteriae* type 1, neither EPEC nor EHEC invade the intestinal mucosa. However, EHEC deliver exotoxin in the immediate vicinity of the enterocyte. Not all VTEC are EHEC. In an extensive review of the bacterial properties of VTEC isolated from humans, the strains that induced hemorrhagic colitis and HUS were more likely to produce VT-2 or VT-2c and to express intimin and hemolysin than organisms from asymptomatic individuals (34).

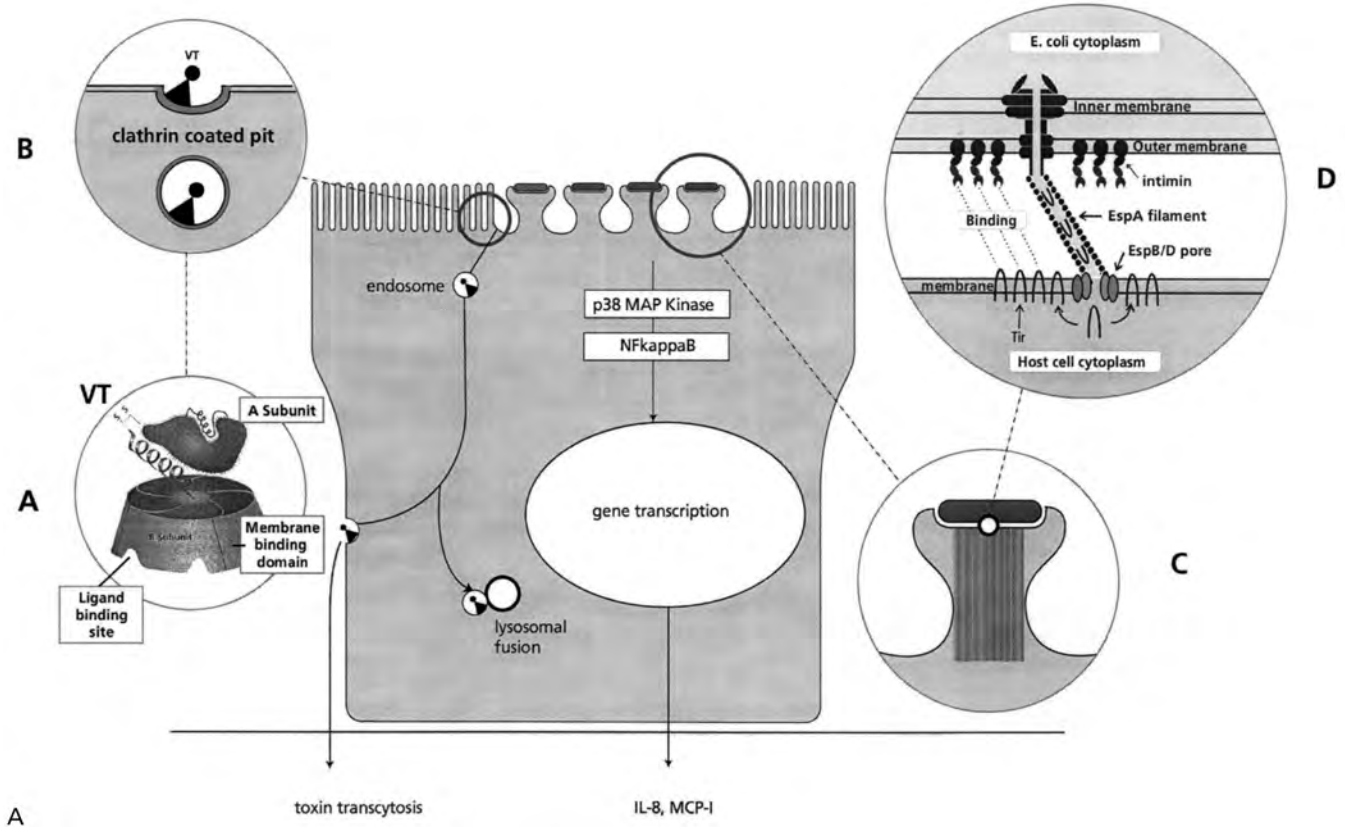

VTEC O157:H7/H– is the predominant cause of HUS in the Americas and western Europe (*O* refers to the lipopolysaccharide serotype of *E. coli*, and *H* to the flagella type). VTEC O157 more often bears VT-2 than VT-1—occasionally both—and consistently contains the locus for enterocyte effacement. Many other serotypes of VTEC also exhibit adhesion and are pathogenic. Each may have its own geographic distribution. O111 is more prevalent in southern Europe and Australia. O118 was recently reported in Germany with two patterns emerging (35). In the first, the organism produced VT-1, bore the genes for intimin and hemolysin, and was associated with colitis and HUS. This strain was traced back to cattle on two farms. The second was the identification of a similar O-serotype that produced VT-2d but neither intimin nor hemolysin. This was found in patients with minor or no symptoms.

Organisms hitherto naïve for VT can acquire the plasmid for VT production by lysogenic phage transfer. If this occurs in a strain with existing covirulence factors, such as enterocyte attachment, humans may be at risk. However, phage transfer is not restricted to *E. coli*. One outbreak of HUS was traced to infection by a VT-2–producing *Citrobacter freundii* (36).

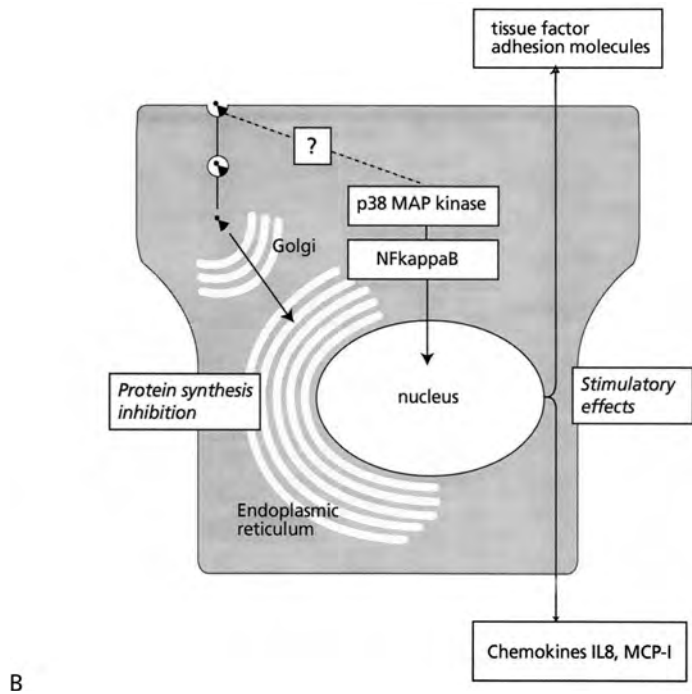

Shiga Toxin Family

All members of the Shiga toxin family have varying degrees of sequence homology and a common structure of an A subunit linked to a pentamer of B subunits. Whereas Shiga toxin is encoded in the chromosome of *S. dysenteriae* type 1, VT is encoded in plasmids. Shiga toxin and VT-1 are identical except for one amino acid in the A subunit, and there is approximately 55% homology between VT-1 and VT-2. VT-1, VT-2, and VT-2c are associated with human disease, VT-2 being the most important. Other VT-2 variants have been recovered from asymptomatic humans, mammals, and birds.

VT needs to be internalized to cause direct cellular toxicity (Fig. 47.6). The B subunit is responsible for cell recognition and uptake by binding the terminal carbohydrate moiety, galactose α 1-4 β galactose of globotriaosylceramide (Gb3) (CD77) expressed on the cell surface (37). Whether a species is susceptible to the toxin, and to some extent the pattern of disease, is determined by the distribution of VT receptors. Gb3 is strongly expressed in primates, mostly on

A toxin transcytosis IL-8, MCP-I

B

FIGURE 47.6. A: Effect of verocytotoxin (VT) on colonic epithelial cells. Main cartoon shows the attachment of VT-producing *Escherichia coli* to the colonocyte. Locally released VT is taken up into endosomes and either digested by lysosomes, transported across the epithelial monolayer, or released into the cytoplasm. **A:** The A-5B structure of VT. (Inset A from Donnelly JJ, Rappuoli R. Blocking bacterial enterotoxins. *Nat Med* 2000;6:257–258, with permission.) **B:** Endocytosis within a clathrin-coated pit after binding of B subunit to Gb3 ligand. **C:** Attaching and effacing lesion showing *Escherichia coli* bound to a pedestal-like structure with reorganization of the underlying cytoskeleton. **D:** Type 3 secretion by which the intimin receptor is injected into the host cell membrane to permit firm attachment. (Courtesy of Dr. S. Knutton.) **B:** Effect of VT on endothelial cells. High levels of toxin exposure induce protein synthesis inhibition, the toxin being transported in a retrograde fashion from the Golgi apparatus to the endoplasmic reticulum and cleaving ribosomal RNA. Low exposure to VT causes cell signaling as shown in the outline. The proximal signaling pathways are unknown. IL, interleukin; MCP, monocyte chemoattractant protein.

renal tubular epithelial cells and gut. Many species, such as domestic cattle, have little expression of Gb3 and are consequently unaffected by the toxin.

After binding to the receptor within a clathrin-coated pit, the intact toxin is endocytosed. From here it may be reex-

ported or fused with a lysosome for degrading. However, some is routed to various intracellular destinations, including the nucleus and the cytosol (38,39). During this, the toxin is cleaved by either furin or calpain to release the A subunit into the cytosol. The A subunit contains an enzyme that

depurinates a specific adenine residue near the 3' end of the 28S ribosomal RNA at a point where aminoacyl transfer RNA is assembled within the 60S ribosome (40). The rate of ribosomal depurination exceeds the ability for repair so that only a very small amount of free A subunit is needed to prevent peptide assembly and arrest protein synthesis.

Effect of Verocytotoxin on Cells

Verotoxins appear to have two different actions on cells, cytotoxicity and stimulatory effects. Experimentally, cytotoxicity requires a higher dosage of toxin or longer exposure than the stimulatory effects.

Cytotoxicity

Cell killing is generally held to be the consequence of protein synthesis inhibition. To some extent, cytotoxicity depends on the stage of the cell cycle (41). VT causes apoptosis in vero cells (42) and cultured foreskin microvascular endothelial cells (43), both of which bear the Gb3 receptor. Primary cultures of human renal epithelial cells are exquisitely sensitive to VT-1 (44) but die through necrosis (45). Both human umbilical and glomerular endothelial cells are comparatively resistant to VT, but pretreatment with the inflammatory cytokines tumor necrosis factor (TNF)- α , interleukin (IL)-1 β , or bacterial lipopolysaccharide makes them sensitive through the upregulation of Gb3 (46,47). Human mesangial cells are resistant to the cytotoxic effects of VT (48). *In vitro*, VT-1 kills cells at a lower concentration than VT-2, although in animal models VT-2 often appears to be more injurious.

Stimulatory Effects

VT induces the release of proinflammatory cytokines and chemokines from various cells at low concentrations that cause neither cell death nor decreased protein synthesis. In human enterocytes, VT induces the production of IL-8 and other members of the C-X-C chemokine family (49,50). VT-2 at sublethal dosage on human endothelial cells upregulates messenger RNA for IL-8 and monocyte chemoattractive protein-1, causing a marked increase in leukocyte adhesion and migration into the endothelial monolayer (51). Moreover, sublethal doses of VT-1 induce the production of tissue factor messenger RNA and the total procoagulant activity of human endothelial cells (52). Given that tissue factor is the primary regulator of coagulation and that coagulation precedes the onset of acute renal failure in HUS, this may be a very important observation. Monocytes have also been shown to produce TNF- α and other cytokines in response to VT (53).

In all these studies, the cell-signaling pathways appear to be similar. They involve the p38/mitogen-activated protein kinase pathway, the primary response gene *c-jun* and the transcription factor NF κ B. How VT initiates the signaling process remains unknown (Fig. 47.6).

Ribotoxin administration to animal models confirms the early and massive release of proinflammatory cytokines and chemokines, an effect that is augmented if there is an independent stimulus such as bacterial lipopolysaccharide (54–56). The site of production of cytokines has not been fully investigated, but in some experiments there is evidence that TNF- α is produced in the kidney itself (54,57,58).

Pathogenesis of Verocytotoxin-Induced Hemolytic Uremic Syndrome

VT is released by adherent VTEC on the apical surface of the colonic epithelium and is delivered to the submucosa by transcytosis. Here it is responsible, either in part or in whole, for causing the microvascular lesion of the colon. There are edema, hemorrhage, thrombosis, and neutrophil infiltration affecting all layers of the bowel wall, and the overlying mucosa is shed.

In the glomerulus, it is widely assumed that direct endothelial cell injury by VT is an initiating event. Early animal studies of VT intoxication showed that sites of endothelial damage, albeit not renal, correlate with receptor expression in the target tissue (59). Human kidneys strongly express Gb3, but on tubular cells rather than vascular. Glomeruli have weak expression, except perhaps in young children (60). This detracts from the idea that toxin is preferentially taken up by glomerular endothelium to cause cell death. However, endothelial Gb3 expression is promoted by TNF- α and IL-1 β , and there is evidence that TNF- α is increased early in human HUS (61), offering some support to the hypothesis.

A previous problem with the hypothesis was that VT could not be identified freely in plasma, raising questions about its systemic distribution. The finding that VT binds to the surface of neutrophils via a receptor with a lower affinity than Gb3 and that it is not internalized raises the possibility that neutrophils might transport VT to target sites outside the colon (62).

Neutrophils may have other important roles in the disease. Neutrophil traffic in the colonic mucosa appears to increase the transport of toxin across the epithelial border (63). Neutrophilia occurs very early in VTEC infection, and higher peripheral blood neutrophil counts predict both the progression to HUS (64) and its severity (65). HUS plasma contains high concentrations of elastase, which suggests that neutrophils are activated within the circulation (66), and there is an excess of neutrophils in the glomeruli of patients coming to postmortem examination in the early phase of the disease (19). This is in keeping with Zojá's observation that very low dosage of VT-2 induces leukocyte adhesion on vascular endothelium (51).

It is now clear that procoagulant events precede the onset of renal impairment, making it almost certain that renal impairment is the consequence of intraglomerular thrombosis, microvascular obstruction, and nephron ischemia (67).

This is in keeping with the *in vitro* findings that VT can induce procoagulant changes in human endothelium (68) and upregulate tissue factor expression (52). It may also be relevant that VT-1 has been shown to exert a proaggregatory effect on platelets (69).

Histopathology

The typical histologic features of VTEC infection are of glomerular TMA, with glomerular capillary thrombosis causing distension of the capillary loops with or without extension into the afferent arteriole (18,19). The distension suggests that thrombosis starts in the glomerular capillaries themselves or at their junction with the efferent arteriole. Cortical necrosis, when present, is patchy, but may be extensive. There is no doubt that glomerular TMA is a destructive process leading to nephron loss. In a follow-up study by Habib (16), the proportion of glomeruli showing fibrosis at 1 year correlated with the proportion of glomeruli with TMA lesions in the acute phase of the illness. In keeping with this, Moghal et al. found marked compensatory glomerular hypertrophy in HUS survivors with ongoing proteinuria 5 years after onset, which fits with the hypothesis of adaptation to a reduced number of functioning nephrons (70).

Epidemiology

Less than 10% of individuals with VTEC-induced diarrhea develop HUS (71,72). The reason for the low risk of disease after exposure is not known. It seems unlikely to be simply a dose effect, as even a small inoculum can induce illness. It was previously assumed that humans did not produce anti-VT antibodies after infection. With more accurate assays, this has been shown to be incorrect and it has been shown that approximately one-half of healthy adults have immunoglobulin (Ig) G antibodies to VT2 (73). Although it is as yet unclear whether VT-2 antibodies are protective, the observation accords with the epidemiology. The lowest prevalence of antibody is seen in early childhood, the period of greatest incidence of HUS. Waning antibody titers in the elderly may explain the greater severity of disease in this age group. The peak age of onset of HUS is 1 to 2 years. In North America and western Europe, it is rare before 9 months, but in some communities, Argentina, for example, a younger onset is seen, probably reflecting different feeding practices.

The annual incidence of VT-induced HUS in children younger than 5 years is as high as 3.4 per 100,000 children in Scotland and approximately four times this in Argentina. However, in western Europe and in Australia and North America, the figure is on the order of 1 to 2. The incidence for children younger than 15 years of age is approximately one-half that of those younger than 5 years of age (7,11,74–76).

Most cases of infection are sporadic, making it difficult to locate the environmental source. Outbreaks provide the opportunity to trace the contaminant. Secondary person-

to-person spread is well recognized, and early sanitary advice is needed to prevent it.

Laboratory Investigation for Verocytotoxin-Producing Escherichia coli

The most important VTEC serotype in the Americas and much of Europe is O157 with or without the flagella-type H7. However, a wide range of serotypes are reported in central Europe and Australia. These are usually O-serotypes already known to be EPEC (e.g., O26, O55, O111). Geography, therefore, has implications for the investigative strategy. Where O157 is the prevalent VTEC serotype, selective culture of stool samples on sorbitol MacConkey's agar is used. O157, characteristically, does not induce sorbitol fermentation. Colonies can then be identified serologically. Although practical, this is not the most sensitive approach. VTEC excretion is transient, usually a few days. In many cases, both the diarrhea and the excretion of VTEC have resolved by the time the diagnosis of HUS is made. Culture enrichment techniques for O157 and serologic tests for O157 lipopolysaccharide antibodies will not detect other strains. A rising antibody titer to a relevant VTEC O-serotype can be diagnostic in patients whose stools no longer contain the pathogen.

A more assured technique for identifying VTEC in stool samples, although laborious, is to use polymerase chain reaction for the relevant VT genes. With this technique, one can identify strains that have more than one VT plasmid. Probe-positive colonies are then cultured, and their O-serotypes can be determined.

In epidemics, it is important to confirm the link between the human cases and the source of infection, for example, in food or cattle. This is achieved by further characterizing the VTEC strains, either by relatively simple lytic bacteriophage typing or by using more sophisticated techniques such as pulse field gel electrophoresis (77). One has to recognize that, at present, negative results are obtained even in carefully investigated outbreaks of D+ HUS.

Clinical Features

Diarrhea and vomiting are typical of VTEC-induced HUS although, rarely, a patient with evidence of infection will develop HUS without intestinal symptoms. It is therefore important that investigation for VTEC is conducted in all cases of HUS, regardless of whether they present with diarrhea. The majority of patients experiences abdominal cramps and diarrhea, which is bloody in more than 70% of cases. Rectal prolapse, intussusception, toxic dilatation of colon, and perforation can occur. Early surgical referral is needed so that if laparotomy proves necessary, the timing is carefully adjudicated.

Hydration at the time of the diagnosis of HUS is variable between cases. Fifty percent appear normally hydrated, but

25% have clinical evidence of vascular volume overload, and the remainder have various degrees of dehydration. Hypovolemic shock occurs in approximately 2% of children. Low plasma sodium concentrations are common at diagnosis and tend to be lower in those with clinical hypovolemia. Low plasma albumin concentrations are common, particularly in hypovolemic and shocked patients, indicating a capillary leak.

The onset of oligoanuria appears between 1 and 14 days after the onset of diarrhea, typically between days 4 and 7, and is preceded by thrombocytopenia and anemia. Anemia is usually maximal approximately 1 day after the onset of oliguria, with 90% of cases being anemic and 95% thrombocytopenic at presentation. Jaundice occurs in 35%. A mild, transient increase in the plasma concentration of liver enzymes occurs in 40%. Approximately one-half of children are anuric at that stage, and up to 75% need dialysis soon after admission (11,15). Hypertension occurs in one-third of patients, usually as a transient feature at approximately the time of the resolution of the oliguric phase.

The most common extrarenal manifestation is central nervous system (CNS) disturbance affecting up to 20% of cases. This usually consists of seizures, typically occurring within the first 48 hours of diagnosis, accompanied by hyponatremia but rarely arterial hypertension. Devastating cerebral edema and encephalopathy can occur suddenly. Children may appear agitated, confused, drowsy, or express hallucinations. This is followed by seizures, coma, cranial nerve palsy, decerebrate posturing, and hindbrain herniation causing respiratory arrest. The speed of progression can be rapid so that a child with early signs of a confusional state should be transferred to an intensive care setting for close monitoring. Rarely, patients will have focal CNS signs and stroke-like events implying large arterial occlusions. Fluctuating neurologic signs are also described in TTP and are not typical of VTEC-induced HUS. CNS imaging is useful in distinguishing microvascular damage and cerebral edema from intracranial hemorrhage. Magnetic resonance imaging (MRI) is more sensitive than tomodensitometry to detect early structural lesions. When these are limited or absent, recovery without sequelae is very likely. Extensive necrotic lesions (Fig. 47.7) are predictive of fatal outcome or of severe neurologic deficit.

Cardiomyopathy and diabetes mellitus due to necrotizing pancreatitis affect less than 5% of patients (78–81).

Treatment

VTEC are sensitive to a wide range of antibiotics, and it has been tempting to consider antibiotic treatment. However, retrospective reviews suggest that antibiotics are associated with an increased risk of HUS (64,82,83). The rationale for this is that certain antibiotics cause increased toxin release from VTEC *in vitro* (84). However, in a Japanese report, the use of an oral form of fosfomycin appeared protective (85). Although the recent metaanalysis of the literature by

FIGURE 47.7. Extensive cerebral necrotic lesions demonstrated by magnetic resonance imaging.

Safdar et al. (86) indicates no definite answer to the question of whether antibiotics do or do not increase the risk of HUS in patients with O157 *E. coli* infection, as a general rule, they should not be given. Antidiarrheal agents may also be harmful and should be avoided (87).

Binding free toxin in the intestine to prevent its absorption is an attractive idea that has not, so far, proved clinically successful. For example, Synsorb, a resin with a moderately high affinity for VT, has not yet been clinically proven. Newer, soluble agents with more increased toxin binding characteristics, such as “starfish,” have yet to be tested. Experimentally, passive immunization with anti-VT antibody can ameliorate disease models and may in the future become a human therapy.

Clinical management is supportive, and patients need close monitoring. Vascular volume, electrolyte disturbance (hyponatremia, hyperkalemia, and acidosis), hypertension, and anemia require correction. Blood transfusion may be required to keep the hemoglobin above 8 g/dL. In undertaking blood transfusion, there must be control of vascular volume and any resulting hyperkalemia. In a few oliguric patients, a high dose of furosemide will induce a diuresis, allowing dialysis to be avoided. Platelet infusions should only be given if there is bleeding not controllable by simple local measures.

There is no evidence that early dialysis improves outcome. If a surgical complication of the colitis is suspected, peritoneal dialysis is contraindicated, and vascular access should be secured for hemodialysis. Anticoagulation and

thrombolytic therapy with streptokinase or urokinase are ineffective. Plasma therapy is unproven, although some use plasma exchange (PE) in cases with encephalopathy.

Confusional states, drowsiness, irritability, hallucination, and seizure are ominous signs and may be the first indication of raised intracranial pressure or an evolving neurologic catastrophe. Management at this point should involve neurologists or intensivists. Seizures require immediate treatment with anticonvulsants, and electroencephalogram monitoring is a helpful guide to therapy.

Outcome

Using D+ HUS as a surrogate for VTEC, the early mortality in children is less than 3% with the exception of epidemics, in which it is sometimes higher. In recent surveys in the United Kingdom (manuscript in preparation) and France (11), in which 80% and 86% of D+ HUS was attributable to VTEC O157 infection, an acute mortality of 1.5% was recorded. Death was due to CNS involvement. Less than 5% of patients do not regain independent renal function.

In the first decade after D+ HUS, up to 30% of survivors experienced adverse renal outcome consisting of proteinuria, hypertension, or renal impairment, including end-stage renal failure in 5 to 10% (15,75,88–90). This percentage may increase up to 60% during the second and third decade after D+ HUS (91–94). These sequelae are more likely if the patient is anuric more than 1 week or requires more than 14 days of dialysis during the acute stage. However, the penalty of reduced nephron mass and increased single nephron filtration in the lifetime of the patient is difficult to predict. Occasionally, individuals who were shown to have normal plasma creatinine protein excretion and blood pressure 5 or more years after onset start to develop albuminuria. Later, some of these patients have evidence of declining renal function (95). It is therefore advisable to follow up patients, especially if there was prolonged anuria at the acute phase, for signs of incipient nephropathy by checking for albuminuria and hypertension. Such changes occur well in advance of any rise of plasma creatinine. Although not formally tested, there is a general view that patients with proteinuria are likely to benefit from angiotensin-converting enzyme inhibitors or receptor antagonists.

Posttransplant Course

The evolution after renal transplantation is known from the literature in 132 children who received 154 kidney transplants after D+ HUS. In most series, no recurrence of HUS was observed (75,96–99). Three patients reported by Eijjenraam et al. had possible recurrence of HUS, although the authors considered the diagnosis between HUS recurrence and rejection as uncertain (100). Finally, only one patient reported by Miller et al. with D+ HUS at 1 year of age had definite recurrence 7

days after transplantation and at 12 years of age, with hemolysis, thrombocytopenia, TMA on graft biopsy, and graft loss due to recurrence (101). Thus, the incidence of definite HUS recurrence after transplantation in children with D+ HUS appears to be less than 1%. Cyclosporine was used in more than one-half of these transplants. Moreover, renal transplantation in children with D+ HUS was not associated with an increased risk of graft failure compared to non-HUS patients (75,97,99,100).

***Shigella Dysenteriae* Type 1 Dysentery-Associated Hemolytic Uremic Syndrome**

S. dysenteriae type 1 dysentery-associated HUS is frequent in endemic areas such as India, Bangladesh, and southern Africa. It may also be encountered in industrialized countries in children returning from these areas. The pathogenesis is similar to that of VTEC-induced HUS. However, *S. dysenteriae* is enteroinvasive, and the overall severity of the disease is greater than that of VTEC-induced HUS. Severe dysentery, high fever, and massive leukocytosis (greater than 30,000 to 40,000/mm³) are common (102–105). In their series of 81 cases from 1994 to 1996 in Kwazulu-Natal, South Africa, Bhimma et al. (105) observed that 18.5% of patients had positive blood culture and 21.0% had disseminated intravascular coagulation. Ninety percent of patients had acute oliguric renal failure. Complications included encephalopathy in 35% of patients, seizures in 15%, and hemiplegia in 2%. Protein-losing enteropathy was observed in 32% of patients, gastrointestinal perforation in 10%, rectal prolapse in 6%, and toxic megacolon in 5%. Myocarditis occurred in 6% of patients, congestive cardiac failure in 4%, and cardiomyopathy in 4%. Mortality was 17%. Only 39% of patients had no sequelae, whereas 42% had chronic renal failure and 1% had end-stage renal failure. The high incidence of cortical necrosis in postdysenteric HUS has been formerly noted (104,106,107).

These patients need urgent appropriate antibiotic therapy, which has been shown to reduce the incidence of HUS (103), and life-support measures.

***Streptococcus pneumoniae*–Associated Hemolytic Uremic Syndrome**

Pneumococcus, Neuraminidase, and Red Cell Polyagglutination

A rare but distinctive form of HUS occurs as a complication of pneumococcal infection. With hindsight, it seems very likely that one of Gasser's original cases had this form of the syndrome (2). Typically, it is accompanied by red cell polyagglutination, the laboratory finding that a patient's red cells are agglutinated *in vitro* by blood group ABO-compatible serum. It is sometimes during an attempt to crossmatch blood for a patient with HUS or pneumococcal infection that this comes to light.

Pathogenesis

On healthy human cells, the membrane-associated Thomsen-Friedenreich (T) antigen is masked by sialic acid of the cell glycocalyx and therefore not exposed. The T epitope bears the motif galactose- β -1-3-galactose-*N*-acetylglucosamine that is recognized by an IgM antibody normally present in plasma. T is also recognized by the peanut lectin *Arachis hypogea*, which is the basis of a useful laboratory test when investigating polyagglutination.

Neuraminidase is produced by various pathogens including *S. pneumoniae*, *Clostridia* species, and influenza viruses. Neuraminidase, released during infection, cleaves *N*-acetylneuraminic (sialic) acid from the cell glycocalyx to reveal the T-cryptantigen. There is good evidence of T-antigen exposure on red cells, platelets, and endothelium in this form of HUS (108). It was originally believed that the T-antigen antibody reaction might explain the pathogenesis. However, the naturally occurring anti-T is a cold antibody and unlikely to cause agglutination *in vivo* (109). The true pathogenesis is unknown. It is of interest that neuraminidase has been shown to remove the complement inhibitory effect of complement factor (fH) on human red cells, making them vulnerable to complement-induced lysis (110).

Clinical Features

Patients are usually infants and preschool-aged children; however, adult cases have been described. More than 50 cases have appeared in the literature; the largest two series only describe 11 and 12 cases, respectively (111,112). To this can be added eight cases from a national survey of childhood HUS in the United Kingdom conducted through the years 1997 to 2001 (C. M. Taylor, *personal communication*).

The diagnosis should be suspected in any child with an MAHA associated with sepsis but normal coagulation. Typically, there is an underlying pneumococcal infection, usually pneumonia and empyema, less often meningitis or septicemia. Pneumococcal infection usually precedes the onset of HUS by not more than a few days. Anemia, thrombocytopenia, and oliguric renal failure occur abruptly with a profound deterioration in the child's clinical condition. HUS can be distinguished from disseminated, consumptive, intravascular coagulation, which can also complicate pneumococcal sepsis, in that the prothrombin and partial thromboplastin times are not prolonged, and plasma fibrinogen concentrations are normal. T antigen exposure on red cells is confirmed by testing with the peanut lectin *A. hypogea*. The histology in this form of HUS shows glomerular thrombosis with or without patchy cortical necrosis.

The microangiopathic process is more severe and more prolonged than in D+ HUS. For example, the average duration of thrombocytopenia is 11.6 days as against the usual 7.0 in D+ HUS (112). Extrarenal manifestations include pancreatitis, elevated plasma concentrations of liver enzymes, cerebrovascu-

lar disease, and cardiac dysfunction. It is important to eradicate the underlying infection promptly. Management is otherwise supportive. It is traditional advice to avoid the administration of plasma products that contain the naturally occurring IgM. For example, if transfusions are required, red cells or platelets are washed to remove plasma. There is no evidence of benefit from this approach, which is now questioned.

The acute mortality remains high. Combining the review in the contemporary report of Brandt et al. (112) and the experience of the recent United Kingdom survey in which two of the eight children died, the acute mortality for cases reported since 1990 is in the order of 20%. Survivors often regain renal function, although there are a number of cases that progress to chronic renal failure. Because the disease is an acquired single episode, relapse does not occur, and one can expect that transplantation would not be complicated by disease recurrence (113).

Human Immunodeficiency Virus 1-Associated Hemolytic Uremic Syndrome

TMA has been reported in several hundred human immunodeficiency virus cases worldwide (114). These patients, some of them children (115,116), often present with HUS or TTP (manifest as acute or rapidly progressing renal failure), MAHA, thrombocytopenia, and, frequently, neurologic symptoms. Most patients progress to end-stage renal failure. In a multicenter autopsy study, 7% of 214 patients whose death was attributable to acquired immunodeficiency syndrome had evidence of TMA (117). In a study from France (118), 32 of 92 human immunodeficiency virus-infected patients with acute or rapidly progressing renal failure had HUS, TMA being confirmed histologically in most cases. The pathogenesis of TMA involves endothelial damage with local activation of coagulation (114), and a role for antiphospholipid autoantibodies has been postulated. Complete deficiency of VWF-cp due to the presence of an IgG1 inhibitor has also been observed in an acquired immunodeficiency syndrome patient (119).

The incidence of human immunodeficiency virus-associated TMA appears to have decreased since the introduction of antiviral therapy.

GENETIC FORMS OF HEMOLYTIC UREMIC SYNDROME

Hemolytic Uremic Syndrome Associated with Complement Factor H Deficiency

Complement abnormalities have been reported in cases of HUS for more than 25 years. Broadly, two patterns have emerged. The first is a transient reduction of plasma C3 with activation of the alternative pathway. This is quite often seen in the acute presentation of infection-related forms of HUS, including that induced by *S. dysenteriae* and D+ HUS

REGULATORS

PATHWAYS

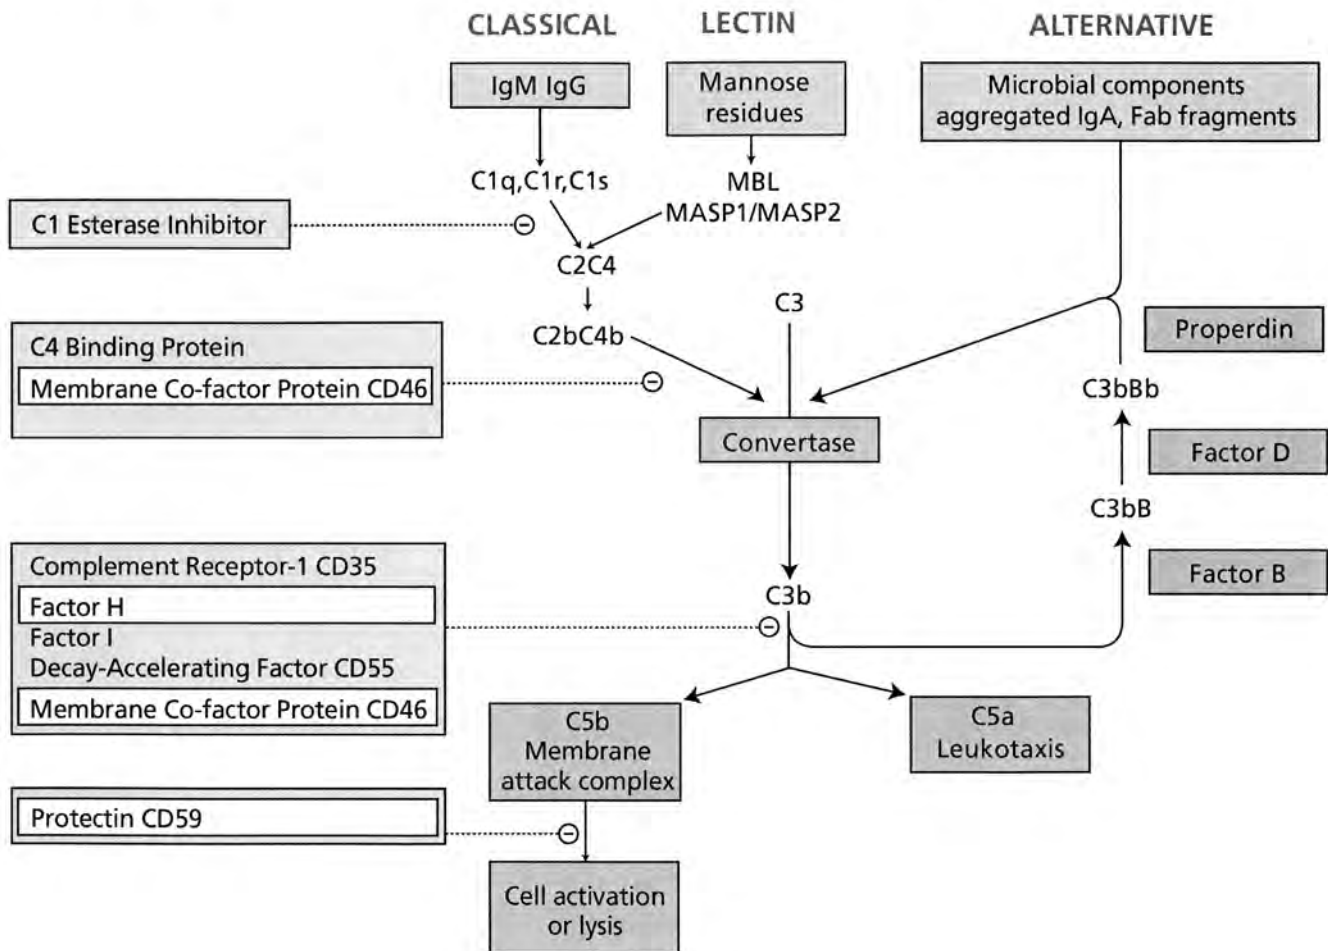

FIGURE 47.8. Regulation of the complement pathways. Regulators known to be located in human renal vasculature are shown in a clear surround. Fab, fragment antigen binding; Ig, immunoglobulin; MBL, Mannose binding lectin.

(102,120). On recovery from the acute episode, the complement profile returns to normal. It is not clear to what extent complement participates in the pathogenesis of infection-related forms of HUS.

The second pattern is one of persistent hypocomplementemia. This points to an innate defect in complement regulation and a rare and distinctive HUS subgroup with deficiency of the complement regulator fH. Furthermore, genetic studies in patients with HUS have found various mutations in the fH gene that extend this phenotype. In this extension, many cases of HUS with fH mutations have normal concentrations of plasma C3. The plasma concentration of fH may be normal or reduced, but the mutations predict loss of fH function.

Pathogenesis

Complement is an integral part of the innate immune system. The alternative and lectin pathways activate immedi-

ately on contact with invading organisms, thus recognizing them as "foreign." Host cells are defended against the indiscriminate activity of complement by a number of downregulators, both soluble and mounted on the cell surface (Fig. 47.8). Different cells and organs have their own specific distribution of complement regulators.

fH plays a central role in the regulation of complement, both in the fluid phase and on the surface of cells. It is a glycoprotein with a molecular weight of 155 kDa produced mainly in the liver. It circulates in plasma and binds to polyanionic sites on vascular endothelium and red cells. The molecule is a single peptide and consists of 20-fold globular domains known as *short consensus repeat* (SCR). There are three binding regions for C3b, each being specific for a different part of the molecule. These appear in SCRs 1 to 4, the site also responsible for factor I cofactor activity, SCRs 6 to 10, and the terminal SCRs 16 to 20 (121,122). fH competes with factor B for freshly generated C3b and acts as a cofactor for factor I in C3b degradation. This arrests both

the amplification step of C3 convertase and the generation of downstream products, leukotactic C5a, and the membrane attack complex C5b–C9.

There are also three binding sites for heparin and other polyanions by which fH becomes attached to cell surfaces. The tertiary structure of the molecule leaves the C-terminal SCR 20 exposed. This suggested an important function for this site, particularly when combined with the observation that this part of the molecule is a hot spot for mutations in HUS (123–125). Confirmation came from functional *in vitro* studies of mutated fH (126) and by mapping of known mutations to models of the fH molecule (127). Moreover, certain C-terminal mutants show impaired binding to both heparin and the C3d component of C3b (128). In summary, the C-terminal mutations of fH implicated in HUS create a molecule that may bind C3b in the fluid phase but cannot attach to anionic sites on cell surfaces to protect them.

How fH deficiency causes HUS is not clear. The fact that some fH-deficient patients do not present until middle age or have long remissions suggests that fH deficiency predisposes patients to HUS but is an insufficient cause by itself. A second hit is needed. As with other forms of HUS, interest has focused on vascular endothelial injury. Any retraction or detachment of endothelial cells reveals sites in the subendothelial space that activate complement (129). Perhaps endothelial injuries that in normal circumstances would resolve lead to complement activation that propagates in the absence of cell-associated fH.

Complement is an essential component of certain models of glomerular TMA that in some respects resemble HUS. One example is the generalized Shwartzman reaction in rabbits in which the injection of bacterial lipopolysaccharide caused glomerular thrombosis. Another is a rat model of immune glomerular injury accelerated by lipopolysaccharide in which the roles of the membrane attack complex C5–9 and the complement regulator CD59 are strongly implicated (44,130). fH deficiency in other species has not, so far, been linked to HUS, but there is an association with mesangio-capillary glomerulonephritis type II in pigs (131), and perhaps humans (132).

Genetics

The first report linking fH deficiency to HUS was of a child with relapsing HUS and low C3. He was found to have homozygous fH deficiency and plasma fH less than 10% of normal, whereas his consanguineous parents had approximately one-half the normal concentrations. A sibling of the index case who did not have signs of disease also had very low concentrations, indicating a homozygous state (133).

Since then, there have been several reports of patients with very low fH concentrations, implying homozygous inheritance (134–137), although some may be compound heterozygotes as has been later shown in the case described by Warwicker et al. (138) (T. H. J. Goodship, *personal communication*). In

these, complement C3 is usually depressed in the range of 0.2 to 0.5 g/dL. HUS is mostly reported in infancy or early childhood, but sometimes there are adult family members with similar fH depletion who have not disclosed disease.

In 1998, Warwicker et al. showed linkage between chromosome 1q32, the site of a gene cluster of complement regulators that includes fH, and HUS in three well-described families (139). Subsequently, mutation analysis confirmed defects in a number of cases of both familial and sporadic, childhood and adult (138,140,141). These include frame shifts introducing stop codons that truncate the fH protein, mutations that appear to affect the tertiary form of the molecule and its export from the endoplasmic reticulum, and a “hot spot” for mutations in the C-terminal, predicted to impair the ability of fH to bind polyanions and C3b.

Many of these patients are heterozygous and have moderate or normal levels of fH and normal levels of C3 and factor B. Although hypocomplementemia and a low fH point to this disease mechanism, normal fH and C3 do not exclude it. It is therefore advisable to carry out genetic investigations in all cases of HUS apart from those with evidence of VTEC infection. It seems very likely that some cases of HUS hitherto associated with pregnancy or use of the contraceptive pill may be related to fH deficiency, reinforcing the need for appropriate molecular investigation. In patients with familial or relapsing HUS, a genetic diagnosis is mandatory.

Clinical Features

These patients present either sporadically or sometimes with a family history (132,142,143). When inquiring after the health of family members, one needs to be suspicious of histories of unexplained anemia or infant deaths, as these may represent undiagnosed cases. The age of onset ranges from the neonatal period to adulthood. There is often a precipitating event, such as an infective illness, often an upper respiratory tract infection. The MAHA is marked in the early stages and in relapse but tends to resolve once anuric end-stage renal failure is reached. However, the plasma haptoglobin often remains suppressed, suggesting ongoing low levels of hemolysis. The clinical course is complicated by persistent severe hypertension, with the attendant problems of end-organ damage, particularly hypertensive encephalopathy. Although individual episodes may resolve, relapse is common, and with each attack, recovery is less certain. Historically, the majority of patients progressed to end-stage renal failure or died, but survival rate for contemporary cases is probably more favorable.

Renal histology typically shows mesangial proliferation with increased matrix giving the glomeruli a solid, lobulated appearance. Mesangial cell interposition leads to the reduplication of the basement membrane and double contours to the capillary walls on silver staining. There may be arterial as well as arteriolar changes. Immunohistochemistry reveals complement deposition in the capillary walls but it is not usually extensive.

Treatment

Treatment of HUS with fresh frozen plasma (FFP) or PE was undertaken empirically long before the role of fH deficiency was proposed. There is now at least some logic behind its use for this subgroup, although experience is fragmentary. Normal plasma contains fH at a concentration of 0.5 g/L. The dose required to regulate complement is not known. Landau et al. (144) showed benefit from biweekly infusions of plasma at a dose of up to 20 mL/kg/day, similar to Nathanson's experience (145). In the case previously reported by Warwicker (138), a PE using 100 mL/kg body weight of FFP was needed to improve the concentration of C3 and normalize factor B, an effect that lasted for approximately 5 days (J. Cansick, *personal communication*). However, fluid phase activity in plasma may not be in itself protective, as fH needs to be bound to cell surfaces to operate.

Posttransplant Course

The outcome of transplantation in patients with this form of HUS is not well documented, but approximately one-third experience recurrence. Of 11 patients in whom the transplant course was documented (124,138–140,144, 146; three cases in Hôpital des Enfants Malades, P. Niaudet, and one in Hôpital Robert Debré, C. Loirat, *unpublished*), 5 lost their graft due to recurrence [sporadic case in (139), patient F34 and F39; and sporadic case in (124), previously published in (140); familial case in (144)].

Seven patients with normal C3 and fH concentrations, but with mutations in the fH gene, have been transplanted (139). Two of them from one family have had HUS recurrence leading to graft loss [family 1 in (139)]. No recurrence was seen in the other five [family 2b and family 3, previously published in (147)] (139).

At present it is not clear why certain individuals relapse, whereas others do not. Most clinicians are wary of using

drugs that are associated with HUS, such as cyclosporine and tacrolimus. When considering live donation by a family member, one needs to ensure that the donor does not have undisclosed fH mutations. Liver (148) or combined liver and kidney transplantation (149) have been undertaken in two cases, with encouraging results.

Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura Associated with von Willebrand Factor–Cleaving Protease (ADAMTS 13) Deficiency

von Willebrand Factor and von Willebrand Factor–Cleaving Protease

VWF is a multimeric glycoprotein with two hemostatic functions (150–152). It acts as a carrier protein for blood-clotting factor VIII in the circulation and is required for both platelet adhesion to sites of vascular damage and platelet aggregation at high shear rates of blood flow present in the microcirculation. VWF is synthesized by vascular endothelial cells and megakaryocytes as a precursor subunit of 275 kDa. Tail-to-tail dimers of VWF precursor subunits are formed by disulfide bonding near the C-terminals. Additional head-to-head disulfide bonds between the N-termini of the dimers creates multimers with up to 40 dimeric subunits and a molecular mass in excess of 20,000 kDa (Fig. 47.9). The multimers are stored in the endothelial Weibel-Palade bodies and the alpha granules of platelets. The larger the VWF multimers, the more effective they are in acting as a bridge between platelets and forming platelet aggregates. However, VWF does not normally circulate in these very large multimeric forms. A specific plasma protease, VWF-cp, physiologically cleaves the largest multimers of VWF released from endothelial cells and platelets (151,154). It does so at a specific site between Tyr 842 and Met 843 to form the smaller multimers normally found in plasma (155) (Fig. 47.9).

FIGURE 47.9. Multimeric structure of von Willebrand factor (VWF) and physiologic proteolysis of multimers by VWF-cleaving protease (VWF-cp). (Modified from Girma J, Veyradier A, Meyer D. ADAMTS 13, la protéase spécifique du facteur von Willebrand. *Med Sci* 2002;18:15–17.)

VWF-cp is a metalloprotease synthesized in the liver that has been identified as the thirteenth member of the ADAMTS (*a* desintegrin-like and metalloprotease with thrombospondin type 1 motif) family (156–159). The gene for VWF-cp has been identified on chromosome 9 and the amino acid sequence determined (158). Plaimauer et al. (160) recently demonstrated the functional activity of ADAMTS 13 gene product (i.e., recombinant VWF-cp), opening the way to the production of a recombinant protein.

von Willebrand Factor–Cleaving Protease in Adults with Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Most studies of VWF-cp have been performed in adults with TTP. They demonstrated that many cases are linked to a profoundly deficient activity of VWF-cp, typically less than 5% of normal. VWF-cp deficiency is occasionally constitutional and probably inherited by autosomal recessive transmission. Much more commonly, it is induced by an acquired inhibitory autoantibody (160–164). By allowing the persistence of unusually large multimers of VWF in plasma, severe VWF-cp deficiency promotes the formation of platelet thrombi in the microcirculation and is responsible for the microangiopathic disease and its ischemic manifestations. Adults with HUS, unlike TTP, were generally found not to be associated with a VWF-cp defect (161–163). The exception being a case of D+ HUS in a woman with a transient total deficiency of VWF-cp in the acute phase and no anti-VWF-cp antibodies (165). In a recent study from the Italian Registry of Recurrent and Familial HUS/TTP, Remuzzi et al. confirmed that most TTP adult patients have VWF-cp deficiency due to the presence of an inhibitor, whereas some have a constitutional and familial deficiency (166). However, these authors also observed that among 28 adult patients with recurrent or familial HUS (with onset in childhood in 16), 5 had VWF-cp constitutional deficiency. None of these had VWF-cp inhibitor.

von Willebrand Factor–Cleaving Protease in Pediatric Hemolytic Uremic Syndrome Associated with a Prodrome of Diarrhea

Hunt et al., Tsai et al., and Schneppenheim et al. studied VWF-cp activity in a total of 62 D+ HUS children (167–169). Only one child had a total VWF-cp deficiency (167). Of interest, this patient had clinical features of TTP requiring plasma therapy, and his VWF-cp deficiency was related to an inhibitor. Veyradier et al. (170) studied 41 children with D+ HUS and found an undetectable VWF-cp in the acute phase in only 1 child who had a VTEC-induced HUS and a clinical presentation and outcome similar to the other patients. In this case, VWF-cp deficiency was not due to an inhibitor and completely recovered after the acute phase of HUS. This is similar to the adult patient with D+

HUS mentioned above (165). The mechanism of these transient VWF-cp deficiencies in D+ HUS remains unclear, as they had none of the other recognized explanations (171).

von Willebrand Factor–Cleaving Protease in Pediatric Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome without a Prodrome of Diarrhea

Antibody-induced VWF-cp deficiency has been reported in a few cases of childhood TTP. In addition to the child with D+ HUS, a TTP-like course and anti-VWF-cp autoantibody mentioned above (167), Robson and Tsai (172) reported an 8-year-old boy with severe VWF-cp deficiency linked to an inhibitor. Among nine children with TTP studied by Schneppenheim et al. (169), all with VWF-cp below 5% of normal, four had antibodies against VWF-cp. These children, aged between 11 months and 11 years, had mild symptoms of TTP. In the remaining five, VWF-cp deficiency was due to mutation in ADAMTS 13 gene.

Constitutional deficiency in VWF-cp due to mutations in the ADAMTS 13 gene accounts for a subgroup of patients with so-called atypical D– HUS. Out of 23 children with D– HUS, Veyradier et al. (170) observed undetectable VWF-cp activity in six, both acutely and in remission, and in the absence of inhibitors. The clinical presentation of these patients appears similar to that of the original patients described in 1960 by Schulman et al. (173) and in 1978 by Upshaw (174), now revisited as congenital TTP due to hereditary VWF-cp deficiency (175). In 20 of 29 reported cases, the disease started at birth with jaundice, severe hemolytic anemia, and thrombocytopenia, needing treatment by exchange blood transfusions (169,170,174,176–183). Nine children with later onset had their first hemolytic crisis between 6 and 56 months of age (169,174,176–178,180,182). All cases relapsed, often after intercurrent infection. The frequency of relapses is unpredictable, with a disease-free interval varying from 1 month to several years. Nevertheless, in some patients, relapses become increasingly frequent, finally occurring every 3 to 4 weeks (170). Some patients have persistent hemolysis and thrombocytopenia.

In the first years of life, the disease is limited to hematologic symptoms, although transient increases of serum creatinine may be seen during hemolytic crises. Later, progressive renal involvement may appear. Proteinuria was observed at 23 months and 3 years of age in two children, respectively (179,183), with chronic renal failure at 4 years of age in one (183). Another patient developed renal failure during a relapse at 16 years of age (181). The six patients reported by Veyradier et al. (170) also had mild proteinuria when they were 2 to 8 years old. Hypertension developed in two of them at 7 and 9 years of age, with progressive renal insufficiency at 10 years of age in one, who reached end-stage renal disease at 14 years of age. Renal histology showed severe glo-

merular and arteriolar TMA lesions (170,184). In addition, five patients have been reported with CNS involvement (170,176,181) with episodes of coma, seizures, hemiparesis, and ischemic lesions on cerebral MRI angiography or tomodensitometry, one of them with severe intellectual sequelae (176). Two children also had retinal ischemia, and one had myocardial ischemia (170).

The phenotype of constitutional VWF-cp deficiency can be so variable that 2 of 50 patients classified as idiopathic thrombocytopenic purpura and one classified as Evans syndrome had complete VWF-cp deficiency (169), and a 16-year-old girl who never had TMA but did have neonatal hemolysis/thrombocytopenia had only mild fluctuating thrombocytopenia (60 to $80 \times 10^9/L$) (170). This variability is in agreement with the results of Furlan's group, which described an age-dependent clustering of congenital TTP (185). Indeed, one-half of all subjects became symptomatic in childhood, whereas the other one-half had their first bout of TTP as adults, mostly between 30 and 40 years. On the other hand, neonatal death from massive hemolysis or death during childhood with multivisceral TMA can also be observed (169,170). The association in one family (170) of a stillborn child and of a propositus with lobster-claw deformity of the hand, an anatomic detail also described in the case-report of Upshaw in 1978 (174), may indicate an ischemic process *in utero*.

The ADAMTS 13 gene has been studied in three series of VWF-cp deficient patients, with a total of 16 patients and 12 pedigrees so far (169,180,186). Twenty-three different mutations have been described, which were missense, nonsense, or truncating mutations. The mutation sites were located throughout the molecule. Most of the patients were compound heterozygotes for two different mutations, and only a few were homozygotes. Of interest, Kokame et al. showed that some mutations abrogated activity of the enzyme, whereas others retained low but significant activity (186). As yet, a correlation between phenotype and genotype cannot be established, but this may change with a larger number of subjects.

Treatment of von Willebrand Factor–Cleaving Protease Deficiency

Patients with the hereditary form can be treated by FFP infusions to replace active VWF-cp. Virus-inactivated plasma contains the same amount of VWF-cp as untreated plasma (165,181). FFP effectively reverses hemolytic crises, prevents relapse when given prophylactically, and limits the progression of organ damage (170,184,187,188). VWF-cp has a half-life of 2 to 3 days (187) and is effective at low concentrations. Plasma infusions (10 mL/kg body weight) every 2 to 4 weeks seem sufficient to maintain remission, whereas increasing the interval beyond 4 weeks risks relapse (170,182). The ideal interval between infusions (i.e., from 2 to 4 weeks) may be established for an individual patient

by monitoring the platelet count after plasma therapy. Plasma infusions are best used preventively as rescue plasma infusions, even given early in a relapse, may not prevent CNS involvement (170).

Plasma treatment, started long before the association with VWF-cp deficiency was known, has maintained its clinical effectiveness in some cases for more than 20 years (170,174,179). These patients have developed neither resistance to plasma therapy nor, as far as is known, anti-VWF-cp antibodies.

The administration of 1-desamino-8-D-arginine vasopressin is contraindicated in patients with VWF-cp deficiency as symptomatic relapse of TTP has been reported within 1 hour of 1-desamino-8-D-arginine vasopressin infusion (189). In 10 healthy volunteers and 3 patients with type 1 von Willebrand disease, Reiter et al. (190) recently demonstrated a decrease of VWF-cp activity to approximately one-half the initial value and the appearance of large VWF multimers 60 minutes after the administration of desmopressin, suggesting a consumption of VWF-cp after desmopressin induced release of larger VWF multimers. Thus, even nasal or oral 1-desamino-8-D-arginine vasopressin to our opinion is contraindicated in VWF-cp-deficient enuretic patients. The question of which prophylaxis to avoid triggering factors of TMA is raised when an asymptomatic sibling is diagnosed in a family and in patients with bouts of TTP. In women, VWF-cp deficiency probably has to be considered as a contraindication to estroprogestatives.

Patients with acquired VWF-cp inhibitors may need more aggressive therapy, including PE, and, in some cases, immunosuppressive treatment, vincristine, or splenectomy (187). Low inhibitor titers can be overcome by the VWF-cp of FFP, and this may explain why plasma therapy or PE (between 1.0 and 2.5 times the plasma volume) is effective in most cases of TTP. Patients with high inhibitor titers are less likely to respond to PE by the end of 9 days (191). Nevertheless, in many cases, VWF-cp activity eventually returns to normal (162). This suggests that in these patients, the inhibitors represent a temporarily deranged immune response to VWF-cp. In some patients, the immune reaction persists, leading to a chronic or refractory disease. These cases may benefit from measures that suppress or block the inhibitor.

Posttransplant Course in Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura Associated with Constitutional von Willebrand Factor–Cleaving Protease Deficiency

Only one patient with constitutional VWF-cp deficiency has had renal transplantation (170,184). MAHA, thrombocytopenia, and renal failure recurred 5 days after transplantation, with arterial TMA lesions in the graft. The child also had transient amaurosis related to retinal ischemia and seizures and coma 35 days after transplantation, with ischemic lesions on cerebral tomodensitometry. PE with FFP

was started empirically on day 7 posttransplantation, which corrected hemolysis and thrombocytopenia and stabilized graft function. Twice-monthly PE was continued during the 9 subsequent years without recurrence. After VWF-cp deficiency was identified in this patient, a second renal transplantation was performed at 24 years of age, under FFP cover. No recurrence has occurred during the year of follow-up after grafting, and the patient is well with twice-monthly FFP infusions (H. Nivet, *personal communication*).

Hemolytic Uremic Syndrome Associated with Congenital Intracellular Defects of Vitamin B₁₂ Metabolism

HUS may occur in children with inherited abnormalities of the intracellular metabolism of vitamin B₁₂ [cobalamin (Cbl)] (192–194). Considering the generally poor prognosis of these diseases and the possibility of prenatal diagnosis, detection is crucial.

Metabolism of Cobalamin

Cbl in the diet binds to intrinsic factor produced by gastric cells. Absorption is effected by binding of the intrinsic factor–Cbl complex to ileal receptors, followed by endocytosis and lysosomal digestion of the complex, releasing Cbl, which attaches to transcobalamin II. The complex Cbl-transcobalamin II is released from the cells into the portal blood stream and is captured by specific receptors of the Cbl-transcobalamin II complex at the surface of a number of cells. Within cells, Cbl follows two different metabolic pathways (Figs. 47.10 and 47.11). In the first one, cytosolic, Cbl is transformed to methylCbl (CH₃-Cbl), the coenzyme of methionine synthase, which catalyzes the methylation of homocysteine to methionine. The second pathway occurs within mitochondria and consists of the adenylation of Cbl to form adenylation-Cbl (Ado-

Cbl). Ado-Cbl is the coenzyme of methylmalonyl-CoA mutase that catalyzes the transformation of methylmalonyl-CoA to succinyl-CoA. So far, seven genetic defects have been demonstrated, which disturb the intracellular metabolism of Cbl (193). Defects in the early steps of these pathways, CblC, CblD, and CblF, result in deficient activity of both coenzymes, Ado-Cbl and CH₃-Cbl, inducing deficient activity of both Cbl-requiring enzymes, methylmalonyl-CoA mutase and methionine synthase. These patients have homocystinuria, hyperhomocysteinemia, hypomethioninemia combined with methylmalonic aciduria, and hypermethylmalonic acidemia. CblE and CblG, due to defective CH₃-Cbl synthesis, induce a functional deficiency of methionine synthase. These patients have homocystinuria without methylmalonic aciduria. CblA and CblB defects both impair the synthesis of Ado-Cbl, leading to a deficient activity of methylmalonyl-CoA mutase. These patients have methylmalonic aciduria without homocystinuria. All these diseases have an autosomal recessive transmission.

Hemolytic Uremic Syndrome in Cobalamin C Defect

HUS has been reported mainly in CblC defect. Among a total of 44 CblC patients from the literature and from their personal experience, Ogier de Baulny et al. in 1998 reported the occurrence of HUS in 17 (194), mainly in the neonatal form of the disease. Out of 32 CblC patients who had clinical symptoms in the neonatal period or early infancy (younger than 3 months), 12 developed full-blown HUS before 3 months of age, and 4 additional patients from the literature had renal signs compatible with HUS before 3 months of age (194). Another CblC patient with HUS at 28 days of age has recently been reported (196). These children display feeding difficulties with anorexia, poor sucking, vomiting, weight loss associated with hypotonia, and lethargy early after birth. Megaloblastic anemia is frequent. Quite often, the diagnosis remains uncertain until the occurrence of HUS. At this stage, MAHA is severe and recurrent, with schizocytosis and thrombocytopenia. Renal involvement consists of hematuria, proteinuria, renal failure of variable severity, and hypertension. HUS is most often associated with multisystem deterioration, including cardiac failure due to cardiomyopathy, respiratory failure due to interstitial lung disease, hepatocellular failure, diarrhea, and gastrointestinal bleeding and further neurologic deterioration with seizures and coma. Tomodensitometry shows nonspecific cortical and subcortical atrophy; MRI shows periventricular demyelination. Retinopathy with visual impairment is frequent. Treatment with hydroxycobalamin (greater than or equal to 1 mg/day initially), oral betaine, and folic acid normalize the metabolic anomalies within a few days, but mortality is extremely high. Among the 16 CblC cases with HUS reviewed by Ogier de Baulny et al. (194), only 2 were alive at 10 years of age (H. Ogier

FIGURE 47.10. The two major chemical reactions catalyzed by cobalamin: the conversion of homocysteine to methionine and of methylmalonyl-CoA to succinyl-CoA. (From Russo P, Doyon J, Sonsino E, et al. Inborn errors of cobalamin metabolism and the hemolytic uremic syndrome. In: Kaplan B, Trompeter S, Moake J, ed. *The hemolytic uremic syndrome and thrombotic thrombocytopenic purpura*. New York: Marcel Dekker, 1992:255–270, with permission.)

FIGURE 47.11. The intracellular conversion of cobalamin to either methylcobalamin or adenosylcobalamin. (From Russo P, Doyon J, Sonsino E, et al. Inborn errors of cobalamin metabolism and the hemolytic uremic syndrome. In: Kaplan B, Trompeter S, Moake J, ed. *The hemolytic uremic syndrome and thrombotic thrombocytopenic purpura*. New York: Marcel Dekker, 1992:255–270, with permission.)

de Baulny, *personal communication*) and 7 months of age (197), with severe visual and neurologic impairment. The patient reported by Kind et al. also was alive at 6 months of age, with visual and neurologic sequels (196).

Thus, the diagnosis of CblC defect must be considered whenever HUS occurs in an infant with feeding difficulties and neurologic impairment preceding the HUS and atypical features like megaloblastosis and leukopenia with hypersegmentation of neutrophils.

At autopsy, widespread TMA with glomerular and arteriolar thrombosis is observed in the kidneys, and possibly in the brain, heart, lungs, and liver. Total atrophy of the gastric mucosa with extensive cystic changes is also characteristic.

Occurrence of HUS in CblC patients with symptoms in late infancy and early childhood is quite exceptional. One child with HUS at 9 months of age has been reported (194). Von Hove et al. (198) reported 2 siblings, a 12 year-old boy and his 4-year-old sister, who presented with proteinuria and hematuria, hypertension, and chronic hemolytic anemia. The boy developed an episode of severe hypertensive encephalopathy

and transient renal failure. Neither child had neurologic symptoms, only minimal pigmentary retinal abnormalities were seen. Renal biopsy showed chronic TMA lesions. Both patients had hyperhomocysteinemia and mild methylmalonic aciduria. Fibroblasts showed decreased Cbl uptake and reduced methyl and adenosyl Cbl formation compatible with the Cbl group, but milder than that found in cells of most patients. After treatment with high doses of hydroxycobalamin (5 mg/day) and betaine, homocysteine levels normalized, hemolysis and hematuria disappeared, proteinuria almost normalized, and creatinine clearance has been stable after 1 year of follow-up.

Hemolytic Uremic Syndrome in Methionine Synthase (Cobalamin G) Defect

One CblG patient with HUS has been reported (199). This 18-month-old girl born from consanguineous parents had macrocytic megaloblastic anemia followed by HUS with schistocytosis, renal failure, and hypertension. Renal biopsy showed glomerular and arteriolar TMA. Methioninemia and the activ-

ity of methionine synthase were decreased, indicating that the patient had CblG defect. Treatment with hydroxycobalamin and folic acid corrected the anemia, but the child progressed to end-stage renal failure at 13 years of age and had pulmonary hypertension at 6 years of age. Most likely, the pulmonary hypertension was due to vascular lesions similar to those observed in the kidney and in some neonatal forms of CblC with pulmonary involvement.

Mechanisms of Hemolytic Uremic Syndrome in Remethylation Defects

The mechanism of HUS in inborn errors of Cbl metabolism is uncertain. TMA is probably secondary to vascular endothelial damage caused by the high homocysteine concentrations. Hyperhomocysteinemia induces endothelium lesions in rats (200) and pulmonary thrombi in mice (201). Hyperhomocysteinemia is a well-established risk of vascular disease in humans (202,203). However, homocysteine alone cannot be the only risk factor, because HUS has not been described in patients with cystathionine synthase, whose plasma homocysteine concentrations are higher than those encountered in Cbl-mutant patients.

DRUG-INDUCED HEMOLYTIC UREMIC SYNDROME

Calcineurin Inhibitors (Cyclosporine, Tacrolimus)

HUS associated with cyclosporine A (CsA) therapy was first reported after bone marrow transplantation. Subsequently, it was reported after liver, kidney, or heart transplantation (204). The syndrome generally occurs during the first few weeks of transplantation and is associated with high blood concentrations of CsA. Most often, there is no full-blown HUS, but TMA lesions at renal pathology, with or without deterioration of renal function (205). Tacrolimus-induced posttransplant HUS cases have also been recognized (206), with a reported incidence of approximately 1% in recipients of renal transplants (207).

Chemotherapy

Several cytotoxic drugs can induce HUS, probably due to toxicity to endothelial cells, mainly mitomycin C, given alone or in association with 5-fluorouracil and doxorubicin (208), bleomycin, epirubicin, cisplatin, and, more recently, the antimetabolite gemcitabine (209).

Ticlopidine, Clopidogrel

HUS/TTP was first reported in patients receiving ticlopidine for 2 to 12 weeks, with an estimated incidence of 1 case

in 1600 to 5000 patients (210). Clopidogrel has largely replaced ticlopidine in clinical practice because it has a more favorable safety profile. Nevertheless, TTP has also developed in some patients receiving clopidogrel (approximately 10 to 15 cases per 3 million people treated). TTP occurred within 2 weeks after initiation of treatment. Antibodies against VWF-cp, inducing a severe VWF-cp deficiency, have been demonstrated in most cases of ticlopidine-induced TTP and PE are efficient both clinically and on the activity of VWF-cp (210,211). This antibody-mediated mechanism was also found in some patients with clopidogrel-induced TTP, but not all (212). Although almost all patients with ticlopidine-associated TTP had a response to PE within seven or fewer sessions and have had no relapses, some patients with clopidogrel-associated TTP require up to 30 PE, and some of them may have relapses up to 7 months after the discontinuation of clopidogrel (210).

Quinine

Patients presensitized to quinine may develop TTP/HUS, sometimes triggered by a single tablet taken many months after a previous exposure. They present with chills, fever, MAHA, thrombocytopenia, and possibly neurologic abnormalities. Renal involvement may be mild or asymptomatic, but acute renal failure is also possible. Out of 17 patients reported by Kojouri et al. (213), four died and seven had chronic renal failure. These patients with quinine-induced TTP/HUS have been shown to have developed quinine-dependent antibodies to erythrocytes, granulocytes, and the glycoprotein Ib/IX and IIb/IIIa expressed on the platelet surface (214).

HEMOLYTIC UREMIC SYNDROME SUPERIMPOSED TO OTHER PATHOLOGIES

De Novo Posttransplantation Hemolytic Uremic Syndrome

De novo posttransplant HUS occurring in renal or nonrenal transplant recipients is usually triggered by calcineurin inhibitors (207), or in exceptional cases, by OKT3 (215) or viral infections, especially cytomegalovirus (216). Influenza A virus (217) and parvovirus B19 (218) have also been reported as triggering a few cases of HUS after renal transplantation. Renal TMA associated with anticardiolipin antibodies has been reported in hepatitis C–positive renal transplant recipients (219). Last, undetectable VWF-cp activity secondary to the presence of inhibitors has been reported in a patient with HUS and TMA after renal transplantation. Discontinuation of CsA and PE increased the VWF-cp activity, which was followed by resolution of MAHA and improvement of graft function. Thus, the role of calcineurin inhibitors in the formation of autoantibodies to VWF-cp remains to be explored (220).

Hemolytic Uremic Syndrome after Bone Marrow Transplantation

A clinical picture resembling HUS may develop after bone marrow transplantation (BMT) (204,221–224). MAHA, thrombocytopenia, renal failure, frequently severe hypertension, and possibly seizures occur several months (e.g., at least 3 months, mean 8 months) after BMT. Pretransplant total body irradiation probably plays a role through its toxicity toward endothelial cells. However, HUS has been described in patients exposed to cytotoxic chemotherapy without renal irradiation (225). Some patients with post-BMT/HUS have also received high doses of CsA. However, in rats, CsA does not appear to exacerbate radiation nephropathy (226), and HUS is well documented in BMT recipients who have never received CsA (227, 228). Besides radiotherapy, the presence of graft versus host disease appears as another risk factor (229).

Renal histology in post-BMT/HUS shows striking glomerular mesangiolysis and diffuse endothelial cells damage with subendothelial expansion and capillary loop occlusion (224,225,230).

In adult patients, the cumulative risk of BMT-induced HUS/TTP is approximately 25%, mainly observed in the first 12 months after BMT (231). Subclinical renal dysfunction is even more frequent (232).

An increase of the plasma levels of IL-8, thrombomodulin, and plasminogen activator inhibitor has been demonstrated in patients with HUS or TTP after BMT, with a close relationship between improvement in symptoms and a decrease of IL-8 levels, suggesting a role of this cytokine (233). VWF-cp levels were normal in six patients with BMT-associated TMA (234). The very low turnover of endothelial cells, with cell death delayed until the cell divides, may explain why radiation HUS/TTP is a late phenomenon, occurring months after the exposure (224).

Hemolytic Uremic Syndrome Associated with Systemic Lupus Erythematosus or Antiphospholipid Syndrome

The coexistence of systemic lupus erythematosus (SLE) and HUS/TTP is rare in adults and has only been reported in approximately 20 children (235–237). Serum haptoglobin concentration must be measured whenever a child with SLE shows thrombocytopenia, Coombs'-negative anemia, and schizocytes. Correct diagnosis is important, as treatment with plasmapheresis and FFP is necessary to control the disease.

HUS/TTP has also been described in the context of catastrophic antiphospholipid syndrome (238), in association with lupus anticoagulant or anticardiolipin or anti-B2 glycoprotein I antibodies. An acquired deficiency of VWF-cp due to an inhibitor has been reported both in SLE patients with (239) or without (240) antiphospholipid antibodies.

Hemolytic Uremic Syndrome Superimposed to Collagen Type III Glomerulopathy

The occurrence of HUS has been reported in children with a hereditary (autosomal recessive) glomerulopathy called *collagen type III glomerulopathy* or *complex basalopathy* (241). This glomerulopathy is characterized by an increase of mesangial matrix, thickening of capillary walls, and double contour appearance of glomerular basement membranes, due to the accumulation of collagen type III. The association with fH deficiency reported in one child (134) raises the question of the role of fH deficiency in the pathogenesis of the glomerular anomalies.

HEMOLYTIC UREMIC SYNDROME OF UNKNOWN MECHANISM

Even when fully investigated, no etiologic diagnosis is found in a high proportion of children with D- HUS. This includes cases with clear indication that there must be an inherited cause.

Autosomal Recessive Hemolytic Uremic Syndrome Not Associated with Prodrome of Diarrhea of Unknown Mechanism

D- HUS with presumed autosomal recessive inheritance is mainly observed in children (242), although the age of onset ranges from neonates (243) to adults (244,245). Age at onset of HUS tends to be similar in siblings. A recurrent course is common. Many patients die, especially those with early onset. Progression to end-stage renal disease is almost constant. The course after renal transplantation is not documented in those with childhood onset. Eleven patients in four families reported by Kaplan et al. (246) had HUS at 17 to 36 years of age and received 14 renal transplants. Recurrence occurred in 9 out of the 14 grafts. The use of CsA or the type of donor had no role in the risk of recurrence. In one family, one patient had HUS posttransplant recurrence, but not his sibling (246). Most probably, the risk of recurrence in children with autosomal recessive HUS is as high as in adults.

Autosomal Dominant Hemolytic Uremic Syndrome Not Associated with Prodrome of Diarrhea of Unknown Mechanism

Autosomal dominant HUS generally starts during adulthood (242,247). Among the 68 patients from 16 families reviewed by Kaplan and Leonard, 18 were children in whom HUS started between 5 months and 17 years of age (247). A recurrent course of HUS has been reported in only 3 cases out of 62. Twenty-eight patients (45%) died, 6 were alive and well (19%) without renal failure, and 28 (45%)

had end-stage renal failure. Twenty patients received 32 kidney grafts. Recurrence occurred in 17 (65%). The nephrectomy of native kidney did not appear to influence the outcome.

Hemolytic Uremic Syndrome of Unknown Mechanism without a Prodrome of Diarrhea

Clinical Course

The clinical pattern of these patients can be gleaned from the main pediatric reviews. A total of approximately 100 cases can be analyzed (15,242,248–251). Age at onset varied from 3 days to 14 years, with several patients developing HUS as neonates. The onset of renal involvement is often insidious. Between 13 (250) and 54% (249) of patients have oligoanuria at onset, but at least one-half have a nonoliguric progressive increase of serum creatinine with proteinuria and hematuria. Thus, the interval between the onset of renal symptoms and the need for dialysis may vary from a few days to several months with three-fourths of patients finally requiring dialysis (15,248,250). Severe hypertension is associated in one-half to 75% of patients. Relapses with exacerbation of MAHA have been reported in 18% of patients of Siegler's series (249), 32 to 55% in 3 other series (15,248,250). The incidence of CNS involvement is highly variable, from 0% (251) to 8 to 13% (15,249), up to 30 to 48% (248) and 48% (250). This, and the variability of the overall severity of the disease, most probably reflects the heterogeneity of patients regrouped under the eponym of unexplained D– atypical HUS. Thus, in the group of patients reported by Siegler et al. (249), mortality rate was 0%, evolution to end-stage renal disease was observed in only 12% of patients (mainly in those with relapses), and recovery without renal sequels in 47%. Other series had mortality rates varying from 13% (251) to 20 to 26% (15,248,250), and end-stage renal disease rates from 21 to 27% (15,248) to 42 to 56% (250,251). Thus, full renal recovery was observed in only 7 to 26% of patients in these series (15,248,250,251).

Treatment

Some rare cases of D– HUS of unknown mechanism have a positive response to FFP infusion or PE (252,253), justifying this empirical approach. The recommended amount of FFP infused is 10 mL/kg over 6 to 7 consecutive days, which cannot be done without PE if the child is anuric. During PE sessions, one or two plasma volumes (40 to 80 mL/kg) are exchanged daily or on alternate days over 1 week. Efficacy is judged on the platelet count, the correction of MAHA, the normalization of haptoglobin, and, eventually, neurologic improvement. Renal function may take several weeks to show an improvement.

Posttransplant Course

The incidence of HUS recurrence can be analyzed from the literature in 59 children with atypical D– HUS of unknown mechanism who received 73 kidney transplants (75,97,98,101,248,250). Thirteen of the 59 children (22%) had recurrence of HUS on one or several grafts, with a total of 18 recurrences on 73 grafts (25%). In addition, there are 7 individual case reports with 11 grafts and 9 recurrences (254–260). Therefore, a total of 27 grafts with HUS recurrence can be analyzed. The time between initial HUS and renal transplantation does not appear to affect the risk of recurrence. In most cases, HUS recurred during the first month after transplantation, but late occurrence several years after transplantation has also been observed. The role of calcineurin inhibitors is unclear. The type of donor, cadaveric or living related, does not appear to have a role in the risk of recurrence. The outcome after HUS recurrence is poor, with graft loss within a few days or weeks in most cases. Those with recurrence in a first graft usually experience recurrence in subsequent grafts. However, there are exceptions to this, and a few who show no recurrence on a first graft will do so on subsequent grafts.

CONCLUSION

Despite its rarity, great progress has been made in understanding the mechanisms of HUS in recent years. However, the high proportion of D– HUS for which no etiology can be found suggests that there may be diagnostic categories still to be discovered. Collaboration between many clinical centers and laboratories will be needed to keep up this momentum.

SICKLE CELL NEPHROPATHY

JON I. SCHEINMAN

The major clinical consequences of sickle cell disease (SCD) are vascular obstruction by sickled cells and anemia because of red blood cell (RBC) destruction. The sickling process may cause hematuria, renal papillary necrosis (RPN), and a urinary concentrating defect. There also is a chronic sickle cell glomerulopathy, which is less directly related to sickling, as well as unusual susceptibility to infections and to a recently reported specific form of malignancy.

Sickle hemoglobin (HbS) differs from normal hemoglobin (HbA) by the substitution of valine for glutamine in the 6 position of the β -globin chain (1). Under low oxygen tension in concentrated solution, HbS aggregates and forms intracellular fibers. These fibers prevent RBCs from deforming normally, so they do not pass easily through the microcirculation and thus cause occlusion. Repeated cycles make some cells irreversibly sickled, and even in well-oxygenated blood they cause abnormal viscosity. In addition, these abnormal cells are easily lysed, which causes anemia.

HEMATURIA AND RENAL PAPILLARY NECROSIS

Clinical Features

Gross hematuria may be the most dramatic clinical event in SCD (2). It is often painless and usually unilateral, more commonly on the left side (3), which is explained by increased venous pressure due to the greater length of the left renal vein. Hematuria can occur at any age. It is more often reported with sickle trait (HbAS), probably because of the higher genetic frequency of HbAS than of HbSS (4). RPN is usually discovered in patients with painless gross hematuria (5). Hematuria is not invariably present, however, and RPN can occur even in young children (3). When it was sought systematically, 40% of patients in one Nigerian series were found to have RPN (6). In another series, there was no difference in the incidence of RPN in symptomatic patients (65%) and in asymptomatic (62%) patients (7). The frequency of RPN on urography therefore suggests that the process develops subclinically without gross hematuria.

Pathogenesis

The pathology associated with isolated hematuria is rarely examined. In the past, kidneys removed from patients with uncontrolled bleeding in SCD showed relatively insignificant changes, primarily medullary congestion (4). The hematuria probably results from the sequence of renal medullary sickling, vascular obstruction, and RBC extravasation. This is precipitated by those factors present in the renal medulla that lead to sickling: The PaO_2 (35 to 40 mm Hg) is below the threshold (45 mm Hg) for sickling (8); the high osmolality of the medulla draws water from the RBC, which leaves the HbS concentrated, promoting the formation of hemoglobin polymers. The acidic environment of the renal medulla further increases the likelihood of sickling. This mechanism of microvascular occlusion explains many of the complications of SCD but is overly simplistic. The distortion of the cell is also partly explained by dehydration of the cell by enhanced KCl co-transport, induced by cell swelling and acidification (9). Furthermore, K^+ and water efflux are enhanced by transiently increased SS cell cytosolic Ca, induced by the membrane distortion.

Pathology

The pathology of RPN in SCD is a focal process, with some collecting ducts surviving within a diffuse area of fibrosis. Within the medullary fibrosis the vasa recta are destroyed, after initial dilation and engorgement (10). The dependence of the papilla on that circulation results from repeated small focal infarctions of the papilla (11). This differs from the RPN found in analgesia abuse, in which the vasa recta typically are spared, and most lesions occur in peritubular capillaries (11). These same factors are present in sickle trait, although with a smaller proportion of sickling cells. Because calyces are affected separately and sequentially in SCD, acute obstruction and renal failure are uncommon (7).

Diagnosis

Continued gross hematuria likely represents a form of renal "sickle crisis" in a patient with known HbSS or HbAS. Other

FIGURE 48.1. Tomographic pyelography of an 18-year-old patient with abdominal pain and hematuria. Papillary necrosis is evident from blunted medullary cavities, especially the upper pole. The bases of the calyces are preserved. The middle pole calyx has a possible sinus tract.

FIGURE 48.2. Ultrasonographic visualization of the same kidney as in Figure 48.1. The middle pole exhibits deep extensions into the papilla, likely sinus tracts, typical of the "papillary" form of renal papillary necrosis.

treatable causes of hematuria, including the distinctive renal medullary carcinoma in patients with sickle hemoglobin, must be excluded (12). Severe pain makes the diagnosis of renal sickle crisis less likely, whereas moderate discomfort often lateralizes the bleeding. Renal and bladder ultrasonography can rule out bleeding from a stone or tumor and diagnose RPN (see later). The increased echodensity of medullary pyramids on ultrasonography is typical of SCD, and in the absence of hypercalciuria, medullary echodensity in a patient with hematuria should suggest a sickle hemoglobinopathy (13). Walker (14) reviewed ultrasonographic reflectivity in young SCD patients (age 10 to 20 years) and found diffuse echogenicity in 9% and medullary echodensity in 3%. Surprisingly, these findings were greater in the milder genotypes, 37% in SC patients and 79% in $S\beta^+$ thalassemia patients. These findings are unexplained but are unlikely to represent RPN. The echodensity was found overall in 20% of patients with sickling processes and was interpreted to suggest subclinical nephrocalcinosis or iron deposition.

The diagnosis of RPN in SCD was traditionally made by urography. In the series of McCall et al., 39% of 189 patients had calyceal clubbing, including 23% with definite RPN (15). Cortical scarring as found in pyelonephritis does not accompany the calyceal clubbing of SCD (16). Other urographic findings of RPN in SCD are distinctive. A "medullary" form in which an irregular medullary cavity is present, often with

sinus tracts, is common (7). The base of the calyx and its normal outline are preserved (16). Sonography can sometimes identify the early medullary form of papillary necrosis (17). A later finding is calcification of the medullary pyramids in a "garland" pattern surrounding the pelvis. This pattern of "shadowing" echodensity may be distinctive. The progression to the "papillary" form results in clubbing and caliectasis (Figs. 48.1 and 48.2). This is more common in analgesic nephropathy, in which an area of sequestration is often found, which results from infarction of a large area of the papilla (18). A prospective survey of symptomatic SCD patients (7) found that 11 of 18 SA patients had a form of RPN, but 8 of these 11 had evidence of infection. Nine of 11 symptomatic SS patients had RPN, of which 5 had evidence of infection. Asymptomatic patients included 16 of 22 SS patients with RPN, 1 of 3 SA patients, 3 of 4 SC patients, and 5 of 8 $S\beta^+$ patients. It is probably not necessary to perform contrast urography to visualize the renal architecture in SCD.

Treatment

In view of the benign pathology in SCD hematuria, conservative management is appropriate (4). Bed rest is often recommended to avoid dislodging hemostatic clots. It is advisable to maintain high rates of urine flow by both hypotonic fluid intake (4 L/1.73 m² surface area per day) and administration

of diuretics (a thiazide or a loop diuretic such as furosemide), which should help clear clots from the bladder (3). In addition, a diuresis reduces medullary osmolality and may therefore help alleviate sickling in the vasa recta. Some caution is necessary in the administration of sodium-containing fluids because of potential sodium retention (see later).

The combination of vasopressin and administration of hypotonic fluid to reduce plasma osmolality has been suggested. Hyponatremia induces water uptake by RBCs *in vitro*, thereby reducing the effective HbS concentration and making the cells less likely to sickle (4). This treatment is neither safe nor proven effective (4). Saline volume expansion would be especially ineffective and, coupled with hypertransfusion, would predispose to congestive heart failure. It would also be surprising if vasopressin were to increase the patient's urine concentration sufficiently to inhibit water diuresis (see later).

Because sickling is increased in an acid environment, alkalization of the urine by 8 to 12 g NaHCO₃ (per 1.73 m²) per day may reduce sickling in a urine environment, but this may not be relevant for medullary sickling (3). Alkalinizing the patient to increase the oxygen affinity of hemoglobin is theoretically valid but not of proven value in practice (4). Transfusions may be necessary for blood loss and could be helpful by increasing the proportion of normal HbAA cells and thus reducing sickling cells.

Epsilon aminocaproic acid (EACA) inhibits fibrinolysis, allowing clots to mediate hemostasis. The effective dosage in an adult is 8 g/day. In one series, 4 of 12 cases required EACA after failure of treatment with fluid administration and alkalization (3). Unless other measures have failed, the risk of thrombosis should impose some caution in use of EACA. Lower dosages may be adequate to arrest hematuria, starting with 1 g (per 1.73 m²) orally three times daily and increasing the dose until hemostasis occurs (4). Nephrectomy is rarely required for uncontrolled bleeding. Arteriographic localization and local embolization of the involved renal segment may avoid nephrectomy.

RPN can be prevented experimentally by either diabetes insipidus or water diuresis, which thereby eliminates the medullary concentration gradient (19). Thus the fluid administration prescribed for gross hematuria is also appropriate to prevent RPN. Angiotensin-converting enzyme (ACE) inhibition can experimentally induce a 50% increase in papillary blood flow (19). This may help prevent RPN, but it could aggravate hematuria acutely by increasing blood flow to a bleeding area.

TUBULAR DYSFUNCTION

The relevant medullary pathology in SCD is found in the region of the collecting ducts, the inner medulla, and the papilla. This results in dysfunction of the collecting duct and juxtamedullary nephrons (19). Sickling and vascular congestion of the medulla, seen in gross hematuria (4), are

probably responsible for reversible concentrating defects. The basis of irreversible medullary dysfunction in RPN is likely the medullary fibrosis and destruction of vasa recta. Juxtamedullary nephrons and collecting ducts are destroyed, as is found in the model of RPN induced by bromoethylenedihydrobromide in rats (20).

Clinicopathologic Features

Urinary Concentration

The most common tubular abnormality in SCD is a urinary concentrating defect. Typically, HbSS patients achieve a urine concentration of 414 mOsm/kg after 8 to 10 hours of thirst, compared with 911 mOsm/kg in controls (21). Patients with sickle trait may have a diminished urinary concentrating capacity (22). This concentrating defect in children with SCD may result in enuresis (1) and an increased risk of dehydration during water deprivation.

The ability to concentrate urine depends on an intact collecting duct. The collecting ducts of juxtamedullary nephrons extend deepest into the medulla and are capable of generating the highest urine concentration. Poor sodium reabsorption in the collecting duct can result if the sluggish blood flow does not remove the reabsorbed sodium (19). The continued low-grade sickling and medullary congestion result in loss of the normal medullary concentration necessary for water reabsorption. This defective urine concentration can be transiently reversed by transfusion (23,24). The permanent destruction of collecting ducts by medullary fibrosis in humans with SCD (10) and in rats (20) results in an irreversible concentrating defect.

Vasopressin generation is normal in SCD, and the concentrating defect is not responsive to vasopressin. The concentrating defect is unique to sickling hemoglobinopathies, in that there is no concentrating defect in other anemias (25).

Diluting Capacity

Urinary dilution depends on the solute reabsorption in the ascending loop of Henle of cortical nephrons, which are not involved in SCD patients. They can usually dilute the urine normally (21,23).

Hydrogen Ion and Potassium Excretion

A proton gradient from tubular cell to lumen underlies acid excretion. Proton secretion is associated with the "intercalated" collecting duct cells, most prominent in the cortical segment of the collecting duct (19). Damage to the papillary segment is therefore unlikely to cause a severe acidification defect. However, juxtamedullary nephrons, which reabsorb HCO₃⁻, are also severely involved in SCD. On this basis, some defect in acid excretion may occur (19).

An incomplete distal renal tubular acidosis (RTA) may complicate SCD, but it is usually not a clinical problem (23). The

minimum urine pH achieved in response to NH_4Cl loading is not as low as in controls (5.8 vs. 5.1), but total NH_4 excretion is normal. Consequently, titratable acidity is reduced (26). Kurtzman has also described a "type IV RTA" in SCD, with a reduced ability to lower urine pH in response to Na_2SO_4 and inadequate K^+ secretion, especially in patients with decreased renal function (27). In one series, six of nine nephrotic SCD patients were reported to have type IV RTA (28).

Plasma renin and aldosterone levels may be increased in the face of medullary fibrosis (23). A protective mechanism likely exists: in the presence of inadequate K^+ secretion, a shift of K^+ to intracellular compartments probably occurs. Because this shift is under β_2 stimulation, beta-blockers or ACE inhibition may result in hyperkalemia (23). The electrolyte abnormalities resemble those in type IV RTA but actually result from an aldosterone-independent end-organ failure secondary to medullary fibrosis.

Proximal Tubular Reabsorption

An increased capacity for sodium reabsorption and a decreased sodium excretion with loop diuretics is seen in SCD (21,29). De Jong and Statius van Eps have proposed that the alterations in renal cortical function are adaptive, compensating for defects in medullary sodium and water conservation (10). The increased proximal sodium reabsorption results in decreased distal sodium delivery. Diuretic response is poor, because it depends on this more distal sodium delivery. Proximal tubular phosphate reabsorption, which usually parallels sodium reabsorption, is also increased. This may cause hyperphosphatemia, especially in the presence of an increased phosphate load generated by hemolysis (23).

Tubular Secretion

A significant disparity is found between creatinine clearance (CCr) and inulin clearance (CIn) in SCD. For example, in a small group of patients with SCD and an increased glomerular filtration rate (GFR) as measured by CIn (119 mL/min versus 97 mL/min for individuals without SCD), CCr was significantly higher than CIn in SCD patients (154 versus 119 mL/min) but not in those without SCD (114 vs. 97 mL/min) (21). This is an expression of increased tubular secretion of creatinine in SCD (23).

Uric acid secretion is similarly increased and is a functional adaptation to high uric acid generation (5). In patients with decreasing total GFR (and increasing GFR per nephron), fractional excretion of urate is further increased by decreased reabsorption (30).

Experimental Models of Tubular Dysfunction in Sickle Cell Disease

The rat model of RPN induced by bromoethylene-hydrobromide exemplifies distal tubule physiologic disturbances

(20). As a baseline, these rats have a more dilute urine than controls. The juxtamedullary nephrons are nonfunctional. Sodium excretion changes little in response to hypervolemia. Although the measured atrial natriuretic peptide (ANP) level increases appropriately, an additional high-dose infusion of ANP can generate a normal response. The normal response to hypervolemia is likely mediated through inner medullary interstitial pressure, damaged in this model (and in SCD). In contrast, the response to salt loading generates a normal increased sodium excretion in experimental RPN, regulated by a more cortical mechanism (20).

Role of Prostaglandins in Tubular Dysfunction in Sickle Cell Disease

A series of studies begun by de Jong and Statius van Eps explored the effects of prostaglandin (PG) inhibition on renal function (10,31). The effect of PG inhibition on tubular function is especially revealing: there was a greater fall (42%) in the fractional excretion of Na in response to PG inhibition by indomethacin in SCD patients than in individuals without SCD (16%). This reflects a greater than normal effect of PGs on the delivery of sodium to the distal diluting segment. Although normal urinary dilution is not affected by PG inhibition, PG inhibition decreases urinary dilution in SCD (21).

PGs increase proximal sodium reabsorption. Under PG inhibition, more solute is delivered to and then reabsorbed by the thick ascending limb of the loop of Henle, which thereby increases interstitial hypertonicity. More free water is then absorbed in the relatively solute-impermeable descending limb, which results in a decreased response to water loading (21). Thus, although urinary diluting capacity is normal in SCD, it is being maintained only by PG and will be decreased by indomethacin (10). PG inhibition increases distal delivery, preventing the appropriate effect of vasopressin suppression during water diuresis in SCD (10). Increased proximal sodium reabsorption in SCD results in a decreased natriuretic response to loop diuretics (20), and PG inhibition restores that response.

Unlike in those without SCD, in SCD patients net acid excretion fails to increase in response to inhibition of PG synthesis by indomethacin (26) because of decreased NH_4^+ excretion. It is likely that NH_4^+ excretion is maintained at a maximum by endogenous PGs.

In summary, the tubular dysfunction of SCD manifests a defect in urine concentration, while dilution is maintained. Hydrogen ion and potassium secretion functions are only mildly affected, and proximal tubular mechanisms are exaggerated.

Treatment

Treatment of tubular disorders in SCD is usually unnecessary if renal function is normal. The risk of dehydration

caused by decreased urinary concentrating ability requires earlier treatment of diarrhea or vomiting. There should be a cautious approach to volume expansion as treatment for sickle crises; administration of large volumes of standard sodium-containing fluids to significantly anemic patients with increased sodium reabsorption may result in congestive heart failure. Acidosis may require earlier treatment in the patient with SCD. Hyperuricemia, resulting from increased urate production, may be aggravated by diuretics (especially thiazides) that inhibit urate secretion. The edema accompanying severe anemia may be difficult to treat because the response to diuretics is diminished. Severe hemolysis may exceed the patient's ability to excrete potassium, especially if there is renal insufficiency. Beta-blockers or ACE inhibition can aggravate hyperkalemia (23), especially in the presence of some degree of renal impairment (27).

SICKLE CELL GLOMERULOPATHY

Clinical Features

The association of significant proteinuria with SCD has been recognized sporadically and usually described as a nephritic process. As early as 1959 (32), nephrotic syndrome was recognized in SCD. Proteinuria was identified in 17 of 54 patients (32). A population study found proteinuria in 20% of 284 patients at a single center, with a prevalence of 29% in adults but only 5% in children younger than 10 years of age (33). Bakir et al. recognized nephrotic syndrome in 12 of 240 adults with SCD, with proteinuria of 2 to 20 g/24 hr (28). In our series, 87 (26%) of 381 adult patients had significant proteinuria, with 12 in the nephrotic range (more than 2.5 g/24 hr) (34). In a more recent study of 34 adult patients with SCD, 7 had albuminuria with normal GFR and 17 had chronic renal failure, with glomerular injury and loss of ultrafiltration coefficient (35). In this series, GFR was related to hematocrit (36).

Lonsdorfer et al. (37) found that 40 to 45% of 31 SS patients aged 16 to 40 years had abnormal proteinuria, mostly selective (albumin). Twelve percent of the 17 patients who were younger than age 16 had abnormal proteinuria. Of 52 SA patients older than age 16, approximately 18% had abnormal proteinuria. Those with S β ⁺ were similar to SS patients, whereas those with SC disease fell between SS and SA patients.

The definition of sickle cell nephropathy that is most accepted is associated with nephrotic-range proteinuria. Although long-term studies have not been done, it appears to have a more rapid course than nephrotic syndrome due to other causes. In the experience of Bakir et al. (28), two-thirds of patients developed renal failure within 2 years. The onset of renal failure was heralded by increasingly inadequate erythropoiesis (38), and survival time after diagnosis was 4 years.

Pathology

The usual finding in sickle cell nephropathy is focal segmental glomerulosclerosis (FSGS), which is intimately associated with glomerular hypertrophy. Glomerular engorgement and hypertrophy were recognized as part of SCD by Berman and Tublin in 1960 (32). FSGS was reported in a 9-year-old nephrotic SCD patient in 1959 (32). Ten of our adult HbSS patients without significant renal impairment underwent renal biopsy because of proteinuria (34). Eight had FSGS involving a mean of 27% of glomeruli, and the other two had focal global sclerosis. There was focal tubulointerstitial fibrosis adjacent to sclerotic glomeruli. The nonsclerotic glomeruli were all enlarged, with diameters of $186 \pm 14.5 \mu\text{m}$ versus $137.9 \pm 19.3 \mu\text{m}$ in ten control biopsies. Immunofluorescence gave positive results only for immunoglobulin M, C3, and C1q irregularly in sclerotic segments. Electron microscopy confirmed the absence of immune complex-type dense deposits. There was focal electron-lucent expansion of the subendothelial zone in six specimens, with occasional mesangial cell interposition. No new mesangial matrix material was observed to suggest membranoproliferative glomerulonephritis (MPGN).

These findings agree with the description by Zamurovic and Churg (39). Glomerular hypertrophy was documented previously in adults with measured glomerular diameter (median, 257 μm ; range, 220 to 316 μm) greater than in controls (median, 193 μm ; range, 142 to 253 μm) (40). Bakir et al. described both the nonimmune MPGN-like lesion in nine patients, and FSGS (in 8% of glomeruli) or global sclerosis (in 14% of glomeruli) (28). In addition to FSGS, focal cortical infarcts have been described as a late finding in sickle cell nephropathy (8).

A report on the renal pathology in six HbSS patients with proteinuria described two patterns of FSGS: a "collapsing" and an "expansive" sclerosis (41). Glomeruli were significantly hypertrophied, with diameters of $233 \pm 25.3 \mu\text{m}$, compared with $158 \pm 12.7 \mu\text{m}$ in subjects without SCD. Glomeruli were more hypertrophied in HbSS disease than in idiopathic FSGS ($188.2 \pm 17.9 \mu\text{m}$). The glomeruli from HbSS patients without clinical evidence of renal disease ($243.5 \pm 12.5 \mu\text{m}$) were the same size as in those with proteinuria.

Renal Function in Sickle Cell Glomerulopathy

Hyperfiltration

An increased GFR has been a recognized feature of SCD, especially in children, in studies dating from the 1950s (10). Renal plasma flow, as estimated by *p*-aminohippurate (PAH) clearance, is elevated in excess of GFR, which results in a lower than normal filtration fraction (12.9 vs. 17.5) (21). The extraction ratio of PAH (normally 90 to 95%) is also lower (24). The cause and mechanism of this physio-

logic alteration are unclear, although it is likely that increased cortical blood flow itself can cause decreased secretion by limiting diffusion from rapidly flowing plasma (24). A more recent analysis suggests a distinctive pattern of increased glomerular permeability (to dextrans) in SCD nephropathy, an increase in pore radius, which is not explained by purely hemodynamic changes. When chronic renal failure develops, the total number of membrane pores is reduced and a size-selectivity defect occurs.

Role of Prostaglandins in Glomerulopathy

The suggestion has been made that hyperfiltration and proximal tubular "hyperfunction" in SCD are a compensation for the distal tubular injury, mediated by the PG systems (10,20). In the studies by de Jong and Statius van Eps (see Tubular Dysfunction) (10), indomethacin decreased GFR and the estimated renal plasma flow (ERPF) in SCD patients but did not alter that of controls, which suggests that the PG system might be responsible for maintaining the GFR in SCD. Measured prostaglandin E₁ (PGE₁) excretion did not differ from that in controls, but prostaglandin F₂ (PGF₂) excretion was lower (42), which thus increased the ratio of the vasodilator PGE₁ to the vasoconstrictor PGF₂. Allon et al. (21) found that indomethacin decreased PGF₁ (prostaglandin, a vasodilator hormone) more in SCD patients (46%) than in control subjects (15%). GFR was decreased 16% by indomethacin in SCD but was unchanged in control subjects. The more dramatically increased ERPF and decreased filtration fraction of SCD were returned toward normal, and the net effect of PG inhibition was to reverse hyperfiltration.

Pathogenesis

Immunopathogenetic Mechanisms

In 1975, Strauss et al. (43) described an SCD membranoproliferative (MPGN) nephropathy in seven patients—four with nephrotic syndrome, and three of these under 15 years of age—with immunopathologic studies suggesting an immunocomplex disease. One proposed cause for the sickle cell nephropathy has been immunologic reaction to renal tubular epithelial cell complexes (10). Most now agree that evidence of immunocomplex deposition is usually lacking in SCD patients with heavy proteinuria.

Relationship to Other Glomerulopathies

The relationship of the pathologic findings of SCD to those of other nephropathies is unclear. Glomerular hypertrophy with FSGS is also found in the setting of reduced renal mass. Examples are reflux nephropathy, severe obesity (44), and rat models of renoprival glomerulosclerosis (45). In FSGS associated with idiopathic nephrotic syndrome, the glomeruli that develop sclerosis are hypertrophied (1).

The nephropathy associated with type 1 glycogen-storage disease (GSD-1) includes both hyperfiltration and FSGS (46). The nephropathy associated with cyanotic congenital heart disease may arise from mechanisms similar to those operating in SCD: low oxygenation and increased blood viscosity from polycythemia (23,47).

Possible Mechanisms of Sickle Cell Disease Nephropathy

Hyperfiltration, in concert with direct endothelial damage by occlusion with sickled cells, might lead to endothelial hyperplasia and ultimately fibrosis (10,23). The iron deposited in tubular cells as hemosiderin has been suspected to have a role in the chronic nephropathy of SCD (8). The non-immune complex deposits found in SCD might derive from iron-protein complexes (8). Experimentally, saturated-iron complexes can induce a nephrotic syndrome in rabbits (24). Lande et al. found decreased renal cortical spin-echo signal by magnetic resonance imaging in SCD, which suggests an abnormal renal cortical iron metabolism (48). This does not occur in β -thalassemia, despite similar iron overload.

It is possible that FSGS is the consequence rather than the cause of interstitial fibrosis, which might obstruct the efferent glomerular capillaries, raising intraglomerular pressure and resulting in progressive (reactive) sclerosis (49). In SCD, in which medullary fibrosis is most prominent, the vasa recta supplying the juxtamedullary nephrons would be most affected by FSGS. Bhatena et al. (41) suggested that the "collapsing" pattern of FSGS, superimposed on already maximally hypertrophied glomeruli, might be a consequence of sickling and ischemic collapse, similar to the glomerular "microinfarcts" suggested by Chauhan et al. (8). The "expansive" form of FSGS is viewed as a mesangial cell reaction to capillary collapse.

Both the pathophysiologic and pathologic findings in sickle cell nephropathy resemble those in the rodent model of glomerular hypertension induced by renal mass reduction (50). Thus hyperfiltration, glomerular enlargement, and focal and segmental glomerulosclerosis could be a result of an increase in intraglomerular pressure as a consequence of efferent arteriolar vasoconstriction. In that model, and in others, the glomerular hypertension and the pathologic consequences are attenuated by angiotensin II-converting enzyme inhibition.

Any hypothesis should take into account the glomerular hypertrophy that is always present in SCD, probably related to the anemia itself. Proteinuria is not invariable in SCD and appears to be unrelated to the number and severity of SCD crises or the presence of hematuria, RPN, and so on. Therefore some other factors are likely to be operative in those at greatest risk of proteinuria and FSGS. Systemic hypertension is notably absent in these patients (34). The presence of hyperfiltration, glomerular hypertrophy,

and FSGS does not imply that these findings are sequential or causative. A common stimulus may be operative, such as the growth-promoting hormones and cytokines (57), to which the glomerulus may be sensitive.

Diagnosis

Hyperfiltration

The upper limit of the normal range for GFR is not certain, even with CIn, the gold standard. The reliability of the clearance methods that can substitute for CIn have not been validated in the elevated range. In adult SCD subjects aged 40 to 75 years, CCr correlated well with the clearance of chromium-51 ethylenediaminetetra-acetic acid (^{51}Cr -EDTA) when clearance did not exceed 110 mL/min, although ^{51}Cr -EDTA exceeded CCr by almost 30% (23). In those without SCD, the urinary clearance of ^{51}Cr -EDTA is 85 to 95% that of CIn, whereas the clearances of technetium-99m diethylenetriamine penta-acetic acid and iodine 125 iothalamate are nearly identical to that of inulin (51). Because CCr usually exceeds CIn in healthy individuals, its validity in SCD is uncertain. The simplest estimation of GFR, by several formulas, uses plasma creatinine (PCr) alone (52), but an additional problem in the use of these formulas is the greater overestimation of GFR by CCr in SCD patients than in those without SCD. The plasma clearance of ^{51}Cr -EDTA after bolus injection approximates CIn in healthy individuals (53) but at high clearances is far less accurate (54).

For most clinical purposes, an accurate measure of GFR is unnecessary. A decrease in GFR, particularly when accompanied by proteinuria, is ominous (55). However, the effects of treatment are difficult to assess in other than a clinical research environment, although simplified methods for nonisotopic iothalamate and PAH measurement are now available (56).

Proteinuria

Proteinuria detected by dipstick in a patient with SCD should be quantified and renal function assessed. Diseases other than sickle cell glomerulopathy should be considered. If hematuria is present, RBC casts may point to pathology other than sickle cell glomerulopathy. Hypertension, hypocomplementemia, and the presence of antinuclear antibodies also suggest other diagnoses. Judging from the relatively uniform findings in our series (34), few other additional studies are indicated.

Treatment

The course of the progression of FSGS to chronic renal insufficiency (CRI) in SCD remains difficult to assess, in part because of the difficulties in quantitation of renal function

described earlier (56). Unless the cause is known, it is difficult to prescribe a treatment for the nephropathy of SCD. The patients with proteinuria in our series (34) were not those with the most frequent sickle crises or the severest anemia. Nevertheless, some factors in the sickle cell condition must predispose to the nephropathy. Therefore it is reasonable to attempt to minimize sickling and those factors known to promote FSGS in other primary diseases or in animal models, but whether hemodynamic alterations can change the progression of FSGS to CRI is controversial (57).

Protein Restriction

A high protein intake accelerates the development of FSGS in uninephrectomized rats without necessarily causing glomerular hyperperfusion (58). It is therefore attractive to consider protein restriction in the management of SCD nephropathy, as is being tried in several forms of renal disease. In children, restriction of protein intake may carry unreasonable risks (59). Delayed growth and development is already a particular risk in the SCD patient. Therefore, we advise only the avoidance of an unusually high protein intake (greater than the recommended dietary allowance).

Angiotensin-Converting Enzyme Inhibition

Glomerular hyperperfusion and proteinuria could be mediated through increased glomerular capillary pressure, reduction of which by ACE inhibition might protect the glomerulus from FSGS.

In a 2-week trial of enalapril treatment of 10 patients with mild SCD nephropathy, blood pressure, GFR (CIn), and ERPF (PAH clearance) did not change significantly, whereas proteinuria diminished by 57%, rebounding after treatment withdrawal (34). A more recent 6-month controlled trial of enalapril therapy in 22 SCD patients with microalbuminuria showed a significant decrease in the treatment group, whereas microalbuminuria increased in the control group (60). Whether long-term ACE inhibitor therapy has a salutary effect in preventing renal insufficiency is untested.

CHRONIC RENAL INSUFFICIENCY

Clinical Features

Renal failure is one of the major organ failures that occurs in SCD, almost certainly the consequence of the progression of FSGS. Of 22 patients with nephrotic syndrome, 68% developed CRI (28). Population studies of SCD have all shown a significant incidence of CRI. Of 368 patients in one sickle cell center, 4.6% had CRI (61) associated with proteinuria and increased age. In our series of 375 patients, 6.7% had CRI (34). In a series of 785 patients from Cali-

fornia, 33 had CRI (4.2%) (62). Overall, 5 to 18% of SCD patients develop CRI (63).

The epidemiology of renal involvement in SCD may depend on other genetic characteristics that affect the levels of fetal hemoglobin (HbF), the tendency to sickle, and other factors. Powars et al. (64) initially reported the association of β -globin gene cluster haplotypes with renal involvement: the Central African Republics (CAR) haplotypes (Bantu, Cameroon) or Benin (intermediate involvement) versus non-CAR (Senegalese and Arab-Indian) phenotypes. Guasch et al. (65) found no association with these haplotypes, but instead an association with microdeletions in the α -globin gene. Microalbuminuria was found in 22 of 76 (29%) adult SCD patients but only 13% with the microdeletions, versus 40% without those microdeletions ($p < .01$). Those factors that affect the interactions of RBCs with endothelium may be equally important (see later).

Treatment

Specific treatment of the patient with SCD and renal failure has been poorly explored, and the problems of CRI are only magnified by SCD. Patients with renal failure, even if it is mild, sometimes have symptomatic anemia requiring transfusion. In some of these patients, treatment with erythropoietin can variably restore hemoglobin concentrations to higher levels (66). A few patients have been treated with hydroxyurea plus erythropoietin with apparent benefit (67).

Dialysis and Transplantation

The U.S. Renal Data System reported the causes of renal failure for 255,573 patients treated from 1989 through 1993 (54). Overall, 235 were SCD patients. This is far fewer than the 1% expected from the incidence of HbSS in the total population. It is possible that physicians do not offer treatment to many SCD patients who develop CRI, assuming that the other problems are insurmountable.

Ojo et al. (68) reviewed the transplant results in SCD and found 82 patients. There was no difference in the 1-year cadaveric graft survival [SCN, 78%; other causes of end-stage renal disease (ESRD), 77%], and the multivariable adjusted 1-year risk of graft loss indicated no significant effect of SCN [relative risk (RR) = 1.39, $p = .149$]. However, the 3-year cadaveric graft survival tended to be lower in the SCN group (48% vs. 60%, $p = .055$) and their adjusted 3-year risk of graft loss was significantly higher (RR = 1.60, $p = .003$). There was a trend toward higher survival in the SCN transplant recipients than in their dialysis-treated, wait-listed counterparts (RR = 0.14, $p = .056$). In comparison to the other-ESRD group (RR = 1.00), the adjusted mortality risk in the SCN group was higher both at 1 year (RR = 2.95, $p = .001$) and at 3 years (RR = 2.82, $p = .0001$) after renal transplantation. A trend was also

found toward better patient survival with renal transplantation than with dialysis in end-stage sickle cell nephropathy.

In an analysis of the United Network of Organ Sharing registry from 1987 to 1996 (69), 54 patients were found with SCD and renal failure and for whom data were available on first renal transplant outcome. Patient survival for individuals with SCD was 90% at 1 year and (of 30 patients) 75% at 3 years. The proportional risk ratio (compared to those with immunoglobulin A nephropathy) was 7.8, the highest for any condition. First-graft survival for SCD patients was 82.5% at 3 years and 54% at 3 years. The proportional risk ratio for graft survival was 1.77, but after correction for deaths of patients with functioning grafts, was only 1.06 (barely an increased risk).

We have explored (J. I. Scheinman and R. Payne, *unpublished data*, 2002) the U.S. Renal Data System data files (2000) for evidence of the effect of SCD on the outcome of chronic renal failure. Although the diagnostic code for sickle cell nephropathy (assigned at the time of renal failure) yielded 904 patients, further exploration of patients discovered by hospitalization codes to have SS disease yielded a total of 1656 patients—237 undergoing transplantation and 1419 not undergoing transplantation. Even after other causes of renal failure (diabetes mellitus, etc.) were eliminated, SCD patients were compared to all other African American patients in life-table survival. Without transplantation, the groups differed significantly, with vastly different numbers, and projected 10-year survival was poor for both groups: 25% for African Americans and 15% for SCD patients.

Furthermore, the 36,264 African American patients undergoing transplantation had better survival rates than the 210 SCD patients, but the life-table projected survivals were still quite close, with approximately 50% survival at 15 years (Fig. 48.3). When an age-adjusted cohort of African American patients were used as controls, the difference

FIGURE 48.3. Life-table analysis of patient survival for end-stage renal failure patients with sickle cell disease (SCD) and age-matched African-American (AA) controls, treated with kidney transplantation or dialysis alone. All curves differ significantly due to the vastly greater numbers of AA patients (J. I. Scheinman and R. Payne, *unpublished data*, 2002). Tx, transplantation.

statistically disappeared ($p < .19$). Among those who did not undergo transplantation, comparison of the African American patients with the SCD patients yielded different findings, but projected survival rates for both groups were extremely poor: 25% for African American patients and 14% for SCD patients at 10 years.

A comparison of the 153 SCD patients undergoing transplantation with those who received no transplant showed a far better survival curve: 56% versus 14% at 10 years. Survival of SCD transplanted patients was also significantly better than the 133 nontransplanted patients who were on the waiting list. This was similar to the difference between all African American patients undergoing transplantation and nontransplanted African American patients assigned to the transplant waiting list. Of 957 patients listed since 1991, essentially the cyclosporin era, only 53 SCD patients received transplants whereas 898 did not undergo transplantation; survival of the patients receiving transplants is projected to be 67% at 7 years compared with 83% for the African American cohort.

These results continue to make the case that transplantation is a better option for the SCD patient with renal failure. Results may be less satisfactory than those for other African American patients, however, and grafts have been lost due to demonstrable massive sickling events.

The problems that have occurred in SCD patients after transplantation, especially the recurrent sickle crises, could have been aggravated by the increased blood viscosity associated with a rising hematocrit. These have been treated with frequent partial exchange transfusions (70). In one early series, seven of eight patients had frequent sickle crises after transplantation (71). Renal venous thrombosis and infarction have been reported (72). In one patient with HbAS, the transplanted kidney was unfortunately removed for an apparently irreversible acute rejection that was actually intrarenal sickling (71).

The management of renal transplantation in SCD patients should then focus on potential immediate problems. It is reasonable to warm the kidney with 37°C saline, to infuse dopamine at 4 µg/kg/min during and immediately after surgery, and to provide 40% oxygen and intravenous fluids to decrease viscosity. Partial exchange transfusion may be provided at 4-week intervals (71). It is possible that before an adequate erythropoietin response occurs from the transplanted kidney, recombinant erythropoietin should be given.

Sickle cell nephropathy has been reported to recur in as little as 3 years, although other factors contributed (73). Accelerated recurrence of native disease has been noted in the transplanted kidney in other diseases, notably diabetic nephropathy (74). It is possible that the use of hydroxyurea, in itself likely to interact with other immunosuppressants, can be used to prevent this. Bone marrow transplantation can cure SCD, and the possibility of coupling it with other transplantations will undoubtedly be

explored. Caution will be needed, in view of the possible increase in infection with parvovirus (75), a common agent of aplastic crises that might be especially dangerous in the transplant patient.

OTHER PROBLEMS IN SICKLE CELL DISEASE RELATED TO NEPHROLOGY

Anemia

In the presence of continued hemolysis, the patient with SCD depends on continued erythropoiesis, which determines the level of anemia. Erythropoiesis can be measured by erythron transferrin uptake (76), independent of iron or transferrin saturation. A heme protein in the kidney senses a decreased level of oxygen delivery to the kidney and stimulates erythropoietin production (77). The SCD patient with renal failure loses this normal homeostatic mechanism and becomes far more anemic. Even in the presence of a competent bone marrow and erythropoietic stimulus, adequate iron is necessary. Patients with ulcers may subtly lose iron (8).

The hemoglobin level should probably be maintained at 50 to 60% of normal in patients with SCD, in view of the serious cardiac consequences of more severe anemia (78). Although an intrinsic cardiomyopathy has been suspected in SCD, a careful autopsy study of 52 patients with a mean age of 17 years concluded that anemia alone caused heart failure (78).

Sickle Crises—Clinical Features

Sickle cell crises (1) are painful episodes of vasoocclusion, often accompanied in the second or third day by fever without documented infection. Neither abnormal blood viscosity nor the number of sickle cells absolutely predicts the frequency of crises (2). The incidence of pain crises is 0.8/yr in SS disease and 1/yr in Sβ+ thalassemia (79). With greater degrees of anemia, there is less pain, probably because of diminished blood viscosity. With increasing HbF, there are proportionally fewer painful crises, which suggests a beneficial effect of even modest increases in HbF (79).

Crises may manifest in infants as the hand-foot syndrome because of poorly developed collateral circulation. The chest syndrome is accompanied by radiologic “white-out” and is life-threatening (80). The abdominal crisis is like a “surgical abdomen” but usually without rebound tenderness. In the presence of hematuria, the origin of the pain could be assumed to be the kidney. Neuromeningitis, multiinfarct dementia, or large-vessel occlusion (stroke) can occur (81), especially in infants and children (8). A sudden anemia may be caused by sequestration crises in the spleen in the first 2 years of life; thereafter, after development of splenic fibrosis, it occurs more often in the liver. Aplastic crises arise from vasoocclusion and hemolysis without compensatory erythropoiesis, often induced by a parvovirus-like agent.

Priapism

Priapism is a specialized vasoocclusion of the penis, which was found in as many as 42% of cases in one series (1). Painful, hot, tender erection, most often on waking, lasts up to 3 hours. This can be preceded by days or weeks of "stuttering." The engorgement is of the corpus cavernosa, usually not the spongiosum in children, with the glans flaccid (8). The pain is referred to the perineum and to the abdomen; analgesia, and often exchange transfusion, is necessary. Few patients require surgical drainage or placement of a shunt. Fibrosis may result, with consequent impotence (8).

Pathophysiology of Sickling

The clinical heterogeneity of SCD is further determined by recently described aggravators of sickling related to oxidative stress. Hemoglobin from RBCs of SCD patients has increased auto-oxidation and increased generation of superoxide and H_2O_2 , OH^- , and lipid peroxidation products (82). In a transgenic model of SCD, increased oxidant stress extends renal sickling from a more limited area in the renal medulla to a more extensive distribution to the cortex (83). The aggravating factors of sickling are likely to include the agents of microvascular inflammation and constriction, and inhibitors of relaxation. Reactive species can divert vasoactive NO from mechanisms of vascular relaxation to agents of inflammation and constriction (82). Integrins ($\alpha_4\beta_1$) of the sickled RBC bind to both fibronectin (an acute-phase reactant) and vascular cell adhesion molecule-1 on endothelial cells, which is increased by inflammatory cytokines such as tumor necrosis factor- α .

Hemoxygenase-1 (HO-1) defends against and degrades heme, a lipophilic pro-oxidant, formed from the splitting of hemoglobin (83), studied in a transgenic sickle mouse. In the HO-1 "knock-out" model, administration of heme protein induces monocyte chemoattractive protein-1, mediated by nuclear factor- κ B, and results in renal interstitial cell inflammation (84).

Thus increased induced oxidative stress from the sickling process precipitates acute vasoocclusive disease by mechanisms that affect the endothelium, and adhesion to it, as well as vasoconstriction.

The distorted sickle cell is partly explained by dehydration of the cell by enhanced KCl co-transport, induced by cell swelling and acidification (9). Furthermore, K^+ and water efflux are enhanced by transiently increased SS cell cytosolic Ca, induced by the membrane distortion.

Acute Renal Failure

A doubling or more of PCr was found in 12 of 116 patients with SCD admitted to the hospital. It was seen most often with infections and evidence of rhabdomyolysis, and in patients with lower hemoglobin levels (mean of 6.4 vs. 8.7

g/dL) (85). Volume depletion was the most common precipitating cause. In that study patient survival rate was an 83%, with recovery of function in all patients who survived, without progression to ESRD. It is likely that non-steroidal antiinflammatory agents are partly responsible for some episodes of acute renal failure (86), in view of the likely maintenance of GFR by PG mechanisms in SCD.

Rhabdomyolysis with acute renal failure and disseminated intravascular coagulation has been seen (rarely) in patients with sickle trait after rigorous military training (87). Similarly, there is an apparently increased risk of sudden unexplained death in patients with sickle trait (88).

Hypertension

Hypertension is unusual in SCD (2 to 6%) compared to the published incidence of 28% for the African American population in the United States at all age ranges, as found by the Cooperative Study of Sickle Cell Disease (89).

In our series (34), hypertension was rare and was found only in one patient with nephrotic-range proteinuria without renal insufficiency. The one-third incidence of hypertension in Powars et al.'s patients with renal insufficiency is unexplained (38). Nevertheless, she found a positive association between blood pressure, stroke, and increased mortality in SCD patients (90).

Infections

Infections occur in HbSS disease as a result of vascular sequestration with tissue necrosis (e.g., osteomyelitis associated with avascular necrosis, or *Salmonella* infection with cholelithiasis) and the immune susceptibility of the splenectomized patient (1). The organisms most commonly found are *Diplococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma*, and parvovirus (8). Prophylactic penicillin therapy is essential, as for any splenectomized patient. *H. influenzae B* vaccination is also appropriate.

Urinary infections are uncommon in SCD, except perhaps in pregnancy. Technetium 99m diphosphonate scan shows an increased renal localization in HbSS. This apparently is not caused by infection but more likely by regional stasis or tubular ischemia, which leads to peritubular extravasation (91).

GENERAL TREATMENT STRATEGIES FOR SICKLE CELL DISEASE

Institution of frequent transfusion can reduce the risk of recurrence of cerebral vasculopathy (81) by decreasing the proportion of rheologically abnormal cells. Because of the risks, transfusion should be reserved for patients at greatest risk of sickling sequelae. Most recently, Doppler ultrasonography has helped identify cerebral vessels at risk of stroke (92).

Other hemoglobins modify the tendency of HbS RBCs to sickle. HbF inhibits sickling. The agent 5-azacitidine can increase HbF levels, probably by recruitment of HbF cells, but may be a carcinogen (93). The only agent able to significantly decrease sickling by myelosuppression of HbSS cells, thus increasing HbF, is hydroxyurea. Hydroxyurea is a cytotoxic agent that inhibits the growth of erythroid burst-forming units (94). In SCD, it is the SS cells that are suppressed, which allows an increase in HbF.

Charache et al. (95) achieved 8 to 18% HbF levels that were maintained over 2 years. It has been deduced that a 20% level of HbF is likely needed to produce a definitive clinical change with regard to either hemolysis or vasoocclusion (96). A trial involving 59 patients (97) suggested that a mean HbF level of 15% could be achieved. Trials of hydroxyurea therapy in adults and children (98) have shown that it provides a safe reduction in acute episodes and allows normal growth and development (99). In addition to its effect on RBC generation, hydroxyurea induces oxidative damage to SS cells that is greater than that to AA cells, even more than to HbF (100). Antioxidants such as α -tocopherol and ascorbate are protective *in vitro* and may enhance the safety of hydroxyurea.

Other mechanisms that can minimize the tendency to sickling and vasoocclusion have been investigated. Reversing the cellular dehydration in SCD has been explored by blocking cation-transport channels in erythrocyte membranes, which can shift cellular cation content and cell density toward normal. Clotrimazole, an antifungal drug, reduced cellular dehydration *in vitro* in transgenic mice with SCD and in patients with sickle cell anemia. Magnesium salts also interfere with cation transport and cause cell rehydration (101).

Whether the cellular changes induced by clotrimazole or magnesium salts are of clinical value is not known. Combinations of hydroxyurea plus clotrimazole and erythropoietin to prevent sickling have been studied in transgenic mice.

Bone marrow transplantation can cure SCD, and the possibility of combining it with other transplantations will doubtless be investigated. Less ablative conditioning for bone marrow transplantation is being explored (102). Because of the possible increase in infection with parvovirus (75), a common agent of aplastic crisis that might be especially dangerous in the transplant patient, caution is in order.

DIABETIC NEPHROPATHY

LEONARD G. FELD

Insulin-dependent diabetes mellitus (IDDM) is an epidemic in our communities. The burden to diagnose and treat is growing as this group of patients continues to expand, and coincident with the disease is the profound morbidity and mortality. It is estimated that 30 to 50% of all patients with IDDM develop renal disease after 5 to 15 years of having the disorder (1). Diabetic nephropathy is characterized by progressive loss of renal function and systemic disturbances, including hypertension, proteinuria, and the numerous sequelae of chronic renal insufficiency. Renal involvement in IDDM typically follows a progressive course to end-stage renal disease (ESRD). IDDM is the most common cause of chronic renal failure requiring dialysis or transplantation in the United States (2). The prevalence of diabetes and chronic renal failure in the entire Medicare medical population is approximately 1.6% or 406,800 individuals (3). With an incidence rate of diabetic ESRD in pediatric patients (0 to 19 years of age) of 15.2 per 1 million population (4) and an incidence rate of diabetes mellitus in children 19 years of age or younger of 16.7 per 100,000 (4), it is essential to implement strategies such as strict control of blood glucose level and blood pressure and monitoring for microalbuminuria to decrease the risk of complications in the pediatric population and improve long-term survival (5). Not only does renal failure represent a significant health problem and affect the quality of life, the yearly costs of care for diabetic patients with renal failure are estimated to total over \$6 billion.

PATHOGENESIS AND RISK FACTORS OF DIABETIC NEPHROPATHY

Despite the lack of a unifying hypothesis to explain the high incidence of renal disease in IDDM, a number of risk factors for the development of nephropathy have been identified. These include increased glomerular filtration rate (GFR) (glomerular hyperfiltration) (6–8), systemic and/or glomerular hypertension (9,10), vascular (endothelial) dysfunction (11–13), poor metabolic control (elevated levels of glycosylated hemoglobin), biochemical alterations

in the glomerular basement membrane (GBM) resulting in increased vascular permeability and structural changes (14–16), genetic factors (predisposition to hypertension, familial clustering) (17,18), and dietary factors (high protein, sodium, and/or fat intake) (19–21).

Renal Hemodynamics

In some experimental animal models of diabetes, increased GFR associated with elevations in glomerular pressures has been implicated in the development and progression of kidney damage (10,22,23). Increased GFR, or glomerular hyperfiltration, is observed in 25 to 50% of patients in the early stages of IDDM. This glomerular hyperfunction may contribute to the initiation of diabetic nephropathy and may predict and/or contribute to its progression. Multiple mediators may initiate hyperfiltration. Although the precise mechanism is not understood, the diabetic milieu (hyperglycemia, insulinopenia, sorbitol accumulation) results in an increased GFR (24–26). The early hyperfiltration may be reversed with normalization of blood glucose concentrations. Whether glomerular hyperfiltration alone is a risk factor for overt nephropathy in humans remains controversial.

Hemodynamic studies have revealed that vasodilation of the resistance vessels in the kidney render glomerular capillaries vulnerable to pressure-related injury (22). Because the resistance in the preglomerular and postglomerular arterioles and systemic blood pressure determine glomerular capillary resistance, the combination of increased systemic blood pressure and the relative dilation (or decreased resistance) of afferent compared with efferent arterioles results in increased glomerular capillary pressure or glomerular hypertension. This abnormal regulation of intrarenal vascular resistance has been postulated to be an important factor in the glomerular injury in diabetes (19,22,27). Under normal circumstances, vascular tone is regulated through the production of potent vasoconstrictor substances (endothelin, angiotensin II, prostaglandin H₂, platelet-activating factor, platelet-derived growth factor) and vasodilatory mediators, namely endothelium-derived relaxing factor (or nitric oxide) and prostacyclin (28,29). In IDDM, vascular

endothelial damage may shift the balance of vasoreactive factors toward vasoconstriction with a resultant increase in efferent (postglomerular) arteriolar resistance, increased glomerular capillary pressure (intrarenal hypertension), and progressive kidney dysfunction.

Metabolism

Glycemic Control

Many studies demonstrate the correlation between blood glucose (glycemic) control and the development of complications from diabetes mellitus (30–32). The Diabetes Control and Complications Trial (DCCT) conducted from 1983 to 1993 and the observational follow-up Epidemiology of Diabetes Interventions and Complications (EDIC) study of the DCCT cohort (30,32) have demonstrated the effect of intensive glycemic control on reducing the microvascular complications of IDDM. The DCCT involved 1441 patients with IDDM at 29 centers in the United States and Canada, and the EDIC study extended the follow-up of 1298 patients for an additional 7 years. The studies compared the effects of standard insulin therapy with intensive control (testing of blood glucose concentrations four or more times per day, four daily insulin injections, diet control, and exercise) on two cohorts. Cohort 1 (primary prevention trial) had no complications and a urinary albumin excretion rate of less than 28 $\mu\text{g}/\text{min}$. Cohort 2 (secondary intervention trial) had background retinopathy, a urinary albumin excretion rate higher than or equal to 28 $\mu\text{g}/\text{min}$ or 40 mg/day (microalbuminuria), and normal GFR.

In the primary prevention trial of the DCCT, the intensive therapy group had a cumulative incidence of microalbuminuria of 16% after 9 years compared with 27% in the conventional treatment group. Overall, there was a 34% reduction in risk for the development of microalbuminuria in the intensive therapy group. In the EDIC, the prevalence of microalbuminuria in patients who did not have it at the end of the DCCT study remained significantly lower in the intensive treatment group than in the conventional therapy group (4.5 vs. 12.3%, $p < .001$). In the secondary prevention trial, the intensive therapy group had a cumulative incidence of microalbuminuria of 26% after 9 years compared with 42% in the conventional therapy arm. The reduction in risk for the development of microalbuminuria in the intensive therapy group was 43%. In the secondary intervention trial, the cumulative incidence of the development of clinical or overt nephropathy was more than two times higher in patients treated conventionally than in those receiving intensive treatment. This 56% reduction in absolute risk with intensive glycemic control at the end of the DCCT rose to 86% in the final years of the EDIC study.

The progression to chronic renal disease (serum creatinine level of greater than or equal to 2 mg/dL) or ESRD (dialysis and/or transplantation) was reached in 6 patients under intensive glycemic control compared to 17 individu-

als under conventional therapy. As discussed later, hypertension worsened in the conventional treatment group (33%) than in the intensive treatment patients (25%) by the end of the EDIC study. The DCCT and the EDIC follow-up study have provided compelling evidence that strict control of blood glucose concentration and near normalization of glycosylated hemoglobin levels reduce the risk of developing microalbuminuria, decrease the development of hypertension, and delay or prevent the progression to overt nephropathy/ESRD in IDDM.

Advanced Glycosylation End Products

An increasing body of information supports the role of advanced glycosylation end products (AGEs) as an important etiologic factor in diabetic nephropathy (33–35). As mentioned earlier, poor glycemic control is a prerequisite for diabetic nephropathy and is related to the accumulation of AGEs, the products of a glucose-protein interaction. A reversible or nonenzymatic glycation occurs as glucose and amino acids form a Schiff base. Over weeks to months, these products continue to be rearranged into irreversibly glycated AGEs. AGEs and their reaction with the receptors of AGE (RAGE) in the blood vessels and within the kidney of patients with diabetes may cause renal damage by increasing the synthesis of basement membrane collagen and mesangial matrix, raising vascular permeability, and increasing growth factor secretion (36–38). This sequence of events leads to glomerular hypertrophy and eventual glomerulosclerosis. AGEs also may contribute to diabetic atherosclerosis through cellular activation and inflammation, cytokine and growth factor release, and increased vascular matrix and endothelial permeability. In addition, AGEs formed in the vascular matrix may limit vasodilation by interfering with the action of endothelium-derived relaxing factor (39). The decreased clearance of these products may contribute to ongoing diabetic tissue injury. In animal studies, the use of an inhibitor of AGEs, aminoguanidine or OPB 9195, can diminish overexpression of type IV collagen, laminin, vascular endothelial growth factor (VEGF), transforming growth factor β (TGF- β), and platelet-derived growth factor (27,40,41), which results in reduced glomerular proliferation and capillary permeability. The clinical implications of AGE inhibition or reduction are obvious, but additional studies are required.

Protein Kinase C

In the hyperglycemic state, enhanced synthesis of diacylglycerol (DAG) results from phosphatidylcholine by phospholipase D. DAG then activates protein kinase C (PKC) on its C1 regulatory domain (42). PKC activation influences expression of inducible nitric oxide within the mesangium, leading to glomerular vasodilation. In rats with streptozotocin-induced diabetes, activation of DAG kinase decreased

PKC activity, which led to restoration of renal hemodynamics. PKC activation may also lead to diabetes-induced renal structural and permeability changes. VEGF induces endothelial cell proliferation and vasopermeability in the microvasculature in diabetes. VEGF expression may be enhanced by hyperglycemia-induced PKC activation, and its proposed effect on glomerular permeability and albuminuria may be mitigated by PKC inhibition.

Activation of PKC stimulates transcription of TGF- β , which leads to mesangial expansion. In studies using a murine model of diabetes, PKC inhibition reduced TGF- β , which significantly reduced mesangial expansion and albuminuria (43).

In diabetes or chronic hyperglycemia, accumulation of DAG and activation of PKC have adverse effects on renal functional and structural changes.

Genetic Predisposition

Genetic approaches are being used to understand the susceptibility to or genesis of diabetic nephropathy. Anchored in the work of Pirart (43a), this research has found limited concordance between diabetic nephropathy and neuropathy or retinopathy. The probability of developing nephropathy is only approximately 25% in patients with neuropathy or retinopathy, whereas a patient with diabetic nephropathy has more than an 85% probability of developing neuropathy or retinopathy (44). Evidence suggests that selected individuals with diabetes mellitus have a genetic predisposition to developing nephropathy (18,45–47). Familial clustering studies of diabetic nephropathy show that, if a proband has nephropathy, the cumulative risk of nephropathy in siblings (72%) is almost 50% higher than in siblings (25%) of a proband without incipient or overt nephropathy (48).

The role of hypertension and the predisposition to diabetic nephropathy is supported by familial clustering, sodium-lithium countertransport activity, and hypertension and nephropathy susceptibility genes. Patients with hypertensive parents who also have hypertension themselves are at greater risk of nephropathy and have higher age-adjusted blood pressures in adolescence (49,50).

Modulations of the renin-angiotensin system (RAS) have been shown to influence the development and progression of changes in renal function and morphology in patients with diabetic kidney disease. This has led to the examination of genes controlling the components of the RAS as candidate genes for the association of hypertension and/or diabetic nephropathy. A relationship has been suggested between an insertion/deletion polymorphism of the angiotensin-converting enzyme (ACE) gene and diabetic nephropathy. Using a candidate gene approach, Doria et al. found a significant variation in the risk for developing diabetic nephropathy associated with the haplotypes at the ACE locus in IDDM patients with disease duration of 16 to 21 years (51). The variants of the ACE gene are in linkage disequilibrium with

one or more ACE haplotypes and contribute to an increased susceptibility to nephropathy. A relationship between RAS gene polymorphism and increased urinary albumin excretion has also been observed in patients with noninsulin-dependent diabetes mellitus (type 2) (52). Deletion polymorphism in the ACE gene may reduce the long-term beneficial effect of ACE inhibition on retarding the progression of diabetic nephropathy (53).

Moczulski et al. performed a linkage study using pairs of siblings with IDDM discordant for diabetic nephropathy. Theoretical considerations supported by simulation studies indicated that discordant pairs, rather than concordant pairs, would be more effective in detecting a major susceptibility gene for diabetic nephropathy. These researchers found that in the regions containing ACE and angiotensinogen genes, loci were not linked with diabetic nephropathy, whereas the region containing the angiotensin II type 1 receptor locus showed linkage with diabetic nephropathy. This provides very strong evidence that a region (20-cM) around the angiotensin II type 1 receptor gene contains a major locus for susceptibility to diabetic nephropathy (54).

Polymorphisms in the endothelial nitric oxide synthase gene may be implicated in the development of nephropathy in patients with IDDM. Using the transmission disequilibrium test, a family-based design to test association and case-control studies, researchers found that DNA sequence differences in the endothelial nitric oxide synthase gene appear to influence the risk of advanced nephropathy in IDDM (55).

In 1999, the National Institute of Diabetes and Digestive and Kidney Diseases developed a consortium to identify genes or genomic regions that are associated with differential risks for the expression or progression of diabetic nephropathy. The consortium will combine multiple genetic strategies with complementary approaches using genetic material in an attempt to decipher the genes that contribute to the development of diabetic nephropathy (56).

NATURAL HISTORY OF NEPHROPATHY: FUNCTION AND STRUCTURE

The annual incidence of diabetic nephropathy reaches a peak after 15 years' duration of IDDM (57). Analysis of the cumulative incidence of persistent albuminuria in patients who have had diabetes for 25 years demonstrated a substantial reduction from 28% (1961 to 1965) to 5.8% (1971 to 1975). This change reflects improved glycemic control (58). In patients fated to develop diabetic nephropathy, the increasing duration of diabetes is associated with a progressive decline in glomerular filtration, increasing albuminuria followed by massive proteinuria, and eventual ESRD (Fig. 49.1) (59).

Renal involvement in patients with IDDM is classified into five stages according to the degree of changes in renal function and morphology. With the onset of diabetes, or

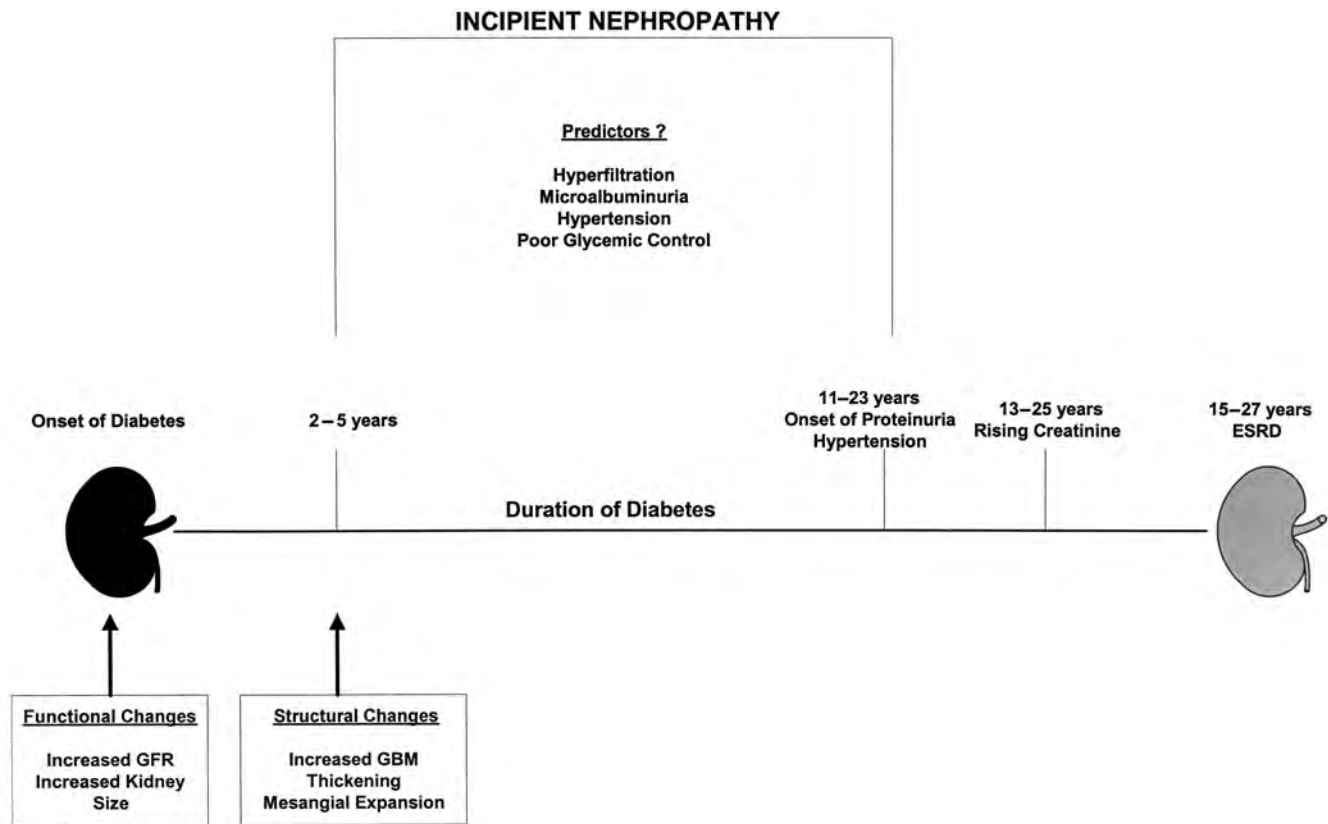

FIGURE 49.1. Natural history of diabetic nephropathy. ESRD, end-stage renal disease; GBM, glomerular basement membrane; GFR, glomerular filtration rate. (Modified from Breyer JA. Diabetic nephropathy in insulin-dependent diabetes. *Am J Kidney Dis* 1992;20:533–547.)

stage 1 nephropathy, the only findings are enlarged kidneys and glomerular hyperfiltration. There is no evidence of histologic lesions in glomeruli or vascular structures. In stage 2, the findings occur over 2 to 5 years and are similar to those in stage 1 except that histopathologic abnormalities can be found on renal biopsy (biopsy is not indicated for patients at this stage). On microscopic examination, basement membranes are thickened and mesangial areas show expansion.

Stage 3, or incipient diabetic nephropathy, is termed the *microalbuminuria phase*. It generally occurs during the second decade of diabetes. At this stage, renal function is normal and the routine dipstick test is negative for protein. Normal urinary albumin excretion is less than 20 $\mu\text{g}/\text{min}$ (median, 2.3 to 6.4 $\mu\text{g}/\text{min}$) or less than 30 mg/day. Microalbuminuria is defined as more than 20 $\mu\text{g}/\text{min}$ but less than 200 $\mu\text{g}/\text{min}$. In comparison, significant albuminuria or overt nephropathy (dipstick-positive proteinuria) is a value higher than 200 $\mu\text{g}/\text{min}$ or 300 mg/day. Given the inherent difficulties of a 24-hour collection, microalbumin level can be indexed to the urinary creatinine concentration in an early morning specimen. The predictive value of the random urine sample albumin to creatinine index of 30 to 300 mg/g in predicting microalbuminuria has a sensitivity between 88 and 100% and a specificity between 81 and

100% (60). With the onset of microalbuminuria, the GFR begins to decrease, usually when the albumin excretion exceeds 70 $\mu\text{g}/\text{min}$. The decrease in the GFR is 3 to 4 mL/min/yr (61). With the onset of stage 3 nephropathy, systemic blood pressure increases and there is a progressive decline in the GFR. Anemia and disturbances in calcium-phosphorus homeostasis start to develop. In addition, patients with IDDM and microalbuminuria have a higher risk of extrarenal atherogenic abnormalities than individuals without microalbuminuria. The risk profile includes proliferative retinopathy; decreased left ventricular function; increased levels of total, very-low-density, and low-density lipoprotein cholesterol; and increased transcapillary escape of albumin.

The onset of stage 4 nephropathy is a harbinger of the need for renal replacement therapy by dialysis or transplantation within 10 years. This is the phase of dipstick-positive proteinuria, rapid decline in the GFR, significant to severe hypertension, and the other sequelae of moderate to severe renal insufficiency. As discussed later, strict glycemic control and effective control of blood pressure with ACE inhibition may slow the rate of decline in renal function. With the progression of renal failure, the stage of dialysis and transplantation (stage 5) is reached.

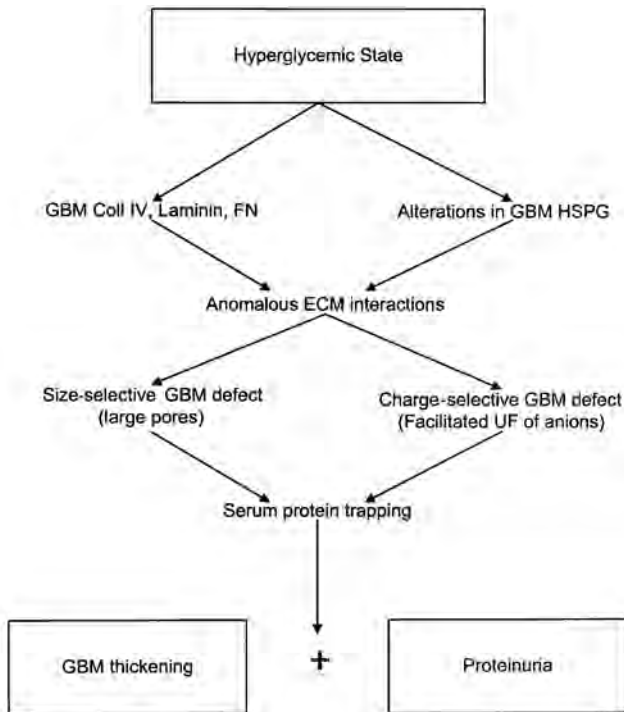

FIGURE 49.2. Hypothetical algorithm linking biochemical changes in the diabetic glomerular basement membrane (GBM) to the observed changes of GBM thickening and proteinuria. Coll, collagen; ECM, extracellular matrix; FN, fibronectin; HSPG, heparin sulfate proteoglycan; UF, ultrafiltration. (From Adler S. Structure-function relationships associated with extracellular matrix alterations in diabetic glomerulopathy. *J Am Soc Nephrol* 1994;5:1165-1172, with permission.)

With established diabetic nephropathy (microalbuminuria, decreased GFR), there is progression of histopathologic changes (renal extracellular basement membrane and mesangial expansion) within the kidney (62). Although Mauer et al. were unable to find a close relationship between duration of IDDM and GBM thickness or mesangial expansion, mesangial expansion (diffuse glomerulosclerosis) was inversely correlated to capillary filtering surface area (63). Based on studies showing an increased content of collagen types IV and V, serum proteins, and laminin in the thickened GBM (64) and alterations in the GBM content of heparan sulfate proteoglycan (HSPG), Alder hypothesized that these changes in the GBM may initiate a series of events leading to changes in the sieving properties of the GBM that result in proteinuria and loss of glomerular filtering surface area (65) (Fig. 49.2).

Although numerous studies exist of the functional, biochemical, and structural relationships in patients with diabetic nephropathy, additional studies are needed to answer the many remaining questions. What is the basis for the significant variability in the expression of diabetic nephropathy? Why does one group of patients with a duration of hyperglycemia of less than 20 years develop renal failure, whereas another group with a

duration of 40 years of hyperglycemia never develops clinical nephropathy?

DETECTION AND MANAGEMENT OF DIABETIC NEPHROPATHY

The management of diabetes mellitus encompasses strict glycemic control, adherence to dietary guidelines established by the American Diabetes Association, lifestyle changes (no alcohol use or smoking), and an exercise program (66). As discussed earlier, the DCCT and other research confirms and extends the results of many other studies that intensive glycemic control reduces microalbuminuria and overt nephropathy. It is intuitive that normalizing the aberrant metabolic state will limit vascular injury in patients with diabetes. With the convenience of home glucose monitoring, office measurements of glycosylated hemoglobin, rapid-acting insulin, and insulin pumps, there are no valid reasons (on the part of patient or physician) that preclude consistent control of stable blood glucose concentrations.

Screening for Microalbuminuria

Measurement of urinary microalbumin excretion rate (UAER) by determination of a 24-hour or early morning albumin/creatinine index should be performed yearly for IDDM patients with disease duration of longer than 5 years. If the UAER value exceeds 20 $\mu\text{g}/\text{min}$ (30 mg/day) or the albumin/creatinine index is higher than 30 $\mu\text{g}/\text{mg}$, a repeat test should be performed in 3 to 6 months to substantiate the diagnosis of microalbuminuria. If the results of the repeat test are below 20 $\mu\text{g}/\text{min}$, the patient returns to annual testing. If the value is increased, however, the initiation of ACE inhibitor therapy to delay progression of nephropathy is indicated (see later). Ketoacidosis, diuresis, acute illnesses, severe cardiac disease, urinary tract infections, menstrual bleeding, severe hypertension, poor glycemic control, vigorous exercise, and coincident nondiabetic renal disease influence the UAER. A diurnal variation in urinary albumin excretion is also seen in all stages of diabetic nephropathy. Postexercise albuminuria occurs in children with IDDM duration of longer than 5 years and normal preexercise UAER (67). Although dipsticks have been introduced to detect microalbuminuria, the radioimmunoassay test is still the most accurate method. In patients with persistent microalbuminuria and acceptable glycemic control or in patients with no reduction in microalbuminuria despite improved glycemic control, consideration should be given to the use of ACE inhibitors (see later) (68,69).

Numerous studies have demonstrated that the use of ACE inhibitors delays the progression of diabetic nephropathy. Animal studies initially demonstrated that ACE inhibitors could retard glomerular damage by normalizing glomerular capillary pressure independently of their antihypertensive

effect. A large multicenter, randomized, prospective study of 409 patients who had IDDM of at least 7 years' duration, serum creatinine concentration of 2.5 mg/dL or lower, and urinary protein excretion higher than 500 mg/day has extended the known benefits of ACE inhibitors. The study found that treatment with an ACE inhibitor (captopril) reduced progression of diabetic nephropathy, improved the clinical outcome by reducing the number of patients requiring dialysis and/or transplantation, and provided renal protection independent of the antihypertensive effect (70). This study also found that 64% of the patients who died and 61% of the patients who required dialysis or transplantation were in the placebo group. Only 25 patients in the captopril group had a doubling of serum creatinine level compared with 43 in the placebo group. This was a 48% reduction in risk in the captopril group. The captopril group had a 50% risk reduction in the combined end points of death, dialysis, and transplantation. Last, significantly less proteinuria was seen in the captopril group than in the placebo-treated group. The study showed that the ACE inhibitor captopril significantly retarded the rate of loss of renal function in patients with stage 4 diabetic nephropathy.

In additional studies, the ACE inhibitor enalapril decreased UAER in IDDM patients with microalbuminuria at rest (incipient nephropathy, stage 3) and after exercise (71). Based on an extensive review of these and other studies, the Ad Hoc Committee of the Council on Diabetes Mellitus of the National Kidney Foundation published recommendations for the screening and management of microalbuminuria, or stage 3 nephropathy (72). Their conclusions and my recommendations follow (Tables 49.1 and 49.2).

It is appropriate to start at the lowest dosage and titrate the final dosage to blood pressure response. To increase compliance, the use of a long-acting ACE inhibitor may be considered. The recommended monitoring of ACE inhibitor therapy is to (a) measure the UAER every 6 months, and (b) monitor the serum creatinine and potassium concentrations 7 to 10 days after starting therapy and then every 3 months. If the microalbumin value is reduced by a lower-than-recommended dosage of an ACE inhibitor and blood pressure and creatinine level are stable, there is no reason to

TABLE 49.1. RECOMMENDATIONS FOR ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITOR THERAPY^a (THE FOLLOWING ARE SUGGESTED ADULT DOSAGES ONLY)

Incipient nephropathy	
Captopril:	12.5–25.0 mg twice daily (maximum, 50 mg twice daily)
Enalapril:	5–20 mg daily (daily or divided twice daily)
Overt nephropathy	
Captopril:	25 mg three times daily
Enalapril:	5–20 mg daily (daily or divided twice daily)

^aBecause the benefit of ACE Inhibitors is a class effect, other agents in this category may be considered.

TABLE 49.2. RECOMMENDATIONS FOR ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITION AND ANTIHYPERTENSIVE THERAPY

Monitoring of ACE inhibitor therapy

Obtain serum creatinine concentration at baseline and within 7–10 days after therapy is started, then at least every 3 months.

If creatinine concentration increases by 0.5 mg/dL, refer to nephrologist.

Obtain serum potassium concentration at baseline and within 7–10 days after therapy is started, then at least every 3 months.

If potassium concentration ≥ 5 mEq/L, refer to nephrologist.

Obtain complete blood count every 3 months.

Check urinary albumin excretion rate every 6 months.

Therapy for hypertension

Initial therapy

ACE inhibitor

Second-line therapy

Low-dose diuretic (up to 25 mg)

α -Receptor blocker

Calcium channel blocker

Problem drugs—use with caution or avoid

Beta-blockers

Potassium-sparing diuretics

alter the dosage. However, if the microalbuminuria value is increasing, an upward dosage adjustment is appropriate.

Insufficient evidence exists to recommend the use of an ACE inhibitor in patients with normoalbuminuria and normotension.

In patients with non-insulin dependent diabetes mellitus (type 2), treatment with angiotensin II receptor antagonists has demonstrated renal protection independent of the blood pressure changes (73–75), whereas use of ACE inhibitors has not demonstrated a consistent beneficial effect. Although there are some data to support the use of angiotensin II receptor antagonists in patients with IDDM (76), their use should be reserved for patients unable to tolerate an ACE inhibitor due to the side effect of cough.

BLOOD PRESSURE CONTROL

Studies using ambulatory blood pressure monitoring in adolescents and young adults with normoalbuminuria and normal blood pressure suggest that an increase in nighttime systolic blood pressure may precede the development of microalbuminuria (77). If nocturnal elevations in blood pressure do identify a cohort of patients with IDDM and a predilection to microalbuminuria, then ACE inhibitor therapy may have value before the development of incipient nephropathy (78).

Effective control of blood pressure delays the progression of chronic renal disease. Numerous studies have demonstrated the efficacy of antihypertensive treatment in slowing the progression of diabetes-induced renal disease.

The approach to antihypertensive therapy for patients with diabetes is no different from that for nondiabetic subjects. Initial therapy should be an ACE inhibitor. The major risk is acute reduction in renal function or acceleration in deterioration of renal function in patients with bilateral renal artery stenosis. Hyperkalemia may occur secondary to renal insufficiency or hyporeninemic hypoaldosteronism (renal tubular acidosis type IV).

Second-line therapy includes calcium channel blocking (CCB) agents, α -receptor blockers, or a low-dose diuretic (hydrochlorothiazide, up to 25 mg/day). The major side effects of CCBs in patients with IDDM are orthostatic hypotension, constipation, edema, and headaches. Some studies report increased blood glucose concentrations with nifedipine secondary to lowering of insulin levels. The CCBs do not adversely effect lipid concentrations or renal function. To prevent electrolyte abnormalities and to limit adverse effects on carbohydrate metabolism, only low-dose diuretics should be prescribed. Diuretics are effective and may be synergistic with ACE inhibitor therapy.

Both potassium-sparing diuretics and beta-blocking agents should be used with caution in patients with IDDM. Beta-blocking agents, such as propranolol, may aggravate glycemic control, limit recognition of hypoglycemic episodes and delay recovery, adversely affect lipoprotein concentrations, and potentiate hyperkalemia after exercise.

SUMMARY

The goals of monitoring and therapy for children, adolescents, and adults with IDDM are to maintain good glycemic control, monitor UAERs after 5 years of diabetes, aggressively control blood pressure, use ACE inhibitors for persistent microalbuminuria, provide dietary and/or pharmacologic treatment of dyslipidemia, and maximize patient and family education regarding the complications of this chronic illness. Management of IDDM in children and adolescents requires the dedicated efforts of an interdisciplinary health care team, which includes the primary care practitioner, pediatric endocrinologist, pediatric nephrologist, dietitian, social worker, and ophthalmologist.

RENAL MANIFESTATIONS OF METABOLIC DISORDERS

WILLIAM G. van't HOFF

Although the majority of children with renal dysfunction have a structural, immunologic, or infective disorder, some have a metabolic defect arising from an abnormality in the biochemical pathways of cell metabolism. In many metabolic disorders, substrate accumulation or an enzyme deficiency can be documented in the kidney but without evidence of renal dysfunction (e.g., some of the lysosomal storage disorders). This review concentrates on those disorders in which there is a clear renal functional or structural abnormality. Several of these conditions are described in detail elsewhere in this book; this chapter highlights a number of other metabolic disorders and provides, in tabular form, the various metabolic causes of renal symptomatology (Tables 50.1 to 50.6). Many metabolic disorders can cause acute or chronic renal failure. It is rare for this to be the sole manifestation, however; therefore, these conditions are listed under the most important renal feature.

The proximal renal tubule has a very high-energy expenditure and is therefore sensitive to metabolic disorders that interfere with the generation of adenosine triphosphate (ATP). Mitochondrial dysfunction and reduced ATP levels are felt to be important in the pathogenesis of Fanconi syndrome, which is one of the most common renal manifestations of metabolic disease (Table 50.1); a fuller description is given in Chapter 41. Nephrocalcinosis and urolithiasis are also common manifestations of metabolic dysfunction, usually arising from defective reabsorption of a solute (e.g., cystine in cystinuria) or as a result of the urinary excretion of abnormally elevated plasma constituents (e.g., oxalate in hyperoxaluria). Renal glomerular involvement is less common but can occur as a result of abnormal deposition of storage material or a defect in the synthesis of the glomerular components (Table 50.4). As a result of improvements in the care of children with metabolic disorders, longer term manifestations are becoming more apparent. Cystinosis was once described as a renal disorder, and it was only as a result of renal transplantation that patients survived into adulthood and were then observed to develop

extrarenal problems (1). In addition, in some disorders increased survival has led to the development of renal dysfunction [e.g., methylmalonic acidemia (MMA)]. Thus pediatric nephrologists need to remain vigilant to the possibility of a metabolic disorder, especially in children with extrarenal symptoms.

METHYLMALONIC ACIDEMIA

MMA is an autosomal recessive disorder of the metabolism of methylmalonyl coenzyme A (CoA) caused either by a defect of methylmalonyl CoA mutase or of the cofactor adenosyl cobalamin (2). Patients usually present in the neonatal period or early infancy with lethargy, vomiting, poor feeding, failure to thrive, and recurrent metabolic acidosis. Patients deficient in the cofactor respond favorably to cobalamin supplementation, but for those who have a partial or complete deficiency of the apoenzyme, the prognosis is poor with a mortality of approximately 50% within the first decade. In cobalamin-unresponsive patients, there is a significant incidence of neurologic and renal manifestations.

Renal Tubular and Glomerular Dysfunction

Children with MMA have evidence of renal tubular dysfunction, which becomes very profound during episodes of metabolic decompensation (usually triggered by intercurrent infection) with massive renal salt and bicarbonate losses. In a study of seven cobalamin-unresponsive patients, five had defects in urine concentration, two had impaired urine acidification, and several had hyporeninemic hypoadosteronism (3). Chronic renal impairment has also been documented in cobalamin-unresponsive MMA patients. Walter et al. documented a low glomerular filtration rate (GFR) in 8 of 12 such children, 5 of whom had a GFR of less than 40 mL/min/1.73 m² (4). In a retrospective survey of patients with *all* forms of MMA, Baumgartner and Viar-

TABLE 50.1. FANCONI SYNDROME

Disorder	Main features	Renal features	References
Cystinosis	Poor growth; vomiting; rickets; often blond, fair hair; corneal cystine crystals; multisystem involvement	Fanconi syndrome, chronic renal failure, rarely urinary tract dilatation, calculi (urate/calcium oxalate)	See Chapter 41 (87)
Tyrosinemia type 1	Hepatomegaly, liver disease, rickets, neurologic crises	Fanconi syndrome, nephromegaly, nephrocalcinosis, calculi, chronic renal impairment	See Chapter 41 (88,89)
Mitochondrial disorders	Myopathy, poor growth, cardiomyopathy, liver dysfunction, neuropathy, retinopathy, ophthalmoplegia, endocrinopathy	Fanconi syndrome, Bartter's syndrome-like features, proteinuria, tubulointerstitial nephritis, cysts	See Chapter 41 (43–59)
Galactosemia	Vomiting, diarrhea, poor growth, jaundice, liver disease, hypotonia, cataracts	Fanconi syndrome	See Chapter 41
Dent's disease	Hypercalciuria, tubular proteinuria, X-linked	Fanconi syndrome, nephrocalcinosis/nephrolithiasis, chronic renal failure	90
Wilson's disease	Liver disease, neurologic symptoms, Kayser-Fleischer rings, cardiomyopathy	Fanconi syndrome, proteinuria, rarely acute renal failure, distal renal tubular acidosis, hypercalciuria, calculi	See Chapter 41 (91,92)
Glycogen-storage disease type 1	Hepatomegaly, hypoglycemia, seizures, poor growth, lactic acidosis	Fanconi syndrome, hypercalciuria, hyperfiltration, rarely distal tubular acidosis, renal calculi, proteinuria, focal segmental glomerulosclerosis, chronic renal impairment	See Chapter 41 (24–36)
Fanconi-Bickel syndrome	Hepatomegaly, rickets, poor growth, hypoglycemia	Fanconi syndrome, hyperfiltration, "diabetic-like" nephropathy	See Chapter 41 (37–41)
Oculocerebrorenal (Lowe) syndrome	Congenital cataracts, other ocular abnormalities, hypotonia, delayed development, X-linked transmission	Fanconi syndrome, chronic renal failure, nephrocalcinosis, rarely calculi	See Chapter 41
Fructosemia	Acute onset after fructose ingestion: poor feeding, vomiting, poor growth, hypoglycemia, liver failure	Fanconi syndrome, rarely acute renal failure	See Chapter 41 (93)

Note: See Chapter 41 for full description.

TABLE 50.2. OTHER TUBULAR DYSFUNCTION

Disorder	Main features	Renal features	References
Carbonic anhydrase II deficiency	Osteopetrosis, fractures, cerebral calcification, mental retardation, poor growth	Mixed type of renal tubular acidosis	94,95
Methylmalonic acidemia	Vomiting, acidosis, hypotonia, poor growth	Type IV renal tubular acidosis, tubulointerstitial changes, chronic renal failure	3
Pyruvate carboxylase deficiency (some forms)	Metabolic acidosis, neurologic symptoms, hepatomegaly	Tubular acidosis, renal impairment	96
Ehlers-Danlos syndrome	Skin fragility, joint hypermobility, visceral or vascular dilatation and rupture	Renal tubular acidosis, medullary sponge kidney, diverticula, hypoplasia	97,98
Carnitine palmitoyltransferase deficiency type I	Fasting or illness leading to encephalopathy, seizures, hepatomegaly	Renal tubular acidosis	99
Adenosine deaminase deficiency	Severe combined immunodeficiency	Transient renal tubular acidosis, proteinuria, mesangial sclerosis	100
Lysinuric protein intolerance	See Table 50.4	Renal tubular acidosis, aminoaciduria, glomerulonephritis, renal failure	101
Nephrogenic diabetes insipidus	Polyuria, polydipsia, hyposthenuria	Hydronephrosis, hydroureter, megacystis (in long term)	See Chapter 40
Kearns-Sayre syndrome	Ophthalmoplegia, retinal degeneration, heart block, ataxia, hyperparathyroidism	Bartter's-like syndrome, hypomagnesemia	49–51
Fabry disease	See text and Table 50.4	Hyposthenuria, renal tubular acidosis, proteinuria, chronic renal failure	75–77
Metachromatic leukodystrophy	Neurologic and intellectual regression, spasticity, incontinence	Renal tubular acidosis, mild aminoaciduria, mild renal impairment	102

TABLE 50.3. NEPHROCALCINOSIS AND UROLITHIASIS

Disorder	Main features	Other renal features	References
Cystinuria	Calculi	—	See Chapter 57
Primary hyperoxaluria	Calculi and nephrocalcinosis	Acute or chronic renal failure (presentation in infants)	See Chapter 42
Familial hyperuricemic nephropathy	Gout, chronic renal failure		66,68
Hypoxanthine-guanine phosphoribosyltransferase deficiency	Lesch-Nyhan syndrome (complete deficiency): developmental delay, choreoathetoid movements, self-mutilation Partial deficiency: gouty arthritis	Acute or chronic renal failure	66,68
Adenine phosphoribosyltransferase deficiency	Calculi (2,8-dihydroxyadenine)	Acute or chronic renal failure	68
Hereditary renal hypouricemia	Urolithiasis (urate/calcium oxalate), hyperuricemia, hypercalciuria	Uric acid nephropathy, acute renal failure	69–72,103
Blue diaper syndrome	Hypercalcemia, hypercalciuria, indicanuria → blue discoloration urine	Nephrocalcinosis	104
Xanthinuria	Calculi, myopathy, arthropathy	Acute or chronic renal failure	See Chapter 57
Hereditary orotic aciduria	Megaloblastic anemia, orotic acid crystalluria, hematuria, immunodeficiency	Crystalluria, obstructive uropathy	105–107
Glycogen-storage disease type 1	See Table 50.1	Tubular dysfunction, nephrocalcinosis, proteinuria, chronic renal impairment	29–30
Wilson's disease	See Table 50.1	Acute renal failure, tubular dysfunction	91
Congenital lactase deficiency	Watery diarrhea, poor weight gain	Nephrocalcinosis, hypercalciuria, hypercalcemia	108
Glucose-galactose malabsorption	Watery diarrhea	Calculi, nephrocalcinosis, hypercalcemia	109
Cystinosis	See Table 50.1	Rarely calculi	See Chapter 41 (87)
Dent's disease/X-linked nephrolithiasis	See Table 50.1	Nephrocalcinosis, aminoaciduria, Fanconi syndrome, chronic renal failure	90
Hypophosphatasia (infantile form)	Rickets, developmental delay, hypercalcemia, craniosynostosis	Hypercalciuria, nephrocalcinosis	110
Cystic fibrosis	Chronic lung disease, poor growth, pancreatic dysfunction	Microscopic nephrocalcinosis, calculi, proteinuria, rarely nephrotic syndrome (amyloidosis), chronic renal failure	111–114
Tyrosinemia type 1	See Table 50.1	Nephrocalcinosis, Fanconi syndrome, nephromegaly, chronic renal impairment	See Chapter 41 (88,89)
McCune-Albright syndrome	Fibrous bony dysplasia, café-au-lait pigmentation, precocious puberty	Nephrocalcinosis	115
Apparent mineralocorticoid syndrome	Hypertension, hypokalemia, alkalosis, reduced plasma renin	Nephrocalcinosis, medullary cysts	116

dot found that 20% of patients had a GFR of less than 60 mL/min/1.73 m² (5). This may be an underestimate of the incidence of renal impairment, because in some patients GFR had to be estimated from plasma creatinine concentrations. Long-term renal function in nine children with early-onset cobalamin-unresponsive MMA, in whom GFR was studied by a single-injection chromium ethylenediaminetetra-acetic acid slope-clearance method, is shown in Figure 50.1. With one exception, every GFR value is below the normal range and every child surviving to 12 years has a GFR of less than 40 mL/min/1.73 m² (6). The mainstay of treatment is a low-protein, high-calorie diet, and many such children have poor growth and reduced muscle bulk. Consequently, plasma creatinine concentrations do not accurately reflect glomerular function in MMA (4). Proteinuria and hematuria are absent and renal histopathology

shows changes of tubulointerstitial nephritis (4,7,8). It is likely that the tubular dysfunction noted in MMA is related to hyporeninemic hypoaldosteronism observed in patients with tubulointerstitial nephritis and renal impairment (3).

The mechanism of nephrotoxicity in MMA is not yet known. Patients with MMA have hyperuricemia, which might lead to renal damage. Urate crystals have not been observed in renal biopsy material, however, and plasma urate is easily controlled in these patients with allopurinol (3). There is structural similarity between methylmalonate (which accumulates as a result of the enzyme deficiency) and maleic acid, used experimentally in animals to create a model of the renal Fanconi syndrome. However, the tubular manifestations of MMA do not correspond to generalized proximal tubular dysfunction. Accumulation of methylmalonate may interfere with mitochondrial function (2,9).

TABLE 50.4. PROTEINURIA AND GLOMERULONEPHRITIS

Disorder	Main features	Renal features	References
Fabry disease	See text; sensory changes in extremities, angiokeratoma, hyperhidrosis, corneal, lens opacities	Hyposthenuria, renal tubular acidosis, proteinuria, chronic renal failure	75-77
Imerslünd-Graesbeck syndrome	See text	Proteinuria, urinary tract abnormalities	20,21,23
Lecithin-cholesterol acyltransferase deficiency	See text	Proteinuria, hematuria, renal failure	83,84
Galactosialidosis (early infantile form)	Hydrops, edema, coarse facies, inguinal hernias, visceromegaly, spinal involvement, corneal and fundal abnormalities, cardiomyopathy, developmental delay, telangiectasias	Proteinuria, nephrotic syndrome	117-120
Glutaryl ribose-5-phosphate glycoproteinosis	Coarse facies, optic atrophy, muscle wasting, failure to thrive, seizures, neurologic deterioration	Proteinuria, chronic renal failure	121
Mucopolysaccharidosis type I (Hurler syndrome)	Coarse facies, corneal clouding, visceromegaly, dysostosis multiplex, developmental delay	Nephrotic syndrome, hypertension (due to aortic luminal narrowing)	122
Congenital disorder of glycosylation type I	See text and Table 50.5	Proteinuria (congenital nephrotic syndrome), microcysts	60-65
Infantile sialic acid storage disease	Hydrops, edema, dysmorphism, hepatosplenomegaly, hypotonia, poor growth	Proteinuria, nephrotic syndrome	123
Cystic fibrosis	See Table 50.3	Proteinuria, nephrotic syndrome (amyloidosis), microscopic nephrocalcinosis, calculi, chronic renal failure	111-114
Alpha-1 antitrypsin deficiency	Liver and lung disease	Hematuria, membranoproliferative glomerulonephritis (only seen with advanced liver disease), chronic renal failure	124,125
Lipoprotein glomerulopathy	Elevated apolipoprotein E	Nephrotic syndrome (resistant to treatment), hematuria, hypertension, renal failure, glomerular lipoprotein thrombi	126,127
Lysinuric protein intolerance	Vomiting, diarrhea after weaning, poor appetite and growth, hypotonia, visceromegaly, interstitial pneumonitis, encephalopathy	Proteinuria, hematuria, nephrotic syndrome, immune complex glomerulonephritis, tubulointerstitial nephritis, renal tubular acidosis, renal failure	101,128
Prolidase deficiency	Rash, dysmorphism, anemia, splenomegaly, recurrent infections	Systemic lupus erythematosus	129
Cobalamin C deficiency	See text	Hemolytic uremic syndrome, glomerulopathy	17-19
Mitochondrial disorders	See text and Table 50.1	Fanconi syndrome; rarely proteinuria, nephrotic syndrome, tubulointerstitial nephritis	43-59
Gaucher disease	Hepatosplenomegaly, hypersplenism	Proteinuria, hematuria, acute glomerulonephritis; calculi (<i>personal communication</i>)	130,131

Management of End-Stage Renal Failure in Methylmalonic Acidemia

A few reports exist of the management of end-stage renal failure (ESRF) in MMA patients. Plasma methylmalonate appears to rise in association with plasma creatinine, either due to reduced filtration or because it is nephrotoxic (10,11). Hemodialysis clearly reduces plasma methylmalonate levels and may improve metabolic and nutritional status (10). Because the deficient methylmalonyl CoA mutase is expressed in liver, a liver transplant should provide replacement enzyme. Several patients with MMA have now received liver transplants, either as an isolated organ in young children or in com-

ination with a kidney transplant in older patients in chronic renal failure. The first patient who received a combined liver-kidney transplant (10) remains well with good renal and hepatic function 6 years after surgery (W. van't Hoff, *personal communication*). Other patients have died shortly after the procedure, however, and it is a worry that liver transplantation does not seem to protect the child from further neurologic toxicity (12,13). A 24-year-old patient demonstrated improved clinical and metabolic control after an isolated renal transplantation, although she developed diabetes mellitus and suffered marked cyclosporin toxicity (14). A similarly favorable outcome with an improvement in urine methylmalonate excretion has been demonstrated in a 17-year-old patient after renal

TABLE 50.5. METABOLIC CAUSES OF RENAL CYSTS

Disorder	Main features	Renal features	References
Zellweger syndrome	Facial dysmorphism, hypotonia, severe developmental delay, hepatomegaly	Microcysts and large cortical cysts	132
Alagille syndrome	Intrahepatic cholestasis, dysmorphism, posterior embryotoxon, butterfly vertebrae, hypogonadism, peripheral pulmonary stenosis	Cysts, multicystic dysplastic kidney, unilateral agenesis, hypoplasia, urinary concentration defect, calculi, glomerular mesangiolipidosis, renal failure	133,134
Carbohydrate-deficient glycoprotein syndrome type I	See text and Table 50.4	Cysts, proteinuria	60–65
Glutaric aciduria type II (neonatal onset)	Prematurity, hepatomegaly, dysmorphism, genitourinary abnormalities, hypotonia, odor, metabolic acidosis, hypoglycemia	Cystic change (microcysts/polycystic kidneys), nephromegaly, renal dysgenesis	135–138
Nephronophthisis	Can be associated abnormalities (Leber amaurosis, retinopathy, liver disease, neurologic and skeletal abnormalities)	Hyposthenuria, chronic renal failure	See Chapter 35
Smith-Lemli-Opitz syndrome	Facial dysmorphism; hypotonia; mental retardation; abnormalities of limbs, brain, genitalia; cholesterol biosynthesis defect	Cystic dysplasia, hypoplasia, agenesis, duplication, pelviureteric junction obstruction, vesicoureteral reflux	139,140
Cystinosis	See Table 50.1	Cysts are very rare	141

transplantation (15). In view of the late neurologic complications in those patients receiving liver transplants, the long-term prognosis for any patient with MMA receiving a transplant remains uncertain (16).

Cobalamin Defects

Early-onset hemolytic uremic syndrome has been reported in a number of patients with cobalamin C or G deficiency

(17,18), in which defects are seen in the synthesis of adenosylcobalamin and methylcobalamin (cobalamin C defect) or of methionine synthase (cobalamin G defect). Patients with cobalamin C deficiency have defective function of the two enzymes dependent on these cofactors (methylmalonyl CoA mutase and N⁵-methyltetrahydrofolate:homocysteine methyltransferase). These children therefore have homocystinuria, hypomethioninemia, and cystathioninuria in addition to methylmalonic aciduria. Most present in

TABLE 50.6. OTHER MANIFESTATIONS

Disorder	Main features	Renal features	References
Menkes syndrome, Ehlers-Danlos syndrome type IX, occipital horn syndrome (OHS)	X-linked disorders Abnormal hair and facies, developmental delay and regression OHS patients have lax skin, herniae, no neurologic features	Bladder or ureteric diverticula	142,143
Homocystinuria	Ectopia lentis, skeletal abnormalities, neuropsychiatric symptoms, thromboembolism	Renal infarction, hypertension	144
Carnitine palmitoyltransferase deficiency type II	Neonatal-onset encephalopathy, hepatomegaly, cardiomyopathy	Renal dysgenesis	145
Glucose-6-phosphatase deficiency	Hemolytic anemia, jaundice	Acute renal failure	146
Porphyria (acute intermittent)	Recurrent abdominal pain, neurologic crises	Acute or chronic renal failure, urinary retention, acute hypertension	147,148
Exercise intolerance and myoglobinuria syndrome (various causes)	Myalgia, limb weakness, raised serum creatine phosphokinase	Recurrent myoglobinuria, acute renal failure	149,150

FIGURE 50.1. Glomerular filtration rate (GFR), determined by single-injection chromium ethylenediaminetetra-acetic acid slope-clearance method, in nine children with early-onset (cobalamin-unresponsive) methylmalonic acidemia. Four children underwent combined liver-kidney transplantation (LKT). Two of these and one other child have died. (From Van't Hoff W, McKiernan PJ, Surtees RA, et al. Liver transplantation for methylmalonic acidemia. *Eur J Pediatr* 1999;158;S2:S70–S74, with permission.)

early infancy with poor feeding, failure to thrive, hypotonia, retinitis, respiratory distress, and cardiomyopathy. Investigation shows a megaloblastic anemia, pancytopenia, and liver dysfunction. Generally the prognosis has been poor. There have been rare case reports of older children with cobalamin C deficiency who developed hypertension, proteinuria, and chronic renal impairment, in association with focal segmental glomerulosclerosis or an unclassified glomerulopathy (18).

A number of patients with defective absorption of the cobalamin–intrinsic factor complex (Imerslünd-Grasbeck syndrome) have persistent proteinuria (20). The cobalamin–intrinsic factor complex binds to cubilin in the intestinal brush border. Cubilin is also expressed in the renal proximal tubule, where it interacts with megalin to form a tandem endocytic receptor complex (21). Cubilin is the major receptor for proximal tubular albumin reabsorption; thus, patients with Imerslünd-Grasbeck syndrome, in which the cubilin gene is defective, have albuminuria (22). Other manifestations include megaloblastic anemia and, biochemically, homocystinuria, homocystinemia, and methylmalonic aciduria (20). In addition to the metabolic abnormalities, two children with this disorder were reported as suffering from recurrent urinary tract infections secondary to neuropathic bladders (23).

GLYCOGEN-STORAGE DISEASES

Clinical Features

The glycogen-storage diseases (GSDs) are genetic disorders of the metabolism and regulation of glycogen. Two forms of GSD have significant renal manifestations: GSD type 1 (GSD-1) and the Fanconi-Bickel syndrome. GSD-1 is characterized by a deficiency of glucose-6-phosphatase in the liver, kidney, and intestine, which causes excessive glycogen storage, hepatomegaly, hypoglycemia, lactic acidosis, hyperuricemia, hyperlipidemia, and poor growth. Long-term complications include delayed puberty, hepatic adenomata, and renal disease. Chen and colleagues drew attention to the complication of ESRF in older GSD patients (24). In their review in 1988, 18 children under 10 years of age had normal renal function, whereas 14 of 20 patients aged 13 to 47 years had renal dysfunction (proteinuria, hypertension, or chronic renal failure). Subsequent investigators have demonstrated renal tubular and glomerular abnormalities. Ultrasonography demonstrates the renal enlargement secondary to glycogen deposition (25–28).

Renal Tubular Dysfunction

Proximal tubular dysfunction occurs as an early feature in GSD-1 but is generally subclinical, and a frank Fanconi syn-

drome is rare. Although tubular proteinuria (retinol-binding protein, β 2M) and enzymuria (*N*-acetyl glucosaminidase) is significantly elevated in GSD-1 patients, plasma electrolytes are less disturbed (26,27). Distal tubular function is also perturbed with hypercalciuria and hypocitraturia, which predisposes GSD-1 patients to nephrolithiasis (29,30). A Gitelman-like syndrome of hypomagnesemia and hypercalciuria has also been described in a patient with GSD type 2 (31).

Glomerular Dysfunction

Patients with GSD-1 develop albuminuria and hyperfiltration (26,27,32). In a Dutch study, mean GFR and effective renal plasma flow were 188 and 927 mL/min/1.73 m², respectively (normal values for adult controls were 90 to 145 and 327 to 697 mL/min/1.73 m², respectively) in a group of 23 patients with GSD-1 aged 2 to 22 years (26). Persistent hyperfiltration leads to focal and global glomerulosclerosis and a decline in GFR (32,33). Other histologic abnormalities include glycogen deposition in proximal tubules, glomerular enlargement, and thickening and lamellation of GBM (34,35). Management of the metabolic abnormalities, which includes frequent feedings and the use of uncooked cornstarch, are the mainstays of treatment of GSD nephropathy. Antiproteinuric and lipid-lowering agents may have a role (36).

Fanconi-Bickel Syndrome

Fanconi-Bickel syndrome is a very rare autosomal recessive disorder of monosaccharide transport, manifesting in the first year of life with hepatomegaly (due to glycogen storage), hypoglycemia, and a severe generalized proximal tubulopathy leading to rickets. The Fanconi syndrome can be equal in magnitude to that in disorders such as cystinosis or tyrosinemia but is particularly characterized by heavy glycosuria and galactosuria (37–39). Treatment includes frequent feedings (and the use of uncooked cornstarch) together with management of the tubulopathy. The condition arises due to mutations in the GLUT2 facilitative glucose transporter, which is expressed in hepatocytes, pancreatic beta cells, and the basolateral membranes of intestinal and renal tubular epithelial cells (40). Decreased monosaccharide uptake by the liver explains the postprandial hyperglycemia and hypergalactosemia, which is exacerbated by inappropriately low insulin secretion due to abnormal glucose-sensing by pancreatic beta cells. The inability of the liver to transport glucose, together with heavy losses of glucose from the renal tubule, contributes to preprandial hypoglycemia (40). Renal glomerular hyperfiltration, microalbuminuria, and diffuse mesangial expansion have been reported in one child (41), and reduced GFR has been observed in some adults.

MITOCHONDRIAL DISORDERS

Description

Mitochondrial disorders are caused by defects in the respiratory chain enzymes that are located in this organelle. The respiratory chain is responsible for the process of oxidative phosphorylation in which electrons are transferred to oxygen, which generates a proton gradient. The flow of protons back through the mitochondrial membrane releases energy, which allows for the formation of ATP. The respiratory chain enzyme complexes are encoded partly by mitochondrial and partly by nuclear DNA. Mitochondrial DNA (mtDNA) differs from nuclear DNA: it is much smaller, has a unique genetic code, exists as a double-stranded loop, and is inherited exclusively from the mother. In contrast to nuclear DNA, mtDNA is randomly segregated during cell division. The proportion of mutant and wild-type mtDNA can therefore vary from tissue to tissue and can also change over time, which explains the enormous heterogeneity of mitochondrial disorders (42). The classification of mitochondrial disorders has been based on clinical, biochemical, and molecular phenotypes. The clinical features are extremely heterogeneous and often change with time, but virtually all patients have neurologic symptoms at some point. Frequent manifestations include myopathy, encephalopathy, seizures, developmental delay, ophthalmoplegia, retinal degeneration, cardiomyopathy, endocrinopathy, and liver disease.

Renal Manifestations

The most common renal manifestation is the Fanconi syndrome. It usually occurs in an infant with multisystem dysfunction, in which case the prognosis is poor (43,44). Generalized proximal tubular dysfunction has also been reported in children with other mitochondrial syndromes, including Kearns-Sayre, Pearson, and Leigh encephalopathy (43,45–49). In some children, hypomagnesemia and hypocalcemia are the predominant electrolyte abnormalities (48–50). Other tubular manifestations include a Bartter-like syndrome (51), renal tubular acidosis, and hypercalciuria (52,53). Renal glomerular involvement with proteinuria, focal segmental glomerulosclerosis, chronic tubulointerstitial nephritis, and chronic renal impairment are rarer associations of mitochondrial disorders (43,54–56). Renal cysts have been reported in both adults and children with mitochondrial disorders (57,58). In most children the renal lesion is part of multisystem dysfunction, but there are occasional reports of patients presenting with focal segmental glomerulosclerosis and later developing other manifestations of mitochondrial disease (54,59). A high index of suspicion is therefore required to diagnose a mitochondrial disorder. Unfortunately, measurement of the plasma lactate/pyruvate ratio, which is the first investigation of a child with mitochondrial dysfunction, may give a normal result in a patient

with a renal tubulopathy due to loss of organic acids in the urine (43). In such a case, careful delineation of other system involvement, biopsy, and detailed biochemical and molecular studies may be required to confirm a defect in mitochondrial function.

CONGENITAL DISORDERS OF GLYCOSYLATION

The congenital disorders of glycosylation (CDGs) are a group of multisystem disorders in which there is defective glycosylation of glycoproteins (60). Several subtypes have been described, and the presentation is very heterogeneous, ranging from developmental delay in older children to a fatal multisystem disorder in infancy (60). In infancy, typical features of CDG type I include dysmorphism, hypotonia, failure to thrive, diarrhea, abnormal fat pads, inverted nipples, abnormal eye movements, hepatomegaly, and cardiomyopathy. Investigations often show hypothyroidism, olivopontocerebellar atrophy, and, diagnostically, abnormal isoelectric focusing of serum transferrin with an increase in asialo- and disialotransferrin and a decrease in tetra- and pentasialotransferrin.

The most common renal manifestation is the presence of microcysts, which produce a hyperechoic picture on ultrasonography (61,62). The cysts are located in the cortex and probably arise from the tubules (63). The kidneys may be enlarged, and single cysts have also been reported (62). Microcysts are not seen in all patients; even within a pair of affected siblings, only one had renal cysts (61). Proteinuria has been recorded in several cases and may contribute to the severe edema and ascites that these infants can develop (62). There have also been reports of nephrotic syndrome occurring within the first 2 months of life (63–65). One of these infants also developed renal failure, and at postmortem the kidneys showed features of diffuse mesangial sclerosis (64). Transferrin isoelectric focusing should be added to the list of investigations required to exclude a metabolic cause of nephrotic syndrome in infants [the test is not affected by the nephrotic state or by renal failure (64)].

DISORDERS OF PURINE METABOLISM AND TRANSPORT

Children who develop renal calculi, acute renal failure in the neonatal period, or crystal nephropathy require investigation of their purine metabolism. Purines are involved in the synthesis of nucleotides and coenzymes, in signal transduction (e.g., cyclic adenosine monophosphate), and in the generation of ATP. The metabolic end product, uric acid, and its immediate precursor (xanthine) are insoluble in urine, so that overproduction can predispose to the development of crystal formation. Urate is normally extensively

reabsorbed in the proximal tubule. The process is age and sex dependent, with children reabsorbing less of the filtered urate and consequently having lower plasma urate concentrations (66). As GFR declines, the fractional excretion of urate increases (67).

Urolithiasis is the most common renal manifestation of a disorder of purine production (see Chapter 57). Children may or may not have typical features of calculi (pain, hematuria, infection). In some the diagnosis is made following family studies or during investigation of crystalluria. Anuric acute renal failure in an infant is a well-described presentation of purine overproduction, for example, adenine phosphoribosyltransferase (APRT) deficiency and hypoxanthine-guanine phosphoribosyl transferase (HGPRT) deficiency (68). In both APRT and HGPRT deficiencies, the urinary urate/creatinine ratio is normal. The plasma urate level is also normal in APRT deficiency but is grossly elevated in HGPRT deficiency (68). In these cases detailed investigation of purine metabolism is required. Both conditions are treated with a high fluid intake, restriction of dietary purines, and administration of allopurinol, which inhibits xanthine oxidase production.

Hyperuricemia with subsequent hyperuricosuria is also a feature of GSD-1. Calculi and renal failure can also occur as a result of disorders of urate transport in the renal tubule. Hyperuricosuria and hypouricemia can occur as a result of generalized proximal tubular dysfunction (e.g., Fanconi syndrome) but has also been described as an isolated transport defect associated with hypercalciuria, decreased bone density, and the development of calculi composed of a mixture of calcium oxalate and urate (69–72).

Familial juvenile hyperuricemic nephropathy is a disorder of unknown cause in which patients develop hyperuricemia, gout, and progressive renal failure (66,67). The onset is frequently in childhood or early adult life. Many families have been described with males and females equally affected and male-to-male transmission supporting the concept of an autosomal dominant pattern of inheritance (66). The disorder is characterized biochemically by hyperuricemia due to a reduced fractional excretion of urate. There is evidence that hyperuricemia predates renal impairment, and it is known that allopurinol reduces the progression of the nephropathy, which suggests that renal damage is related to hyperuricemia (73,74). The genetic defect of this disorder is under investigation, and it is thought likely to be due to an abnormality in urate transport.

FABRY DISEASE

Fabry disease is an X-linked disorder in which glycosphingolipids (predominantly globotriaosylceramide) accumulate in plasma and tissues as a result of a deficiency of α galactosidase A (75). Affected males usually present in late childhood with recurrent painful crises of the hands and

feet, a characteristic skin rash (angiokeratoma corporis), and hypohidrosis. Slit-lamp examination reveals corneal and lenticular opacities.

Progressive glycosphingolipid deposition in the heart, blood vessels, and kidneys leads to the development of valvular and conduction abnormalities, angina, cerebrovascular disease, and progressive renal damage, usually in adult life. However, proteinuria, chronic renal failure, and even ESRF can occur by 15 years of age (76,77). The urine may show casts and desquamated cells containing lipid globules (78). Subsequently, polyuria and polydipsia indicate defective tubular function, and ESRF occurs typically around the fourth decade (76,77). Histologic examination of the kidney will demonstrate inclusions with a characteristic "onion skin" appearance in tubular epithelia, glomerular cells (especially podocytes), and endothelium (79). Glycosphingolipid deposits are seen in endothelial and epithelial cells of the glomeruli, in Bowman capsules, and in the distal tubules (79). The renal prognosis may bear some relationship to the level of detectable α galactosidase A activity. Onset of chronic renal failure was significantly later in those with more than 1% activity compared to those with undetectable activity (77). Studies indicate that approximately 1% of adult males with undiagnosed causes of ESRF have Fabry disease (80,81). Affected females (heterozygotes) generally have much milder manifestations, although, as a result of random X inactivation, these can be variable (76). There are some reports of proteinuria and hyposthenuria; renal failure has been described in a rare variant (75,76). Fabry patients with ESRF can be treated with dialysis and renal transplantation as for other causes of renal failure. Peritoneal dialysis may be preferable in view of the potential endothelial and cardiac complications of the disorder. There is some evidence of amelioration of the nonrenal manifestations after kidney transplantation. However, a more promising therapeutic approach is with recombinant α galactosidase A, which has been shown in a placebo-controlled double-blind study to reduce microvascular deposits of globotriaosylceramide in many organs, including the kidney (82).

LECITHIN-CHOLESTEROL ACYLTRANSFERASE DEFICIENCY

Lecithin-cholesterol acyltransferase (LCAT) is required for the esterification of cholesterol with unsaturated fatty acid derived from lecithin. Patients with LCAT deficiency accumulate unesterified cholesterol and phosphatidylcholine in plasma and tissues (83). Sequelae of tissue accumulation occur during childhood and include grayish corneal opacities, a hemolytic anemia, and proteinuria (sometimes in the nephrotic range) leading to progressive renal failure in adulthood (83–85). Tendon xanthomata and atherosclerosis have been described in a few cases. Biochemically, LCAT

deficiency is characterized by a low total cholesterol concentration, variable triglyceride concentration, and abnormalities of lipoprotein structure and composition. The histology of the kidney shows mesangial hypercellularity and expansion with foam lipid deposits, holes and vacuolization in the glomerular basement membrane, arteriolar narrowing due to intimal thickening, and subendothelial lipid deposits (85). Creation of an LCAT "knock-out" mouse has provided further information on the pathogenesis of this disorder (86). Some of the null mice accumulated lipoprotein X and developed proteinuria secondary to glomerulosclerosis. Biochemically, although high-density lipoproteins were markedly reduced, aortic atheroma was attenuated in the "knock-out" mice, which suggests a role for other lipoproteins in generating atheroma.

INFECTIOUS DISEASES AND THE KIDNEY

**AMITAVA PAHARI
SAM WALTERS
MICHAEL LEVIN**

The kidney is involved in a wide range of bacterial, viral, fungal, and parasitic diseases. In most systemic infections, renal involvement is a minor component of the illness, but in some, renal failure may be the presenting feature and the major problem in management. Although individual infectious processes may have a predilection to involve the renal vasculature, glomeruli, interstitium, or collecting systems, a purely anatomic approach to the classification of infectious diseases affecting the kidney is rarely helpful because most infections may involve several different aspects of renal function. In this chapter, a microbiologic classification of the organisms affecting the kidney is adopted. Although they are important causes of renal dysfunction in infectious diseases, urinary tract infections and hemolytic uremic syndrome (HUS) are not discussed in detail because they are considered separately in Chapters 53 and 47, respectively.

Elucidation of the cause of renal involvement in a child with evidence of infection must be based on a careful consideration of the geographic distribution of infectious diseases in different countries. A history of foreign travel; exposure to animals, insects, or unusual foods or drinks; outdoor activities such as swimming or hiking; and contact with infectious diseases must be sought in every case. The clinical examination should include a careful assessment of skin and mucous membranes and a search for insect bites, lymphadenopathy, and involvement of other organs. A close collaboration with a pediatric infectious disease specialist and hospital microbiologist will aid the diagnosis and management of the underlying infection.

A tantalizing clue to the pathogenesis of glomerular disease is the marked difference in the incidence of nephrosis and nephritis in developed and underdeveloped areas of the world. In several tropical countries, glomerulonephritis (GN) accounts for up to 4% of pediatric hospital admissions; the incidence in temperate climates is 10- to 100-fold less. This difference might be explained by a complex interaction of several different factors, including nutrition, racial and genetically determined differences in immune responses, and exposure to infectious diseases. A growing

body of evidence, however, suggests that long-term exposure to infectious agents is a major factor in the increased prevalence of glomerular diseases in developing countries.

Renal involvement in infectious diseases may occur by a variety of mechanisms: direct microbial invasion of the renal tissues or collecting system may take place in conditions such as staphylococcal abscess of the kidney as a result of septicemic spread of the organism or as a consequence of ascending infection; damage to the kidney may be caused by the systemic release of endotoxin or other toxins and activation of the inflammatory cascade during septicemia or by a focus of infection distant from the kidney; ischemic damage may result from inadequate perfusion induced by septic shock; the kidney may be damaged by activation of the immunologic pathways or by immune complexes resulting from the infectious process. In many conditions, a combination of these mechanisms may be operative. In the assessment of renal complications occurring in infectious diseases, the possibility of drug-induced nephrotoxicity caused by antimicrobial therapy should always be considered. The nephrotoxic effects of antibiotics and other antimicrobial agents are not addressed in this chapter but are covered in Chapter 52.

BACTERIAL INFECTIONS

Bacterial infections associated with renal disease and the likely mechanisms causing renal dysfunction are shown in Table 51.1.

Systemic Sepsis and Septic Shock

Impaired renal function is a common occurrence in systemic sepsis (1). Depending on the severity of the infection and the organism responsible, the renal involvement may vary from insignificant proteinuria to acute renal failure requiring dialysis. The organisms causing acute renal failure as part of systemic sepsis vary with age and geographic location and also differ in normal and immunocompromised children. In the

TABLE 51.1. LIKELY MECHANISMS CAUSING RENAL DYSFUNCTION IN BACTERIAL INFECTIONS

Organism	Site/infection	Infection localized to kidney	Systemic infection; toxin/inflammation	Ischemia/hypoperfusion; vasomotor nephropathy	Distant infection; "immunologic/delayed"	Others
<i>Neisseria meningitidis</i>	Septicemia		++	++		
	Chronic meningococcemia				+	
<i>Staphylococcus aureus</i>	Renal abscess	++				
	Distant abscess/endocarditis (see Table 51.2)				++	
	Sepsis		++	++		
	Toxic shock		++	++		
<i>Staphylococcus epidermidis</i>	Shunt infection (see Table 51.2)				++	
Group A <i>Streptococcus</i>	Sepsis		++	++		
	Toxic shock		++	++		
	APSGN				++	
<i>Haemophilus influenzae</i> (new biotype)	Brazilian purpuric fever		++	++		
<i>Leptospira interrogans</i>	Leptospirosis, Weil disease	++		++		
<i>Streptococcus pneumoniae</i>	Sepsis		++	++		
	Pneumonia					+ (HUS)
<i>Escherichia coli</i> and <i>Shigella</i>	Sepsis		++	++		
	Diarrhea			++		
	Colitis					++ (HUS)
<i>Salmonella</i> species	Sepsis		+++?	++	+	
	Diarrhea			++		+ (HUS)
<i>Vibrio</i> species	Cholera			++		
<i>Klebsiella</i>	Sepsis		++	++		
<i>Yersinia</i> species	Enteritis				+	+ (HUS)
<i>Campylobacter jejuni</i>	Enteritis				+	
<i>Mycobacteria tuberculosis</i>	Tuberculosis	+			+	
<i>Treponema pallidum</i>	Syphilis				+	
<i>Mycoplasma pneumoniae</i>	Pneumonia				+	+ (HUS)
<i>Legionella</i>	Pneumonia	+?				Rhabdomyolysis
<i>Rickettsia rickettsii</i>	Rocky Mountain spotted fever	+		+		
<i>Coxiella burnetii</i>	Q fever				+	

++, frequent complication of infection; +, uncommon but recognized complication; APSGN, acute poststreptococcal glomerulonephritis; HUS, hemolytic uremic syndrome.

neonatal period, group B streptococci, coliforms, *Staphylococcus aureus*, and *Listeria monocytogenes* are the organisms usually responsible. In older children, *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *S. aureus* account for most of the infections. In people who are immunocompromised, a wide range of bacteria are seen, and, similarly, in tropical countries other pathogens, including *Haemophilus influenzae*, *Salmonella* species, and *Pseudomonas pseudomallei*, must be considered. Where *H. influenzae* type B vaccine has been introduced, however, the incidence of severe systemic infections due to this organism has shown a sharp fall.

Systemic sepsis usually presents with nonspecific features: fever, tachypnea, tachycardia, and evidence of skin

and organ underperfusion. The pathophysiology of renal involvement in systemic sepsis is multifactorial (1,2). Hypovolemia with diminished renal perfusion is the earliest event and is a consequence of the increased vascular permeability and loss of plasma from the intravascular space. Hypovolemia commonly coexists with depressed myocardial function because of the myocardial depressant effects of endotoxin or other toxins. The renal vasoconstrictor response to diminished circulating volume and reduced cardiac output further reduces glomerular filtration, and oliguria is thus a consistent and early event in severe sepsis (1,3). The plasma kallikrein-kinin system is a potent vasodilator pathway, activated by endotoxin. Vasodilation

of capillary beds leading to warm shock is common in adults with sepsis due to Gram-negative organisms but is less commonly seen in children, in whom intense vasoconstriction is the usual response to sepsis. If renal underperfusion and vasoconstriction are persistent and severe, the reversible prerenal failure is followed by established renal failure with the characteristic features of vasomotor nephropathy or acute tubular necrosis. Other mechanisms of renal damage in systemic sepsis include direct effects of endotoxin and other toxins on the kidney, and release of inflammatory mediators such as tumor necrosis factor (TNF) and other cytokines, arachidonic acid metabolites, and proteolytic enzymes (3). Nitric oxide (NO) is postulated to play a key role in the pathophysiology of renal failure in sepsis. Whether the renal effects of increased NO are beneficial or harmful remains unclear. Trials of selective NO synthetase inhibition did not offer any advantages over saline resuscitation (4). NO in endotoxemia is possibly beneficial because it maintains renal blood flow and glomerular filtration.

The renal findings early in septic shock are oliguria, with high urine/plasma urea and creatinine ratios, low urine sodium concentration, and a high urine/plasma osmolarity ratio. Once established, renal failure supervenes, and the urine is of poor quality with low urine/plasma urea and creatinine ratios, elevated urine sodium concentration, and low urine osmolarity. Proteinuria is usually present, and the urine sediment may contain red cells and small numbers of white cells (1).

Management of Acute Renal Failure in Systemic Sepsis

The management of acute renal failure in systemic sepsis depends on early diagnosis and administration of appropriate antibiotics to cover the expected pathogens. In addition, management is directed at improving renal perfusion and oxygenation. Volume replacement with crystalloid or colloid should be undertaken to optimize preload. Central venous pressure or pulmonary wedge pressure monitoring is essential to guide volume replacement in children in severe shock (1,2). The use of low-dose (2 to 5 µg/kg/min) dopamine to reduce renal vasoconstriction together with administration of inotropic agents such as dobutamine or epinephrine to improve cardiac output may reverse prerenal failure. Early elective ventilation should be undertaken in patients with severe shock. If oliguria persists despite volume replacement and inotropic therapy, dialysis should be instituted early, because septic and catabolic patients may rapidly develop hyperkalemia and severe electrolyte imbalance.

In most children who develop acute renal failure as part of systemic sepsis or septic shock, the renal failure is of short duration, and recovery can be expected within a few days of achieving cardiovascular stability and eradication of

the underlying infection. Occasionally, renal cortical necrosis or infarction of the kidney may result in prolonged or permanent loss of renal function.

Specific Infections Causing the Systemic Sepsis Syndrome

Meningococcus

N. meningitidis continues to be a major cause of systemic sepsis and meningitis in both developed and underdeveloped parts of the world (5). In developed countries, most cases are caused by group B strains, particularly after introduction of meningococcal C vaccination, whereas epidemics of *Meningococcus* groups A and C continue to occur in many underdeveloped regions of the world (5,6). Infants and young adults are most commonly affected, but cases in adolescents and young children are also common. There are two major presentations of meningococcal disease (5): Meningococcal meningitis presents with features indistinguishable from those of other forms of meningitis, including headaches, stiff neck, and photophobia. Lumbar puncture is required to identify the causative agent and distinguish this from other forms of meningitis. Despite the acute nature of the illness, the prognosis is good, and most patients with the purely meningitic form of the illness recover without sequelae.

Meningococcemia with purpuric rash and shock is the second and more devastating form of the illness. Affected patients present with nonspecific symptoms of fever, vomiting, abdominal pain, and muscle ache. The diagnosis is only obvious once the characteristic petechial or purpuric rash appears. Patients with a rapidly progressive purpuric rash, hypotension, and evidence of skin and organ underperfusion have a poor prognosis, with a mortality of 10 to 60%. Adverse prognostic features include hypotension, a low white cell count, absence of meningeal inflammation, thrombocytopenia, and disturbed coagulation indices (7).

Renal failure was seldom reported in early series of patients with meningococcemia, perhaps because most patients died rapidly of uncontrolled septic shock. With advances in intensive care, however, more children are surviving the initial period of profound hemodynamic derangement, and renal failure is more often seen as a major management problem. Approximately 10% of children with fulminant meningococcemia develop renal failure, which usually occurs 24 to 48 hours after the onset of illness (8).

The pathophysiology of meningococcal septicemia involves the activation of cytokines and inflammatory cells by endotoxin (5,6). Mortality is directly related to both the plasma endotoxin concentration and the intensity of the inflammatory response, as indicated by levels of TNFs and other inflammatory markers (9). Patients with meningococcemia have a profound capillary leak leading to severe hypovolemia. Loss of plasma proteins from the intravascular space is probably the major cause of shock (10). However, intense vasoconstriction

further impairs tissue and organ perfusion, and vasculitis with intravascular thrombosis and consumption of platelets and coagulation factors is also present (5).

Oliguria is invariably present in children with meningococemia during the initial phase of the disorder. This is pre-renal in origin and may respond to volume replacement and inotropic support. If cardiac output cannot be improved and renal underperfusion persists, established renal failure supervenes. Occasionally, cortical necrosis or infarction of the kidneys occurs. Children with meningococemia should be aggressively managed in a pediatric intensive care unit, with early administration of antibiotics (penicillin or a third-generation cephalosporin), volume replacement, hemodynamic monitoring, and the use of inotropic agents and vasodilators. If oliguria persists despite measures to improve cardiac output, elective ventilation and dialysis should be instituted early (5,6). Because activation of coagulation pathways occurs, severe acquired protein-C deficiency may result and is usually associated with substantial mortality (11). In survivors, end-organ failure including renal failure is not uncommon. Protein C is a natural anticoagulant which also has important antiinflammatory activity. Early replacement therapy with activated protein-C concentrate together with supportive treatment in meningococemia may have an important role in reducing the complications, including the renal manifestations (12). Most patients who survive the initial 24 to 48 hours of the illness and regain hemodynamic stability will ultimately recover renal function.

The least common presentation of meningococcal sepsis is chronic meningococemia. Patients with this form of the illness present insidiously with a vasculitic rash, arthritis, and evidence of multiorgan involvement. The features may overlap those of Henoch-Schönlein purpura or subacute bacterial endocarditis (SBE), and the diagnosis must be considered in patients presenting with fever, arthritis, and vasculitic rash, often accompanied by proteinuria or hematuria. Response to antibiotic treatment is good, but some patients may have persistent symptoms for many days resulting from an immune-complex vasculitis.

Staphylococcus aureus

Staphylococcal infections may affect the kidneys by direct focal invasion during staphylococcal septicemia, forming a renal abscess; by causing staphylococcal bacteremia; or by toxin-mediated mechanisms, as in the staphylococcal toxic shock syndrome.

Staphylococcal Abscess. Staphylococcal renal abscess presents with fever, loin pain and tenderness, and abnormal urine sediment, as do abscesses caused by other organisms (13). The illness often follows either septicemia or pyelonephritis. The diagnosis is usually considered only when a patient with clinical pyelonephritis shows an inadequate response to antibiotic treatment. The diagnosis is confirmed by ultrasonography or computed tomographic scan,

which shows swelling of the kidney and intrarenal collections of fluid. Antibiotic therapy alone may result in cure, but if the patient remains unwell with evidence of persistent inflammation despite use of appropriate antibiotics, surgical intervention may be required. Percutaneous drainage under ultrasonographic or computed tomographic scan guidance is often effective and may avoid the need for a more direct surgical approach (13,14).

Staphylococcal Toxic Shock Syndrome. The staphylococcal toxic shock syndrome is a systemic illness characterized by fever, shock, erythematous rash, diarrhea, confusion, and renal failure. The disorder was first described by Todd et al. in 1978 in a series of seven children (15). During the 1980s, thousands of cases were reported in the United States, mostly cases in menstruating women associated with tampon use. Although most cases worldwide are seen in women and are associated with menstruation, children of both sexes and of all ages are affected (16).

The illness usually begins suddenly with high fever, diarrhea, and hypotension, together with a diffuse erythroderma (17). Mucous membrane involvement with hyperemia and ulceration of the lips and oral mucosa or vaginal mucosa, strawberry tongue, and conjunctival injection are usually seen. Desquamation of the rash occurs in the convalescent phase of the illness. Confusion is often present in the early stages of the illness and may progress to coma in severe cases. Multiple organ failure with evidence of impaired renal function, elevated levels of hepatic transaminases, thrombocytopenia, and disseminated intravascular coagulation (DIC) is often seen.

The diagnosis is made on the basis of the clinical features of fever, rash, hypotension, and subsequent desquamation along with deranged function of three or more of the following organ systems: gastrointestinal (GI), mucous membranes, renal, hepatic, hematologic, central nervous system, and muscle. Other disorders causing a similar picture, such as Rocky Mountain spotted fever, leptospirosis, measles, and streptococcal infection, must be excluded.

The staphylococcal toxic shock syndrome is now known to be due to infection or colonization with strains of *S. aureus* that produce one or more protein exotoxins (18). Most cases in adults are associated with toxic shock toxin I; in children, many of the isolates associated with the syndrome produce other enterotoxins (A to F). The staphylococcal enterotoxins appear to induce disease by acting as superantigens (19), which activate T cells bearing specific V β regions of the T-cell receptor; this causes proliferation and cytokine release (20). The systemic illness and toxicity are believed to result largely from an intense inflammatory response induced by the toxin. The site of toxin production is often a trivial focus of infection or simple colonization, and bacteremia is rarely observed.

Renal failure in toxic shock syndrome is usually caused by shock and renal hypoperfusion. In the early stages of the

illness, oliguria and renal impairment are usually prerenal and respond to treatment of shock and measures to improve perfusion. In severe cases and in patients in whom treatment is delayed, acute renal failure develops as a consequence of prolonged renal underperfusion, and dialysis may be required. In addition to underperfusion, direct effects of the toxin or inflammatory mediators may also contribute to the renal damage. Recovery of renal function usually occurs, but in severe cases with cortical necrosis or intense renal vasculitis, prolonged dialysis may be required.

The management of staphylococcal toxic shock syndrome depends on early diagnosis and aggressive cardiovascular support with volume replacement, inotropic support, and, in severe cases, elective ventilation. If oliguria persists despite optimization of intravascular volume and administration of inotropic agents, dialysis should be commenced early (17).

Antistaphylococcal antibiotics should be started as soon as the diagnosis is suspected and the site of infection identified. Initial empiric antimicrobial therapy should include an antistaphylococcal antibiotic effective against β -lactamase-resistant organisms and a protein synthesis-inhibiting antibiotic such as clindamycin to stop further toxin production (21). If there is a focus of infection such as a vaginal tampon, surgical wound, or infected sinuses, the site should be drained early to prevent continued toxin release into the circulation. The intravenous administration of immune globulins may be considered when infection is refractory to several hours of aggressive therapy, an undrainable focus is present, or persistent oliguria with pulmonary edema occurs (21). With aggressive intensive care, most affected patients survive, and renal recovery is usual, even in patients who have had severe shock and multiorgan failure. Relapses and recurrences of staphylococcal toxic shock syndrome occur in a proportion of affected patients because immune responses to the toxin are ineffective in some individuals.

Streptococcus pyogenes

The group A streptococci (GAS) are a major worldwide cause of renal disease, usually as poststreptococcal nephritis. However, in addition to this postinfection immunologically mediated disorder, in recent years there have been increasing reports of GAS's causing acute renal failure as part of an invasive infection with many features of the staphylococcal toxic shock syndrome (22).

Acute Poststreptococcal Glomerulonephritis. Acute poststreptococcal GN (APSGN) is a delayed complication of pharyngeal infection or impetigo with certain nephritogenic strains of GAS. Different strains can be serotyped according to the antigenic properties of the M protein found in the outer portion of the bacterial wall. APSGN after pharyngeal infection is most commonly associated with serotype M12. In contrast, in APSGN after impetigo, serotype M49 is most commonly

identified (23). On occasions, other serotypes and nontypeable strains have been described as causing GN.

The pathology and pathogenesis of the disorder is discussed in detail in Chapter 30. APSGN has a worldwide distribution. Epidemiologic differences are observed between pharyngitis-associated and impetigo-associated streptococcal infections. Pharyngitis-associated APSGN is most common during school age and has an unexplained male/female ratio of 2:1. It occurs more often in the cooler months, and familial occurrences are commonly described. The latent period is 1 to 2 weeks, in notable contrast to impetigo-associated cases, which have a latent period of 2 to 6 weeks. In many developing countries, children have chronic skin infections, and it may be difficult to establish the latent period with accuracy. Impetigo-associated cases are more common in the warmer months, sex distribution is equal, and children tend to be younger. Introduction of a nephritogenic strain into a family often results in the occurrence of several cases within that family, and in some cases, attack rates of up to 20% have been described (24). The incidence is linked to poor socioeconomic conditions.

Renal involvement in APSGN can be mild, and in many patients, the disease may not be manifested clinically. Studies of epidemics with nephritogenic strains of streptococci have shown that up to 50% of those infected had subclinical evidence of renal disease (24,25). In a typical case a sudden onset of facial or generalized edema occurs. Hypertension is usually modest but is severe in 5% of cases, and occasionally may lead to encephalopathy or left ventricular failure. The urine is smoky or tea colored in 30 to 50% of cases. Pallor, headache, backache, lethargy, malaise, anorexia, and weakness are all common nonspecific features.

The urine volume is decreased. Proteinuria is present (up to 100 mg/dL), and microscopy shows white cells, red cells, and granular and hyaline casts. Urea, electrolyte, and creatinine levels are normal in subclinical cases but show features of acute renal failure in severe cases. It may be possible to culture GAS from the skin or the throat in some patients. Other evidence of infection with a GAS can be obtained through the antistreptolysin-O titer (ASOT), which is increased in 60 to 80% of cases. Early antibiotic treatment can reduce the proportion of cases with elevated ASOT to 30%. Anti-deoxyribonuclease B and antihyaluronidase testing has been shown to be of more value than ASOT in confirming group A streptococcal infection in impetigo-associated cases. Measurement of anti-M protein antibodies is of more value for epidemiologic purposes than for the diagnosis of individual cases (25). Decreased C3 and total hemolytic complement levels are found in 90% of cases during the first 2 weeks of illness and return to normal after 4 to 6 weeks.

Penicillin should be given to eradicate the GAS organisms. Erythromycin, clindamycin, or a first-generation cephalosporin can be given to patients allergic to penicillin. Antibiotic treatment probably has no influence on the course

of renal disease but will prevent the spread of a nephritogenic strain (26). Close contacts and family members who are culture-positive for GAS should also be given penicillin, although antibiotic treatment is not always effective in eliminating secondary cases. Recurrent episodes are rare, and immunity to the particular nephritogenic strain that caused the disease is probably lifelong. Antibiotic prophylaxis is therefore unnecessary.

Most studies suggest that the prognosis for children with APSGN is extremely good, with more than 90% making a complete recovery. However, 10% of cases may have a prolonged and more serious course with long-term chronic renal failure (27).

Other Streptococci. APSGN has also been described after outbreaks of group C *Streptococcus* infection (28). This has occurred after consumption of unpasteurized milk from cattle with mastitis. Patients developed pharyngitis followed by APSGN. Endostreptosin was found in the cytoplasm of these group C strains, and during the course of the illness, patients developed antiendostreptosin antibodies. This antigen has been postulated to be the nephritogenic component of GAS.

In addition, strains of group G streptococci have been implicated in occasional cases of APSGN (29). Isolates possessed the type M12 protein antigen identical to the nephritogenic type M12 antigen of some group A streptococcal strains.

Streptococcal Toxic Shock Syndrome and Invasive Group A Streptococcal Infection. Since 1988, there have been several reports of an illness with many similarities to the staphylococcal toxic shock syndrome, occurring in both children (30) and adults, associated with invasive group A streptococcal disease (26,31,32). Patients with this syndrome present acutely with high fever, erythematous rash, mucous membrane involvement, hypotension, and multiorgan failure. Unlike staphylococcal toxic shock syndrome, in which the focus of infection is usually trivial and bacteremia is seldom seen, the streptococcal toxic shock syndrome is usually associated with bacteremia or a serious focus of infection such as septic arthritis, myositis, or osteomyelitis (30,32). Laboratory findings of anemia, neutrophil leukocytosis, thrombocytopenia, and DIC are often present, together with impaired renal function, hepatic derangement, and acidosis. Acute renal failure requiring dialysis occurs in a significant proportion of cases.

The reason for the emergence of streptococcal toxic shock syndrome and the increasing numbers of cases with invasive disease caused by the GAS is unclear. Strains causing toxic shock syndrome and invasive disease appear to differ from common isolates of GAS in producing large amounts of pyrogenic toxins that may have superantigen-like activity. The pathophysiology of streptococcal toxic shock syndrome and that of the streptococcal toxins are similar in that both

organisms produce superantigen toxins that induce release of cytokines and other inflammatory mediators.

Treatment of streptococcal toxic shock syndrome depends on the administration of appropriate antibiotics, aggressive circulatory support, and treatment of any multiorgan failure. Surgical intervention to drain the infective focus in muscle, bone, joint, or body cavities is often required. Recovery of renal function occurs in patients who respond to treatment of shock and the eradication of the infection.

Leptospira

Leptospirosis is an acute generalized infectious disease caused by spirochetes of the genus *Leptospira* (33). It is primarily a disease of wild and domestic animals, and humans are infected only occasionally through contact with animals. Most human cases occur in summer or autumn and are associated with exposure to leptospire-contaminated water or soil during recreational activities such as swimming or camping. In adolescents and adults, occupational exposure through farming or other contact with animals is the route of infection.

The spirochete penetrates intact mucous membranes or abraded skin and disseminates to all parts of the body, including the cerebrospinal fluid (CSF). Although leptospire do not contain classic endotoxins, the pathophysiology of the disorder has many similarities to that of endotoxemia. In severe cases, jaundice occurs because of hepatocellular dysfunction and cholestasis. Renal functional abnormalities may be profound and out of proportion to the histologic changes in the kidney (34). Renal involvement is predominantly a result of tubular damage, and spirochetes are commonly seen in the tubular lesions. The inflammatory changes in the kidney may result from either a direct toxic effect of the organism or immune-complex nephritis. However, hypovolemia, hypotension, and reduced cardiac output caused by myocarditis may contribute to the development of renal failure. In severe cases, a hemorrhagic disorder caused by widespread vasculitis and capillary injury also occurs (34,35).

The clinical manifestations of leptospirosis are variable. Of affected patients, 90% have the milder anicteric form of the disorder, and only 5 to 10% have severe leptospirosis with jaundice. The illness may follow a biphasic course. After an incubation period of 7 to 12 days, a nonspecific flu-like illness lasting 4 to 7 days occurs, associated with septicemic spread of the spirochete. The fever then subsides, only to recur for the second, "immune," phase of the illness. During this phase, the fever is low grade and there may be headache and delirium caused by meningeal involvement, as well as intense muscular aching. Nausea and vomiting are common. Examination usually reveals conjunctival suffusion, erythematous rash, lymphadenopathy, and meningism.

The severe form of the disease (Weil disease) presents with fever, impaired renal and hepatic function, hemorrhage, vascular collapse, and altered consciousness. In one

series the most common organs involved were the liver (71%) and kidney (63%). Cardiovascular (31%), pulmonary (26%), neurologic (5%), and hematologic (21%) involvements were less common (36). Vasculitis, thrombocytopenia, and uremia are considered important factors in the pathogenesis of hemorrhagic disturbances and the main cause of death in severe leptospirosis (37). Urinalysis results are abnormal during the leptospiremic phase with proteinuria, hematuria, and casts. Uremia usually appears in the second week, and acute renal failure may develop once cardiovascular collapse and DIC are present (35).

The clinical features of leptospirosis overlap with those of several other acute infectious diseases, including Rocky Mountain spotted fever, toxic shock syndrome, and streptococcal sepsis. The diagnosis of leptospirosis should be considered in febrile patients with evidence of renal, hepatic, and mucous membrane changes and rash, particularly if a history of exposure to fresh water is found. Diagnosis can be confirmed by isolation of the spirochetes from blood or CSF in the first 10 days of the illness or from urine in the second week (35). The organism may be seen in biopsy specimens of the kidney or skin or in the CSF by dark-field microscopy or silver staining. Serologic tests to detect leptospirosis are now sensitive and considerably aid the diagnosis. Immunoglobulin M (IgM) antibody may be detected as early as 6 to 10 days into the illness, and antibody titers rise progressively over the next 2 to 4 weeks. Some patients remain seronegative, and negative serologic test results do not completely exclude the diagnosis. In one series levels of IgM and IgG anticardiolipin concentrations were significantly increased in leptospirosis patients with acute renal failure (37). Leptospirosis is treated with intravenous penicillin or other β -lactam antibiotics. The severity of leptospirosis is reduced by antibiotic treatment, even if started late in the course of the illness (38). Supportive treatment with volume replacement to correct hypovolemia, administration of inotropics, and correction of coagulopathy is essential in severe cases. Dialysis may be required in severe cases and may be needed for prolonged periods until recovery occurs.

Streptococcus pneumoniae

Infection with *S. pneumoniae* is one of the most common infections in humans and causes a wide spectrum of disease, including pneumonia, otitis media, sinusitis, septicemia, and meningitis. Despite the prevalence of the organism, significant renal involvement is relatively rare but is seen in two situations: Pneumococcal septicemia in asplenic individuals or in those with other immune deficiencies presents with fulminant septic shock in which renal failure may occur as part of a multisystem derangement. The mortality from pneumococcal sepsis in asplenic patients is high, even with early antibiotic treatment and intensive support.

The second nephrologic syndrome associated with *S. pneumoniae* is a rare form of HUS. In 1955, Gasser and colleagues described HUS as a clinical entity in children, and they included two infants with pneumonia among the five patients

they described (39). HUS associated with *Pneumococcus* infection is induced by the enzyme neuraminidase released from *S. pneumoniae* (40,41). Thomsen-Friedenrich antigen (T antigen) is present on the surface of red blood cells, platelets, and glomerular capillary endothelia against which antibodies are present in normal serum. Neuraminidase causes desialation of red blood cells, and possibly other blood cells and endothelium, by the removal of terminal neuraminic acid, which leads to unmasking of the T antigen. The resultant widespread agglutination of blood cells causes intravascular obstruction, hemolysis, thrombocytopenia, and renal failure. Results of the direct Coombs test are frequently positive, either from bound anti-T IgM or from anti-T antibodies. The diagnosis of Thomsen-Friedenrich antibody-induced HUS should be suspected in patients with acute renal failure and hemolysis after an episode of pneumonia or bacteremia caused by *S. pneumoniae*.

Association with *S. pneumoniae* is defined by culture of pneumococci from a normally sterile site within a week before or after onset of signs of HUS. Clues to a pneumococcal cause, in addition to culture results, include severe clinical disease, especially pneumonia, empyema, pleural effusion, or meningitis; hemolytic anemia without a reticulocyte response; positive results on a direct Coombs test; and difficulties in ABO crossmatching or a positive minor crossmatch incompatibility (42). However, when renal disease is seen in the context of severe pneumococcal infection, it is important to maintain a broad diagnostic perspective, because the occurrence of acute tubular necrosis due to septic shock and DIC is well described (43,44).

Therapy for this syndrome should be with supportive treatment and antibiotics (usually penicillin); dialysis may be required if renal failure occurs. Because normal serum contains antibodies against the Thomsen-Friedenrich antigen, blood transfusion should be undertaken with washed red blood cells resuspended in albumin rather than plasma (40,41). Exchange transfusion and plasmapheresis have been used in some patients, with the rationale that these procedures may improve outcome by eliminating circulating neuraminidase (40,44,45). Intravenous IgG has been used in a patient and was shown to neutralize neuraminidase present in the patient's serum (46).

In comparison to patients with the more common diarrhea-associated HUS, *S. pneumoniae*-induced HUS patients have a more severe renal disease. They are more likely to require dialysis. Their long-term outcome may be affected by the severity of the invasive streptococcal disease itself, and a significant proportion of surviving patients (30 to 70%) develop end-stage renal failure (47,48).

Gastrointestinal Infections (*Escherichia coli*, *Salmonella*, *Campylobacter*, *Yersinia*, *Shigella*, *Vibrio cholerae*)

The diarrheal diseases caused by *Escherichia coli*, *Salmonella*, *Shigella*, *Campylobacter*, vibrios, and *Yersinia* remain impor-

tant and common bacterial infections of humans. Although improvements in hygiene and living conditions have reduced the incidence of bacterial gastroenteritis in developed countries, these infections remain common in underdeveloped areas of the world, and outbreaks and epidemics continue to occur in both developed and underdeveloped countries. Renal involvement in the enteric infections may result from any of four possible mechanisms.

Severe Diarrhea and Dehydration

Regardless of the causative organism, diarrhea results in hypovolemia, abnormalities of plasma electrolyte composition, and renal underperfusion. If severe dehydration occurs and is persistent, oliguria from prerenal failure is followed by vasomotor nephropathy and established renal failure.

Systemic Sepsis and Endotoxemia

E. coli, *Shigella*, and *Salmonella* (particularly *Salmonella typhi*) may invade the bloodstream and induce septicemia or septic shock. Acute renal failure is commonly seen in infants with *E. coli* sepsis but is also reported with *Klebsiella*, *Salmonella*, and *Shigella* infections. Its pathophysiology and treatment were discussed previously.

Enteric Pathogen–Associated Nephritis

Enteric infections with *E. coli*, *Yersinia*, *Campylobacter*, and *Salmonella* have been associated with several different forms of GN, including membranoproliferative GN (MPGN), interstitial nephritis, diffuse proliferative GN, and IgA nephropathy (49–51).

In typhoid fever, GN ranging from mild asymptomatic proteinuria and hematuria to acute renal failure may occur (50,52–54). Renal biopsy findings show focal proliferation of mesangial cells, hypertrophy of endothelial cells, and congested capillary lumina. Immunofluorescent studies show IgM, IgG, and C3 deposition in the glomeruli, with *Salmonella* antigens detected within the granular deposits in the mesangial areas. In the IgA nephropathy after typhoid fever, *Salmonella* vi antigens have been demonstrated within the glomeruli.

Yersinia infection has been reported as a precipitant of GN in several studies (51,55). Transient proteinuria and hematuria are found in 24% of patients with acute *Yersinia* infection, and elevated creatinine levels in 10%. Renal biopsy reveals mild mesangial GN or IgA nephropathy. *Yersinia* antigens, immunoglobulin, and complement have been detected in the glomeruli. *Yersinia pseudotuberculosis* is well recognized as one of the causes of acute tubulointerstitial nephritis causing acute renal failure, especially in children; patients have histories of drinking untreated water in endemic areas (56–58). The illness begins with the sudden onset of high fever, skin rash, and GI symptoms. Later in the

course, periungual desquamation develops, mimicking Kawasaki disease. Elevated erythrocyte sedimentation rate, C-reactive protein level, and thrombocytosis are noticeable, and mild degrees of proteinuria, glycosuria, and sterile pyuria are common. Acute renal failure, which typically develops 1 to 3 weeks after the onset of fever, follows a benign course with complete recovery. Renal biopsy mainly reveals findings of acute tubulointerstitial nephritis. Antibiotic therapy, although recommended, does not alter the clinical course, but reduces the fecal excretion of the organism (59,60).

Enteric Pathogen–Induced Hemolytic Uremic Syndrome

HUS is characterized by three distinct clinical signs: acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia. It was first described in 1955 and was associated with infection by Shiga toxin–producing *Shigella dysenteriae*. A major breakthrough in the search for the cause of HUS occurred in the 1980s when Karmali et al. reported that 11 of 15 children with diarrhea-associated HUS had evidence of infection with a strain of *E. coli* that produced a toxin active on vero cells (61). In diarrhea-associated HUS in the United States and most of Europe, *E. coli* O157:H7 is the most important of these strains. *E. coli* O157:H7 occurs naturally in the GI tract of cattle and other animals, and humans become infected through contaminated food products. Most outbreaks have been associated with consumption of undercooked meat, but unpasteurized milk and cider, drinking water, and poorly chlorinated water for recreational use have also been implicated as vehicles for bacterial spread. HUS is discussed in detail in Chapter 47.

Mycobacterium tuberculosis

The global epidemic of *Mycobacterium tuberculosis* is growing. Several factors have contributed to this increase, including the emergence of the human immunodeficiency virus (HIV) infection epidemic, large influxes of immigrants from countries in which tuberculosis (TB) is common, the emergence of multiple-drug–resistant *M. tuberculosis*, and breakdown of the health services for effective control of TB in various countries. It is generally estimated that, overall, one-third of the world's population is currently infected with the TB bacillus. There are more than 8 million cases of TB, which result in the death of approximately 2 million people each year. Furthermore, 5 to 10% of people who are infected with the TB bacillus develop TB disease or become infectious at some time during their lives (62,63). After respiratory illness in children, mycobacteria are widely distributed to many organs of the body during the lymphohematogenous phase of childhood TB (64). Tubercle bacilli can be recovered from the urine in many cases of miliary TB. Hematogenously spread tuberculomata develop in the glomeruli, which results in caseating, sloughing lesions that discharge

bacilli into the tubules. In most cases, the renal lesions are asymptomatic and manifest as mycobacteria in the urine or as sterile pyuria.

Tuberculomata in the cortex may calcify and cavitate or may rupture into the pelvis, discharging infective organisms into the tubules, urethra, and bladder. Dysuria, loin pain, hematuria, and pyuria are the presenting features of this complication, but in many cases, the renal involvement is asymptomatic, even when radiologic and pathologic abnormalities are very extensive. Continuing tuberculous bacilluria may cause cystitis with urinary frequency and, in late cases, a contracted bladder (65). The intravenous urogram is abnormal in most cases. Early findings are pyelonephritis with calyceal blunting and calyceal-interstitial reflux. Later, papillary cavities may be seen, indicating papillary necrosis. Ureteric strictures, focal calcification, hydronephrosis, and cavitation may also be seen. Renal function is usually well preserved, and hypertension is uncommon. In some cases, either the infection itself or reactions to the chemotherapeutic agents may result in renal failure with evidence of an interstitial nephritis (65–67).

Classic symptomatic renal TB is a late and uncommon complication in children, rarely occurring less than 4 or 5 years after the primary infection, and therefore is most commonly diagnosed after adolescence (64,66). Adult studies have shown that 26 to 75% of renal TB coexists with active pulmonary TB and 6 to 10% of screened sputum-positive pulmonary TB patients have renal involvement.

The diagnosis is established by isolation of mycobacteria from the urine or by the presence of the characteristic clinical and radiographic features in a child with current or previous TB. Renal TB is treated with drug regimens similar to those used for other forms of TB, with isoniazid, rifampicin, and pyrazinamide administered initially for 2 months, and isoniazid and rifampicin then continued for a further 7 to 10 months. Late scarring and urinary obstruction may occur in cases with extensive renal involvement, and such patients should be followed by ultrasonography or intravenous urogram.

Mycobacteria, both *M. tuberculosis* and atypical mycobacteria, have also emerged as important causes of opportunistic infection in immunocompromised patients undergoing dialysis and in patients undergoing renal transplantation. The possibility of mycobacterial disease must be considered in patients with fever of unknown origin or unexplained disease in the lungs or other organs. Results of the Mantoux test are usually negative, and diagnosis depends on maintaining a high index of suspicion and isolating the organism from the infected site.

Treponema pallidum

Renal involvement has been well documented in both congenital and acquired syphilis, with an estimated occurrence of 0.3% in patients with secondary syphilis and up to 5%

in those with congenital syphilis (68,69). The most common manifestation of renal disease in congenital syphilis is the nephrotic syndrome, with proteinuria, hypoalbuminemia, and edema. In some patients, hematuria, uremia, and hypertension may be seen. The renal disease is usually associated with other manifestations of congenital syphilis, including hepatosplenomegaly, rash, and mucous membrane findings.

Nephritis in congenital syphilis is usually associated with evidence of complement activation, with depressed levels of C1q, C4, C3, and C5. Histologic findings are a diffuse proliferative GN or a membranous nephropathy. The interstitium shows a cellular infiltrate of polymorphonuclear and mononuclear cells (70). Immunofluorescent microscopy reveals diffuse granular deposits of IgG and C3 along the glomerular basement membrane (GBM). Mesangial deposits may also contain IgM. On electron microscopy, scattered subepithelial electron-dense deposits are seen, with fusion of epithelial cell foot processes (70).

Good evidence exists that renal disease is due to an immunologically mediated reaction to treponemal antigens. Antibodies reactive against treponemal antigens can be eluted from the glomerular deposits, and treponemal antigens are present in the immune deposits. Treatment of both congenital and acquired syphilis with antibiotics results in rapid improvement in the renal manifestations (68,70).

Mycoplasma pneumoniae

Renal involvement is surprisingly rare in *Mycoplasma pneumoniae* infection considering the prevalence of this organism and its propensity to trigger immunologically mediated diseases such as erythema multiforme, arthritis, and hemolysis. Acute nephritis associated with *Mycoplasma* infection may occur 10 to 40 days after the respiratory tract infection (71,72). Renal histopathologic findings include type 1 MPGN, proliferative endocapillary GN, and minimal change disease (73). Antibiotic treatment of the infection does not appear to affect the renal disease, which is self-limited in most cases (71,72).

RICKETTSIAL DISEASES

The rickettsial diseases are caused by a family of microorganisms that have characteristics common to both bacteria and viruses and that cause acute febrile illnesses associated with widespread vasculitis. With the exception of Q fever, all are associated with erythematous rashes. There are four groups of rickettsial diseases:

1. The typhus group includes louse-borne and murine typhus, spread by lice and fleas, respectively.
2. The spotted fever group includes Rocky Mountain spotted fever, tick typhus, and rickettsial pox, which

are spread by ticks and mites, with rodents as the natural reservoir.

3. Scrub typhus is spread by mites.
4. Q fever is spread by inhalation of infected particles from infected animals.

Rickettsial diseases have a worldwide distribution and vary widely in severity, from self-limited infections to fulminant and often fatal illnesses (74). In view of the widespread vasculitis associated with these infections, subclinical renal involvement probably occurs in many of the rickettsial diseases. However, in Rocky Mountain spotted fever, tick typhus, and Q fever, the renal involvement may be an important component of the illness.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is the most severe of the rickettsial diseases (75,76). The onset occurs 2 to 8 days after the bite of an infected tick. High fever develops initially, followed by the pathognomonic rash, which occurs between the second and sixth days of the illness. The rash initially consists of small erythematous macules, but later these become maculopapular and petechial, and in untreated patients, confluent hemorrhagic areas may be seen. The rash first appears at the periphery and spreads up the trunk. Involvement of the palms and soles is a characteristic feature (74).

Headache, restlessness, meningism, and confusion may occur together with other neurologic signs. Cardiac involvement with congestive heart failure and arrhythmia are common. Pulmonary involvement occurs in 10 to 40% of cases. Infection is associated with an initial leukopenia, followed by neutrophil leukocytosis. Thrombocytopenia occurs in most cases.

Histopathologically, the predominant lesions are in the vascular system (77). Rickettsiae multiply in the endothelial cells, which results in focal areas of endothelial cell proliferation, perivascular mononuclear cell infiltration, thrombosis, and leakage of red cells into the tissues. The renal lesions involve both blood vessels and interstitium, and acute tubular necrosis may occur. Acute GN with immune-complex deposition has been reported (78), but in most cases the pathology appears to be a direct consequence of the invading organism on the renal vasculature (76,79).

Renal dysfunction is an important complication of Rocky Mountain spotted fever. Elevation of urea and creatinine levels occurs in a significant proportion of cases, and acidosis is common. Prerenal renal failure caused by hypovolemia and impaired cardiac function may respond to volume replacement and inotropic support, but acute renal failure may subsequently occur, necessitating dialysis.

Rocky Mountain spotted fever is diagnosed by the characteristic clinical picture, the exclusion of disorders with similar manifestations (e.g., measles, meningococcal disease, and leptospirosis), and detection of specific antibodies

in convalescence. Culture of *Rickettsia rickettsii*, immunofluorescent staining, and polymerase chain reaction (PCR) testing of blood and skin biopsy specimens are available only in reference laboratories. Antibiotics should be administered in suspected cases without awaiting confirmation of the diagnosis (79). Doxycycline is the drug of choice for children of any age. Chloramphenicol is also effective (80). Intensive support of shock and multiorgan failure may be required in severe cases, and peritoneal dialysis or hemodialysis may be required until renal function returns. Before the advent of specific therapy, mortality was 25%. Today the overall mortality in the United States is still 5 to 7%. Death predominantly occurs in cases in which the diagnosis is delayed.

Q Fever

Q fever is caused by *Coxiella burnetii* and has a worldwide distribution, with the animal reservoir being cattle, sheep, and goats. Human infection follows inhalation of infected particles from the environment. The clinical manifestations range from an acute self-limited febrile illness with atypical pneumonia to involvement of specific organs that causes endocarditis, hepatitis, osteomyelitis, and central nervous system disease (81).

Proliferative GN may be associated with either Q fever endocarditis or a chronic infection elsewhere in the body (82). Renal manifestations range from asymptomatic proteinuria and hematuria to acute renal failure, hypertension, and nephrotic syndrome. Renal histologic findings are those of a diffuse proliferative GN, focal segmental GN, or mesangial GN. Immunofluorescent studies reveal diffuse glomerular deposits of IgM in the mesangium, together with C3 and fibrin. *C. burnetii* antigen has not been identified within the renal lesions.

Treatment of the underlying infection may result in remission of the renal disease, but prolonged treatment may be required for endocarditis. Tetracycline has been used in conjunction with rifampicin, co-trimoxazole, or a fluoroquinolone.

Legionnaires' Disease

Since its recognition in 1976, Legionnaires' disease, caused by *Legionella pneumophila*, has emerged as an important cause of pneumonia. The disease most commonly affects the elderly but has been reported in both normal and immunocompromised children (83,84). Renal dysfunction occurs in a minority of patients (84). Patients who develop renal impairment present with oliguria and rising urea and creatinine levels. They are usually severely ill, with bilateral pulmonary infiltrates, fever, and leukocytosis. Shock may be present, and the renal impairment has been associated with acute rhabdomyolysis with high levels of creatine phosphokinase and myoglobinuria. Renal histologic examination usually shows a tubulointerstitial

nephritis or acute tubular necrosis (84,85). The pathogenesis of the renal impairment is uncertain, but the organism has been detected within the kidney on electron microscopy and immunofluorescent studies, which suggests a direct toxic effect. Myoglobinuria and decreased perfusion may also be contributing factors, however. Mortality has been high in reported cases of Legionnaires' disease complicated by renal failure. Treatment is based on dialysis, intensive care, and antimicrobial therapy with erythromycin (84). Steroid therapy may be effective for tubulointerstitial nephritis (85).

INTRAVASCULAR AND FOCAL INFECTIONS

Nephritis has been reported in association with the presence of a wide range of microorganisms that cause chronic or persistent infection (Table 51.2) (49,86). It is likely that any infectious agent that releases foreign antigens into the circulation, including those of very low virulence, can cause renal injury either by deposition of foreign antigens in the kidney or by the formation of immune complexes in the circulation, which are then deposited within the kidney. Nephritis is most commonly seen in association with intravascular infections such as SBE or infected ventriculoatrial shunts, but it is also seen after focal extravascular infections; ear, nose, and throat infections; and abscesses.

Bacterial Endocarditis

Renal involvement is one of the diagnostic features of bacterial endocarditis. Virtually all organisms that cause endocarditis also produce renal involvement (Table 51.2). Although endocarditis caused by bacteria is the most common and is readily diagnosed by blood culture (86), unusual but important causes of culture-negative endocarditis include Q fever (87) and *Legionella* infection (88). In the immunocompromised individual, opportunistic pathogens such as fungi and mycobacteria are important causes.

The usual renal manifestations of SBE are asymptomatic proteinuria, hematuria, and pyuria. Loin pain, hypertension, nephrotic syndrome, and renal failure may occur in more severe cases.

The renal lesions occurring in endocarditis are variable, and focal embolic and immune-complex-mediated features may coexist (86,89,90). Embolic foci may be evident as areas of infarction, intracapillary thrombosis, or hemorrhage. More commonly, there is a focal necrotizing or diffuse proliferative GN. Immunofluorescent studies show glomerular deposits of IgG, IgM, IgA, and C3 along the GBM and within the mesangium. Electron microscopy reveals typical electron-dense deposits along the GBM and within the mesangium (86,89,90).

Early reports suggested that the renal lesions were caused by microemboli from infected vegetations depositing in the kidney, a hypothesis supported by the occasional presence of bac-

TABLE 51.2. FOCAL INFECTIONS CAUSING GLOMERULONEPHRITIS

Site of infection	Organism
Infective endocarditis	Coagulase-negative staphylococci <i>Staphylococcus aureus</i> Pneumococci Viridans streptococci Enterococci Anaerobic streptococci Diphtheroids <i>Haemophilus influenzae</i> Coliforms <i>Bacteroides</i> <i>Coxiella burnetii</i> <i>Legionella</i> <i>Candida albicans</i>
Shunt infections	Coagulase-negative staphylococci <i>S. aureus</i> Diphtheroids Gram-negative bacilli Anaerobes
Focal abscess	<i>S. aureus</i> Gram-negative bacilli
Osteomyelitis	<i>S. aureus</i> /streptococci
Pyelonephritis	Coliforms
Pneumonia	<i>Streptococcus pneumoniae</i> <i>Klebsiella</i> <i>S. aureus</i> <i>Mycoplasma</i>
Otitis media	Pneumococcus/ <i>S. aureus</i>
Gastrointestinal infection	<i>Yersinia</i> , <i>Campylobacter</i> <i>Salmonella</i> , <i>Shigella</i>

teria within the renal lesions. Most subsequent evidence, however, indicates that immunologic mechanisms rather than emboli are involved in the pathogenesis in most cases: bacteria are rarely found within the kidney, and renal involvement occurs with lesions of the right side of the heart, which would not be likely to embolize to the kidney. Immune complexes containing bacterial antigens are present in the circulation, and both bacterial antigens and bacteria-specific antibodies can be demonstrated within the immune deposits in the kidney. Serum C3 level is usually low, and complement can be found within both the circulating and the deposited immune complexes. These features all support an immune-complex-mediated pathogenesis of the renal injury (86,89,90).

Treatment of the endocarditis with antibiotics usually results in resolution of the GN and is associated with the disappearance of immune complexes from the circulation and return of C3 levels to normal. The prognosis of the renal lesions in SBE generally depends on the response of the underlying endocarditis to antibiotics or, in cases of antibiotic failure, to surgical removal of the infective vegetations (91).

Shunt Nephritis

The well-documented association of GN with infected ventriculoatrial shunts is another example of an immune-complex

nephritis similar to that seen in endocarditis (92). Coagulase-negative staphylococci are the causative organisms in 75% of cases. The clinical and pathologic findings are similar to those in SBE. Presenting features are proteinuria, hematuria, and pyuria, and they may progress to renal failure. Immune complexes containing the bacterial antigens and complement are present in the serum, and C3 is depressed. Histologic findings are those of a diffuse mesangiocapillary GN. Immunofluorescent microscopy demonstrates deposits of immunoglobulin and C3 along the GBM, and bacterial antigen can be demonstrated in the renal lesions (93).

The prognosis for the renal lesion is good if the infection is treated early. This usually involves removal of the infected shunt and administration of appropriate antibiotics (92,94). The possible progression to end-stage renal disease requires frequent nephrologic monitoring of patients with ventriculoatrial shunts (92). There are a few reports in the literature of a similar renal complication occurring in chronic infection of ventriculoperitoneal shunts.

Other Focal Infections

GN has been reported after chronic abscesses (49), osteomyelitis, otitis media, pneumonia, and other focal infections (Table 51.2). Acute renal failure has been the presenting feature of focal infections in various sites, including the lung, pleura, abdominal cavity, sinuses, and pelvis. Many different organisms have been responsible, including *S. aureus*, *Pseudomonas*, *E. coli*, and *Proteus* species. This is probably another example of immune-complex GN. C3 level is decreased in approximately one-third of reported cases, and immunofluorescent studies reveal diffuse granular deposits of C3 in the glomeruli of all reported instances, with a variable presence of immunoglobulin. The renal lesion is that of MPGN and crescentic nephritis. The renal outcome is reported to be good with successful early treatment of the underlying infection.

VIRAL INFECTIONS

The role of viral infections in the causation of renal disease has been less well defined than that of bacterial infections. Clearly defined associations of renal disease have been made with hepatitis B virus (HBV), hepatitis C virus (HCV), HIV, and hantaviruses, but the role of most other viruses in the pathogenesis of renal disease is not clearly defined. Most viruses causing systemic infection may trigger immunologically mediated renal injury. With increasing application of molecular techniques, it may be that a significant proportion of GNs currently considered to be idiopathic will ultimately be shown to be virus induced. In children with immunodeficiency states and those undergoing renal transplantation, viruses such as cytomegalovirus (CMV) and polyoma virus have been recognized to be associated with nephropathy.

Hepatitis B Virus

Since the discovery of hepatitis B surface antigen (HB_sAg) in 1964, hepatitis virus has been shown to infect more than 5% of the world's population and is a major cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma worldwide. Some 150 million to 200 million people have HB_sAg in the circulation. The infection is most common in Africa and the Orient, where it is acquired in childhood by vertical transmission from infected mothers or by horizontal transmission from other children or adults. In developed countries, transmission in adults occurs more often by blood product exposure, sexual contact, or intravenous drug use.

HBV is a complex DNA virus with an outer surface envelope (HB_sAg) and an inner nucleocapsid core containing the hepatitis B core antigen (HB_cAg), DNA polymerase, protein kinase activity, and viral DNA. Incomplete spherical and filamentous viral particles consisting solely of HB_sAg are the major viral products in the circulation and may be present in concentrations of up to 10¹⁴ particles per milliliter of serum. Hepatitis B e antigen (HB_eAg) can be released from HB_cAg by proteolytic treatment and may be found in the circulation either free or complexed to albumin or IgG antibodies. The presence of HB_eAg correlates with the presence of complete viral particles and the infectivity of the individual (95).

Infection with HBV may result in either a self-limited infectious hepatitis followed by clearance of the virus and complete recovery, or a chronic or persistent infection in which the immune response is ineffective in eliminating the virus. Chronic HBV infection with continued presence of viral antigens in the circulation caused by an ineffective host immune response provides the best-documented example of immunologically mediated renal injury caused by persistent infection (96).

Patterns of Hepatitis B Virus Immunologically Mediated Renal Disease

Serum Sickness

A serum sickness–like illness occurs in 10 to 25% of patients in the early prodromal phase of HBV hepatitis. Fever, maculopapular or urticarial rash, and transient arthralgias or arthritis are common. Occasionally, proteinuria, hematuria, or sterile pyuria are observed. The syndrome usually lasts 3 to 10 days and often resolves before the onset of jaundice (96,97). There have been no histologic studies of the renal changes during HBV serum sickness.

Hepatitis B Virus–Associated Polyarteritis Nodosa

Since 1970, numerous reports have linked HBV infection with polyarteritis nodosa (PAN). Most of these cases have been in adults, but the disorder has also been reported in children (98,99). HBV-associated PAN most commonly occurs after intravenous acquisition of the virus, often dur-

ing intravenous drug usage. HBV PAN appears to be uncommon in Africa and the Orient, where infection is usually acquired in childhood.

HBV PAN presents weeks to months after a clinically mild hepatitis but may occasionally predate the hepatitis. After a serum sickness–like illness, frank vasculitis affecting virtually any organ appears. Abdominal pain, fever, mononeuritis multiplex, and pulmonary and renal involvement may occur. The renal involvement may appear as hypertension, hematuria, proteinuria, or renal failure (see Chapter 44). Laboratory investigations reveal a florid acute-phase response, leukocytosis, and anemia. Transaminase levels are usually elevated, and HB_sAg is present in the circulation. The pathology consists of focal inflammation of small and medium-sized arteries, with fibrinoid necrosis, leukocyte infiltration, and fibrin deposition. Renal pathology may be limited to the medium-sized arteries or may coexist with GN (96,100).

Circulating immune complexes containing HB_sAg and anti-HB_s antibodies are usually present in the circulation (96,100). C3, C4, and total hemolytic complement levels are depressed. HB_sAg, IgG, and IgM antibodies to HBV and C3 have been identified by immunofluorescence in the blood vessels (100). Although most evidence suggests that the pathogenesis involves an immune-complex-mediated vasculitis, autoantibody or cell-mediated vascular injury may coexist. If the condition is untreated, the mortality is high (98). Most studies suggest that steroids or immunosuppressants help to suppress the vasculitis but potentially predispose to chronic infection or progressive liver disease (96,98). Successful treatment of hepatitis B–associated PAN with lamivudine, a nucleoside analogue, either alone or in combination with interferon-alpha and conventional immunosuppressive therapy, have been reported (101–103).

Hepatitis B Virus–Associated Membranous Glomerulonephritis

HBV is now the major cause of membranous GN (MGN) in children worldwide. The proportion of patients with MGN caused by HBV is directly related to the incidence of HB_sAg in the population, with 80 to 100% of all cases of MGN in some African and Oriental countries being associated with HBV (96,104) (see Chapter 33).

HBV MGN usually presents in children aged 2 to 12. There is a striking male predominance; in the United States, 80% of patients are males (105). The virus is usually acquired by vertical transmission from infected mothers or horizontally from infected family members. Unlike adults with HBV MGN, children do not usually have a history of hepatitis or of active liver disease, but liver function test results are generally mildly abnormal. Liver biopsy specimens may show minimal abnormalities, chronic persistent hepatitis, or (occasionally) more severe changes (105).

The renal manifestations are usually of proteinuria, nephrotic syndrome, microscopic hematuria, or (rarely) macro-

scopic hematuria. Hypertension occurs in less than 25% of cases, and renal insufficiency is rare.

HB_sAg and HB_eAg are usually present in the circulation, and HB_e antigenemia is seen in a high proportion of cases. Occasionally, HB_sAg may be found in the glomeruli but is absent from the circulation. C3 and C4 levels are often low, and circulating immune complexes are found in most cases.

Immunohistologic study reveals deposits of IgG and C3 and (less commonly) IgM and IgA in subepithelial, subendothelial, or mesangial tissue. HBV particles may be seen on electron microscopy, and all the major hepatitis B antigens, including HB_sAg, HB_eAg, and HB_cAg, have been localized in the glomerular capillary wall on immunofluorescence.

Immunologic deposition of HBV and antibody in the glomerular capillary wall is clearly involved in the glomerular injury, but the underlying immunologic events are incompletely understood (96,106). Passive trapping of circulating immune complexes may be involved, but the circulating immune complexes containing HB_sAg are usually larger than would be expected to penetrate the basement membrane. HB_sAg and HB_eAg are anionic and are therefore unlikely to penetrate the glomerular capillary wall. In contrast, HB_cAg forms smaller complexes with anti-HB_e antibodies and may readily penetrate the GBM. This may explain the observation that HB_cAg in the circulation frequently correlates with the severity of the disease (96). An alternative mechanism for immune-mediated glomerular injury is the trapping of HBV antigens by antibody previously deposited in the kidney. Anti-HB_e antibodies are cationic and may readily localize in the glomerulus and subsequently bind circulating antigen and complement. The third possibility is that the depositions of HBV and antibodies are consequences of glomerular injury by cellular mechanisms or autoantibodies. Little evidence supports this view at present (96).

Other Hepatitis B Virus Glomerulonephritides

HBV infection has been associated with a variety of other forms of GN in both adults and children. In a recent series in children MPGN was found to be equal in incidence to MGN in the spectrum of HBV-associated GNs (107). Both MPGN and mesangial proliferative GN may be triggered by HBV. In several countries where HBV is common, the proportion of patients with these forms of nephritides who test positive for HBV greatly exceeds the incidence of positivity in the general population (106). As with MGN and HBV-associated PAN, circulating immune complexes and localization of HBV antigens in the glomeruli have been reported in both MPGN and mesangial proliferative GN, and it is likely that similar mechanisms are occurring (96,108). Several other forms of GN have been associated with HBV, including IgA nephropathy, focal glomerulosclerosis, crescentic nephritis, and systemic lupus erythematosus, but the evidence for these associations is less consistent than for the entities discussed earlier (108).

Treatment of Hepatitis B Virus Glomerulonephritis

HBV is normally cleared as a result of cell-mediated responses in which cytotoxic T cells and natural killer cells eliminate infected hepatocytes. It is not surprising, therefore, that the administration of steroids and immunosuppressive agents either may have no effect on HBV disease or may increase the risk of progressive disease (109). Children with HBV MGN have a good prognosis, and two-thirds undergo spontaneous remission within 3 years of diagnosis. Steroid therapy does not appear to provide any additional benefit (96,104,110). Antiviral therapy with interferon-alpha and lamivudine shows promise in facilitating clearance of HBV, and reports of elimination of the infection with antiviral therapy in both children and adults, together with improvement or resolution of the coexisting renal disease, are increasing (110–113).

Hepatitis C Virus

HCV is an enveloped, single-stranded RNA virus of approximately 9.4 kilobases in the Flaviviridae family. There are six major HCV genotypes. Hepatitis C is a common disease affecting approximately 400 million people worldwide. In the United States, 3.9 million persons are estimated to be anti-HCV positive, and 2.7 million may be chronically infected (114). An estimated 240,000 children in the United States have antibody to HCV and 68,000 to 100,000 are chronically infected (115). Children become infected through receipt of contaminated blood products or through vertical transmission. The risk of vertical transmission increases with higher maternal viremia and maternal co-infection with HIV.

Acute HCV infection is rarely recognized in children outside of special circumstances such as a known exposure from an HCV-infected mother or after blood transfusion. Most chronically infected children are asymptomatic and have normal or only mildly abnormal alanine aminotransferase levels. Although the natural history of HCV infection during childhood seems benign in the majority of instances, the infection can take an aggressive course in a proportion of children, leading to cirrhosis and end-stage liver disease during childhood. The factors responsible for this more aggressive course are unidentified (115). Even in adults, the natural history of HCV infection has a variable course, but a significant proportion of patients will develop some degree of liver dysfunction, and 20 to 30% will eventually have end-stage liver disease as a result of cirrhosis. The risk of hepatocellular carcinoma is significant for those who have established cirrhosis. Hepatitis C is currently the most common condition leading to liver transplantation in adults in the Western world.

GN has been described as an important complication of chronic infection with HCV in adults. The clinical presenta-

tion is usually of nephrotic syndrome or proteinuria, hypertension, or hematuria, with or without azotemia (116). MPGN, with or without cryoglobulinemia, and MGN are most commonly described. Isolated case reports of other, more unusual patterns of glomerular injury, including IgA nephropathy, focal segmental glomerulosclerosis, crescentic GN, fibrillary GN, and thrombotic microangiopathy, have also been associated with HCV infection (116,117). Glomerular deposition of hepatitis antigens and antibodies has been described and is believed to play a role in pathogenesis. Cryoglobulinemia is a common accompaniment of GN that is associated with the depression of serum complement levels (116). Renal failure may develop in 40 to 100% of patients who have MPGN (116,118). The presence of virus-like particles as well as viral RNA within the kidney sections of patients with HCV-associated glomerulopathies has been reported (119).

The diagnosis should be suspected if glomerular disease is associated with chronic hepatitis, particularly with the presence of cryoglobulins, but renal biopsy is necessary to establish a definitive diagnosis.

HCV infection is relatively common in children with end-stage renal disease and is an important cause of liver disease in this population. Acquisition of HCV infection continues to occur in dialysis patients because of nosocomial spread (120). Elevation of transaminase level is not a sensitive marker of infection in children and HCV enzyme-linked immunosorbent assay or PCR testing should be used to increase sensitivity (121). HCV-infected renal transplant recipients had higher mortality and hospitalization rates than other transplant recipients (122), and HCV infection has been reported to be associated with *de novo* immune-mediated GN, especially type 1 MPGN, in renal allografts, resulting in accelerated loss of graft function (123,124).

No large randomized, controlled trials of treatment of children with chronic hepatitis C have been performed. Small heterogeneous studies of interferon monotherapy have reported sustained virologic response rates of 35 to 40% (115). In adults, improvement of proteinuria and renal function often follows interferon-alpha treatment (116,118), but relapses are common after cessation of treatment. Combination of interferon with ribavirin in patients with chronic liver disease has been shown to increase the rate of sustained response in these patients (125). As yet, however, there are few data regarding the use of combination therapy with interferon and ribavirin in children. Moreover, interferon-alpha therapy is associated with acute or subacute renal failure in more than one-third of the patients with renal transplants (126).

Herpes Viruses

Cytomegalovirus

CMV is one of the eight human herpes viruses. Transmission of the virus requires exposure to infected body fluids

such as breast milk, saliva, urine, or blood. Individuals initially infected with CMV may be asymptomatic or display nonspecific flu-like symptoms. After the initial infection CMV, like all herpes viruses, establishes latency for life but will be periodically excreted by an asymptomatic host. CMV replicates within renal cells, and on biopsy samples from immunocompromised hosts, viral inclusions can be visualized by light microscopy in cells of the convoluted tubules and collecting ducts (127). Glomerular cells and shed renal tubular cells may have characteristic inclusions, but clinically evident renal disease is rare and is seen virtually only in immunocompromised or congenitally infected children (127,128).

The clinical manifestations of CMV-induced renal disease in congenitally infected infants are variable and range from asymptomatic proteinuria to nephrotic syndrome and renal impairment. In congenital CMV infection, histologic changes of viral inclusions commonly occur in the tubules. In addition, proliferative GN has been reported, with evidence on electron microscopy of viral immune deposits in glomerular cells (128,129). In CMV-infected immunocompromised patients, immune-complex GN has been documented with mesangial deposits of IgG, IgA, C3, and CMV antigens within glomeruli. Eluted glomerular immunoglobulins have been shown to contain CMV antigens (130).

CMV is the most common viral infection after kidney transplantation. Experience with pediatric kidney transplant recipients suggests a 67% incidence of CMV infection (131). The direct and indirect effects of CMV infection result in significant morbidity and mortality among kidney transplant recipients. CMV-negative patients who receive a CMV-positive allograft are at risk for primary infection and graft dysfunction. Patients who are CMV seropositive at the time of transplantation are also at risk of reactivation and superinfection. Tubulointerstitial nephritis is a well-characterized pathologic feature of renal allograft CMV disease, which can be difficult to distinguish from injury caused by rejection. Histologic evidence of endothelial cell injury and mononuclear cell infiltration in the glomeruli has been reported (130). CMV glomerular vasculopathy in the absence of tubulointerstitial disease, causing renal allograft dysfunction, has also been reported (132). Beyond the acute allograft nephropathy associated with CMV viremia, CMV is known to cause chronic vascular injury. This may adversely affect the long-term outcome of the allograft and may be the explanation for the observed association with chronic allograft nephropathy (133).

Newer techniques for rapidly diagnosing CMV infection are becoming widely available and include shell vial culture, pp65 antigenemia assay, PCR, and the hybrid-capture RNA-DNA hybridization assay for qualitative detection of CMV PCR. Quantitative plasma PCR testing (PCR viral load) is increasingly used for diagnosis and monitoring of CMV viremia in renal transplant recipients.

Antiviral agents that have been shown to be effective against CMV include ganciclovir, valganciclovir, foscarnet,

and cidofovir. Ganciclovir remains the drug of choice for treating established disease. Intravenous ganciclovir therapy is preferred in children because of the erratic absorption of oral ganciclovir. Major limitations of ganciclovir therapy are the induction of renal tubular dysfunction and bone marrow toxicity, principally neutropenia and thrombocytopenia. Dosage adjustments are necessary for recipients with renal dysfunction. Recent studies suggest that valganciclovir given orally is at least as good as ganciclovir in preventing CMV infection (134). Use of other antiviral agents such as foscarnet and cidofovir is limited because of nephrotoxicity and difficulty of administration. A number of reports have demonstrated the effectiveness of high-titer CMV immune globulin therapy in reducing severe CMV-associated disease when used in combination with ganciclovir (131,135).

Varicella-Zoster Virus

The association of varicella with nephritis has been known for more than 100 years since Henoch reported on four children with nephritis that occurred after the appearance of varicella vesicles. Varicella, however, is rarely associated with renal complications (136). In fatal cases with disseminated varicella and in the immunocompromised individual, renal involvement is more common. Cases in which varicella infection caused GN in renal transplant recipients have been reported (137). Histologic findings in fatal cases include congested hemorrhagic glomeruli, endothelial cell hyperplasia, and tubular necrosis. In mild and nonfatal cases and in nonimmunocompromised individuals, varicella is occasionally associated with a variety of renal manifestations, ranging from mild nephritis to nephrotic syndrome and acute renal failure (138). Histologic findings include endocapillary cell proliferation, epithelial and endothelial cell hyperplasia, and inflammatory cell infiltration (136). Rapidly progressive nephritis has also been reported. Immunohistochemical studies reveal glomerular deposition of IgG, IgM, IgA, and C3. On electron microscopy, granular electron-dense deposits have been found in the paramesangial region, and varicella antigens may be deposited in the glomeruli. The features suggest an immune-complex nephritis. Elevated circulating levels of IgG and IgA immune complexes and depressed C3 and C4 levels support this possibility (136).

Fulminant disseminated varicella and varicella in immunocompromised patients should be treated with intravenous acyclovir.

Epstein-Barr Virus

Renal involvement is common during acute infectious mononucleosis, usually manifesting as an abnormal urine sediment, with hematuria in up to 60% of cases. Hematuria, either microscopic or macroscopic, usually appears within the first

week of the illness and lasts for a few weeks to a few months. Proteinuria is usually absent or low grade. More severe renal involvement with proteinuria, nephrotic syndrome, or acute nephritis with renal failure is much less common. Acute renal failure may be seen during the course of fulminant infectious mononucleosis with associated hepatic failure, thrombocytopenia, and encephalitis. It is usually caused by interstitial nephritis that is likely the result of immunopathologic injury precipitated by Epstein-Barr virus (EBV) infection. However, the identification of EBV DNA in the kidney raises the possibility that direct infection might play a role (139). The renal involvement must be distinguished from myoglobinuria caused by rhabdomyolysis, which may occur in infectious mononucleosis, and from bleeding into the renal tract as a result of thrombocytopenia.

Renal histologic findings in EBV nephritis are an interstitial nephritis with mononuclear cell infiltration and foci of tubular necrosis. Glomeruli may show varying degrees of mesangial proliferation. On immunohistochemical study, EBV antigens are seen in glomerular and tubular deposits. The prognosis for complete recovery of renal function is good. Treatment with corticosteroids may have a role in the management of EBV-induced acute renal failure and may shorten the duration of renal failure (140).

EBV-associated posttransplantation lymphoproliferative disease is a recognized complication in renal transplant recipients. Latent infection of EBV in renal proximal tubular epithelial cells has recently been described as causing idiopathic chronic tubulointerstitial nephritis (141).

Herpes Simplex Virus

The herpes simplex virus (HSV) causes persistent infection characterized by asymptomatic latent periods interspersed with acute relapses. As in other chronic and persistent infections, immunologically mediated disorders triggered by HSV are well recognized, and it is perhaps surprising that HSV has rarely been linked to nephritis. Acute nephritis and nephrotic syndrome have been associated with herpes simplex encephalitis. Renal histology shows focal segmental GN with mesangial and segmental deposits of IgM, C3, and HSV antigens. As with other herpes viruses, HSV has been suggested as a trigger for IgA nephritis, MPGN, and membranous nephropathy. Elevated levels of HSV antibodies have been reported in patients with a variety of forms of GN, but no conclusive evidence exists of an etiologic role for HSV (142).

Adenovirus, Enterovirus, and Influenza Virus

Adenovirus, enterovirus, and influenza virus are unrelated ubiquitous pathogens that infect large proportions of the population annually and yet are rarely associated with renal disease. The literature contains scattered reports of acute nephritis after infection with each of these viruses.

Adenovirus is a major cause of hemorrhagic cystitis and was implicated as the cause of hemorrhagic cystitis in 23 to 51% of children with this disorder (143). Boys are affected more often than girls, and hematuria persists for 3 to 5 days. Microscopic hematuria, dysuria, and frequency may occur for longer periods. Adenovirus types 11 and 21 are the usual strains isolated.

Influenza virus and enteroviruses, including echovirus and coxsackievirus, have been linked with acute nephritis and acute renal failure associated with rhabdomyolysis. In the newborn, enteroviruses cause fulminant disease with DIC, shock, and liver failure, and acute renal failure may occur.

Measles Virus

Renal involvement from measles virus is uncommon, although measles virus can be cultured from the kidney in fatal cases. An acute GN has been reported to follow measles with evidence of immune deposits containing measles virus antigen within the glomeruli. The nephritis is generally self-limiting (144).

Mumps Virus

Mild renal involvement is common during the acute phase of mumps infection. One-third of children with mumps have abnormal urinalysis results, with microscopic hematuria or proteinuria. Mumps virus may be isolated from urine during the first 5 days of the illness, at a time when urinalysis findings are abnormal. Plasma creatinine concentrations usually remain normal, despite the abnormal urine sediment, but more severe cases in adults have been associated with evidence of acute nephritis with impaired renal function. Renal biopsy specimens demonstrate an MPGN with deposition of IgA, IgM, C3, and mumps virus antigen in the glomeruli, which suggests an immune-complex-mediated process (145).

Human Immunodeficiency Virus

The World Health Organization estimated that there were 38.9 million adults and 3.2 million children living with HIV infection and acquired immunodeficiency syndrome (AIDS) in December 2002. Nearly 800,000 children were infected with HIV in 2002, mostly through their mothers before or during birth or through breast feeding (vertical transmission). A total of 610,000 children died of HIV/AIDS in 2002. Renal involvement in HIV infection was first described in 1984 in adults (146–148) and in children (149), and renal involvement occurs in 2 to 15% of HIV-infected children in the United States (150–152). Since the development of highly active antiretroviral therapy (HAART), however, the incidence of renal disease in HIV infection in both adults and children in industrialized countries has declined.

HIV-associated nephropathy (HIVAN) is characterized by both glomerular and tubular dysfunction, the pathogenesis of which is not entirely known. HIVAN is a clinicopathologic entity that includes proteinuria, azotemia, focal segmental glomerulosclerosis or mesangial hyperplasia, and tubulointerstitial disease (152). In adults in the United States, there is a markedly increased risk of nephropathy among African American persons with HIV infection. This appears to be true in children as well, but the data are sparse. The spectrum of HIVAN seems to be coincident with the degree of AIDS symptomatology. It is thought that HIVAN can present at any point in HIV infection, but most patients with HIVAN have CD4 counts of less than $200 \times 10^6/200$ cells/mL, which suggests that it may be primarily a manifestation of late-stage disease (153).

Although a spectrum of clinicopathologic entities including mesangial hyperplasia, focal segmental glomerulosclerosis, minimal change disease, and systemic lupus erythematosus nephritis has been described, the classic pathologic feature of HIVAN is the collapsing form of focal and segmental glomerulosclerosis (154). In the affected glomeruli, visceral epithelial cells are hypertrophied and hyperplastic, and contain large cytoplasmic vacuoles and numerous protein resorption droplets. There is microcystic distortion of tubule segments, which contributes to increasing kidney size. Podocyte hyperplasia can become so marked that it causes obliteration of much of the urinary space, forming "pseudocrescents" (155). Capillary walls are wrinkled and collapsed with obliteration of the capillary lumina. The interstitium is edematous with a variable degree of T-cell infiltration (156). The Bowman capsule can also be dilated and filled with a precipitate of plasma protein that represents the glomerular ultrafiltrate. One of the most distinctive features of HIVAN, however, is the presence of numerous tubuloreticular inclusions within the cytoplasm of glomerular and peritubular capillary endothelial cells (155).

Immunofluorescence testing is positive for IgM and C3 in capillary walls in a coarsely granular to amorphous pattern in a segmental distribution (154,156).

The presence of the HIV genome in glomerular and tubular epithelium has been demonstrated using complementary DNA probes and *in situ* hybridization. Proviral DNA has been detected by PCR in the glomeruli, tubules, and interstitium of microdissected kidneys from patients who had pathologic evidence of HIVAN, but it has also been detected in the kidneys of HIV-positive patients with other glomerulopathies (157). A combination of both proliferation and apoptosis of renal cells may cause the loss of nephron architecture. Apoptosis has been demonstrated in cells in the glomerulus, tubules, and interstitium of biopsy specimens from HIV-positive patients with focal segmental glomerulosclerosis. In addition, the role of various cytokines and growth factors, specifically transforming growth factor β (TGF- β), in the development of sclerosis has been studied (158,159).

Transgenic murine models provide some of the strongest evidence for a direct role of HIV-1 in the induction of

HIVAN. These mice do not produce infectious virus but express the HIV envelope and regulatory genes at levels sufficient to re-create the HIVAN that is seen in humans (158). The kidneys of these transgenic mice have also been found to have elevated levels of TGF- β messenger RNA and protein (159). Additional factors such as genetic predisposition may explain the fact that African Americans have a greater likelihood of developing HIVAN than other racial groups.

HIV infection is also associated with other forms of renal disease. Glomerular syndromes other than HIVAN include MGN that resembles lupus nephritis and immune-complex GN, with IgA nephropathy and HCV-associated MPGN being the most common forms. There have also been several case reports of amyloid kidney (152,155,160). The kidneys may be affected by various other mechanisms. Opportunistic infections with organisms such as BK virus (BKV) that give rise to nephropathy and hemorrhagic cystitis have been reported in association with HIV infection (161). Systemic infections accompanied by hypotension can cause prerenal failure leading to acute tubular necrosis. Acute tubular necrosis has also been reported in HIV patients after the use of nephrotoxic drugs such as pentamidine, foscarnet, cidofovir, amphotericin B, and aminoglycosides. Intratubular obstruction with crystal precipitation can occur with the use of sulfonamides and intravenous acyclovir. Indinavir is well recognized to cause nephropathy and renal calculi (162). MPGN associated with mixed cryoglobulinemia and thrombotic microangiopathy/atypical HUS in association with HIV infections have been reported (163,164).

HIVAN can manifest as mild proteinuria, nephrotic syndrome, renal tubular acidosis, hematuria, and/or acute renal failure (149–152). Nephrotic syndrome and chronic renal insufficiency are late manifestations of HIVAN. Children with HIVAN are likely to develop transient electrolytic disorders, heavy proteinuria, and acute renal failure due to systemic infectious episodes or nephrotoxic drugs.

Early stages of HIVAN can be identified by the presence of proteinuria and "urine microcysts" along with renal sonograms showing enlarged echogenic kidneys. Urinary renal tubular epithelial cells are frequently grouped together to form these microcysts, which were found in the urine of children with HIVAN who had renal tubular injury (152). Advanced stages of HIVAN typically present with nephrotic syndrome with edema, heavy proteinuria, hypoalbuminemia, and few red or white blood cells in urinary sediments. Hypertension may be present, but usually blood pressure is within or below the normal range. HIVAN in adults follows a rapidly progressive course, with end-stage renal disease developing within 1 to 4 months, but in children this rapid progression does not necessarily occur. Definitive diagnosis of HIVAN should be based on biopsy results, and biopsy should be performed if significant proteinuria is present, because in approximately 50% of HIV-infected patients with

azotemia and/or proteinuria (>1 g/24 hr) who undergo renal biopsy, the specimen will have histologic features consistent with other renal diseases (153).

When available, HAART should be given to children with symptomatic HIV disease. Specific treatment of HIVAN remains controversial. Several studies have looked at the role of HAART, angiotensin I-converting enzyme (ACE) inhibitors, steroids, and even cyclosporin with somewhat encouraging results. However, as yet no randomized case-controlled trials have been undertaken. Most of the studies have been small and retrospective, and many have included patients both with and without renal biopsy-proven HIVAN. Cyclosporin has been used to treat HIVAN in children with remission of nephrotic syndrome (150). Similar responses have been reported to treatment with corticosteroids in various studies (165–168). ACE inhibitors have been used with encouraging results (169).

The general regimen used to treat patients with HIV, including HAART, should be applied to children with HIVAN. The dosages of some medications must be adjusted to the patient's glomerular filtration. There are reports of spontaneous regression of HIVAN with supportive management and treatment with HAART, particularly with regimens containing protease inhibitors (170–173). It should be emphasized that the improvement reported with other modalities of treatment such as corticosteroids, cyclosporin, and ACE inhibitors always occurs when these agents are given in conjunction with antiretroviral therapy.

Several other therapeutic options have been suggested, aimed specifically at the presumed role of TGF- β in the pathogenesis of HIVAN. Treatment directed at its synthesis using gene therapy to block TGF- β gene expression is being explored. Therapy directed at decreasing the activity of TGF- β using anti-TGF- β antibodies or other inhibitory substances is also an area of investigation. In addition, blocking renal receptors for chemokines such as RANTES (regulated upon activation, normal T cell expressed and secreted), interleukin-8, and monocyte-chemoattractant protein-1 has been proposed as another possible treatment alternative (174).

Most reports of HIV-infected patients on hemodialysis have shown poor prognosis, with mean patient survival times ranging from 14 to 47 months. Mortality is therefore still close to 50% within the first year of dialysis. In general, improved survival is associated with younger age at initiation of hemodialysis and with higher CD4 counts. Access complications such as infection and thrombosis tend to occur at a higher rate in HIV-infected hemodialysis patients. Cross infection with HIV in dialysis patients is very rare. No patient-to-patient HIV transmission has yet been reported in a hemodialysis unit in the United States, although several such cases have occurred in South America (174,175).

Peritoneal dialysis is an alternative for HIV-infected patients. The incidence of peritonitis varies across studies, but some studies did report a higher incidence of *Pseudomonas* and fungal peritonitis in the HIV-positive population

(174). Infections with unusual organisms such as *Pasteurella multocida*, *Trichosporon beigeli*, and *Mycobacterium avium-intracellulare* complex have also been reported. Several studies, however, have suggested that there is no significant difference between the HIV-infected and non-HIV-infected populations. Of note is that virus capable of replication *in vitro* has been recovered from the peritoneal dialysis effluent, and it can be recoverable for up to 7 days in dialysis bags at room temperature and for up to 48 hours in dry exchange tubing (174).

In general, long-term dialysis is thought to be preferable to renal transplantation, primarily because of the concern that the immunosuppressive therapy required after transplantation could promote progression of HIV/AIDS. The safety and efficacy of organ transplantation in the HAART era have not been described. A multicenter prospective study has been initiated to address these questions (176). However, a preliminary report presented at the Conference on Retroviruses and Opportunistic Infections in 2002 noted that the survival and graft function rates for HIV-infected transplantation recipients appeared to be good and that the rate of development of opportunistic infections is low in those with well-controlled HIV and relatively high CD4 counts (177).

Human Polyoma Virus

The human polyoma viruses (HPV) are members of the papovavirus family and have received increasing attention as pathogens in immunocompromised patients. They are nonenveloped viruses ranging in size from 45 to 55 nm, with a circular, double-stranded DNA genome that replicates in the host nucleus. The best-known species in this genus are the BKV, the JC virus (JCV), and the simian virus SV40. BKV was first isolated from the urine of a 39-year-old man who developed ureteral stenosis 4 months after renal transplantation (178). The name of the virus refers to the first patient's initials, which is also true of JCV. BKV establishes infection in the kidney and the urinary tract, and its activation causes a number of disorders, including nephropathy and hemorrhagic cystitis. BKV-associated nephropathy has become an increasingly recognized cause of renal dysfunction in renal transplantation patients (179–183). JCV establishes latency mainly in the kidney, and its reactivation can result in the development of progressive multifocal leukoencephalopathy. Recent studies have reported SV40 in the allografts of children who received renal transplants and in the urine, blood, and kidneys of adults with focal segmental glomerulosclerosis, which is a cause of end-stage renal disease and an indication for kidney transplantation (184).

BKV infection is endemic worldwide. Seroprevalence rates as high as 60 to 80% have been reported among adults in the United States and Europe. The peak incidence of primary infection (as measured by acquisition of antibody)

occurs in children 2 to 5 years of age. BKV antibody may be detected in as many as 50% of children by 3 years of age, and in 60 to 100% of children by 9 or 10 years of age; antibodies wane thereafter. BKV infection may be particularly important in the pediatric transplantation population, in whom primary infection has a high probability of occurring while the children are immunosuppressed (185).

Primary infection with BKV in healthy children is rarely associated with clinical manifestations. Mild pyrexia, malaise, vomiting, respiratory illness, pericarditis, and transient hepatic dysfunction have been reported with primary infection. Investigators hypothesize that after an initial round of viral replication at the site of entry, viremia follows with dissemination of the virus to distant sites at which latent infection is established. The most frequently recognized secondary sites of latent infection are renal and uroepithelial cells. Secondary infection has been reported to cause tubulointerstitial nephritis and ureteral stenosis in renal transplantation patients. It may be that renal impairment in immunocompromised patients and in nonrenal solid organ transplant recipients is found to be frequently associated with BKV infection.

BK Virus Nephropathy in Patients Undergoing Renal Transplantation

The reported prevalence of BKV nephropathy in renal allografts is between 1 and 8% (179,180,183,186). Asymptomatic infection is characterized by viral shedding without any apparent clinical features. Viruria, resulting from either primary or secondary infection, can persist from several weeks to years. Tubulointerstitial nephritis associated with BKV in renal transplant recipients is accompanied by histopathologic changes, with or without functional impairment. "Infection" and "disease" must be differentiated carefully. BKV infection (either primary or reactivated) can progress to BKV disease, but will not always do so (185). Furthermore, not all cases of BKV disease lead to renal impairment. However, infection can progress to transplant dysfunction and graft loss, although the diagnosis may be complicated by the coexistence of active allograft rejection.

BKV nephritis is reported to have a bimodal distribution, with 50% of BKV-related interstitial nephritis cases occurring 4 to 8 weeks after transplantation and the remainder of patients developing disease months to years after transplantation (187). Allograft failure is due mainly to extensive viral replication in tubular epithelial cells leading to frank tubular necrosis (181). Although damage is potentially fully reversible early in the disease, persisting viral damage leads to irreversible interstitial fibrosis. Tubular atrophy and allograft loss has been observed in 45% of affected patients (181,188).

In most cases, BKV nephropathy in adult renal transplant recipients represents a secondary infection associated with rejection and its treatment. In children, however, pri-

mary BKV infection giving rise to allograft dysfunction may occur (185).

The definitive diagnosis of BKV nephropathy requires renal biopsy. Histopathologic features include severe tubular injury with cellular enlargement, marked nuclear atypia, epithelial necrosis, denudation of tubular basement membranes, focal intratubular neutrophilic infiltration, and mononuclear interstitial infiltration, with or without concurrent tubulitis. This constellation of histologic features, particularly severe tubulitis, is often misinterpreted as rejection, even by the experienced pathologist. The presence of well-demarcated basophilic or amphophilic intranuclear viral inclusions, primarily within the tubular and parietal epithelium of the Bowman capsule, can help distinguish BKV disease from rejection (180,181,183). Additional tests such as immunohistochemistry, PCR analysis, or electron microscopy of biopsied tissue aimed at the identification of BKV may be required.

A practical diagnostic approach for identifying BKV in renal transplant patients is summarized in Table 51.3.

Ureteral Stenosis in Renal Transplantation

BKV infection may cause ureteral obstruction due to ureteral ulceration and stenosis at the ureteric anastomosis. BKV-associated ureteral stenosis has been reported in 3% of renal transplant patients and usually occurs between 50 and 300 days after transplantation. Ulceration due to inflammation, proliferation of the transitional epithelial cells, and smooth muscle proliferation may lead to partial or total obstruction.

Hemorrhagic Cystitis in Bone Marrow Transplantation

BKV may be involved in acute, late-onset, long-duration hemorrhagic cystitis after bone marrow transplantation (189).

Treatment

Whether patients with asymptomatic viremia or viruria need specific therapeutic intervention is not certain. Review of the literature suggests that careful reduction of immune suppression, combined with active surveillance for rejection, will result in clinical improvement. Reduction in immunosuppression may precipitate episodes of acute cellular rejection, which need to be judiciously treated with corticosteroids. The outcome of BKV nephropathy is unpredictable, and stabilization of renal function may occur regardless of whether maintenance immunotherapy is altered or not (190).

Some reports favor the use of cidofovir. Cidofovir has important nephrotoxic side effects in the usual therapeutic dosage recommended for the treatment of CMV infection, and for BKV nephropathy a reduced dosage regime is generally used. The efficacy of cidofovir in reducing viremia

TABLE 51.3. DIAGNOSIS OF BK VIRUS (BKV) IN RENAL TRANSPLANT RECIPIENTS

Tests	Comments
Urine:	
Cytology: decoy cells BKV PCR	Presence of BKV by PCR or decoy cells in urine signifies BKV replication. Decoy cells are caused by infection of the urinary epithelial cells with HPV. The nuclei are enlarged and nuclear chromatin is completely homogenized by viral cytopathic effect. Positive PCR results for BKV viruria and presence of decoy cells have poor predictive value. Specificity is increased if >10 cells/Cytospin along with presence of inflammatory cells.
Serum:	
Antibody assays BKV	Presence of antibody is usually indicative of previous infection; however, positive results for BKV DNA PCR on serum signifies BK viremia. BKV PCR testing of plasma has proven to be a sensitive (100%) and specific (88%) means to identify BKV-associated nephropathy in adults. Viral load has also been used to monitor infection and clearance. However, because primary infection occurs in childhood, it might not be applicable to the pediatric population.
Tissue:	
Histopathology Electron microscopy BKV PCR	The definitive diagnosis of BKV nephropathy requires renal biopsy. Histopathology might mimic rejection or drug toxicity. However, characteristic findings have been described. Electron microscopy and immune staining are helpful in confirming the diagnosis. PCR assays of viral load in tubular cells have been reported to be a sensitive marker for diagnosis and monitoring.

HPV, human polyoma virus; PCR, polymerase chain reaction.

has been demonstrated (191). However, spontaneous clearance of viral infection after reduction of immunosuppression (without cidofovir) has also been reported.

Viral Hemorrhagic Fever

Viral hemorrhagic fever involves at least 12 distinct RNA viruses that share the propensity to cause severe disease with prominent hemorrhagic manifestations (Table 51.4). The viral hemorrhagic fevers, widely distributed throughout both temperate and tropical regions of the world, are important causes of mortality and morbidity in many countries. Most viral hemorrhagic fevers are zoonoses (with the possible exception of dengue virus), in which the virus is endemic in animals and human infection is acquired through the bite of an insect vector. Aerosol and nosocomial transmissions from infected patients are important for

Lassa, Junin, Machupo, and Congo-Crimean hemorrhagic fevers, and Marburg and Ebola viruses (192).

Viral hemorrhagic fevers have many clinical similarities but also important differences in their severity, major organs affected, prognosis, and response to treatment. In all viral hemorrhagic fevers, severe cases occur in only a minority of those affected; subclinical infection or nonspecific febrile illness occurs in the majority. Fever, myalgia, headache, conjunctival suffusion, and erythematous rash occur in all the viral hemorrhagic fevers (193). Hemorrhagic manifestations range from petechiae and bleeding from venipuncture sites to severe hemorrhage into the GI tract, kidney, and other organs. A capillary leak syndrome, with evidence of hemoconcentration, pulmonary edema, oliguria, and ultimately shock, occurs in the most severely affected patients (193). Renal involvement occurs in all the viral hemorrhagic fevers, proteinuria is common, and prerenal failure is seen in all severe cases complicated by shock. However, in Congo-Crimean hemorrhagic fever and hemorrhagic fever with renal syndrome (HFRS), an interstitial nephritis, which may be hemorrhagic, is characteristic, and renal impairment is a major component of the illness.

Dengue

Dengue is endemic and epidemic in tropical America, Africa, and Asia, where the mosquito vector *Aedes aegypti* is present (194). Classic dengue is a self-limited nonfatal disease; dengue hemorrhagic fever and dengue shock syndrome, which occur in a minority of patients, have a high mortality. After an incubation period of 5 to 8 days, the illness begins with fever, headache, arthralgia, weakness, vomiting, and hyperesthesia. In uncomplicated dengue the fever usually lasts 5 to 7 days. Shortly after onset a maculopapular rash appears, sparing the palms and the soles, and is occasionally followed by desquamation. Fever may reappear at the onset of the rash.

In dengue hemorrhagic fever and dengue shock syndrome, the typical febrile illness is complicated by hemorrhagic manifestations, ranging from a positive tourniquet test result or petechiae to purpura, epistaxis, and GI bleeding with thrombocytopenia and evidence of a consumptive coagulopathy. Increased capillary permeability is suggested by hemoconcentration, edema, and pleural effusions (194). In severe cases, hypotension and shock supervene, largely as a result of hypovolemia. Renal manifestations include oliguria, proteinuria, hematuria, and rising urea and creatinine. Acute renal failure occurs in patients with severe shock, primarily as a result of renal underperfusion. However, glomerular inflammatory changes may also occur. Children with dengue hemorrhagic fever show hypertrophy of endothelial and mesangial cells, mononuclear cell infiltrate, thinning of basement membranes, and deposition of IgG, IgM, and C3. Electron microscopy shows viral particles within glomerular mononuclear cells (195).

The diagnosis of dengue is made by isolation of the virus from blood or by serologic testing. There is no specific anti-

TABLE 51.4. VIRAL HEMORRHAGIC FEVERS (HF)

Virus	Geographic distribution	Source of human infection	Incubation period (d)	Renal involvement	Renal pathology	Treatment
Dengue	Tropical Africa, South America, Asia	Mosquito	5–8	Rare, only in Dengue HF or shock	Vasomotor nephropathy, immune complex	Supportive
Yellow fever	Africa, South America	Mosquito	3–6	Common	Vasomotor nephropathy	Supportive
Congo-Crimean	Eastern Europe, Africa, Asia	Tick, nosocomial	2–7	In severe cases	Vasomotor nephropathy	Supportive
Hantaan viruses (Puumala, Seoul strains)	Europe, Asia, Africa, America	Rodents	4–42	HF and renal syndrome (Korean, Chinese, and Japanese epidemic HF, nephropathia epidemica)	Vasomotor nephropathy	? Ribavirin Supportive
Rift Valley fever	Sub-Saharan Africa	Mosquito, contact with infected animals	3–7	Rare, only in fulminant cases	Interstitial nephropathy Vasomotor nephropathy	? Ribavirin Supportive
Lassa fever	West Africa	Rodents, nosocomial	3–16	In cases with shock	Vasomotor nephropathy	Supportive and ribavirin
Junin, Argentine HF	Argentina	Rodents, nosocomial	5–19	In cases with shock	Vasomotor nephropathy	Supportive
Machupo, Bolivian HF	Bolivia	Rodents, nosocomial	5–19	In cases with shock	Vasomotor nephropathy	Supportive
Marburg	Africa	?, nosocomial	5–10	In cases with shock	Vasomotor nephropathy	Supportive
Ebola	Africa	?, nosocomial	5–10	In cases with shock	Vasomotor nephropathy	Supportive
Omsk	Eastern Europe	Tick	2–4	In cases with shock	Vasomotor nephropathy	Supportive
Kyasanur forest	India	Tick	3–8	In cases with shock	Vasomotor nephropathy	Supportive

ral treatment, and management of patients with dengue shock syndrome or dengue hemorrhagic fever depends on aggressive circulatory support and volume replacement with colloid and crystalloid. With correction of hypovolemia, renal impairment is usually reversible, but dialysis may be required in patients with established acute renal failure.

Yellow Fever

Yellow fever remains an important public health problem in Africa and South America. Renal manifestations are common and include albuminuria and oliguria. Over the next few days after first manifestation of infection, shock, delirium, coma, and renal failure develop, and death occurs 7 to 10 days after onset of symptoms. Laboratory findings include thrombocytopenia and evidence of hemoconcentration, rising urea and creatinine levels, hyponatremia, and deranged liver function test results. Pathologic findings include necrosis of liver lobules, cloudy swelling and fatty degeneration of the proximal renal tubules, and, often, petechiae in other organs. The oliguria appears to be prerenal and is due to hypovolemia; later, acute

tubular necrosis supervenes. At present, there is no effective antiviral agent for yellow fever.

Congo-Crimean Hemorrhagic Fever

Congo-Crimean hemorrhagic fever, first recognized in the Soviet Union, is now an important human disease in Eastern Europe, Asia, and Africa (196). Severely affected patients become stuporous or comatose 5 to 7 days into the illness, with evidence of hepatic and renal failure and shock. Proteinuria and hematuria are often present. The disease is fatal in 15 to 50% of cases. The virus is sensitive to ribavirin, but there have been no clinical trials to confirm its efficacy.

Rift Valley Fever

Rift Valley fever is found in many areas of sub-Saharan Africa. In humans, most infections follow mosquito bites or animal exposure. The infection may present as an uncomplicated febrile illness, with muscle aches and headaches. In 10% of patients, encephalitis or retinal vasculitis occurs as a

complication. In a small proportion of cases, a fulminant and often fatal hemorrhagic illness occurs with hematemesis, melena, epistaxis, and evidence of profound DIC. Severe hepatic derangement, renal failure, and encephalopathy are often present. Despite intensive care, mortality is high.

Hemorrhagic Fever and Renal Syndrome (Hantavirus)

The viruses causing HFRS all belong to the *Hantavirus* genus in the Bunyaviridae family. The hantaviruses are distributed worldwide and are maintained in nature through chronic infection of rodents and small mammals. Transmission to humans is by aerosolized infectious excreta. Human disease usually occurs in summer among rural populations with exposure to rodent-infested barns or grain stores. Urban transmission can occur, however. At least five hantaviruses are known to cause HFRS: Hantaan, Seoul, Puumala, Poro-gia, and Belgrade viruses (197). HFRS is endemic in a belt from Norway in the west through Sweden, Finland, the Soviet Union, China, and Korea to Japan in the east. The clinical severity of HFRS varies throughout this belt (198). Clinical entities include Korean hemorrhagic fever, nephropathia epidemica in Scandinavia, and epidemic hemorrhagic fever in Japan and China.

In general, HFRS due to Hantaan, Poro-gia, and Belgrade viruses is more severe and has higher mortality than that due to Puumala virus (nephropathia epidemica) or Seoul virus. Hantaan is predominant in the Far East, Poro-gia and Belgrade in the Balkans, and Puumala in Western Europe; Seoul has a worldwide distribution (197). The clinical features of the disease vary. The incubation period is 4 to 42 days. Although HFRS occurs with the same clinical picture in children as in adults, both incidence rates and antibody prevalence rates are very low in children under 10 years of age. Men of working age make up the bulk of clinical cases (198). Mild cases are indistinguishable from other febrile illnesses. In more severe cases, fever, headache, myalgia, abdominal pain, and dizziness are associated with the development of periorbital edema, proteinuria, and hematuria. There is often conjunctival injection, pharyngeal injection, petechiae, and epistaxis or GI bleeding. The most severely affected patients develop shock and renal failure. The disease usually passes through five phases: febrile, hypotensive, oliguric, diuretic, and convalescent. Laboratory findings include anemia, lymphocytosis, thrombocytopenia, prolonged prothrombin and bleeding times, and elevated levels of fibrin degradation products. Liver enzyme levels are elevated, and urea and creatinine levels are elevated during the oliguric phase. Proteinuria and hematuria are consistent findings.

The renal histopathologic findings are those of an interstitial nephritis with prominent hemorrhages in the renal medullary interstitium and renal cortex. Acute tubular necrosis may also be seen. Immunohistochemical analysis reveals deposition of IgG and C3, and the GBM, mesangial, and subendothelial deposits may be seen on electron microscopy (199).

Recovery from *Hantavirus*-associated disease is generally complete, although chronic renal insufficiency is a rare sequela of HFRS. In mildly affected patients, the disease is self-limiting and spontaneous recovery occurs. However, in severe cases, with shock, bleeding, and renal failure, dialysis and intensive circulatory support may be required (200). Mortality rates vary depending on the strain of virus; rates are 5 to 15% for hemorrhagic fever and renal syndrome in China and significantly lower for the milder Finnish form associated with the Puumala virus strain.

Ribavirin is active against Hantaan viruses *in vitro*, and clinical trials indicate that both mortality and morbidity can be reduced by treatment with this antiviral agent if it is administered early in the course of illness. Dosages of 33 mg/kg followed by 16 mg/kg every 6 hours for 4 days and then 8 mg/kg every 8 hours for 3 days have been used (201).

Lassa Fever

Lassa fever is a common infection in West Africa and usually manifests as a nonspecific febrile illness. In 10% of cases, a fulminant hemorrhagic disease occurs. In severe cases, proteinuria and hematuria are usually present, and renal failure may occur. Ribavirin is effective in decreasing mortality. As in other hemorrhagic fevers, intensive hemodynamic support and correction of the hemostatic derangements are important components of therapy (202).

Argentine and Bolivian Hemorrhagic Fevers

Junin and Machupo viruses, the agents of Argentine and Bolivian hemorrhagic fever, respectively, cause hemorrhagic fevers with prominent neurologic features and systemic and hemorrhagic features similar to those of Lassa fever. Oliguria, shock, and renal failure occur in the most severe cases.

Marburg Disease and Ebola Hemorrhagic Fever

Marburg and Ebola viruses have been associated with outbreaks of nosocomially transmitted hemorrhagic fever. Both viruses cause fulminant hemorrhagic fever. Onset is with high fever, headache, sore throat, myalgia, and profound prostration. An erythematous rash on the trunk is followed by hemorrhagic conjunctivitis, bleeding, impaired renal function, shock, and respiratory failure. The mortality rate is high. Renal histopathologic findings in fatal cases are of tubular necrosis, with fibrin deposition in the glomeruli. There is no specific treatment for these disorders.

PARASITIC INFECTIONS

Chronic exposure to infectious agents is a major factor in the increased prevalence of glomerular diseases in developing countries. Malaria is the best-documented parasitic

infection associated with glomerular disease, but other parasitic infections including schistosomiasis, filariasis, leishmaniasis, and possibly helminth infections may also induce nephritis or nephrosis.

Malaria and Renal Disease

Malaria is estimated to cause up to 500 million clinical cases of illness and more than 1 million deaths each year (203). The association of quartan malaria and nephritis has been well known in both temperate and tropical zones since the end of the nineteenth century.

Epidemiologic studies provide the most conclusive evidence for a role of *Plasmodium malariae* in glomerular disease (204,205). Chronic renal disease was a major cause of morbidity and mortality in British Guiana in the 1920s. The frequent occurrence of *P. malariae* in the blood of these patients led to detailed epidemiologic studies that implicated malaria as a cause of the nephrosis. After the eradication of malaria from British Guiana, chronic renal disease ceased to be a major cause of death in that country (204).

The link between malaria and nephrotic syndrome was strengthened by studies in West Africa in the 1950s and 1960s that demonstrated a high prevalence of nephrotic syndrome in the Nigerian population (206). The pattern of nephrotic syndrome differed from that in temperate climates, with an older peak age, extremely poor prognosis, and unusual histologic features. The incidence of *P. malariae* parasitemia in patients with the nephrotic syndrome in Nigeria was vastly in excess of that occurring in the general population, whereas the incidence of *Plasmodium falciparum* parasitemia was similar to that in the general population. The age distribution of nephrotic syndrome also closely paralleled that of *P. malariae* infection (206). In some affected patients, circulating immune complexes and immunoglobulin, complement, and antigens were present in the glomeruli that were recognized by *P. malariae*-specific antisera.

Clinical and Histopathologic Features of Quartan Malaria Nephropathy

Most patients have poorly selective proteinuria and are unresponsive to treatment with steroids or immunosuppressive agents. The characteristic lesions of *P. malariae* nephropathy are capillary wall thickening and segmental glomerular sclerosis, which lead to progressive glomerular changes and secondary tubular atrophy (206). Cellular proliferation is conspicuously absent. Electron microscopy shows foot-process fusion, thickening of the basement membrane, and increase in subendothelial basement membrane-like material. Immunofluorescent studies show granular deposits of immunoglobulin, complement, and *P. malariae* antigen in approximately one-third of patients.

In addition to the histologic pattern, termed *quartan malaria nephropathy*, *P. malariae* infection is associated with

a variety of other forms of histologic appearance, including proliferative GN and MGN (207).

Although quartan malaria nephropathy has been clearly linked to *P. malariae* infection in Nigeria, a number of studies from other regions in Africa have not revealed the typical histopathologic findings described in the Nigerian studies (208). Furthermore, quartan malaria nephropathy may be seen in children with no evidence of *P. malariae* infection or deposition of malaria antigens in the kidney. This, together with the fact that antimalarial treatment does not affect the progression of the disorder, raises the possibility that factors other than malaria might be involved in the initiation and perpetuation of the disorder. Although there is undoubtedly a strong association between *P. malariae* infection and nephrotic syndrome on epidemiologic grounds, the direct causal link is not proven. Most likely, a number of different infectious processes, including malaria, hepatitis B, schistosomiasis, and perhaps other parasitic infections that cause chronic or persistent infections and often occur concurrently in malaria areas, may all result in glomerular injury and a range of overlapping histopathologic features. The prognosis for the nephrotic syndrome in most African studies has been poor, regardless of whether the histologic findings were typical of quartan malaria nephropathy or whether *P. malariae* parasitemia was implicated. Treatment with steroids and azathioprine is generally ineffective, and a significant proportion of patients progress to renal failure.

Renal Disease Associated with Plasmodium falciparum Infection

P. falciparum appears to be much less likely to cause significant glomerular pathology. Epidemiologic studies have failed to show a clear association between *P. falciparum* parasitemia and the nephrotic syndrome. Whereas renal failure appears to be a common complication of severe malaria in adults, it seldom occurs in children.

Renal biopsy specimens from adult patients with acute *P. falciparum* infections who have proteinuria or hematuria show evidence of glomerular changes, including hypercellularity, thickening of basement membranes, and hyperplasia and hypertrophy of endothelial cells (209). Electron microscopy reveals electron-dense deposits in the subendothelial and paramesangial areas. Deposits of IgM, with or without IgG, are localized mainly in the mesangial areas. *P. falciparum* antigens can be demonstrated in the mesangial areas and along the capillary wall, which suggests an immune-complex GN. The changes, generally mild and transient, are probably unrelated to the acute renal failure that may complicate severe *P. falciparum* infection (209). Renal failure occurring in severe *P. falciparum* malaria is usually associated with acute intravascular hemolysis or heavy parasitic infection that leads to acute tubular necrosis. Heavily parasitized erythrocytes play a central role in the various pathologic factors (210). Although renal failure

is usually associated with infection by *P. falciparum*, acute renal failure has been described with *Plasmodium vivax* infection and mixed infections (211).

Blackwater Fever

The term *blackwater fever* refers to the combination of severe hemolysis, hemoglobinuria, and renal failure. It was more common at the start of the twentieth century in nonimmune individuals receiving intermittent quinine therapy for *P. falciparum* malaria. Blackwater fever has become rare since 1950, when quinine was replaced by chloroquine. However, the disease reappeared in the 1990s, after the reuse of quinine because of the development of chloroquine-resistant organisms. Since then, several cases have been described after therapy with halofantrine and mefloquine, two new molecules similar to quinine (amino-alcohol family) (212). Renal failure generally occurred in the context of severe hemolytic anemia, hemoglobinuria, and jaundice. The pathophysiology of the disorder is unclear; however, it appears that a double sensitization of the red blood cells to the *P. falciparum* and to the amino-alcohols is necessary to provoke the hemolysis. Histopathologic findings include swelling and vacuolization of proximal tubules, necrosis and degeneration of more distal tubules, and hemoglobin deposition in the renal tubules. Recent studies indicates a better outcome with earlier initiation of intensive care and dialysis combined with necessary changes in antimalarial medications.

Schistosomiasis

Schistosomiasis affects 200 million people living in endemic areas of Asia, Africa, and South America (213). The infection is usually acquired in childhood, but repeated infections occur throughout life. *Schistosoma japonicum* is found only in the Orient, whereas *Schistosoma haematobium* occurs throughout Africa, the Middle East, and areas of southwest Asia. *Schistosoma mansoni* is widespread in Africa, South America, and southwest Asia.

Human infection begins when the cercarial forms invade through the skin, develop into *schistosomula*, and move to the lungs via the lymphatics or blood. They then migrate to the liver and mature in the intrahepatic portal venules. Sexual multiplication of adult worms takes place in the venules of the mesenteric venous system of the large intestine (*S. mansoni*) or in the venules of the urinary tract (*S. haematobium*). The females release large numbers of eggs, which may remain embedded in the tissues, embolize to the liver or lungs, or pass into the feces or urine.

Clinical manifestations may occur at any stage of the infection. Cercarial invasion may cause an intense itchy papular rash. Katayama fever is an acute serum sickness-like illness that occurs several weeks after infection, as eggs are being deposited in the tissues. Deposition of the eggs in tissues results in inflammation of the intestines, fibrosis of

the liver, and portal hypertension. With *S. haematobium*, chronic inflammation and fibrosis of the ureters and bladder may lead to obstructive uropathy (214).

Renal manifestations of schistosomiasis occur most commonly in *S. mansoni* infection. Schistosomal nephropathy usually presents with symptoms including granulomatous inflammation in the ureters and bladder, but glomerular disease (probably on an immune-complex basis) may also occur. Renal disease usually occurs in older children or young adults with long-term infection, but serious disease may also occur in young children (214).

The early renal tract manifestations of schistosomiasis are suprapubic discomfort, frequency, dysuria, and terminal hematuria. In more severe cases, evidence of urinary obstruction appears. Poor urinary stream, straining on micturition, a feeling of incomplete bladder emptying, and a constant urge to urinate may be severely disabling symptoms. The fibrosis and inflammation of ureters, urethra, and bladder may be followed by calcification and may result in hydronephrosis, hydro-nephrosis, and bladder neck obstruction. Renal failure may ultimately develop, and there is a suspicion that carcinoma of the bladder may be linked to the chronic infective and inflammatory process. Secondary bacterial infection is common within the obstructed and inflamed urinary tract (213).

The hepatosplenic form of *S. mansoni* infection may be accompanied by a glomerulopathy in 12 to 15% of cases, manifested in the majority as nephrotic syndrome (215). Histopathologic findings include mesangioproliferative GN, focal segmental glomerulosclerosis, mesangiocapillary GN, MGN, and focal segmental hyalinosis (216). Immune complexes may be detected in the circulation of these patients, and glomerular granular deposition of IgM, C3, and schistosomal antigens are seen on immunofluorescence. Usually *Schistosoma*-specific nephropathy is a progressive disease and is not influenced by antiparasitic or immunosuppressive therapy (217), but isolated case reports of remission after treatment with praziquantel have been reported (218).

The diagnosis is confirmed by the detection of *Schistosoma* eggs in feces, urine, or biopsy specimens. Eggs are shed into the urine with a diurnal rhythm, and urine collected between 11 AM and 1 PM is the most useful. Urinary sediment obtained by centrifugation or filtration through a Nuclepore membrane should be examined.

In cases in which studies of urine and feces yield negative results in patients in whom the diagnosis is suspected, rectal biopsy specimens taken approximately 9 cm from the anus have a high diagnostic yield for both *S. mansoni* and *S. haematobium* infection. Biopsy of liver or bladder may be required to establish the diagnosis.

Antibodies indicating previous infection can be detected using enzyme-linked immunosorbent assay or radioimmunoassay. The tests are sensitive but lack specificity and may not differentiate between past exposure and current infection.

Praziquantel is the drug of choice for treatment of schistosomiasis. A single oral dose of 40 mg/kg is effective in *S.*

haematobium and *S. mansoni* infection and is usually well tolerated. The alternative drug for *S. mansoni* infection is oxamniquine. Complete remission of urinary symptoms may occur in renal disease of short duration, but in late disease with extensive fibrosis, scarring, and calcification, obstructive uropathy and renal failure may persist after the infection has been eradicated. There are reports of a drastic decrease in the number of severe hepatosplenic forms of *S. mansoni* infection after mass treatment of the population in endemic areas with oxamniquine. This also reduced schistosomal nephropathy (215).

Leishmaniasis

Visceral leishmaniasis is a chronic protozoan infection characterized by fever, hepatosplenomegaly, anemia, leukopenia, and hyperglobulinemia. Proteinuria and/or microscopic hematuria or pyuria have been reported in 50% of patients with visceral leishmaniasis (219). Acute renal failure in association with interstitial nephritis has also been reported (220). Renal histologic analysis in patients with visceral leishmaniasis reveals glomerular changes, with features of a mesangial proliferative GN or a focal proliferative GN, or a generalized interstitial nephritis with interstitial edema, mononuclear cell infiltration, and focal tubular degeneration. Immunofluorescence reveals deposition of IgG, IgM, and C3 within the glomeruli, as well as electron-dense deposits in the basement membrane and mesangium on electron microscopy (219). Circulating immune complexes together with immunoglobulin and complement deposition in the glomeruli suggests an immune-complex cause.

Renal disease in leishmaniasis is usually mild and may resolve after treatment of the infection. Renal dysfunction may be associated with treatment for visceral leishmaniasis with antimony compounds.

Filariasis

Proteinuria is more common in filarial hyperendemic regions of West Africa than in nonfilarial areas. Renal histologic analysis has shown a variety of different histopathologic appearances; the most common is diffuse mesangial proliferative GN with C3 deposition in the glomeruli (221). Renal biopsy specimens also demonstrate large numbers of eosinophils in the glomeruli, and microfilariae may be seen in the lumen of glomerular capillaries. Filarial antigens have been detected within immune deposits within the glomeruli.

Hydatid Disease

Echinococcus granulosus causes chronic cysts within a variety of organs. In addition, nephrotic syndrome in association with hydatid disease has been reported. Membranous nephropathy, minimal change lesions, and mesangiocapil-

lary GN have been described in association with hydatid disease (222,223). Immunofluorescence reveals deposits of immunoglobulin, complement, and hydatid antigens within the glomeruli. Remission of nephrotic syndrome has been reported with treatment by antiparasitic agents such as albendazole (222,223).

Trypanosomiasis

Few reports have been published of renal disease occurring in patients with trypanosomiasis. The trypanosomal antigens can induce GN in a variety of experimental animals (224).

Toxoplasmosis

Nephrotic syndrome has occasionally been reported as a manifestation of congenital toxoplasmosis.

Dissemination of previously latent *Toxoplasma* infection in patients undergoing treatment with immunosuppressive drugs has been increasingly recognized in recent years. Reactivation of toxoplasmosis or progression of recently acquired primary infection should be considered in patients undergoing renal transplantation or immunotherapy for renal disease who develop unexplained inflammation of any organ.

FUNGAL INFECTIONS

Fungal infections of the kidneys and urinary tract occur most commonly as part of systemic fungal infections in patients with underlying immunodeficiency, as focal urinary tract infections in patients with obstructive lesions, or as a result of indwelling catheters. Although *Candida* infection is the most common fungal infection in both immunocompromised and nonimmunocompromised hosts, virtually all other fungal pathogens may invade the renal tract during severe immunocompromise.

Urinary infection with *Candida albicans* is most commonly a component of systemic candidiasis in patients who are severely immunocompromised. Systemic candidiasis is also seen in premature and term infants with perinatally acquired invasive candidiasis. Presentation is usually with systemic sepsis, fever or hypothermia, hepatosplenomegaly, erythematous rash, and thrombocytopenia. Systemic candidiasis may be seen on ophthalmologic investigation as microemboli in the retina. The first clue to the underlying diagnosis may be the presence of yeasts in the urine (225).

Candida involvement of the urinary tract may affect all structures including the glomeruli, tubules, collecting system, ureters, and bladder. Microabscesses may form within the renal parenchyma, and large balls of fungi may completely obstruct the urinary tract at any level. Acute renal failure caused by systemic candidiasis or obstruction of the renal tracts with fungal hyphae is a well-recognized complication of systemic candidal infection (225,226).

Indwelling catheters (which form a nidus for persistent infection) should be removed. Successful treatment of nonobstructing bilateral renal fungal balls by fluconazole either alone or in combination with liposomal amphotericin B has been reported (227,228). In the presence of obstruction, however, percutaneous nephrostomy to relieve the obstruction with antegrade amphotericin B irrigation, coupled with systemic antifungal therapy, is the mainstay of treatment (226). Amphotericin B is the most effective antifungal agent, but it is not excreted in the urine. Local irrigation via nephrostomy provides good results, however. For treatment of urinary tract candidiasis, it is usually combined with fluconazole or 5-flucytosine, both of which are excreted in high concentrations in the urine. Treatment is required for weeks to months to ensure complete elimination of the fungus, and the ultimate outcome is largely dependent on whether there is a permanent defect in immunity.

MISCELLANEOUS CONDITIONS

Hemorrhagic Shock and Encephalopathy

In 1983, Levin et al. first described hemorrhagic shock and encephalopathy, which appeared to be distinct from previously recognized pediatric disorders (229). Other cases have subsequently been reported from several centers in the United Kingdom, Europe, Israel, the United States, and Australia, and the syndrome is now recognized as a new and relatively common severe childhood disorder (230).

Hemorrhagic shock and encephalopathy usually affect infants in the first year of life, with a peak onset at 3 to 4 months of age. A prodromal illness with fever, irritability, diarrhea, or upper respiratory infection occurs 2 to 5 days before the onset in two-thirds of cases. Affected infants develop profound shock, coma, convulsions, bleeding and evidence of DIC, diarrhea, and oliguria. Laboratory findings include acidosis, falling hemoglobin and platelet levels, elevated urea and creatinine levels, and elevated levels of hepatic transaminases. Despite vigorous intensive care, the prognosis is poor, and most affected infants die or are left severely neurologically damaged (230,231). A small number of patients have been reported to survive without residual sequelae.

The renal impairment appears to be largely prerenal in origin, and when aggressive volume replacement and treatment of the shock results in improved renal perfusion, rapid improvement in renal function is usually observed. In patients with profound shock unresponsive to initial resuscitation, vasomotor nephropathy supervenes and dialysis may be required. Myoglobinuria in association with hemorrhagic shock and encephalopathy has been reported.

Kawasaki Disease

Following the description of the mucocutaneous lymph node syndrome by Kawasaki in 1968, Kawasaki disease has

been recognized as a common and serious childhood illness with a worldwide distribution. Although the etiology remains unknown, epidemiologic features clearly suggest an infective cause. The disease occurs in epidemics, and wave-like spread has been demonstrated during outbreaks in Japan (see Chapter 44).

Amyloidosis

Deposition of amyloid within the kidney is an important complication of chronic and persistent infection. Amyloidosis is most common in patients with chronic osteomyelitis and chronic pulmonary infections such as bronchiectasis and is seen occasionally in those with persistent infections such as leprosy or malaria.

NEPHROTOXINS

RUSSELL W. CHESNEY
DEBORAH P. JONES

Because of its vital role as an excretory organ, the kidney is responsible for the elimination and metabolism of many foreign organic compounds, including pharmacologic agents. Ultimately these agents reach the urinary space for excretion via glomerular filtration or tubular secretion (Fig. 52.1). In some instances drugs must undergo transformation into metabolites, a reaction that may actually take place within tubular cells before secretion into the tubular lumen. Unfortunately, while performing its role as an excretory and metabolic organ, the kidney may undergo anatomic or functional changes as a result of drug-induced toxicity.

Factors that contribute to the distinct susceptibility of the kidney to injury include exposure to potentially harmful compounds, given the magnitude of blood flow through glomeruli and peritubular vessels; the large surface area available for uptake of potentially harmful compounds; the concentration of toxic species within the tubular lumen to promote accumulation of the toxin within the renal tubular cell; dependence of the renal tubular cell on a high metabolic rate to maintain function; and the distribution of unique transport systems that concentrate drugs or toxins within the tubular cell (1).

Certain nephrotoxins may preferentially damage specific nephron segments, depending on the area of maximal exposure, the location of specific uptake systems, and the nephronal location of specific intracellular sites that are susceptible to the toxin (1). The concentration of a drug within the renal tubular cell may be affected by the dissociation constant of the compound, its lipid solubility, tubular secretory or reabsorptive activity, water handling, competitive tubular transport mechanisms, urinary pH, and urinary flow rate. The concentration also may be affected by the distribution of enzymes that metabolize individual drugs and intracellular protective systems important in the maintenance of normal cell metabolism.

Potential mechanisms for drug-induced renal dysfunction include alterations in renal perfusion and glomerular filtration, tubular cell damage, and tubular obstruction (Fig. 52.2) (1). Toxic nephropathy, or drug-induced renal dysfunction, is primarily a disorder of the renal tubule; however, significant tubular damage eventually results in alterations in glomerular function as well. In addition, drugs or their metabolites may

alter glomerular blood flow through vasoconstriction of the glomerular capillaries (1). This may be a primary event through actions on the endothelial cell or a secondary event via activation of tubuloglomerular feedback after tubular damage allows increased distal delivery of solute and fluid.

Drugs may undergo redox recycling, which results in oxidative stress within the cell and alters the normal antioxidant defense mechanisms. The elaboration of reactive oxygen species by the cytochrome P-450 system may enable reactive intermediates to initiate damage directly or to combine with glutathione (GSH) to deplete available GSH (2). GSH protects cells from oxidant stress as it participates in detoxification reactions during vital cell processes such as protein and nucleic acid synthesis. Depletion of cellular levels of GSH is a common pathway for nephrotoxic injury (2). Drugs or metabolites may either directly conjugate GSH or be metabolized to compounds that are reactive and may bind to GSH. Ultimately, reactive species promote injury, which interferes with normal cellular functions such as energy production, detoxification, transport, and macromolecular synthesis. Although they may come from widely different chemical classes and have different renal distributions, toxic compounds may ultimately affect renal integrity and function through inhibition of cellular energy production, disruption of membrane integrity, perturbation of vital cell functions such as protein or nucleic acid synthesis, or alteration in intracellular calcium homeostasis (Fig. 52.3).

This chapter focuses on the clinical characteristics, mechanisms of injury, if known, and potential methods to reduce or prevent drug-associated renal damage and dysfunction. The most common offending agents have been chosen; this discussion is not meant to be all inclusive.

NEPHROTOXICITY FROM ANTIBIOTICS

The concentration of antibiotics by renal tissue exposes them to a toxicity that other organs do not experience (3).

FIGURE 52.1. Renal drug elimination is a combination of glomerular filtration and tubular secretion. Many factors have an impact on renal cell accumulation and nephronal excretion.

Nephrotoxic clinical syndromes include acute tubular necrosis (ATN), acute interstitial nephritis (AIN), direct tubular effects on transport systems (electrolytes, protons leading to acidosis, concentration defects, or the full-blown Fanconi syndrome), and tubular obstruction from drug precipitation. Other mechanisms of antimicrobial toxicity include the induction of rhabdomyolysis or hemolytic anemia, which leads to release of cell products—myoglobin, phosphate, or hemoglobin. Macrolide antibiotics, which interfere with the metabolism of calcineurin inhibitors, may indirectly lead to renal damage (4).

Aminoglycosides

Aminoglycoside antibiotics are widely used antimicrobials that are particularly nephrotoxic (5). Although ATN is the most

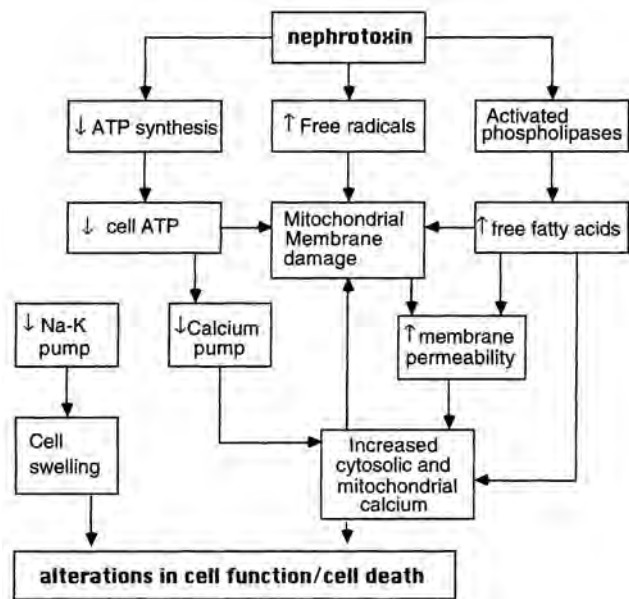

FIGURE 52.2. Biochemical pathways resulting in cell injury and dysfunction. ATP, adenosine triphosphate.

FIGURE 52.3. Mechanisms whereby drugs induce renal functional changes at the glomerulus and tubule. **A:** Vasoconstriction, which may be a primary or secondary event (drug examples are amphotericin B and cyclosporine). **B:** Tubular obstruction (drug examples are acyclovir and contrast media). **C:** Tubular cell injury and necrosis with backleak from loss of epithelial integrity (drug examples include aminoglycosides, amphotericin B, cisplatin, and ifosfamide).

common mechanism of toxicity, a variety of tubular dysfunction states have been noted, including hypomagnesemia, hypocalcemia, hypokalemia, and full-blown Fanconi syndrome (3). Certain risk factors predispose to aminoglycoside toxicity: drug dosage, timing, and duration of administration; age group (especially neonates and geriatric populations); preexisting renal insufficiency, which may not be recognized by the caretaker; concomitant administration of other nephrotoxic agents, such as amphotericin B, certain cephalosporins, and cyclosporin; extracellular volume depletion; and potassium depletion. Other risk factors include use of a contrast medium, presence of shock or liver disease, and excessive use of diuretics (5).

Aminoglycosides are excreted primarily by glomerular filtration. Reabsorption by the proximal tubule cell occurs after charge interaction and binding of aminoglycosides, which are strongly cationic, with the brush-border membrane of the proximal tubule, followed by transport into the cell by pinocytosis into vesicles directed to lysosomes (6,7). Although less significant, reabsorption from the basolateral surface of the tubular cell may also contribute to total intracellular uptake (8). Accumulation of the drug within the lysosome results in phospholipid hydrolysis and the formation of electron-dense myeloid bodies, which are membranous structures found within lysosomes (5). Aminoglycosides appear to have a generalized effect on phospholipid membranes, which results in decreased surface charge and alterations in fluidity and permeability of tubular cell membranes (3,5).

Pathologic alterations have been reported after a single dose of aminoglycoside, but most animal models of aminoglycoside toxicity use multiple doses over several days to produce a model of toxic nephropathy. Once appreciable injury occurs, lysosomal membranes release sequestered aminoglycosides as well as lysosomal enzymes, which cause generalized cell injury and eventual necrosis (9,10).

The main pathologic finding in aminoglycoside nephrotoxicity is tubular cell necrosis, involving principally the most proximal segments of the nephron: the convoluted tubule and pars recta (S1 and S2) (1,11). The earliest pathologic finding is an increased number of lysosomes, followed by alterations in the brush-border architecture and mitochondrial swelling (12). This process may be focal or diffuse. Of interest, even during continued aminoglycoside administration, tubular cell regeneration can be evident. One component of the insensitivity of the regenerating tubule cell is the inhibition of aminoglycoside uptake across the apical membranes of S1 and S2 cells (13). Gentamicin also interferes with mitochondrial respiration by enhancing hydrogen peroxide generation, which includes iron mobilization from the mitochondria. Hydroxy-radical scavengers and iron chelators are protective in the rat model of aminoglycoside toxicity (2).

Clinical features of aminoglycoside nephrotoxicity initially include subtle indications of tubular or glomerular dysfunction, and the nephrotoxicity occasionally progresses to oliguria and renal failure. The earliest clinically detectable abnormality is enzymuria, which results from loss of brush-border membrane segments bearing the enzymes (14). Tubular damage may rarely produce a Fanconi syndrome with proximal tubular wasting of glucose, phosphate, amino acids, and bicarbonate as well as numerous ions including magnesium (5,11). Urine volume initially may be increased with mild to moderate tubular toxicity because of a vasopressin-resistant concentrating defect. Renal dysfunction is most commonly detected after a rise in serum creatinine concentration or elevated aminoglycoside trough levels. Although it is rare, severe, sustained renal dysfunction has been described with peak serum creatinine levels at 3 to 10 days after cessation of aminoglycoside therapy and full recovery in weeks (15).

Glomerular filtration rate (GFR) may decrease after gentamicin administration in the absence of tubular necrosis from angiotensin II-mediated afferent arteriolar vasoconstriction. Prostaglandin synthetase inhibitors potentiate the vasoconstriction and hypofiltration, which provides indirect evidence of a palliative role of locally produced vasodilatory prostaglandins in this form of nephrotoxic injury (16). In addition to the microvascular and tubular changes, K_f (glomerular capillary ultrafiltration coefficient) is decreased because of a decrease in the number and density of glomerular capillary wall fenestrae (17,18).

The relative toxicity of the aminoglycosides, in order from most toxic to least, is neomycin, gentamicin, tobramycin, and amikacin (11). This order is dependent on the number of ion-

izable amino groups, which affects brush-border membrane binding: six for neomycin, five for gentamicin, four for amikacin and kanamycin, and three for streptomycin (19). Several factors may contribute to or predispose to aminoglycoside nephrotoxicity. Drug dosage and duration of therapy, particularly repeated and prolonged courses, determine the severity of the tubular toxicity. Concomitant administration of other nephrotoxic drugs, concomitant administration of cationic amino acids, volume depletion, potassium depletion, endotoxemia, hypokalemia, and hyperphosphatemia further potentiate renal injury (6,11,20). Nephrotoxicity may be attenuated by increased intake of dietary calcium, alkalization of the urine, solute diuresis, and use of calcium-channel blockers or captopril (6).

Prevention of aminoglycoside toxicity involves the prudent use of aminoglycosides and alertness to iatrogenic potential. Careful dosing schedules reduce toxicity. The time of aminoglycoside administration also may affect toxicity. Both animal and human studies indicate that clearance is slower during periods of inactivity such as sleep (20). In addition, once-daily dosing has been adopted by some practitioners as a means of reducing toxicity without interfering with efficacy (21). Although not yet adopted by all pediatric centers, once-daily dosing proved to be effective, with higher peak levels and no difference in toxicity among a group of neonates (22). Animal studies also support this mode of therapy as a means of reducing the risk of nephrotoxicity while maintaining or even increasing bactericidal activity (23). It is prudent to avoid standard aminoglycoside dosages and administration intervals during periods of volume contraction or after vigorous diuresis. Blood levels of aminoglycosides should be monitored during administration with a target for the trough level of less than 2.0 $\mu\text{g/mL}$. Recognition of the interaction of certain drugs with each other allows anticipation of renal toxicity. For example, furosemide enhances renal aminoglycoside toxicity by leading to volume contraction. Cephalothin, not currently available in the United States, is the most potent interacting cephalosporin (3).

β -Lactam Antibiotics

The β -lactam antibiotics are related to the penicillins. Structurally, they are bicyclic compounds that acylate bacterial wall proteins and penetrate the bacterium to inactivate vital enzymes. Whereas most penicillin-like compounds are not nephrotoxic, certain cephalosporins and carbapenem compounds are associated with renal toxicity (24).

The β -lactams are extracted from renal venous blood by the organic acid transport system located on the basolateral surface of the tubular cell (organic anion transporter I, II, III). Intracellular accumulation results because of the limited ability of the proximal tubular cell to secrete the β -lactam at the luminal membrane into the luminal fluid (urine). Differences in organic acid transporter characteristics between basolateral and

apical membranes result in marked accumulation with high intracellular levels, sometimes a thousand times higher than the levels found in plasma or other types of cells (24). Because of the very specific distribution of *p*-aminohippuric acid-sensitive organic acid transporters, renal injury in the form of tubular cell necrosis is limited to the proximal tubule (24). The initial event is thought to be lipid peroxidation with particular damage to the mitochondrial membrane, possibly through acylation of important membrane-associated transporters. Mitochondrial damage interferes with energy production, which leads to decreased levels of adenosine triphosphate and subsequent cell damage and death. Replacement of deficient cellular substrates can reverse toxicity (10). Damage secondary to β -lactams is related to decreased mitochondrial respiration and decreased succinate uptake by mitochondria within hours after drug administration (24).

The original compounds cephaloridine and cephaloglycin are no longer used; the new compound imipenem, which is a carbapenem, is nephrotoxic and is used only in combination with cilastin, an inhibitor of brush-border dehydropeptidase I. Cilastin inhibits the metabolism of imipenem to metabolites with structural similarity to cephaloridine (25). Meropenem, another agent in the carbapenem class, is not metabolized to an appreciable degree and therefore does not require co-administration with cilastin.

Clinical characteristics of β -lactam-associated nephrotoxicity include ATN with or without oliguria, which lasts days to weeks. Drug dosage should be adjusted according to the patient's renal function. Administration of organic anion transporter inhibitors (probenecid) may help to prevent injury. However, because these agents also impair tubular secretion, and thus drug elimination, blood levels of the β -lactam would be expected to be higher in the presence of organic anion inhibitors.

Renal toxicity from β -lactams can also result from hypersensitivity reactions. The molecular weights of all β -lactams are insufficient to be directly immunogenic. These antibiotics or their metabolites can bind to larger molecules, which then act as haptens. Although exposure to many penicillins and cephalosporins can result in AIN, AIN is most common with methicillin (26,27). This syndrome consists of fever, rash, oliguria, and, rarely, arthralgias. Laboratory findings are prominent in the urine with pyuria, eosinophiluria, and proteinuria with azotemia. The main therapy is discontinuation of the β -lactam, but glucocorticoids have been used and may enhance recovery (28).

Other Antibiotics

Because antibiotics are concentrated in tubules and urine, the opportunity for toxicity is great. *Sulfonamides* and their acetylated metabolites are poorly soluble in aqueous solutions and may lead to intrarenal obstruction. The use of sulfonamide mixtures, particularly the inclusion of *trimethoprim*, reduces this danger (3). Trimethoprim, which blocks

bacterial and protozoal dihydrofolate reductases to inhibit tetrahydrofolic acid synthesis, has an amiloride-like influence on the distal tubule, which can result in hyperkalemia and metabolic acidosis (29,30).

Macrolide antibiotics, including *erythromycin*, *clarithromycin*, *azithromycin*, and *dirithromycin*, inhibit the cytochrome P-450 isoenzyme CYP 3A4, which interferes with the metabolism of cyclosporin or tacrolimus and results in indirect renal toxicity (31).

Although *vancomycin* was initially felt to be extremely nephrotoxic, this was likely the result of impurities when it was introduced in the 1950s, and its direct toxicity is difficult to demonstrate (3).

Tetracyclines have an interesting profile of nephrotoxicity. AIN along with nephrogenic diabetes insipidus has been described after use of demeclocycline. In cirrhotic patients, tetracyclines can potentiate acute renal failure. Use of outdated tetracyclines can lead to Fanconi syndrome. This latter result was due to a degradation product, anhydro-4-epitetracycline. Finally, syndromes of inappropriate secretion of antidiuretic hormone and phosphaturia have been described (3). Because of tooth staining, this class of agents is little used in children.

The polypeptide antibiotics polymyxin B, polymyxin E (*colistin*), and *bacitracin* are lipophilic agents that readily bind to plasma membranes. They have a mode of toxicity similar to that of aminoglycosides. This potential for nephrotoxicity has largely prevented their parenteral use. In the United States only topical preparations remain available (3).

ANTIFUNGAL AGENTS

Amphotericin B

Amphotericin B is an antifungal agent that exerts its effect by interaction with membrane sterols. This chemical interaction is the basis for its antifungal action as well as renal toxicity (11). Amphotericin B has two major pathophysiologic effects on the kidney: renal tubular cell injury, which is manifest as hypokalemia, hypomagnesemia, and acidosis; and decreased GFR secondary to afferent arteriolar vasoconstriction (5,32).

Unlike in most other drug-associated renal tubular toxicity, the primary tubular site of amphotericin B-induced injury is the distal tubule (11). The interaction of this drug with membrane cholesterol leads to the formation of aqueous pores, which greatly increase the permeability of the normally tight epithelium of the distal tubule; this results first in a backleak of H^+ , Na^+ , and Cl^- , and then to a vasopressin-resistant polyuria (11,33). Use of this agent will result in the formation of pores in all patients exposed. Increased permeability to Cl^- may stimulate increased tubuloglomerular feedback and reduce GFR, which ultimately results in renal ischemia and azotemia. In a canine model, amphotericin administration led to a decrease in urine flow and GFR

within 1 hour, accompanied by increased renal vascular resistance as a result of afferent arteriolar constriction (34). Aminophylline blocks amphotericin B–induced vasoconstriction, which suggests a role for adenosine as a potential mediator (35). Verapamil also protects the kidney from vasoconstriction, which indicates that increased calcium in vascular smooth muscle may mediate the acute effects (36).

Amphotericin B nephrotoxicity may become clinically evident as a reduction in GFR, usually detected as an increase in plasma creatinine level or as distal tubular dysfunction with metabolic acidosis (secondary to the distal type of renal tubular acidification defect), salt wasting, polyuria, hypomagnesemia, or hypokalemia (6,11). Nephrotoxicity is predictable and usually reversible, although irreversible azotemia has been observed at large dosages. The severity of tubular toxicity and hypofiltration is proportional to the cumulative dose. In adults, a cumulative dose exceeding 5 g was associated with significant renal dysfunction, whereas patients who received less than a 600-mg cumulative dose rarely suffered renal toxicity (37). Newborn infants are equally susceptible to amphotericin nephrotoxicity (38). Concomitant use of diuretics, cyclosporine, or aminoglycoside antibiotics and abnormal pretreatment renal function increase the risk of amphotericin toxicity (11,37). This is especially true in the bone marrow transplant patient.

Sodium loading appears to have a beneficial effect on amphotericin B–induced nephrotoxicity by maintaining intravascular volume and reducing renal vasoconstriction (11,37). Mannitol has been shown to ameliorate nephrotoxicity in animal studies, but the benefit of this agent in humans has not been consistently demonstrated (39,40).

Lipid formulations of amphotericin B have been developed in an attempt to reduce renal toxicity and deliver more drug to treat serious fungal sepsis or resistant fungal disease. The aim of the lipid preparations of amphotericin B is to direct the drug to preferentially bind to fungal membranes rather than mammalian membranes. Several formulations of lipid-associated amphotericin B have been tested. Efficacy and toxicity vary depending on which lipid compounds are used. Neutropenic rabbits treated with Ambisome (5 mg/kg/day), which is a unilamellar vesicle formulation, did not exhibit the increased creatinine levels observed in animals given standard amphotericin B (41). Amphotericin B lipid complex was used in 228 immunocompromised patients with refractory mycoses or toxicity from standard amphotericin B. Renal toxicity was minimal. A prospective study comparing administration of regular amphotericin B with and without co-administration of lipid emulsion found that approximately two-thirds of those who received regular amphotericin B alone exhibited signs of renal toxicity, whereas minimal renal toxicity was seen in the group who received amphotericin B with lipid emulsion (42). In the setting of established renal insufficiency from administration of the standard amphotericin B formulation, renal function

may not appreciably improve with use of liposomal or lipid-associated amphotericin B. Comparative clinical trials need to be performed to define the best preparation and dosage for various clinical situations.

Azoles

The azole antifungals consist of the imidazole ketoconazole and the two triazoles fluconazole and itraconazole (3). Each acts to inhibit ergosterol synthesis by blockade of the fungal cytochrome P-450 system.

These azoles are not directly toxic. Each—and ketoconazole, in particular—may lead to indirect nephrotoxicity in patients treated with calcineurin inhibitors by inhibiting CYP 3A4 metabolism of cyclosporin or tacrolimus (43).

Griseofulvin

Griseofulvin actually enhances cytochrome P-450 metabolism, so that it could theoretically increase calcineurin-inhibitor metabolism and lead to transplant rejection (3).

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit cyclooxygenase and inhibit prostaglandin synthesis from arachidonic acid. The kidney synthesizes and metabolizes prostaglandins. Cortical prostaglandins modify regional blood flow, glomerular filtration, and renin release (44). Medullary prostaglandins regulate medullary blood flow, tubular response to arginine vasopressin, and sodium chloride reabsorption in the loop of Henle. Prostaglandin production can be stimulated by angiotensin II, arginine vasopressin, catecholamines, and renal sympathetic nerve stimulation. Stimulation of prostaglandin synthesis occurs by hormone-mediated activation of phospholipases, which release arachidonic acid from membrane-associated phospholipids (44).

Under normal conditions prostaglandins exert minimal effect on renal blood flow. Under conditions such as impaired GFR, alterations in renal hemodynamics, and sodium depletion, however, the compensatory release of vasodilatory prostaglandins I_2 and E_2 helps to maintain renal blood flow and GFR, and modifies the effect of local vasoconstrictive substances such as angiotensin II (44). Therefore, it is in the presence of such altered physiologic states that renal functional alterations associated with NSAIDs are likely to occur, because the normal compensatory mechanisms are blocked. NSAIDs potentiate prerenal ischemia, increasing sodium reabsorption by the proximal tubule and the ascending limb of the loop of Henle. NSAIDs also increase the sensitivity of the collecting tubule to vasopressin, which further adds to salt and water retention and may produce a hyporeninemic hypoaldosteronism through reduction of renin release (44).

Acute renal failure secondary to NSAIDs results from excessive vasoconstriction at the level of the afferent arteriole. An acute phenomenon often associated with oliguria, NSAID-induced acute renal failure usually is reversible. Risk factors include volume depletion from states such as dehydration, hemorrhage, congestive heart failure, hepatic failure with ascites, and hypoalbuminemia (44).

In addition to having physiologic actions that produce renal functional changes, NSAIDs also may produce a tubulointerstitial nephritis. Arising after 2 to 18 months of therapy, this syndrome is associated with an interstitial mononuclear cell infiltrate and occasionally epithelial cell podocyte fusion on electron microscopy (45). NSAIDs are also associated with polyuric acute renal failure with nephrotic syndrome. Renal functional recovery typically occurs when the agent is discontinued.

Long-term use of NSAIDs may cause papillary necrosis as well as chronic renal insufficiency through chronic ischemia (45). The risk of chronic renal disease (serum creatinine level above 1.5 mg/dL) in daily users of NSAIDs was 2.1% (34). Although most epidemiologic studies were performed in adults, children also are at risk for renal failure (46). Prenatal exposure may lead to renal failure-associated deaths after administration of 140 to 400 mg of indomethacin per day for anywhere between 2 and 11 weeks of therapy (47). Risk factors for renal functional changes are underlying volume depletion and renal disease (44). Acute administration of NSAIDs to patients with chronic renal insufficiency results in decreased renal plasma flow, decreased GFR, decreased fractional excretion of sodium, and decreased fractional free water clearance (48). Most healthy, normal subjects who take NSAIDs for a limited duration tolerate these agents without adverse events, but a subset of individuals appears to be at risk. Because ibuprofen is now commercially available for treatment of fever in children, the incidence of NSAID-related renal disease may increase. Febrile children often have reduced fluid intake in the face of increased insensible fluid losses with clinically mild but significant hypovolemia, which places them at risk for NSAID toxicity.

ANTIVIRAL AGENTS

Acyclovir and ganciclovir are active against herpes viruses and cytomegalovirus (CMV). Acyclovir is excreted primarily by the kidney. Anywhere from 30 to 90% of the drug is excreted unchanged in the urine in patients with normal glomerular filtration. Acyclovir is probably excreted by both glomerular filtration and tubular secretion (49). Pretreatment with probenecid decreases renal clearance of the drug by 32%, which supports a role for tubular secretion as a partial mechanism of excretion. The dosing interval must be adjusted in the setting of a decreased GFR (49).

Acyclovir administration is complicated by renal, hepatic, and neurologic dysfunction (49). Renal toxicity is

associated with plasma concentrations of acyclovir exceeding 20 µg/mL. Renal levels of acyclovir can be 20 times the plasma levels. The solubility of acyclovir in water is 2.5 mg/mL, but solubility in urine is lower. Crystals form within the renal tubule (usually the collecting duct), which leads to intratubular obstruction followed by a rise in the serum creatinine concentration within 24 to 48 hours (50,51). Needle-shaped crystals may form in the urine even in those who do not have clinical evidence of renal dysfunction. In most cases, renal failure is not associated with oliguria and GFR returns to normal within 1 week. Urinary findings include hematuria, pyuria, proteinuria, and crystalluria. Histologically, ATN may be observed along with patchy interstitial infiltration (51).

Renal toxicity was noted in rats during preclinical toxicology studies. An obstructive nephropathy developed, with associated drug crystallization within the collecting ducts. The development of crystalluria was dosage related. Acyclovir administration to rats was accompanied by a reduction in GFR and significant increase in total renal vascular resistance without changes in urinary flow rate (52). Acute changes appeared to be secondary to increased arteriolar resistance, whereas chronic toxicity was associated with a decline in K_f in addition to vasoconstriction. Ganciclovir administration did not induce a decrease in GFR or change in renal vascular resistance in this rat model (52).

In a large series of patients who received acyclovir for serious infections, 58 of 354 adult patients experienced elevations of the serum creatinine level. In a separate study, 12% of children given acyclovir had elevated serum creatinine concentrations. Some of the elevations were transient, with improvement in the creatinine levels during continued administration of the drug. In most patients renal function returns to normal after discontinuation of the drug. Most importantly, one must adjust dosing intervals in the face of decreased GFR.

Risk factors for renal toxicity include high peak concentrations after rapid intravenous administration, dehydration (or conditions in which urine flow is diminished), and preexisting renal disease (53). Therefore, consideration of the individual's renal function, adequate hydration, and slow infusion rates (over a minimum of 1 hour) should lower the risk for renal toxicity.

Ganciclovir is excreted entirely by glomerular filtration, with 99% of the dose appearing in the urine (49). In addition, plasma clearance is highly correlated with creatinine clearance and is approximately twice that of creatinine clearance, which indicates significant elimination by proximal tubular secretion. Ganciclovir is seldom associated with renal insufficiency or damage except in the setting of impaired GFR and concomitant administration of nephrotoxic agents.

Foscarnet is an antiviral agent with promising results against herpes viruses. Foscarnet is a pyrophosphate analogue that interferes with viral replication by binding to a

site on the herpes virus DNA polymerase or human immunodeficiency virus (HIV) reverse transcriptase (54,55). Foscarnet most commonly is used to treat CMV infection alone or in combination with ganciclovir, usually in the setting of CMV prophylaxis, CMV retinitis, or disease after bone-marrow transplantation or in immunodeficient states.

Foscarnet appears to be excreted primarily by glomerular filtration, with little contribution by tubular secretion (54). Foscarnet causes reversible decreases in GFR in 20 to 60% of patients. The incidence of acute renal failure is dependent on the definition used by the investigators (55). Two mechanisms for renal damage have been reported: tubular necrosis and crystallization within glomerular capillaries with crescentic glomerulonephritis. Hydration at the time of administration is thought to reduce the incidence of acute renal failure considerably.

Functional renal tubular effects of foscarnet include hypophosphatemia, hypokalemia, renal tubular acidosis, and vasopressin-resistant diabetes insipidus (56). Alterations in mineral metabolism associated with foscarnet therapy include hyperphosphatemia, hypocalcemia, and transient increases in parathyroid hormone level (57). Explanation of these alterations is difficult because animal studies demonstrated inhibition of proximal tubular reabsorption of phosphate and would have predicted hypophosphatemia. One group of investigators postulated that direct binding of foscarnet with ionized calcium is responsible for the acute hypocalcemia and that reducing the dosage may allow continued therapy.

In a series of bone marrow transplant recipients, increased creatinine levels occurred in 17 of 19 patients, with 4 requiring hemodialysis (58). Hypocalcemia was reported in 16, and hypophosphatemia in 17. When 26 courses of foscarnet were given to patients with HIV infection, two patients experienced a creatinine level higher than 3.0 mg/dL, six had hyperphosphatemia, three had hypophosphatemia, three had hypocalcemia, and two had hypokalemia (59). Acute renal failure associated with foscarnet also has been reported (60). Hydration with saline may reduce the risk of nephrotoxicity. An increase in the serum creatinine level (defined as more than 25% above baseline) occurred in 66% of nonhydrated adults but only 13% of hydrated adults. Even those with abnormal pretreatment GFR tolerated foscarnet therapy if the drug was given along with hydration (61). Protocols using a combination of foscarnet and ganciclovir at lower dosages have not been complicated with renal toxicity or electrolyte abnormalities (62).

Cidofovir is a nucleoside analogue of cytosine and an antiviral agent with activity against herpes viruses and potentially the BK virus (polyoma virus). The drug is filtered in its parent state without significant biotransformation. It causes increased creatinine concentration and proteinuria by direct proximal tubular toxicity charac-

terized by proximal tubular necrosis. Although the precise mechanism of renal damage is not known, one theory proposed that cidofovir may interfere with synthesis or degradation of membrane phospholipids (63). Cidofovir (as well as adefovir) uses the basolateral organic anion transporter for tubular secretory elimination. Renal toxicity of cidofovir is dependent on its uptake into the proximal tubular cells via this organic acid exchanger (63).

Administration of saline and probenecid are thought to reduce renal toxicity. Renal damage is occasionally irreversible (64). In the days before the administration of protective treatment, acute renal insufficiency was reported in one-third of patients.

CYCLOSPORINE

Cyclosporine is a cyclic peptide extracted from the fungus *Tolypocladium inflatum*. Cyclosporine is an immunosuppressive agent used in posttransplantation combination therapy and treatment of nephrotic syndrome and several autoimmune diseases. It is highly lipophilic, which makes its administration problematic from the standpoint of formulation and absorption. A newer formulation known as Neoral has replaced the previous form Sandimmune in most centers. Cyclosporine is metabolized by the cytochrome P-450 system. Concomitant administration of compounds that stimulate the hepatic cytochrome P-450 system can result in increased plasma clearance, whereas those that inhibit cytochrome P-450 increase cyclosporine plasma levels and potentiate toxicity (65). Numerous drug interactions with cyclosporine have been reported and are listed in Table 52.1.

In addition, metabolism is age related, with younger children having faster metabolic clearance (66). Because infants and children have a more rapid clearance and larger volume of distribution than adults, children require larger dosages to achieve comparable blood concentrations.

TABLE 52.1. DRUGS THAT INTERACT WITH CYCLOSPORINE

Increase cyclosporine level	Decrease cyclosporine level	Increase toxicity
Azithromycin	Carbamazepine	Acyclovir
Cimetidine	Methylprednisolone	Aminoglycosides
Diltiazem	Nafcillin	Amphotericin B
Doxycycline	Phenobarbital	Ciprofloxacin
Erythromycin	Phenytoin	Clotrimazole
Ketoconazole	Rifampin	NSAIDs
Metoclopramide		Trimethoprim
Nicardipine		
Verapamil		

NSAIDs, nonsteroidal antiinflammatory drugs.

Cyclosporine-related renal toxicity may be detected in the form of a proximal tubulopathy with proteinuria, bicarbonate or electrolyte wasting, and enzymuria, or as glomerular dysfunction. Glomerular effects of cyclosporine result in a reduction of GFR and hypertension. Early functional changes include vasoconstriction of the afferent arteriole accompanied by an increase in serum creatinine level and blood pressure, and positive fluid balance. The toxicity appears to be dosage related. Intravenous administration and the rate of intravenous infusion also have an impact on renal toxicity (67).

Proximal tubule functional defects include impaired secretion of urea and uric acid; reduced fractional excretion of sodium, potassium, and phosphate; and reduced bicarbonate reabsorption with hyperchloremic metabolic acidosis. Acute nephrotoxicity is manifested by decreased urinary flow rate, usually in the setting of a cadaveric renal transplant or intravenous administration (68). Administration of other nephrotoxic agents, particularly amphotericin B, catecholamines, NSAIDs, and radiocontrast agents, may potentiate acute toxicity. Subacute injury, which is reversible, may be difficult to distinguish from renal transplant rejection, so that a renal biopsy is required.

Chronic nephrotoxicity, defined as a 20% or greater irreversible reduction in the GFR, is characterized by morphologic changes, including tubular atrophy, interstitial fibrosis, and vascular hyalinosis and sclerosis (69). Analysis of data from the North American Pediatric Renal Transplant Cooperative Study revealed that pediatric transplant recipients who were given higher cyclosporine dosages tended to have higher yet stable plasma creatinine levels 2 years after transplantation. Graft survival among children receiving higher cyclosporine dosages was better, however, which has led most transplant centers to tolerate a modest reduction in GFR to achieve better long-term graft survival. Most centers monitor whole blood trough levels to avoid overdosing and to ensure adequate immunosuppression. Since the introduction of Neoral, which was anticipated to reduce dosage requirements, reports of increased toxicity in the form of reduced graft function and hypertension indicate that targeting similar trough levels for Neoral as were targeted for Sandimmune results in greater total area under the curve, or greater cyclosporine exposure; this makes adjustment of the dosage independently of trough levels necessary in selected children (70).

Calcium-channel blockers such as diltiazem may prevent the renal vascular changes associated with cyclosporine (71). Although diltiazem interacts with the cytochrome P-450 system, which results in increased blood levels of the drug, it does appear to prevent delayed graft function in cadaveric transplants and to reduce the vasoconstrictive effects.

Endothelin may play a significant role in cyclosporine-associated vasoconstriction as a result of increased release and increased receptor density (71). Cyclosporine induces endothelin release from endothelial, mesangial, and renal

tubular cells. Urinary excretion of endothelin is increased as well. In addition, endothelin receptors appear to be upregulated in a rat model of cyclosporine nephrotoxicity. Part of the protective effect of the calcium-channel blockers may be related to their attenuation of endothelin release. Endothelin receptor antagonists have also shown protective effects in cyclosporine-mediated toxicity.

RADIOCONTRAST AGENTS

Radiographic contrast agents are triiodinated benzoic acid derivatives, usually the sodium or methylglucamine salts of diatrizoate or iohalamate. Contrast agents are freely filtered at the glomerulus and are excreted primarily by the kidney. Some concentration of the drug may occur within the renal tubular cell, but most of a bolus of contrast material is excreted directly and rapidly into the urine (11).

The incidence of nephrotoxicity after administration of radiocontrast agents is difficult to assess accurately because of differences in the definition of contrast nephropathy and the populations included in the clinical studies. Studies of adults indicate that between 1 and 20% of the general population may be at risk for acute renal failure after radiocontrast administration, with a somewhat higher incidence among hospitalized or critically ill patients (72). Studies in children are lacking. Certainly, one might view contrast agents as potentially harmful, although not usually so unless other contributing factors are present. Risk factors include preexisting renal insufficiency, diabetes mellitus, multiple myeloma, dehydration, and hyperuricemia (72). Preexisting renal dysfunction is associated with a much greater risk of acute renal failure. Of patients who have renal insufficiency after radiocontrast administration, 50 to 75% had preexisting renal dysfunction, defined as a serum creatinine level of 2 to 3 mg/dL (11). These situations are less likely in children than in elderly adults.

Nephrotoxicity may be mild, with minimal clinical symptoms. Most cases are manifested as nonoliguric acute renal dysfunction, although renal injury may be more severe with typical oliguric renal failure. The peak rise in the serum creatinine level usually occurs 3 to 5 days after contrast administration, with return to baseline by 10 to 14 days. If nephrotoxicity is severe, pronounced oliguria may be evident within 24 hours of the injection (11). Pathologic changes are localized to the proximal tubular cell in the form of pronounced vacuolization, termed *osmotic nephrosis* (11). This form of acute tubular toxicity is characterized by a low fractional excretion of sodium.

Mechanisms responsible for the development of radiocontrast-induced renal dysfunction are not entirely understood. Several factors may interact to induce injury: tubular obstruction, direct tubular toxicity, and ischemia (72,73). Contrast agents induce the precipitation of intratubular proteins such as the myeloma proteins and urinary muco-

proteins (Tamm-Horsfall protein), which potentially leads to tubular obstruction by casts (74). Although this theory often has been proposed as a mechanism for renal toxicity after contrast agent administration, studies have failed to support a significant role of cast formation and secondary tubular obstruction in the development of contrast nephropathy (75). Contrast agents are uricosuric and lead to urate crystal formation within renal tubular lumens, especially if urine flow or pH is reduced (76).

In support of a direct tubular toxicity, pathologic changes after radiocontrast administration include vacuolization of the proximal tubules, interstitial edema and inflammation, and tubular cell necrosis (72). Many studies demonstrate increased urinary excretion of enzymes and tubular proteins after administration of contrast agents. This is indicative of nonspecific renal tubular damage. Exposure of isolated proximal tubule segments to diatrizoate-containing contrast media resulted in cellular injury, and this effect was potentiated by hypoxia and addition of meglumine, a cationic compound often combined with diatrizoate (72). In addition, selected studies suggest altered renal tubular cell function secondary to the inhibition of tubular cell metabolism (11,77). Both organic acid transport and sodium transport are reduced in experimental forms of contrast nephropathy. A direct tubulotoxic effect was found when renal tubular cells in culture were incubated in various concentrations of contrast agent (77).

The renal hemodynamic response to intravenous radiocontrast administration is transient vasodilation (increased renal blood flow) followed by vasoconstriction and a decrease in the renal blood flow and GFR (72,78). The vasoconstriction occurs within minutes after injection of contrast agents and lasts for 10 to 20 minutes. This biphasic response in blood flow appears to be unique to the renal vasculature. The diminished filtration rate observed after administration of contrast agents cannot be mediated entirely by hypoperfusion because GFR remains decreased even after normalization of renal blood flow. Vasoconstriction is mediated by increased lipid peroxidation from the increased production and local release of oxygen free radicals and adenosine, a potent vasoconstrictor (72,78). If there is a role for the renin-angiotensin system, it has not been consistently demonstrated (72,73,78). Reduced renal production of prostacyclin is associated with contrast-induced injury (78). Additional vasoconstrictive forces may involve endothelin, because plasma and urinary levels of endothelin are increased after administration of high-osmolar contrast media. Recent studies demonstrate attenuation of contrast-induced vasoconstriction with administration of endothelin receptor antagonists (79). Contrast agents may induce structural and functional alterations in the erythrocyte, which results in hyperviscosity with sludging in small blood vessels and hypoxemia (80). This phenomenon could explain the preferential distribution of ischemia to the medulla.

Prevention of contrast nephropathy requires identification of potential risk factors. These include dehydration, NSAID use, diabetes, and conditions associated with decreased effective plasma volume, such as congestive heart failure, nephrosis, or cirrhosis, in which renal perfusion may already be compromised (72,73). Hydration has been said to be completely effective in prevention of injury. Administration of furosemide did not appear to offer protection. Mannitol administration was protective in nondiabetic patients but may have potentiated injury in diabetic patients (72). Likewise, dopamine afforded some renal protection in nondiabetic patients, yet offered no benefit in diabetic patients (72). Administration of agents that prevent the formation of oxygen free radicals attenuates the decline in GFR observed after the administration of radiocontrast in a canine model (72). Calcium-channel blockers also provide protection against this form of injury, which raises the possibility that increased intracellular calcium may mediate the hypofiltration (72).

The use of more expensive but less toxic nonionic contrast media has been proposed as a means to avoid the renal risk of standard contrast media, but there is insufficient evidence to justify their use in patients with normal renal function. These agents may prove beneficial to patients with impaired GFR (72).

IFOSFAMIDE

Ifosfamide is a cancer chemotherapeutic agent with impressive activity against a wide variety of solid tumors in children, including neuroblastoma, osteosarcoma, rhabdomyosarcoma, soft tissue sarcomas, testicular tumors, and Wilms' tumor (81). Ifosfamide is a structural isomer of cyclophosphamide. The tumoricidal action of these compounds is related to the alkylation and cross-linking of DNA to inhibit cell replication. Although both ifosfamide and cyclophosphamide are associated with hemorrhagic cystitis as well as myelosuppression, alopecia, and gastrointestinal symptoms, ifosfamide is associated with significant renal toxicity, which is not observed after administration of cyclophosphamide.

Ifosfamide may induce tubular wasting of glucose, amino acids, protein, and phosphate as well as decreased GFR (81,82). Although there is a great deal of interpatient variability in the pattern of ifosfamide-induced renal toxicity, in general ifosfamide toxicity is initially manifest as subclinical tubular damage with increased urinary excretion of brush-border enzymes from cell membrane loss, and a transient increase in urinary excretion of amino acids, phosphate, glucose, and protein. A progressive increase in renal tubular toxicity was observed in 11 patients after the initial three or four courses of ifosfamide treatment, with return to normal in between courses (82). Subsequent courses were characterized by failure to return to pretreatment levels between courses, with fixed tubular functional changes. In addition,

glomerular damage and decreased GFR (presumably secondary to chronic tubular damage and fibrosis) were observed in five of seven patients at the end of therapy. Although less commonly observed, distal tubular dysfunction may occur after ifosfamide administration. Skinner reported a concentrating defect in 50% of the 12 patients in his series (81), and hypokalemia occurred in 4 patients reported by Husband et al. (83). In some patients a sign that ifosfamide has significantly affected renal function is a delay in the clearance of drugs such as methotrexate. In some patients tubulopathy becomes fixed, and in many of these, glomerular function also is affected. One should be reminded that, even in patients with obvious renal toxicity, the plasma creatinine level is often within normal limits because it is an insensitive marker of glomerular function in these patients. In general, patients do not manifest reductions in GFR in the absence of established tubular injury.

Not only are there acute effects of ifosfamide administration, but a subset of patients experience continued renal dysfunction, manifest as tubular wasting syndromes, or reduced GFR. The incidence of chronic renal failure secondary to ifosfamide therapy is reported to be 1 to 4% (82). Another late complication of ifosfamide administration is the occurrence of rickets caused by chronic hypophosphatemia (84–86). Of 12 children on whom Skinner reported, 8 had what was considered to be significant renal damage, 6 had reduced GFR, 4 had hypophosphatemia, 5 had glycosuria, 10 had generalized aminoaciduria, and 3 had radiographic evidence of rickets (87).

The incidence of ifosfamide-associated renal injury is highly variable, depending on the cumulative dosage, rapidity of administration, previous or concomitant administration of platinum or other nephrotoxic drugs or radiation, presence of a unilateral kidney, and age. Ifosfamide nephrotoxicity seems to be dose dependent and is more likely to occur in younger children or those who have undergone nephrectomy (81,84,88). Previous or sequential administration of other nephrotoxic agents increases the likelihood that renal toxicity will be observed with ifosfamide treatment. Most notably, patients who have previously been treated with cisplatin are at a greater risk for ifosfamide nephrotoxicity (88,89). Carboplatin administration also increases the risk of tubular toxicity after ifosfamide therapy (90). This phenomenon is interesting, because the major site of injury after the platinum is the late proximal and collecting duct, whereas that after ifosfamide appears to be the early proximal tubule.

The clinical pattern of renal injury is one of initially transient, reversible tubular wasting of glucose, potassium, bicarbonate, phosphate, and amino acids as well as low-molecular-weight proteins such as β_2 -microglobulin. With early toxicity, tubular function tends to return nearly to baseline at the time of the next course. A few long-term follow-up studies have been published. These suggest that the renal defect in many of these children is chronic and may

be progressive in nature. This is in contrast with results of long-term follow-up of cisplatin injury, in which GFR may improve over time although tubular defects may persist.

Numerous studies have looked at the incidence and pattern of renal injury associated with ifosfamide. Findings are highly variable, and partly this reflects the aggressiveness with which the studies of renal tubular and glomerular function were performed. If serum creatinine or creatinine clearance is used to assess the presence of decreased GFR, the incidence of glomerular dysfunction is underestimated, as evidenced by the study of Ashraf et al., who found that 7 of 20 patients had abnormal GFR values as assessed by chromium ethylenediaminetetra-acetic acid (Cr-EDTA) clearance, yet none of these had elevated plasma creatinine levels compared to age-related controls (91). In addition, nine children demonstrated increased fractional excretion of phosphate, six had decreased tubular threshold for phosphate, and only two had overt hypophosphatemia.

The activation of ifosfamide to its tumoricidal metabolites, 4-hydroxyifosfamide (4-OH-IF) and aldoifosfamide, occurs in the liver, with further metabolism to either isophosphoramidate or carboxyifosfamide. The parent drug and its metabolites are excreted in the urine (92). When attempts are made to contrast the metabolites of cyclophosphamide and ifosfamide to incriminate the nephrotoxic species, ifosfamide metabolism is found to produce significantly greater quantities of chloroacetaldehyde than cyclophosphamide. Because this compound has been noted to be toxic to cells and is found in high concentration in both the urine and plasma, it may play a role in the renal toxicity after ifosfamide therapy.

The mechanism of the renal tubular injury secondary to ifosfamide administration is unknown. Studies in which cultured proximal tubular cells are incubated in the parent drug or metabolites have been performed (93). The parent drug, ifosfamide, did not have an effect on amino acid or glucose transport, but the metabolite 4-OH-IF clearly inhibited transport of both substrates after 24 hours in 100 $\mu\text{mol/L}$. Another potentially active metabolite, chloroacetaldehyde, stimulated uptake at low concentrations (<200 $\mu\text{mol/L}$) and shorter incubations but inhibited uptake at higher concentrations and longer exposure times. In low concentrations, 4-OH-IF stimulated phosphate transport, but transport was decreased at higher dosages (100 $\mu\text{mol/L}$). At even higher concentrations (300 to 400 $\mu\text{mol/L}$), $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase ($\text{Na}^+\text{-K}^+\text{-ATPase}$) activity was inhibited. Chloroacetaldehyde (at concentrations greater than 175 $\mu\text{mol/L}$), reduced phosphate transport and the activity of the mitochondrial enzyme succinate cytochrome *c* oxidoreductase.

The bladder toxicity of the oxazaphosphorine compounds results primarily from the metabolite acrolein, although 4-OH-IF has also been implicated (81). Mesna, sodium-2 mercaptoethane sulfonate, has been used to reduce ifosfamide- and cyclophosphamide-related bladder

toxicity without alteration of tumoricidal effects. Mesna binds to acrolein, chloroacetaldehyde, and 4-OH-IF (94). Unfortunately, mesna does not seem to offer protection against tubular toxicity, although its failure to do so has been postulated to be related to the availability of mesna at the site of tubular injury (95). Mesna is oxidized to dime-sna, which has no protective action. Dimesna can be converted back to mesna by renal tubular cells, but at the dosages currently used in clinical practice, free mesna levels may not be adequate or may be highly variable and thus inadequate for tubular protection.

PLATINUM COMPOUNDS

Cisplatin (*cis*-diaminedichloroplatinum II) is an inorganic platinum compound that may induce both acute and chronic renal toxicity with magnesium, sodium, and potassium wasting as well as decreased GFR (96). The drug contains a platinum atom surrounded by two chloride atoms and two ammonia molecules in the *cis* position. Carboplatin (*cis*-diamine-1,1-cyclobutane-dicarboxylate) platinum (II) has been introduced as a less nephrotoxic form of platinum, although it is now known that this compound also may cause renal injury. Cisplatin and carboplatin may undergo aquation with substitution of the chloride ions with hydroxyl groups, a reaction favored by low chloride concentrations such as are found in the cell, to form positively charged complexes that are likely to be the active form of the drug. Platinum compounds are excreted by the kidney via glomerular filtration. Platinum is concentrated in the renal cortex, with levels higher than in plasma, and appears to be accumulated via some transport process. Data suggest that elimination of the drug is delayed in the setting of a decreased GFR.

Proximal tubular cells are believed to accumulate platinum compounds by an energy-requiring mechanism or possibly by the organic base transport system (96). Differences in uptake of the platinum compounds might be related to stereospecificity or relative solubility and reactivity. Shortly after intravenous injection of cisplatin into rats, accumulation can be observed in the juxtamedullary region and outer stripe. This pattern is consistent with localization within the S3 portion of the proximal convoluted tubule, which is thought to be particularly susceptible to platinum. Acute changes in renal function occur after cisplatin administration, and these appear to be hemodynamically mediated, with reduced renal blood flow as well as tubular injury. Histologically, platinum-induced renal toxicity is characterized by tubular dilation, cytoplasmic vacuolization, nuclear pyknosis, and hydropic degeneration of cells in the corticomedullary region or S3 segment of the proximal tubule.

In a series of 22 children receiving cisplatin, 18 demonstrated GFR of less than 80 mL/min/1.73 m² as assessed by

Cr-EDTA clearance (97). There was a mean decrease in GFR of 8% per course, but a great deal of individual variability was seen. In addition, the authors noted that neither plasma creatinine nor creatinine clearance was reliable in screening patients with significant reductions in GFR.

Long-term outcome for children who received cisplatin (median cumulative dose of 500 mg/min, range of 120 to 1860 mg/min) as part of their anticancer chemotherapy was studied by Brock et al. (98). Of 40 children available for study at the completion of therapy, 16 had a GFR above 80 mL/min/1.73 m², 13 had a GFR of 60 to 80 mL/min/1.73 m², and 11 had a GFR below 60 mL/min/1.73 m². Clearance measurements were repeated a mean of 2 years and 6 months from the end of therapy. A statistically significant improvement in GFR was found. Children with a GFR between 60 and 80 mL/min/1.73 m² at the end of treatment had a better chance of regaining a normal GFR; however, all of the 11 children with a GFR below 60 mL/min/1.73 m² improved, and 3 had normal GFR at last follow-up. Hypomagnesemia was found in 6 of 21 children at last follow-up.

The mechanism of platinum-related renal injury is being debated. It has been suggested that cisplatin is a direct tubular toxin and must be present in the tubular lumen at a minimum concentration of 1 mmol/L or 200 µg/mL (96). Several cellular perturbations have been identified in renal proximal tubular cells. These include inactivation of Na⁺-K⁺-ATPase, impaired mitochondrial function, altered gluconeogenesis, impaired substrate transport, lipid peroxidation, oxidation of sulfhydryl groups, and inhibition of nucleic acid and protein synthesis (99). The nephrotoxicity of cisplatin, transplatin, and carboplatin was examined in two continuous proximal tubular cell lines: primary cultures of rabbit cortical cells and OK cells (a continuous proximal tubular cell line). OK cells were spared from injury, probably because of decreased cellular uptake of the compounds. The rabbit proximal cells exhibited reduced viability at concentrations of cisplatin approximating 100 fmol/L, similar to peak levels in cancer patients. Toxicity was related to intracellular levels of platinum (99).

Isolated S3 segments of proximal tubules from rats given either transplatin or cisplatin were examined for alterations in oxygen consumption and respiration. No consistent abnormalities were detected, which makes mitochondria unlikely candidates for early nephrotoxicity (96). Other studies noted changes in mitochondrial function. Cisplatin also increased the oxidation of mitochondrial sulfhydryl groups, depleting GSH and leading to perturbations in mitochondrial calcium uptake and membrane potential (100). Antioxidants did not prevent the associated nephrotoxicity, which indicates that platinum probably exerts its effect by interacting directly with thiol groups rather than by inducing lipid peroxidation. Unfortunately, the concentrations of cisplatin used were considerably higher than would be expected from *in vivo* dosing. DNA synthesis was

significantly inhibited by small concentrations of cisplatin, whereas greater concentrations of the other compounds were required. Cisplatin in the concentration range of 30 to 100 $\mu\text{mol/L}$ induced a decrease in the activity of $\text{Na}^+\text{-K}^+\text{-ATPase}$ as well as glucose uptake; the effect on glucose transport is probably secondary to a reduction in $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity because the sodium gradient would be decreased. Other experiments have shown that cisplatin may decrease glucose as well as phosphate transport. Similar findings were observed with carboplatin, but concentrations 20 times higher were necessary to induce the same alterations in cell functions (99).

Many favor inhibition of DNA synthesis as the primary biochemical effect. Cisplatin damages DNA by inducing interstrand and intrastrand cross-links and preventing normal replication. The amount of platinum cross-linkage correlates with toxicity as well as mutagenicity (96). Intrastrand cross-links are not found with transplatin, which is a much less toxic form of this class of agent.

Polyuria is a common finding after cisplatin administration and appears in two phases: urine osmolality falls over the first 24 to 48 hours after administration, and the second phase of increased urine volume and decreased osmolality occurs between 72 and 96 hours and is accompanied by decreased GFR as well (96). During the early phase, blood vasopressin levels are low and the kidney may concentrate urine in response to large doses of vasopressin. The latter phase of polyuria is thought to be secondary to the dilution of the medullary urea gradient, possibly related to abnormal urea recycling in the loop of Henle. In a model of chronic cisplatin nephrotoxicity, rats received three doses over 3 weeks. Polyuria, increased urinary sodium excretion, and decreased GFR along with decreased urinary cyclic adenosine monophosphate (cAMP) excretion were observed in the cisplatin-treated animals (101). Production of cAMP by inner medullary collecting duct cells was decreased after vasopressin stimulation in cisplatin-treated rats. Forskolin, a direct activator of adenylyl cyclase, induced similar cAMP production in treated and control rats. In contrast, cAMP production after administration of sodium fluorescein, an agent that stimulates cAMP production via the guanine nucleotide regulatory protein, was significantly lower in cisplatin-treated animals than in controls. These results led the investigators to conclude that the polyuria associated with cisplatin is caused by an abnormality in signal transduction at the level of the G-protein component of the vasopressin receptor (101).

Hypomagnesemia is another common manifestation of cisplatin-induced renal toxicity and commonly persists long after therapy ceases (102). Rats receiving intraperitoneal cisplatin (2.5 mg/kg) for 3 weeks developed hypomagnesemia by the second week, which persisted to the eighth week after therapy (103). Urinary excretion of magnesium was inappropriately elevated. In addition, gut absorption of magnesium was decreased. Calcium and

magnesium transport by the superficial proximal and distal tubules appeared to be unaffected when measured at 7 weeks, even though urinary excretion was elevated. Bone and muscle magnesium levels were significantly reduced at the end of the eighth week, which suggests depletion of mineral stores. Cisplatin increases distal tubular sodium conductance. Infusion of cisplatin into rat distal tubular segments caused an attenuation of the normally negative luminal charge generated by active sodium reabsorption in this segment (104). The effect of cisplatin on the luminal charge was reversed by addition of amiloride, a diuretic that blocks sodium channels. The authors conclude that cisplatin may interact with distal tubular Na^+ channels to increase potassium and magnesium excretion and that this is attenuated by co-administration of amiloride (104).

Therapeutic intervention to reduce renal toxicity associated with cisplatin has been aimed at reduced production and enhanced excretion of highly reactive metabolites (104,105). Infusion of mannitol and saline is the clinical intervention most commonly used to reduce cisplatin nephrotoxicity. In addition to providing optimal hydration before, during, and after administration, the co-administration of saline may reduce the spontaneous aquation reaction. In addition, these maneuvers may enhance excretion of the drug and minimize the period of contact between the renal tubule and toxin. The compound sodium thiosulfate reverses cisplatin-induced DNA cross-links and has been reported to reduce cisplatin injury in animals and humans (106,107). This compound is believed to protect the renal tubule through chelation of the drug and/or active metabolites. The concern that tumoricidal activity will be reduced has prevented widespread use of thiosulfates or other thiol compounds. Disulfiram, the disulfide dimer of diethyldithiocarbamate, differs from other chelating agents in that it offers protection when given after cisplatin, and it does not appear to alter chemotherapeutic efficacy (105,108). Despite some promising preliminary findings, co-administration of thiol compounds is not yet standard practice. One study used a novel method for reduction of cisplatin-induced renal toxicity in the rat. Administration of erythropoietin to rats after development of acute cisplatin-induced renal failure enhanced histologic and functional recovery primarily by improving tubular regeneration (109). The results observed with erythropoietin might potentially be applicable to other hemopoietic growth factors now commonly administered in coordination with cancer chemotherapeutic agents to speed bone marrow recovery. Human studies using growth factors in this setting are lacking.

Another potential method for minimizing renal toxicity is to avoid increasing the exposure to renal toxins by detecting reduced GFR early and by taking the GFR into account in dosing. Dosing of carboplatin based on the patient's GFR has been practiced by many centers and may potentially prevent toxicity by allowing dosage modifications in patients who have experienced otherwise undetectable reductions in GFR.

COMBINATION CHEMOTHERAPY

The combination of ifosfamide and cisplatin potentiates renal injury (110). One study compared glomerular function (unfortunately, creatinine clearance was used as the measure) and tubular function after either low-dose ifosfamide or a combination of ifosfamide and cisplatin and then high-dose cisplatin. Tubular functions such as amino acid excretion and albuminuria were comparable for the high-dose ifosfamide and combination groups, but phosphate wasting was more pronounced in the combination group (110). Despite delivering a much lower cumulative ifosfamide dose, combination therapy resulted in lower phosphate reabsorption in significantly more patients and a trend toward more frequent occurrence of tubular dysfunction. The aminoglycoside gentamicin did not appear to contribute significantly to observed renal toxicity. Of the 14 children with overt renal tubular wasting syndrome, eight had received combination therapy. Experience with combination therapy reveals that acute toxicity from ifosfamide is higher when carboplatin is administered within the same week than when a period of months elapses between these toxic therapies (90).

In conclusion, renal dysfunction as a result of drug administration may be manifest as a reduction of GFR or tubular dysfunction, most commonly of the proximal tubule. In most cases, this form of renal injury is reversible. Occasionally, there may be long-term renal dysfunction, as in the case of amphotericin B, cisplatin, and ifosfamide. The clinician must be aware of the potential for renal toxicity and must be prepared to make adjustments in the dosage or discontinue the offending agent. Anticipation of potential renal toxicity allows for maneuvers that may prevent renal damage and subsequent functional changes. Drug-induced renal dysfunction provides a model for acute renal failure and provides insight into renal injury in the general sense, which gives hope that in the future it will be possible to prevent injury or enhance recovery.

NATURAL NEPHROTOXINS

Marine animals, reptiles, and insects produce a number of biologic nephrotoxins (111) (Table 52.2).

Many of these toxins result in acute renal failure either directly or indirectly. The main indirect mechanism of nephrotoxicity is biologic-toxin-induced rhabdomyolysis (112). Although these natural nephrotoxins are uncommon causes of acute renal failure, they are of considerable interest.

Marine Animal Nephrotoxins

Fish poisons include at least three forms of biotoxins that result in ATN. First, there is an association between the ingestion of raw bile from the gall bladder of carp and acute renal failure. The belief that the raw bile of carp improves

vision and rheumatism is found in Asia (113). Many of these Asian carp species have been introduced into the United States, and at least five species of carp have been implicated (114). All five carp species have ichthyogallotoxin in their bile, and this may represent the toxin. Alternatively, A C-27 bile alcohol, termed *cyprinol* and found in carp bile, is nephrotoxic in animals (111).

A second toxin as yet unidentified is responsible for Haff disease. Haff disease, characterized by acute rhabdomyolysis, can occur in humans and other animals that eat eels and burbot fish. Rhabdomyolysis can be found in subjects who ingest buffalo fish, a member of the carp family (115). These myotoxins or ichthyosarcotoxins are unidentified.

A third agent is the palytoxin of the blue humphead parrotfish. Ingestion of this toxin can also result in cardiac muscle damage (116). Factors contributing to the pathogenesis of acute renal failure from rhabdomyolysis include the quality of myoglobin in nephrons, an acidic, highly concentrated urine, and delayed recognition of the disease.

Envenomation-Induced Acute Renal Failure

Snake Venoms

Four families of venomous snake are responsible for 40,000 deaths/yr, and 5 to 30% of subjects bitten by these snakes develop acute renal failure. Two families are responsible for most deaths and cases of renal failure: (a) the cobras, African mambas, and coral snakes, and (b) the vipers, adders, moccasins, and rattlesnakes (117). Approximately 90% of venoms are proteins that are proteolytic enzymes, phospholipases, and hyaluronidases. Other enzymes include ribonucleases, deoxyribonucleases, nucleotidases, and acidic and basic phosphatases. Procoagulants that activate the clotting cascade via factors V and X are also present. Myotoxins can also lead to rhabdomyolysis and myocardial damage, which reduce cardiac contractility, and pigment nephropathy.

Patients may show ATN, hypersensitivity reactions, extracapillary glomerulonephritis, AIN, and necrotizing arteritis of interlobular arteries on histologic studies (118,119). Laboratory investigations show evidence of intravascular hemolysis, disseminated intravascular coagulation, and azotemia (120). A number of snakebites lead mainly to rhabdomyolysis, including those of the king brown snake, sea snakes, diamondback rattler, canebrake rattler, and several vipers (112).

Spider Venoms

Two groups of spiders produce venom responsible for acute renal failure: the recluse spiders and the widow spiders (112). The mechanism of toxicity of the venom of the 56 recluse species is the presence of sphingomyelinase D, which leads to necrotic skin lesions, edema, erythema, chills, nausea, and myalgias (121). The main recluse spider in the United States is the brown recluse. These bites are generally more serious in young children.

The widow spiders excrete neurotoxins that produce cramping and muscle spasms. These toxins can lead to a neurogenic bladder with urinary obstruction. The venom of the black widow spider of the United States can also lead to rhabdomyolysis.

Bee and Wasp Venoms

Acute renal failure due to bee and wasp venoms requires massive numbers of stings, usually more than 100, which generally follows disturbance of a hive or nest (111). The toxins include melittin and other hemolysins, hyaluronidase, and others (Table 52.2). The toxins in wasps differ and consist of active amines, kinins, and antigen 5. The mechanisms of renal failure include hemolysis, rhabdomyolysis, direct toxic effects, and dehydration. The venom of the dark scorpion of the southwest United States may also cause rhabdomyolysis (112). Hypersensitivity reactions to bee and wasp venoms may also occur. The treatment of acute renal failure is symptomatic and dialysis may be required.

Chinese Herb Nephropathy

Chinese herb nephropathy, initially described in the early 1990s by Vanherweghem et al. in Belgium, is characterized by a tubulointerstitial disease (122). Proximal tubular dysfunction with a Fanconi syndrome or, more commonly, insidious chronic renal failure has been described (123). Aristolochic acids are the likely etiologic agent. Substitution of *Aristolochia fangchi* for *Stephania tetrandra*, herbs which differ in name in Chinese by only one character, is thought to have been the historical event leading to the increased incidence of this indolent renal disorder. These herbs were generally taken for the purpose of weight loss.

Aristolochic acids are naturally occurring compounds with carcinogenic and nephrotoxic effects. Although there is still

debate as to whether they are solely responsible for all of the reported cases of Chinese herbal nephropathy (124), they have been shown to cause an interstitial nephropathy in the rabbit (125) but not the rat (126). Isolated case reports also describe proximal tubular dysfunction with hypokalemia, abnormal urinary excretion of low-molecular-weight proteins, and glycosuria as the presenting features in several adults (127–129).

Pathologic evidence of renal injury was demonstrated in the rabbit model. As with human pathologic changes, there was a distinct corticomedullary gradient of acellular interstitial fibrosis. Three patterns of injury were described: (a) restriction of fibrosis to the medullary ray (S3 segments), (b) extension to the outer cortical labyrinth (convoluted proximal tubules, S1 and S2 segments), and (c) extension to the inner cortical labyrinth and outer medulla (proximal tubules of deep nephrons) (125). The exact mechanism of aristolochic acid-induced injury is not known.

Renal function continues to deteriorate despite cessation of consumption of herbal remedies. Oral corticosteroid therapy may slow the progression of renal insufficiency. A group of 81 adults with Chinese herb nephropathy were subdivided according to pattern of renal failure (130). Thirty-nine demonstrated moderate renal failure with progression. Of these, 14 received oral prednisone initiated at 1 mg/kg for 1 month and then tapered to 0.15 mg/kg. The rate of increase in the serum creatinine level was less in the steroid-treated group.

Pediatric cases have not been reported.

ENVIRONMENTAL TOXINS

Organic Solvents: Ethylene Glycol, Diethylene Glycol, Propylene Glycol

Ethylene glycol is a major constituent of antifreeze and may be accidentally ingested because it has a sweet taste. It is metabolized initially by alcohol dehydrogenase to glycoaldehyde and eventually to oxalate. Intermediate metabolites include glycolic acid and glyoxylic acid, which contribute to the associated metabolic acidosis. A change in the ratio of the unreduced form of nicotinamide adenine dinucleotide to the reduced form favors the accumulation of lactic acid. Central nervous system symptoms and cardiovascular instability precede the onset of renal disease. Renal toxicity takes two forms: crystallization of oxalate within the renal tubules and direct tubular damage resulting in acute renal failure. Metabolic acidosis with elevated anion gap and altered mental status should prompt the consideration of this poisoning. Examination of the urine sediment early in the course may reveal either needle-shaped calcium oxalate monohydrate crystals or octahedral calcium oxalate dihydrate crystals. An elevated plasma osmolar gap may also be an indirect clue. Treatment is aimed at clearance of the toxic metabolites and may include hemodialysis in the case of renal failure or severe metabolic acidosis.

Diethylene glycol has been responsible for accidental poisoning associated with acute renal failure in the form of medication contamination. Recently, an outbreak of renal failure in Haiti resulted after two acetaminophen preparations were inadvertently contaminated with diethylene glycol during manufacture using contaminated glycerin. The mechanism of renal toxicity is thought to be proximal tubular damage and necrosis. Other organ systems, including the liver, pancreas, and brain, are often severely injured and contribute to the overall mortality of this accidental poisoning.

Propylene glycol (PG) may be responsible for ATN. The renal failure is usually the result of intravenous administration of medication solubilized in PG (131). Parenteral medications that contain PG include diazepam, digoxin, esmolol, hydralazine, nitroglycerin, pentobarbital, phenobarbital, phenytoin, and sulfamethoxazole/trimethoprim. Vitamin preparations may also contain PG. Clinical manifestations are similar to those of ethylene glycol toxicity, including metabolic acidosis with increased anion gap. A potential mechanism for toxicity has been postulated to be the inhibition of proximal tubular transport processes and membrane disruption (132).

Heavy Metals (Excluding Platinum)

Lead, mercury, gold, bismuth, and copper are uncommon but serious causes of nephrotoxicity. They have common mechanisms of renal tubular toxicity, and chronic exposure may lead to presentation with an acute syndrome or dysfunction. The primary site of injury is the proximal renal tubule, where heavy metals cause impaired mitochondrial function and secondary alterations in membrane integrity. Exposure to mercury and lead is generally accidental due to environmental contamination and is much less common now than several decades ago. The reader is referred to previously published comprehensive reviews of heavy metal renal toxicity (133,134).

URINARY TRACT DISORDERS

URINARY TRACT INFECTION

SVERKER HANSSON
ULF JODAL

At the beginning of the twentieth century, the mortality rate of neonates and infants hospitalized because of acute pyelonephritis was approximately 20% (1–3). With the advent of antibiotics and modern aggressive diagnostic and therapeutic approaches, the mortality today is close to zero. However, long-time consequences of urinary tract infection (UTI) such as progressive renal deterioration to uremia, development of hypertension, and pregnancy complications remain. Most children with UTI have no such problems, so it is important to identify those at risk. Most of those at risk have anomalies within the urinary tract, such as obstruction or vesicoureteral reflux with dilatation of the upper tract. It is important to detect these anomalies early and to institute preventive measures promptly. The ideal goal is to diagnose the very first UTI, especially in infants, and to identify risk factors for subsequent complications. There is also great value in identifying children with a low risk of future problems so that the investigations and follow-up in these patients can be kept to a minimum, with a low frequency of invasive procedures.

Our knowledge of the natural history of UTI in childhood is still incomplete. Most children with UTI are treated at the primary care level, with each practitioner handling a limited number of children. It is, therefore, difficult to create the population-based registries necessary for large epidemiologic studies. Furthermore, the course of UTI often runs over several decades, and it is difficult to follow patients over such long periods. Finally, there is continuous change in management that influences and ideally improves the long-term prognosis but can make comparisons between different time periods difficult. An example is the switch from urography to dimercaptosuccinic acid (DMSA) scanning to study renal damage (4,5).

TERMINOLOGY

Urinary tract infection is the common term for the heterogeneous group of conditions in which there is growth of bacteria in the urinary tract.

Bacteriuria is presence of bacteria in bladder urine. Growth of 100,000 colony-forming units (CFU) in freshly voided urine is mostly used as the cutoff point between contamination and true bacteriuria. However, considerably higher levels occur because of contaminated urine, especially in small children. The optimal method for obtaining urine in small children is suprapubic aspiration. Any growth with this method signifies UTI.

Symptomatic UTI can be classified into *acute pyelonephritis* (with fever as the major symptom), which are infections involving the renal parenchyma, and *acute cystitis* (with acute voiding symptoms as the major feature), which are infections limited to the lower urinary tract. Such a classification is of practical importance, because renal infection carries a risk of renal scarring and requires more aggressive treatment, investigation, and follow-up than an infection restricted to the lower urinary tract. The 10 to 20% of the symptomatic infections that cannot be classified as either pyelonephritis or cystitis by history and simple laboratory investigations are called *unspecified UTIs*. For practical purposes, children with unspecified UTIs are best treated as having pyelonephritis.

Asymptomatic (or covert) bacteriuria (ABU) is the term used when bacteriuria is found in repeated samples from a child who does not report symptoms, usually at a health investigation or routine checkup.

There are major differences in sensitivity between the methods that can be used to identify renal parenchymal damage. It is, therefore, important to state the technique by which the investigation has been performed. *Pyelonephritic renal scarring* (often called *reflux nephropathy*) is focal or generalized damage of a kidney as seen on urography with reduction of the parenchyma, usually with related calyceal clubbing or blunting (6). This scarring is often associated with past or present vesicoureteral reflux, but renal damage can develop without demonstrable reflux. The more sensitive scintigraphic techniques, such as the DMSA scan, can visualize acute inflammation as well as permanent uptake defect. Acute inflammatory changes may be transient and disappear within 6 months of the acute infection.

The term *chronic pyelonephritis* has been used with varying meanings, which has led to a great deal of confusion; it should be used only in cases with typical histologic findings verified in biopsy specimens.

CLINICAL PRESENTATION

The symptoms of UTI depend not only on the intensity of the inflammatory reaction (host-parasite interaction) but also on the level of the infection and the age of the patient. High fever often is the only symptom of acute pyelonephritis. Children usually cannot report back or loin pain until they are 4 to 5 years old or even older, but renal tenderness can sometimes be found in small children who cooperate well at the physical examination.

Children with acute bacterial cystitis often have a temperature of around 38°C, but fever of 38.5°C or more should be taken as a sign of upper urinary tract involvement. Symptoms from the lower urinary tract such as pain at micturition and frequency are not often recognized before the age of 1.5 to 2.0 years and are frequently lacking in children with acute pyelonephritis. On the other hand, acute voiding problems are not synonymous with acute bacterial cystitis. Inspection of the genital area may reveal local inflammation such as vulvitis or balanitis.

In the newborn, the ability to prevent bacterial dissemination is poorly developed, and it is not unusual for children with malformations of the urinary tract to develop septicemia, sometimes in combination with meningitis. During the first month of life, the symptoms of infection may be nonspecific with low or no fever in about one-half of the cases. Thereafter, high fever is the most important symptom of acute pyelonephritis. In the newborn, a subnormal or only slightly elevated body temperature or symptoms such as apathy, anorexia, grayish color, and body tenderness can indicate a serious infection. UTI in infancy may also lead to failure to thrive.

EPIDEMIOLOGY

UTI is one of the most common bacterial diseases in children. Of 3556 7-year-old school entrants in Göteborg, Sweden, 7.8% of the girls and 1.6% of the boys had had symptomatic UTIs verified by urine culture (7). In one-half, the UTI had been associated with high fever, according to the original records from hospital or outpatient clinics, and, in most of these, a diagnosis of acute pyelonephritis was supported by laboratory tests.

The incidence of first-time UTI is highest during the first year of life. This is most marked for boys but also evident for girls. The numbers shown in Figure 53.1 represent approximately 90% of children with febrile UTI diagnosed in the population and approximately 50% of those with

FIGURE 53.1. All children [264 boys (A) and 448 girls (B)] below 7 years of age with first-time symptomatic urinary tract infection identified at the Children's Hospital in Göteborg 1992-1995 according to age and temperature.

nonfebrile symptomatic UTI. Infections diagnosed during the first year of life are mostly acute pyelonephritis. A first-time UTI classified as acute cystitis occurs especially in girls 2 to 6 years of age.

Figure 53.2 shows in more detail the difference between boys and girls during the first year of life. This material is taken from the Swedish UTI study in children carried out during the years 1993 to 1995 (8,9). There were many more boys than girls during the first months of life; after 6 months of age, girls became the majority. UTI without high fever occurred predominantly during the first few months of life. From this study, the minimal incidence of UTI during the first 2 years of life was estimated. The cumulative incidence was 2.5% in both boys and girls (9).

Identifying an epidemiologic pattern, such as that in the figures, requires that clinicians at the primary care level be highly aware of the high incidence of UTI in infants and small children. If these infections are undetected, many of the children will have UTI later and may already have permanent renal damage by that time. An example of a skewed epidemiologic pattern is given in a study from the Aber-

FIGURE 53.2. All children [892 boys (A) and 772 girls (B)] below 1 year of age with first-time symptomatic urinary tract infection (UTI) identified in the Swedish UTI study 1993–1995 according to age (months) and temperature.

deen area (10). Only 38 of 572 children (7%) referred for radiologic investigation during a 10-year period were under 2 years of age; comparative figures for Göteborg, with a similar child population of approximately 80,000, were 431 of 1177 (37%) (11).

In epidemiologic studies from the 1960s, 30% of girls with a first-time UTI were found to have a repeat infection within 1 year and 50% within 5 years; some had a long series of recurrences (12). However, these figures included symptomatic as well as asymptomatic recurrences, the latter having been detected by culturing of urine at frequent controls. Because it is now well known that ABU is principally an innocent condition (see later), urine cultures today are performed mainly in children with symptoms and not for screening purposes. The rate of new infections is also influenced by the use and duration of low-dose long-term antibacterial prophylaxis to prevent recurrences in high-risk patients. In our material, the overall recurrence rate in girls is approximately 15%. In boys, the recurrence rate is 15% during the first year of life; after 1 year of age, boys have few recurrences, and repeated infections are uncommon.

Obstructive malformations are found in 2% of girls and 10% of boys investigated because of UTI (12). In the previously mentioned Swedish UTI study in 1993 to 1995 there were 1953 children younger than 2 years with first-time UTI who were investigated by voiding cystourethrography. Vesicoureteral reflux was seen in 36% of the girls and 24% of boys; dilatation of the upper urinary tract was seen in one-half of them (8).

CAUSES AND PATHOGENESIS

The urinary tract normally is sterile, with the exception of the distal part of the urethra. Yet, UTI is one of the most common bacterial infections in children. Some individuals have a marked tendency to get repeated UTIs, and their defense against bacterial entry, persistence, and growth within the urinary tract is deficient.

Escherichia coli causes 80 to 90% of first-time UTIs in children; other commonly found bacteria are *Klebsiella*, *Proteus*, and *Staphylococcus saprophyticus*. *Proteus* species are found in approximately 30% of boys with uncomplicated cystitis, and *S. saprophyticus* is found in a similar proportion of adolescents of both sexes with acute UTI. However, patients with malformation or dysfunction of the urinary tract may become infected by other bacterial species that have low virulence for the urinary tract (e.g., enterococci, *Pseudomonas*, *Staphylococcus aureus* or *epidermidis*, *Haemophilus influenzae*, and group B streptococci) (12,13).

Bacteria causing recurrence in the first several months after antibiotic treatment frequently are resistant to the previously used drug. The reason for this is an antibiotic-induced change in the normal bowel flora and not persistence of resistant bacteria within the urinary tract (14). Bacteria that invade the urinary tract usually originate in the bowel. Boys also have a reservoir under the prepuce.

Periurethral Bacterial Flora

The periurethral area is colonized by both anaerobic and aerobic bacteria. These bacteria are part of the normal defense barrier against pathogenic microorganisms. A first step in the development of UTI is often a disturbance of the normal flora and colonization by Gram-negative strains, mostly *E. coli* (15). Such a change can be induced by antibiotic treatment. During the first years of life, however, the periurethral area mostly contains bacteria from the bowel, and enterobacteria and enterococci are indeed part of the normal periurethral flora of healthy children of this age (16). This colonization with such bacteria starts to decrease during the first year of life, and, after the age of 5 years, enterobacteria and enterococci are rarely present. In small girls, *E. coli* is the dominating Gram-negative periurethral species. In boys, *E. coli* dominates during the first 0.5 year of life; later, *Proteus* is as common. Because of this periurethral colonization in children aged 0 to 5 years, the bacterial prerequisites for ascending infections are often present. In older girls with high susceptibility to UTI, daily sampling has shown that periurethral colonization of Gram-negative bacteria precedes the development of bacteriuria (17).

Ascending Bacteria

The bacteria enter the urinary tract by ascending up the urethra. The importance of the ascending route is emphasized by

the fact that the rate of UTI in infant boys circumcised at birth is only 10 to 30% of that in the noncircumcised (18,19).

The marked greater susceptibility of girls to UTI after the first 6 months of life can be explained by the difference in urethral length; the short female urethra provides an easy access to the bladder. Temporary ascent of bacteria to the bladder is probably not uncommon in the female; transient bacteriuria occurred in 5 of 23 healthy infant girls prospectively followed by weekly cultures for 10 weeks (Jodal et al., unpublished data, 1986). The reason why boys have a high frequency of UTI during the first 6 months of life is unclear.

Further ascent of bacteria from the bladder to the kidneys is facilitated through vesicoureteral reflux. Invasion of the upper urinary tract in children without demonstrable abnormalities may be explained by the capacity of some *E. coli* to adhere to uroepithelial cells (see later) (20).

Bacterial Properties

E. coli isolated from patients with different types of infections or from the fecal flora of healthy children express different virulence factors. These factors are lipopolysaccharides of certain serogroups (O antigens or endotoxin), capsular or K antigens, resistance to the bactericidal effect of serum, and adhesive capacity (21). The O-antigen is toxic and induces fever and inflammation, the K antigen enhances bacterial survival in tissues by conferring resistance to phagocytosis, resistance to killing by the bactericidal effect of serum improves bacterial survival in tissues, and adhesive capacity enhances bacterial persistence in the urinary tract.

The uropathogenic *E. coli* strains are a selected subset of the bacteria that colonize the bowel. They express a limited number of O:K:H surface antigen combinations as well as other virulence factors. These include adherence factors such as fimbriae and toxins. The bacteria causing acute pyelonephritis stimulate epithelial and other cells to produce cytokines and other proinflammatory factors (22). The systemic spread of cytokines such as interleukin-6 induces fever and activation of an acute phase response. The chemotactic cytokines such as interleukin-8 recruit polymorphonuclear granulocytes to the mucosal surface, and, in parallel, the bacteria are eliminated. A specific immune response to the infection follows later.

The severity of UTI correlates with the capacity of the infecting *E. coli* strain to adhere to epithelial cells. In 70% of girls with pyelonephritis, the *E. coli* isolated from urine have adhesins that specifically bind to receptors on the surface of epithelial cells in the urinary tract (23,24). Approximately 10% of healthy children have such *E. coli* in feces. Strains causing ABU rarely have binding ability. The factor that is most characteristic for the pyelonephritogenic *E. coli* clones is its adhesive capacity, which facilitates the bacterial invasion and which is especially important in individuals without anatomic or functional abnormalities (25). Bacterial adhesion triggers inflammation by activating the epi-

thelial cells to which they attach (26). When this happens at the ureteral orifice, ureteritis is induced, leading to a functional disturbance with impaired flow of urine and increased chances for the bacteria to ascend further and cause renal infection (20,27).

The adherence of *E. coli* to epithelial cells is a specific process in which bacterial fimbriae bind to glycoconjugate receptors. Most pathogens express adhesins with several specificities, and most cells carry more than one potential receptor molecule. P-fimbriae recognize receptors that are antigens in the P blood group system and are associated with acute pyelonephritis. The receptor-specific part is located at the tip of the fimbrial rod. The binding depends on recognition of the Gal α 1-4Gal β -disaccharide, which is common to the globoseries of glycolipid receptors. Such receptors are expressed on epithelial cells in the colon and P-fimbriated *E. coli* were shown to become resident and to persist longer in the large intestine than other *E. coli* strains (28). It was also shown that of *E. coli* strains in the fecal flora, those carrying the genetic code for P-fimbriae (*pap*-positive) outcompeted other strains to cause UTI (29). Furthermore, adhesin-positive P-fimbriae stimulated cells to secrete significantly more interleukin-6 than adhesin-negative P-fimbriae (30).

Type 1 fimbriae bind to mannose-containing receptors, which are found on cells but also on secreted glycoproteins such as the Tamm-Horsfall protein and secretory immunoglobulin A (31). When these substances coat uroepithelial cells, they may provide receptor epitopes for bacterial surface colonization. When secreted, they may eliminate type 1 fimbriated *E. coli* strains and prevent colonization or infection. Type 1 fimbriae have been shown to increase the persistence of virulent *E. coli* in the kidneys and bladders of mice; the inflammatory response was increased compared to type 1 negative strains (32).

Tissue Properties

Uroepithelial cells from children with recurrent UTI have a higher receptivity for attaching bacteria than do cells from healthy controls (33,34). Several mechanisms have been proposed as explanations for this increased receptivity, all supported by some evidence, but relative importance and clinical relevance remain uncertain. The globoseries of glycolipids that are antigens in the P blood group system are present on cells all along the urinary tract. The structural prerequisites for fimbrial-receptor interactions are, therefore, present. The expression of these receptors on uroepithelial cells varies depending on P blood group, ABH blood group, and secretor state of the individual. Those who belong to the P blood group phenotype are unable to synthesize Gal α 1-4Gal β containing glycolipids; they lack functional receptors for P-fimbriated *E. coli*. However, the low frequency of P individuals in the population has precluded an evaluation of the relative morbidity in infections

by P-fimbriated *E. coli* in individuals of the P compared to the P1 and P2 blood group phenotypes. P1 individuals were shown to have an 11 times increased risk of attracting recurrent episodes of acute pyelonephritis with P-fimbriated *E. coli* compared to P2 individuals (35). This risk was not related to a greater number of specific receptors in the children of the P1 compared to the P2 blood group; instead it was shown that P1 individuals had a greater tendency to carry P-fimbriated *E. coli* strains in the fecal flora (36). The mechanism of this increased carriage is not clear but a possibility is that P1 individuals express more or better receptors for P-fimbriated *E. coli* in the large intestine.

Host Resistance

Bladder Defense Mechanisms

Urine is an excellent medium for bacterial growth. Once bacteria reach the bladder, they multiply easily unless they are eliminated by defense mechanisms; however, the normal bladder is resistant to infection. This resistance is provided by at least two mechanisms: elimination of bacteria by bladder emptying and killing by epithelial cells (37).

Bacteria are washed out of the urinary bladder by repeated voiding. In animal experiments, more than 99.9% of inoculated bacteria were eliminated by voiding (38). Although most bacteria are cleared out by the emptying process, some remain in the film of urine lining the bladder epithelium. These organisms are eliminated by the antibacterial activity of the bladder wall. The nature of this activity is not known; however, it has been shown that a significant proportion of bacteria attaching to uroepithelial cells were killed within 15 minutes in normal children (39). Uroepithelial cells from girls with recurrent bacteriuria lacked this killing ability. The capacity of this local defense is limited, and it will have little effect if the volume of remaining urine is high.

Incomplete bladder emptying with residual urine means an ineffective hydrokinetic defense mechanism. In patients with vesicoureteral reflux and obstructive malformations, the disturbance of the urinary flow is evident. Most children with UTIs have no such abnormality demonstrable by the commonly used visualizing techniques. Instead, functional disturbance of the urinary bladder and residual urine are probably major factors in their recurring UTIs. In schoolgirls with ABU, approximately one-half had more than 5 mL of residual urine (40). Those with more than 5 mL residual urine had a recurrence rate of 75% within 1 year, compared with 17% in those with 0 to 5 mL. More than one-half of children with acute cystitis had residual urine at the time of the infection as well as 6 months later (41). This suggests that the inability to empty the bladder is a primary defect in these children and not a secondary one induced by the bacterial toxins.

Incomplete bladder emptying may be a factor in infants with a high frequency of UTIs. Most children younger than

2 years have around 5 mL of residual urine, a high proportion of their total bladder capacity of 20 to 100 mL (42). Bladder storing and emptying ability increased during the third year of life, when children normally start to achieve bladder control. The residual volume in schoolchildren usually is less than 5 mL (43).

Antiadherence Mechanisms

The susceptibility to infection with attaching bacteria can be modified by the secretion of antiadhesive receptor molecules or by individual differences in receptor expression.

Urine contains glycoproteins that interact with type 1 fimbriae. The Tamm-Horsfall glycoprotein and secretory immunoglobulin A express terminal mannose residues. Binding to these molecules hinders the attachment of type 1 fimbriated *E. coli* strains to the mucosal surface (44). However, antiadhesive Gal α 1-4Gal β -containing receptor analogs have not been described in human urine. It has been suggested that the special role of the globoseries of glycolipid receptors for the virulence of *E. coli* arises in part from the lack of secreted antiadhesive analogs in the urine (26).

Another possible mechanism to block the binding of bacteria to epithelial cells is specific antibodies against surface structures on bacteria. Acute pyelonephritis results in a specific immune response approximately 1 week after the first infection. However, the importance of the specific immunity in the defense against UTI is unclear, largely because of the considerable variability of antigenic expression on uropathogenic bacteria. Nevertheless, a vaccine against UTI is being developed. Preliminary results in monkeys suggest that a vaccine based on the FimH adhesin of *E. coli* type 1 pili may have use in preventing cystitis in humans (45).

Inflammation

Bacteria elicit an inflammatory response in the urinary tract. The magnitude and localization of this inflammatory response may explain many of the clinical features of UTI. Patients with acute pyelonephritis have inflammation of the kidneys combined with a generalized inflammatory response [fever, C-reactive protein (CRP), and leukocytes]. Patients with acute cystitis have an inflammatory reaction restricted to the lower urinary tract. Patients with ABU may show signs of local inflammation of the urinary tract (i.e., follicular cystitis seen at cystoscopy), but the magnitude of the reaction is not sufficient to make them symptomatic (46).

The binding of bacteria to uroepithelial cells is the first step in the cascade of events leading to inflammation that is important for both protection and damage of the urinary tract. Svanborg et al. have proposed that P fimbriae use the globoseries of glycosphingolipids as the primary receptors for adherence to epithelial cells and that they activate these cells by recruiting Toll-like receptor 4 as co-receptors for signal

transduction (47). In experiments with mice they showed that Toll-like receptor 4–signaling deficiency disrupts the inflammatory response. The mice failed to develop symptoms and were unable to clear the infection, but no renal damage was seen. This carrier state resembled the situation in ABU patients. Further studies will show whether genetic variation in the receptor repertoire is of importance for development of symptomatic disease or asymptomatic carriage in humans.

The activation of uroepithelial cells by bacteria triggers the synthesis and secretion of inflammatory mediators and increases chemokine receptor expression by epithelial cells (48). A chemotactic gradient is created, and, in the response to the gradient, neutrophil cells leave the bloodstream, migrate through the tissues, and cross the epithelial barrier into the lumen of the urinary tract. These molecular and cellular interactions explain the emergence of leukocytes in urine—that is, pyuria (47). Interleukin-8 appears to be the main driving force for neutrophils to cross the human urinary tract epithelium, and the most important chemokine receptor seems to be CXCR1 (49). The blocking of this receptor in infected mice resulted in dysfunctional neutrophil migration with failure to cross the epithelium. The neutrophils accumulated under the epithelial barrier and abscesses were formed in the kidney parenchyma. The result was severe tissue damage with fibrosis and other signs of renal scarring (50,51). In control mice, neutrophils appeared in the kidneys within a few hours after infection and were seen crossing the epithelial barrier into the lumen. In the process, infection was cleared with no evidence of tissue damage. To test whether the CXCR1 genotype could be of relevance in human UTI, children with at least one episode of pyelonephritis were compared with age-matched controls with no history of UTI. The CXCR1 expression was lower in the patients than in the controls (51). These results suggest that children with UTI have a reduced neutrophil function caused by a low chemokine receptor expression. Further studies are required to define the importance of this deficiency.

PERMANENT RENAL DAMAGE

UTI is associated with permanent renal damage. The process of scarring after acute pyelonephritis is slow; it takes 1 to 2 years for a scar to develop fully as seen by urography (52). Children with unilateral damage, which accounts for approximately 85% of those with damage, have a compensatory hypertrophy of the other kidney, and the total glomerular filtration remains within the normal range. In children with bilateral damage, the glomerular filtration rate (GFR) often is decreased, and there is risk of progressive deterioration.

The frequency with which damage is found in children that have had febrile UTI depends on the sensitivity of the imaging technique used to reveal the damage, and also on the timing of the investigation. This variation can be illus-

trated by a study of 157 children (median age, 0.4 years; range, 5 days to 5.8 years) assessed at the time of their first symptomatic UTI and 1 year later by DMSA scintigraphy as well as urography (53). At the time of the UTI, 68 (43%) of the children had abnormal findings on scintigraphy and 10 (6%) on urography. One year later, the corresponding figures were 59 (38%) and 18 (11%). DMSA scintigraphy has a higher sensitivity to detect renal damage, but some of the early acute uptake defects seen with this test disappear. Urography, on the other hand, demonstrates additional cases with damage after 1 year as the scarring process progresses.

However, permanent damage (often described as reflux nephropathy although reflux is not a prerequisite for damage) may have developed *in utero* (congenital maldevelopment or renal dysplasia) or be acquired as a sequel of renal infection. When permanent renal damage is detected in older children and adults, it is usually not possible to distinguish between congenital and acquired damage, especially when there have been recurrent UTIs. Although this distinction may be difficult to determine, there are some important differences between the two conditions. Risdon demonstrated that among those with permanent renal damage detected in the early post-natal period, there was a close association with gross reflux, damaged kidneys tended to be small with smooth outlines rather than segmentally scarred, and the majority of the affected infants were boys (54,55). These results were corroborated in a study of an unselected group of 1221 children prospectively followed from their first symptomatic UTI. In this cohort, 74 children were ultimately found to have permanent renal damage by urography (renal scarring). There were significant differences between the 21 boys and 53 girls with damage (56). The median age at the first UTI was 0.3 years in the boys and 2.8 years in the girls. Damage was present already at the first urography in 18 of the 21 boys, and the damage was generalized in 15. Vesicoureteral reflux with dilatation was seen in 12 of the boys with damage on the first urography. Damage was seen on the first urography in 16 of the 53 girls and was generalized in 6. Reflux with dilatation was seen in only three of the girls with damage on the first urography. Thus, the damage was congenital in the majority of the boys, whereas it was acquired in most girls. Furthermore, the most important factor associated with development of renal scarring in the girls was the number of attacks of febrile UTI. There is also a gender difference, with a male predominance among infants with primary reflux detected after a prenatal diagnosis of hydronephrosis (57,58). Yeung et al., in children with antenatally diagnosed hydronephrosis, found that boys had dilated reflux and renal damage, whereas girls had mild reflux but normal kidneys (59).

LONG-TERM CONSEQUENCES

UTI cause significant morbidity and suffering for children, inconvenience and anxiety for families, and considerable con-

sumption of medical resources. Although most children with UTIs have an excellent long-term prognosis, there is an important risk of serious complications in a small group, especially in those with hypoplastic or dysplastic congenital anomalies and dilated reflux. There may be impaired renal function, sometimes leading to chronic renal failure and even end-stage renal disease, hypertension, and complications of pregnancy.

Chronic Renal Failure

The more aggressive diagnostic and therapeutic approaches used in infancy and early childhood during the last decades seem to have decreased the risk of UTI leading to chronic renal failure. In a British report reflecting the management of the 1960s and 1970s, the major cause of end-stage renal failure was pyelonephritis with or without reflux accounting for 21% (60). In a French study covering the years 1975 to 1990, pyelonephritis with reflux was given as the etiology of 12% of children with chronic renal failure (61). For the period 1986 to 1995, only 1 of 102 children reaching end-stage renal disease in Kansas had a primary diagnosis of UTI with reflux (62). In Sweden, with a total population of 8.5 million, the situation is even better: Not a single child with chronic renal insufficiency, defined as GFR below 30 mL/min/1.73 m², because of UTI has been detected since 1986 (63).

Smellie et al. studied a group of 226 adults after a follow-up of 10 to 35 years (64). They were originally referred to a UTI clinic because of symptomatic UTI during childhood. Most of these had recurrent UTI and vesicoureteral reflux. Of the 226 patients, 85 had radiologic renal scarring by the age of 10 years, and no scars were detected later. Among the 72 adults with renal scarring that were reinvestigated at a mean age of 27 years, 18 (25%) had raised or borderline levels of plasma creatinine; three of them had reached end-stage renal disease.

In Göteborg, we recently performed a follow-up study 16 to 26 years after the first recognized UTI in childhood in 57 patients with renal scarring and 51 matched patients without scarring (65). They were a subgroup of an unselected cohort of 1221 cases with first-time UTI in the community during the years 1970 to 1979. The median GFR measured by chromium-51–edetic acid clearance was 99 mL/min/1.73 m² in both groups. There were eight subjects with GFR below 80 mL/min/1.73 m², and the lowest value was 69 mL/min/1.73 m². In patients with unilateral scarring, the total GFR remained unchanged over the years, whereas the individual GFR of the scarred kidneys declined significantly from 46 to 39 mL/min/1.73 m². In seven patients with bilateral scarring, GFR was significantly lower at follow-up than in those with unilateral scarring—84 and 101 mL/min/1.73 m², respectively. Thus, the renal function was well preserved, and the risk of renal impairment in these young adults was lower than previously described, most likely as a consequence of early detection and close supervision during childhood.

Hypertension

In Australian and British studies, development of hypertension has been shown in 10% of children and young adults with pyelonephritic renal scarring (reflux nephropathy) (66,67). The risk correlated to the extent of damage; 15 to 30% of children with bilateral scarring developed hypertension within 10 years (66). In a study 27 years after identification of nonobstructive focal renal scarring, 30 adults were reinvestigated; seven (23%) had hypertension >140/90 mm Hg (68). Smellie et al. in their long-term follow-up demonstrated hypertension in 14 (19%) of the 72 with radiologic renal scarring (64).

However, there is reason to believe that the frequency of hypertension in these studies is higher than we would find in unselected materials treated according to principles used during the last decades. In a population-based study from Göteborg, 54 women with renal scarring were followed continuously for a median of 23 years from the 1950s and 1960s; three (6%) developed hypertension (69). In the recent follow-up study from Göteborg described earlier (65), we also performed ambulatory 24-hour blood pressure monitoring 16 to 26 years after the first UTI in childhood (70). There was no difference between the two groups with and without renal scarring, not even when patients with more extensive or bilateral scarring were analyzed separately. These promising results indicate that at least in the perspective of 20 years from childhood, good care may be effective to minimize long-term risks.

Complications of Pregnancy

Women who had a tendency to recurrent UTIs as girls have an increased risk of new infections during pregnancy (71–73). Women with renal scarring have a significant rise of blood pressure during pregnancy. In women with severe reflux nephropathy, most pregnancies are complicated (74,75). Female patients with renal scarring should be followed carefully into adulthood and through the reproductive period.

DIAGNOSIS

The diagnostic procedure is based on urinalysis, with culture as the most important investigation. Urine in the normal bladder is sterile, but urine frequently becomes contaminated by bacteria during the passage from the bladder to the sampling container, especially in infants and small children. If this leads to a false diagnosis of UTI, the child is subjected to unnecessary treatment, investigations, and follow-up. On the other hand, failure to identify the child with UTI is associated with a risk of progressive renal damage. Therefore, the quality of the urine sample is crucial.

Methods of Urine Collection

The ideal sample of voided urine is a midstream specimen with a long bladder time, collected after uncovering the

urethral orifice. A long interval between micturitions allows the bacteria to multiply and reach high counts, which decreases the overlap between samples representing contamination and true bacteriuria. The midstream technique means that the first urine containing most of the contaminating bacteria in the periurethral region is omitted. This method should always be used in children with adequate bladder control.

In infants and small children, urine is mostly obtained as a bag sample. The use of adhesive bags carries a high risk of contamination, however, and approximately 10% of such samples from healthy infants grow at least 50,000 CFU/mL (76). The skin should be dried thoroughly after cleaning the periurethral area, the child kept in an upright position to prevent having urine come in contact with the skin or entering the vagina, and the bag removed immediately after the child has voided. A single bag specimen should not be relied on for a diagnosis of UTI, even if there is pure growth of more than 100,000 CFU/mL urine; verification by a repeat sample is essential, preferably one obtained by suprapubic aspiration or catheterization.

Another technique to obtain urine for screening purposes is to use an absorbent pad placed inside the diaper (77). As soon as the child has voided, urine is recovered with the help of a syringe. The pad must be of the older fluffy type since it is not possible to extract urine from the modern gel-containing super-absorbing pads. The main advantage of the pad technique is that there are no skin reactions, which is a common problem with adhesive bags. The risk of getting a contaminated urine sample is as high with pads as with adhesive bags.

The best technique for obtaining an uncontaminated urine specimen is direct aspiration from the bladder by a suprapubic puncture. This is a simple procedure in infants, because the bladder is an intraabdominal organ during the first years of life. With the child in supine position, a thin needle attached to a syringe or a vacuum container is inserted vertically in the midline, 1 to 2 cm above the symphysis. Urine is usually obtained at a depth of 2 to 3 cm. The trick is to know when there is urine in the bladder. The chance is best when the diaper has been dry for at least 30 minutes, especially after the baby has been fed and the diuresis is high. The presence of bladder dullness by percussion over the suprapubic area or the demonstration of a bladder diameter of at least 30 mm by ultrasonography is associated with a high success rate (78,79).

Suprapubic aspiration causes no more pain to the child than any other needle puncture. Complications are rare; transient macroscopic hematuria occurs in approximately 2%, but microscopic hematuria is present in most suprapubic aspirations, making this technique unsuitable for evaluation of hematuria. Accidental penetration of the bowel does not lead to any problems beyond contamination of the sample. There are few problems of interpretation, however, because bowel aspiration results in growth of colonies of

many different types, which is typical of contamination; more than 99% of children with true bacteriuria have growth of only one type of bacteria. Suprapubic aspiration is the preferred method to obtain urine for verification of UTI in small children. For patients older than 1 year, needle aspirations may be difficult for psychological reasons, although the anatomic prerequisites remain until the age of 4 or 5 years.

Catheterization of the bladder is another method of obtaining urine with minimal contamination. In many centers, this technique is rarely used, mainly because of the risk of introducing infection and of the negative psychological effects on children older than 1 year of age. Other centers use catheterization more commonly. We prefer catheterization if suprapubic aspiration has failed, especially if the child is severely ill and a reliable urine sample is needed before antibacterial treatment is started.

Culture of Urine

Urine should always be immediately refrigerated at 4°C until cultured to prevent growth of contaminating bacteria. It is essential that this temperature be maintained during transport.

Most bacteriologic laboratories use a calibrated loop containing approximately 0.002 mL of urine for routine culture. This means that growth of one colony of bacteria on the culture medium is equivalent to 500 CFU/mL. To obtain higher sensitivity, a larger volume of urine has to be cultured.

A dipslide culture has approximately the same sensitivity as the calibrated loop technique. With proper training, dipslides can be used and interpreted locally, provided that the staff uses them regularly to retain the skill of evaluating growth. It is possible to perform sensitivity testing on a dipslide, but it is usually better if the bacteriologic laboratory performs this analysis.

Two possible pitfalls with the dipslide should be mentioned. The most common problem is confluent growth of colonies of different types. This usually indicates contamination but may be caused by massive numbers of one bacterial strain combined with only a few contaminating bacteria. Such quantitative differentiation is hardly possible on the dipslide but is usually easy in a traditional culture. Instead of sending the positive dipslides to the laboratory for characterization of the bacteria, it is usually better to send the urine, provided that it has been kept overnight in the refrigerator and that it can remain cooled during the transportation. The other pitfall with the dipslide is that some bacteria that can cause UTI do not grow on cystine-lactose electrolyte-deficient or McConkey agar, which are most commonly used. Such bacteria are not common but should be considered in infants with sepsis, especially during the first months of life, and in those with recognized malformations of the urinary tract. Most of these bacteria are identified by a laboratory using blood agar or other rich culture media.

The interpretation of culture depends on the method of urine collection and on the clinical background. In urine obtained by suprapubic aspiration, any growth is considered significant. In catheter urine, the level of significance is mostly given as 1000 to 10,000 CFU/mL, but more precise reference values are lacking. Hoberman et al. have suggested a cutoff point of 50,000 CFU/mL (80). For voided specimens, the traditional cutoff level of 100,000 CFU/mL is roughly valid, but the probability of true bacteriuria in a single culture is not higher than 70 to 80%. However, in combination with acute localizing symptoms from the urinary tract such as marked dysuria and frequency together with pyuria, one urine sample with bacteriuria can be considered adequate for a diagnosis of UTI. A similar evaluation can be made in a child presenting with high fever and back pain together with pyuria. For all patients lacking symptoms specific for the urinary tract, a second urine specimen should be obtained before antibacterial treatment is started; when suprapubic aspiration is used, one urine sample is adequate. Another advantage with the latter technique is the absence of equivocal results. Low bacterial counts may occur; 20% of urine samples obtained with suprapubic aspiration had counts of 1000 to 50,000 CFU/mL (81). With such a finding, it is difficult to discriminate between true bacteriuria and contamination using any other sampling technique.

A diagnosis of ABU requires repeated samples over a period of several days in a child without fever or acute urinary symptoms within the preceding 2 weeks.

Other Urine Findings

Pyuria is measured most precisely by microscopy of unspun urine using a counting chamber; more than 10 leukocytes/ μ L in a boy and 50 in a girl is abnormal. A more crude but mostly adequate estimate of pyuria is obtained by analysis of urine sediment or by the use of test strips that react to granulocyte esterase activity in the urine.

Determination of pyuria is a helpful rapid investigation in a child suspected of having symptomatic UTI. Pyuria is present in 80 to 90% of episodes of symptomatic UTI; a urine sample without pyuria speaks against but does not exclude symptomatic UTI. However, the presence of leukocytes in the urine is not diagnostic of UTI. It may be found in febrile children with infections outside the urinary tract (82), in inflammatory diseases of other types in or near the urinary tract, and as a contamination from the vagina. Pyuria should be taken as an indication to obtain a urine sample of high quality for culture.

The *nitrite test* is based on the ability of most uropathogens to reduce nitrate to nitrite. The reduction is time dependent, and a positive test requires a long bladder time, often more than 4 hours, or significant residual urine. Therefore, the sensitivity of the nitrite test is low in infants and small children with frequent voiding. The sensitivity

was only 11% with bacterial counts less than 100,000 CFU/mL in suprapubic aspirates in infants, whereas with higher counts the sensitivity was 44% (81). The predictive value of a positive test is more than 99% in girls and, thus, practically equivalent to bacteriuria. In small boys, the nitrite test is less reliable because nitrite-producing bacteria may accumulate under the prepuce and give a false-positive result. Another reason for a false-positive reaction is macroscopic hematuria, which can cause discoloration of the test strip. Furthermore, the test must be performed on a fresh urine sample or one that has been refrigerated immediately, because growing contaminating bacteria produce nitrite.

Hematuria is common in children with symptomatic UTI and is macroscopic in 20 to 25% of those with acute cystitis (83). However, determination of hematuria or albuminuria is of no value in establishing a diagnosis of UTI.

Site of Infection

A number of tests for defining the site of infection or level of UTI have been described. Some of these tests are complicated and require special facilities or skills; others are simple but may be nonspecific. Unfortunately, there is no universally accepted test that is applicable in everyday practice. One of the major obstacles to development of such a test is that there is no gold standard for establishing the true character of UTI. Localization of bacteria by ureteral catheterization (84) or bladder washout (85) has been used, but these tests are difficult in infants and small children. Pitfalls of diagnostic testing include intermittent discharge of bacteria from the kidney, resulting in false-negative results, and vesicoureteral reflux, which may lead to false-positive findings (86).

Another principle used to evaluate the site of infection is the measurement of host reactions to renal inflammation. An example of this principle is temporary tubular dysfunction leading to decreased renal concentrating capacity for several weeks after renal infection (87). Another is determination of antibodies to the infecting bacteria; this has a high predictive value for renal involvement, but the infecting bacteria must be available (88). Yet another is detection of antibody-coated bacteria in urine using fluorescein-labeled antiimmunoglobulin; this technique is unreliable in children, because there is a delay of several days before antibody is produced (89,90).

Renal imaging may reveal an inflammatory process in the kidney. Swelling of the kidney and dilatation of the collecting system may be seen on urography (91). General swelling can be seen on ultrasonography; this requires measurement and comparison with age-matched reference values for renal volume (92,93).

Another technique that shows an inflammatory process in the kidney is scintigraphy (e.g., technetium-99m DMSA scanning). Affected areas are seen as uptake defects. A metaanalysis of animal studies of acute pyelonephritis showed an overall sensitivity of 86% and a

specificity of 91% (94). In clinical practice, a problem with the scintigraphic techniques is the difficulty of distinguishing between acute inflammatory changes and already established renal scars (95–97). Acute inflammatory changes may disappear shortly after start of treatment but may also persist for up to 4 to 5 months before they disappear; thus, timing of the investigation is important (98,99).

In primary care, a method for determining the site of infections should be rapid and inexpensive. White cell casts in urinary sediment are a classic finding indicating renal infection. However, these casts are easily overlooked if pyuria is massive, and they are easily dissolved, especially in alkaline urine. The sensitivity of this method, therefore, is low. Serum CRP level and sedimentation rate may be high in any inflammatory reaction with significant tissue involvement. Even though these methods lack specificity for kidney involvement, we find them to be of value in identifying those children with UTI who have marked host reactions (86). In acute cystitis, the infection is mostly superficial, involving only the bladder mucosa, and a generalized host reaction is not elicited. Another test that has recently attracted attention as a potential marker of bacterial disease is determination of procalcitonin in plasma. High concentrations were found to correlate with the severity of the acute renal lesions in children with pyelonephritis (100,101). Because these tests are all unspecific, they are usually of no help in patients with diseases in several organ systems.

In typical cases of acute pyelonephritis, there is little reason to perform tests for determining the site of infection in routine medical care. These patients should be treated immediately; most clinicians agree that diagnostic imaging and follow-up are indicated. Diagnostic tests designed to determine the site of infection are needed primarily in patients older than 1 to 2 years with no or equivocal signs of renal involvement to identify low-risk patients who can be excluded from investigations and further follow-up. These tests are also of value in children with suspected UTI who concurrently have symptoms and signs suggesting infections in other organs.

TREATMENT

Antibiotic Treatment

Children with symptomatic UTIs should be given antibiotics without delay but not until a urine sample of high quality has been acquired. The drug is chosen on the basis of the resistance pattern of uropathogens in the area as well as of recent antibacterial treatment received by the patient. With adequate treatment, the urine usually is sterile after 24 hours. Persisting growth indicates bacterial resistance or a severe abnormality of the urinary tract.

Oral medication is effective in most children with febrile UTI. Intravenous therapy may be needed, especially when vomiting prevents effective oral treatment or in infants with suspected septicemia. However, in this field, local traditions and beliefs guide the choice of treatment strategy; controlled studies are few indeed. The largest clinical trial using random allocation to different treatment modalities is by Hoberman et al. (102). A total of 306 children aged 1 to 24 months with fever and UTI were given either oral cefixime for 14 days or initial intravenous cefotaxime for 3 days followed by oral cefixime for 11 days. There was no difference between the groups regarding time to sterilization of the urine (24 hours in all children), time to defervescence, incidence of reinfection, and incidence and extent of permanent renal damage as evaluated by DMSA scintigraphy after 6 months. Two smaller studies of children with febrile UTI resulted in similar findings. In one, 3 and 7 days of intravenous temocillin were compared in both arms followed by oral amoxicillin with or without clavulanic acid until day 21 (103). In the other, one group of children was given a single intramuscular dose of ceftriaxone followed by 10 days of oral co-trimoxazole and the other 10 days of oral co-trimoxazole (104). Further studies addressing the efficacy of different routes of administration of the antibiotics are needed, but, so far, there is no evidence that parenteral is superior to oral treatment.

The most common drugs or groups of drugs for treating children with UTI are given in Table 53.1, which also includes the resistance pattern of bacteria isolated from children with UTI in 1992 to 1995 in Göteborg. There has been a marked

TABLE 53.1. ANTIBACTERIAL DRUGS IN CHILDHOOD URINARY TRACT INFECTION (UTI)

Drug	Frequency of resistant bacteria in children with Primary UTI in Göteborg 1992–1995 (%)			Serious adverse reactions
	<i>Escherichia coli</i>	Non- <i>E. coli</i>	All	
Ampicillin derivatives	27	61	31	—
Cephalosporins	1	29	4	—
Trimethoprim (with or without sulfonamide)	10	13	10	Bone marrow depression, mucocutaneous syndromes
Nitrofurantoin	1	61	7	Pulmonary
Ciprofloxacin	1	15	2	Cartilage (before puberty)
Aminoglycosides	1	1	1	Ototoxicity, renal toxicity

increase in resistance to ampicillin to approximately 30%, making this group of agents inappropriate as first choice; the combination with clavulanic acid may solve this problem. The resistance to the other drugs was 1 to 10%. However, there are considerable geographic variations in bacterial patterns and resistance properties (e.g., depending on local habits regarding prescription of antibacterial drugs). Rapid emergence of strains resistant to trimethoprim to a level of approximately 50% of urine isolates has been reported (105). Therefore, the choice of antibiotic must be based on knowledge of the local situation rather than on international reports.

Treatment of a child with an antibacterial drug for 10 days eradicates sensitive bacteria, irrespective of the localization of the UTI. In children with renal infections, the main objectives are to relieve symptoms and to prevent permanent renal damage. In children with infections limited to the lower urinary tract, the main objective is to relieve discomfort. Many patients with acute cystitis are free from symptoms after one or two doses of an antibiotic. Treatment for 5 days is adequate in children with cystitis (83).

Some have speculated that uptake defects on DMSA scintigraphy should lead to a more aggressive antibacterial treatment (106). There is no evidence to support this hypothesis. It is true that there is a correlation between extent of inflammation and uptake defect on scintigraphy. However, killing of the bacteria is usually a rapid process, and prolonged antibacterial treatment is not likely to influence the inflammatory process that can cause renal damage. Rather, we need the methodology to moderate inflammation to be able to decrease or prevent development of permanent renal damage. It is important to start antibacterial treatment without delay, because there is a correlation between duration of infection and extent of inflammation.

Antibacterial Prophylaxis

Low-dose, long-term prophylaxis has been traditionally used in patients at high risk for developing renal scarring, those with vesicoureteral reflux with dilatation of the upper urinary tract, and those who are prone to develop recurrent acute pyelonephritis. In these patients, prophylaxis sometimes is used for several years (107). It should be pointed out, however, that controlled studies comparing the long-term results of renal function in children given prophylaxis or immediate treatment at recurrences have not been performed. Probably, the most important measure in preventing deterioration of renal function is to inform the parents to seek medical advice early when the child gets fever and to have urine tested for bacteriuria. The efficacy of antibacterial treatment may be questioned. In the Swedish national UTI study, the recurrence rate in children with reflux grade IV to V was 45% in boys and 71% in girls (Esbjörner et al., unpublished, 2003).

Another indication for prophylaxis may be repeated attacks of cystitis. The frequency and severity of infections must be balanced against the difficulty of taking the drug

TABLE 53.2. ANTIBIOTICS FOR LOW-DOSE PROPHYLAXIS AGAINST URINARY TRACT INFECTION

Antibiotic	Recommended dosage (mg/kg/24 h)	Resistant bacteria that may cause breakthrough infections	Rate of breakthrough infections/yr (%)
Nitrofurantoin	1	<i>Klebsiella</i>	26
Trimethoprim	0.5	<i>Staphylococcus epidermidis</i>	26
Trimethoprim-sulfonamide	0.5 ^a	Enterobacteria	18
Cefadroxil	3–5	Enterococci	Unknown
Ciprofloxacin	1	Enterococci	Unknown

^aExpressed as trimethoprim component.

regularly and the likelihood of adverse reactions. The duration of prophylaxis in this type of patient is mostly a subjective decision. However, the first measure should be to ensure regular bladder and bowel emptying.

Drugs that tend to select resistant bacteria in the bowel are not suitable for long-term prophylaxis. Antibiotics that have a minimal risk of selecting resistant strains and are effective in preventing recurrent UTI are given in Table 53.2. The drug is typically administered as a single bedtime dose. A high frequency of resistant uropathogens in an area makes a drug unsuitable for prophylaxis. The pharmacokinetic properties of the drugs are important. Antibiotics that are rapidly excreted (serum half-life of approximately 1 hour) have no antibacterial activity in urine after 8 to 12 hours; examples are nitrofurantoin and cefadroxil. However, one dose per day is effective, but failure to take the drug for 1 to 2 days increases the risk of reinfection. Examples of drugs with a longer excretion time are trimethoprim and ciprofloxacin, which usually give effective antibacterial activity in the urine for more than 24 hours.

Compliance is crucial to prophylaxis. The patient and family must be motivated and understand why it is important to take the drug every day, sometimes for several years. Repeated discussions on this subject are usually needed. Patient acceptance of the drug is necessary for successful prophylaxis; a medication that the child opposes has a low chance of being taken regularly. During prophylaxis, recurrences caused by bacteria sensitive to the drug usually indicate noncompliance; insufficient dosage is uncommon.

Breakthrough infections caused by resistant bacteria are seen with all drugs. The bacterial pattern varies, however, and the most commonly encountered bacteria are given in Table 53.2. These bacteria can cause pyelonephritis in the compromised host. In Göteborg, the rate of breakthrough infections with these drugs was 18 to 26% per treatment year. Double antimicrobial prophylaxis with nitrofurantoin and trimethoprim-sulfamethoxazole has been reported to be effective in girls with a high rate of breakthrough infections on a single-drug schedule (108).

RISK EVALUATION

It is essential that children with an increased risk of progressive renal deterioration be identified early; detection of malformations such as obstruction and renal hypoplasia and dysplasia is most important. Many of the children with these types of congenital problems have reduced renal function already from birth; superimposed UTIs may lead to further loss of function and chronic renal failure.

A number of risk factors are associated with permanent pyelonephritic renal damage (Table 53.3). Vesicoureteral reflux is detected by voiding cystourethrography; it is evaluated on a 5-grade scale (109). In studies using urography to detect renal scarring, the severity of reflux was related to the frequency of scarring of 444 children with first-time pyelonephritis (Table 53.4) (11). When the more sensitive DMSA technique was used for identification of permanent damage, more than one-half of the damaged kidneys were not related to reflux (53,110,111). These findings show that reflux is not a prerequisite for permanent renal damage. Still, reflux remains an important risk factor for renal damage; the extent of acute as well as permanent renal involvement has been reported to be higher in children with dilating reflux (24,53,111,112).

Malformations and reflux are diagnosed by imaging the urinary tract. The practical problems are deciding which patients should be investigated and timing the procedures. At first evaluation in the emergency room, it is often possible to identify the serious infections with a greater likelihood of underlying abnormalities that call for prompt investigation. The severely sick infant only a few months old and the child with sepsis are examples. The physical examination may reveal abnormalities that require rapid workup (e.g., hypertension, abdominal mass, or genital or lumbosacral midline anomalies). Similarly, laboratory findings such as hyponatremia, acidosis, or increased serum creatinine and bacteriologic findings such as uncommon bacteria or continued growth in urine obtained 24 hours after start of treatment indicate a more serious background.

Another factor that relates to the development of scarring is the time between the start of symptoms and the initiation of antibacterial treatment. This means that in suspected acute pyelonephritis there should be no unnecessary delay in starting treatment; antibiotics should be given as soon as adequate urine samples have been obtained, without awaiting report from the bacteriologic laboratory.

TABLE 53.3. RISK FACTORS ASSOCIATED WITH PERMANENT PYELONEPHRITIC RENAL DAMAGE

Obstruction
Reflux with dilatation
Age
Delay of treatment
Number of pyelonephritic attacks
Uncommon bacteria (non- <i>Escherichia coli</i>)

TABLE 53.4. RENAL SCARRING DETECTED BY UROGRAPHY DURING FOLLOW-UP IN 444 CHILDREN WITH FIRST URINARY TRACT INFECTION DIAGNOSED AS ACUTE PYELONEPHRITIS IN RELATION TO REFLUX STATUS

Reflux grade	Number of children	Number with renal scarring (%)
0	278	15 (5)
1	29	3 (10)
2	99	17 (17)
≥ 3	38	25 (66)

The severity of the permanent renal damage is associated with the number of pyelonephritic attacks (Table 53.5) (11,56,113). Therefore, early and prompt treatment of recurrences is essential. Prevention of new infections by antibacterial prophylaxis can be used in children with high risk of recurrences.

Low age has been related to an increased risk for renal scarring as detected by urography (114,115). Based on findings using DMSA scintigraphy for renal evaluation, the importance of low age for the development of damage has been challenged; the frequency of permanent damage was found to be higher in children older than 2 years (116). There may be several explanations for these divergent findings. Urography and scintigraphy have different sensitivity to detect permanent renal damage; the extent of the damage has to be taken into account and not just presence or absence of damage. In infants, especially in boys, the number of patients with prenatally acquired damage is higher, and there is often an association with gross reflux (54–56). The latter group was probably included in the older studies but may now be detected prenatally by ultrasound screening and thereby prevented from having the UTI needed for inclusion. A major problem is to ascertain that the patient materials are representative and not unintentionally selected; there is a definite risk that young children are referred for investigation more liberally and that there is a higher proportion of severely sick children in the older ones subjected to imaging procedures. Further studies are needed on this issue, but it is evident that pyelonephritic renal damage can develop also after the first

TABLE 53.5. RENAL SCARRING DETECTED BY UROGRAPHY DURING FOLLOW-UP IN 664 CHILDREN IN RELATION TO NUMBER OF PYELONEPHRITIC ATTACKS

Number of attacks	Number of children	Number with renal scarring (%)
0	141	7 (5)
1	366	32 (9)
2	98	15 (15)
3	38	12 (35)
≥ 4	24	14 (58)

year of life and that there is a considerable risk at least through the preschool years (111,113,117,118).

However, most children with UTI do not develop permanent renal damage. Children older than 2 years with single episodes of acute cystitis (i.e., with acute dysuria, without high fever, and with normal concentrating capacity) constitute a group with low risk of urinary tract anomalies in whom renal scarring is rare. In these cases, investigations may be omitted if there is no suspicion of UTI in the history and a high detection rate of pyelonephritis in infants in the community.

INVESTIGATIONS

The aim of the imaging investigations is early detection of patients at risk of progressive renal damage. Ultrasonography reveals dilatation of the upper urinary tract, severe loss of renal parenchyma, and major bladder anomaly. Urography shows obstructive malformation and established renal scarring; it also gives information about renal function and bladder status. Voiding cystourethrography can reveal vesicoureteral reflux and infravesical obstruction, especially posterior urethral valves in boys. Isotope cystography is useful for detection of reflux but cannot visualize the urethra. DMSA scintigraphy shows areas of acute inflammation as uptake defects in the early phase of renal infection; 6 months after an infection uptake, defects represent areas of permanent renal damage. DMSA scans also show the side-distribution of the renal function. Mercaptoacetyltriglycine (MAG3) renography visualizes the passage of the tracer through the urinary tract, gives a crude picture of the function of the kidneys that can be used to identify areas of major acute or permanent damage, and shows the side-distribution of the renal function. After the initial study, the tracer substance can be followed during a micturition (indirect cystography).

Consideration of which techniques to use in routine care of patients should include the availability of the method and, perhaps most importantly, the experience and skill of the diagnostic department. Ultrasonography is the first investigation of choice because of its availability and noninvasiveness; severe abnormalities of the urinary tract are rapidly revealed. However, at the present level of technical development, an isolated ultrasonographic investigation is not sufficient to detect reflux or renal scarring.

For the choice of additional investigations and their timing, there are several possibilities. If DMSA scintigraphy is not available, voiding cystourethrography is recommended as most appropriate for risk evaluation (dilating reflux and urethral obstruction in boys), with a follow-up urography after 1 to 2 years. When DMSA scintigraphy is available, the identification of risk patients should be done with this technique. A normal scan means a low risk and no need for further investigations, provided there are no pyelonephritic recurrences (99,110,119).

There is also discussion of whether to investigate all children with UTI or use a selective approach (120,121). Our policy is to reserve imaging studies for all infants with UTI and to older children (older than 1 year) with acute pyelonephritis. The policy of not performing imaging studies in children older than 2 years with a clinical diagnosis of acute cystitis is based on our observation that radiologic abnormalities are rarely found in this group. Although this may be true in a community with a very high detection rate of UTIs in infants and small children, it must be emphasized again that children with previous undetected UTI and renal scarring may present later with afebrile symptomatic infections.

Another important aspect of UTI is an evaluation of the bladder and bowel functions. A detailed history of voiding and defecation habits often reveals abnormal patterns that warrant further investigation. A simple step is to register a flow curve and measure residual urine. Some children need a more complete urodynamic investigation.

MONITORING

A standardized protocol for treating children with UTIs has many advantages. Relevant diagnostic information is obtained, imaging and other investigations are carried out with less personal bias, and follow-up is easier when the patient and family understand the proposed schedule. Because there are differences in organizations, local facilities, and medical tradition, it is impossible to design a universally acceptable protocol. The one described here is a modification of the Göteborg model.

In the Emergency Room

Important points in the history are previous UTIs, recent episodes of high fever, and bladder- and bowel-emptying habits. It is essential to perform a full physical examination to exclude another focus of infection, lumbosacral or genital anomalies, abdominal mass (hydronephrosis or bladder distention), and hypertension. Urine is obtained, preferably by suprapubic aspiration or midstream technique, and is cultured and investigated for nitrite and pyuria. Serum is taken for analysis of CRP and creatinine. Further management depends on the diagnosis and the age of the child. All infants (younger than 1 year) with a UTI and older children with acute pyelonephritis are investigated with ultrasonography within a few days. In infants, we also perform a voiding cystourethrography and a DMSA scintigraphy. In older children, voiding cystourethrography is used selectively in those with dilatation at the ultrasound or in whom DMSA scintigraphy reveals renal damage.

Early Follow-Up

By early checkup, children with abnormal primary healing may be detected. Within 24 hours, the urine should be ster-

ile; signs of inflammation persist longer. Fever and other symptoms should be normalized within 2 to 3 days and CRP below 20 mg/L after 4 to 5 days. The sedimentation rate may remain elevated for 2 to 3 weeks and the concentrating capacity decreased for some weeks to 2 to 3 months after start of treatment. After 4 to 5 days, children treated as outpatients are seen to ascertain that healing is uneventful.

Further Follow-Up

The schedule should be adapted to local traditions and resources. In our unit, there is only one checkup of children with an uneventful cystitis, but all other children are followed for at least 1 year after the UTI. At the visits, educational information is repeated, and the patient is encouraged to return whenever symptoms occur that can be related to UTI.

Repeat radiologic investigations or alternative procedures are primarily performed to detect development or progress of renal scarring. This routine is recommended after 1 to 2 years in patients considered to be at risk (Table 53.3).

Long-time follow-up of patients with renal scarring into adulthood is essential, with at least yearly blood pressure measurements. The patient is provided with immediate service at suspected recurrences and other complications.

ASYMPTOMATIC BACTERIURIA

The introduction of the quantitative culture during the 1950s resulted in a marked interest in silent urinary infections. These were believed to cause renal scarring, and many screening programs were started with the intention of early detection, treatment, and cure. The objective was prevention of both symptomatic UTI and damage to the kidneys. It was shown that pregnant women with untreated ABU had a considerable risk of developing acute pyelonephritis and that this risk could be avoided by detection and treatment of the bacteriuria.

During the 1960s, Kunin et al. conducted a long-term study of the epidemiology and natural history of UTI in schoolchildren in Virginia (122–124). They found significant bacteriuria in 1.2% of girls and 0.03% of boys. An annual incidence of 0.3% in girls was seen at repeated screening, and the accumulated risk for girls to acquire bacteriuria during school age was calculated as 5%. Vesicoureteral reflux was detected in 19%, and renal abnormalities with blunting of calyces were detected in 13% of these with UTI. All patients with bacteriuria were treated using short courses of antibacterial therapy for each episode of bacteriuria. Recurrences occurred in 80%, and pyelonephritis was seen in 10% of the cases, even when carefully followed and treated.

During the 1970s, prospective studies on ABU in schoolgirls were initiated using both treatment and nontreatment (125–129). Prevalence figures of 1.2 to 1.8% were found. The marked tendency to recurrence after treatment shown by

Kunin et al. was confirmed. However, the main interest was in the practicality of nontreatment. In contrast to the situation in pregnant women, there was no evidence of a higher risk of acute pyelonephritis in untreated patients than in those who were treated. In addition, there was no impairment of renal growth or GFR in untreated patients (130–132). In girls with renal scarring, progression was seen equally among treated and untreated patients. Thus, no evidence suggested that ABU left untreated was detrimental to the kidneys or that antibacterial treatment had any beneficial effect.

Instead, studies during the 1980s indicate that treatment increases the risk of complications (131). Elimination of bacteria of low virulence in asymptomatic children resulted in recurrences in 80%; these recurrences were in the form of acute pyelonephritis in 15% of the children with normal kidneys and in 30% of those with renal scarring. In girls left untreated, the original strain usually remained in the urinary tract for many years without development of symptoms (133). An established bacterial strain in the urinary tract seems to prevent invasion by other bacteria, thus functioning as a biologic prophylaxis against colonization by potentially virulent bacteria.

Bacteriuria in Infancy

Mass screening for bacteriuria in infancy has been discussed as a means of preventing pyelonephritic renal scarring. Studies of bacteriuria in infancy pose problems of reaching a relevant population of adequate size and difficulties in obtaining uncontaminated urine samples. In an unselected group of 3581 newborn infants repeatedly screened for bacteriuria during the first year of life, ABU was confirmed by suprapubic aspiration in 36 (2.5%) of the boys and 14 (0.9%) of the girls (76). In the boys, bacteriuria was found almost exclusively during the first 6 months of life; in the girls, it was found throughout the first year. Two infants developed pyelonephritis within 2 weeks of the verification of bacteriuria, and the others remained free of symptoms. The bacteriuria cleared spontaneously within a few months in 36 of 45 untreated infants and in response to antibiotics given for infections in the respiratory tract in a further eight (134). Recurrences of bacteriuria were observed in 20% of the children, but only one had pyelonephritis (135).

Radiologic abnormalities were uncommon. Of the boys, three (9%) had vesicoureteral reflux, all without dilation, and none had renal anomalies. Of the girls, one had a scarred duplex kidney with reflux and another had moderate hydronephrosis. During a 6-year follow-up, no indications of renal damage were found; a repeat urography performed in 36 of the 50 children did not reveal development of renal scarring in any child (135). Mass screening for bacteriuria in infancy seems to result primarily in the detection of innocent bacteriuric episodes and is not recommended. Although screening for bacteriuria in healthy children has no place in any age group, it is important to

perform urine cultures freely in symptomatic children, especially in infants with high fever or failure to thrive (136,137).

Symptoms in Schoolgirls with Asymptomatic Bacteriuria

Although the schoolgirls with ABU had not complained of symptoms that lead to medical consultation, most of them did give a history of symptoms such as urgency, urge incontinence, and difficult micturition when asked specific questions about voiding habits. This finding was emphasized by Savage et al. when they proposed the term *covert bacteriuria* as more appropriate than *asymptomatic bacteriuria* (138). Bladder dysfunction is common among girls with ABU (139). The pathogenesis is probably multifactorial, and it is difficult to know whether the bladder dysfunction is the cause of the bacteriuria or the bacteriuria is the cause of the abnormal bladder function. However, the symptoms do not seem to be temporally related to the acquisition of bacteriuria. Furthermore, there is no evidence that antibacterial treatment affects the lower urinary tract symptoms in these children. In a controlled study, Savage et al. found no improvement of enuresis, frequency, or urgency after antibacterial treatment (125). These patients probably have an underlying functional disturbance of the lower urinary tract and a secondary liability to urinary infections corresponding to the situation in children with neurogenic bladder disorders. This dysfunction may have been initiated by a previous symptomatic UTI or an inflammation of the genital area such as vulvitis. Painful voiding may have started a cycle of lower urinary tract dysfunction and recurrent UTIs. Bladder rehabilitation programs have been shown to be effective in children with dysfunctional voiding (140,141).

Relationship between Symptomatic and Asymptomatic Bacteriuria

Untreated symptomatic urinary infections may heal spontaneously or they may turn into ABU. How often this happens is not yet known. Recurrences after treated infections were asymptomatic in approximately one-third of the cases if the previous infection was symptomatic (12) but in two-thirds if it was asymptomatic (127). The explanation may be that the new bacteria are of low virulence or that the defense mechanisms of the child prevent the bacteria from attaching by blocking the binding sites (e.g., by antimicrobial antibodies induced by the previous infection).

Of greater practical interest perhaps is the frequency with which ABU develops into symptomatic infection. During follow-up of schoolgirls with untreated ABU, the risk of developing symptomatic pyelonephritis was found to be small. In most girls the same bacterial strain persisted within the urinary tract (133). In the few who developed

them, acute symptoms were associated with a change from one bacterial strain to another with greater virulence. This change was often brought about by antibacterial treatment of upper respiratory infections, which eliminated the urinary bacteria (142). The urinary tract was thereby left open to new colonization, and development of symptoms depended on the properties of the bacteria that happened to invade.

In the Göteborg study of infants with screening bacteriuria, only 2 of 45 untreated infants developed acute pyelonephritis; the others remained symptom free (134). The study population contained another 20 (1.1%) girls and 22 (1.3%) boys with verified bacteriuria who were investigated because of symptoms. Of those with symptomatic bacteriuria diagnosed after 1 month of age, all had participated in the screening program with normal results before the diagnosis (76). These findings suggest that infants with primary asymptomatic and symptomatic bacteriuria make up two subpopulations with little overlap.

Treatment of Children with Asymptomatic Bacteriuria

There is no evidence that screening for bacteriuria in healthy children is of value in preventing renal disease, and general screening programs should be discontinued (143). Still, bacteriuria may be found accidentally or during follow-up after treatment of symptomatic UTI. Before a diagnosis of ABU is made in such cases, it is essential to confirm the bacteriuria in repeat urine samples and to ascertain that the child really is symptom free. Obtaining a detailed history is mandatory, including recent febrile episodes and failure to thrive. Specific questions about voiding and bowel habits are given in Table 53.6.

The physical examination includes the same points as in children with symptomatic UTI (e.g., abdominal palpation, inspection of the genitals and back for abnormalities, and blood pressure measurement).

Our general policy is to avoid the use of antibiotics in children with ABU, provided that there are no symptoms or signs indicating renal involvement (144). In children without such indications in the history or physical status, we use a normal CRP (below 20 mg/L) and a normal concentrating

capacity for age as further support for a nontreatment policy. In every such child, we do an imaging procedure of the kidneys to rule out renal anomalies. The bladder function is studied by measuring residual urine by ultrasonography, and the flow pattern is visualized using a flow meter.

VESICoureTERAL REFLUX AND SCARRING

H. GIL RUSHTON, JR.

Vesicoureteral reflux (VUR) is the backup of urine from the bladder into the ureters. Normally, a flap-valve mechanism at the ureterovesical junction prevents this reflux. Inadequate development of this flap is the underlying cause of reflux. The recognition of VUR and its significance has evolved only over the past 30 years. It is now evident that the anatomy of the ureterovesical junction is an inherited trait and that VUR is a familial phenomenon.

VUR is a risk factor for pyelonephritis. VUR alone does not cause renal damage, but intrarenal reflux (IRR) in combination with bacteriuria permits invasion of the renal parenchyma by bacteria. Identifying children with VUR at an early age offers an opportunity to prevent episodes of acute pyelonephritis and the resultant renal scarring that leads to reflux nephropathy, hypertension, and renal insufficiency. Urinary tract infection (UTI) is the most common factor leading to recognition of VUR. Because it is usually the combination of UTI and reflux that leads to renal damage, it is important to perform cystography in children who develop UTI to identify those at risk.

CAUSES AND DEFINITIONS

Primary VUR is congenital and is not associated with any underlying neuromuscular or obstructive phenomenon. The antireflux mechanism is the result of a flap-valve mechanism (reviewed in reference 1). The submucosal portion of the ureter abuts bladder musculature and collapses during bladder emptying. Intravesical pressure plays a role in coapting the lumen during voiding. The orifice of a refluxing ureter tends to be located laterally and more cephalad in the bladder, resulting in shortening of the intravesical ureter (Fig. 54.1) (2). Efficiency of the antireflux mechanism correlates directly with the length of the submucosal ureter. This length may be genetically dictated. A number of specific uroepithelial genes and genetic polymorphisms have been causally related to primary VUR (3,4).

The grading of reflux was standardized when the International Reflux Study (IRS) was initiated (5). *Grade I* reflux fills the ureter only, whereas *grade II* fills the ureter and collecting

system without dilation (Fig. 54.2). These are often called mild reflux. *Grade III* or *moderate reflux* causes mild blunting of the calyces with loss of the sharp delineation of the fornical angles. *Grade IV* reflux has more than 50% of calyces blunted to the extent that the fornical angles are no longer evident. *Grade V* reflux is defined by all calyces being blunted and papillary impressions lost. With each grade, ureteral dilation becomes more severe; in grades IV and V reflux, often called *severe* or *high-grade reflux*, the ureter is also tortuous.

Duplication of the collecting system plays a role in the incidence of VUR. The lower segment ureteral orifice of a duplicated system commonly is abnormally located; this increases the risk for VUR. Duplication also is an inherited trait (6). Although the incidence of reflux is greater and tends to be higher grade in patients with duplication, the prognosis, as with primary reflux, correlates well with orifice position and grade of reflux (7–9).

Secondary VUR is the consequence of pathologic bladder dynamics. Urethral obstruction, neuromuscular disease, or abnormal voiding patterns may be the underlying cause for VUR in those who might otherwise have no intrinsic ureterovesical abnormality. The classic obstructive state associated with reflux is a posterior urethral valve. VUR occurs in approximately one-half of boys with urethral obstruction secondary to a valve. However, approximately one-half of that reflux ultimately resolves with treatment of the obstruction.

In 1952, Hutch recognized the association of neuropathology with VUR (10). Abnormally high intravesical pressure may distort the ureterovesical junction, disrupting the normal antireflux mechanism. This may be associated with outpouching of bladder mucosa at the ureteral hiatus (paraureteral diverticulum). As is true in patients with a urethral valve, treatment of the neuropathic bladder also may result in resolution of reflux (11). Cohen et al. report that reflux resolved in 62% of 72 patients who were treated nonsurgically with clean intermittent catheterization and oxybutynin (Ditropan), when indicated, to reduce uninhibited bladder contractions (12). Similar results are reported by other groups (13–15).

FIGURE 54.1. Normal and refluxing ureterovesical junctions. Refluxing ureterovesical junction has the same anatomic features as nonrefluxing orifice, except for inadequate length of intravesical submucosal ureter. Some orifices with borderline submucosal tunnels reflux intermittently. (From Glenn J, ed. *Urologic surgery*, 2nd ed. New York: Harper & Row, 1975, with permission.)

More recently, the relationship between dysfunctional voiding and VUR has been emphasized (16–18). Increased intravesical pressure from dyssynergic voiding (voluntary sphincter contraction instead of relaxation during detrusor contractions) can cause secondary reflux. Mayo and Burns report a significantly higher incidence of VUR (50%) in 30 children with dyssynergia (73% with UTI) compared with

24% of 97 wet children with bladder instability alone (45% with UTI) and only 8% of 64 children with normal urodynamic findings (31% with UTI) (19). However, as evidenced in this study, the relationship between reflux and voiding dysfunction is clouded because most studies of children with voiding dysfunction include a significant number of children with UTIs—a group known to have a high incidence of VUR (30 to 50%). Nevertheless, in a prospective study of 308 children with day and night wetting, reflux was detected in 23% of children with no history of UTI. In contrast, reflux was present in 34% of those with wetting and a history of UTI (20). Scholtmeijer et al. suggest that urodynamic evaluation be used to plan better treatment regimens for all children with reflux (21). That is probably impractical, because urodynamic studies in small children are difficult and often unreliable. Furthermore, most children with persistent underlying bladder instability after toilet training can be identified with a good voiding history, allowing one to be more selective with urodynamic evaluation. Once identified, instituting better voiding habits and reducing intravesical pressure with an anticholinergic may lead to resolution of reflux and reduction in UTIs (22,23).

The most severe form of dysfunctional voiding, the *Hinman syndrome* (24), often is associated with reflux. In this group, voluntary sphincter spasm is severe enough to produce a picture of true outlet obstruction. Enuresis, encopresis, incomplete bladder emptying, UTI, hydronephrosis, reflux, and renal failure sometimes result from this syndrome, which is thought to be emotionally induced. Failure to recognize dysfunctional voiding is one of the major causes of complications after ureteral reimplantation (25).

EPIDEMIOLOGY

The prevalence of VUR in healthy individuals is unknown. Ransley, in a compilation of several publications, reports reflux in 7 of 535 (1.3%) presumably healthy children (26). Because most patients evaluated have had UTI, most of the information about reflux has been gathered from that group. Reflux has been identified in 29 to 50% of children, mostly white girls, evaluated after UTI (27,28). In another study, only one-third as many African American as white girls with UTI had reflux (29). The incidence of UTI in African American girls also was reduced, resulting in a frequency of reflux in African American girls approximately one-tenth of that in whites.

As early as 1966, it was recognized that reflux associated with UTI was more common in younger children (30). In this review, reflux was present in 70% of children younger than 1 year, 25% of those younger than 4 years, 15% of those younger than 12 years, and 5% of adults. Despite this age-related incidence of VUR, Smellie et al. found no age-related difference between children with or without VUR who presented with UTI (31).

FIGURE 54.2. International classification of vesicoureteral reflux (VUR). Grade I: ureter only. Grade II: ureter, pelvis, calyces; no dilation, normal calyceal fornices. Grade III: mild or moderate dilation or tortuosity of the ureter, and mild or moderate dilation of the pelvis, but no or slight blunting of the fornices. Grade IV: moderate dilation or tortuosity of ureter and mild dilation of renal pelvis and calyces; complete obliteration of sharp angle of fornices but maintenance of papillary impressions in most calyces. Grade V: gross dilation and tortuosity of ureter; gross dilation of renal pelvis and calyces; papillary impressions are no longer visible in most calyces. (Modified from International Reflux Committee. Medical versus surgical treatment of primary vesicoureteral reflux. *Pediatrics* 1981;67:392.)

Stratification of the incidence of UTI by gender is difficult because the incidence of UTI (the presenting cause for evaluation) is so much greater in females than in males. Snodgrass found an equal incidence of reflux in males and females evaluated for dysfunctional voiding, approximately 12% in each (32). Scott found equal numbers of boys and girls with high-grade reflux (33). In the European branch of the IRS, females only slightly outnumbered males; in the U.S. branch, females outnumbered males by 10:1. The difference may be attributed to different circumcision practices in Europe and the United States and the higher incidence of UTI associated with the uncircumcised penis (34,35). In one retrospective review, only 14% of 545 patients with reflux were male (36); in another, 15% of 281 patients with reflux were male (37).

INHERITANCE AND SIBLING REFLUX

There has been increasing recognition of the familial occurrence of VUR. The mode of inheritance is poorly understood; it has been suggested that it is inherited in an autosomal-dominant manner, making it one of the most common inherited disorders (38). In several reviews, the relationship in siblings has been clearly identified. VUR has been identified consistently in 27 to 33% of siblings of index patients with VUR (39–41). The reflux in siblings was not associated with a history of UTI or with the severity of reflux, age, or incidence of renal scarring in the index case. An even higher incidence has been reported in children of parents who had reflux (42). Resolution of sibling VUR has been reported in up to 53% after a mean follow-up of 18.5 months (43). However, in one study, 27% of affected siblings were older than 10 years at the time of diagnosis (41). The inheritance of reflux is further supported by its significantly reduced incidence in African Americans.

DIAGNOSIS

VUR generally is detected during radiographic evaluation of children with UTI. Prompt evaluation of UTIs in children is predicated on the high prevalence of VUR in children with UTIs: Approximately one-third of white girls with UTI have reflux (27). Clinical features have proven unreliable in distinguishing children with UTI who have reflux from those who do not (31,44).

When should a child with UTI be evaluated radiographically? The signs and symptoms that typically accompany UTIs in infants and toddlers are not specific, making it difficult to determine whether an infection represents the first episode in those at greatest risk for renal damage (Table 54.1). Renal scarring may occur after a single episode of kidney infection (45–47). Up to 80% of all white girls and 60% of all African American girls experience reinfection

TABLE 54.1. PROMINENT SYMPTOMS IN NEONATAL NONOBSTRUCTIVE URINARY TRACT INFECTION

Symptom	Percentage
Weight loss ^a	76
Fever	49
Cyanosis or gray color	40
Distended abdomen	16
Central nervous system symptoms (purulent meningitis not included)	23
Generalized convulsions	7
Purulent meningitis	8
Jaundice (conjugated bilirubin increased)	7
Other	16

Note: N = 75, 0 to 30 days old.

^aRegistered for only 46 patients falling ill on days 0 to 10. Weight loss was not explained by vomiting, diarrhea, or refusal to eat.

Modified from Bergström T, Larson H, Lincoln K, et al: Studies of urinary tract infections in infancy and childhood. XII: Eighty consecutive patients with neonatal infection. *J Pediatr* 1972;80:858.

within 18 months of their initial UTI (48,49). The incidence of renal scarring is higher in children with recurrent UTIs than in those with a single infection (31,50,51).

Taken together, all of the aforementioned factors warrant early evaluation of young children after their first documented UTI. Waiting until the child has two or more infections before proceeding with evaluation clearly increases the risk for permanent scarring. Most authorities agree that evaluation should be carried out after the first culture-documented UTI in children younger than 3 years; many suggest that this policy should be followed up to age 5 years. Any child with a febrile UTI and boys of any age should be evaluated (44). Because of the low incidence of VUR, evaluation of African American girls with UTIs might be reserved for infants and those with febrile UTIs or recurrences.

VUR is also detected when screening siblings for reflux and when infants who had hydronephrosis on prenatal ultrasonography are evaluated postnatally. In fact, recent studies suggest that VUR is one of the most common causes of prenatally detected hydronephrosis, occurring in up to one-third of patients evaluated postnatally (52–54). Patients with prenatal hydronephrosis should be evaluated with a cystogram even if the postnatal sonogram is negative, because as many as 25% of patients with grade III to V VUR have normal postnatal sonograms (55). VUR is also found more commonly in children with functional or structural anomalies such as neuropathic bladders, severe voiding dysfunction, prune-belly syndrome, multicystic kidneys, imperforate anus, unilateral renal agenesis, ureteropelvic junction obstruction, and other obstructive uropathies. Therefore, cystographic evaluation is recommended in the evaluation of patients with any of these findings.

Cystography

Both direct and indirect cystography techniques are used. Direct cystography involves filling the bladder by urethral

FIGURE 54.3. Contrast cystogram demonstrates bilateral vesicoureteral reflux, grade III (*right*) and grade IV (*left*). Ureteral and pelvic dilation are similar on both sides, but the sharp fornical angles in the left kidney have been lost (*arrows*).

catheterization or percutaneous suprapubic infusion. Both standard contrast medium and radiolabeled nuclides are satisfactory. In boys, contrast cystography is preferred because it allows the clinician to visualize the urethra and grade reflux (Fig. 54.3). It is also more reliable for detecting duplication, ureteral ectopia with or without ureterocele, posterior urethral valves, bladder trabeculation, bladder diverticula, and foreign bodies. Many also prefer its use for the initial examination in girls because the grade of reflux can be determined. Several methods for grading are used (37); the IRS method is most widely accepted (Fig. 54.2) (5).

The reliability of contrast voiding cystography for demonstrating VUR is affected by a number of variables related to technique or patient. These include the size and type (straight vs. Foley) of catheter, rate of bladder filling, height of the column of contrast media, state of hydration, whether reflux is transient, and the volume, temperature, and concentration of the contrast medium (56). Jequier evaluated the reliability of contrast cystography for detection of VUR in children undergoing evaluation for first-time UTIs by using multiple fillings of the bladder (57). In patients with no reflux on the initial filling, VUR was demonstrated on repeat filling of the bladder in only 4%. Greater variation was observed in the grade of VUR detected when multiple fillings were used. A disadvantage of standard contrast cystography is the high gonadal radiation dosage it entails, particularly with multiple studies or fluoroscopic monitoring. The recent addition of digital fluoroscopy reduces gonadal radiation exposure (58). When a low-dose fluoroscopic system is combined with a computer-based video

FIGURE 54.4. Sequential posterior images from a direct radionuclide cystogram demonstrate left vesicoureteral reflux during the filling, voiding, and postvoiding phases of the study. Reflux in the filling phases (*upper panel*) is mild but becomes moderate immediately before and during voiding (*lower panel*).

frame grabber, the ovarian radiation dosage compares favorably to radionuclide cystography (59,60).

Direct radionuclide cystography allows continuous monitoring for reflux throughout the study without additional radiation exposure. It is reported to be more sensitive than contrast cystography for the diagnosis of reflux (61,62). In a recent study, contrast cystography had a sensitivity of only 65% compared with radionuclide studies and did not detect any additional VUR not seen by nuclear cystography (63). Whereas precise grading of VUR is limited, it usually can be categorized as mild, moderate, or severe (Fig. 54.4). Although radionuclide cystography has been criticized for being unable to detect grade I VUR, a recent study found that direct radionuclide cystography demonstrated VUR to the renal pelvis in all 17 kidneys studied with grade I VUR on contrast cystography (64). The radiation dosage from radionuclide cystography is 50 to 200 times less than that with standard techniques using contrast cystography, making it ideal for the follow-up of children with VUR and for following results of antireflux surgery (65). It also helps confirm the absence of transient VUR when clinically suspected reflux has not been demonstrated by contrast voiding cystography (66). There is little justification for carrying out cystography with the child under anesthesia. The risk and cost of anesthesia cannot be justified, and the information derived from the static cystogram is vastly inferior to that obtained from the dynamic voiding study (67).

Indirect radionuclide cystography uses technetium-99m (^{99m}Tc)-diaminotetraethylpentacetic acid, which is excreted by glomerular filtration. Most of the radioisotope is in the bladder within 20 minutes. The presence of reflux can be assumed when radioisotope counts increase in the renal areas after voiding. Indirect cystography is less reliable for

the detection of VUR than direct radionuclide cystography (68). Furthermore, significant patient cooperation in allowing adequate bladder filling and being able to void on command is required with indirect cystography (69). More recently, indirect radionuclide cystography using ^{99m}Tc -mercaptoacetyltriglycine (MAG-3) was reported to be unreliable for the detection of VUR, missing approximately two-thirds of reflux (70).

The interval between the UTI and lower tract evaluation has been controversial. A waiting period of 4 to 6 weeks after an acute infection has been suggested before the cystogram is obtained to avoid demonstrating transient, mild reflux secondary to inflammatory changes of the ureterovesical junction. However, reflux detected at the time of infection, which then immediately disappears after treatment, is rare (71). Furthermore, because the significance of VUR is greatest at the time of bacterial infection, demonstration of even transient reflux at that time may be meaningful. Of course, the urine should be sterile at the time of the study. One potential disadvantage of obtaining a cystogram early in the course of a febrile infection is that ureteral dilation resulting from the smooth-muscle paralyzing effects of *Escherichia coli* endotoxins may result in overestimation of the reflux grade (72–74). Nevertheless, waiting several weeks to obtain a cystogram is not required. Regardless of timing, antibiotic prophylaxis should be maintained in all patients until evaluation is completed (74).

Upper Tract Imaging

Recommendations for evaluation of the upper urinary tract in children with infection vary. The ideal study should be painless, safe, cost-effective, and associated with minimal or no radiation and yet be capable of detecting clinically significant structural malformations and renal scarring. Unfortunately, no such all-encompassing study exists. A tailored approach to the evaluation of children with UTI, beginning with a cystogram, is recommended (Fig. 54.5) (75–77). At the time of the cystogram, a renal ultrasound is obtained to exclude hydronephrosis or other major upper tract malformations. If both studies are normal, further imaging is usually not pursued. Certainly, cystoscopy is *not* indicated. However, if reflux is demonstrated, a renal cortical scan using ^{99m}Tc -DMSA (dimercaptosuccinic acid) is recommended to detect renal scarring. If renal scanning is unavailable, intravenous pyelography (IVP) is acceptable.

The unreliability of routine clinical and laboratory findings for confirming the diagnosis of pyelonephritis suggests the necessity for renal isotope scanning in some children with febrile UTIs (78,79). Both experimental studies in the pig and clinical studies have proven that cortical scintigraphy is highly reliable and useful for the detection of both acute and chronic inflammatory changes of pyelonephritis (79–81). DMSA scintigraphy should be the primary upper tract imaging modality in neonates and infants with febrile UTIs.

FIGURE 54.5. Algorithm for evaluation of children with urinary tract infection (UTI). DMSA, dimercaptosuccinic acid (renal scan); DTPA, diethylenetriamine-pentaacetic acid (renal scan); IVP, intravenous pyelogram; VCUG, voiding cystourethrogram. (From Rushton HG. Genitourinary infections: nonspecific infections. In: Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, 3rd ed. Philadelphia: WB Saunders, 1992, with permission.)

Paradoxically, recent clinical studies reveal that most children (60 to 68%) with DMSA scan–documented acute pyelonephritis do not have VUR (78,79). Therefore, infants with febrile UTIs should be considered for evaluation by DMSA scintigraphy regardless of the presence or absence of VUR (78,79,82). Sonography is also indicated in the acutely ill child to exclude upper tract obstruction, particularly in those who do not respond to appropriate treatment.

PYELONEPHRITIS AND RENAL SCARRING

Renal scarring refers to the spectrum of radiographic abnormalities in the kidney, often called chronic atrophic pyelonephritis, which is associated with focal or diffuse areas of irreversible parenchymal damage. The term *chronic pyelonephritis* is actually a misnomer because renal scarring generally is not associated with indolent infection of the kidney. In 1973, Bailey recommended that the term *chronic atrophic pyelonephritis* be replaced by *reflux nephropathy* (83). The acceptance of this term underscores the consensus that VUR is the primary prerequisite for renal scarring in the absence of obstruction. The critical role that infection coupled with VUR plays in renal scarring was initially demonstrated in piglets with surgically induced VUR (84). Recent clinical studies report that renal scarring may also occur after pyelonephritis in the absence of demonstrable reflux (47,79,85). In one study, 62% of kidneys with new postpyelonephritic scarring were drained by nonrefluxing ureters (85). However, renal scarring was still significantly more common in kidneys with grade III or higher VUR than in kidneys with no or mild VUR. In other studies, VUR was present in only 20 to 50% of kidneys that developed new renal scarring after DMSA scan–documented acute pyelonephritis (79).

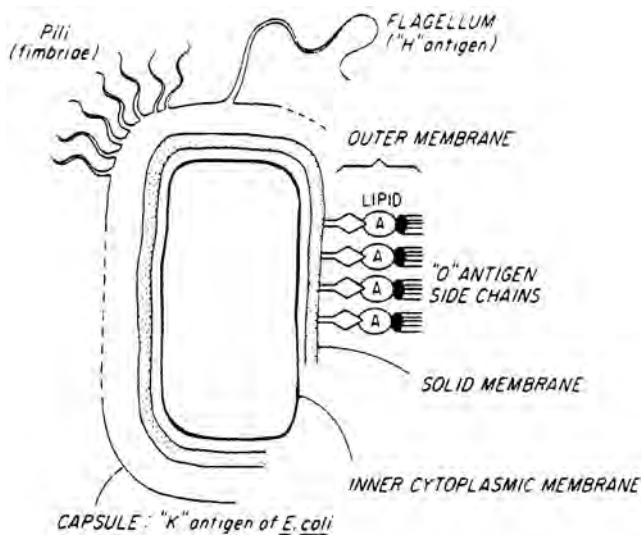

FIGURE 54.6. Schematic presentation of the antigenic structure of gram-negative enteric bacteria. (Modified from Young LS, Martin WJ, Meyer RD, et al. Gram-negative rod bacteremia: microbiologic, immunologic, and therapeutic considerations. *Ann Intern Med* 1977;86:456.)

These and other reports emphasize the role of bacterial virulence and host defense factors in acute pyelonephritis (86). The most prominent of these bacterial virulence factors is adherence of bacteria to specific urothelial receptors, mediated by the attachment of P-fimbriae located on the bacterial surface (Fig. 54.6) (87). Attachment to urothelial cells allows bacteria to ascend into the upper urinary tract, even in the absence of VUR. Supporting this conclusion, a disproportionately high percentage of P-fimbriated *E. coli* strains are isolated from patients with clinical acute pyelonephritis, compared with isolates from patients with cystitis or asymptomatic bacteriuria (Table 54.2) (88,89). However, when present, VUR remains the most significant host risk factor for acute pyelonephritis and renal scarring. When VUR is present, 80 to 90% of patients with febrile UTIs have abnormal DMSA renal scan findings (79). This is particularly true for kidneys with grade III to V VUR, which are at least twice as likely to have DMSA scan defects as are kidneys with no VUR or grade I or II VUR (90,91). When

VUR is present, attachment properties such as P-fimbriae are less important in causing acute pyelonephritis (92). Furthermore, the significance of P-fimbriae in the development of postpyelonephritic renal scarring has been questioned (93).

Diagnosis

Renal Scarring

In the past, renal scars have been detected primarily by IVP, which shows the affected area as focal thinning of the renal parenchyma with a corresponding calyceal deformity or clubbing. For reasons discussed later, renal scars are more often found in the upper and lower poles of the kidney. Scarring varies in severity. It can be limited to a single papilla in the pole of the kidney or it may be extensive, resulting in a small, shrunken, end-stage kidney with little or no function. For an IVP to detect renal scarring reliably, high-quality delineation of the renal outlines and calyceal systems is mandatory. This is difficult to achieve in young children (the group at greatest risk for renal scarring) with overlying bowel gas, stool, and poor renal concentrating ability and in children with bony abnormalities such as spina bifida (12). Tomography may increase the accuracy but also increases radiation exposure. Other limitations of IVP include the risk of contrast-induced reactions, fluid and electrolyte disturbances (particularly in infants), and an inability to detect acute pyelonephritis (94). Pyelographic evidence of renal scarring may not be evident for up to 2 years after the acute episode (95).

In many centers, ^{99m}Tc-DMSA renal scintigraphy has replaced IVP for the detection and assessment of renal scars. DMSA localizes in the proximal tubular cells; excretion is minimal. It is the preferred method for visualizing functioning renal parenchyma (96,97). DMSA can also provide quantitative assessment of differential renal function. Additional advantages over IVP include reduced gonadal radiation exposure and avoidance of contrast-induced reactions. Visualization is not hampered by overlying bowel gas, stool, or bony abnormalities or by renal position.

Renal scars detected by DMSA scintigraphy appear as focal or generalized areas of diminished uptake in the renal cortex. This may appear as thinning or flattening of the cortex in some kidneys; in others, renal scars appear as discrete wedge-shaped parenchymal defects (Fig. 54.7) (98). In more severe cases, generalized damage may be associated with multifocal or diffusely scarred kidneys and reduced differential renal function. A grading system for the severity of renal scarring as depicted by DMSA renal scans has been suggested (Table 54.3) (99).

DMSA scan is more sensitive than IVP for detecting renal scarring. Merrick et al. compared the findings in 79 children who had proven UTI and had been followed for 1 to 4 years (100). The sensitivity of IVP for the detection of renal scars was 80%, and specificity was 92%, whereas cortical scintigraphy had a sensitivity of 92% and specificity of 98%. Greater

Posterior oblique view demonstrates a classic wedge-shaped scar in the midzone of the right kidney (*closed arrow*). Left kidney is normal.

sensitivity of the DMSA scan for the detection of renal scarring has been reported by others (99,101,102). When both IVP and DMSA scintigraphy demonstrate scars, an excellent correlation on a site-by-site basis has been reported (99–102). Nevertheless, some investigators citing examples in which each modality failed to detect renal scars demonstrated by the other suggest that both IVP and DMSA renal scintigraphy are necessary in the evaluation of renal scarring (103,104). That recommendation is not widely supported.

Pyelonephritis

Another major advantage of DMSA scintigraphy in the evaluation of children with reflux is its ability to detect acute

pyelonephritic changes in the renal parenchyma (78–82). As opposed to the characteristic defects of renal scarring that are associated with loss or contraction of functioning cortex, the defects on DMSA scintigraphy caused by acute pyelonephritis are typically focal or diffuse areas of diminished uptake that are associated with preservation (or at times even bulging) of the renal cortical outline (78). Differentiating defects caused by acute pyelonephritis from those caused by renal scarring is difficult when acute pyelonephritis is superimposed over an area of cortical scarring. In 1995 and 1996, some authors advocated the application of single-photon emission computed tomography to DMSA scintigraphy, reporting greater sensitivity when compared to traditional planar imaging (105,106). However, in these clinical studies, histologic confirmation of acute pyelonephritis was not possible. In an experimental study in pigs with surgically induced VUR of infected urine, these two techniques were directly compared with histology (107). The sensitivity of single-photon emission computed tomography was higher than planar imaging (96 vs. 87%), but the specificity was lower (71 vs. 100%). Overall, agreement was 90% for both when compared with histology.

DMSA changes associated with acute pyelonephritis usually resolve after antibiotic treatment (Fig. 54.8) (79). Acute lesions may resolve as early as 2 weeks after treatment of acute pyelonephritis (108). However, they may persist for up to 4 months. Acute defects result in scarring in 36 to 52% of kidneys (Fig. 54.9) (47,79,85). The pathophysiologic mech-

FIGURE 54.8. Technetium-99m-dimercaptosuccinic acid (DMSA) renal scan obtained during the evaluation of a 6-month-old uncircumcised boy with suspected acute pyelonephritis. Posterior oblique (RPO) image reveals severe acute inflammatory changes of the entire upper moiety of the right kidney. Follow-up DMSA renal scan 18 months later reveals complete resolution of inflammatory changes without residual scarring (posterior view). (From Rushton HG. Serial technetium-99m–dimercaptosuccinic acid (DMSA) renal scans in a 3-year-old girl with previous febrile urinary tract infections associated with right vesicoureteral reflux and severe scarring of the right kidney. 1: Previously normal left kidney. 2: Acute pyelonephritis in the left upper pole (*closed arrow*) after successful right ureteral reimplantation. Repeat cystogram confirmed the *absence* of reflux on either side. 3: Follow-up DMSA renal scan 15 months later shows progression to renal scarring (*open arrow*).

anisms that account for the DMSA changes caused by acute infection include changes in intrarenal blood flow and proximal tubular cell membrane transport function (109,110). Both of these result in diminished uptake.

Pathogenesis of Renal Scarring

Renal scarring is a term that applies to both congenital or embryologic and acquired or postnatal renal abnormalities (111). Most cases of scarring associated with reflux are detected during evaluation of children with UTI. However, recent reports of infants with prenatally detected hydronephrosis associated with reflux have confirmed cases of congenital renal functional abnormalities documented by DMSA scan even in the absence of known infection (112–115). There is also a high prevalence of renal functional abnormalities and scarring in children with reflux secondary to functional or anatomic bladder outlet obstruction. Lumping the renal sequelae from all of these pathophysiologic entities under the terms *renal scarring* or *reflux nephropathy* has hampered attempts at understanding the pathogenic mechanisms involved.

Renal pathology associated with reflux has been explained in several ways: an embryonic ectopic ureteral bud inducing abnormal renal development with subsequent dysplasia or a primary developmental arrest inducing dysplasia; renal damage resulting from sterile reflux and its water-hammer effects, perhaps mediated by an immunologic response; or IRR of infected urine into susceptible renal papilla, resulting in an inflammatory response and damage to the renal parenchyma.

Embryologic Dysplasia

Mackie and Stephens propose that renal dysplasia or hypoplasia is related to abnormal development of the embryonic ureteral bud (116). They propose that a ureteral bud that arises abnormally from the most caudal end of the wolffian duct is associated with an ectopic orifice located laterally on the trigone. As a consequence, a short or absent intramural tunnel results in a refluxing ureter. Meanwhile, the abnormally arising ureteral bud fails to penetrate the normal, central renal blastema, resulting in a hypoplastic or dysplastic kidney (Fig. 54.10). This theory, initially proposed to

explain abnormalities in duplicated kidneys, was later extended to include single-system kidneys associated with reflux (117). Although this theory may explain renal pathology in selected cases of severe reflux or duplication anomalies with ectopic ureters, most kidneys associated with primary VUR do not exhibit histologic evidence of dysplasia (118).

Developmental theories may explain some of the functional abnormalities found in kidneys in which high-grade primary VUR was detected initially by the finding of hydronephrosis on prenatal sonography (112–115). Many of these infants with reflux detected by prenatal sonography were evaluated by renal scintigraphy before any known episodes of infection. Renal functional abnormalities in those kidneys suggest a congenital fetal nephropathy rather than an acquired abnormality. One study compared renal parenchymal damage demonstrated by DMSA renal scans in 17 infants with VUR detected after UTI, with 19 detected by prenatal sonography who were maintained on prophylaxis to prevent infection (119). A higher percentage of the chil-

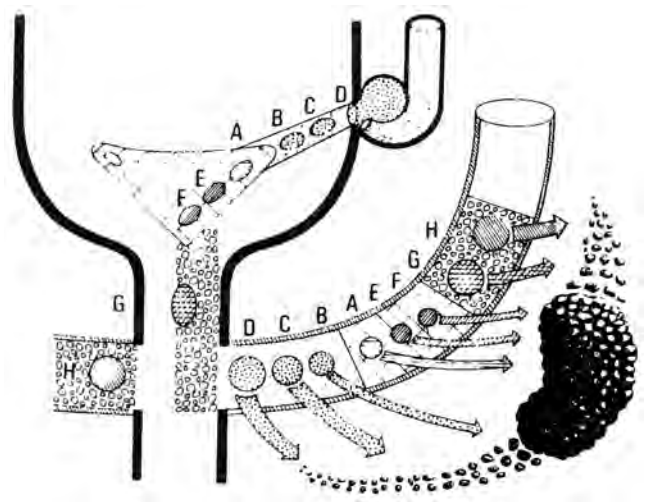

FIGURE 54.10. Relationship of ureteral bud positions on wolffian duct to nephrogenic blastema and orifice zones in bladder and urethra. (From Mackie GG, Stephens FD. Duplex kidneys: a correlation of renal dysplasia with position of the ureteral orifice. *J Urol* 1975;114:274, with permission.)

dren studied post-UTI had renal damage than did those who were detected prenatally and placed on prophylaxis before any UTI. Similarly, Crabbe et al. categorized typical patterns of DMSA abnormalities in a group of patients with prenatally uninfected primary VUR (15 children, 24 kidneys) compared with a group of patients with infected primary VUR (8 children, 15 kidneys) (115). In the uninfected group 4 of 24 kidneys (17%) were abnormal and these demonstrated global loss (i.e., small kidneys without focal scars). In contrast, 4 of 15 kidneys (27%) in the infected group were abnormal, and these all demonstrated evidence of focal renal scarring. A third group of patients with noninfected VUR associated with obstruction, including seven patients (nine kidneys) with posterior urethral valves and two with ureteropelvic junction obstruction, demonstrated total or near total loss of function in 9 of 11 kidneys (82%).

One must be cautious in extrapolating findings in these studies to the general population of children with reflux. Infants with reflux detected prenatally represent a select group of patients characterized by male predominance and a high incidence of severe reflux. Urodynamic evaluation has demonstrated hypercontractility with markedly elevated voiding pressures in most of these boys, which resolved within 1 to 2 years (120–122). Coincident with this, a higher than expected percentage of VUR resolved in this select group of patients. In contrast, children with reflux detected postnatally are predominantly female, and most have less severe reflux and a history of UTI. However, it is clear that not all reflux-associated renal abnormalities are acquired postnatally.

Sterile versus Infected Reflux

The theory that sterile reflux might produce renal scarring was proposed by Hodson et al., based on their experimental piglet model, in which reflux was produced by unroofing the intramural ureter (123). However, to potentiate reflux, obstruction of the bladder outlet was also created by placing a constricting ring around the urethra. Renal scarring was produced from reflux of sterile urine, with the most intense areas of scarring corresponding to areas shown by cystography to have IRR (pyelotubular backflow or urine from the renal pelvis into the collecting ducts). Previous clinical observations had also suggested a relationship between renal scarring and IRR in young children with moderate and severe VUR (124).

Evidence arguing against a role for sterile reflux in the pathogenesis of renal scarring comes from the studies of Ransley and Risdon, again using the multipapillary piglet model (84). As in Hodson and colleagues' model, VUR of urine was induced by unroofing the intramural ureter. However, bladder outlet obstruction was not created. In contrast to the findings of Hodson et al. (123), Ransley and Risdon did not find scarring in their animals with reflux of

FIGURE 54.11. Papillary configuration in intrarenal reflux. **A:** Convex papilla (nonrefluxing papilla): crescentic or slit-like openings of collecting ducts opening obliquely onto the papilla. **B:** Concave or flat papilla (refluxing papilla): round collection ducts opening at right angles onto flat papilla. (From Ransley PG. Intrarenal reflux: anatomical, dynamic, and radiological studies. *Urol Res* 1977;5:61, with permission.)

sterile urine. Instead, they found that when voiding pressure is normal, as in primary reflux, scarring occurred only when urinary infection was present in association with VUR and IRR.

IRR in the multipapillary kidneys of piglets occurs only in renal papillae that have specific morphologic features. With piglets, as with children, Ransley and Risdon discovered two basic types of renal papillae (Fig. 54.11) (125,126). Some are simple, conical structures with a convex calyceal surface onto which the papillary ducts open obliquely with slit-like orifices. These papillae do not allow IRR to occur. In contrast, papillae that fuse into larger papillae with flat or concave tips and have papillary ducts opening onto the calyx with gaping orifices do allow IRR to occur. These fused or compound papillae are most commonly found in the polar regions of the kidney, where scarring is noted most often. Postmortem studies performed on children dying from other causes revealed that approximately two-thirds of all human kidneys contain at least one potentially refluxing papilla (126). In one-fifth of all human kidneys, 30% of the papillae are potentially refluxing. Transformation of marginally competent nonrefluxing to incompetent refluxing papillae may result from reflux of infected urine or from scarring in adjacent papillae (80,84). This exposes a greater proportion of the kidney to IRR, increasing the risk for pyelonephritis and progressive renal scarring if UTI recurs. In contrast, kidneys that are populated entirely by nonrefluxing papillae may be protected from renal scarring, even if UTI and VUR are present.

In subsequent studies in pigs with varying degrees of bladder outlet obstruction, Ransley et al. demonstrated that renal scarring in the absence of infection could be produced only by *sustained* high intravesical pressure (127). These changes were associated with detrusor decompensation, defined by elevated resting pressures between voids and ineffective bladder emptying associated with large postvoid residuals. The clinical correlates to this type of sustained high-pressure reflux are few, primarily some boys with posterior urethral valves and some children with noncompliant neuropathic bladders and severe nonneuropathic voiding

FIGURE 54.12. Hypothesis for the pathogenic chain of events in acute pyelonephritis. [Modified from Roberts JA. Mechanisms of renal damage in chronic pyelonephritis (reflux nephropathy). *Curr Top Pathol* 1995;88:265–287.]

dyssynergia (Hinman's syndrome). In contrast, intermittent high voiding pressure in the absence of infection was not sufficient to produce scarring. Therefore, one can conclude that the water-hammer effect of VUR is not a contributor to renal damage in the absence of bladder outlet obstruction.

Role of Infection

Experimental studies by Roberts and others suggest that the acute inflammatory response that is responsible for the eradication of bacteria is also responsible for the early pyelonephritic damage to renal tissue and subsequent renal scarring (128). Using the primate model, Roberts developed a unified theory of the events that ultimately lead to renal scarring (Fig. 54.12). The initiating event is bacterial inoculation of the renal parenchyma, which elicits both immune and inflammatory responses. Whereas the immune response can be elicited by either live or heat-killed bacteria, the acute inflammatory response occurs only after inoculation with live bacteria (129). Because inoculation with heat-killed bacteria does not cause renal scarring, it appears that the acute inflammatory response is critical to the development of permanent renal damage.

The inflammatory response of pyelonephritis is triggered by complement activation from bacterial lipopolysaccharides (endotoxin). This leads to chemotactic migration of granulocytes to the site of infection. Experimentally, either complement depletion (induced by cobra venom) or granulocyte

depletion (induced by nitrogen mustard) decreases the acute inflammatory response of pyelonephritis; this reduces renal tissue damage (130,131). Chemotaxis of granulocytes to the site of infection is followed by phagocytosis of bacteria, initiating the sequence of events that leads to renal injury. Granulocytes kill bacteria, releasing toxic enzymes (lysozymes) both within the granulocyte and into the lumen of renal tubules, which causes renal cell damage. The respiratory burst releasing superoxides occurs. This phenomenon, universal to acute inflammatory responses, generates oxygen radicals that are toxic not only to bacteria but also to the granulocytes and surrounding renal tubular cells (132). Tubular cell death releases the toxic inflammatory agents into the interstitium, causing further damage. Superoxides are also produced by cell reaction during reperfusion of ischemic tissue. Focal parenchymal ischemia, resulting from intravascular granulocyte aggregation and edema, occurs with bacterial infection of the renal parenchyma (90,133,134). In ischemic tissue, hypoxanthine is produced during anaerobic metabolism of adenosine monophosphate. During reperfusion, hypoxanthine in the presence of xanthine oxidase and oxygen yields superoxides and hydrogen peroxide (135). Treatment with allopurinol, an inhibitor of xanthine oxidase, protects against tissue damage from reperfusion injury and from that associated with bacteria in the renal parenchyma (136). It appears that the interstitial damage associated with the acute inflammatory response of pyelonephritis results from ischemia-related injury and from toxic enzymes. This leads to renal scarring.

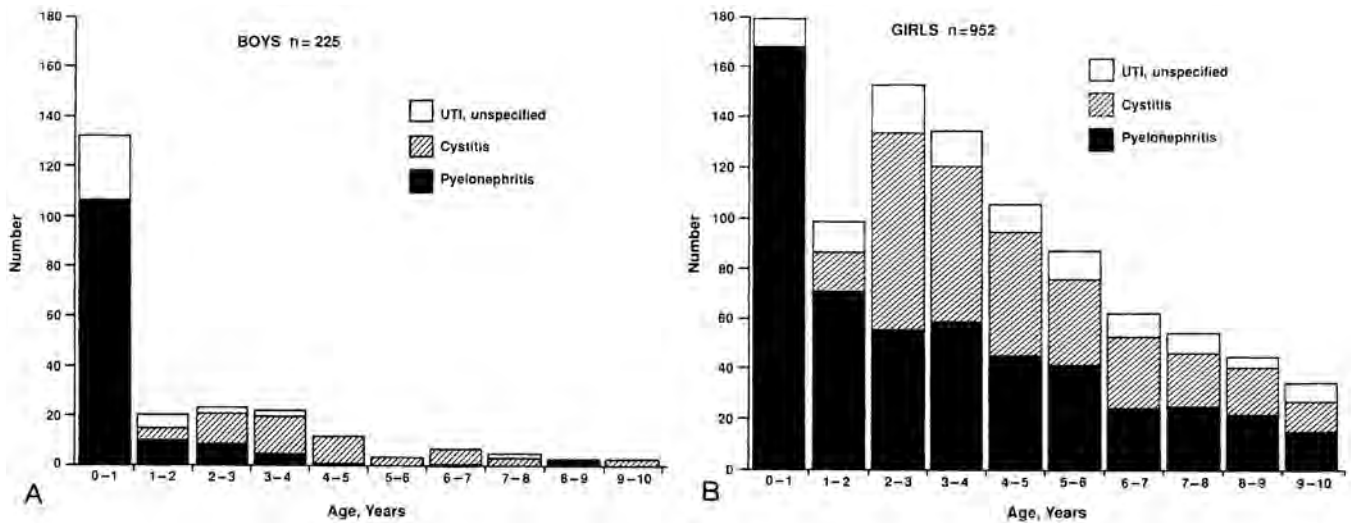

FIGURE 54.13. Children with first-time diagnosis of urinary tract infections (UTI) at the Children's Hospital in Göteborg, Sweden, from 1970 to 1979, according to age and clinical diagnosis. [From Jodal U. Host risk factors in pyelonephritis. In: Rushton HG, guest ed. *Pyelonephritis: pathogenesis and management update*. Ehrlich RM, ed. *Dialogues in pediatric urology*. Pearl River, NY: William J Miller, 1990;13(2):4-5, with permission.]

Clinical Studies

Most clinical knowledge about renal scarring comes from studies of patients with VUR. Clinical studies confirm the close association between UTI, VUR, and renal scarring (137-142). Older studies reported that 30 to 60% of children with VUR and a history of symptomatic UTIs have renal scarring at the time of their initial studies. More recent investigations suggest that the incidence of scarring may not be so high, perhaps reflecting the current trend toward earlier diagnosis and management (36). The onset of renal scarring is thought to occur early in life, usually before age 5 years and most often before 3 years of age (143,144). Although less common, new renal scarring may be acquired in older children (46).

The increased risk of renal scarring in infant kidneys is probably multifactorial. First, clinical pyelonephritis complicates UTIs much more commonly in infants (both boys and girls) younger than 1 year than in older children (Fig. 54.13) (51). In fact, approximately one-half of all febrile UTIs in childhood occur in infants 1 year old or younger (79). This may be in part the consequence of a higher incidence of IRR (145). Another contributing factor in infants is an incompletely developed immune system, which allows bacteria access to the urinary tract and reduces bactericidal activity. Finally, the diagnosis of UTIs is often delayed in infants, who typically have nonspecific signs and symptoms (143). All these factors increase the risk of damage and scarring.

New or progressive scarring is almost always associated with a prior UTI, most often clinical pyelonephritis (46,140-143,146). The correlation between the severity of VUR and renal scarring is well established (27,36,51,142,146-148) (Table 54.4). However, both new and preexisting renal scar-

ring have been reported in some children who have had symptomatic urinary infection even without VUR (47,85,143, 150). A clear association between the number of pyelonephritic attacks and the incidence of renal scarring has been reported (Fig. 54.14) (46,145). Furthermore, both clinical and experimental studies have documented acute pyelonephritic damage, often associated with the presence of P-fimbriated *E. coli*, in the absence of demonstrable reflux (68,75,146). Renal scarring may be prevented or diminished in some instances by early antibiotic treatment of acute pyelonephritis (Fig. 54.8) (78,79,82,91,149). When reflux is present, new renal scarring is prevented by keeping the patient free of infection using low-dose antibiotic prophylaxis (36,148,151). This contrasts with the 10 to 20% incidence of new scarring and 62 to 66% incidence of progressive scarring reported in earlier studies in which recurrent UTIs in children were treated only with intermittent antibiotic therapy (140,152).

FIGURE 54.14. Relationship of renal scarring to number of episodes of acute pyelonephritis. (Modified from Jodal U. The natural history of bacteriuria in childhood. *Infect Dis Clin North Am* 1987;1:713.)

Martinell et al. prospectively studied 87 females with either renal scarring (45) or recurrent UTI (42) followed for a mean of 23 years after their first UTI in childhood (153). The attack rate (number of UTIs per patient per observation year) was highest in the first year of life (1.9), with a gradual decrease to the lowest rate (0.2) at age 11 to 15 years. Pyelonephritic episodes correlated with the presence of VUR, and renal scarring correlated with young age at the time of initial UTI, total number of pyelonephritic attacks, and the presence of reflux. Females with renal scarring continued to have a high number of pyelonephritic episodes after 10 years of age, implying that they should be followed closely into adulthood.

Additional clinical support for the role of infection in the development of acquired renal scarring is derived from prospective studies of children with acute pyelonephritis demonstrated by DMSA scintigraphy (47,85). Follow-up DMSA scans demonstrated new scarring in kidneys both with reflux and without reflux. All new scarring occurred at sites that exactly corresponded to areas of acute inflammation on the initial DMSA scans (Fig. 54.9). Areas of uninvolved parenchyma in pyelonephritic kidneys and contralateral normal kidneys remained normal on follow-up DMSA renal scans. It appears that once acute pyelonephritis had occurred, as demonstrated by DMSA scintigraphy at the time of infection, scarring is independent of reflux.

SEQUELAE OF RENAL SCARRING

Hypertension

Pyelonephritic scarring is the most common cause of unilateral renal parenchymal disease (nonvascular small kidneys) in patients and is a common cause of hypertension in children and young adults (154–157). The risk of hypertension in patients with renal scarring varies, based on length of follow-up and severity of scarring. In follow-up studies of children with renal scarring, approximately 6 to 13% of children with scarring develop hypertension (158–161). In some cases, it may be associated with progressive renal insufficiency (162). A recently reported long-term follow-up of an older cohort of 294 patients (mean age at presentation 17.3 years) with reflux nephropathy noted that the risk of hypertension increased with age and length of follow-up (163). Whereas 8.5% of these patients had hypertension at presentation, 38% were hypertensive at last follow-up (mean age, 34.2 years). Hypertension was significantly more common in those with severe bilateral parenchymal scarring. Similarly, in another series, 13% (11 of 83) of children with renal scarring were hypertensive at initial evaluation and another 17% (14 of 83) developed hypertension over the subsequent 4 to 20 years (164).

The development of hypertension associated with renal scarring is controversial. Some investigators report no evidence that the renin-angiotensin-aldosterone system (165,166) contributes; others report that it does (167–170). Although plasma renin activity levels are higher in patients with renal scarring than in controls, they are individually not predictive of the development of hypertension (160). Controversy also exists regarding the value of selective renal vein renin studies in hypertensive patients with scarred kidneys. In one study, segmental renal vein renin tests helped to localize sites of renin production (171). Others report that these tests are often falsely negative in hypertensive patients with unilateral nonvascular disease (154,164,172). In a prospective randomized study of the effect of nephrectomy on hypertension in patients with unilateral reflux nephropathy, nephrectomy was beneficial (173). Nephrectomy should be considered in young patients with hypertension associated with unilateral scarring when the contralateral kidney is normal and the involved kidney has less than 10 to 15% relative differential function (157,165). Despite these controversies, all would agree that the risk for hypertension in patients with reflux nephropathy is significant, and long-term follow-up is mandatory because hypertension may take 10 to 20 years to develop.

Renal Insufficiency

Reflux nephropathy also causes chronic renal insufficiency (174). It is reported in 5 to 10% of patients with end-stage renal disease (ESRD) presenting for dialysis or renal transplantation and in an even higher percentage of patients younger than 16 years (175–178). In one study, the inci-

dence of renal insufficiency in 30 adults who were diagnosed with severe renal scarring as children was 10% (161). A more recent study of an older cohort of 294 patients (mean age at presentation, 17.2 years) with reflux nephropathy found that a 2% incidence of renal insufficiency [glomerular filtration rate (GFR) below 40 to 69 mL/min] at presentation had increased to 24% at last follow-up (mean age, 34.2 years). The more extensive the renal scarring, the higher the proportion with renal insufficiency (162). The current rate of patients presenting with ESRD associated with reflux nephropathy in Australia and New Zealand is 3.9 and 4.89 per million population each year, respectively (177).

The development of chronic renal insufficiency in children with reflux nephropathy is incompletely understood. Progression is almost always associated with proteinuria (179–181). In one review, ESRD developed in patients at a mean age of 21 years (175). Most patients who develop ESRD with reflux nephropathy have had hypertension at some time during their clinical course (176,180). The clinical course resulting in ESRD does not appear to be altered by either late surgical correction of VUR or control of UTI and hypertension (175,180,182). In one report, 4% (37 of 908) of children with reflux had reduced renal function, some of whom had secondary reflux associated with posterior urethral valves (183). GFR declined over a 5-year follow-up period in those with proteinuria and an initial creatinine clearance below 25 mL/min/m² (178). Chronic renal failure in women with reflux nephropathy may be exacerbated by pregnancy, particularly in those with hypertension and reduced GFR in the initial stage of pregnancy (184–186). In one study, 36% of women with moderate renal insufficiency developed hypertension, and 8% had accelerated deterioration of renal function during pregnancy (187).

Most patients (90 to 100%) with reflux nephropathy and ESRD have focal segmental glomerulosclerosis, almost always associated with proteinuria (179–181,187). A number of recent studies report elevated levels of a variety of protein markers in the urine of children with VUR and renal scarring, including β_2 -microglobulin, retinol-binding protein, microalbumin, *N*-acetyl- β -D-glucosaminidase, and α_1 -microglobulin (188–191). One such study that compared several of these protein markers reported that elevated urinary α_1 -microglobulin was more predictive of abnormal renal function in children with reflux nephropathy, even before the appearance of significant proteinuria (188).

The pathogenesis of proteinuria and glomerulosclerosis in patients with reflux nephropathy and progressive renal insufficiency is controversial. At least four mechanisms have been proposed to explain these findings: immunologic injury, macromolecular trapping and mesangial dysfunction, vascular alterations and hypertension, and adaptive hemodynamic alterations that lead to glomerular hyperfiltration (192). The evidence at this time seems to favor the latter explanation, although the precise mecha-

nism that leads to progressive glomerulosclerosis remains unknown (192–194). As of 1991, it was suggested that a common mechanism for hypertension and renal functional deterioration in patients with reflux nephropathy may be altered intrarenal or glomerular hemodynamics thought to be mediated, at least in part, by the intrarenal renin-angiotensin system (195). It was postulated that the selective use of angiotensin-converting enzyme inhibitors in these patients may not only control systemic blood pressure but also modify intrarenal hemodynamics to preserve renal function.

MANAGEMENT

Nonsurgical

It should have been obvious, with recognition that incidence of reflux diminished with increasing age, that reflux was a self-limiting process (30). An early series of patients followed nonsurgically was marred by the fact that these patients were not on continuous prophylaxis (152). Progression of scarring occurred in many of these patients and, in a commentary by one of the authors (152), was attributed to recurrent UTI. Subsequently, numerous reports showed the ability to prevent renal scarring by maintaining sterile urine (36,148,151). Smellie et al. found that renal growth was proportionate to somatic growth in 100 of 111 refluxing kidneys when infection was prevented (196). In the other 11, renal growth impairment was attributed to recurrent UTI. Sterile reflux was not thought to play a role in upper urinary tract scarring.

Large retrospective reviews confirm that moderate grades of reflux (I to III) resolve (36,148). In one study, 80% of reflux that resolved did so within 5 years of diagnosis (36). However, no data are available to predict the absolute resolution of reflux by grade. Smellie and Normand report resolution of reflux in 80% of renal units when reflux occurred into nondilated ureters (corresponding to grades I and II/V) (164). However, reflux resolved in only 40% of those with dilated systems (grades III to V). The report by the European Branch of the IRS found a significant difference in resolution between those with bilateral grades III and IV reflux and those with unilateral reflux of the same grades (34). Spontaneous resolution occurred in 60% of those with unilateral grade III reflux and 40% of those with grade IV. In those with bilateral grade III or IV reflux, spontaneous resolution occurred in only 10%. Whereas Skoog et al. found a significantly improved spontaneous resolution rate in children younger than 1 year ($p < .05$) (36), the European IRS branch found that to be true for boys but not for girls (34). In the American branch of the IRS, spontaneous resolution occurred within 5 years in only 25% of patients (35). Grade IV reflux accounted for 87% of the total group, influencing the low resolution rate.

Current management is predicated on the realizations that uninfected primary reflux does not initiate new renal damage and that most reflux will resolve. Therefore, children should be maintained on an antibiotic until evaluation is carried out. When VUR is identified, continuous prophylaxis using low-dose trimethoprim-sulfamethoxazole, nitrofurantoin, trimethoprim alone, or in the young infant, amoxicillin or cefaclor, once daily, generally prevents UTI (197). Nalidixic acid twice daily is also effective, but it is generally reserved for those who cannot tolerate or have had allergic reactions to the more commonly used medications. Using trimethoprim-sulfamethoxazole, only 1.5 breakthrough infections per 100 treatment months occurred in one study of 44 girls (198). Some children with breakthrough UTIs benefit from double antimicrobial prophylaxis using a combination of trimethoprim-sulfamethoxazole and nitrofurantoin (199).

As reported by both the European and American branches of the IRS, there was no difference in the incidence of UTIs in surgically and medically treated children (34,35). However, in those treated medically the infections were, by definition, breakthrough UTIs on prophylaxis, whereas most of those who had had surgical correction were no longer on prophylaxis. Furthermore, the incidence of clinically diagnosed pyelonephritis was three times higher in the nonsurgically treated group ($p < .01$) in the American branch (35).

Quarterly urine cultures are recommended as a routine, and urine culture at the time of any urinary symptoms or unexplained fever is mandatory. We recommend annual isotope cystograms and measurement of blood pressure, height, weight, and serum creatinine level. Our practice is to obtain an initial DMSA renal scan to detect preexistent scarring and determine baseline renal function, particularly in those with moderate or severe reflux and those with a history of a febrile UTI. DMSA scans are repeated after any breakthrough UTI and on the cessation of reflux. New scarring or loss of renal function can almost exclusively be attributed to breakthrough UTI (36,46,152).

Although retrospective reports suggest that renal growth as a consequence of surgical correction of reflux was more favorably affected than reflux treated nonsurgically (138,200), prospective studies suggest that there is no difference in renal growth or new renal scarring between medically and surgically treated groups and nonsurgically treated groups (201). Both the European and American branches of the IRS noted no difference in new renal scarring between medically and surgically treated patients (34,35). Younger patients were more likely to develop new scars, as were boys. Goldraich and Goldraich, using the more sensitive DMSA renal scan to evaluate kidneys, found new scars in only 7 of 202 children treated nonsurgically; all were associated with breakthrough UTI (202). Their study was confined to children who met their criteria for close follow-up. Measurement of renal mass by IVP, as reported by the European branch of the IRS, also demonstrated no difference between medically and surgically treated groups (203). Small kidneys with moderate and severe reflux (grades above

II) grew poorly in both groups, whereas more normal sized kidneys grew normally.

Increased somatic growth has also been reported after surgical treatment of reflux (204,205), but it was also reported to be normal in girls treated with long-term prophylactic antibiotics for VUR (206). There is no evidence that growth is affected by sterile reflux. However, short stature associated with renal tubular acidosis has been reported in some patients with VUR and renal scarring (207,208).

Children with VUR who are dysfunctional voiders often become a difficult treatment group. For those who have this problem, gaining an understanding of coordinating voiding may be a complex task. Management must be tailored to the type of voiding abnormality (209). The mainstay of treatment of children with underlying bladder instability involves the long-term use of anticholinergics, primarily oxybutynin 2.5 to 5.0 mg two to three times a day. They can be helped by instituting a nonhurried, timed voiding schedule (five times daily). In contrast, many older girls with dysfunctional voiding and VUR are infrequent voiders (also called the *lazy bladder syndrome*). Treatment of these children is directed primarily toward the establishment of a regular or timed voiding schedule (every 2 to 3 hours). Multialarm wristwatches can be a useful and inexpensive reminder for school-aged children. These children also tend to be constipated. A high-fiber diet, including fiber supplements, as well as a daily toilet habit are part of the overall treatment program if voiding dysfunction is to be improved. Biofeedback therapy has also been used successfully in the management of cases of detrusor-sphincter dyssynergia (210).

Surgical

Probably no other topic in pediatric urology and nephrology has been so hotly debated as the surgical management of VUR. All would agree that antireflux surgery was performed too often during the 1960s and early 1970s. It is also clear that there are a number of highly successful surgical techniques for correcting VUR, each with its own advantages and disadvantages. Success rates exceeding 95% can be anticipated by those with experience performing the various procedures (35). However, the unanimity of opinion is lost when discussing the indications for and effects of surgical correction of reflux, in part because of the controversy about the goal of management in patients with reflux. Those whose ultimate goal of treatment is the cure of reflux commonly recommended surgery. Those whose primary goal is the prevention of pyelonephritis and new renal damage recommend surgery less commonly. Other alleged goals of successful surgery, including improved renal growth and function, improved statural growth, and prevention of scarring and UTI, have not been realized in prospective randomized studies comparing surgery with medical management (34,35,201). However, antireflux surgery does reduce pyelonephritic episodes (34,211). Today, most would agree

that medical management is appropriate for patients with mild to moderate (grades I to III) VUR and reflux of any grade in the child younger than 1 year. The primary indications for surgery in this group of patients are uncontrolled breakthrough and symptomatic UTI. Some would restrict this indication to episodes of breakthrough acute pyelonephritis because persistent asymptomatic bacteriuria does not appear to be associated with progressive renal damage (212–214). Other reasons for surgical consideration include poor compliance with medical management or intolerance of medication, problems that are probably much more common than generally recognized (215).

Most also would agree that severe primary reflux (grade V) persisting beyond 1 or 2 years of age should be surgically corrected. These ureters are often associated with urinary stasis, creating an increased risk for upper tract infection. Preoperative evaluation includes differential renal function and drainage using renal scintigraphy. Small, poorly functioning kidneys (less than 10 to 15% total functional contribution) should be removed. Ureteral tailoring or tapering is often necessary when reimplanting ureters with grade V VUR. In experienced hands, success rates using these reconstructive techniques are 90 to 95% (216).

Greater controversy surrounds the optimal management of grade IV VUR. Medical management in these patients is as effective as surgery in the maintenance of renal function. However, the spontaneous resolution rate of grade IV is less than 40% after a follow-up of 5 years (34,35,217). Therefore, the decision for surgical intervention in these patients must be individualized, taking into account the need for continuous prophylaxis and repeated examinations. The age of the patient at presentation, patient compliance, the character of previous UTIs, and the presence or absence of renal scarring all play a role in the decision. Persistent grade IV reflux in children older than 3 years is unlikely to resolve; surgical management is probably the best treatment if it fails to improve after 2 years of medical management.

Another unanswered question remaining at this juncture centers around the ideal treatment of the child who approaches adolescence with continued mild to moderate reflux. Many urologists recommend surgical correction of VUR in any child with persistent reflux before puberty. The concern relates to the assumed increased risk of pyelonephritis in pregnancy with its affect on both mother and fetus. However, the patient who had UTI in childhood continues to be at risk for UTI in the future, regardless of whether reflux has resolved spontaneously, has been surgically corrected, or persists. During pregnancy, the prevalence for UTI in the general population is reported to range from 2 to 8%, compared with 37% in those with a history of childhood UTI (218,219). In one review, 41 women who had UTIs in childhood were followed up through 65 pregnancies (219). Nineteen had renal scarring, and 22 did not. They were compared with matched controls. The incidence of bacteriuria in pregnancy was higher in those with renal

scarring (47%) than in those without scarring (27%) but both were significantly greater (less than .001 and less than .01, respectively) than in the controls without a history of UTI (2%). However, the incidence of pyelonephritis was higher in the group who had not had resolution of reflux at the time of their last follow-up (three of eight) than in those who had resolution of reflux (2 of 33, $p = .08$).

Treated UTI, including pyelonephritis, appears to have little negative effect on pregnancy or fetal outcome if renal function is normal (220–222). In the absence of preexisting bilateral renal scarring or impaired renal function, persistent VUR is not associated with increased fetal loss or maternal risk (223). However, there is an increased risk of preeclampsia and hypertension in those with preexisting renal scarring (218).

Correction of VUR does not guarantee prevention of problems in the future. Mansfield et al. reported on 104 women followed for an average of 25 years (224). Sixty-seven had surgical reimplantation of refluxing ureters, and 37 had persisting reflux at the time of last evaluation. Bacteriuria of pregnancy occurred in 40% of those with surgical correction and 15% of those whose reflux was not corrected. Eighteen percent of those surgically corrected had pyelonephritis of pregnancy, whereas only 1.5% with persisting reflux had pyelonephritis during pregnancy. These results should not be interpreted as a condemnation of surgery. Instead, these findings are probably a function of the patients who came to surgical correction as compared with those who did not. Those who underwent surgery were probably more susceptible to febrile infection, leading to more aggressive management during childhood.

Although many urologists recommend surgical correction of persisting VUR in the older child, some advocate stopping prophylaxis in the older child who has persistent mild or moderate VUR (225). Surgical correction is then reserved for those who might benefit from it, such as the girl who returns after cessation of prophylaxis with clinical evidence of pyelonephritis, ideally proven by renal cortical scan. Others would recommend this approach only in patients without significant renal scarring. Prospective study is needed to further validate this philosophy. Regardless, long-term follow-up and screening for bacteriuria during pregnancy should be emphasized for all girls with a history of recurrent UTIs.

Endoscopic Correction

Endoscopic correction of reflux is a new development that may be useful in some patients. Matouchek introduced this method, using Polytef paste injected under the ureteral orifice (226) (Fig. 54.15). O'Donnell and Puri subsequently popularized this technique, using 0.2 to 0.8 mL of Teflon paste injected subureterically at the ureterovesical junction (227). Results from a recent multicenter European survey involving 975 boys and 3191 girls report that 76% of refluxing ureters are cured with one injection, increasing to 85% after a second injection (228). Another 10.7% of refluxing ureters showed

FIGURE 54.15. Endoscopic injection of Teflon paste beneath the intramural segment of ureter.

significant improvement. Ureteral obstruction was rare, occurring in only 0.32%. Lower success rates have been reported in cases of duplex systems, severe VUR, and neuropathic bladders (229–233). Long-term (2.0 to 5.5 years) follow-up has revealed recurrences in 12% of both low- and high-grade reflux (234). Concern about the long-term safety of injected Polytef in children has limited its acceptance by pediatric urologists in the United States and has resulted in increasing concern about its use in Europe. Animal studies have demonstrated that Polytef paste injected periurethrally for treatment of incontinence migrates to lymph nodes as well as lungs and brain, where it produces a foreign-body giant cell reaction with multinucleated giant cells (235). Similar migration has been reported in primates after subureteric injection. Large granulomatous reactions have been found at the injection sites (236). Isolated instances of distant (including pulmonary) migration and local giant cell response with granulomas at the injection site have also been reported (237–239). Concerns have been raised regarding risks in children who carry the Teflon implant for many decades. Longer-term clinical follow-up of children treated with Polytef paste will determine whether these concerns are warranted.

Although the actual long-term consequences of the migration and associated histologic changes are unknown, these safety concerns have stimulated a search for alternative substances. Several groups report results of endoscopic injection of glutaraldehyde cross-linked bovine dermal collagen in

patients with VUR. Initial cessation of VUR has been reported in 63 to 75% after one injection (240,241). However, recurrence has been seen in up to 40% after 6 to 12 months (240,242). Results seem to be stable after 2 years of follow-up (243). Success rates were even lower in duplicated systems and ureters with high-grade reflux (240,243). However, minimal localized inflammatory reaction at the injection site without granuloma formation has been reported by these investigators (244). A variety of alternative substances are currently being investigated, including polyvinyl alcohol, silicone, autologous fat and cartilage, bioglass, dextranomer microspheres, and a self-detachable balloon system. A safe and effective substance for endoscopic correction of reflux is likely. At that time, the indications and pros and cons of medical, endoscopic, and surgical management of VUR will surely be the topic for renewed debate.

SUMMARY

Most laboratory and clinical evidence strongly supports the concepts that both VUR and urinary infection are underlying conditions in most cases of acquired renal scarring and that this damage is irreversible. It occurs primarily in regions of the kidney associated with IRR. The acute inflammatory response associated with renal parenchymal infection is the prerequisite for acquired renal scarring. VUR, when present, is the single most significant host risk factor for acute pyelonephritis and subsequent renal scarring. Renal scarring can be decreased or prevented by early treatment of initial episodes of acute pyelonephritis. Most kidneys with VUR are not scarred, despite a history of UTI. However, new scarring does occur in some patients after acute pyelonephritis, and it appears to be more likely in infants or children younger than 3 years. Therefore, it is often present at the time of initial investigation. Although scarring is more often associated with higher grades of reflux, it can occur with lower grades and in the absence of VUR after an episode of pyelonephritis. Kidneys with higher grades of VUR are at significantly greater risk for acute pyelonephritis than are kidneys with no or mild VUR.

Undoubtedly, some kidneys associated with high-grade VUR are congenitally abnormal (hypoplasia and dysplasia), which is easily confused radiographically with acquired postinfective renal scarring. Because most renal scarring is established at the time of initial investigation, it may be difficult to know whether preexistent scarring represents postinfective damage or developmental abnormalities. Finally, sterile primary VUR has not been shown to produce renal scarring, but sterile secondary VUR associated with obstruction and sustained high intravesical pressures may occasionally result in scarring. Clinical examples of this are uncommon but may include some boys with posterior urethral valves and some children with noncompliant bladders associated with neuropathic conditions (spina bifida, spinal cord injury) and severe voiding dyssynergia.

OBSTRUCTIVE UROPATHY

ROBERT L. CHEVALIER
JONATHAN A. ROTH

Urinary tract obstruction initiates a complex sequence of events resulting in impaired renal function (1). In early development, chronic urinary tract obstruction impairs renal growth and development. In view of its clinical importance, the pathophysiology of urinary tract obstruction has been studied intensively, leading to the development of numerous experimental models, including complete and partial ureteral obstruction, unilateral and bilateral obstruction, and acute and chronic obstruction. Most experiments have been performed in adult animals; therefore, comparisons with obstructive nephropathy in human infants and children must be made with caution. In this chapter, attention is focused on studies of the effects of urinary tract obstruction on the developing kidney and are compared to those in the adult. The functional effects of obstruction are directly dependent on the cellular responses, with the resultant effects on renal growth. The latter are of particular importance in the period of rapid somatic growth.

EFFECTS OF URINARY TRACT OBSTRUCTION ON RENAL GROWTH AND MATURATION

Unlike the human and guinea pig, in which nephrogenesis is completed before parturition, only 10% of nephrons are present in the rat at birth, with the remainder being formed by 14 days of age (2). Thus, the early postnatal period in the rat may be analogous to the midgestational period in the human. The rat, therefore, serves as a model for urinary tract obstruction during the critical period of rapid nephrogenesis.

A number of studies indicate that the developing kidney is uniquely susceptible to impaired growth from chronic ipsilateral unilateral ureteral obstruction (UUO). Complete UUO in the neonatal rat impairs the normal maturational increase in renal mass and DNA content of the ipsilateral kidney (Fig. 55.1A) (3). In the adult, in contrast, kidney DNA content is significantly increased by UUO (4). Chronic UUO in the neonatal rat results in prolonged renal expression of Wnt-4 and impairs the normal differentiation

of mesenchyme to epithelium (5). Three weeks of partial UUO in the neonatal rat increases interstitial collagen deposition (primarily types I, III, and V), with an increase in type IV in the thickened and tortuous tubular basement membrane (6). The quantity of collagen deposited is directly correlated with the degree of pelvic distention (6).

Number of Nephrons

In both human studies and animal models, fetal and neonatal urinary tract obstruction is associated with a significant reduction in nephron number. Two days of UUO in the fetal rabbit reduces the number of nephrons by one-third, whereas UUO in the fetal sheep can decrease the number of nephrons by 50% (7–9). In the human fetus, urinary tract obstruction also reduces the number of nephrons (10). After partial UUO in neonatal pigs, the number of glomeruli is reduced by 28% (11). Either partial or complete UUO in the neonatal rat decreases the number of nephrons, with the magnitude of reduction being dependent on the duration of obstruction (12,13). Interestingly, UUO in the neonatal rat in the period immediately after the completion of nephrogenesis also significantly reduces the number of nephrons, most likely owing to massive cystic tubular dilatation that compresses neighboring nephrons (13). Severe tubular dilatation also contributes to nephron loss in human obstructive nephropathy (14).

Renal Vascular Development

Chronic UUO in the neonatal rat leads to a marked increase in renal renin expression and persistence of the fetal pattern of renin distribution (Figs. 55.1B and 55.2B) (3,15). It is now clear that renin expression by the renal microvasculature is a marker of vascular immaturity rather than of terminal differentiation (16). As described in Glomerular Development, relief of obstruction reduces the extent of renin distribution along afferent arterioles of the neonatal rat (17) and normalizes the renin content of the postobstructed kidney of the neonatal guinea pig (18).

Growth factors and apoptosis in neonatal ureteral obstruction. *J Am Soc Nephrol* 1996;7:1098-1105, with permission.)

Glomerular Development

After the induction of glomeruli, glomerular capillaries increase in number, associated with flattening of podocytes and increasing surface area for filtration (19). Chronic UUO in the neonatal rat either during nephrogenesis or during the subsequent maturational phase delays glomerular maturation (13,17)—a response that can be prevented by the administration of exogenous epidermal growth factor (EGF) (20).

Tubular Development

Tubular maturation can be measured by the progressive disappearance of markers normally expressed only in early development, such as Wnt-4 and clusterin (glycoproteins) (5,21) or KS (a kidney-specific gene with unknown function) (22). Chronic UUO in the neonatal rat leads to persistent tubular expression of clusterin (Figs. 55.1E and 55.2E), Wnt-4 (5), and KS (4,22). In addition, chronic UUO in the neonatal rat suppresses the normal maturational increase in tubular expression of EGF (Figs. 55.1D and 55.2D) (3), whereas administration of exogenous EGF reduces clusterin expression (23).

Renal Interstitial Development

The normal maturation of renal interstitial fibroblasts is reflected by the transformation of myofibroblasts to fibroblasts, such that fibroblasts lose their expression of vimentin and α -smooth muscle actin (24). Chronic UUO in the neonatal rat causes prolonged expression of α -smooth muscle actin by interstitial fibroblasts (Figs. 55.1F and 55.2F) (3), and dilated tubules from infants with severe congenital obstructive nephropathy are also surrounded by myofibroblasts (25).

Summary

The effects of chronic UUO on maturation of the developing kidney are shown in Figure 55.3. During normal renal development, nephrogenesis proceeds with increasing numbers of glomeruli and progressive glomerular maturation with proliferation of capillary loops. The maturing renal vasculature is characterized by the disappearance of renin from the length of the afferent arteriole, such that its localization is restricted to the juxtaglomerular region. Tubular maturation is reflected by the disappearance of vimentin and the increasing expression of EGF, whereas interstitial fibroblasts lose their expression of α -smooth muscle actin and vimentin. Chronic UUO causes a delayed or arrested maturation of the entire nephron.

ROLE OF APOPTOSIS

Urinary tract obstruction results in distal tubular epithelial cell apoptosis, characterized by condensed chromatin and cytoplas-

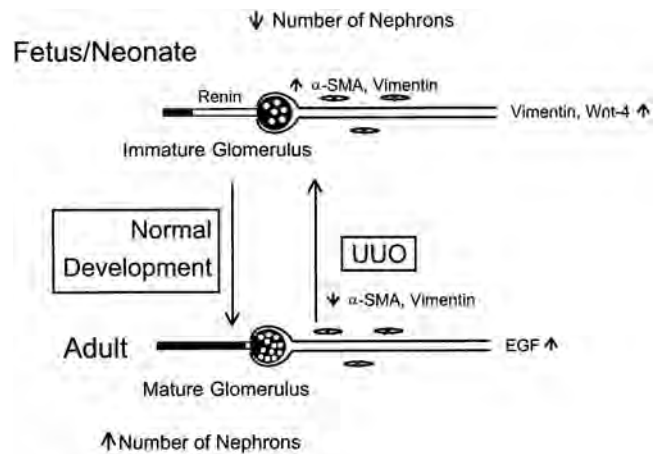

FIGURE 55.3. Effects of unilateral ureteral obstruction (UUO) on the developing kidney. The fetal/neonatal nephron is shown in the upper panel and the adult nephron in the lower panel. With normal maturation, the number of nephrons increases, and the glomeruli develop increased numbers of capillary loops. In addition, whereas renin extends along the afferent arteriole in the fetal kidney, renin is localized to the juxtaglomerular region of the mature kidney. During maturation, renal tubular vimentin and Wnt-4 expression disappears, and epidermal growth factor (EGF) expression increases. Whereas fetal interstitial fibroblasts express vimentin and α -smooth muscle actin (α -SMA), fibroblasts normally lose these markers with maturation. As a consequence of chronic UUO, the immature pattern of renal development persists. (Adapted from Chevalier RL. Molecular and cellular pathophysiology of obstructive nephropathy. *Pediatr Nephrol* 1999;13:612–619.)

mic blebs (Fig. 55.2A) (26,27). UUO in the neonatal rat results in greater ipsilateral renal apoptosis compared to the adult (4). This may account at least in part for the fall in renal DNA content in the neonatal kidney (Fig. 55.1A) (4). Apoptosis has also been reported in renal tubules of fetuses and infants with obstructive nephropathy (28,29). Because renal tubular apoptosis leads to tubular atrophy (26), attention has focused on factors regulating apoptosis in the hydronephrotic kidney.

Chronic UUO in the neonatal mouse results in necrosis of renal proximal tubular cells and apoptosis of distal tubular and collecting duct cells (30). Because proximal tubules undergo significant hypoxia after UUO, it is likely that necrosis of this tubular segment is consequent to decreased oxygen tension, as is the case after ischemic acute renal failure. Whereas the proximal tubule undergoes minimal dilatation after UUO, the collecting duct is significantly dilated (30). Moreover, tubular apoptosis is directly related to the magnitude of dilatation. Because apoptosis can be triggered by mechanical stretch of tubular cells and is proportional to the magnitude of axial strain, it is likely that the greater compliance of distal tubules contributes to the greater apoptosis of this tubular segment.

Growth Factors

Ureteral obstruction in the adult rat decreases the expression of ipsilateral renal prepro-EGF (31,32). Although EGF does not appear in the kidney until after birth (33), it

FIGURE 55.4. Relative renal tubular apoptosis, tubular (Tub.) atrophy, and interstitial (Int.) fibrosis in 1-week-old rats subjected to unilateral ureteral obstruction in the first 48 hours of life. The results have been normalized to control animals receiving vehicle injections (black bars). Experimental groups of rats received daily injections of epidermal growth factor (EGF, gray bars), or insulin-like growth factor-1 (IGF-1, white bars). For each parameter, experimental groups differ significantly from controls. (Data from Chevalier RL, Goyal S, Wolstenholme JT, et al. Obstructive nephropathy in the neonate is attenuated by epidermal growth factor. *Kidney Int* 1998;54:38–47; and Chevalier RL, Goyal S, Kim A, et al. Renal tubulointerstitial injury from ureteral obstruction in the neonatal rat is attenuated by IGF-1. *Kidney Int* 2000;57:882–890.)

is likely that activation of the EGF receptor plays a role in perinatal renal development (34). The normal developmental increase in renal EGF expression is prevented by ipsilateral UUO in the neonatal rat (Figs. 55.1D and 55.2D) (3). Administration of exogenous EGF to neonatal rats with UUO decreases tubular apoptosis in the obstructed kidney by 80% (Fig. 55.4) (23). In addition, EGF treatment reduces clusterin expression by renal tubular cells and significantly reduces tubular atrophy (23). Moreover, short-term administration of EGF markedly attenuates both tubular and interstitial renal injury 1 month after the release of UUO in the neonatal rat (35). Although the renal expression of insulin-like growth factor-1 (IGF-1) or its receptor is not altered by UUO in the neonatal rat, the administration of exogenous IGF-1, like EGF, significantly reduces renal tubular apoptosis, tubular atrophy, and interstitial fibrosis (36) (Fig. 55.4). Chronic UUO induces transient tubular expression of heparin-binding EGF, which can be induced in tubular cells subjected to stretch (37). Because heparin-binding EGF is also antiapoptotic, it is likely that expression of this growth factor serves to minimize apoptotic damage in the hydronephrotic kidney.

The mechanism whereby growth factors reduce apoptosis in the hydronephrotic kidney has been localized to the phosphorylation state of BAD, a pro-apoptotic molecule. When stretched, rat tubular cells undergo apoptosis, which can be reduced by 50% by treatment with either EGF or IGF-1 (38). Either UUO *in vivo* or cell stretch *in vitro* decreases tubular cell BAD phosphorylation, which is inhibited by the growth factors (38). As shown in Figure 55.5, when dephosphorylated, BAD dissociates from cytoplasmic chaperone proteins and complexes with BclX on

FIGURE 55.5. Shifting the balance between cell death and survival. **A:** Mechanical stretch injury induces activation of phosphatases, which dephosphorylate BAD, causing it to dissociate from chaperone proteins. Dephosphorylated BAD then forms a complex with BclX on the outer mitochondrial membrane, leading to release of cytochrome C into the cytoplasm, initiating apoptosis. **B:** The administration of growth factors [epidermal growth factor (EGF) or insulin-like growth factor-1 (IGF-1)], increases MAPK and Akt kinase activity to levels that compensate for the stretch-induced phosphatase action on BAD. As a result, BAD is phosphorylated and sequestered by the chaperone proteins to maintain cell survival. [From Kiley SC, Thornhill BA, Tang SS, et al. Growth factor-mediated phosphorylation of proapoptotic BAD reduces tubule cell death *in vitro* and *in vivo*. *Kidney Int* 2003;63(1):33–42, with permission.]

the mitochondrial membrane, resulting in the release of cytochrome C and the initiation of apoptosis. EGF and IGF-1 activate their respective kinases to maintain BAD phosphorylation and thereby increase cell survival.

Although transforming growth factor β 1 (TGF- β 1) is generally considered a fibrogenic cytokine (see Fibroblasts and Transforming Growth Factor- β), it also plays a significant role in promoting apoptosis in the hydronephrotic kidney (39). Stretching of tubular epithelial cells stimulates their expression of TGF- β 1 and induces their apoptosis—a response that can be inhibited by antibody to TGF- β 1 (40). The stretch-induced apoptotic response may, therefore, result at least in part from increased production of this pro-apoptotic cytokine. The action of TGF- β 1 can be attenuated by an endogenous renal proteoglycan, decorin.

Mice lacking a functional decorin gene manifest increased tubular apoptosis and tubular atrophy after UUO (41).

Other Molecules Modulating Apoptosis

Chronic UUO induces the renal expression of a number of apoptosis-promoting molecules, including Fas, Fas ligand, tumor necrosis factor-R1, TRAIL, TRADD, RIP, caspases, FADD, and FAP (42,43). The rise and fall of expression of these molecules parallel changes in renal apoptosis in the hydronephrotic kidney. The presence of a nonfunctioning Fas receptor in C57B16/lpr mice reduces distal tubular apoptosis resulting from chronic UUO (44). Similarly, p53-deficient mice exhibit a significant reduction in apoptosis after UUO (45). These findings underscore the importance of apoptosis-regulatory molecules in the hydronephrotic kidney. Complete UUO in the fetal opossum kidney induces tubular apoptosis that is associated with an increase in Bax, a pro-apoptotic molecule, and a decrease in Bcl-2, an antiapoptotic molecule (46). In the neonatal rat subjected to UUO, renal tubular Bcl-2 expression is reduced in dilated apoptotic tubules but not in nondilated tubules (47). This is consistent with endogenous Bcl-2 normally inhibiting tubular apoptosis, which is dysregulated in the obstructed kidney.

While tubular cells themselves generate molecules regulating their own apoptosis, infiltrating cells can do so as well. Chronic UUO in mice deficient in selectin (an adhesion molecule) leads to reduced interstitial macrophage infiltration, along with decreased tubular apoptosis and tubular atrophy (48). The tubular cell apoptosis is due to soluble factors released by macrophages adjacent to the tubules in the hydronephrotic kidney.

In 1997, the sphingolipid ceramide was shown to induce apoptosis in the kidney (49). The very high prevalence of renal apoptosis in the developing rat is associated with similarly elevated levels of intrarenal ceramide, and both ceramide production and endogenous renal apoptosis decrease to adult levels during the first month of life (50). Prolonged UUO in the neonatal rat (but not the adult rat) increases endogenous renal ceramide and likely contributes to the prolonged renal apoptotic response of the neonatal obstructed kidney (51).

Summary

As shown in Figure 55.6, the regulation of tubular apoptosis in the hydronephrotic kidney is extremely complex and represents a balance between factors promoting apoptosis and countering survival factors. Stimuli for apoptosis include mechanical stretching of tubular cells, which results from the initial increase in hydrostatic pressure in a compliant tubular segment. Infiltrating macrophages contribute to apoptosis of tubular cells. Enhanced renal production of ceramide may also contribute to the increased susceptibility of the developing kidney to apoptosis. Apoptosis can be

FIGURE 55.6. Regulation of apoptosis in the hydronephrotic kidney. Renal tubular cell apoptosis is enhanced by a variety of stimuli in the immature hydronephrotic kidney, including mechanical stretch of dilated tubular segments, release of pro-apoptotic molecules by infiltrating macrophages, and increased renal generation of ceramide. The ultimate fate of the cell is decided by the balance of signals mediating cell death [transforming growth factor β 1 (TGF- β 1), FAS, p53, caspases], and those acting as survival factors [epidermal growth factor (EGF), insulin-like growth factor-1 (IGF-1), hepatocyte growth factor (HGF), and heparin-bound epidermal growth factor (HB-EGF)].

activated by TGF- β 1, FAS, p53, or caspases. In contrast, growth factors such as EGF, IGF-1, hepatocyte growth factor, and heparin-bound EGF can inhibit apoptosis and tilt the balance in favor of survival. A better understanding of the renal cell biology of apoptosis should lead to improved means of preserving renal mass in patients with obstructive nephropathy.

INTERSTITIAL INFILTRATION AND FIBROSIS

After UUO in the adult rat, the renal interstitium of the ipsilateral kidney is infiltrated with leukocytes, beginning after 4 hours and becoming maximal at 24 hours (52). The cells produce a variety of vasoactive compounds, including prostaglandins, thromboxanes, and leukotrienes (53,54).

Macrophages

Although lymphocyte infiltration is not required for progressive tubular atrophy and interstitial fibrosis after UUO (55), macrophages appear to play a major role. Adhesion molecules, such as selectins, play a significant role in localizing macrophages to the renal interstitium in the developing kidney subjected to UUO (48). The macrophages, in turn, induce apoptosis of adjacent tubular epithelial cells (48). Infiltrating macrophages may produce tissue inhibitors of metalloproteinase, which in turn prevent degradation of extracellular matrix (56,57). After partial UUO in juvenile rats, renal expression of monocyte chemoattractant protein-1 is increased (58). Because urinary excretion follows renal expression of monocyte chemoattractant pro-

tein-1, and levels parallel the severity of obstruction, this molecule shows promise as a prognostic marker for infants and children with congenital hydronephrosis (59). Moreover, therapeutic inhibition of such chemokines may attenuate interstitial cellular influx and interstitial fibrosis in the hydronephrotic kidney (60,61). Whereas plasminogen activator inhibitor-1 contributes to interstitial fibrosis resulting from UUO (62,63), tissue inhibitor of metalloproteinase-1 does not (64).

Fibroblasts and Transforming Growth Factor- β

The source of interstitial fibroblasts appearing in the obstructed kidney is not clear at this time. Possibilities include proliferation of resident interstitial fibroblasts, pericytes, or transdifferentiation of renal tubular epithelial cells (65). Myofibroblast transformation, in which fibroblasts express α -smooth muscle actin, takes place in the interstitium of the obstructed kidney (66). Whereas α -smooth muscle actin normally disappears from the interstitium in the neonatal rat, this process is delayed by ipsilateral UUO (3). Myofibroblasts appear to be involved in extracellular matrix accumulation (67) and may play a role in the enhanced contractility of the renal cortex after UUO (68).

TGF- β 1, a cytokine, stimulates extracellular matrix synthesis, inhibits its degradation, and induces the expression of α -smooth muscle actin in myofibroblasts (69,70). It is possible that expression of α -smooth muscle actin by fibroblasts is controlled by the increased generation of TGF- β 1 in the obstructed kidney (66,67,71). TGF- β 1 has been localized to renal tubular epithelial cells (72) and renal interstitial cells (73,74). Chronic UUO results in a significant increase in renal TGF- β 1 expression (Figs. 55.1C and 55.2C) (3,32,72,73). TGF- β 1 inhibits collagen degradation, and UUO results in a tenfold reduction in interstitial collagenolytic activity (75). Administration of a cyclooxygenase-2 inhibitor reduces TGF- β 1 and interstitial fibrosis in the obstructed kidney (76). The role of TGF- β 1 in mediating renal interstitial fibrosis after UUO has been elegantly demonstrated by the introduction of TGF- β 1 antisense oligodeoxynucleotides into interstitial fibroblasts (77). Administration of exogenous hepatocyte growth factor to mice with UUO markedly reduces endogenous TGF- β 1 expression, myofibroblast activation, and interstitial fibrosis in the hydronephrotic kidney (78,79). Although it appears likely that apoptosis of renal tubular epithelial cells contributes to the development of tubular atrophy, apoptosis may also be beneficial in countering fibrosis by clearing myofibroblasts from the interstitium (80,81). Although interstitial cells play a role in progressive interstitial fibrosis resulting from UUO, tubular cells also contribute to the fibrotic process. Administration of osteogenic protein-1 inhibits tubular apoptosis in rats with UUO, as well as inhibiting interstitial cellular infiltration (82).

Oxidative Stress

As a consequence of UUO, oxidative stress increases in the renal interstitium of the hydronephrotic kidney (83). Inhibition of oxidative stress reduces interstitial fibrosis resulting from UUO (84). After UUO, endogenous renal antioxidant enzyme activity is reduced (85). Whereas sodium depletion stimulates renal antioxidant enzyme production in the intact kidney, UUO inhibits this normal adaptive response (85). The impaired antioxidant production by the hydronephrotic kidney is a maladaptive response that presumably contributes to the progressive renal injury resulting from urinary tract obstruction.

RENIN-ANGIOTENSIN SYSTEM

Cellular and Molecular Role of Angiotensin in Hydronephrosis

The increased generation of a pressor material in the kidney with ipsilateral UUO has been known for more than 50 years. Beckwith reported that extracts of kidneys from rats with UUO induce hypertension when injected into normal animals (86). More recent detailed studies of the intrarenal renin-angiotensin system have been performed in rats subjected to complete UUO during the first 48 hours of life. In contrast to kidneys from sham-operated rats, in which 55% of juxtaglomerular apparatuses contain immunoreactive renin, the fraction is increased to approximately 75% of glomeruli in kidneys of 4-week-old rats with chronic ipsilateral UUO (15). Moreover, in contrast to the pattern of distribution in sham-operated rats, in which immunoreactive renin is localized to the juxtaglomerular apparatus, renin protein extends along the length of the afferent arteriole of 4-week-old rats with UUO (Fig. 55.2B) (15). This pattern is similar to that of the late gestational normal rat fetus (87). While renal renin content is increased in the kidney with ipsilateral UUO, it is suppressed in the intact opposite kidney (15). In contrast to the neonate, UUO in the adult rat does not result in redistribution of immunoreactive renin along the renal microvasculature.

Studies of renin secretion *in vivo* or in isolated perfused kidneys generally rely on measurements of plasma renin activity. The hemolytic plaque assay, however, permits direct measurement of hormone secretion by isolated cells (88). This technique has been used to determine whether renin secretion is increased by cortical cells from the rat kidney with ipsilateral UUO since birth. Rather than there being an increased amount of renin secretion per cell, the obstructed neonatal rat kidney demonstrates a recruitment of cortical cells secreting renin (89). It is likely that the enhanced secretion results from the increased transcription and storage of renin in the microvasculature of the immature kidney.

After acute UUO in the adult rat, renin expression is increased after only 1 hour (90). After 24 hours of UUO in

the adult rat, blood vessels of the postobstructed kidney overexpress angiotensin-converting enzyme and angiotensinogen (91). In addition to increased renin production, these changes may contribute to increased intrarenal angiotensin II production after ipsilateral UUO. The adult rat responds differently to 4 weeks of UUO, because the distribution of renin messenger RNA and protein is not altered in the ipsilateral kidney (15,92). These studies reveal that the profound effects of UUO on the renin-angiotensin system of the immature kidney are markedly attenuated in the adult, presumably as a result of the developmental decrease in the activity of the renin-angiotensin system.

Additional studies in the neonatal rat with UUO have addressed the mechanism of activation of the renin-angiotensin system in both ipsilateral and intact opposite kidneys. Renal denervation ("chemical sympathectomy" produced by chronic administration of guanethidine) in developing rats with UUO prevents the expected increased proportion of juxtaglomerular apparatuses containing detectable immunostaining renin, as well as extension of renin along afferent arterioles (93). In addition, denervation also suppresses the increased renin gene expression of the immature kidney with ipsilateral UUO, indicating that renal nerves modulate renin gene expression (93). Although renal nerves do not mediate the vasoconstriction of the obstructed kidney, they modulate vascular tone of the intact opposite kidney (94). Renal nerves have also been shown to play a role in the enhanced renin gene expression normally observed at the time of birth in the fetal sheep (95). Chronic UUO in the guinea pig increases angiotensin-dependent vasoconstriction in the obstructed kidney independent of renal innervation (96). However, UUO decreases angiotensin-dependent vasoconstriction of the opposite kidney, an effect unmasked by sympathectomy (96).

Modulation of growth by ANG II depends on the type of receptor present on the cell (97). Whereas the angiotensin AT1 receptor appears to mediate many forms of renal vascular and tubular growth (98,99), activation of the AT2 receptor has been shown to inhibit cell growth (97,100) and even to induce apoptosis (101,102). AT1 receptors are present along the afferent and efferent arterioles, proximal tubules, and the luminal surface of the distal nephron (103). Although renal AT1 and AT2 receptors are downregulated after acute UUO in the neonatal rat, the AT1 receptor is upregulated after 28 days of UUO, at a time when intrarenal angiotensin II is increased (104). El-Dahr et al. have shown that renal angiotensinogen, angiotensin-converting enzyme, and ANG II are also increased in the obstructed kidney (105). It is possible that increased ANG II levels contribute to upregulation of AT1 receptor levels, as has been described in the proximal tubule (106). UUO in the neonatal rat reduces proliferation and stimulates apoptosis at least in part through the activation of AT2 receptors (107). In addition, ANG II stimulation of AT2 receptors promotes clusterin expression in the neonatal obstructed kidney (108).

FIGURE 55.7. Renal interstitial collagen deposition in the hydronephrotic kidney is dependent on angiotensin II. Shown is the relative distribution of renal interstitial collagen in kidneys from neonatal mice with ipsilateral unilateral ureteral obstruction. There is a linear relationship between interstitial collagen deposition in the hydronephrotic kidney and the number of copies of functional angiotensinogen for 0 to 2 copies. There is no additive effect of additional copies of angiotensinogen (3 or 4 copies). Dashed line represents linear regression of individual data points. *, $p < .05$ vs. sham; ‡, $p < .05$ vs. other Agt genotypes. (From Fern RJ, Yesko CM, Thornhill BA, et al. Reduced angiotensinogen expression attenuates renal interstitial fibrosis in obstructive nephropathy in mice. *J Clin Invest* 1999;103:39–46, with permission.)

The quantitative contribution of angiotensin to interstitial fibrosis resulting from neonatal UUO has been demonstrated using mice having zero to four functional copies of the angiotensinogen gene (109). Renal interstitial collagen in neonatal mice with chronic UUO increases linearly with angiotensinogen expression, from a fractional area of 25% in zero-copy mice to 54% in two-copy mice (Fig. 55.7) (109). Thus, angiotensin regulates at least 50% of the renal interstitial fibrotic response in obstructive nephropathy. The remaining fibrotic response may be due in part to endogenous renal production of tumor necrosis factor- α (110), whose expression is greater in the neonatal kidney than the adult kidney after UUO (111).

Angiotensin-Induced Molecules

In addition to its direct actions as a growth factor, angiotensin also stimulates other growth-related compounds, including TGF- β 1 (112), platelet-derived growth factor (113), osteopontin (114), adhesion molecules (115), and α -smooth muscle actin (113). These are associated with deposition of collagen, the development of interstitial fibrosis, and tubular atrophy and dilatation (113).

The increase in TGF- β 1 in the obstructed adult kidney is regulated by ANG II (72,74,116,117), and inhibition of angiotensin AT1 receptors by losartan in neonatal rats with UUO reduces the expression of TGF- β 1 in the obstructed

kidney (118). In addition, ANG II has been shown to convert TGF- β 1 to its active form (119). Thus, delayed treatment with enalapril reduces TGF- β 1 expression and halts tubulointerstitial fibrosis in the obstructed kidney (117).

Whereas α -smooth muscle actin normally disappears from the interstitium in the neonatal rat, this process is delayed by ipsilateral UO (3). Because ANG II exerts transcriptional regulation of the human α -smooth muscle actin gene (120), the persistent α -smooth muscle actin expressed by the interstitial vasculature of the neonatal obstructed kidney may be due to greater generation of tissue angiotensin resulting from recruitment of renin-secreting cells (89). It is also possible that expression of α -smooth muscle actin by fibroblasts is controlled by increased generation of TGF- β 1 in the obstructed kidney (66,67,71).

Angiotensin and the Genesis of Obstructive Nephropathy

Although the AT2 receptor mediates apoptosis induced by ANG II, this receptor also appears to be important in limiting renal interstitial myofibroblast transformation in the hydronephrotic kidney (121). Moreover, there is evidence that by interfering with the apoptosis of undifferentiated mesenchymal cells, mutations in the AT2 receptor may underlie a variety of urinary tract malformations, including obstructive nephropathy (122). However, such mutations could not be confirmed in all populations (123).

In addition to the importance of ANG II in mediating the renal response to UO, this peptide may also play a role in the development of the lower urinary tract. Mice lacking a functional AT1 receptor develop functional urinary tract obstruction similar to wild-type mice subjected to complete UO (124). The renin-angiotensin system clearly plays a critical role in many of the processes involved in congenital obstructive nephropathy, and many of its protean effects remain to be elucidated.

RENAL FUNCTIONAL EFFECTS OF URETERAL OBSTRUCTION

Ureteral ligation initially causes increased ureteral pressure and a transient increase in renal blood flow (RBF), followed 12 to 24 hours later by decreased RBF (125,126). A decrease in glomerular filtration rate (GFR) follows the decline in RBF due to ipsilateral ureteral obstruction (127). Ureteral obstruction does not affect all nephrons equally: Deeper nephron function is lost at the expense of compensation by cortical nephrons (128). After the release of 18 hours of UO in the weanling rat, however, superficial nephron GFR is reduced to a greater extent than that of juxtamedullary nephrons (129). After either UO or bilateral ureteral obstruction (BUO), the number of filtering nephrons increases steadily during the first hours after relief of obstruction (130).

The chromium EDTA technique has been used to measure GFR in adult rats with complete UO (131). GFR is reduced more severely than RBF, and, after relief of obstruction of 7 to 14 days, recovery of GFR diminishes with the duration of obstruction (131). Scanning electron microscopic examination of the rat kidney 24 hours after release of 2 weeks of UO reveals ballooning of tubular epithelial cells, resulting in obliteration of the lumen despite relief of obstruction (132). After 2 weeks of recovery, the epithelial lining normalizes in some tubules but deteriorates further in others, indicating a marked heterogeneity in nephron injury (132). Tubular fluid flow is present in most nephrons 5 to 7 weeks after relief of 2 to 35 days of UO and subsequent contralateral nephrectomy in the adult rat (133). However, the number of nephrons capable of recovery decreases with the duration of obstruction (133).

Hemodynamic Effects of Urinary Tract Obstruction

In all mammalian species studied to date, complete postnatal ipsilateral UO results in significant renal vasoconstriction. Complete UO in the neonatal rat reduces RBF by 77% (94). It is likely that at least some of the renal consequences of UO are the result of ischemia secondary to afferent arteriolar vasoconstriction, which develops even after single nephron obstruction (134). However, there is no catchup growth of the ipsilateral kidney despite improved RBF after relief of partial UO in the neonatal guinea pig (135). The dissociation of renal growth from renal vasoconstriction resulting from neonatal UO suggests that hemodynamic factors alone cannot account for the impaired renal growth. Alterations in renal growth factors (discussed earlier) likely contribute to these effects.

Eicosanoids

The severity of reduced RBF resulting from ureteral obstruction has prompted a thorough investigation of potential mediators of renal vasoconstriction. Much attention is focused on eicosanoids as mediators of vascular tone, and the initial increase in RBF resulting from ipsilateral UO is shown to be associated with increased renal production of vasodilator prostaglandins (136). The later increase in vasoconstriction, on the other hand, has been ascribed in the past to increased production of the vasoconstrictor prostanoid, thromboxane A₂ (137–139). Glomeruli from rats with BUO produce increased amounts of prostaglandin E₂, 6-keto-prostaglandin F_{1 α} , and TxB₂, all of which can be suppressed by angiotensin-converting enzyme inhibition (140). This suggests that phospholipase A₂ or cyclooxygenase is stimulated by enhanced angiotensin II formation by glomeruli from kidneys with BUO. In rats with congenital unilateral hydronephrosis, the reduction in single nephron GFR is due to a reduction in the ultrafiltration coefficient mediated by both

angiotensin II and thromboxane A₂ (141). Urinary excretion of prostaglandin E₂ and thromboxane B₂ is increased in human neonates and infants with congenital obstructive uropathy (142). A balance between vasoconstrictors and vasodilators may play an important role in determining the vascular tone of kidneys with ureteral obstruction. Increased glomerular phospholipase A₂ and cyclooxygenase activity are reduced to normal when animals with BUO are treated with either angiotensin or thromboxane inhibitors (143).

There is an increased production of vasodilator prostanooids by glomeruli from the intact kidney (as well as the obstructed kidney) of rats with UUO (144). This increased prostaglandin synthesis could be suppressed by angiotensin-converting enzyme inhibition and restored by angiotensin II, suggesting that the prostaglandin production is angiotensin dependent (144). The reverse may also be the case: The increased renin release by glomeruli from kidneys with UUO can be abolished by prostaglandin inhibition (136).

Angiotensin

The role of the renin-angiotensin system in mediation of vasoconstriction resulting from ureteral obstruction is of particular interest in the maturing animal, because the activity of this system is markedly enhanced in early development. The involvement of the angiotensin in renal vasoconstriction is suggested by a doubling of the renin content of the obstructed kidney during partial UUO and its normalization after relief of obstruction (18). Chronic administration of enalapril (an angiotensin converting enzyme inhibitor) to neonatal guinea pigs with partial UUO prevents the decrease in RBF and glomerular contraction normally resulting from obstruction (145,146). This confirms the dependence of vasoconstriction on angiotensin. The effect of angiotensin can also be demonstrated during chronic obstruction of individual nephrons, in which angiotensin blockade by captopril or saralasin improves glomerular blood flow (147).

Although RBF does not return to normal after relief of 5 or 10 days of partial UUO in the neonatal guinea pig, enalapril has no additional salutary effect (18). Although enalapril has no effect on RBF of the intact kidney of neonatal guinea pigs with persistent contralateral UUO, after relief of obstruction, enalapril reduces renal vascular resistance of the intact kidney by 40% (18). Moreover, the vasoconstrictor response of the intact kidney to exogenous angiotensin II infusion is increased, suggesting an increased sensitivity of angiotensin II receptors in the intact kidney in response to relief of obstruction in the contralateral kidney. Thus, other factors are presumably responsible for the persistently depressed RBF of the postobstructed neonatal kidney. However, administration of captopril to rats during 1 to 3 weeks of UUO resulted in better preservation of kidney weight and GFR of the postobstructed kidney 3 months after relief of obstruction (148).

Atrial Natriuretic Peptide

Plasma concentration of atrial natriuretic peptide (ANP) is increased in adult rats with BUO, but not in those with UUO (149). ANP has been shown to act as a potent vasodilator in obstructed kidneys, and part of this effect is through stimulation of prostacyclin (150). These experiments suggest that the greater RBF of kidneys subjected to BUO compared to UUO may be due to higher circulating levels of ANP. Of particular interest is a report that infusion of ANP may have salutary effects on GFR of the kidney after relief of 24 hours of UUO (151). Saline loading has a similar beneficial effect, possibly through stimulation of secretion of endogenous ANP (151). Circulating ANP may also alter the vascular resistance of the obstructed kidney by inhibition of renin.

Arginine Vasopressin

Plasma levels of vasopressin are elevated in rats with 24 hours of BUO but not in those with UUO (152). The increase in vasopressin in rats with BUO is most likely due to hypernatremia and hyperosmolality. Treatment of animals with a specific antagonist of vasopressin V1 receptors increases GFR of the postobstructed kidney by 60%, and effective renal plasma flow more than doubles (152). These results suggest that vasopressin contributes to the vasoconstriction and renal functional impairment resulting from BUO.

Kininogen-Kinin System

Earlier studies of the adult rat after relief of 24 hours of UUO showed that administration of either carboxypeptidase B (which destroys kinins) or an inhibitor of kinin synthesis does not diminish the salutary effect of captopril on RBF of the postobstructed kidney (137). This suggests that angiotensin-converting enzyme inhibition does not act through potentiation of vasodilator kinins in this model. In fact, inhibition of kallikrein by aprotinin further decreases renal vasoconstriction after relief of 24 hours of UUO (153). This action appears to be due to stimulation of thromboxane and angiotensin by kinins in the postobstructed kidney (153). However, kallikrein messenger RNA and protein are significantly reduced by chronic ipsilateral UUO in the rat (154). The role of the kininogen-kinin system in ureteral obstruction therefore remains to be clarified.

Endothelial Factors

There has been much recent interest in the role of endothelial factors in the regulation of vascular tone. After unilateral release of BUO in adult rats, infusion of L-arginine, the substrate for nitric oxide synthase, increases effective renal plasma flow and GFR (155). Because nitric oxide is known to be an endothelium-derived relaxing factor (EDRF), it

appears that in the setting of BUO EDRF activity is decreased. This contrasts with the UUO model, in which endogenous EDRF activity appears to be increased and is not limited by availability of substrate (156). Enhanced production of EDRF by the kidney with UUO reduces the renal vasoconstriction resulting from UUO (156,157). This may be due in part to inhibition of renin release by EDRF. Treatment of rats subjected to UUO with enalapril prevents many of the sequelae of obstruction in part by an increase in nitric oxide generation (158). Additional effects of UUO include an increase in glomerular soluble guanylyl cyclase activity (through angiotensin II stimulation) while blocking phosphodiesterase activity (159). By increasing the production of cyclic guanosine monophosphate, a vasodilator, these actions would serve to counter angiotensin-dependent vasoconstriction. Endogenous nitric oxide production also counters tubular apoptosis triggered by tubular stretch secondary to UUO (160) and attenuates interstitial fibrosis resulting from UUO (161).

Endothelial cells also produce endothelin—a potent vasoconstrictor. After relief of temporary UUO in the rat, abnormal responses of the postobstructed kidney to angiotensin II are mediated by endogenous endothelin (162).

Summary

Urinary tract obstruction induces marked changes in the activity of local vasoconstrictors and vasodilators, with a shift in the balance toward vasoconstriction. The role of angiotensin and eicosanoids appears to be clearly established, whereas that of other compounds, such as kinins and endothelial factors, remains to be elucidated. Interpretation of studies is made more difficult by the complex interactions among the vasoactive compounds, including stimulation of vasoconstrictors by vasodilators and vice-versa. In addition, the protean effects of many vasoactive compounds include the regulation of cell proliferation, apoptosis, and fibrogenesis, all of which are profoundly affected by urinary tract obstruction.

TUBULAR RESPONSES TO URINARY TRACT OBSTRUCTION

Postobstructive Diuresis

After the relief of BUO, natriuresis and diuresis are increased—a phenomenon described as *postobstructive diuresis*. Much of the effect is presumably due to an osmotic diuresis resulting from excretion of accumulated solutes. However, in addition to changes in tubular transport characteristics, altered circulating factors, such as increased circulating ANP and enhanced synthesis of prostaglandins, may play a role (149,163). In addition, altered sensitivity of the tubuloglomerular feedback mechanism also contributes to the diuresis (164). It is of interest that in addition to

BUO, relief of UUO in neonates can be associated with postobstructive diuresis (165). This may be due to a relative glomerulotubular imbalance.

Sodium

Ureteral obstruction results in decreased reabsorption of sodium and water in juxtamedullary proximal tubules (129). After relief of obstruction, sodium reabsorption is decreased in the thick ascending limb of Henle, which contributes to a reduction in medullary tonicity. Sodium transport is reduced also in the medullary-collecting duct (166). It appears that the impaired sodium transport can be explained at least in part by alteration in the lipid environment of the basolateral membrane, leading to reduced Na-K-ATPase activity (167,168). Another factor implicated in postobstructive diuresis is a “functional denervation” of the kidney after relief of BUO (169). Acutely, postobstructive natriuresis may be beneficial in providing mobilization of extracellular fluid and reducing hypertension. However, prolonged salt wasting in some patients can lead to severe volume contraction and circulatory impairment. Chronic sodium depletion can also aggravate renal interstitial fibrosis resulting from UUO (85). Whereas sodium depletion normally stimulates endogenous renal antioxidant enzyme activity, UUO impairs this response, thereby contributing to the fibrogenic stimulus of renal oxidant injury that results from UUO (83,85). Because infants and children with severe obstructive uropathy frequently have significant salt wasting, adequate sodium supplementation may be beneficial in slowing progression of renal interstitial fibrosis.

Urinary Concentration

As indicated earlier, reduced removal of solute from the thick ascending limb of Henle leads to decreased solute content of the papillary interstitium and reduces the urinary concentrating capacity. A relative increase in blood flow to the papilla increases washout of solute, contributing further to loss of concentrating capacity. A third factor leading to impaired concentrating capacity is a reduced response of the cortical collecting duct to vasopressin. This occurs at a site distal to the generation of cyclic adenosine monophosphate (170). Frokiaer et al. have demonstrated that BUO and release of obstruction in the rat is associated with downregulation of the vasopressin-regulated water channel aquaporin (171,172). The maximal urinary concentration after administration of deamino-8-D-arginine vasopressin to young rabbits with UUO and contralateral nephrectomy is inversely proportional to the degree of hydronephrosis (173). This may be due at least in part to distortion of the medullary architecture: loops of Henle are splayed and tortuous 3 to 4 days after UUO in the rabbit (174). Temporary ureteral occlusion in the adult rat results in ischemic tubular necrosis in the inner and outer

FIGURE 55.8. Kidney weight (factored for body weight) of obstructed (*black bars*) and contralateral (*white bars*) kidneys of neonatal rats 28 days after sham operation, after relief of 1 to 5 days' ureteral obstruction, or with persistent ureteral obstruction (UUO). There is a fine balance between the growth of the obstructed and opposite kidneys, such that combined renal mass remains constant. *, $p < .05$ vs. opposite kidney; #, $p < .05$ vs. sham. (From Chevalier RL, Thornhill BA, Wolstenholme JT, et al. Unilateral ureteral obstruction in early development alters renal growth: dependence on the duration of obstruction. *J Urol* 1999;161:309–313, with permission.)

medulla, which also presumably contributes to the concentrating defect (175). In addition, there is a disproportionate loss of juxtamedullary nephrons. The severity of the renal concentrating defect in children with obstructive nephropathy is highly variable but in some patients can approach that of nephrogenic diabetes insipidus, leading to episodes of hypernatremia in affected infants (176). Chronic polyuria secondary to obstructive nephropathy may accelerate renal injury: In weanling rats with partial UUO, chronic high urine flow rates induced by osmotic diuresis resulted in a significant decrease in GFR (177).

Potassium and Hydrogen Ion Handling

Obstructive nephropathy leads frequently to defective distal tubular potassium and hydrogen ion secretion (*type 4* renal tubular acidosis) (178,179). This can be due to impaired turnover of the sodium/potassium pump, diminished sensitivity of the distal tubule to aldosterone, or the loss of H⁺-ATPase in the apical surface of intercalated cells. Clinically, these changes lead to hyperkalemia and metabolic acidosis, even with unilateral obstruction, and may not resolve after surgical correction of obstruction (179–181).

Calcium and Phosphorus Handling

Experimental UUO results in reduced urinary calcium and phosphorus excretion due in part to a decreased renal response to parathyroid hormone. In patients with distal renal tubular acidosis due to obstructive nephropathy (*type I*), urinary calcium excretion can be increased. Release of UUO in thyroparathyroidectomized dogs results in hypophosphaturia due to reduced filtered load of phosphate and increased tubular phosphate reabsorption (182).

RENAL COUNTERBALANCE

Although the UUO model represents an extreme case of asymmetrical kidney function, the severity of urinary tract obstruction in clinical practice is often unequally distrib-

uted between the two sides. Partial UUO in the immature guinea pig results in a compensatory increase in GFR of the intact opposite kidney; the younger the animal at the time of ureteral obstruction, the greater the response (183). The concept of “counterbalance” by the intact kidney in response to loss of function by the obstructed kidney was developed by Hinman in 1923 (184). The exaggerated adaptive response by the intact kidney of animals undergoing UUO in early development is also demonstrated by the remaining kidney after loss of renal mass in the neonate (185,186). The dynamic nature of the response is illustrated by the attenuation of compensatory hypertrophy of the intact kidney after relief of UUO in the guinea pig at 10 days of age (135). Temporary UUO in the neonatal rat inhibits growth of the obstructed kidney and accelerates growth of the opposite kidney in direct proportion to the duration of obstruction (Fig. 55.8) (187). This demonstrates clearly the very fine-tuning of the counterbalance mechanism in early development. Also demonstrating the plasticity of the counterbalance phenomenon is the maintenance of normal RBF and glomerular volume in kidneys of neonatal guinea pigs with ipsilateral UUO, if the contralateral kidney is removed at the time of birth (188).

EFFECTS OF URINARY TRACT OBSTRUCTION ON THE FETAL KIDNEY

Although the models described earlier have elucidated a number of mechanisms underlying the renal response to urinary tract obstruction, they do not address the intrauterine changes in the developing kidney with congenital obstruction. A question of primary clinical importance is the effect of relief of fetal urinary tract obstruction on functional development of the kidney. Moreover, in view of the association of pulmonary hypoplasia and oligohydramnios, the effect of severe urinary tract obstruction on development of the lung is of more immediate importance to the neonatal infant. Several laboratories have attempted to develop such models in the fetus or embryo (189). Ureteral obstruction in the chick embryo results in hydronephrosis but not in dys-

plastic changes, as are present in infants with severe degrees of obstruction (190). Ureteral ligation in the fetal rabbit results in a rapid decrease in the number of glomeruli, whereas relief of obstruction partially restores them (7,191). The opossum has also been studied because it is a marsupial, and most "fetal" development is completed in the maternal pouch rather than while attached to a placenta *in utero*. Obstruction in the fetal opossum results in tubular atrophy and interstitial fibrosis, with interstitial fibroblasts appearing similar to undifferentiated mesenchyme (192). In this model, relief of UO does not affect weight or function of the ipsilateral kidney (193). In fact, relief of obstruction tends to decrease further the weight and function of the kidney, an effect that is ascribed to a renal inflammatory response (193). In addition, growth of the intact opposite kidney is also greater after relief of obstruction (193), results that are the reverse of those after relief of partial UO in the postnatal guinea pig (135). As in the neonatal rat (36), the administration of IGF ameliorates the development of interstitial fibrosis in the fetal opossum subjected to complete UO (194). This supports the role of growth factors in mediating or modulating the renal cellular response to UO in the fetus as well as postnatally.

Because of their larger size and presumed greater similarity to the human fetus, a number of investigators have studied urinary tract obstruction in the fetal sheep. Initial studies in this species revealed that urethral obstruction before closure of the urachus results in a persistent umbilical fistula that prevents the development of hydronephrosis (195). Ureteral ligation performed during the first half of gestation results in dysplastic changes, whereas delay in obstruction until the last half of gestation results in preservation of renal architecture with little interstitial fibrosis or inflammation (196). It is likely that the dependence of the renal response to the timing of obstruction in the fetus relates to the changing rate of cellular proliferation, which is maximal near the midpoint of gestation (197). Partial bladder outlet obstruction in the fetal sheep increases renal renin expression and increases renal expression of the AT₂ receptor (198). A greater abundance of the AT₂ receptor is expected to enhance the apoptotic response to endogenous angiotensin.

Harrison and his colleagues have described an elegant model of bladder outlet obstruction in the fetal sheep, in which the urachus as well as the urethra are obstructed (199). Relief of obstruction at 112 to 124 days' gestation after 15 to 27 days' obstruction in the fetus lessens the degree of hydronephrosis and of pulmonary hypoplasia, resulting in a marked improvement in viability (199). Ureteral obstruction in the first trimester (43 to 45 days' gestation) or early midtrimester (58 to 66 days' gestation) results in marked interstitial fibrosis, primitive epithelial structures, and parenchymal disorganization typical of dysplasia (200,201). One animal developed a wrinkled, distended abdomen; deficient abdominal wall musculature; and

undescended testes, comparable to the prune belly syndrome in humans. Recovery of renal function after relief of obstruction was found to be directly proportional to the duration of intrauterine decompression and inversely proportional to the duration of obstruction (202). As in the fetal rabbit model, relief of obstruction before the completion of nephrogenesis in the fetal sheep can lead to preservation of nephrons (203).

Chronic partial bladder obstruction in midtrimester in the sheep actually increases RBF and GFR, while renal architecture appears normal despite thinning of the cortex (204). These findings, which are the reverse of those described in postnatal animals, underscore the importance of the degree of obstruction in the determination of the renal response in the fetus. As with the results in the opossum described earlier, the response of the fetal kidney to obstruction *in utero* may differ significantly from the postnatal effects.

Complete UO in the fetal sheep decreases RBF but not as severely as in adults (205). Peters et al. (9) report that UO early in gestation results in compensatory growth of the opposite kidney in the fetal lamb. This finding illustrates the operation of counterbalance in the fetus, which indicates that compensatory renal growth is not dependent on functional demand.

Experimental ureteropelvic junction (UPJ) obstruction in the fetal monkey impairs growth of the kidney, which exhibits cystic dysplastic changes, interstitial expansion, and collecting duct apoptosis (206). A novel observation in this model is the prominent glomerular abnormality, with significant podocyte apoptosis (206). Although data are limited, congenital human obstructive nephropathy is also associated with glomerular changes (207).

CLINICAL IMPLICATIONS OF EXPERIMENTAL STUDIES OF URINARY TRACT OBSTRUCTION

The results of the fetal studies described earlier have important implications for the management of infants found to have severe obstructive nephropathy *in utero*: Prenatal intervention may allow preservation of renal mass before completion of nephrogenesis, as well as improved pulmonary development. The major problem is the lack of accurate prognostic criteria for identification of infants who would benefit from intervention. The primary limiting factor at present is the difficulty in visualizing the developing kidneys by ultrasonography before 18 weeks' gestation (208). In a report of a 10-year experience with prenatal intervention for hydronephrosis, successful vesicoamniotic shunt placement may aid pulmonary development, but does not prevent renal insufficiency (209). Significant technical advances are required to allow the development of a required anatomic definition, as well as the development of reliable functional parameters. Most needed, however, is a

better understanding of the molecular and cellular mechanisms leading to the anomalies themselves. One promising approach is the study of a mouse strain with congenital progressive bilateral UPJ obstruction and hydronephrosis, a characteristic that is inherited as an autosomal recessive trait (210). Identification of the genetic basis for the abnormality may reveal some of the underlying developmental processes.

The lack of reliable markers of significant urinary tract obstruction is a critical issue. The numerous experimental studies showing renal activation of TGF- β 1 in the hydronephrotic kidney may provide an index of obstruction: Urinary TGF- β is increased in children with severe urinary tract obstruction, and the correlation provides 90% sensitivity (211). Suppression of renal EGF is also a hallmark of experimental hydronephrosis, and urinary EGF concentration is markedly reduced in children with severe UPJ obstruction (59).

One of the primary concerns in the management of infants with obstructive nephropathy is the expected recoverability of renal mass and renal function after relief of the obstruction. Temporary UUO in the neonatal rat impairs renal growth proportional to the duration of obstruction before relief (Fig. 55.8) (187). Although relief of obstruction attenuates the renal cellular injury, alterations persist in the renal vasculature, tubules, and interstitium (17). Although relief of obstruction does not reverse a 40% reduction in the number of nephrons, the GFR of the post-obstructed kidney is normal 1 month after relief (17). This suggests that remaining nephrons undergo hyperfiltration. One year after relief of obstruction, GFR is decreased by 80%, and proteinuria has developed (212). Importantly, glomerular sclerosis, tubular atrophy, macrophage infiltration, and interstitial fibrosis are increased not only in the postobstructed kidney but also in the opposite kidney (212). Fibrosis in the opposite kidney may be due in part to the increased renal expression of TGF- β receptors in both obstructed and opposite kidneys after UUO (213). These findings suggest that despite normal early postoperative GFR in infancy, children undergoing pyeloplasty for UPJ obstruction should be followed into adulthood. After relief of 5 days' UUO immediately after the completion of nephrogenesis, renal damage and loss of renal function are even more severe than those after relief of UUO during nephrogenesis (13). This suggests that if significant urinary tract obstruction is diagnosed in the prenatal or neonatal period, its relief should not be delayed.

Timing the relief of obstruction in the postnatal period is complicated by differences in available experimental models. As described earlier, severe partial UUO in the neonatal guinea pig leads to arrested growth of the ipsilateral kidney, which is not improved by relief of obstruction after 10 days (135). This suggests that any delay in relief of neonatal obstruction results in irreversible damage. In contrast, based on studies of the effects of partial UUO in the

neonatal rat, Claesson and associates have concluded that early release of obstruction can prevent the reduction in ipsilateral kidney weight (214,215). However, the reduction in GFR in this model is only 10% when measured 9 to 12 weeks later (216), and the morphologic changes appear to stabilize after 3 weeks of UUO (217). Measurement of renal function by nuclear scintigraphy in rats studied up to 1 year after neonatal UUO reveals a 40% reduction in function and a similar reduction in kidney weight (218). If weanling rats are subjected to partial UUO, the morphologic effects are less severe than those resulting from UUO within the first 2 days of life (219). If partial UUO is delayed even longer (performed at 6 weeks of age), the impairment in GFR is minimal and does not progress over 15 weeks despite the presence of hydronephrosis (220). Thus, in the rat, as in the guinea pig, susceptibility of the kidney to injury from ipsilateral ureteral obstruction decreases with age. In the adult dog, complete recovery of renal function is possible after relief of UUO for 7 days (221). With 2 weeks of obstruction, there is 70% recovery 6 months after relief of obstruction (221). These experiments demonstrate the importance of the duration of obstruction in determining the capacity for recovery.

The dependence of recovery on the degree of obstruction has also been demonstrated in adult rats. Two to 6 weeks after the induction of partial UUO, there is a progressive decrease in the ratio of dry kidney weight to body weight, with the severity of loss of renal mass being proportional to the degree of obstruction (222). Six weeks after relief of obstruction of 8 weeks' duration, no enhancement of growth was observed (222). This indicates that the timing of relief of obstruction is critical, even in the adult.

Whereas all agree that the infant with bladder outlet obstruction should have prompt relief of obstruction, management of unilateral UPJ obstruction is not as clear. A major problem is the variability in the severity of obstruction in these patients and the difficulty in reliably assessing the degree of functional obstruction. Although a large proportion of infants with equivocal hydronephrosis identified prenatally appear to have normal renal functional development without intervention (223), others may demonstrate progressive impairment (224). Peters has, therefore, defined obstruction as "a condition of impaired urinary drainage, which, if uncorrected, will limit the ultimate functional potential of a developing kidney" (225).

The solution to this dilemma depends on improved methods for imaging the developing kidney, as well as more reliable means of monitoring renal function. In view of the exaggeration of renal "counterbalance" in early development, the greater adaptation of intact nephrons may mask the deterioration of obstructed ones, necessitating the accurate measurement of differential renal function. Such advances, along with improved understanding of the mechanisms underlying the renal response to urinary tract obstruction during maturation, should allow intervention

before the development of irreversible changes in remaining nephrons.

Complete urinary tract obstruction has been clearly shown to cause renal deterioration. The natural history of partial urinary tract obstruction in humans is less well defined; however, basic science observations support early surgical intervention over a nonoperative approach when obstruction exists. Although a common radiologic technique such as ultrasonography accurately describes dilation of the upper urinary tract in both the pre- and postnatal settings, it cannot determine mechanical obstruction, which is a functional characteristic. The finding of hydronephrosis, then, can be a clinical challenge to the physician caring for infants and children. The purpose of early detection and accurate diagnosis of upper urinary tract obstruction is to determine which patient may benefit from surgical therapy or, in other words, to determine when dilation of the renal collecting system indicates the existence of worrisome pathology (a process of renal damage or deterioration). It is hoped that the loss of nephrons can be prevented or minimized.

CAUSES OF OBSTRUCTIVE UROPATHY: SPECIFIC CLINICAL DISEASES

Ureteropelvic Junction Obstruction

Classic *ureteropelvic junction obstruction* is defined as congenital hydronephrosis characterized by impaired urine flow from the renal pelvis into the proximal ureter. An intrinsic or extrinsic narrowing or blockage at the UPJ, this lesion causes progressive dilation of the renal pelvis and calyces and the potential for nephron loss. This is a common renal anomaly in children, with an incidence of 1 in 1500, and is the most common cause of hydronephrosis detected prenatally (226,227). It has been classified as extrinsic, intrinsic, or secondary. Historically, it was usual for children to present between 5 and 15 years of age with symptoms of infection, flank pain, abdominal mass, renal nephrolithiasis, or hematuria (Figs. 55.9 and 55.10). Because these children had abnormal imaging studies and were symptomatic, surgery was routinely performed. Today, hydronephrosis secondary to presumed UPJ obstruction is much more commonly detected during prenatal ultrasonography, as is discussed in

FIGURE 55.9. **A:** Seven-year-old girl with a 2-year history of intermittent left flank pain with nausea and vomiting. This intravenous urogram (here, 60 minutes postinjection of contrast) was performed while the patient was actively symptomatic and demonstrates a distended renal pelvis and calyces in comparison to the normal caliber ureter. The ureteropelvic junction (UPJ) is not well delineated. **B:** Left retrograde pyelogram performed several days later in the same patient at time when she was asymptomatic. Note the marked decrease in pelvicaliectasis (relative to the normal caliber ureter), as well as the concentric filling defect at the UPJ, highly suggestive of extrinsic compression. Open exploration with surgical repair later during the same procedure revealed extrinsic compression of the left UPJ due to a lower pole, crossing vessel. Dismembered pyeloplasty was performed.

FIGURE 55.10. Twelve-year-old girl with a history of intermittent left flank pain and nausea. This plain film demonstrates a large, left abdominal opacity that pushes the colon medially. This markedly distended renal pelvis is palpable on physical examination.

Ultrasonography. UPJ obstruction is more commonly found on the left side, occurring in 60%; is more common in males than females (2:1); and occurs bilaterally in lesions in 10 to 40% of affected neonates in some reported series (228–230).

If the lumen of the ureter is narrow at the UPJ either in the presence or absence of ureteral kinking, then the obstruction is generally considered to be *intrinsic*. The ureteral wall is generally characterized by reduced amounts of smooth muscle with excess collagen deposition. Other findings with light microscopy include muscular disorientation, thickened adventitia, and inflammation, although it is not known which is causative of the other—the obstruction versus the histologic changes (231,232). It is also not known whether intrinsic UPJ obstruction is due to incomplete recanalization of the ureter, which begins at 42 days' gestation in the middle of the ureter and continues both distally and proximally, such that the very last parts of the ureter to recanalize are the ureterovesical junction (UVJ) and UPJ. Persistent muscular folds or kinks during recanalization have been described, as well as ureteral polyps and dysfunctional ureteropelvic muscular contractions (233–239).

The resistance to urine flow may cause a relatively constant partial obstruction or one that is intermittent (or flow-dependent). In other words, a particular flow rate may

produce a configurational change at the UPJ that causes increased resistance (240).

If there is a dynamic character to flow across the UPJ, then obstruction may be episodic in nature due to intermittent kinking. This pattern is more commonly seen in older children or even adults, as opposed to classic neonatal UPJ obstruction. If an acute increase in urine output is not well compensated by the renal pelvis anatomically, then acute, transient flank pain with nausea may result. This has been called Dietl's crisis when bilateral (241,242).

Intermittent obstruction may also be caused by proximal ureteral compression by accessory or abnormal lower pole renal vasculature. These *extrinsic* lesions have been described as a compression of the proximal ureter between a crossing vessel and the fixed UPJ or a flattening of the ureter as it passes over a crossing vessel (233,243).

In high-grade vesicoureteral reflux (VUR), a very tortuous and dilated ureter may obstruct proximally, secondary to kinking—a phenomenon called *secondary UPJ obstruction*. VUR has been reported in 15% of children with UPJ obstruction; however, the percentage of those children in whom the upper tract obstruction is directly caused by the reflux is not clear (244–246).

Surgical repair of UPJ obstruction is an effective procedure with success rates of more than 90% and with low complication rates. Whereas some pediatric urologists approach the UPJ from the patient's flank, others approach more posteriorly via a dorsal lumbotomy incision. At the time of reconstruction, the diseased segment is excised (or transected and brought to the opposite side of the obstructing, crossing vessel), and the pelvis and spatulated ureter are reanastomosed. The redundant renal pelvis may also be trimmed, if necessary. To date, endoscopic (retrograde endopyelotomy) and percutaneous treatment of UPJ obstruction has been better established in adults than in children.

Ureterovesical Junction Obstruction

Ureterovesical junction obstruction is also an obstructive lesion of the ureter; however, it is characterized by pathology where the distal ureter meets the bladder. UVJ obstruction may be a primary process, or it may be a secondary process due to extrinsic compression of the ureter by a thickened bladder wall from other diseases, such as posterior urethral valves (PUVs) or neurogenic bladder dysfunction. UVJ obstruction has commonly been called an *obstructed megaureter*. Congenital megaureter is just that, a dilated ureter, and it accounts for approximately 20% of cases of hydronephrosis in the newborn. Its types include nonrefluxing-nonobstructed (idiopathic), refluxing-nonobstructed, nonrefluxing-obstructed, and refluxing-obstructed.

Obstructed megaureter is thought to be due to an abnormality in the distal ureteral muscle that causes an aperistaltic segment. UVJ obstruction may share a similar etiology with UPJ obstruction, and spontaneous improve-

ment has been observed in both diseases, suggesting a maturational process in peristaltic function (247,248).

Ultrasonography may detect the presence of upper tract dilation in UVJ obstruction; however, additional studies are required to determine its etiology and importance, as outlined in Posterior Urethral Valves. If the UVJ obstruction is thought to be secondary to other diseases, such as PUV, VUR, or neurogenic bladder dysfunction, then treatment is directed toward the underlying cause. If obstruction is present, then surgical treatment is directed toward removing the aperistaltic lower ureteral segment, tapering the dilated distal ureter, and reimplanting the tailored ureter back into the bladder in an antirefluxing manner.

Posterior Urethral Valves

Posterior urethral valves are obstructing membranous folds within the lumen of the prostatic (posterior) urethra. They occur only in male infants and are the most common congenital cause of bladder outlet obstruction. PUV account for approximately 10% of cases of hydronephrosis in the newborn (249). The incidence of PUV has been estimated to be approximately 1 in 5000 to 8000. The pathophysiologic effects of lower urinary tract obstruction on the developing kidney are similar to those of upper tract obstruction; however, congenital bladder outlet obstruction can have immediate life-threatening consequences, as well as long-term, deleterious effects on both renal and bladder function.

There is no known genetic or familial predisposition toward the development of PUV, and their etiology has not been established. Some authors have theorized that the wolffian ducts in patients with PUVs have integrated abnormally into the prostatic urethra, which develops from the urogenital sinus by the eighth week of life (250).

PUVs typically appear as two thin leaflets running between the urethral floor and roof, causing a high-grade obstruction. Elevated pressures are transmitted to the kidneys as the developing bladder becomes thickened, trabeculated, and noncompliant as it carries out high-pressure work to empty. Normal bladder cycling does not occur, which may result in oligohydramnios prenatally. Elevated voiding pressures cause dilation of the posterior urethra and distortion of the bladder neck. The noncompliant bladder transmits elevated pressures to the renal parenchyma during filling and urine storage. Upper tract findings include pelvicaliectasis, ureterectasis, urinary stasis, parenchymal compression, and renal dysplasia. Bilateral hydroureteronephrosis may be present with or without high-grade VUR. Elevated upper tract pressure may cause urinary extravasation from a fornical rupture resulting in a retroperitoneal urinoma or urinary ascites, if urine crosses the peritoneum. It is believed that pop-off mechanisms that relieve bladder pressure, such as VUR, may have a protective effect on renal function (251,252). It has been observed that contralateral renal function is preserved in patients with unilateral reflux

into a nonfunctioning kidney, and this has been called the *VURD syndrome* (*valves, unilateral reflux, renal dysplasia*). Bladder diverticulae and renal urinary extravasation are less commonly occurring pop-off mechanisms than VUR.

The majority of patients with PUV are diagnosed prenatally, which permits treatment of the obstruction in the first few days of life; however, there is a wide clinical spectrum of progressive renal failure depending on the degree of *in utero* obstruction and bladder dysfunction. Some infants are diagnosed postnatally with conditions of respiratory distress (secondary to pulmonary hypoplasia from oligohydramnios), sepsis, azotemia, failure to thrive, or abdominal distention. The presence of a distended, palpable bladder may suggest PUV, as well as the failure to void in the first 24 hours of life or an abnormal urine stream. A good urine stream, however, does not rule out PUV. A tense abdomen may suggest the presence of urinary ascites or markedly hydronephrotic upper tracts. A voiding cystourethrogram (VCUG) is necessary to make the diagnosis of PUV before surgical intervention, with typical radiologic findings of a thick-walled, trabeculated bladder; an elongated, dilated posterior urethra; and an elevated bladder neck (Fig. 55.11).

FIGURE 55.11. One-day-old boy with a history of bilateral hydroureteronephrosis and a thickened bladder wall detected prenatally. This voiding cystourethrogram demonstrates a markedly thickened and trabeculated bladder wall with dilation of the posterior urethra secondary to posterior urethral valves. A 5 French feeding tube was placed per urethra, and the boy was taken to the operating room before discharge for cystoscopy and transurethral resection of the valves.

Older boys have been diagnosed with PUV during a workup for urinary tract infections or symptoms such as frequency, daytime incontinence, and straining to void. These symptoms may be a result of bladder wall thickening, decreased detrusor compliance, or a renal concentrating defect with polydipsia and polyuria.

Once the diagnosis of PUV is suspected or made, initial management includes treatment of acute illness (respiratory distress, sepsis, dehydration, electrolyte abnormalities) and temporary drainage of the urinary tract with a small urethral catheter, such as a 5 French feeding tube. A Foley catheter is not recommended, as the balloon may fall back into the dilated posterior urethra, preventing the bladder from draining completely. Ultrasonography can confirm proper position of the urethral catheter in the bladder. Serial serum creatinine measurements over 7 to 10 days of total bladder decompression define the preoperative creatinine nadir before primary endoscopic ablation of the valves. Creatinine levels in the first few days of life reflect maternal levels. Secondary obstruction at the UVJ may coexist because of severe bladder thickening, and this may be reflected by persistent azotemia or sepsis despite adequate bladder decompression. Temporary supravescical urinary diversion (cutaneous ureterostomies) may then be required. A cutaneous vesicostomy may be required if the caliber of the urethra is too small for endoscopic ablation of the PUV.

Many patients with PUV have significant lower urinary tract dysfunction (incontinence) or worsening hydronephrosis despite successful primary valve ablation. Loss of bladder compliance, incontinence, and deterioration of renal function with poor renal concentrating ability are all part of a spectrum of the *valve bladder syndrome*. Long-term urodynamic follow-up as well as upper tract surveillance are required to ensure preservation of renal function, avoidance of infection, compliant low-pressure urine storage, and urinary continence. Whereas some authors have described a poor outcome (renal failure) with late presentation of PUV, others have demonstrated that a presentation before 1 year of age is a poor prognostic sign, as well as bilateral VUR at that time or incontinence after the age of 5 years (253–257).

DIAGNOSIS OF OBSTRUCTIVE UROPATHY

A diagnosis of obstructive uropathy is investigated further when hydronephrosis or hydroureteronephrosis is discovered on ultrasonography during either routine prenatal screening or during a clinical workup postnatally for the child with flank pain, hematuria, an abdominal mass, urinary tract infection, or incontinence. Hydronephrosis is the most common congenital condition that is detected by prenatal ultrasound and represents 50% of all abnormalities. Patients with imperforate anus, contralateral multicystic dysplastic kidney, congenital heart disease, VATER (*v*ertebral, *a*nus, *t*racheo*e*sophageal, *r*adial and renal) syndrome, or esophageal atresia should be screened with a renal ultrasound to rule out associated hydronephrosis.

Ultrasonography

Initial prenatal sonography is usually performed between 16 and 20 weeks of gestation. Approximately 20% of abnormalities evident *in utero* are not present after birth (258). When prenatal hydronephrosis is detected, the degree of dilation is calculated by measuring the anteroposterior diameter of the renal pelvis in the transverse plane of the kidney and is correlated with the current gestational age. Although there is no generally agreed-on definition of prenatal hydronephrosis, persistent postnatal renal abnormalities have been described when the anteroposterior diameter of the fetal renal pelvis measures greater than 6 mm at less than 20 weeks, greater than 8 mm at 20 to 30 weeks, and greater than 10 mm at more than 30 weeks of gestation (259). Prenatally or postnatally, the ultrasonographer should determine not only the degree of dilation but also whether it is unilateral or bilateral, if the ipsilateral ureter is dilated, and if the contralateral kidney is normal (parenchyma echotexture, presence of cystic disease). Prenatally, amniotic fluid volume is quantified carefully, because oligohydramnios can determine prognosis. Fetal urine comprises up to 90% of the amniotic fluid, and its contribution progressively increases from 16 to 20 weeks of gestation. The bladder of the fetus or child is imaged to assess its thickness, distention, and ability to empty. Lesions within the bladder, such as ureterocele, are assessed, as well as relevant lesions of other organ systems, such as spinal dysraphism. The gender of the fetus or child is also important to determine, because many congenital abnormalities causing hydronephrosis have a strong gender association, as most of the obstructive urologic malformations occur in males, with a male to female ratio of 3 to 4:1 (260). Duplication anomalies and ectopic ureterocele are more common in females.

Obstructive and nonobstructive processes can both cause dilation of the urinary tract. In the prenatal setting, obstructive etiologies include UPJ obstruction (44%), UVJ obstruction (21%), multicystic dysplastic kidney, ureterocele/ureteral ectopia, duplex kidney (12%), PUV (9%), urethral atresia, sacrococcygeal teratoma, and hydrometrocolpos. Nonobstructive etiologies include VUR (14%), physiologic dilation, prune belly syndrome, renal cystic disease, and megacalycosis (congenitally dilated calyces without pelviectasis and obstruction) (260).

On ultrasound, UPJ obstruction is characterized by pelvicaliectasis, no ipsilateral ureteral dilation, and normal bladder thickness and emptying. Measuring bladder thickness can differentiate potential PUV from megacystis or megaureter. The most important diagnosis to be made prenatally is PUV in the male fetus, because, as described earlier, surgical correction is needed in the early postnatal period (and in select cases may even be indicated prenatally). If the ipsilateral ureter is visualized (and therefore by definition is dilated) and pelvicaliectasis detected, then the following diagnoses are considered: VUR, PUV, megaureter, or ureterocele/ectopic ureter. Hydroureteronephrosis in the male with a thin-walled bladder and normal renal parenchyma is most likely not PUV but rather VUR.

Unilateral or bilateral hydronephrosis with a trabeculated/thick-walled bladder and abnormal renal parenchyma (hyperechoic, cystic changes), with or without oligohydramnios (prenatal setting) in the male, is PUV until proven otherwise with a cystogram. If a ureterocele is visualized in the bladder and/or there is asymmetric upper pole caliectasis, then a duplication anomaly is suspected (261).

Renal duplex Doppler ultrasonography can be used to calculate the renal resistive index (RI). It is hypothesized that measuring changes in intra-RBF can distinguish between obstructive and nonobstructive hydronephrosis (262). The addition of furosemide to the Doppler protocol may help further discriminate between obstructive and nonobstructive hydronephrosis (263). An RI equal to or greater than 1.1 as well as an RI difference with furosemide diuresis of 70% or more are both Doppler sonographic variables that may correlate with obstruction (264). However, the use of the RI to determine obstruction is limited due to variability in technique, interpretation, and established normal variables of infants and children.

Ultrasonography, then, can correctly identify hydronephrosis, and specific findings of increased echogenicity, severe calyceal dilation, contralateral hypertrophy, or ipsilateral parenchymal loss can be worrisome for potential obstruction. However, physiologic assessment is not possible until functional studies are performed, typically with excretory urography or renography.

Excretory Urography

The intravenous urogram is an excellent study for evaluation of the older child with intermittent flank pain; however, it is most useful when performed while the child is symptomatic (Fig. 55.9A). Pelvicaliectasis with delayed excretion of contrast and poor visualization of the ipsilateral ureter are findings consistent with UPJ obstruction, especially when compared to a normal intravenous urogram or ultrasound performed when the child is asymptomatic. The finding of a delayed nephrogram may be consistent with obstruction; however, when excretion and antegrade flow are prolonged, then delayed imaging is necessary to visualize the ureter and its caliber to distinguish a UVJ lesion versus one at the UPJ. Obtaining postvoid views can help rule out bladder dysfunction as a contributing factor to the columnation of contrast, especially when a lesion at the UVJ is suspected. Urography can be a superior modality in preparation for surgery—when it is necessary to clarify complex anatomy—particularly in duplication anomalies.

Nuclear Renography

Nuclear medicine renal scans are more commonly used than urography as the method of choice to diagnose obstruction in the setting of hydronephrosis. Renography can quantitate individual and relative renal function, cortical transit time,

and the antegrade drainage of the collecting systems before and after the administration of furosemide. Functional nuclear medicine studies are best performed after 1 month of age when renal concentrating ability has matured. The radiopharmaceuticals used include technetium-99m diethylenetriamine pentaacetic acid and mercaptoacetyl triglycerine (MAG-3), and a bladder catheter should be inserted for the test, especially if VUR is present.

Obstruction at the UPJ or UVJ is reflected by the half-time to washout of radioisotope-labeled urine and percentage of tracer retained within the renal pelvis or distal ureter beyond approximately 20 minutes (Fig. 55.12). In the hydronephrotic system, if the washout is quick after the furosemide is given, then the patient is said to have a dilated, nonobstructed system. Prolonged washout times in otherwise satisfactorily functioning kidneys may support the diagnosis of physiologically significant obstruction; however, no gold standard for obstruction exists. Some reports have described stable renal function despite impaired drainage on renography in some infants with hydronephrosis; however, this is not well established (265).

Upper Tract Urodynamics: Whitaker Test

Whereas imaging modalities such as ultrasonography and renography delineate the renal effects of impedance to urine flow, upper tract urodynamic studies demonstrate the pressure-flow characteristics of the upper urinary tract collecting system itself. The pressure changes described by antegrade perfusion pressure-flow studies (Whitaker test) are dependent on the compliance (the change in volume or flow over the change in pressure) and capacity of the renal pelvis, as well as the degree of outlet resistance. For this reason, upper tract urodynamic studies can be helpful in measuring the response of the renal pelvis to distention in equivocal cases of UPJ obstruction. Percutaneous access of the hydronephrotic renal collecting system is obtained, and perfusion of the kidney at a flow rate to mimic diuresis (10 mL/min) is performed. Pressures greater than 22 cm H₂O have been called obstructive, and those less than 15 cm H₂O have been described as nonobstructive, with a gray area in between (266–268). Because this flow rate may not be physiologic and because UPJ resistance changes as the pelvis distends, the traditional Whitaker test is somewhat limited. Great advances have been made to standardize urodynamics and to define obstruction in the hydronephrotic upper urinary tract; however, these studies are not able to predict future improvement or deterioration in function (269–272).

Cystography

Cystography is typically performed to rule out VUR and/or PUV. In the infant the study, it is usually accomplished through retrograde bladder filling via a 5 French feeding tube or similar Foley catheter. In general, a feeding tube is prefera-

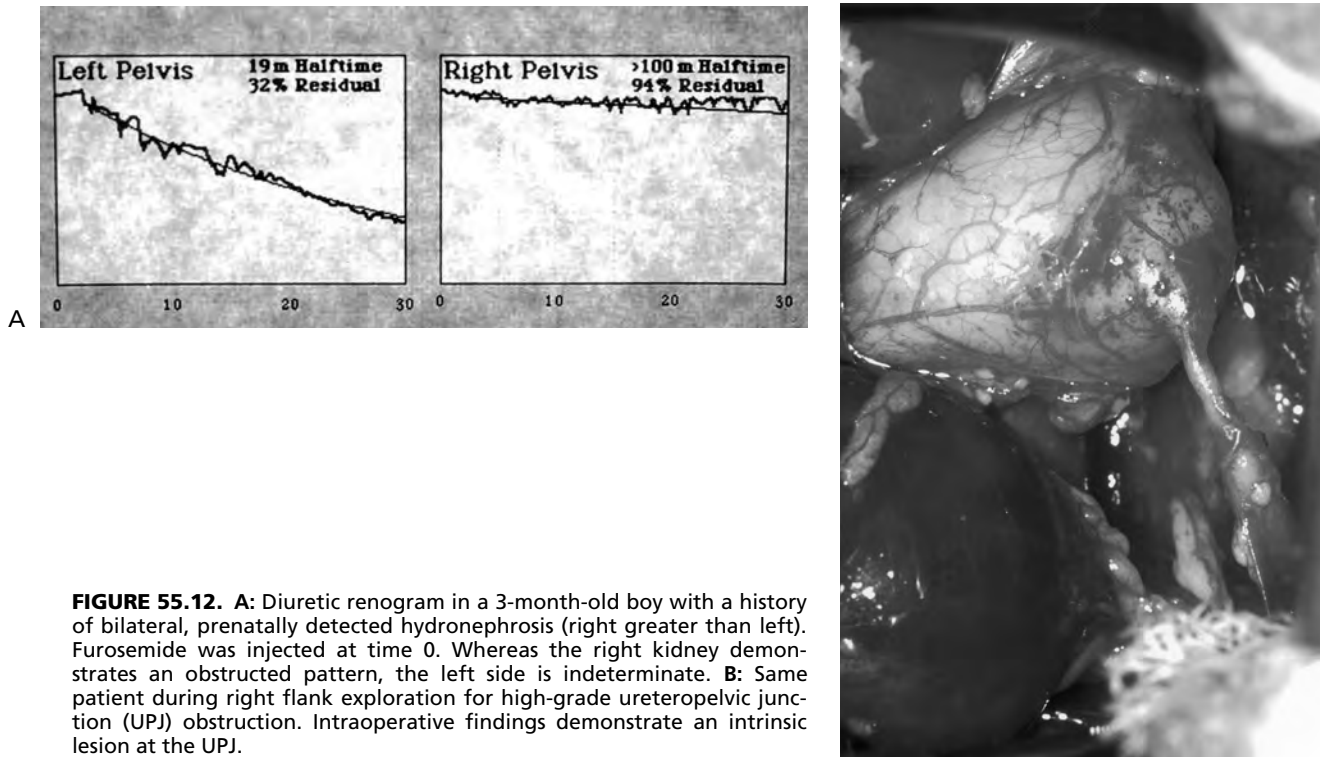

FIGURE 55.12. A: Diuretic renogram in a 3-month-old boy with a history of bilateral, prenatally detected hydronephrosis (right greater than left). Furosemide was injected at time 0. Whereas the right kidney demonstrates an obstructed pattern, the left side is indeterminate. B: Same patient during right flank exploration for high-grade ureteropelvic junction (UPJ) obstruction. Intraoperative findings demonstrate an intrinsic lesion at the UPJ.

ble, because it is less likely to obscure the diagnosis of a ureterocele. Cyclical filling and emptying of the bladder is necessary to distend the bladder and urethra (to rule out PUV) or to visualize VUR (when an ectopic ureter to the bladder neck or urethra refluxes only with cycles of voiding). If there is high-grade VUR, then the bladder may not fully distend until refluxed contrast drops back down. In this situation, obtaining delayed views may visualize antegrade flow across the UPJ and UVJ, which may help distinguish an obstructive component to the hydronephrosis.

Retrograde Pyelography

If the anatomy of the distal ureter has not been defined in the workup for UPJ obstruction, then cystoscopy with a retrograde pyelogram can be performed at the time of open surgical correction to determine the location and length of the obstruction (Fig. 55.9B). This helpful technique can exclude distal ureteral disease, but it should only be performed in conjunction with upper tract surgery for fear of introducing lower urinary tract bacteria into an obstructed or partially obstructed system.

MANAGEMENT OF OBSTRUCTIVE UROPATHY

Although hydronephrosis is not necessarily equivalent to obstruction (a process of potential renal deterioration), neither is it a normal finding (273). There is great interest,

then, in the prognostic significance of findings associated with hydronephrosis. Various studies have proposed the factors that independently predict an adverse outcome. One report followed prospectively 148 children with a history of prenatal hydronephrosis for a mean of 39 months. Oligohydramnios, prematurity, and postnatal GFR lower than 20 mL/min were independent predictors of chronic renal failure by multivariate analysis (274). In a second multivariate study of prenatal hydronephrosis, oligohydramnios and megacystis (distended bladder) were highly predictive of fetal urethral obstruction on postnatal follow-up (275).

A pediatric urologist should evaluate and follow the infant with a history of prenatal hydronephrosis or the child with a history of flank pain, gross hematuria, nephrolithiasis, or febrile urinary tract infection. The physical examination is usually normal, and most of these children with unilateral hydronephrosis and a contralateral normal kidney appear entirely healthy.

Evaluation with VCUG, radionuclide imaging, and/or excretory urography further characterize the abnormality detected by ultrasound, as described earlier. Initial postnatal imaging includes ultrasonography in the first week of life to confirm the prenatal diagnosis if bilateral hydronephrosis was detected and at 3 to 4 weeks if unilateral hydronephrosis was noted prenatally. Follow-up prenatal ultrasonography is shown to give some false-negative results, thus supporting the need for postnatal scanning (276). Early postnatal dehydration and oliguria (first 24 to 48 hours of

FIGURE 55.13. A: Renal ultrasound on day of life number 1 for this term boy with a history of prenatally detected, right hydronephrosis. Note the severe pelvicaliectasis. The ipsilateral ureter is not visualized and, therefore, by definition, not dilated. B: Same patient on day of life number 4 after a period of rehydration. Note the marked increase in dilation of the pelvis and blunting of the calyces, as well as thinning of the renal cortex.

life) may transiently mask the high-grade lesion in moderate to severe hydronephrosis (Fig. 55.13). Therefore, a normal or moderately abnormal ultrasound performed within the first 2 to 3 days of life for an infant with a history of higher-grade prenatal hydronephrosis may give a false sense of security and will need to be repeated after adequate rehydration. An immediate cystogram is performed in any infant with suspected bladder outlet obstruction before discharge from the hospital. In males, the most important early diagnosis to be made is PUV, because catheter drainage is necessary. In females, an obstructing ectopic ureterocele may need to be ruled out. Prenatal bladder outlet obstruction secondary to ureterocele requires early postnatal endoscopic decompression; however, the affected upper tract renal pole may not necessarily be salvaged (277).

All infants or children with hydronephrosis are placed on antibiotic prophylaxis pending the outcome of further evaluation. An infection in the setting of ureteral obstruction can cause significant morbidity in the uroseptic infant, and renal damage is a potential comorbidity. Oral amoxicillin (10 mg/kg/day) is the most commonly used prophylactic antibiotic. Trimethoprim-sulfamethoxazole, however, is not used in the early postnatal setting, because the neonate has only limited ability to metabolize the drug by acetylation in the liver.

When to obtain postnatal VCUG with a history of prenatal hydronephrosis is controversial, with some authors recommending VCUG in all infants and others only when there is bilateral hydronephrosis, ureteral dilation, or variable hydronephrosis (278–280). If VUR is noted, then antibiotic prophylaxis is started or continued with appropriate radiologic follow-up. Approximately 10 to 15% of prenatal cases of hydronephrosis result in the postnatal diagnosis of VUR. The majority of these infants are boys with bilateral, high-grade disease, and early circumcision has been hypothesized

by some authors to decrease the incidence of breakthrough urinary tract infection in this subpopulation (278).

Because the natural history of prenatal hydronephrosis due to UPJ or UVJ obstruction remains to be well defined, it can be difficult to know whether to intervene surgically to potentially maximize renal function or to observe and allow for spontaneous resolution of hydronephrosis without risking normal renal growth and development. Some have argued that 85% of infants with prenatally detected hydronephrosis do not have a true obstruction (but rather a temporary physiologic impedance) and do not require surgery, as they will improve spontaneously (281,282). However, there are no prospective randomized studies comparing operative and nonoperative treatments of UPJ obstruction for comparable degrees of hydronephrosis. There are longitudinal follow-up studies on prenatal hydronephrosis that allow for crossover from observation to surgery when relative renal function is reduced by 10% or more or symptoms of UPJ obstruction occur. In one review of 321 patients with prenatal hydronephrosis, surgery did not significantly improve renal function in those with both UPJ obstruction and abnormal preoperative renal function (defined by decreased relative function on nuclear renography). However, in those patients with prenatal UPJ obstruction managed with observation alone, there was a small but significant risk of a modest loss of renal function as measured by MAG-3 (283). Overall, in series taking a nonoperative approach to patients with good initial relative renal function, a 25% crossover to surgery over long-term follow-up has been recognized.

It has been argued that renal function does not improve regardless of the initial level of relative renal function (284). A second study has concluded that poor renal function may not improve after obstruction is relieved (285).

Other authors, however, recommend early surgical treatment to prevent obstructive damage to the immature infant kidney, because better recovery of function may be possible when surgery is done in the first year of life (286,287). Furthermore, it has been shown in another series that only 18% of patients with obstructive parameters on nuclear renography resolved with conservative management (288). Concerns about conservative management are also raised in a review of 121 children in which renal function did improve in those undergoing early surgery but less so in those who were initially observed before surgery (289). Chertin et al. have described significant improvement in hydronephrosis and nuclear renography parameters in all 113 patients undergoing surgery for UPJ obstruction detected prenatally (290). These observations support early surgical intervention over a nonoperative approach for UPJ obstruction.

The long-term morbidity of mild hydronephrosis (pelviectasis without calyceal dilation) is low—rarely is surgery required. Moderate hydronephrosis (dilated pelvis and calyces without parenchymal thinning) may be associated with gradual improvement in severity of dilation and drainage parameters, without loss of relative renal function. It is severe hydronephrosis (pelvic dilation, calyceal blunting, and parenchymal thinning) that commonly requires surgical intervention for declining renal function, infection, or symptoms.

LONG-TERM FOLLOW-UP

The long-term prognosis for infants and children with congenital obstructive nephropathy is poorly defined. Unfortunately, many children undergoing pyeloplasty for UPJ obstruction and found to have a satisfactory immediate postoperative course are lost to follow-up after several years. In light of the experimental evidence, as well as the limited clinical data available, it is likely that some of these patients will eventually develop proteinuria, hypertension, or chronic renal insufficiency. The prognosis for children with PUV is more grim: A majority of patients diagnosed in fetal or neonatal life develop renal insufficiency by age 10 years (291,292). At a minimum, all children with obstructive nephropathy should have regular measurement of blood pressure, plasma creatinine, urinalysis, and periodic renal ultrasound. Every attempt must be made to maintain normotension and to minimize proteinuria. Nonsteroidal antiinflammatory drugs should be avoided. In the transition of care from pediatrician to internist, this follow-up should be maintained throughout adulthood.

BLADDER DYSFUNCTION

DAWN L. McLELLAN
STUART B. BAUER

INTRODUCTION

Physiology of Bladder Function

The function of the bladder is to store urine at low pressure and empty efficiently at a socially acceptable time. This complex process involves integration of activity from the brain, brainstem, spinal cord, detrusor muscle, and external urinary sphincter. The detrusor muscle is composed of relatively large, interlacing smooth muscle fibers in three layers—the outer longitudinal, the middle circular, and the inner longitudinal—that surround the mucosa and submucosa (1). At the level of the bladder neck in males the middle circular layer forms an incomplete ring of the internal (or preprostatic) sphincter mechanism. There is no actual internal sphincter muscle per se, but the smooth muscle arrangement around the bladder neck and proximal urethra act as such. This layer is not prominent in females (1). The external (or voluntary) urinary sphincter in both sexes is composed of smooth and skeletal muscle (2). It is located just distal to the prostate in males and at the midurethra in females.

The innervation of the bladder and sphincter mechanisms is via the autonomic and somatic nervous systems. The somatic input originates from the Onuf nucleus in the anterior horn of the S2 to S4 segments of the spinal cord (3) and travels via the pudendal nerve to the skeletal muscle component of the external urethral sphincter (4). The neurotransmitter acetylcholine provides excitatory stimulation to muscarinic receptors of the external urinary sphincter. In the filling phase, this enables tonic contraction of the external sphincter to keep the bladder outlet closed and aids in the maintenance of continence (2). The primary excitatory input to the bladder that causes a detrusor contraction and a rise in intravesical pressure is the parasympathetic nervous system. The preganglionic parasympathetic input originates at spinal levels S2 to S4 and travels via the pelvic splanchnic nerves (3). The primary neurotransmitter of the parasympathetic system is acetylcholine. Its effect is mediated by the muscarinic receptors of postganglionic nerve fibers distributed primarily in the fundus of the bladder wall (5).

The sympathetic nervous system input to the bladder originates from spinal cord levels T10 to L2. Postganglionic sympathetic fibers originate from the paravertebral ganglia as the superior hypogastric plexus, which becomes the right and left hypogastric nerves. The hypogastric nerves blend with the pelvic parasympathetic nerves to form the pelvic plexus (3). Both α and β receptors play a role in the sympathetic input to the bladder, which facilitates bladder storage (6). The β receptors are distributed predominantly over the fundus of the bladder. Release of the neurotransmitter norepinephrine permits relaxation of the detrusor muscle, which allows accommodation of increasing volumes of urine at low pressure. Stimulation of α receptors located almost exclusively at the trigone, bladder outlet, and proximal urethra causes contraction of these smooth muscles (3,6,7), which results in an increase in bladder outlet resistance and thus promotes urine storage and continence.

Coordination of the autonomic and somatic systems to facilitate urine storage and voiding is mediated via the central nervous system. The details of this system are not yet fully understood. It is known that multiple areas of the brain play a role, including the brainstem, hypothalamus, cerebellum, and frontal and parietal lobes of the cerebral cortex (8–10). Within the brainstem, the pontine micturition center plays a crucial role in normal bladder function (5,11).

During bladder filling, sympathetic outflow via the hypogastric nerves promotes relaxation of the majority of bladder muscle bundles through stimulation of β receptors and contraction of the bladder neck mechanism via stimulation of α receptors (12). The guarding reflex causes activation of the striated muscle of the external sphincter (13) through pudendal nerve efferents. This reflex arc is active in response to sudden increases in abdominal pressure (i.e., coughing, Credé maneuver, or Valsalva maneuver) and becomes maximal at bladder capacity, which promotes continence.

Micturition is a reflex initiated by myelinated A-fiber receptors in the mucosa and submucosa of the bladder (14). These free nerve endings act as mechanoreceptors, activated by bladder stretch with low pressure thresholds (≤ 10 mm Hg). They may also function as chemoreceptors because they

are activated by intravesical instillation of noxious agents (15), although unmyelinated C fibers are thought to be the predominant pathway for afferent noxious stimuli (16). The normal micturition reflex elicited by A-fiber afferents is initially lost in cats with a suprasacral transection of the spinal cord. A spinally mediated bladder micturition reflex gradually returns, but it is elicited by C fibers (14).

Bladder stretch activates A-fiber mechanoreceptors in the bladder mucosa. This signal travels to the spinal cord via afferents within the pudendal nerve. Ascending pathways in the lateral spinothalamic tract relay the signal to the pontine micturition center, where it is modulated by descending input from higher, cerebral centers. Descending signals from the pontine micturition center then cause inhibition of the pudendal motor neurons, inhibition of the sympathetic outflow to the bladder, and stimulation of the parasympathetic outflow via the pelvic nerve, which results in a coordinated relaxation of the bladder neck mechanism and external sphincter along with a sustained detrusor contraction leading to low-pressure voiding (12,17).

Development of Urinary Control

A standard pattern is seen for the attainment of urinary and bowel continence. Normally, children achieve nighttime bowel control first, followed by daytime bowel control, then daytime urinary control, and finally nighttime dryness (13). The age at which children attain urinary continence is variable, ranging from 2 to 4 years of age for daytime control (10,18). Eighty-five percent of children have achieved continence at night by age 10 years (13). Cultural differences are known to exist in this achievement and in parental expectations for attainment of developmental milestones (19).

Within an individual there is great variation in the normal voiding pattern with respect to frequency of micturition, volume voided, and postvoid residual urine volume (PVR) (20–22). The infant normally voids approximately once per hour (20,22,23). This frequency gradually decreases with increasing age to 11 voids per 24 hours at age 3 years (23,24). Infants and children are known to empty their bladders almost completely, with minimal PVRs (20,25,26). Bladder capacity is known to increase with age (23,24,26–28). Several formulas have been developed to estimate normal bladder capacity based on age (27,28). For example, for children younger than 2 years of age, the estimated bladder capacity can be calculated by the following equation: $2 \times \text{age (years)} + 2 = \text{capacity (ounces)}$. For children older than 2 years of age, the following equation is used: $\text{age (years)} / 2 + 6 = \text{capacity (ounces)}$ (27).

In the past, voiding in the infant was believed to be automatic and uninhibited, a reflex initiated by a specific bladder volume confined to the level of the sacral spinal cord without cortical input. The development of urinary control was thought to be related to maturation of neural pathways (10,18,29). Animal studies have demonstrated the plasticity and maturation of the neural pathways responsible for mic-

turition (30–32). More recent studies of childhood micturition patterns challenge the concept of uninhibited infant voiding unmodified by higher cortical input. Specifically, the demonstration that infants void while awake or during arousal from sleep and never during quiet sleep is evidence of cortical arousal in response to bladder distension (33). It is suggested that the pathways between the peripheral and central nervous systems are well formed at birth, and the development of voluntary control represents a modification of preexisting reflexes (33). Further support is lent to this theory by the demonstration of a higher proportion of fully awake voiding in normal neonates than in premature infants (34). Also supporting this concept is the stepwise decrease in the percentage of interrupted voiding episodes. Interrupted voiding is thought to be a discoordination between the sphincter and detrusor, and is demonstrated in 58% of premature infants (34), 33% of infants 3 months of age, and rarely after 2 years of age (23). The demonstration that voiding pressures in infants are not excessive (23,26,35) and that the bladder wall in normal infants is not thickened (36,37) further substantiates the theory that higher cortical input plays an important role in the voiding reflex of neonates.

Voiding Dysfunction

Voiding dysfunction is an all-encompassing term used to describe abnormalities of the micturition cycle. It may refer to structural or functional causes of abnormal bladder storage and emptying. Normal bladder function requires accommodation by the detrusor of increasing volumes of urine at low pressure with normal sensation, a closed bladder outlet despite increases of abdominal pressure, and the absence of involuntary bladder contractions (38). Therefore, any alteration of bladder compliance or detrusor storage function, innervation of bladder or sphincter mechanisms, or structural changes of the bladder or bladder outlet could result in voiding dysfunction. The symptoms of voiding dysfunction include urgency and urge incontinence, daytime and/or nighttime incontinence, urinary frequency, painful voiding, straining with urination, and urinary tract infection (UTI). The possible causes of voiding dysfunction in children, which will be discussed in detail, are listed in Table 56.1.

In summary, the complex motor and neuronal pathways responsible for micturition are most likely present in infancy but undergo maturation in the early childhood years. Most children attain the ability to voluntarily void by the age of 4 years. However, the age at which continence is achieved, as well as the voiding pattern, varies greatly among individuals and in part is influenced by culture. Over time, the voiding frequency decreases and the bladder capacity increases. The causes and symptoms of voiding dysfunction are diverse. Appropriate evaluation of these disorders will rule out any significant abnormalities that require intervention while minimizing harm from invasive investigations in the pediatric patient.

TABLE 56.1. CAUSES OF DYSFUNCTIONAL VOIDING IN CHILDREN

Neurogenic bladder dysfunction
Neurospinal dysraphisms
Myelodysplasia
Lipomeningocele and other spinal dysraphisms
Sacral agenesis
Associated conditions—imperforate anus
Central nervous system insults
Cerebral palsy
Traumatic injuries to the spine
Nonneurogenic bladder dysfunction
Nonneurogenic neurogenic bladder
Unstable bladder
Infrequent voiding syndrome
Functional bowel disturbances
Daytime urinary frequency syndrome

EVALUATION OF VOIDING DYSFUNCTION

Some advocate a thorough evaluation of all children with voiding symptoms by means of invasive testing such as cystoscopy and urodynamic and radiographic studies (39,40). However, most accept that a more selective approach is warranted in children who do not have continuous day and night symptoms, anatomic anomalies, neurologic abnormalities, or UTI because of the very low incidence of significant pathology in these patients (41). This selective approach usually includes taking a thorough history, including prenatal, perinatal, and early postnatal information, a physical examination, and urinalysis with culture (42–44). The urine should be checked for abnormal specific gravity and glycosuria to exclude diabetes insipidus and diabetes mellitus, respectively. It is crucial that UTI (often an insidious issue) is excluded as the cause of the voiding dysfunction (45). A history of UTI in a young boy or a girl should be evaluated by a voiding cystourethrogram (VCUG) (males) or nuclear cystography (females) to rule out vesicoureteral reflux (VUR) or another anatomic abnormality (44). Renal ultrasonography should be performed to detect possible congenital causes of obstruction of the urinary tract presenting with UTI. A plain radiograph of the abdomen (kidneys, ureters, and bladder) will reveal evidence of chronic stool retention (46), which indicates a dysfunctional elimination syndrome, and should be obtained when history or symptoms warrant it. Boys with persistent daytime and nighttime wetting with or without UTI or with elevated voiding pressures and hyperreflexia noted on urodynamic studies must have a VCUG to evaluate for posterior urethral valves (47,48).

History and Physical Findings

A complete history should begin with details of the mother's pregnancy and the perinatal period, including insulin-dependent gestational diabetes, prematurity, fetal distress leading to emergency cesarean section, neonatal

anoxia, infection, seizures, traumatic birth, birth injury, or respiratory distress requiring pulmonary assistance and/or oxygen administration. Any family history of renal or urologic abnormalities should be elucidated.

The history should be tailored to the age of the patient. For an infant, the number of wet diapers per day and the interval between changes should be detailed. The characteristics of the urinary stream should be noted. Does the infant seem to strain to void or is there constant dribbling of urine? A history of chronic genital dermatitis may also be important for evaluating the possibility of an ectopically placed ureteral orifice. For children of toilet-training age or older, the frequency of voiding and volume voided provide crucial information. A voiding and bowel-emptying diary completed with the assistance of the parents over several days may be the best way to obtain this information. The occurrence of daytime or nighttime incontinence should be detailed with respect to onset, duration, and frequency. Symptoms of urinary frequency or urgency should be documented. Use of a Valsalva or Credé maneuver to void with or without a poor urinary stream may indicate obstruction or a neurologic cause of voiding dysfunction. Postvoid wetting in girls without any nighttime incontinence suggests vaginal trapping of urine during voiding. In females, a normal voiding pattern associated with continuous wetting may indicate the presence of an ectopic ureter that inserts distal to the urethral sphincter. This diagnosis is corroborated by renal ultrasonographic findings of a dilated upper-pole collecting system and a dilated ureter extending behind the bladder beyond the bladder neck. Specific posturing, such as leg crossing, squatting, and Vincent curtsy should be noted (49). Delayed achievement of milestones, impaired fine motor coordination of the upper extremities, poor school performance, or inability to stay focused on activities may be signs of central nervous system dysfunction affecting the lower urinary tract. Hemiatrophy and left-handedness in a family without a history of left-handedness (referred to as pathologic left-handedness) suggests an early perinatal brain injury, which may be associated with voiding dysfunction (50). A history of polyuria or polydipsia is suggestive of undiagnosed diabetes mellitus or insipidus. For patients of all ages, specific questions about the frequency and consistency of bowel movements, fecal soiling, or fecal incontinence should be investigated to elucidate a possible history of constipation or encopresis. UTI or multiple febrile illnesses of unknown cause should be identified. If available, culture documentation of a UTI and means of urine collection (bag vs. catheterization) can provide helpful information. For each UTI, a history of systemic signs or fever should be sought, as this may suggest possible renal parenchymal scarring (5,41,51).

A focused physical examination of the abdomen, back, external genitalia, and lower extremity neurologic system should be performed. Palpation of the abdomen may reveal an enlarged or hydronephrotic kidney, a distended bladder, or evidence of impacted fecal material. The back should be

examined for subtle findings suggestive of an occult spinal abnormality, including lipoma, telangiectasia, abnormal pigmentation, spinal dimple, hair patch, gluteal asymmetry, or abnormal gluteal cleft (52). Absence of the upper gluteal cleft suggests sacral agenesis. As well, the presence of the sacrum and completeness of the vertebrae should be confirmed by palpation. In girls, the labia should be separated and the external genitalia examined for separate urethral and vaginal openings, the presence labial adhesions, or epispadias (denoted as a bifid clitoris or patulous urethra). In boys, the urethral meatus should be visualized by gentle retraction of the foreskin to identify its position and appearance. Skin excoriation or genital dermatitis should be noted. The examiner should be alert to signs of sexual abuse. In cases of suspected neurologic dysfunction, the absence or presence of perianal sensation and an anal wink (anocutaneous reflex) should be demonstrated. The bulbocavernosus reflex may be elicited by gently squeezing the glans penis or clitoris while observing a contraction of the anal sphincter (if necessary, this may be accomplished with a digital rectal examination). Assessment of gait, muscle mass, symmetry, and deep tendon reflexes of the lower extremities completes the neurologic examination (45,51).

Worrisome Signs and Symptoms

Certain signs and symptoms should alert the clinician that further investigation is warranted (Table 56.2) (41). Lumbosacral and neurologic abnormalities may be indicative of an occult spinal dysraphism. In this case, further radiographic imaging [spinal ultrasonography for infants younger than 3 months of age and spinal magnetic resonance imaging

TABLE 56.2. WORRISOME SIGNS AND SYMPTOMS IN EVALUATION OF DYSFUNCTIONAL VOIDING IN CHILDREN

Signs

- Lumbosacral spine abnormalities
 - Hairy patch (hypertrichosis)
 - Lipoma
 - Cutaneous abnormalities/dermal vascular malformation (pigmentation, telangiectasia) or dimple
 - Bony irregularities (scoliosis, abnormally appearing gluteal cleft)
- Reduced anal sphincter tone
- Lack of lower extremity deep tendon or bulbocavernosus reflex
- Fixed low urine specific gravity or glycosuria
- Urinary tract infection

Symptoms

- Day and night frequency and wetting
- Painful urination
- Rectal pain
- Penile or vaginal pain or discharge
- Straining to void

Modified from Koff SA. Evaluation and management of voiding disorders in children. *Urol Clin NA* 1988;15(4):769-775.

(MRI) for older children] and urodynamic testing are required. Low specific gravity of the urine could be related to diabetes insipidus. Further investigation for diabetes mellitus should be carried out if glycosuria is detected. As noted earlier, a history of UTI calls for renal ultrasonography and VCUG in males or a radionuclide cystogram in females. Any child with a history of genital pain or discharge should be thoroughly evaluated for possible sexual abuse.

Urodynamic Evaluation

Urodynamic studies in children are a time-consuming endeavor and require the patience and experience of a trained pediatric urodynamics nurse. A urodynamic suite tailored to the pediatric patient with toys, videotapes, or other personal security items (e.g., blanket, teddy bear) is beneficial. The importance of patient cooperation cannot be overstated (51). Urodynamic studies may be difficult to interpret when the child is uncooperative.

Noninvasive urodynamic studies do not require catheterization and are easy to perform. Noninvasive studies include urinary flow rate and PVR determination, and an assessment of bladder wall thickness by ultrasonography. More invasive urodynamic studies require catheterization and possibly the placement of perineal electromyographic (EMG) needle electrodes when a neuropathy is considered. These evaluations should be used selectively in those patients who require more thorough investigation.

Children with incontinence, with or without UTI, who have negative findings on physical examination and normal radiographic imaging results are not usually candidates for initial, more invasive studies because they usually respond to empiric therapeutic options such as bladder and bowel retraining and/or anticholinergic medication (51). See Table 56.3.

The most commonly used urodynamic tests are urinary flow rate, cystometrogram (CMG), EMG, and urethral pressure profilometry. The urinary flow rate is the voided volume per unit time, expressed in milliliters per second. This test also provides the volume voided and a flow tracing. The normal flow-tracing voiding pattern is a bell-shaped curve. A Valsalva voider has an intermittent and prolonged curve. Staccato or interrupted voiding is seen in a considerable number of girls with recurrent UTI (53). Nomograms for flow rate and voided volume are available (51).

CMG is a pressure-volume study that characterizes both the filling and voiding phases of bladder function. High intravesical filling pressures and high pressures at urinary leakage (leak point pressure) are associated with upper urinary tract deterioration (54). The CMG can also provide a measurement of bladder compliance, the change in bladder volume divided by the change in bladder pressure, expressed as milliliters per centimeter of water. No standard compliance values are available for children. The filling CMG may also demonstrate involuntary detrusor contractions, or detrusor instability. It is important to fill the bladder slowly with warmed saline to

TABLE 56.3. INDICATIONS FOR URODYNAMIC TESTING IN CHILDREN

^aIn some of these cases noninvasive studies and treatment are attempted first.

avoid inducing bladder contractions (51). Even at these rates compliance measurements may be falsely low when compared to pressures obtained during natural filling (14,55).

EMG is the study of the electrical potentials generated by the depolarization of striated muscle bundles. In urodynamic studies EMG provides information about the degree of denervation of the external urinary sphincter, responses to sacral reflexes, and presence or absence of detrusor-sphincter dyssynergia (51).

Static urethral pressure profilometry measures the passive resistance at a particular point in the urethra at a specific point of bladder stretch. This provides an assessment of bladder outlet resistance. Dynamic urethral pressure profilometry provides the continuous monitoring of a particular point in the urethra as the bladder fills to capacity and then empties (51).

Urodynamic studies can provide useful information in children with voiding dysfunction. One must remember the limitations in performing and interpreting these evaluations of bladder function. These methods are invasive and should be reserved for refractory cases or patients with neurologic or structural abnormalities, with the specific test used to obtain the most valuable information for efficient treatment.

NEUROGENIC CAUSES OF BLADDER DYSFUNCTION IN CHILDREN

Spinal dysraphism, or myelodysplasia, is the most common cause of neurogenic bladder dysfunction in children. The number of children born with myelodysplasia in the United

TABLE 56.4. TYPES OF SPINAL DYSRAPHISM

Lipomyelomeningocele
Dermoid cyst
Dermal sinus

States is approximately 1 per 1000 births (56). The incidence of this disorder is decreasing (57). The reason for the decreasing frequency is unknown, but some speculate that it may be related to elective termination of pregnancy (58) as well as the recommendation that women ingest 400 µg of folic acid daily before becoming pregnant (59). This practice has been shown to reduce the incidence of giving birth to a child with spina bifida by 50% (60). The variations of congenital spinal anomalies classified as spinal dysraphism are listed in Table 56.4 (52). Of the myelodysplastic states, myelomeningocele accounts for more than 85% of cases and usually presents at birth with an obvious open lesion of the back. Lipomeningocele is the second most common type of myelodysplasia. Approximately half of the cases present later in childhood with symptoms of voiding dysfunction and subtle findings on physical examination (61,62). Other causes of neurogenic bladder dysfunction in children include sacral agenesis, imperforate anus, cerebral palsy, and traumatic spinal cord injury.

Myelomeningocele

During embryonic life, the edges of the neural plate proliferate to form the neural folds by 3 weeks of gestation. Starting in the cranial region, these neural folds close in the midline to create a tube that progresses caudally. The lateral ectoderm migrates medially to cover the neural tube, thus separating the neural tissue from the overlying ectodermal surface. This process is complete by the 35th day of gestation (63). The exact etiology of spinal dysraphism is unknown, but a commonly accepted theory is incomplete closure of the neural tube and failure of the mesoderm to encircle the cord and/or ectoderm to cover the underlying tissue (64). The most frequently affected region is the lumbar spine followed by the sacral, thoracic, and cervical areas in descending order of frequency (65,66).

The description of neural tube defects is based on the degree of involvement of the neural elements. *Meningocele* refers to a defect in which the meninges extend beyond the confines of the vertebral canal with no neural elements contained within the sac; *myelomeningocele* refers to a defect that includes neural elements, such as nerve roots or part of the spinal cord, that have protruded along with the meninges; if fatty tissue develops within in the cord structures, it is described as a

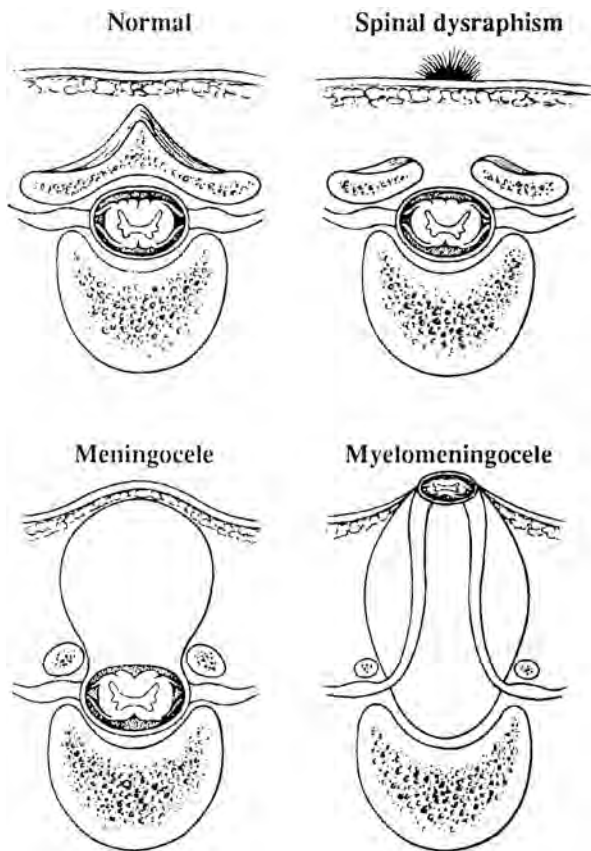

FIGURE 56.1. Defects and locations of neural elements in spinal dysraphism. (From Barrat TM, Avner ED, Harmon W, eds. *Pediatric nephrology*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 1993, with permission.)

lipomeningocele (Fig. 56.1). It has been demonstrated that neural elements may be abnormal both above and below the site of the bony defect (64). This explains why the level of the bony defect may not always correlate with the type or extent of the neurologic deficit (65,67). The neural elements are usually covered by a thin sac or membrane. Urgent surgical repair and sterile precautions are necessary to prevent progression of neurologic damage and to reduce the risk of infection.

Most children with spinal dysraphism have other associated abnormalities, including orthopedic anomalies and the Arnold-Chiari malformation, a herniation of the cerebellar tonsils through the foramen magnum, which prevents cerebrospinal fluid from entering the subarachnoid space by obstructing the fourth ventricle. Because of the varied defects in these children, a multidisciplinary approach that includes neurosurgical, urologic, and orthopedic assessment and treatment is optimal.

Urologic Evaluation of the Newborn with Myelodysplasia

Initial evaluation of the neonate with myelodysplasia should include a urinalysis, serum creatinine level, and measurement of PVR. Clean intermittent catheterization

(CIC) should be initiated if the PVR is greater than 5 mL (approximately one-third of the expected bladder capacity) with spontaneous voiding or following a Credé maneuver. After back closure has been completed, renal ultrasonography and a urodynamic study should be performed. Back closure has been shown to have little effect on detrusor function in neonates (68). It is well known that the neurologic status of patients with myelodysplasia is dynamic, and neonatal urodynamic studies act as an important baseline for future comparisons. The urologic manifestations of the neurologic deficit may improve or worsen over time (67,69,70). The urodynamic studies also guide management and define the risk of neurourologic deterioration (66,71). The bladder capacity of children with myelomeningocele is approximately 25% less than that of age-matched neurologically normal children. Expected bladder capacity for these children may be calculated by the following equation: $24.5 \times \text{age (years)} + 62 = \text{capacity (mL)}$ (72).

If the renal ultrasonogram is abnormal or if urodynamic studies reveal detrusor sphincter dyssynergia (DSD), a VCUG should be performed to identify possible VUR. If reflux is severe or significant renal parenchymal changes are noted on ultrasonography, a renal scan should be performed to assess renal function and parenchymal damage.

Management of the Neonate with Myelodysplasia

In the past, patients with myelomeningocele were managed expectantly. Therapeutic intervention with sterile (62) or CIC (54) was initiated only when complications such as hydronephrosis or reflux arose. However, up to 50% of the patients managed by self-voiding develop urinary tract deterioration (66,67,70,73,74). Prospective studies have clearly demonstrated that the patients at highest risk of deterioration are those with DSD, high voiding pressure, or high leak point pressure (54,65,71,74–76). Deterioration is most likely to occur within the first 3 years of life (70,76). Early management with CIC and anticholinergic medication for children at high risk has significantly decreased the occurrence of urologic deterioration (74,76).

Because not all children are at risk for deterioration, the primary management and follow-up regimen can be tailored to the initial neonatal urodynamic profile. Three groups may be distinguished on the basis of the urodynamic findings: those with detrusor–external urethral sphincter incoordination (dyssynergy), those with detrusor–external urethral sphincter coordination (synergy), and those with a complete neurologic lesion or no bioelectric activity in the external urethral sphincter (65).

Detrusor sphincter dyssynergy occurs when the external urinary sphincter contracts involuntarily during a detrusor contraction in patients with neurologic lesions of the suprasacral spinal cord (77,78). Because these children are at high risk for urinary tract deterioration and prophylactic

therapy has been shown to reduce this risk, CIC should be instituted as standard therapy along with yearly urodynamic studies and renal ultrasonography (76,79). If high bladder filling pressures, high leak point pressure (greater than 40 cm H₂O), or persistent incontinence occurs, anticholinergic medication should be added (74,76,80). If these measures fail to stop progression, urinary tract diversion with cutaneous vesicostomy (81) or bladder augmentation (79) may be required.

Synergy of the voiding reflex is characterized by complete silencing of the external urinary sphincter during a detrusor contraction. Patients with a synergic sphincter are at lower risk of urinary tract deterioration unless they develop dys-synergy (70,71). Therefore, they should undergo annual urodynamic studies and renal ultrasonographic examination to monitor for a change in their neurologic picture. Continence may be improved with timed voiding, CIC, and anticholinergic medication if necessary.

When no bioelectric potentials are detectable in the region of the external urinary sphincter during the voiding cycle or in response to sacral reflex stimulation (including the Credé maneuver), a complete neurologic lesion exists. In this condition the bladder acts as a urinary conduit without any obstruction. These children are at low risk of urinary tract deterioration (74) unless they develop denervation fibrosis of the skeletal muscle component of the external urinary sphincter as evidenced by an increase in residual urine volume or urodynamic study demonstration of an elevated urethral leak point pressure (65). Thus, these children require annual renal ultrasonographic examination and documentation of PVR.

Management of incontinence includes CIC and administration of alpha-agonists to increase bladder neck outlet resistance. If conservative measures fail, surgical options such as artificial urinary sphincter, bladder neck reconstruction, or urinary diversion with a continent catheterizable stoma may be necessary.

Management of Vesicoureteral Reflux

Initial therapy for VUR includes CIC and anticholinergic therapy to establish effective bladder emptying and decrease elevated intravesical pressures (79,82). The indications for surgical repair of VUR in children with myelomeningocele are similar to those in children with primary reflux. They include recurrent UTI despite adequate antibiotic prophylaxis and a routine CIC schedule; development or progression of renal parenchymal damage or scarring, or planned bladder neck reconstruction (83). When combined with CIC, success rates for surgical repair of reflux in neurogenic bladders approaches that of repair in nonneurogenic bladders (84). The Credé maneuver should be avoided in children with reflux who also have an intact sacral reflex arc because they will have a reflexive increase in external urinary sphincter tone when abdominal pressure is increased. This results in inefficient bladder emptying due to increas-

ing urethral resistance, which may cause a worsening in the degree of reflux (85).

Occult Spinal Dysraphisms

Like myelomeningocele, occult spinal dysraphisms have a structural defect of the caudal end of the vertebral canal and spinal cord. However, there is no open vertebral canal. Occult spinal dysraphisms include diastematomyelia, lipoma, dermoid cyst or sinus, aberrant sacral roots, fibrous traction on the conus medullaris, or a tight filum terminale (62). The diagnosis is usually suspected in neonates because of a cutaneous lesion overlying the spine (86). If the dysraphism is not noted in the neonatal period, children usually present between the ages of 2 and 4 with difficulty in toilet training for bladder and/or bowels, or present with urinary tract symptoms around 9 to 13 years of age due to an acceleration in growth during puberty (62,86). These symptoms may include incontinence, UTI, and encopresis or fecal soiling (62,87). Other, less common presenting symptoms include weakness or incoordination of the feet and legs, leg numbness, and back, testicular, or leg pain (63,88). Physical findings include the characteristic cutaneous back lesions listed in Table 56.2, poor anal tone, decreased perianal sensation, high arched foot or feet, leg length discrepancy, abnormal gait, asymmetrical lower leg muscle mass, lower extremity weakness, and altered sensation or deep tendon reflexes of the lower extremities (88,89).

The presenting signs and symptoms of occult dysraphic states are similar to those in patients presenting with tethered spinal cord syndrome, the pathologic fixation of the cord in an abnormal caudal position (87). Patients with a history of prophylactic spinal surgery for repair of a lipomeningocele before 18 months of age have a lower risk of developing secondary tethering of the spinal cord than children who do not have surgery until obvious neurologic abnormalities occur (87,88). The mechanism of neurologic dysfunction is thought to be the result of impaired mitochondrial oxidative metabolism with constant or intermittent cord stretching (90).

Evaluation of suspected occult dysraphic states and tethered spinal cord should include a thorough history taking and physical examination. The diagnosis should be confirmed with spinal ultrasonography in children younger than 3 months of age (91) and with MRI of the spine in children older than 3 months (88,89). A baseline urinalysis, creatinine level, renal ultrasonography, and PVR should be obtained. Urodynamic evaluation is critical, as many of these patients have a normal neurologic examination but a significant neurologic abnormality on urodynamic studies (86,91,92). In fact, up to 40% of children with lipomeningocele may have abnormal urodynamic findings as their sole neurologic deficit (92).

Management of the urinary tract in children with occult dysraphic states and tethered spinal cord is identical to that described earlier for the various urodynamic patterns of myelomeningocele. Early surgical correction of the spinal

cord abnormality is associated with a better improvement rate of urinary tract and lower extremity abnormalities than is late repair (61,69,88,91,92).

Sacral Agenesis

Congenital absence of part of one or more of the sacral vertebrae or coccyx is very rare and is referred to as sacral agenesis (93,94). If the lumbar spine is also affected, the term *caudal regression syndrome* is used (94,95). Neurogenic bladder dysfunction will result if the sacral neural segments S2 to S4 are involved (94). As with myelomeningocele, the level of bony abnormality does not predict the level of neurologic abnormality (94,95). The etiology is unknown, but exposure to teratogenic influences is thought to play a role (94). One percent of infants born to diabetic mothers have sacral agenesis, and the incidence of maternal diabetes in children with this anomaly is 12 to 16% (94,96–98).

Approximately half of the cases present in the neonatal period and the remainder are diagnosed at age 4 to 6 years when an evaluation for urinary incontinence is performed (94,99). Presenting signs and symptoms include urinary frequency and urgency, urinary incontinence, recurrent UTI, and constipation (99). Physical examination may reveal flattening of the buttocks, loss of the gluteal cleft, widely spaced buttock dimples, and a palpable sacral defect (98). Perineal sensation is normal in up to 75% of these children (94,97). The bulbocavernosus reflex may or may not be intact (94). Early diagnosis and management help to avoid complications such as renal functional impairment, recurrent UTI, and renal scarring (97,99,100). Associated orthopedic and genitourinary anomalies include club foot or feet, skeletal defects of the tibia and fibula, unilateral renal agenesis, VUR, and renal ectopia (93,94,96,98,99).

The diagnosis is confirmed by anterior-posterior and lateral radiographs of the sacrum, which demonstrate the bony deformity (98,99). Renal ultrasonography or intravenous pyelogram will reveal any associated genitourinary anomalies (97). A VCUG will determine if VUR is present (94). Urodynamic studies show a variable pattern of either an upper motor neuron lesion with hyperreflexia and DSD with an intact sphincter EMG, or detrusor areflexia with extensive denervation in the sphincter (94,97,99).

Management is tailored to the urodynamic profile and includes CIC to achieve complete bladder emptying, antibiotic therapy for infection or reflux, and administration of anticholinergics to improve continence or to help lower abnormally high bladder pressures (94,97,99,100).

Associated Conditions—Imperforate Anus

Ongoing problems with urinary incontinence in some patients with imperforate anus was thought to be related to peripheral nerve injury at the time of the anal pull-through procedure. It was eventually deduced that many of these patients had sacral

agenesis or neurospinal dysraphism that resulted in neurogenic bladder dysfunction and incontinence (101). Up to 30% of children with an anorectal malformation have sacral dysplasia (102), and the majority of them have neurogenic bladder and sphincter dysfunction (95). The incidence of sacral agenesis and genitourinary abnormalities, including VUR and DSD, is much greater in those with high lesions of imperforate anus than in those with low lesions (101–103). To determine if sacral agenesis or spinal dysraphism is present, prompt investigation of children with imperforate anus by imaging examination, including plain radiography, ultrasonography, or MRI of the spine, is recommended (88,89,91). A urodynamic study is required if either abnormality is noted. Urodynamic studies may demonstrate a normal voiding pattern, detrusor hyperreflexia or areflexia, and normal or partial denervation of the sphincter with or without DSD (101,104). Urologic management is based on the initial urodynamic profile as described earlier for myelomeningocele.

Central Nervous System Insults

Cerebral Palsy

The incidence of moderate to severe cerebral palsy is estimated to be 1.5 to 2.5 per 1000 live births (105). One-third will report urinary symptoms (106). The most common presenting symptom of voiding dysfunction is daytime urinary incontinence. Patients may be prone to incontinence because of impaired cognitive and communication skills as well as decreased mobility (107). Urgency, urinary frequency, stress incontinence, difficulty initiating voiding, or UTI may also be noted (106–109).

Routine screening of the urinary tract is not warranted in patients with cerebral palsy because fewer than 2% have been demonstrated to have unexpected genitourinary abnormalities by renal ultrasonography (110). If a patient has a history of UTI, however, there is a high likelihood of a structural defect or a significant urodynamic abnormality, such as DSD; therefore, renal ultrasonography and urodynamic studies should be performed (109). Urodynamic studies often show detrusor hyperreflexia and/or a small capacity bladder. An incomplete lesion of the external urinary sphincter may be seen in 10 to 15% of cases, suggesting a spinal cord as well as a central nervous system abnormality. DSD is rare (108,109). Management includes anticholinergic therapy for urgency, incontinence, and hyperreflexia, and CIC for incomplete bladder emptying or DSD (107,109). In children not requiring CIC, the anticholinergic drugs should be administered gingerly with monitoring of residual urine, because these children may develop urinary retention (111).

Traumatic Spinal Cord Injury

Spinal cord injury in the child is a rare event. The incidence of traumatic spinal cord injury is higher in boys than in girls, and the risk of injury increases with age (112,113).

The most likely causes are a sports injury or birth trauma from a high forceps delivery (114). Immediately after the injury, a period of spinal shock exists, the bladder is often areflexic, and the urethral sphincter is nonreactive with normal bioelectric potentials on EMG (115). Initial management of the urinary tract involves placement of an indwelling Foley catheter to maintain bladder emptying until the patient is stable. CIC may then be initiated (116,117). When bladder function returns, there is usually an upper-motor-neuron type of injury with detrusor hyperreflexia and DSD (115). The goals of management are to preserve renal function, achieve continence, and avoid infection and stone formation. Urodynamic studies can help determine which patients are at risk for urinary tract deterioration and should be performed within 2 to 3 months of the initial injury. Follow-up urodynamic studies at 6 to 9 months and again at 2 years after injury help to determine the stability of lower urinary tract function, the need for continued catheterization, and the necessity of further pharmacologic or surgical intervention. Periodic renal ultrasonography to evaluate for hydronephrosis and stone formation is recommended (115).

NONNEUROGENIC CAUSES OF BLADDER DYSFUNCTION IN CHILDREN

As noted previously, the distinction between functional and organic causes of voiding dysfunction can be elucidated by careful history taking and physical examination with special attention to worrisome signs and symptoms (Table 56.2). Children with symptoms of voiding dysfunction will likely fit into one of the following categories of dysfunctional elimination syndromes: the nonneurogenic neurogenic bladder, the unstable bladder, the infrequent voiding syndrome, and functional bowel disturbance. The presence of these dysfunctional elimination syndromes is associated with increased recurrence of UTI, delayed resolution of VUR, and unsuccessful surgical outcome for VUR (118,119). This highlights the importance of diagnosing and treating these syndromes.

Nonneurogenic Neurogenic Bladder (Hinman-Allen Syndrome)

Hinman first described a syndrome that he designated as nonneurogenic neurogenic bladder (120). The disorder was further characterized and described by others and thus has many other names, including Hinman-Allen syndrome (121), occult neuropathic bladder (122), subclinical neurogenic bladder (123), pseudo-obstructed bladder (124), unstable bladder of childhood (125), and occult neurologic bladder (126).

Hinman wrote about a symptom complex of enuresis and daytime wetting associated with UTI, often with upper uri-

nary tract dilatation, as seen in 14 boys in whom no neurologic defects or obstructive lesions could be identified. Incoordination between a detrusor contraction and contraction of the pelvic floor was postulated as a possible cause (127). For the end stage of bladder dysfunction associated with nonneurogenic neurogenic bladder to develop, there must be a failure to inhibit the detrusor reflex and overcompensation by the external sphincter (121). This acquired disorder occurs after toilet training and usually presents before puberty. Symptoms include daytime and nighttime incontinence, fecal retention and soiling, and UTI. Varied degrees of urinary tract changes including renal functional compromise in children with "failure" personalities and domineering parents are noted (122,125,127,128).

Radiologic abnormalities that can be seen include hydronephrosis, a trabeculated bladder with diverticula, a large PVR, VUR, renal parenchymal scarring, and the classic "spinning top urethra" (persistent narrowing of the sphincter area during voiding) (122,124,127,128). Urodynamic study with anal sphincter EMG confirms failure of relaxation or increased external sphincter activity with voiding (125,128). This causes elevated detrusor filling and voiding pressures, which ultimately result in the radiologic changes noted previously.

A multitude of approaches are necessary for successful management of the nonneurogenic neurogenic bladder. Bladder retraining with a timed voiding schedule and double voiding (120,128) are recommended. CIC may be required to achieve adequate bladder emptying (125,129). Biofeedback techniques have been highly successful in modifying learned patterns of bladder sphincter incoordination (130). Some have recommended psychotherapy and hypnosis to assist in the bladder retraining (125). Long-term suppressive antibiotic therapy may be necessary to prevent recurrent UTI (120,131). Management of fecal impaction and constipation plays an important role (120,131). Drug therapy includes anticholinergics to decrease unstable bladder contractions (120,131) and bethanechol chloride to improve bladder contractility; alpha-blockers and diazepam may reduce bladder outflow resistance (125,132).

Unstable Bladder

Children with an unstable bladder have the ability to void normally on command but experience premature detrusor contractions with bladder filling (125). This disorder is thought to arise from a delay in nervous system maturation or a regression in development (10). Therefore, it has also been referred to as "infantile" or "uninhibited" bladder (41). These children often present with symptoms of urgency, urge incontinence, urinary frequency, and enuresis. Characteristic postures such as Vincent curtsy or squatting are often noted by parents (39,41,45,49,125,133). Children with attention deficit disorder (134,135), abnormal neurologic examinations, learning disabilities, or poor

fine motor coordination, and left-handed children in a family without left-handedness may present with voiding dysfunction of this type (50).

Urodynamic studies may demonstrate a bladder that is smaller than estimated for the patient's age, a normal voiding pattern, and normal PVR (39,133). Radiographic studies usually do not reveal any abnormalities (125).

Management of the unstable bladder includes a timed voiding schedule with frequent voids (41) and anticholinergic medication to increase the threshold of detrusor filling before an unstable contraction has occurred (41,125,133).

Infrequent Voiding Syndrome

Children with infrequent voiding syndrome tend to delay voiding, eventually developing extremely large bladder capacities (up to 2 standard deviations greater than the mean for their age) with a weak or absent detrusor contraction at capacity (45,125,136). This entity is often referred to as the "lazy bladder syndrome." Patients often complain of urinary leakage, which is due to overflow or stress urinary incontinence (45,125,137). The condition is more common in females and is likely to present after toilet training has been initiated (125,137). Some common presenting signs include infrequent voiding (one to two voids per day), UTIs, a palpable abdominal mass, voiding by straining or Valsalva maneuver, weak urinary stream, constipation, and abdominal pain associated with nausea and vomiting (39,45,125,136–140).

Physical examination may disclose a palpably enlarged bladder. Radiographic studies generally show a normal upper urinary tract (125), an enlarged, smooth-walled bladder (137), and fecal retention. Urodynamic studies confirm incomplete emptying with large PVR, weak flow with voiding by straining, and a weak or absent detrusor contraction at capacity (125,136,137,140). VUR may or may not be present (137).

Management of this disorder is focused on bladder retraining, including double voiding and use of a timed voiding schedule with frequent voids, and improved bowel emptying (45,125,137,138,140). Infection should be treated with an appropriate antibiotic (137,138,140). For those in whom this conservative management fails, CIC may be required to achieve complete bladder emptying (129). Some have suggested the use of alpha-antagonists to relax the bladder outlet and improve bladder emptying (45).

Functional Bowel Disturbances

Constipation usually refers to infrequent hard stools that are difficult and uncomfortable to pass (141,142). A commonly accepted definition is a stool frequency of less than three times a week. Impaired bladder emptying has been demonstrated with constipation and fecal impaction (143). The mechanism by which this occurs is thought to be a

physical obstruction of the bladder outlet by the fecal mass in the neighboring rectum (139,144).

Patients present with firm, hard stools that are difficult to pass, infrequent bowel movements, blood-streaked stools from rectal fissures, history of laxative or suppository use, abnormally large-sized bowel movements, or fecal soiling (145). Clinical suspicion can be confirmed and the condition graded by a plain radiograph of the abdomen (46,143).

Constipation and fecal impaction have been noted with multiple urinary tract abnormalities, such as hydronephrosis (139), nonneurogenic neurogenic bladder (122), acute urinary retention (144,146,147), diurnal and nocturnal incontinence (147), and recurrent UTI (141,145,147). Management of constipation without other specific urinary tract therapy has decreased PVRs and hydronephrosis (143,148). Management of constipation had also been shown to significantly reduce the recurrence rate of UTI (145,147) and to eliminate diurnal incontinence in 90% and nocturnal incontinence in 60% of patients (145).

Initial management of severe constipation usually involves digital disimpaction or disimpaction with oral laxatives and enemas (143,147). Dietary modification through increased intake of fiber and water is important (143,145). Scheduled toileting has been very effective (145,147). Continued medical management with daily oral laxatives and lubricants such as mineral oil may be required (143,145). On rare occasions a Malone antegrade continence enema procedure has been performed to provide a means of emptying the colon proximal to the large intestine on a regular basis, with good results reported (149,150). When medication is needed for bladder dysfunction, it is preferable to avoid oxybutynin and instead to use a more bladder-specific (and less constipating) antimuscarinic drug, such as tolterodine (151).

Extraordinary Urinary Frequency

The syndrome of extreme daytime urinary frequency of small volumes has a sudden onset in a previously well, toilet-trained child without evidence of structural urinary tract abnormalities or UTI (152–155). Its cause is unknown, but it has been related to the presence of psychological stresses (152,156). It has been referred to as *pollakiuria* from the Greek *pollakis*, which means "often" (154). Initially, the condition was thought to be quite rare (155); however, it may have been underrecognized, as many large case series now have been reported (152–154,156,157).

This syndrome generally occurs more frequently in boys (154,155). The symptoms are isolated to daytime events for most children. When nocturia does occur, it correlates with an increased incidence of recurrence of symptoms (154,155,157). The age of presentation ranges from 2 to 14 years, with most children developing symptoms between 4 and 6 years of age (153,154,156,157). Generally, there are no other symptoms noted (152). Physical examination is within normal limits (155,156). In some boys, however,

signs of urethral meatal stenosis or urethritis may be noted, and the symptom of a thin, fine, forceful, upwardly directed stream can be elicited on querying the child or his parents.

A noninvasive investigation is needed to rule out significant abnormalities. Urinalysis and urine culture results are normal, but these studies should be performed to rule out diabetes mellitus, diabetes insipidus, and UTI (154–156). Renal and bladder ultrasonographic images are also normal (152,153,155,156). Further invasive testing such as urodynamic studies or voiding cystography is not indicated if results of the aforementioned investigations are normal (153,156).

This entity usually resolves spontaneously. Reassurance that the symptoms will resolve between 1 and 3 months from the syndrome's onset is all that is required (152,155,156). Drug therapy, such as administration of anticholinergics, has not improved symptoms (153).

UROLITHIASIS

DAWN S. MILLINER

Urolithiasis is increasingly recognized in pediatric patients and is encountered in a variety of clinical settings: the 8-year-old boy with idiopathic hypercalciuria and a single stone, the 14-year-old with cystinuria experiencing her fourth episode of renal colic in the past 6 years, the 10-year-old with inflammatory bowel disease whose two renal stones were recognized incidentally during imaging for evaluation of abdominal pain, the premature infant with asymptomatic nephrocalcinosis and a stone, the 4-year-old with human immunodeficiency virus infection in the emergency room with gross hematuria and abdominal pain after recently starting indinavir medication. All have in common particulate material of mineral origin within the urinary tract, the development of which depends on fundamental physicochemical principles. An understanding of these principles, along with the pathophysiologic states that promote urinary tract calculi, provides the basis for effective clinical management.

MECHANISMS OF STONE FORMATION

Several steps are required for stone formation, beginning with crystallization and followed by crystal growth, aggregation, and adherence of crystals to epithelium. Supersaturation in a specific crystal system is a precondition for solutes to precipitate in the urine and form crystals. Although the concentration of solutes is the principal determinant, supersaturation is dependent on other factors as well, including ionic strength and pH. Promoters and inhibitors present in the urine also play a role in crystallization. Concentrations of mineral solutes, ionic strength, pH, promoters, and inhibitors in the urine vary throughout the day as influenced by fluid intake, dietary constituents, and body metabolism. Urine in healthy individuals is often supersaturated with calcium oxalate, calcium phosphate, or sodium urate. A dynamic process of crystal formation, crystal growth, aggregation, disaggregation, and dissolution of crystals accompanies the diurnal variations in the physicochemical state of the urine. Thus, despite frequent periods of supersaturation, most children do not form urinary tract stones.

Promoters of crystallization are not well characterized but may include urinary macromolecules and lipids (1). Lipids are integral to the organic matrices of mineralized tissues as well as to pathologic calcifications (1). Urinary tract stones are no exception. Khan et al. (1) found that the urine of calcium and uric acid stone formers contained significantly more cholesterol, cholesterol ester, and triglycerides than the urine of healthy controls, with more acidic phospholipids observed in calcium oxalate stone formers only. In addition to reflecting renal cell damage with release of membrane phospholipids into the urine, the lipids appear to promote crystallization of both calcium oxalate and calcium phosphate. Another type of promotion that has received attention is the role played by crystals of one salt in inducing crystallization of another. For example, sodium urate (2–3) or calcium phosphate (4) can act as a nidus for calcium oxalate crystal formation. This circumstance occurs because there is a metastable region between the ion solubility product (below which the urine is undersaturated) and the ion formation product. In this metastable region there is the potential for heterogeneous crystal formation and growth (5). Above the formation product, the solution is unstable and spontaneous homogeneous crystal formation occurs. These principles help to explain the observation that patients with calcium stones are often hyperuricosuric (6).

Inhibitors of crystallization act at the crystal surface, most often interfering at active crystal growth sites (5). Naturally occurring inhibitors of calcium oxalate and calcium phosphate crystal formation in the urine include citrate, pyrophosphate, magnesium, and urinary macromolecules such as glycosaminoglycans, and nephrocalcin. Citrate, phosphate, magnesium, and sulfate also interfere with crystallization by forming soluble complexes with potential crystal ions. These properties can be used to therapeutic advantage in patients with calcium oxalate and calcium phosphate stones (7–8).

From the time filtrate is formed at the glomerulus until the urine reaches the bladder there is an environment of constant flow, so that crystals formed are generally washed out of the urinary tract. For stones to form, the crystals must either aggregate to a size sufficient to obstruct a renal

tubule and impair flow (free particle theory) or the crystal must adhere to the renal epithelial cell, the papillary tip, the wall of a calyx, or another location in the urinary tract (fixed particle theory). Adherence is favored by injury to the renal tubular epithelium or the urothelium. Injury may be induced by toxins, by infection, or by crystals themselves. Metabolic factors such as high concentrations of oxalate, which is now recognized to cause direct injury to renal tubular epithelial cells (9), may also play a role. Attention has turned to the interaction of urinary constituents and renal epithelial cells as determinants of crystal formation, crystal structure and growth, and attachment (10–12). Once crystals are relatively stationary in the urinary tract, which permits growth and aggregation, a stone may develop. Stasis of the urinary tract, with or without frank obstruction, is an important contributor. The balance of all of these processes is such that most individuals do not form urinary tract stones. Among children who do form stones, predisposing metabolic factors, infection, and/or urinary stasis are identified in the majority (13).

EPIDEMIOLOGY OF UROLITHIASIS IN CHILDREN AND ADOLESCENTS

Urinary tract calculi have been perceived as uncommon in children and adolescents and account for between 1 in 1000 and 1 in 7600 hospital admissions in this age group in the United States (14–16), a rate that is one-fiftieth to one-seventy-fifth of that reported in adults (13). Because many patients with urolithiasis do not require hospitalization, such data underestimate the incidence and prevalence. There are few population-based studies. That of Johnson et al. found the incidence of urolithiasis in patients older than 10 years to be 109 per 100,000 population per year in men and 36 per 100,000 population per year in women. Patients aged 10 to 19 years accounted for just 3.7% of the total episodes (17).

An explanation for the lower incidence of urolithiasis observed in children is incomplete, but the reason may be related to observations that concentrations of inhibitors of crystal formation and crystal cell attachment such as citrate, magnesium, and certain macromolecules are higher in the urine of children than in that of adults (12,18–19). The ratio of citrate to calcium and magnesium to calcium in the urine is higher in children (18). Miyake et al. (18) noted that nucleation of calcium oxalate crystals was more strongly inhibited in random urine samples from children than from those of adults as determined by measurement of the metastable limit for calcium oxalate. Robertson et al. defined a risk index for calcium oxalate lithiasis and also found this index to be lower in children (20). In another study, Miyake and colleagues (12) found that urinary macromolecules from pediatric patients more strongly inhibited the adhesion of calcium oxalate crystals to renal

tubular epithelial cells *in vitro* than did those from adults. This effect may have been potentiated by the higher concentrations of citrate observed in the urine from pediatric patients in the study.

Nonetheless, with appreciation that the presenting symptoms of urolithiasis may be different in children and that improved radiographic techniques are used more liberally than in the past, the diagnosis is now being made more often in pediatric patients. The frequency of occurrence has also been influenced in recent years by factors predisposing premature infants to nephrocalcinosis and urinary tract stones, and advances in medical care that have resulted in the survival through childhood and adolescence of increasing numbers of patients with medical conditions such as cystic fibrosis that are associated with urolithiasis. Finally, an increasing incidence of urolithiasis overall in recent decades has been noted in population-based studies in industrialized countries (21).

Among children and adolescents, boys show a mild preponderance for stone disease overall (17,22–25). Four pediatric series reported a male to female ratio of 1.4:1 to 2.1:1 in the United States, United Kingdom, Brazil, and Armenia (26–29). These ratios contrast with those for symptomatic adult stone formers, among whom males predominate in a ratio of 2:1 to 3:1, and reach a maximum of 4.8:1 from ages 40 to 60 years (21). There are exceptions among certain specific groups, such as young children with developmental anomalies of the urinary tract and associated infection, who tend to be male and younger in age (22,27). It is important to keep in mind that most pediatric series are small and subject to referral bias. The only population-based study showed a ratio of 1.3:1 (17) but did not include children younger than 10 years of age.

CLINICAL FEATURES

Symptoms of renal colic and gross hematuria, pathognomonic of urolithiasis in adults, are seen less reliably in children (22,30). Flank or abdominal pain or hematuria were the initial presenting features in 94% of adolescents and 72% of school-aged children, but in just 56% of children from birth to 5 years of age in one series (Fig. 57.1). In younger children, pain with features of renal colic was the exception, with most reporting or observed to have nonspecific abdominal pain. Indeed, among children up to 5 years of age the diagnosis of urolithiasis was made during investigation of a urinary tract infection or as an incidental radiographic finding during evaluation of other problems in 44% of patients (22).

In North American series, 60 to 78% of urinary tract calculi are found in the kidney at the time of diagnosis (22,26,31). The majority of those found in the ureters, bladder, or urethra have also originated in the kidneys. The bladder appears to be the site of stone formation in fewer

FIGURE 57.1. Clinical features at time of initial presentation of 221 children and adolescents with urolithiasis. (From Milliner DS, Murphy ME. Urolithiasis in pediatric patients. *Mayo Clin Proc* 1993;68:241–248, with permission.)

than 10% of North American children, although in other areas of the world bladder calculi may be seen more often and are often referred to as endemic bladder stones (29,32). Primary bladder stones tend to occur in younger children (21,29). Such stones appear related to dietary factors in developing countries (33,34). A diet with a high content of whole-grain cereals and/or oxalate-rich vegetables together with a low content of calcium, animal protein, and phosphate is believed to be responsible (21,32). The resulting urinary biochemical profile favors precipitation of ammonium acid urate and calcium oxalate, the most frequently occurring constituents of endemic bladder stones (32). Endemic bladder stones of childhood are frequent in several areas of the world, including Thailand, India, Turkey, Syria, Iran, Iraq, Tunisia, Pakistan, Indonesia, and the Sudan (21). There has been a striking decline in such stones in Europe and other developed countries over the last century (21,34). Calculi that form in the bladder in North American children are nearly always associated with bladder malformations or prior surgery such as augmentation cystoplasty and are characterized by infection.

Composition of stones from the upper urinary tract is calcium oxalate in 40 to 60%, calcium phosphate in 15 to 25%, mixed (usually calcium oxalate and calcium phosphate) in 10 to 25%, magnesium ammonium phosphate (struvite) in 17 to 30%, cystine in 6 to 10%, and uric acid in 2 to 10% of stones analyzed in several pediatric series (14,22–24,26,29,35).

CAUSATIVE FACTORS IN UROLITHIASIS

Seventy-five percent of children and adolescents with urolithiasis have identifiable predisposing causes for stone formation (22–24,35). In a compilation of studies that

included 492 North American pediatric patients with urolithiasis, Polinsky et al. (13) noted that metabolic causes accounted for approximately 33%, structural urinary tract abnormalities for 32%, and infection for 4% of stones although differences in classification complicated the combining of multiple studies. In most published series, complete metabolic evaluations were not performed for all patients, which likely led to underestimation of the contribution of metabolic factors. This impression is supported by a study in which all patients were screened for metabolic abnormalities (36). In this study, a metabolic cause for stone formation was identified in 25 of 47 patients (53%). In some pediatric reports, especially those from Europe, infection is cited as the cause of urolithiasis in a higher proportion of patients (54% in Polinsky et al.'s combined series of European children) (13,27,29,37). In most series, infants and young children have infection-related stones more frequently than do older children or adolescents (22,27), whereas adolescents account for the majority of those with idiopathic stone disease. No contributing cause for stone formation was identified (idiopathic) in 28% of North American patients and 14% of the European patients in the compilation by Polinsky (13).

It is common to find more than one predisposing factor in a given patient (22). In one study of 221 pediatric patients with urolithiasis, 36% of those with structurally abnormal urinary tracts were also found to have metabolic abnormalities predisposing to stone formation and 39% had chronic infection (22). Among the patients with infection-related stones, 29% also had metabolic abnormalities. Thus the presence of infection, obstruction, or structural anomaly in the urinary tract does not obviate the need for careful metabolic assessment. Among patients with metabolic abnormalities, 21% also had structural anomalies and 10% had chronic infection as additional predisposing factors (22). Because of the high likelihood of identifying causes for stone formation in children and adolescents and in view of the early onset and potential for many years of stone-forming tendency, complete assessment for stone-forming factors is indicated in all children.

Metabolic Factors Predisposing to Stone Formation

High urinary concentrations of calcium, oxalate, uric acid, or cystine resulting from either increased renal excretion or low urine volume results in supersaturation of the urine for the respective crystal systems and thus favors crystal and stone formation. Among naturally occurring inhibitors of stone formation in the urine, citrate, magnesium, and pyrophosphate are the best defined. A number of urinary macromolecules, including glycosaminoglycans, osteopontin, and urinary prothrombin fragment 1, appear to play a role but as yet are not well studied in children and adolescents (38). Identification of the specific predisposing metabolic

factors (Table 57.1) in each patient is of importance in developing the most effective therapeutic regimen.

Solute Excess

Hypercalciuria as currently defined (greater than 4 mg/kg/day or urinary calcium/creatinine ratio greater than 0.21) is common, occurring in 2.9 to 3.8% of healthy children (39,40), and can predispose to hematuria, dysuria, urinary urgency, and perhaps recurrent urinary tract infections (41–44) as well as to urolithiasis. Hypercalciuria accounts for 30 to 50% of identified metabolic factors in children and adolescents with urolithiasis. Most hypercalciuria is idiopathic, identified as an isolated finding, and may be sporadic or inherited. Inherited forms have been well described, may account for up to 40 to 60% of cases of idiopathic hypercalciuria, and appear to follow an autosomal

dominant or codominant pattern (45–48). The gene or genes responsible remain to be identified.

Among children and adults with idiopathic hypercalciuria, two subtypes of the disorder have been described, one related to enhanced gastrointestinal absorption of calcium and the other related to increased renal tubular secretion of calcium (49,50). The former is characterized by hypercalciuria after an oral calcium intake, with normal urine calcium/creatinine ratios in the fasting state. Renal leak hypercalciuria is present in the fasting as well as postprandial state and persists despite dietary calcium restriction. The use of oral calcium loading tests has been advocated to distinguish between these two types (40,49–51), but they often do not allow clear separation among subtypes of hypercalciuria in children (43,52). The inability of this test to distinguish between the two types is in part due to the confounding role of sodium on renal tubular secretion of calcium and the recognition that

some children identified as having idiopathic hypercalciuria have sodium-dependent hypercalciuria related to high dietary sodium intake. Other mechanisms of idiopathic hypercalciuria have also been implicated and include renal tubular phosphate leak, increased 1,25-dihydroxyvitamin D synthesis, increased renal prostaglandin E₂ production, and bone resorption (53).

Among children with idiopathic hypercalciuria who did not have urolithiasis at initial diagnosis, the likelihood of developing calculi was 4 to 17% during 1 to 11 years of follow-up in three studies involving a total of 146 patients (42,43,54). The risk of urolithiasis appears to increase with age (44). In addition to playing a role in the development of urolithiasis and urinary tract symptoms, idiopathic hypercalciuria may be associated with reduced bone mass (55,56).

Secondary forms of hypercalciuria are common and occur most often in response to dietary salt excess, long-term use of corticosteroids, and use of loop diuretics such as furosemide. Prolonged immobilization in children or adolescents, excess intake of calcium or vitamin D, and high concentrations of circulating parathyroid hormone all predispose to hypercalciuria. Phosphate depletion causes hypercalciuria mediated by an increase in 1,25-dihydroxyvitamin D synthesis (57). Chronic metabolic acidosis from any cause has the potential to result in hypercalciuria due to bone resorption. In distal renal tubular acidosis (RTA), the deficiency in acid secretion results in significant hypercalciuria. Once the metabolic acidosis is corrected with exogenous administration of base, the hypercalciuria resolves. Hypercalcemia of any cause is likely to result in secondary hypercalciuria.

Rare, inherited forms of hypercalciuria include the X-linked disorders related to mutations of the CLCN5 chloride channel, the gene for which is located on chromosome band Xp11.22. This chloride channel is expressed in the cortical proximal tubule, medullary thick ascending limb of the loop of Henle, and α -intercalated cells of the human nephron (58). Mutations of this channel have now been demonstrated in four conditions previously described as separate clinical entities: X-linked nephrolithiasis with renal failure, Dent's disease, X-linked recessive hypophosphatemic rickets, and low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis. These conditions have in common hypercalciuria, nephrolithiasis, nephrocalcinosis, renal tubule dysfunction characterized by low-molecular-weight proteinuria and impaired absorption of phosphorus, progressive renal insufficiency, and in some cases rickets (59). The syndromes differ in degree from one another, but it is now established that they are phenotypic variants of a single disease. Although a large number of mutations have been identified, there appears to be no consistent correlation between genotype and phenotype (59). Thus, here all are referred to collectively as Dent's disease (60).

Hypercalciuria in patients with Dent's disease is typically moderate, although it may be as high as 10 mg/kg/day in

some children. The reason for the hypercalciuria is not well understood (61). Both fasting hypercalciuria and an exaggerated response to an oral calcium load have been demonstrated in affected patients (62). Parathyroid hormone concentrations are typically below the mean of normal, and 1,25-dihydroxyvitamin D levels are above the mean of normal and are frequently elevated (59). Serum phosphorus level is normal or low. The hypercalciuria may be the result of abnormal regulation of 1α -hydroxylation of vitamin D, perhaps related to generalized proximal renal tubule cell dysfunction (59). Others have suggested that defective CLCN5 channel function resulting in abnormal vesicle acidification may underlie a renal tubular failure to reabsorb low-molecular-weight proteins and calcium (61,63). Notably, both parathyroid hormone and vitamin D-binding protein are normally reabsorbed from luminal fluid and are increased in the urine of CLCN5 "knock-out" mice (61). Hypercalciuria in Dent's disease is responsive to thiazides, which indicates that inactivation of the CLCN5 chloride channel does not impair calcium transport in the distal convoluted tubule (64).

Tubular proteinuria of up to 1 g/day in children is a diagnostic feature of boys affected with Dent's disease (59) and is frequently present in lesser amounts in carrier girls (63). The level of retinol-binding protein is distinctly elevated, and this protein has been shown to be better than β_2 -microglobulin or α_1 -microglobulin in identifying the tubular proteinuria of Dent's disease (63). Renal tubular dysfunction may be evident as early as the neonatal period; hypophosphatemic rickets may develop in the first years of life; and nephrocalcinosis is often seen in childhood (65). Evidence of other renal tubule dysfunction including aminoaciduria, phosphate or potassium wasting, and glycosuria is observed less consistently. Impaired renal concentrating capacity is often observed in conjunction with nephrocalcinosis or renal insufficiency (59).

Urolithiasis is common in childhood in affected boys, although it is not universal. Occasionally, carrier girls have significant clinical manifestations and may develop nephrolithiasis or renal impairment (66). The most important factor contributing to stone formation appears to be the hypercalciuria. Urine citrate and oxalate excretion rates are typically normal when studied at times of good renal function (59). The hypercalciuria of Dent's disease appears responsive to treatment with thiazide diuretics. However, amiloride was not found to be helpful (59,64).

Other rare, inherited disorders are associated with hypercalciuria, including mutations of the calcium-sensing receptor that lead to hypocalcemia and hypercalciuria (67), and familial hypomagnesemia-hypercalciuria (68).

Hyperoxaluria accounts for 2 to 20% of metabolic factors identified in children and adolescents with urolithiasis (22,69,70). Mild idiopathic hyperoxaluria (ranging from 0.45 to 0.6 mmol/1.73 m²/24 hr) may be seen and is not infrequently observed in conjunction with mild hypercalci-

uria in patients with idiopathic stone disease (70,71). The cause of the hyperoxaluria is unknown but has variably been ascribed to metabolic changes that result in increased oxalate production or to enhanced gastrointestinal absorption (71–73). Ten percent to 20% of the oxalate in the urine has traditionally been regarded as derived from dietary sources (74), although some have argued that the contribution of dietary oxalate is higher (75). Marked dietary oxalate excess (particularly if there is concomitant low dietary calcium) (71,75) can lead to hyperoxaluria. Ingestion of starfruit (carambola) has been associated with acute oxalate nephropathy (76). Ethylene glycol, found in antifreeze, is metabolized to oxalate. Ingestion may result in acute renal failure due to oxalate nephropathy.

Under normal conditions, less than 10% of oxalate ingested is absorbed from the gastrointestinal tract (73,77,78). There has been interest in the disposition of fecal oxalate by certain anaerobic bacteria that populate the colon in a significant proportion of healthy individuals. It has been hypothesized that loss of colonization with organisms such as *Oxalobacter formigenes* may result in increased gastrointestinal absorption of oxalate leading to hyperoxaluria (70,79). As of 2003, this interesting hypothesis remains to be convincingly demonstrated.

Increased absorption of oxalate resulting from gastrointestinal disease is termed *enteric hyperoxaluria*. Any abnormality of the intestinal tract that is associated with malabsorption of fat can result in enhanced enteric absorption of oxalate (80). Mechanisms include binding of calcium by fatty acids. This leaves less calcium in the lumen to combine with oxalate, and oxalate is thus absorbed more avidly. In addition, bile salts cause injury to the colonic epithelium, which promotes enhanced oxalate absorption. The degree of hyperoxaluria caused by enteric disease is highly diet dependent and quite variable from mild to severe. Consequences can include not only recurrent urolithiasis but also oxalate nephropathy leading to renal failure. Treatment includes reduction in dietary oxalate, addition of calcium supplements to bind oxalate in the intestinal tract, increased oral fluid intake, a low-fat diet, and in some patients administration of sequestrants of bile acids. If hypocitric aciduria or hypomagnesuria is present, supplementation may be helpful to improve urinary inhibition of calcium oxalate crystal formation.

The primary hyperoxalurias are autosomal recessive inborn errors of metabolism due to deficiency of hepatic alanine:glyoxylate aminotransferase (AGT) (type I) or glyoxylate reductase/hydroxypyruvate reductase (type II) and are associated with moderate to marked elevation of urine oxalate excretion (81,82). Both of these enzymes are important in the metabolic disposition of glyoxylate, a precursor of oxalate found in hepatic cells. The gene encoding AGT is located on chromosome band 2q37.3 (81). A large number of mutations of the gene have been described that lead to a reduction in AGT enzyme activity and/or to a mistar-

getting of the enzyme from the peroxisome to the mitochondria where it is ineffective in disposition of glyoxylate. A marked increase in the hepatic production of oxalate and variable increases in glycolate result. Excess oxalate must be excreted by the kidney, and the resulting high urinary concentrations lead to supersaturation of the urine with calcium oxalate. The gene responsible for encoding glyoxylate reductase/hydroxypyruvate reductase resides on chromosome 9 (83). Deficiency of enzyme activity leads to hyperoxaluria and hyperglyceric aciduria. Studies in France suggest a prevalence of type I disease of 1.05 per 1 million population (84). Type II is rare, with fewer than 35 cases to date reported in the literature. A small number of children have been reported who have marked hyperoxaluria and clinical features similar to those of type I and II disease, but who have normal hepatic AGT and glyoxylate reductase/hydroxypyruvate reductase activity. Whether these children have an as yet undefined error of hepatic metabolism or whether another mechanism for the hyperoxaluria is responsible remains to be established (70,78,85).

Mean urine oxalate excretion in a comparative study of patients with primary hyperoxaluria was 2.2 mmol/1.73 m²/24 hr in type I disease and 1.61 mmol/1.73 m²/24 hr in type II primary hyperoxaluria (86). Due to the degree of hyperoxaluria and the presence of the abnormality from birth, primary hyperoxaluria is characterized by particularly aggressive stone formation. The majority of patients demonstrate urolithiasis and/or nephrocalcinosis during infancy or childhood (Fig. 57.2). Over time, due to repeated stone episodes that may involve obstruction or infection and due to nephrocalcinosis and other effects of oxalate on the renal tubules and

FIGURE 57.2. Multiple calcium oxalate stones in both kidneys of a 5-year-old boy with primary hyperoxaluria type I.

interstitium, renal failure often results. Clinical expression of type I disease is more severe than that of type II (86), with a higher proportion of type I patients progressing to end-stage renal disease at an earlier age. However, there is wide variability of clinical expression in both types, with some patients in renal failure in infancy and others retaining satisfactory renal function until the fourth or fifth decade (87,88). Once the glomerular filtration rate is reduced below 30 mL/min/1.73 m², plasma oxalate concentration increases rapidly, with resulting deposition of calcium oxalate in multiple organ systems (oxalosis). If oxalosis cannot be reversed by intensive dialysis and early transplantation, severe morbidity and mortality are the consequence.

Approximately one-third of patients with type I primary hyperoxaluria respond to pharmacologic doses of pyridoxine with a marked reduction in, and in some cases normalization of, oxalate excretion (87,89). Patients with primary hyperoxaluria type I should receive a trial of pyridoxine to assess their response. In all patients with primary hyperoxaluria, intensive efforts to minimize calcium oxalate crystallization and stone formation in the kidneys appear to be helpful in preservation of renal function (87). Neutral phosphate therapy has been shown both to reduce urinary supersaturation of calcium oxalate and to increase urinary inhibitory activity for calcium oxalate crystal formation. Mechanisms include a decrease in total urinary calcium and a decrease in urinary free calcium due to complexing of calcium by phosphate. There is an increase in the urinary concentration of pyrophosphate, an effective inhibitor of calcium oxalate crystal formation, and inhibition is further augmented by the accompanying increase in pH (90). In long-term studies of patients with primary hyperoxaluria, this treatment, along with increased fluid intake, appears beneficial in reducing stone-forming activity and in preserving renal function (87). Citrate therapy has also been advocated (91).

Cystinuria is identified in 2 to 7% of children with metabolic stones (13,22). An inherited defect in the renal tubular reabsorptive transport of cystine and the dibasic amino acids (ornithine, arginine, and lysine) accounts for the high concentrations of cystine in the urine of patients with this disorder. Cystine stones form because cystine excretion rates exceed cystine solubility at usual urine volumes. At a physiologic pH of less than 7, solubility is limited to 1000 $\mu\text{mol/L}$ (240 mg/L) (92). Cystine solubility is enhanced at an alkaline urine pH, so that alkalization of the urine is an important component of treatment regimens. Even at an optimal urine pH of 7, however, cystine solubility in urine is limited to approximately 1250 $\mu\text{mol/L}$ (300 mg/L) of urine (92). The increased urinary concentrations of the other dibasic amino acids and the accompanying intestinal dibasic amino acid transport defect appear to be without clinical consequence. The prevalence of cystinuria in the general population in the United States and Europe is estimated at 1 in 7000 but varies widely in various parts of the

world, ranging from 1 in 2500 in Jews of Libyan origin to 1 in 15,000 in parts of the United States to 1 in 100,000 in Sweden (93,94). The mutant gene appears to be common, with a frequency approaching 1% (93–95).

Three clinical subtypes have been described, based on the level of urinary cystine in obligate heterozygotes (96). Type I accounts for approximately 70% of patients with clinically evident cystinuria and is completely recessive. Patients with type I/I show cystine excretion rates that are generally higher than 1000 $\mu\text{mol/g}$ creatinine by 1 year of age with a mean excretion rate of 4500 $\mu\text{mol/g}$ creatinine (96). Half or more of such patients develop stones within the first decade of life (96). Mutations of the SLC3A1 gene on chromosome arm 2p encoding the rBAT protein important in dibasic amino acid transport have been shown to be responsible (97,98). Types II and III are identified by elevated cystine excretion in obligate heterozygotes (99). Heterozygotes with type II/N have cystine excretion of 400 to 2400 $\mu\text{mol/g}$ creatinine and may form stones. Those with III/N have lower cystine excretion and typically do not develop urolithiasis. Patients with types II/II and III/III have cystine excretion rates similar to that in type I/I. Compound heterozygotes are common. Type I/III patients appear to excrete less cystine and are unlikely to form stones within the first decade of life (96). Other compound heterozygotes have not been as well studied. Mutations of the SLC7A9 gene on chromosome 19 are responsible for types II and III (98,100). With increasing molecular genetic information, some have challenged the traditional classification system (101). Due to the immaturity of renal tubule function during infancy and the complexity of compound heterozygosity, it is difficult definitively to establish the diagnosis of cystinuria before 1 year of age (102).

Patients with homozygous forms of cystinuria have lifelong recurring stone formation (Fig. 57.3). Medical therapy can be highly beneficial. First-line therapy consists of increased

FIGURE 57.3. Staghorn calculus in the right kidney of a patient with cystinuria.

oral fluid intake and a low-salt diet with urinary alkalinization to a pH of 7.0. If formation of cystine stones is not well controlled with these measures, addition of tiopronin (Thiola) or D-penicillamine is recommended. The use of captopril has been advocated but results have been inconclusive (103). Even with optimal medical management, however, urologic procedures are periodically required. With advancing age, elevated serum creatinine concentrations can be encountered in as many as 50% of patients, and a small proportion (approximately 3%) eventually require dialysis (103,104).

Hyperuricosuria is found in 2 to 10% of children and adolescents with metabolic stones. Mild idiopathic hyperuricosuria may be a cause of hematuria (52) and is often found in conjunction with hypercalciuria (22,105). A defect in renal tubular transport of uric acid, due either to reduced proximal tubular reabsorption or to increased secretion, may be found (52,106,107). Idiopathic renal hyperuricosuria is often familial and asymptomatic. Secondary hyperuricosuria may result from diets high in protein or ketogenic diets (108); from medications, including dicumarol, ascorbic acid, probenecid, phenylbutazone, salicylates, and citrate; and from pancreatic extract therapy in patients with cystic fibrosis (52). It can be seen in association with diabetes (109) and the syndrome of inappropriate secretion of antidiuretic hormone (110).

Although uric acid crystals in the urine may contribute to urolithiasis by forming a nidus for calcium oxalate crystallization, uric acid stones are uncommon in childhood. When they occur in children, uric acid stones are generally due to marked overproduction of uric acid such as occurs in tumor lysis syndrome, lymphoproliferative or myeloproliferative disorders, or rare inborn errors of metabolism such as complete (Lesch-Nyhan syndrome) or partial deficiencies of hypoxanthine phosphoribosyltransferase enzyme activity. Urolithiasis occurs in a high proportion of patients with Lesch-Nyhan syndrome and not infrequently develops during the first year of life. Of those with partial hypoxanthine phosphoribosyltransferase deficiency, up to 75% develop uric acid urolithiasis (13). High fluid intake and restriction of dietary purines are recommended. Treatment to achieve urinary alkalinization to a pH of 7.0 will increase solubility, and a trial of allopurinol may be beneficial (80).

Xanthine calculi may occasionally be seen in patients treated with allopurinol for hyperuricemia related to Lesch-Nyhan syndrome or tumor lysis syndrome during chemotherapy (111). Markedly increased urine concentrations of xanthine and hypoxanthine are also seen in patients with a rare autosomal recessive deficiency of xanthine oxidase activity. Xanthine calculi develop in approximately one-third of patients with hereditary xanthinuria (75,112). Urinary tract stone disease in childhood may result from urinary solute excess due to other rare inborn errors of metabolism, including adenine phosphoribosyltransferase deficiency leading to 2,8-dihydroxyadeninuria (113,114), orotic aciduria, and alkaptonuria (115). Treatment with

allopurinol is effective in adenine phosphoribosyltransferase deficiency because it blocks production of 2,8-dihydroxyadenine.

Inhibitor Deficiencies

Citrate is a naturally occurring inhibitor of calcium oxalate and calcium phosphate crystallization. Hypocitric aciduria is a frequent finding in a subset of adult patients with idiopathic urolithiasis (80,116). In a study of pediatric patients by Tekin and colleagues, urinary citrate excretion was significantly lower in calcium stone formers than in a control group of healthy children (117). Baggio et al. found lower urinary concentration and excretion rates of citrate in stone-forming children than in control subjects, but the differences did not reach statistical significance (118). Whether or not citrate deficiency is a primary contributing factor to stone formation in a particular patient, increasing a lower citrate concentration to a higher one can be beneficial in minimizing stone-forming activity.

Deficiency of urinary citrate occurs predictably as a result of hypokalemia and systemic or intracellular acidosis. In most such situations, however, the hypocitric aciduria is transient. In distal RTA, hypocitric aciduria appears to be a major contributor to stone formation. The hypocitric aciduria persists until the metabolic acidosis is corrected. The measured urine citrate concentration is predictably reduced in the presence of a urinary tract infection, and measurement should be repeated after antibiotic treatment. Interpretation of urinary citrate concentrations is complicated by relatively few studies of urinary citrate in healthy children of various ages and the fact that citrate is influenced by prandial state, dietary composition, and age.

Pyrophosphate and magnesium in the urine are also known to act as inhibitors of calcium oxalate and calcium phosphate crystal formation. Although both are used for therapeutic benefit, deficiencies of pyrophosphate or magnesium have not been described as a primary cause of urolithiasis.

There has been interest in a variety of urinary macromolecules that appear to inhibit calcium oxalate crystal formation. Those studied include glycosaminoglycans, osteopontin, nephrocalcin, and urinary prothrombin fragment 1, among others. Some researchers have observed relatively lower concentrations of these inhibitors in children who form stones than in the urine of children who do not (119). However, considerable controversy still exists regarding the role of urinary macromolecules in clinical disorders of stone formation (38).

Clinical Conditions Associated with Urolithiasis

A number of clinical conditions are associated with metabolic factors that predispose to stone formation. Distal RTA results in hypocitric aciduria, hypercalciuria, low titratable

FIGURE 57.4. Small radiopaque stones scattered throughout both kidneys in a patient with distal renal tubular acidosis (RTA). The pattern is characteristic for RTA.

acidity, and high urine pH. Multiple calcifications comprised of calcium phosphate and/or calcium oxalate in the region of the papillary tips of the kidneys are typical and are seen with both incomplete and complete forms of distal RTA (Fig. 57.4). In long-term follow-up of distal RTA in childhood, Caldas et al. (120) found nephrolithiasis and/or nephrocalcinosis in 14 of 28 patients. Nephrocalcinosis tends to occur with increasing age (120). The experience of others suggests that early initiation of alkali therapy may obviate the development of nephrocalcinosis by correcting the hypocitric aciduria and hypercalciuria (121,122). A few patients have been reported among kindreds with RTA that appeared to develop nephrolithiasis and/or nephrocalcinosis due to hypercalciuria without systemic acidosis (123). This and other observations regarding hereditary RTA suggest that the relationships among hypercalciuria, the renal tubule acidification defect, and nephrocalcinosis-urolithiasis are complex (123).

Several autosomal recessive mutations resulting in carbonic anhydrase II deficiency have been described that are accompanied by variable degrees of distal and/or proximal RTA and associated urolithiasis and nephrocalcinosis (124–126). Mutations in the red cell anion exchanger (Band 3, AE1) gene have been confirmed in several families (127), are associated with distal RTA, and usually show autosomal dominant transmission (128). Urolithiasis is a frequent manifestation (127). Secondary distal RTA such as occurs in Wilson's disease and Sjögren's syndrome has also been associated with urolithiasis (129,130). Hypercalciuria and hypocitric aciduria, which increase with age, and distal RTA have been implicated in the nephrolithiasis associated with type 1a glycogen storage disease (131–134). Incomplete distal RTA and urolithiasis have been reported in cerebrotendinous xanthomatosis, an autosomal recessive lipid metabolic disorder (135).

Urolithiasis is not typically associated with proximal RTA (136,137) nor with type IV RTA (138). Although

hypercalciuria occurs in proximal RTA, the high associated urinary citrate concentrations may protect against stone formation. In type IV RTA, citrate excretion is reduced, but reduced excretion of calcium appears sufficient to compensate for the reduced urine citrate so that urinary saturation of calcium oxalate remains within normal limits (138). Lower phosphorus and uric acid excretion in patients with type IV RTA may also help prevent stone formation (138).

Medullary sponge kidney is frequently associated with recurrent calcium urolithiasis. Hypercalciuria, hypocitric aciduria, incomplete RTA, and increased urine pH have been variably observed in such patients (139). Nephrolithiasis is seen in 20 to 36% of patients with autosomal dominant polycystic kidney disease, with approximately half of the stones comprised of calcium oxalate and the other half of uric acid (140). The most consistent metabolic abnormality is hypocitric aciduria, with a minority of the patients having hyperuricosuria or hypercalciuria (140,141). Thin basement membrane nephropathy has been associated with hypercalciuria, hyperuricosuria, and resulting nephrolithiasis (142). An increased frequency of urolithiasis and nephrocalcinosis has also been reported in cystinosis (143–146). Children and adults with Wilson's disease may develop urolithiasis. Distal RTA is the most commonly observed factor (129). Some patients, however, demonstrate hypercalciuria and urolithiasis without evidence of RTA (147). Because urolithiasis may be diagnosed before Wilson's disease is clinically evident, any patient with renal stones and unexplained neurologic, bony, or hepatic abnormalities should be screened for Wilson's disease (129). Hypercalciuria and hypocitric aciduria, which increase with age, and distal RTA have been implicated in the nephrolithiasis associated with type 1a glycogen storage disease (131–133).

Inflammatory bowel disease and other diseases of the gastrointestinal tract associated with malabsorption can cause hypocitric aciduria and hypomagnesuria due to loss of bicarbonate and magnesium in the stool, hyperoxaluria from enhanced enteric oxalate absorption, hyperuricosuria due to increased cell turnover, and low urine volume because of diarrhea, which together result in reduced inhibitor activity and high solute concentrations in the urine (148,149).

Calcium oxalate urolithiasis has been reported in 5.2 to 10.4% of young patients with cystic fibrosis (77,150,151), and nephrocalcinosis has been observed in another 6.3% (77). Katz et al. found microscopic nephrocalcinosis at autopsy in 35 of 38 patients (92%) with cystic fibrosis, including 6 patients who were younger than 1 year of age at the time of death (152). Hyperoxaluria appears to be the primary factor (77,150,151,153), although hypocitric aciduria (77,151) and hyperuricosuria (77) have also been observed. Urine calcium has been variably reported as reduced (153), normal (77), or increased (77,151). Crystaluria is commonly seen (150,151). Pancreatic insufficiency with fat malabsorption and resulting enteric hyperoxaluria

FIGURE 57.5. Ultrasonographic evaluation showing nephrocalcinosis and a shadowing stone in the pelvis of the kidney of a 3-month-old infant born prematurely.

are suggested by the clinical setting, although no correlation could be established between the degree of fat malabsorption and urine oxalate excretion in two studies (151,153). Deficiency of enteric *O. formigenes* due to repeated courses of antibiotics has also been suggested as a risk factor for hyperoxaluria in this patient population (79). Pancreatic enzyme replacement and high-protein diets may contribute to hyperuricosuria. Damage to renal tubules by antibiotic treatment has been implicated by some authors as a contributing cause due to hypercalciuria after a renal phosphate leak (151).

Premature infants have a higher incidence of nephrocalcinosis and nephrolithiasis than healthy term infants (Fig. 57.5). In three prospective studies of infants born at less than 1500 g or less than 32 weeks' gestation, renal calcifications were found to occur in 64%, 16%, and 28% of infants (154–156). The risk of renal calcifications appears higher in smaller infants, those receiving furosemide or postnatal corticosteroids, those undergoing a longer period of mechanical ventilation and parenteral nutrition, white infants, and those with a family history of urolithiasis (156). Metabolic disturbances including hypercalciuria (154), hypophosphatemia and hypercalcemia (both of which can induce hypercalciuria) (157), and hyperoxaluria related to parenteral nutrition (158) have been implicated. Abnormalities of urine composition associated with renal tubule immaturity may play a role. Nephrocalcinosis resolves with time in approximately half of the patients, and new stone formation appears to abate in the majority of patients. However, longer-term studies performed at 4 to 12 years of age in very-low-birth-weight children who had a history of renal calcifications demonstrated hypercalciuria, hypocitric aciduria, and reduced ammonium excretion in response to furosemide in comparison to a control group of children born at term (159). At the time of study 18% of the children still had renal cortical hyper-

echogenicity and 9% had urolithiasis. Whether the renal tubular abnormalities are the long-term result of renal tubular immaturity at birth, are secondary to renal damage from nephrocalcinosis, or are due to other factors remains to be established.

Nephrocalcinosis is often seen together with urolithiasis and appears to share many of the same metabolic risk factors. In one study of 152 children and adolescents with nephrocalcinosis, idiopathic hypercalciuria was found in 34% and various hereditary renal tubular disorders in 32% (160). A family history of nephrocalcinosis or urolithiasis was noted in 7.2% and 19.1%, respectively (160).

Pharmacologic Agents Implicated in Urolithiasis

Urolithiasis can result from pharmacologic use of a variety of medications. Calculi may result from excretion of concentrations of the medication or a metabolite in the urine that exceed solubility or may occur due to metabolic effects induced by the medication. The protease inhibitor indinavir, used widely in the treatment of human immunodeficiency virus infection, precipitates in the urine as radiolucent crystals and stones; these can cause ureteral obstruction and colic, which are observed in 2 to 28% of patients treated with this agent (161–163). Up to 20% of this parent drug is filtered by the kidney. The drug is poorly soluble at a pH level higher than 5. Distinctive birefringent crystals with plate and starburst structures are observed in 20 to 25% of patients receiving this antiretroviral agent (162,164). The indinavir crystals or small stones may also act as a nidus for calcium oxalate or calcium phosphate, and are also associated with stones of mixed composition that may be radiopaque. There are a number of reports of such effects in children (161,165,166). Due to the radiolucent nature of indinavir stones, they are not visible on noncontrast renal tomography and may be difficult to distinguish from soft tissue by computed tomography (CT) (165). Ultrasonography, intravenous pyelography, or contrast-enhanced CT may be needed to demonstrate indinavir stones and associated ureteral obstruction. Dissolution of stone material may be observed with discontinuation of indinavir, increased fluid intake, and urine acidification (166).

Other medications that can precipitate to form urinary tract stones are ceftriaxone (167,168), sulfonamides, ampicillin, amoxicillin, triamterene, guaifenesin (169), phenazopyridine, and oxypurinol (170). Urinary tract stones are observed only rarely with these agents.

Carbonic anhydrase inhibitors, administered for management of epilepsy and glaucoma among other uses, result in alkaline urine, reduced urine citrate levels, and hypercalciuria (170,171). Agents of this class, including zonisamide, topiramate, and dorzolamide, have been reported to be associated with calcium phosphate and calcium oxalate urolithiasis in children and adolescents (172–174). Commonly

used agents such as corticosteroids, calcium supplements, and vitamin D and its analogues are associated with hypercalciuria and can predispose to stone formation. Aminopylline use results in hypercalciuria, alkaline urine, and phosphaturia, countered in part by its diuretic effects (175). Lithium use can induce hypercalcemia and hypercalciuria.

Dietary Considerations

Diets low in animal protein but high in cereals contribute to formation of bladder stones in children (34,176). Large dietary intake of sodium or calcium may induce hypercalciuria. High intake of animal protein predisposes to higher urine uric acid, calcium, and oxalate excretion and reduced urinary citrate and pH, all of which favor calcium oxalate stone formation (21). Frassetto et al. noted that contemporary net acid-producing diets (rich in animal protein and deficient in plant protein and potassium alkali salts) produce a low-grade systemic acidosis in otherwise healthy adults (177). He and others have postulated that the ensuing metabolic changes may, in part, explain the increasing prevalence of urolithiasis in industrialized countries in recent decades (21,177).

Ketogenic diets used for the management of seizures have been reported to be associated with nephrolithiasis in 3 to 10% of children receiving this form of therapy (178). Stones may be comprised of uric acid, calcium phosphate, mixed calcium and uric acid, or ammonium urate (108,178). Urolithiasis appears to be related to ensuing hypercalciuria, hypocitric aciduria, and reduced oral fluid intake (108,178,179). Urine uric acid excretion is normal in most but not all patients (108,178), so that uric acid stone formation appears related primarily to the low volume and acidic pH of the urine. Stone formation has been noted between 7 and 22 months after initiation of the diet (108,178).

Infection as a Lithogenic Factor

Infection of the urinary tract with bacteria producing the enzyme urease leads to hydrolysis of urea with resulting production of ammonium and bicarbonate ions in the urine. In the presence of the increased pH, dissociation of phosphate occurs, with supersaturation of the urine for magnesium ammonium phosphate (struvite) and calcium phosphate apatites, including carbonate apatite (180). Precipitation of stone material follows. A variety of bacterial species produce urease, including *Proteus*, *Staphylococcus*, *Klebsiella*, *Providencia*, *Pseudomonas*, *Enterobacter*, *Ureaplasma urealyticum*, *Corynebacterium urealyticum*, and some anaerobes. Struvite tends to form staghorn calculi that can grow rapidly and are challenging to treat. It is difficult to eradicate infection while stone material remains, because antibiotics do not penetrate well within the interstices of the stone where bacteria reside. Just under half of the patients with infected staghorn calculi can be rendered

stone free by extracorporeal shock wave lithotripsy (ESWL) (181), so that combined procedures including percutaneous ultrasonic lithotripsy are often needed (182). Retained stone fragments can serve as a nidus for early recurrence.

Xanthogranulomatous pyelonephritis is a rare but serious infectious process leading to nonfunction of the infected kidney. Obstruction caused by renal calculi has been found in 68% of affected children (183), with approximately half of such calculi being of the staghorn variety (183). Another author reported nephrolithiasis and/or nephrocalcinosis in 71% of such children (184). *Proteus*, *Escherichia coli*, *Klebsiella*, *Pseudomonas*, and *Enterobacter* bacteria (several species of which produce urease) are most often responsible (185). In xanthogranulomatous pyelonephritis, renal stones, obstruction, and infection exacerbate each other. Nephrectomy is required in most circumstances (183–185).

Encrusted pyelitis is another unusual manifestation of infection and mineralization (186). Infection of the kidney with *C. urealyticum*, a urea-splitting organism, leads to encrustation of the wall of the renal pelvis with struvite and associated apatite crystals and proteins (187). Infection with this slow-growing aerobic organism is usually acquired after urologic manipulations of the urinary tract and is most often observed in immunosuppressed patients. Most reports in the literature cite cases in renal allograft recipients (186,188,189). Obstructive uropathy and loss of renal function are common (188,189). The encrustations are tightly adherent to the mucosa and are difficult to dislodge. In addition to prolonged antibiotic therapy, placement of percutaneous nephrostomy tubes for irrigation with acidic Thomas solution (186) or use of acetohydroxamic acid (186,189,190) has been advocated.

Although infection with urease-producing organisms can produce de novo urolithiasis, often the infection exacerbates underlying metabolic factors. With careful evaluation, 20 to 61% of patients with infection-related stones can also be demonstrated to have metabolic factors predisposing to stone formation (22,80,191). Stasis due to urinary tract abnormalities also predisposes to infection, which further illustrates the interaction among infection, metabolic factors, and structural abnormalities of the urinary tract in the genesis of calculi.

Structural Abnormalities of the Urinary Tract

Stasis of urine often accompanies structural abnormalities of the urinary tract, whether congenital or acquired. By compromising the normal continuous flow of urine from the upper urinary tract and interfering with regular and complete emptying of urine from the bladder, stasis promotes crystal retention and stone formation as well as infection. A wide range of structural abnormalities has been associated with urolithiasis, including medullary sponge kidney (139), autosomal dominant polycystic kidney disease, calyceal divertic-

ula (192), ureteropelvic junction obstruction (117,193), horseshoe kidney (194), ureterocele, primary megaureter (31), posterior urethral valves (31), and the bladder extrophy-epispadias complex (195). Medullary sponge kidney is frequently associated with recurrent calcium urolithiasis. In medullary sponge kidney and autosomal dominant polycystic kidney disease, tubular ectasia and cyst formation, respectively, are felt to contribute to stasis of the urine that exacerbates metabolic abnormalities. Patients with myelodysplasia often have impaired bladder emptying, recurrent urinary tract infections, and hypercalciuria from relative immobilization. Partial obstruction can result in renal acidification deficiencies with accompanying hypocitric aciduria. Patients who have undergone enterocystoplasty and urinary diversion using intestinal mucosa are particularly prone to local formation of stones, with 16 to 50% of patients undergoing enterocystoplasty reported to form bladder stones (196–198). The difficulty in eradicating bacteria from the enteral mucosa, stasis, an alkaline urine pH due to infection or to exchange of chloride for bicarbonate across the mucosa, and the presence of mucus in the bladder all favor stone formation (197). Foreign bodies such as sutures or staples, or indwelling stents also can act as a nidus for stone formation.

With the exception of those undergoing enterocystoplasty, however, the overall incidence of stones in children with structurally anomalous, obstructed, or infected urinary tracts is low, on the order of 1 to 5% (199). This suggests that, although these factors are permissive, children who form stones may also have underlying metabolic abnormalities. Hypercalciuria, hyperoxaluria, or hypocitric aciduria have been identified in 66 to 80% of patients with structural abnormalities of the kidneys or ureters who also had urolithiasis and underwent metabolic evaluation (193,200). Tekin and colleagues demonstrated a similar degree of hypocitric aciduria and hyperoxaluria in patients with ureteropelvic junction obstruction and urolithiasis as in those with calcium stone formation but without urinary tract abnormalities. The incidence in both groups was significantly different from that in the control group of healthy children (117). The importance of metabolic abnormalities in patients with stones and urinary tract abnormalities is further suggested by long-term follow-up of a group of pediatric patients with ureteropelvic junction obstruction and renal calculi. Recurrent urolithiasis developed in 68% of the patients despite successful ureteropelvic junction repair. Furthermore, 10 of 19 recurrent stones (53%) formed in the contralateral, uninvolved kidney (193). Accordingly, complete metabolic evaluation is just as important in children with structural abnormalities of the urinary tract or infection-related stones as it is in those without.

DIAGNOSTIC EVALUATION

Recommended initial evaluation of children or adolescents with urolithiasis includes taking medical and diet histories;

obtaining family history; performing urinalysis with determination of pH, osmolality, and presence or absence of crystals; and measurement of serum levels of calcium, phosphorus, uric acid, bicarbonate, sodium, potassium, creatinine, alkaline phosphatase, and albumin. An estimate of daily fluid intake is an important aspect of the dietary history, as is an estimate of the daily intake of calcium, sodium, oxalate, and protein. The medical and diet history taking should include an inquiry regarding use of over-the-counter food supplements, vitamins, minerals, or herbal preparations. Analysis of stone composition should always be performed when stone material is available. Urine concentrations and, when possible, excretion rates of solutes should be measured. For infants or young children, older children with developmental delay, or cases in which a reliable timed urine collection cannot be obtained, taking random urine specimens and measuring solute to creatinine ratio can be very useful. Care is advised in interpretation, however, because normal values often vary by age, time of day, and prandial state. Whenever a child is able to cooperate with a timed 24-hour urine collection, this will provide more complete information, including assessment of daily urine volume. Completeness of each collection should be verified with measurement of urine creatinine level. Urine should be analyzed for calcium, oxalate, citrate, uric acid, sodium, cystine, creatinine, and total volume. Metabolic evaluation should be performed while the patient is on his or her usual diet, usual fluid intake, and normal activity level. The studies should not be performed shortly after ESWL or a stone removal procedure and should not be obtained when the child is receiving intravenous fluids. If abnormalities are found, further metabolic evaluation may be indicated.

Normal values for urine analytes are shown in Table 57.2. Solute to creatinine ratios are higher in infancy. After 2 years of age, urine uric acid/creatinine and oxalate/creatinine ratios vary, decreasing by age, but excretion rates are fairly consistent throughout childhood when determined in a timed collection and expressed as milligrams per 1.73 m² per 24 hours (201–204). Uric acid can also be expressed as milligrams per deciliter glomerular filtration rate, measured in either a random or timed urine collection (205). Reported normal values for some analytes vary from study to study and vary for oxalate by the measurement method. Because information on normal values is used for diagnosis and treatment, it is helpful to keep in mind that the excretion rate of each of these analytes is a continuous variable and should be regarded as a modifiable risk factor rather than compared to a strictly defined threshold for normal.

Evaluation should include imaging studies of the urinary tract. Stones comprised of calcium oxalate or calcium phosphate are radiodense and are readily seen. Struvite and cystine stones are of intermediate radiodensity. Uric acid, xanthine, 2,8-dihydroxyadenine, and orotic acid stones are radiolucent by conventional radiography but visible by

TABLE 57.2. URINE CHEMISTRY: NORMAL VALUES

Urine constituent	Age	Random	Timed	Comments
Calcium (52,230)	0–6 mo	<0.8 mg/mg creat		Prandial variation
	7–12 mo	<0.6 mg/mg creat		Sodium dependent
	≥2 yr	<0.21 mg/mg creat	<4 mg/kg/24 h	
Oxalate ^a (204,231)	<1 yr	0.15–0.26 mmol/mmol creat		Random urine mmol/mmol highly age dependent
	1 yr to <5 yr	0.11–0.12 mmol/mmol creat		
	5–12 yr	0.006–0.15 mmol/mmol creat	≥2 yr; <0.5 mmol/1.73 m ² /24 h	Excretion rate/1.73 m ² constant through childhood and adulthood
	>12 yr	0.002–0.083 mmol/mmol creat		
Uric acid (201,205)	Term infant	3.3 mg/dL GFR ^b	<815 mg/1.73 m ² /24 h	Excretion rate/1.73 m ² from >1 yr age constant through childhood
	>3 yr	<0.53 mg/dL GFR		
Magnesium (13,230)	>2 yr	<0.12 mg/mg creat	<88 mg/1.73 m ² /24 h	Excretion rate/1.73 m ² constant through childhood
Citrate (232)		>180 mg/g creat (232) >400 mg/g creat (13)		Limited data available for children
Cystine (13,30)		<75 mg/g creat	<60 mg/1.73 m ² /24 h	Cystine >250 mg/g creat suggests homozygous cystinuria

creat, creatinine; GFR, glomerular filtration rate.

^b(mg/dL uric acid) (serum creatinine concentration/urine creatinine concentration).

ultrasonography or unenhanced CT. Ultrasonography is sufficient in many circumstances (206), whereas CT, urography, or intravenous pyelography is required at times, as is voiding cystourethrography. Nimkin and colleagues compared imaging modalities for detection of stones in the pediatric population and reported a sensitivity of 57% for plain films and 77% for ultrasonography compared with stone detection by CT (16). Others have reported better overall sensitivity for ultrasonography (207), but it may fail to detect 30% of small papillary or calyceal stones (208) and may miss ureteral calculi (207). For acute renal colic, non-contrast helical CT scanning is considered the imaging modality of choice, because it is more sensitive and specific for ureteral calculi than all other imaging modalities (209). CT also has the advantage of providing detailed anatomic information (usually without the need for intravenous contrast administration) and improved sensitivity for very small stones or those that are poorly radiopaque (206). Concern has been expressed regarding the degree of radiation exposure from CT (210). With careful attention to radiographic technique, the radiation exposure with CT can be significantly reduced while maintaining good imaging quality (209,211) and may be less than that with other renal imaging techniques such as an intravenous pyelography (212).

Urine culture should be performed for every patient with stones. Colony counts of bacteria in the urine of patients with infected stones may not reach the threshold of 10⁵ colony-forming units/mL, so that lower colony counts should be further evaluated. In selected circumstances, such as suspected *Ureaplasma*, *C. urealyticum*, or anaerobic bacterial infection, special culture techniques may be needed.

TREATMENT

Stones causing obstruction or acute renal colic, stones with a high potential for causing acute obstruction (e.g., a large stone in the renal pelvis), and infected stones should be evaluated jointly with a urologist. The majority of stones smaller than 5 mm in diameter will pass spontaneously, even in young children (25). Larger symptomatic stones are likely to require surgical intervention. The range of effective surgical interventions continues to increase, and now even very young patients can often undergo ESWL, ureteroscopic lithotripsy or removal, or percutaneous ultrasonic lithotripsy procedures. Open lithotomy is rarely required. Due to the potential for high-energy shock waves to permanently damage renal tissue, there has been concern regarding possible long-term adverse effects of ESWL on the developing kidney. A careful study of 16 children treated for a single stone found no morphologic changes in the kidneys by ultrasonography after ESWL and no significant changes in serum creatinine level but did document significant posttreatment increases in urinary β₂-microglobulin and enzymuria (213). These changes were considered evidence of proximal renal tubule dysfunction and resolved by 14 days after the procedure. This value can be compared to 7 days for resolution of similar changes in adult patients and may indicate more significant injury in children (213). One study suggested impairment in growth of the kidneys in children after ESWL (214). However, most information involving second-generation or later lithotriptors does not indicate clinically significant renal parenchymal scarring, impaired renal growth, permanent renal function abnormalities, or hypertension in children after ESWL treatment (215). Information is still rel-

actively limited, particularly in children who were under the age of 6 at the time of treatment.

Patients with infected stones who need ESWL, percutaneous ultrasonic lithotripsy, or an open procedure require attentive antibiotic management because bacteria may be released rapidly from stone material on fragmentation during lithotripsy or instrumentation. Struvite stones may be soft and friable, with particular vulnerability to stone fragment retention after ESWL. Any stone fragments remaining may harbor bacteria in the interstices of the fragments, where they are less accessible to antibiotic penetration; this makes eradication of the infection very difficult. In addition, stone fragments provide a nidus for new struvite stone formation, which can occur rapidly. It is for this reason that percutaneous ultrasonic lithotripsy or nephrolithotomy is still sometimes required to assure complete removal of infected stone material.

Stones that are not causing symptoms and are not associated with impending or established obstruction may be managed medically. For all forms of urolithiasis, increased oral fluid intake to maintain a urine volume of greater than 750 mL/day in infants, 1000 mL/day in children under the age of 5, 1500 mL/day to the age of 10, and greater than 2 L/day in preadolescents and adolescents is most helpful to minimize stone growth and recurrent stone formation and is recommended. Increased urine volume has been shown to be significantly associated with a lower risk of stone recurrence in adults with idiopathic stone formation (216). Avoidance of dietary excesses of calcium, oxalate, and sodium is important. However, reduction to less than the recommended daily allowance, particularly of dietary calcium, may be problematic with respect to nutritional adequacy, normal growth, and development. Reduction to the appropriate recommended daily allowance for age for calcium, and no lower, is recommended even in children with known hypercalciuria. Indeed, epidemiologic studies in adults suggest that dietary calcium reduction is associated with an *increased* likelihood of urolithiasis (217), perhaps due to greater absorption of dietary oxalate when less calcium is present in the intestinal tract. Dietary sodium restriction is of particular importance in patients with hypercalciuria and those with cystinuria, because it can reduce the urinary excretion of calcium (54,218) and cystine (219–222), respectively.

Patients with idiopathic urolithiasis who have normal urine chemistry results or mild hypercalciuria only and a single stone may be managed initially with increased fluid intake and dietary modification alone. If metabolic stone-forming activity is not adequately controlled by this approach, addition of potassium citrate therapy—or, for those with hypercalciuria, therapy with a thiazide—is the next step. Treatment of patients with metabolic factors should be directed specifically to the abnormality(ies) found. Suggested initial therapy, and second-line therapy if problems persist despite the initial intervention, are shown in Table 57.3.

TABLE 57.3. SUGGESTED THERAPY FOR UROLITHIASIS CAUSED BY METABOLIC ABNORMALITIES

Metabolic abnormality	Initial treatment	Second-line treatment
Hypercalciuria	Reduction of dietary Na ⁺ Dietary calcium at RDA Thiazides	Potassium citrate Neutral phosphate
Hyperoxaluria	Adjustment of dietary oxalate Potassium citrate	Neutral phosphate ^a Magnesium Pyridoxine ^a
Hypocitric aciduria	Potassium citrate Bicarbonate	
Hyperuricosuria	Alkalinization	Allopurinol
Cystinuria	Alkalinization Reduction of dietary Na ⁺	Tiopronin (Thiola) D-penicillamine Captopril

RDA, recommended daily allowance.

^aInitial therapy in primary hyperoxaluria.

Urolithiasis in children and adolescents, like that in adults, recurs frequently. In one study of 221 children followed for a mean of 59 months (median, 36 months), 67% developed two or more stones during initial evaluation and follow-up (22). Other authors have reported recurrence rates of 20 to 40% with variable follow-up periods (25). Recurrence rates are higher in children with demonstrable metabolic abnormalities (25). Because of the persistence of underlying metabolic abnormalities and known risk of recurrence, long-term follow-up with periodic reassessments of the activity of stone formation is indicated. Evaluation of metabolic stone-forming activity over time, as determined by growth in size of existing stones or formation of new stones, is an important aspect of treatment. The frequency of renal imaging required depends on the type and number of stones and the severity of the metabolic abnormalities detected. In most circumstances and in the absence of symptoms or infection, imaging once yearly or every other year is sufficient. Patients with significant metabolic problems such as primary hyperoxaluria, cystinuria, or marked hypercalciuria, and those with infected stones (which can develop and grow quickly) may require more frequent evaluations. Ultrasonography has the advantage of visualization of radiolucent as well as radiopaque stones, detection of hydronephrosis, and the absence of radiation exposure, and is preferred for most routine follow-up assessments. However, its lack of sensitivity for small stones, the difficulty in comparing the sizes of individual stones over time, its lower sensitivity for visualization of ureteral stones, and the possibility of obstruction in the absence of hydronephrosis will, at times, dictate other imaging modalities. Acute symptoms should prompt reevaluation.

If increase in the size of existing stones or new stone formation occurs despite treatment, a more intensive regimen should be implemented. In patients with active stone formation, additional studies can be helpful in assessing the degree of metabolic stone formation and providing guidance as to the most effective therapies. These may include determination of crystalluria by phase-contrast microscopy, determination of supersaturation of the urine by modelling of various components, measurement of urinary inhibitor activity, evaluation for subtype of hypercalciuria (absorptive, renal leak, sodium dependent), or measurement of enteral absorption of oxalate, among others.

In children of all ages, if compliance with recommendations can be secured, response to treatment is typically excellent, with reduced frequency or elimination of active stone formation. Many metabolic abnormalities, such as idiopathic hypercalciuria, are lifelong, however. Subtle degrees of damage to the renal tubule are suggested by studies showing increased urinary excretion of renal *N*-acetyl- β -glucosaminidase in children with hypercalciuria (223) and in those with urolithiasis (224); a deficiency of distal acidification in children with hypercalciuria and urolithiasis that is not seen in children with hypercalciuria alone (225); and the identification of families in which hypercalciuria appears to be the primary event, with distal RTA developing over the years as an apparent complication of hypercalciuria (123,226). Others have argued that the renal tubule acidification deficiency is primary and that the hypercalciuria and urolithiasis occur secondarily (227). Jaeger and colleagues studied renal tubular function in patients with urolithiasis related to primary hyperparathyroidism, medullary sponge kidneys, hyperuricemia, cystinuria, struvite stone disease, idiopathic hypercalciuria, and normocalciuric idiopathic urolithiasis (219). They found that a significant number of stone formers have dysfunction of the proximal renal tubule, that the abnormalities are found in patients in all of the diagnostic groups, and that the occurrence is related to the presence of stones in the collecting system at the time of study (219). The authors concluded that in nephrolithiasis tubulopathy is the consequence, rather than the cause, of stone disease.

The risk of renal insufficiency has been estimated at 1.7% in idiopathic calcium oxalate urolithiasis (228). In a group of 40 patients with a mean duration of cystinuric stone disease of 26 years, renal insufficiency was found in 70% of patients, although none had reached end-stage renal disease (229). In these patients, stone-preventive treatment appeared effective in preserving renal function (229). Infection-related staghorn stones are associated with end-stage renal disease in 20 to 30% of adult patients with unilateral involvement and a higher percentage of those with bilateral stones (228). Several forms of more severe urolithiasis, such as primary hyperoxaluria, Dent's disease, and 2,8-dihydroxyadeninuria are frequently associated with renal insufficiency or end-stage renal disease.

For these reasons, and despite the excellent response to treatment noted in most children with urolithiasis, long-term nephrologic care is indicated, particularly for those with more complex forms of renal stone disease.

PEDIATRIC RENAL TUMORS

CHRISTOPHER S. COOPER
JACK S. ELDER

WILMS' TUMOR

Incidence

Wilms' tumor is the most common renal malignancy in children and the fourth most common pediatric malignancy (1). Seventy-five percent of Wilms' tumors are seen in children between 1 and 5 years of age, and 90% occur in children younger than 7 years of age; age of peak incidence is 44 months. Boys and girls are almost equally affected by Wilms' tumor (1,2).

Etiology and Pathophysiology

Wilms' tumor is thought to arise from abnormal renal development, with proliferation of metanephric blastema without normal differentiation into tubules and glomeruli. Alterations in genes controlling growth and differentiation have been associated with Wilms' tumor (2).

Nephrogenic rests or nephroblastomatosis may be precursor lesions that have the potential to undergo change and become a Wilms' tumor. A nephrogenic rest consists of a focus of abnormally persistent embryonic kidney cells. Nephrogenic rests occur in 1% of kidneys in newborns but usually regress or differentiate early in childhood. Nephroblastomatosis describes the condition in which multifocal or diffuse nephrogenic rests are present. More than 40% of kidneys from children with Wilms' tumor contain nephrogenic rests, and almost 100% of children with bilateral Wilms' tumors have rests in their kidneys. Children with a Wilms' tumor 1 (*WT-1*) or 2 (*WT-2*) gene mutation have an increased incidence of nephrogenic rests, and a second factor may induce the transformation of these rests into malignancies (3).

Nephrogenic rests can be divided into two categories based on their position relative to the renal lobe. Intralobar nephrogenic rests consist of rests anywhere within the renal lobe, sinus, or pelvicaliceal system. Perilobar nephrogenic rests occur in the lobar periphery. The latter rests probably occur later in development because the renal lobe develops in a centrifugal fashion. Intralobar nephrogenic rests are found in a younger age group, are less common, and are

often associated with the WAGR (Wilms tumor, aniridia, genitourinary malformations, and mental retardation) and Denys-Drash syndromes, which occur in association with *WT-1* mutations (4). Perilobar nephrogenic rests occur more frequently than intralobar nephrogenic rests and are associated with overgrowth syndromes such as hemihypertrophy and the Beckwith-Wiedemann syndromes.

The majority of nephrogenic rests undergo regression and become sclerotic or obsolescent, including those associated with *WT-1* mutations. Some rests grow and become hyperplastic, but even hyperplastic rests may regress. Unfortunately, a dormant, hyperplastic, or regressing rest maintains neoplastic potential, and the microscopic appearance of Wilms' tumor and nephrogenic rests can be indistinguishable. Consequently, the diagnosis of Wilms' tumor depends on the shape and growth characteristics of the lesion. With hyperplasia, a rest tends to maintain its original shape, unlike with a neoplasm, which is often spherical. Serial imaging studies to determine the growth characteristics of a lesion may be required to determine its malignant potential (3).

Multiple genetic mutations have been associated with the development of Wilms' tumor. The *WT-1* gene is located in the 11p13 region and is critical for normal genitourinary development. *WT-1* mutations have been associated with the development of Wilms' tumor as well as Wilms'-associated syndromes such as the Denys-Drash and WAGR syndromes. Mutations in the *WT-1* gene occur in only 6 to 18% of cases of Wilms' tumor (2). Other gene mutations distal to the *WT-1* gene in the 11p15 (*WT-2*) region are associated with Wilms' tumors occurring in the Beckwith-Wiedemann syndrome (5). The putative Wilms' tumor gene at 11p15 has not been identified, and there exist at least 10 imprinted genes at the *WT-2* locus. Several of these genes have been implicated in Wilms' tumorigenesis. Other locations of Wilms' tumor susceptibility genes occur at chromosome arms 16q, 1p, and 7p (2).

Associated Anomalies

Almost 10% of Wilms' tumors occur in children with congenital anomalies and syndromes (2,6). Aniridia consists of

hypoplasia of the iris, and the sporadic form occurs in 1 in 50,000 people. The incidence of aniridia in children with Wilms' tumors increases to 1 in 70. The *PAX6* gene is responsible for aniridia and is located next to the *WT-1* gene at 11p13. The familial form of aniridia occurring with an isolated *PAX6* mutation and normal *WT-1* is not associated with Wilms' tumor, but 1.5% of children with the sporadic form of aniridia develop Wilms' tumor (2,7).

The WAGR syndrome includes Wilms' tumor, aniridia, genitourinary anomalies, and mental retardation. This syndrome is associated with deletion of the *WT-1* gene. Children with the WAGR syndrome generally present before 3 years of age; they also have deformities of the external ear and may have facial or skull dysmorphism (8).

Denys-Drash syndrome occurs as a result of a point mutation in the *WT-1* gene. This mutation results in testicular dysgenesis, male pseudohermaphroditism, and a nephropathy characterized by diffuse mesangial sclerosis. Approximately 90% of these children develop Wilms' tumors. Bilateral nephrectomy and transplantation are indicated in patients with Denys-Drash chromosome due to the progressive nephropathy and high risk of developing Wilms' tumors (90%) in the native kidneys (9).

Hemihypertrophy, in which an asymmetry of the body exists, occurs in 1 in 14,300 people; however, it occurs in 1 in 32 children with Wilms' tumor (2.9%). The tumor may occur on either side. These children have an increased incidence of genitourinary anomalies and other cancers, including adrenal cortical carcinomas and hepatoblastomas.

Children with Beckwith-Wiedemann syndrome have a mutation at chromosome band 11p15. These children develop organomegaly, including enlargement of the adrenal cortex, kidney, liver, pancreas, and gonads. Other associated anomalies in Beckwith-Wiedemann syndrome include omphalocele, hemihypertrophy, microcephaly, ear pits, mental retardation, macroglossia, and hyperinsulinemic hypoglycemia. Neoplasia occurs in one out of ten children with this syndrome and affects the same organs as those with hemihypertrophy, including the liver, adrenal cortex, and kidney (10).

Almost 3% of children with Wilms' tumor have musculoskeletal anomalies. Dermatologic lesions, including hemangiomas, multiple nevi, and café-au-lait spots, occur in 7.9% of children with Wilms' tumors. Genitourinary anomalies, including renal hypoplasia, ectopia, fusions, duplications, cystic disease, hypospadias, cryptorchidism, and pseudohermaphroditism, occur in 4.4% of children with Wilms' tumors (11).

Pathology

Wilms' tumor frequently consists of an encapsulated solitary tumor occurring in any part of the kidney. Necrosis and hemorrhage within the tumor are common. Occasionally the tumor will contain true cysts. The tumor may grow into the renal pelvis and cause obstruction or hematuria

FIGURE 58.1. Gross pathologic view of bivalved kidney demonstrating a superior-pole renal tumor invading the renal pelvis along with thrombus in the renal pelvis and hydronephrosis of the lower pole.

(Fig. 58.1). Multiple renal lesions may occur with nephroblastomatosis. Invasion of the renal vein by the tumor occurs in up to 20% of patients. The lymph nodes are frequently enlarged at the time of surgery without metastatic disease, making gross assessment of nodal involvement unreliable.

Microscopically, the tumor typically demonstrates a triphasic histologic appearance consisting of blastemal, epithelial, and stromal cells. The "nephrogenic" cells demonstrate a tubuloglomerular pattern against a background of "stromagenic" cells (Fig. 58.2A). The stromal component may differentiate into striated muscle, cartilage, or, rarely, fat or bone. The epithelial component varies from well differentiated, resembling mature tubules, to a very primitive appearance. Most tumors are considered to have "favorable histologic features," which means that they typically demonstrate a favorable response to surgical removal and chemotherapy, with or without radiation therapy.

Some tumors contain anaplasia, which consists of a threefold variation in nuclear size with hyperchromatism and abnormal mitotic figures. The histologic demonstration of anaplasia portends a worse prognosis, is associated with resistance to chemotherapy (Fig. 58.2B), and is termed "unfavorable histologic features." Anaplasia occurs more frequently in older children. Anaplasia is categorized as diffuse

FIGURE 58.2. A: Well-differentiated Wilms' tumor with tubular formation (magnification $\times 150$). B: Anaplastic Wilms' tumor with evident mitotic activity (magnification $\times 50$). (Images courtesy of Dr. Dale S. Huff.)

or focal. Diffuse anaplasia is diagnosed when anaplastic tissue is present in more than one part of the tumor or at any extrarenal or metastatic site. Diffuse anaplasia conveys a worse prognosis than focal anaplasia, in which sharply localized clusters of anaplastic cells are contained only in the primary tumor. The rhabdoid tumor and clear cell sarcoma of the kidney were once considered forms of Wilms' tumor with poor prognoses but are now considered separate entities (12).

Staging

The staging system used by the National Wilms' Tumor Study Group (NWTSG) is outlined in Table 58.1 (13). The system is based on surgical and pathologic findings and correlates with prognosis.

Presentation

Most children with Wilms' tumor present with an abdominal mass or increasing abdominal girth. Approximately 30% of patients present with abdominal pain, but most children with Wilms' tumor appear well and are asymptomatic. Occasionally, a sudden subcapsular hemorrhage creates pain of acute onset and fever associated with anemia and hypertension. Children with tumor rupture may present with an acute abdomen (14).

Physical examination of the child with Wilms' tumor reveals a firm, nontender, smooth mass that rarely crosses the midline, in contrast with a nodular neuroblastoma, which grows across the midline and presents in an ill-appearing child. Hypertension may occur in up to two-thirds of children with Wilms' tumor and may be secondary to elevated renin levels resulting from renal ischemia caused by the pressure of the tumor. With tumor propagation into the vena cava, a child may develop a varicocele or even congestive heart failure. Physical examination should

also assess the presence of any associated anomalies described previously, such as aniridia or hemihypertrophy.

Radiologic Evaluation

Ultrasonography allows the rapid distinction between a renal and nonrenal mass and permits identification of hydronephrosis and multicystic kidney, which also may present as an abdominal mass. Wilms' tumor characteristically demonstrates a solid renal mass with a heterogeneous echo pattern on ultrasonography. Ultrasonographic examination should include assessment of the renal vein and inferior vena cava for tumor thrombus. Excretory urography is used infrequently and demonstrates a mass effect that deforms the calyces.

Magnetic resonance imaging (MRI) accurately evaluates the extent and size of the Wilms' tumor, which frequently gives variable signal intensities (Fig. 58.3). Areas of hemorrhage show increased signal intensity on T1- and T2-weighted pulse sequences. Regions of necrosis demonstrate a decreased signal on T1- but not on T2-weighted pulse sequences (15). MRI is the most accurate study to demon-

TABLE 58.1. NATIONAL WILMS' TUMOR STUDY GROUP STAGING SYSTEM

Stage I:	Tumor within the kidney and completely excised.
Stage II:	Tumor beyond the kidney and completely excised. May have involvement of extrarenal vessels by tumor thrombus or local tumor spillage may have occurred. Includes tumor biopsy.
Stage III:	Residual tumor left within the abdomen; positive lymph nodes, positive surgical margins, peritoneal metastases, diffuse nonconfined tumor spillage.
Stage IV:	Hematogenous metastases (e.g., lung, liver, bone, brain).
Stage V:	Bilateral Wilms' tumor (irrespective of tumor extent/metastases).

FIGURE 58.3. Magnetic resonance image demonstrating left lower pole Wilms' tumor.

strate tumor extension into the renal vein and inferior vena cava. Computed tomography (CT) with contrast also provides precise anatomic delineation of the renal and retroperitoneal anatomy (Fig. 58.4). Attention must also be directed to the contralateral kidney to assess the presence of lesions and determine contralateral function. Despite the accuracy of these techniques, false-negative results do occur. Consequently, intraoperative contralateral renal exploration is necessary, because bilateral involvement occurs in 10% of cases of Wilms' tumor. Treatment of bilateral Wilms' tumors is different from that for unilateral disease. A chest radiograph should also be obtained to evaluate the lung fields and rule out significant metastatic disease. If the diagnosis of Wilms' tumor is relatively certain, preoperative chest CT may be appropriate (16).

Treatment

Effective treatment of Wilms' tumor relies on the appropriate use of surgery, radiation, and chemotherapy. Refinements in radiation and multiagent chemotherapy have increased survival while minimizing side effects. There have been two multicenter trials of the management of Wilms' tumor in children:

1. National Wilms' Tumor Study (NWTSG) (<http://www.nwtsg.org>) in the United States, in which primary nephrectomy followed by chemotherapy with or without radiotherapy has been used. A total of four cooperative trials have been completed, and children are now being enrolled in NWTSG-5. Currently the 4-year survival rate for children with all stages of Wilms' tumor with favorable histologic features exceeds 90% (17).
2. In Europe, cooperative studies by the International Society for Paediatric Oncology (SIOP) (<http://www.siop.nl>), in which preoperative biopsy with chemotherapy, with or without radiation therapy, fol-

FIGURE 58.4. Computed tomographic scan demonstrating large right-sided Wilms' tumor.

lowed by tumor removal has been used. The concept is that preoperative therapy reduces the risk of tumor rupture or spill and may allow renal preservation.

Surgical Therapy

The goal of surgical management is removal of the primary tumor. Before the tumor is removed, however, the extent of the tumor is evaluated and the renal vessels, inferior vena cava, liver, and lymph nodes are assessed. Because preoperative imaging misses approximately 7% of bilateral Wilms' tumors, the contralateral kidney should be explored by opening Gerota's fascia and inspecting the entire surface at the time of surgery (18). Biopsy of any suspicious lesion is necessary, because children with bilateral Wilms' tumor are managed with preoperative chemotherapy followed by tumor nephrectomy.

When the kidney can be removed, it is taken along with the adrenal gland if the tumor involves the upper pole. Tumor rupture with diffuse spillage increases the chance of abdominal relapse. Preoperative radiation in addition to chemotherapy decreases this risk. Formal lymph node dissection does not improve survival, although biopsy specimens should be obtained from hilar, paraaortic, iliac, and celiac nodes, because positive lymph node findings portend a worse prognosis and affect postsurgical therapy (5). If the primary tumor involves surrounding organs and cannot be removed safely or if there is inferior vena caval extension above the hepatic vein, preoperative chemotherapy is advised, followed by tumor removal.

Chemotherapy

Actinomycin D, vincristine, and doxorubicin (Adriamycin) have been effective in the treatment of Wilms' tumor. A summary of the current treatment for Wilms' tumor used by NWTSG-V is given in Table 58.2. At present all children in

TABLE 58.2. SUMMARY OF NATIONAL WILMS' TUMOR STUDY GROUP V TREATMENT FOR TUMORS OF STAGES I TO IV AFTER TOTAL NEPHRECTOMY

Stage I or II favorable histologic features, stage I anaplasia: pulse-intensive dactinomycin and vincristine (18 weeks)
Stage III or IV favorable histologic features, stage II-IV focal anaplasia: pulse-intensive dactinomycin, vincristine, doxorubicin (24 weeks), and abdominal radiation based on local tumor stage; stage IV tumors with favorable histologic features: also radiation therapy to both lungs
Stage II-IV diffuse anaplasia: dactinomycin, vincristine, doxorubicin, cyclophosphamide, etoposide, and radiation therapy

NWTSG receive chemotherapy. One NWTSG protocol evaluated the treatment of children younger than 24 months of age who had stage I Wilms' tumor with favorable histologic features, using nephrectomy alone (19). The relapse-free survival rate was marginally inferior to that of children receiving adjuvant chemotherapy, so at this time chemotherapy for all children with Wilms' tumor remains the standard of care. The treatment of bilateral disease (stage V) includes a biopsy followed by preoperative chemotherapy and bilateral partial nephrectomies. When metastatic or recurrent disease is encountered, doxorubicin is routinely given if the patient has received only dactinomycin and vincristine. For those who have already received three-agent chemotherapy, there is no well-established regimen.

Preoperative chemotherapy can be used selectively and is appropriate for inoperable tumors, tumors with vena caval extension above the hepatic vein, or bilateral tumors. SIOP investigators routinely administer preoperative chemotherapy to all patients with the presumptive diagnosis of Wilms' tumor. This approach differs from the NWTSG approach, in which radical nephrectomy is performed before adjuvant chemotherapy (20). The SIOP approach of preoperative chemotherapy may shrink the tumor and produce lower morbidity. It does not influence long-term survival, however, and it may result in down-staging of the tumor with the potential for undertreatment of a tumor that would have been associated with positive lymph node findings. The use of these agents as well as of radiation therapy varies with the tumor stage and histologic findings (5).

Radiation Therapy

The application of radiation therapy in the treatment of Wilms' tumor is shown in Table 58.2. Radiation to the operative site or whole abdomen occurs 1 to 3 days after surgery. The current NWTSG-V protocol recommends 10.8 Gy as the abdominal dose for Wilms' tumor regardless of age (21). Supplemental radiation is directed to regions with residual tumor. In cases of pulmonary metastases radiation is delivered to both lungs regardless of the number or location of metastases. Postoperative brachytherapy has been used in selected children with chemoresistant bilateral Wilms' tumors. The radioactive

source is delivered through a catheter left in the tumor bed at the time of surgery (22,23).

Bilateral Wilms' Tumor

Synchronous bilateral Wilms' tumors occur in approximately 6% of children with Wilms' tumor, and metachronous bilateral Wilms' tumors affect another 1%. The mean age of presentation of a child with synchronous bilateral Wilms' tumors is 32 months. These children have more genitourinary anomalies and a higher incidence of hemihypertrophy than those with unilateral Wilms' tumor. The incidence of unfavorable histologic findings is 10%, which is similar to that in children with unilateral disease. Anaplasia is less frequent in children under the age of 2 years with bilateral Wilms' tumors and, accordingly, younger children tend to have a better prognosis.

The overall survival of patients with synchronous bilateral Wilms' tumors with favorable histologic features is 76% at 3 years. In contrast, of children who develop a metachronous bilateral Wilms' tumor, only 39% are disease free 2 years after developing the second Wilms' tumor. The survival rate for children with bilateral Wilms' tumor and anaplasia is severely decreased and ranges from 10% to 26% (22,24,25). The stage of the most advanced lesion, histologic findings, and presence of lymph node metastases are important prognostic indicators in cases of bilateral Wilms' tumors.

Therapy for bilateral Wilms' tumors after diagnosis by radiographic imaging and/or biopsy is chemotherapy and then surgery. The chemoresponsiveness of many large tumors permits a renal-sparing approach with partial nephrectomy or excisional biopsy, and, at times, the larger tumor responds better to chemotherapy than the smaller tumor. In one study, 80% of children treated in this manner retained normal renal function 6 years after treatment (24). Bilateral nephrectomy and renal transplantation are rarely required for children with bilateral Wilms' tumors but may be appropriate for those with anaplasia, given the dismal prognosis and chemoresistance of the tumors (22).

Treatment Complications

A report of surgical complications from NWTSG-IV suggests an incidence of approximately 13% (26). The most frequent surgical complications were bowel obstruction (5.1%), extensive bleeding (1.9%), infection (1.9%), and vascular (1.5%) or splenic (1.1%) injury. Deaths related to surgical complications occurred in 0.5%. Risk factors for surgical complications included tumor extension into the inferior vena cava, tumors larger than 10 cm in diameter, and performance of the procedure by a surgeon not specializing in pediatric urology or pediatric surgery.

There are numerous potential complications of chemotherapy and radiation therapy for Wilms' tumor (Table 58.3).

TABLE 58.3. COMPLICATIONS OF CHEMOTHERAPY AND RADIATION THERAPY FOR WILMS' TUMOR

Bone marrow toxicity—chemotherapy induced
Gastrointestinal toxicity—chemotherapy-induced nausea, vomiting, and diarrhea; radiation-induced enteritis
Hepatic toxicity—induced by chemotherapy (dactinomycin is hepatotoxic) or radiation therapy
Vertebral hypoplasia and scoliosis—radiation induced
Renal toxicity—chemotherapy-induced tubular necrosis or radiation-induced nephritis
Pulmonary toxicity—acute interstitial radiation pneumonitis, reduced lung capacity
Cardiac toxicity—doxorubicin-induced cardiomyopathy, increased when combined with radiation therapy
Gonadal toxicity—ovarian failure after radiation therapy or oligospermia after chemotherapy or radiation therapy
Secondary neoplasms—1.6% of long-term survivors (sarcomas, adenocarcinomas, leukemias); most develop within radiation fields

One of the most common complications is acute hematologic toxicity due to the suppressive effects of chemotherapy on the bone marrow. Chemotherapy also frequently induces an acute gastrointestinal toxicity manifest by nausea, vomiting, and diarrhea. Radiation has the potential to adversely affect any exposed organ and can do so over a long period of time.

There is a low risk of renal failure in patients with a unilateral Wilms' tumor (0.25%) (18). This risk increases with bilateral Wilms' tumor (15% at 5 years). Children treated with nephrectomy and abdominal irradiation are also at increased risk for renal dysfunction. This risk appears to be dose dependent, with dysfunction occurring in over 70% of patients receiving 24 Gy to the remaining kidney and in fewer than 20% of patients receiving 12 Gy (27).

Second malignant neoplasms occur in 1.6% of survivors 15 years after diagnosis. These malignancies are most often leukemias, lymphomas, and skeletal system neoplasms (28). Abdominal irradiation increases the risk of second malignant neoplasms, and doxorubicin potentiates this effect (29). These tumors often arise in the irradiated field and may include sarcomas, adenocarcinomas, bone tumors, and breast and thyroid cancer (27).

Prognosis

Overall survival of patients with Wilms' tumor is almost 90%. Prognosis depends on multiple factors, including the stage and grade of the tumor. The 4-year postnephrectomy survival results from NWTSG-III and NWTSG-IV are listed in Table 58.4 (12,17,30–32). The most important prognostic factor in Wilms' tumor is histologic findings. Approximately 5% of children with Wilms' tumor have anaplasia, and it occurs more frequently in the older child. Children with anaplasia are four times more likely to experience relapse and nine times more likely to die from their disease than children without anaplasia. When

TABLE 58.4. FOUR-YEAR SURVIVAL (%) OF PATIENTS WITH WILMS' TUMOR AFTER NEPHRECTOMY AND CHEMOTHERAPY WITH OR WITHOUT RADIOTHERAPY

Stage	Favorable histologic features		Unfavorable histologic features
	RFS ^a	Overall	
I	94	99	68
II	88	96	55
III	92	96	45
IV	83	90	4

^aRelapse-free survival.

anaplasia is well circumscribed and focally contained within the primary tumor, it is not considered unfavorable. Focal anaplasia in a stage I Wilms' tumor does not alter the prognosis when the tumor is treated with total nephrectomy and chemotherapy (12).

Hematogenous metastases also worsen the prognosis and are present at diagnosis in 10% to 15% of patients. Metastatic disease to the lungs occurs most often (85%), followed by metastases to the liver, bone, and brain. Metastases to the lymph nodes also predict a worse outcome with increased risk of local recurrence, and thus abdominal radiotherapy is added to chemotherapy. A tumor with renal vascular invasion carries a higher risk of local relapse. When metastatic or recurrent disease occurs, doxorubicin is routinely given if the patient has previously received only dactinomycin and vincristine. For those children already receiving three-agent chemotherapy, there is no well-established regimen.

Follow-Up

Follow-up is directed at detecting recurrence of cancer or the complications of treatment. The abdomen should be palpated and any suspicious findings evaluated with radiologic imaging. For patients with low-stage disease, evaluation of the abdomen with physical examination and of the lungs with a chest radiograph for recurrence may be all that is required, because the most likely site of relapse is in the lungs. In children at risk for abdominal recurrence, such as those with a history of higher-stage disease or contralateral nephrogenic rests, abdominal sonography should be performed every 3 months for at least 4 years. For patients with a history of hematogenous metastasis (brain, lung, liver, and bone), the site of metastasis should be evaluated with imaging every 3 months for the first year, then every 6 months for 2 years, and then yearly until 5 years. Irradiated bone should be monitored for life for any radiation-associated neoplasms. Follow-up for children with Wilms' tumor should include measurement of blood pressure and urinalysis to check for protein and serum creatinine (27).

CLEAR CELL SARCOMA OF THE KIDNEY

Clear cell sarcoma originally was considered to be a variant of Wilms' tumor. The age at diagnosis and the location are the same as for Wilms' tumor. However, unlike Wilms' tumor, clear cell sarcoma is associated with bone and brain metastases. In addition, it is not observed in children with associated congenital anomalies such as aniridia and hemihypertrophy. Treatment includes nephrectomy and systemic chemotherapy with actinomycin D, vincristine, and in many cases doxorubicin. In a review of 351 such tumors, predictors of survival included lower stage, younger age at diagnosis, and absence of tumor necrosis (33). Patients with stage I tumors had a 98% survival rate. In long-term follow-up, 30% of relapses occurred more than 3 years after diagnosis, and in some cases 10 years later (17).

RHABDOID TUMOR OF THE KIDNEY

Rhabdoid tumor is the most aggressive renal tumor in children. This tumor may metastasize to the lungs, abdomen, or liver, as well as the brain. It is also associated with second primary tumors in the brain such as cerebellar medulloblastoma, pineoblastoma, neuroblastoma, and subependymal giant cell astrocytoma. The median age of occurrence is younger than 16 months, and the tumor usually is resistant to chemotherapy (17).

CONGENITAL MESOBLASTIC NEPHROMA

Congenital mesoblastic nephroma (CMN) is a solid renal tumor that is found in neonates and is distinguished from Wilms' tumor in its morphology and relatively benign behavior. This tumor develops in approximately 1 in 500,000 infants and accounts for fewer than 3% of pediatric renal neoplasms. CMN is usually diagnosed at birth or within the first 3 months of life, whereas Wilms' tumor has a peak incidence between 2 and 4 years of age.

The pathogenesis of CMN is controversial. One theory relates to the two-hit concept for Wilms' tumor development; if neoplasia is induced during the early stromagenic phase, a conventional CMN might develop (34). Another theory is that the tumor originates from uninduced nephrogenic mesenchyme (35). Another observation is that trisomy 11 is common in many children with CMN tumors, particularly those with the "cellular" and "mixed" histologic subtypes of CMN (36). It has been proposed that the insulin-like growth factor-II gene, which has been mapped to the short arm of chromosome 11 and is expressed in mesenchymal cells during renal development, may play a key role in the acquisition of the growth properties of neoplasia (36).

Pathology

Three histologic types of CMN have been described: the classic pattern of CMN, the cellular or atypical variant, and a third type, which shows mixed features. A rare cystic variant also has been described.

Classically the involved kidney is enlarged and distorted by the tumor, which ranges from 0.6 to 9.0 cm (Fig. 58.5). The mass has a slightly bulging cut surface that has a whorled, coarsely trabeculated appearance, similar to that of a uterine leiomyoma. Cellular CMNs are softer than the classic type and show areas of hemorrhage, necrosis, and cystic degeneration.

Classic CMN is composed of uniform spindle-shaped cells arranged in interlacing bundles. The cells have pale eosinophilic cytoplasm and ovoid, elongated vesicular nuclei. Foci of extramedullary hematopoiesis are frequently observed. Mitotic activity ranges from zero to one mitotic figure per 10 high-power fields. The cellular variant contains diffuse sheets of closely packed cells with scanty cytoplasm, and thin-walled vascular spaces are scattered throughout. Necrosis and hemorrhage are common. Mitotic activity ranges from 10 to 30 mitotic figures per 10 high-power fields.

Clinical Features

CMN usually presents as an asymptomatic abdominal mass in the newborn or infant, although it has been detected by prenatal sonography (37). Tumors are more common on the left side. Renin-mediated hypertension is common in infants with CMN. Immunochemical studies in removed kidneys indicate that renin production by CMN cells is minimal but is highest in areas of renal cortex entrapped by the tumor (38).

In the majority of cases CMN is a relatively benign lesion, but local invasion, recurrence, and metastasis to

FIGURE 58.5. Gross photograph of infant kidney replaced with congenital mesoblastic nephroma.

the lung and brain can occur. The cellular variant is thought by some to be more likely to exhibit aggressive characteristics. Most infants with aggressive lesions are older than 3 months of age at diagnosis. Consequently, infants older than 3 months of age with a CMN cellular variant or tumor with atypical histologic features should be considered for adjunctive therapy after radical nephrectomy (39).

Diagnosis

In the newborn and infant the abdominal mass is the key to diagnosis, and the tumor usually is confirmed by ultrasonography, which demonstrates a solid mass. Abdominal and chest CT (or MRI) is done to stage the neoplasm preoperatively. MRI of the head should be performed if central nervous system metastases are suspected.

Treatment and Follow-Up

Both the classic and cellular variants of CMN are typically cured by radical nephrectomy. Unlike in Wilms' tumor, bilateral involvement is rare. Adjuvant therapy generally is not required. Recurrent or metastatic tumors may occur, however, usually in the lungs or brain, and close observation of these patients is important.

Congenital Mesoblastic Nephroma and Wilms' Tumor

Several differences exist between CMN and Wilms' tumor:

- CMN usually is diagnosed at birth or within the first 3 months of life, whereas Wilms' tumor has a peak incidence between 2 and 4 years.
- Wilms' tumor is a primitive embryonal neoplasm that is thought to develop from residual metanephric blastemas and histologically mimics different stages of renal development, whereas CMN typically consists of spindle cells that resemble primitive mesenchymal tissue of less definite derivation with few or no neoplastic epithelial cells.
- Clinically, CMN usually is cured by surgery alone, whereas Wilms' tumors require systemic chemotherapy.
- Both CMN and Wilms' tumors arise from primitive renal cells. However, molecular analysis demonstrates significant differences. Wilms' tumor frequently is associated with loss of heterozygosity at chromosome band 11p13 and/or 11p15, but CMN is not. Insulin-like growth factor-II, *N-myc* oncogene, and *WT-1* are highly expressed in Wilms' tumors and fetal kidneys. Insulin-like growth factor-II is detected in CMN, but *N-myc* and *WT-1* are not.
- Bilateral renal involvement is significantly more common in Wilms' tumor.

RENAL ANGIOMYOLIPOMA

Renal angiomyolipoma (AML) is a benign mesenchymal nodule consisting of blood vessels with thickened walls, smooth muscle, and adipose tissue. Between 20% and 40% of AMLs occur in individuals with the tuberous sclerosis complex (TSC) and 40% to 80% of TSC patients develop an AML (40). AML is predominant in females, with a 3:1 or 4:1 female/male ratio. Although AML is common in patients with TSC, distinguishing this tumor from renal cell carcinoma is important (41).

Etiology

TSC is an autosomal dominant condition with genetic locus heterogeneity. Half of patients are mentally retarded, and most have seizures as well as one of the characteristic dermatologic lesions, including adenoma sebaceum (facial angiofibromas), hypopigmented macules (ash leaf patches), and unguinal fibromas. Involvement can occur in areas other than the kidney, including cortical tubers, subependymal nodules, retinal astrocytomas, and cardiac rhabdomyomas. Two major gene loci have been identified, including chromosome bands 9q34 (*TSC1*) and 16p13.3 (*TSC2*). These may act as growth suppressor genes in a way analogous to the two-hit model of the traditional tumor suppressor gene in the Knudson hypothesis (42).

Clinical Features

Renal AMLs with tuberous sclerosis are rare in children younger than 5 years of age. They are more common in children between 6 and 10 years of age, and most common in children older than 10 years. There are often tumors of various sizes, and they are usually bilateral. Through screening of tuberous sclerosis patients with ultrasonography or CT, many asymptomatic lesions are being discovered. Symptoms and signs of tumor growth may occur if any of the tumors enlarges significantly.

The vast majority of children with renal AML have some or all of the stigmata of tuberous sclerosis. Among children with renal AML, renal cysts are also common. Cysts that are more than 4 cm in diameter are more likely to cause symptoms such as flank pain, a palpable tender mass, and gross hematuria that require treatment (43–45). Retroperitoneal hemorrhage associated with spontaneous rupture of AML is the most life-threatening presentation of the tumor. The risk of tumor rupture has been attributed to the weak, elastin-poor vascular structures in the tumor.

Pathology

AMLs are vascular tumors consisting of smooth muscle, adipose tissue, and blood vessels with thickened walls. They range in size from small punctate "tubers" to huge masses exceeding 20 cm. The amount of fat in the tumor varies. Microscopic examination shows fat necrosis and collections of xanthoma cells. The

FIGURE 58.6. Computed tomographic scan demonstrating large right lower pole angiomyolipoma (AML) in a teenaged girl with tuberous sclerosis. The patient previously underwent removal of a large aneurysm within an AML in the left kidney.

blood vessels either lack elastic tissue or contain abnormally distributed elastic tissue, which possibly explains their tendency to rupture. In children these tumors are considered benign.

Renal cell carcinoma develops in 1 to 3% of patients with tuberous sclerosis, but these patients are most likely to be young women, not children (46).

Diagnosis

AML is diagnosed most often by sonography or CT. Sonography shows the tumor to be echodense, because of the fatty tissue, and well circumscribed. Similarly, CT establishes the diagnosis if there is a significant amount of fat in the lesion, because the x-ray attenuation of these tumors typically is less than -10 to -15 Hounsfield units. The use of thin cuts on nonenhanced CT scans improves the chances of detecting and measuring these small areas of fat (Fig. 58.6).

On MRI, the fat component has a high signal intensity on unenhanced T1-weighted images and lower intensity on T2-weighted images (47). MRI is particularly useful if sonography and CT scan are inconclusive.

Treatment

The risk of untreated AML includes development of abdominal or flank pain, palpable mass, hemorrhage, hematuria, anemia, and hypertension (43). These tumor complications occur primarily in individuals with tumors larger than 4 cm in diameter. If the lesion is smaller than 4 cm, follow-up with sonography or CT every 6 to 12 months is recommended. Over a period of 4 years, a significant increase in AML size occurred in 39% of males and 100% of females (44). If the lesion is over 4 cm and is growing, or if it is large, selective angiographic embolization or partial nephrectomy may be necessary (41,43,47).

The use of angiographic embolization was reviewed by Nelson and Sanda (45). Various materials have been used for embolization, including absorbable gelatin sponge, absolute alcohol, iodized oil, polyvinyl alcohol particles, and metal coils. Complications were reported in 10% of cases, most commonly

abscess formation. Eighty-five percent of the patients experienced a postembolization syndrome of flank pain, fever, leukocytosis, and nausea attributed to inflammatory mediators. Administration of a tapering dose of prednisone over a 2-week period significantly ameliorated these problems (48). After embolization, reduced tumor size is expected. In addition, this form of treatment appears durable for the affected tumor.

Partial nephrectomy is another option for treatment of AML, provided there is significant residual functioning renal tissue (49). In recent years there has been interest in performing this procedure laparoscopically, as well as using cryotherapy, although the latter procedure is experimental.

RENAL CELL CARCINOMA

Older children with solid renal tumors may have a renal cell carcinoma. Radiographically, renal cell carcinoma cannot be distinguished from Wilms' tumor. Although the natural history of renal cell carcinoma appears to be similar in children and adults, it may have a more favorable prognosis in children younger than 10 years of age (50). Adjuvant interferon-alpha therapy may be beneficial also (51).

HYPERTENSION

EPIDEMIOLOGY OF HYPERTENSION

JEAN U. BENDER
MELVIN A. BONILLA-FELIX
RONALD J. PORTMAN

Hypertension (HTN) is of immense national importance. Mild to moderate HTN remains one of the major risk factors for the development of atherosclerosis and subsequent cardiovascular disease (CVD) and cerebrovascular disease. The role of the pediatric nephrologist and others caring for children includes not only the management of patients with established high blood pressure (BP) but also the identification of children at risk for HTN and the initiation of preventive measures when indicated. In addition, new evidence suggests that the most prevalent form of HTN in pediatrics is now essential or primary HTN. The prevalence is increasing in concert with the epidemic of childhood obesity. Further, essential HTN during childhood is associated with end-organ damage (EOD) and thus is not benign. The existing definitions of HTN have, by necessity, been epidemiologic in nature. New definitions for both casual and ambulatory measurements must be functional and based on the presence of EOD.

The treatment of HTN has greater beneficial impact on CVD risk than any other intervention. There is renewed interest in the issues surrounding BP measurement. These issues have major impact on the interpretation of important major national and international treatment trials. For example, changes in nocturnal BP when casual BP (CBP) measurements are normal have been correlated with the development of microalbuminuria. Thus, the issues of BP measurement in the assessment of HTN and its treatment require careful scrutiny (1).

This chapter reviews the epidemiology of HTN in childhood, including discussions of the controversial issue of BP measurement; the chronobiology of BP; definitions of HTN; the effects of age, gender, ethnicity, maturation, diet, body mass, and birth weight on BP; genetics of HTN; the course of primary HTN; and the association of BP with EOD.

MEASUREMENT OF BLOOD PRESSURE

Casual Blood Pressure

The proper techniques for the diagnosis and evaluation of HTN in children remain unclear although several decades

have passed since the first large-scale normative data became available (2,3). BP is defined as the pressure of the blood within the arteries, maintained by the contraction of the left ventricle, the elasticity of the arterial walls, as well as the viscosity and volume of the blood. Systolic BP (SBP) is defined as the pressure occurring at the moment of ventricular systole, whereas diastolic BP (DBP) is the pressure noted during ventricular diastole, immediately preceding systole. Technical problems exist with all forms of BP measurement. Even the gold standard of intraarterial BP measurement has technical problems and shows variability depending on the chosen artery, catheter positioning within the artery, and the equipment used. The available normative data have been developed using noninvasive techniques. BP measurement by palpation is inaccurate, but because the reappearance of the pulse is an approximation of SBP, it can be used to determine the starting point for an auscultatory measurement. The two major noninvasive CBP techniques are auscultatory and oscillometric. Both present significant technical challenges that are affected by the technology itself, the patient, and the person taking the measurement.

Patient Issues

Patient-related issues are similar for all types of CBP measurement and include the ingestion of stimulants (e.g., caffeine, pseudoephedrine), inclusion of an appropriate resting period, patient position, ambient temperature, and level of anxiety. As outlined in the *Update on the 1987 Task Force Report on High Blood Pressure in Children and Adolescents* (3), the environment should be controlled and the child should rest for 3 to 5 minutes before BP measurements are taken. BP readings are obtained from a child in the seated position (supine for infants) from a fully exposed right arm resting on a supportive surface at heart level with back supported and feet firmly on the floor. One must ensure that the inflatable bladder that encircles the circumference of the arm is wide enough to cover more than 40% of the distance from the acromion to the olecranon and neither

obstructs the placement of the stethoscope bell at the antecubital fossa nor interferes with the axilla. Use of a small BP cuff may result in falsely elevated readings; use of too large of a cuff may cause minimally lower readings. Clark et al. (4) described the difficulty in selecting appropriate cuffs from the many available sizes and its critical importance to accurate BP measurement in children with all BP measurement techniques. Incorrect measurement can result in unnecessary investigations, treatment, or follow-up for the misdiagnosis of HTN. Cuff selection is of particular importance in children, who have normal age-dependent variations in body size and BP. One cannot rely on the size listed on the proprietary cuff, for example, "infant" or "child" cuff, as there is tremendous variation between companies in this labeling. Rather, one must measure the arm to select a cuff fulfilling Task Force criteria. Larger BP cuffs are required if upper arm length is used as the primary criterion for cuff selection. In contrast, smaller cuffs are required if 40% of the upper mid-arm circumference is used as a criterion for cuff selection. No single cuff, when used in accordance with current recommendations, yields accurate SBP as well as DBP. How to select a proper cuff size for an accurate measurement of BP remains unresolved, but until better data are available, the Task Force recommendations should be followed.

Technical Issues

Although the proper BP measurement techniques may be debated for years, the critical issue is not comparison of one technique with another but comparison of the readings obtained using any chosen technique with the occurrence of hypertensive EOD.

Auscultation

To obtain a measurement using auscultation, the BP cuff is inflated to approximately 20 mm Hg higher than the pressure necessary to occlude the brachial pulse as determined by palpation; pressure is then released at 2 to 3 mm Hg/sec while the observer identifies Korotkoff sounds over the brachial artery. Too rapid or too slow a rate of deflation results in inaccurate readings, as does parallax when a mercury manometer is used. Two readings should be obtained and averaged at each visit to estimate a child's BP level. Studies from our group show that when three measurements are used, the second of three measurements had the best correlation to the mean of the three, which confirms that 2 measurements are generally sufficient (5).

Identification of appropriate Korotkoff sounds presents an area of difficulty in measuring BP in children. K1 (SBP) is recorded when the first tapping sound is heard as the pressure in the BP cuff is released and is caused by the opening of the artery. K2 is characterized by a constant murmur after the tapping sounds, and K3 occurs as the pressure is further released and the sounds become crisper

and more intense. K4 is a low-pitched, muffled sound; K5 is the disappearance of all sounds. In some children, K4 and K5 occur so closely that they are indistinguishable; in others K5 never occurs. By adolescence, however, K5 is easily identified. Despite these difficulties, the American Heart Association and the updated Task Force guidelines (3) have identified K5 as a reliable definition of DBP for children and adolescents of all ages. If K5 is not observed, the DBP can be recorded as K4 if heard. Difficulties in performing auscultatory techniques in smaller children, in developing acceptable definitions of DBP (K4 vs. K5), and in minimizing interobserver variability have led many physicians' offices and clinics to opt for technically easier and more reproducible ways to measure BP.

Despite their status as the gold standard, mercury manometers, when systematically evaluated, show a significant number of problems that may preclude accurate use, even if the observer and patient issues are overcome. In several studies in the United Kingdom, a high prevalence of technical problems (18 to 38%) was noted, such as dirty columns, oxidized mercury, faded column markings, mixing of air in the mercury column, or mercury leakage, which led to inaccurate measurement by 21% of monitors (6-8). In a systematic evaluation of sphygmomanometers, *none* of the 356 instruments tested met all standards, and 86% did not meet safety standards (9). For these reasons, mercury manometers soon are likely to be phased out in Europe and the United States (10) in spite of recommendations by the American Hospital Association and the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII) to retain their use (6).

The aneroid manometer functions through a system composed of a metal bellows, a mechanical amplifier, springs, and a gauge that displays the pressure in the cuff. Aneroid devices are often felt to be less accurate than mercury columns because of the difficulty in keeping them functional (11,12). Aneroid manometers were evaluated in many of the same studies cited for the assessment of mercury manometers and demonstrated even more inaccuracies.

A trained individual must have good hearing acuity, must be aware of digit preference, and must know the "rules" of the auscultatory method. So prevalent are these technical difficulties that the random zero manometer was developed. With this device, the observer is blinded to the reading until after the measurement has been completed. Although such units are the gold standard for research, they are not readily available on a clinical basis.

If "ideal" auscultation is assumed, how good is the match between BP measured using the Korotkoff sounds and direct measurements of BP? Because they are all measuring some component of BP, the statistical correlations are quite strong. Nevertheless, there can be some remarkable differences between the two. K1 appears on average 3

mm Hg below direct systolic pressures. K5 disappears on average 9 mm Hg above direct diastolic pressure (13). There is still controversy in pediatrics over whether K4 or K5 should be used to assess the “true” diastolic pressure (14). If the data cited here apply to children, K4 would clearly be much higher than true diastole.

Oscillometry

All of these difficulties in measurement, the time required for the measurement in a busy practice, and the interobserver variability led to the development of oscillometric monitors. Development of the first commercial oscillometric device for BP measurement started in the early 1970s and resulted in the Dinamap, an acronym for “device for indirect noninvasive mean arterial pressure” (15). Many oscillometric devices for automated BP measurement have been introduced and new models of the Dinamap updated. With oscillometric devices, cuff inflation and deflation are automated and BP determination is made by a microprocessor using information sent to it from a pressure transducer. A great advantage that makes this technique popular is its ease of use and the elimination of observer bias. The BP cuff automatically inflates on first measurement to a set value determined by algorithm and, with subsequent measurements, inflates to 20 to 35 mm Hg above the previously recorded systolic value. Deflation occurs in a set bleed step such as 4, 8, or 10 mm Hg that varies by device and, in some, can be set at different levels. As the cuff pressure decreases, oscillations of the arterial wall increase in amplitude and reach a maximum when the cuff pressure approaches the mean arterial pressure. With further deflation of the BP cuff, oscillations diminish and eventually stop. The monitor then computes the information and displays heart rate (HR) and mean BP, SBP, and DBP. The precise method of BP determination is complex and uses an algorithm that varies from one device to another. It is unknown whether the device is actually measuring or calculating the displayed values. These algorithms are considered proprietary information and thus are not made public. It is therefore impossible for investigators to verify the accuracy of their underlying physiologic principals. The measurement results of these devices cannot be used interchangeably because of their different algorithms (16). Measurements obtained using both oscillometric and mercury manometers correlated well with intraarterial measurements (17), including those determined with pediatric and neonatal Dinamap models.

What is the agreement between auscultatory and oscillometric measures? In fact, it is not particularly good for many devices. Unfortunately, the most commonly used monitors have been demonstrated to give variable results in multiple studies. This should not be a surprise, because the techniques are not measuring the same “pressure.” We have a dilemma facing us. The available normative data from the Task Force are based mostly on auscultatory and mercury technology. The easier-to-use oscillometric technique is now the prevalent technology, but we do not have adequate

epidemiologic normative data. Although the techniques measure different “pressures,” the definitions of HTN that must be developed are those that are predictive of EOD. Standardized oscillometric monitor certification for use on children, development of new epidemiologic normative data in comparison with EOD, and, finally, careful ongoing calibration of monitors by biotechnicians are needed.

Self-Measurement of Blood Pressure

Measurement of BP outside the clinician’s office may provide valuable information for the initial assessment of patients with HTN and for monitoring of the response to treatment (19). Self-measurement of BP (SMBP) has four general advantages: (a) distinguishing sustained HTN from *white-coat HTN* (WCH), (b) assessing response to antihypertensive medication, (c) improving patient adherence to treatment, and (d) potentially reducing costs. There is no universally agreed-upon upper limit of normal home BP, but readings of 135/85 mm Hg or higher in adults should be considered elevated (18). No data are available on pediatric norms for SMBP. SMBP appears to allow improved assessment of BP and its control under pharmacologic therapy. Mercury and aneroid sphygmomanometers are generally not practical for home use. Therefore, validated electronic devices (oscillometric) that have proven to be accurate according to standard testing are recommended for use, along with appropriately sized cuffs. Wrist and finger monitors are inaccurate. Periodically, the accuracy of the patient’s device should be checked by comparing its readings with simultaneously recorded auscultatory readings taken with a mercury device. Few of the many self-monitors on the market have passed the criteria of the British Medical Society (20) or the Association for the Advancement of Medical Instrumentation (21). A Task Force of the European Society of Hypertension has suggested new criteria for this assessment (22). A review of available monitors has been published (23).

BPs measured outside of the physician’s office tend to have lower values. Six studies comparing SMBP and CBP demonstrated a consistently lower BP by SMBP (SBP 5.4 ± 17.7 mm Hg lower and DBP 1.5 ± 6.3 mm Hg lower). Three studies comparing ambulatory BP (ABP) and SBP show similar daytime BP results. Some preliminary studies have examined the prevalence of WCH determined using SMBP and have compared the results to determination of the same diagnosis by ABP, finding similar results (approximately 20% WCH). There were significant methodologic concerns, however, that suggest some problems with this conclusion, such as small sample sizes of heterogeneous populations, variable definitions of HTN by CBP and SMBP, and no reproducible data. Only one study has examined the correlation of SMBP results with clinical events. SMBP showed a marginally better correlation with left ventricular hypertrophy (LVH) than did CBP (SBP: SMPB $R = 0.47$ vs. CBP $R = 0.44$; DBP: SMBP $R = 0.4$ vs. CBP $R = 0.37$) but no advantage in correlation with microalbuminuria (19).

Better data are available regarding monitoring of the efficacy of antihypertensive therapy using SMBP. Interventions that included SMBP showed improved BP control in 6 of 12 trials (19). SMBP enables monitoring of both BP and BP variation. Along with BP measurements, the time of the measurement and the time and dose of antihypertensive medication should be recorded as specified by the Joint National Committee. In two trials using technology that stored the BP data in a computer, both documented reduced BP from intervention that included this technology. Although the results are inconsistent, there is promise, especially with report-generating monitors, that SMBP can lead to improved BP control.

The reliability and accuracy of the monitors themselves are important; however, another important issue that must be addressed in the use of SMBP is the reliability of the measurement recording. There are several studies performed using a BP device that stores the readings on an internal chip. In the majority of the studies, the devices were given to patients without their knowledge of this capability. The patients were asked to record their BP in a log as usual and then the stored results were compared with the patient-generated log books. Patient reports had mean differences in BP of a least 10 mm Hg for SBP and 5 mm Hg for DBP compared with stored BP readings (24). In another study, 36% of patients underreported and 9% overreported BP readings. Log books also contained phantom readings; conversely, patients failed to report measurements that were taken and stored (25). This type of patient reliability in home monitoring is not unique to BP measurement. Similar findings were observed with the use of glucometers by diabetic patients (26) and in records of metered dose inhaler usage by asthmatic patients (27). Thus, although SMBP has the potential to make an important contribution in BP diagnosis and management, objective recording of the data is strongly advised. SMBP is a useful adjunct to CBP measurement, can be performed by many patients, and is consistent with the goal of self-management.

Ambulatory Blood Pressure Monitoring

The use of ABP monitoring (ABPM) in children has been described in detail by Portman et al. (28). In brief, the ABPM device is attached to the subject's nondominant arm with an appropriately sized BP cuff using Task Force criteria. SBP and DBP levels are measured at 20-minute intervals during the 24-hour period. To avoid subject biofeedback, the monitors can be programmed not to display BP measurements. A bleed step of 8 mm Hg allows accurate readings that are well tolerated by children. These monitors are small and lightweight and have appropriately sized cuffs for use in children of all ages. The keys to successful monitoring are adequate patient instruction, which includes the need to keep the monitor dry, holding the arm motionless during the reading, applying the cuff in the appropriate way, and maintaining an adequate diary and provision of a person to contact about any problems. The diary

should include at a minimum the time of going to sleep and the time of waking, including naps or disrupted nighttime sleep, as well as the timing of any medications taken during the period. The monitor's accuracy (within approximately 5 mm Hg) must be validated by comparison with mercury manometry before use. Adequate study is approximately 85% confirmed successful readings. ABPM use is feasible in children, and the measurements obtained using this device correlate well with those obtained using mercury manometry, which conforms to the guidelines proposed by O'Brien et al. (29) for ABPM validation. Monitors using different technologies, including oscillometric, auscultatory, auscultatory with electrocardiogram gating and intraarterial monitors, and Finapres beat-to-beat constant monitoring are available. The authors prefer the oscillometric monitor because it provides fewer nonsense readings in loud environments usually associated with children and is well tolerated. Although standards for monitoring children have yet to be developed, the use of the ABPM in children has great promise for the diagnosis and management of HTN in children.

Chronobiology of Blood Pressure

Biologic functions and processes are organized not only in space, as in physical anatomy, but also in time, as biologic rhythms. These rhythms are endogenous, heritable traits that can be described in specific, quantifiable terms (30). Knowledge of BP rhythms and the factors controlling them is important for the proper diagnosis and treatment of HTN. BP demonstrates a circadian rhythm composed of a daytime (diurnal) period and a nighttime (nocturnal) period. However, the environmental day-night rhythm is superseded by the biologic clock as reflected by the periods of wake and sleep (31). Although a low-amplitude circadian rhythm can be identified, shift workers have BP patterns more closely related to their activity. In addition, BP is the same during a daytime nap as during nighttime sleep. Consequently it is important to classify ABPM data not in terms of day and night, but rather wake and sleep. BP not only follows a circadian rhythm but also varies minute to minute. Thus, the use of a single random BP measurement to characterize circadian BP levels or long-term behavior of a continuous variable is as unrealistic as use of a weekly single measurement of blood glucose level compared to glycosylated hemoglobin (32).

Healthy individuals display a sleep-related fall in BP. Its multifaceted etiology is determined by physical activity, emotional factors, and circadian rhythms in the sympathetic nervous system (SNS), hormone levels, and the cardiovascular system (31). A person whose mean BP falls by 10% from wake to sleep (sleep/wake ratio of <0.9) is termed a *dipper*; an individual whose BP fails to do so is termed a *nondipper*. A person whose BP is higher during sleep periods has a reversed BP rhythm. Reproducibility of "dipper" status on repeated studies remains unclear (33).

TABLE 59.1. THRESHOLDS FOR AMBULATORY BLOOD PRESSURE MEASUREMENTS (mm Hg) IN ADULTS

	95th percentile	Normotension	Hypertension
24 h	132/82	≤130/80	≥135/85
Daytime	138/87	≤135/85	≥140/90
Nighttime	123/74	≤120/70	≥125/75

Note: Thresholds are based on epidemiologic studies of normotensive and hypertensive individuals as well as morbidity and mortality. From Staessen JA et al. *Blood Press Monit* 1999;4:127–36, with permission.

During the active process of sleep (31) there is a progressive fall in BP in the first hour as the stages of sleep progress; BP maximally decreases 15 to 20% after approximately 2 hours of sleep, which coincides with sleep stages 3 and 4. This fall in BP with sleep is accompanied by a decrease in HR and cardiac

output. BP tends to rise during REM (rapid-eye-movement) sleep but remains lower than values during wakefulness. BP and HR rapidly increase on awakening in association with activation of the SNS and its receptors. There are normal sleep-related changes in renal function that during pathologic states may contribute to HTN. Renal blood flow and glomerular filtration rate (GFR) fall by approximately 20% in association with a pronounced decrease in urine flow due to an increased tubular reabsorption of water, sodium, and chloride. Plasma catecholamine levels also fall during sleep consistent with diminished SNS activity, whereas plasma renin, aldosterone, and antidiuretic hormone levels steadily rise concomitantly throughout the night. Renin secretion also rises during non-REM sleep and minimally during REM sleep.

Considerable data now define ABPM values in normotensive adults based on EOD (Table 59.1) (34,35). An increasing number of studies in children describe age- and

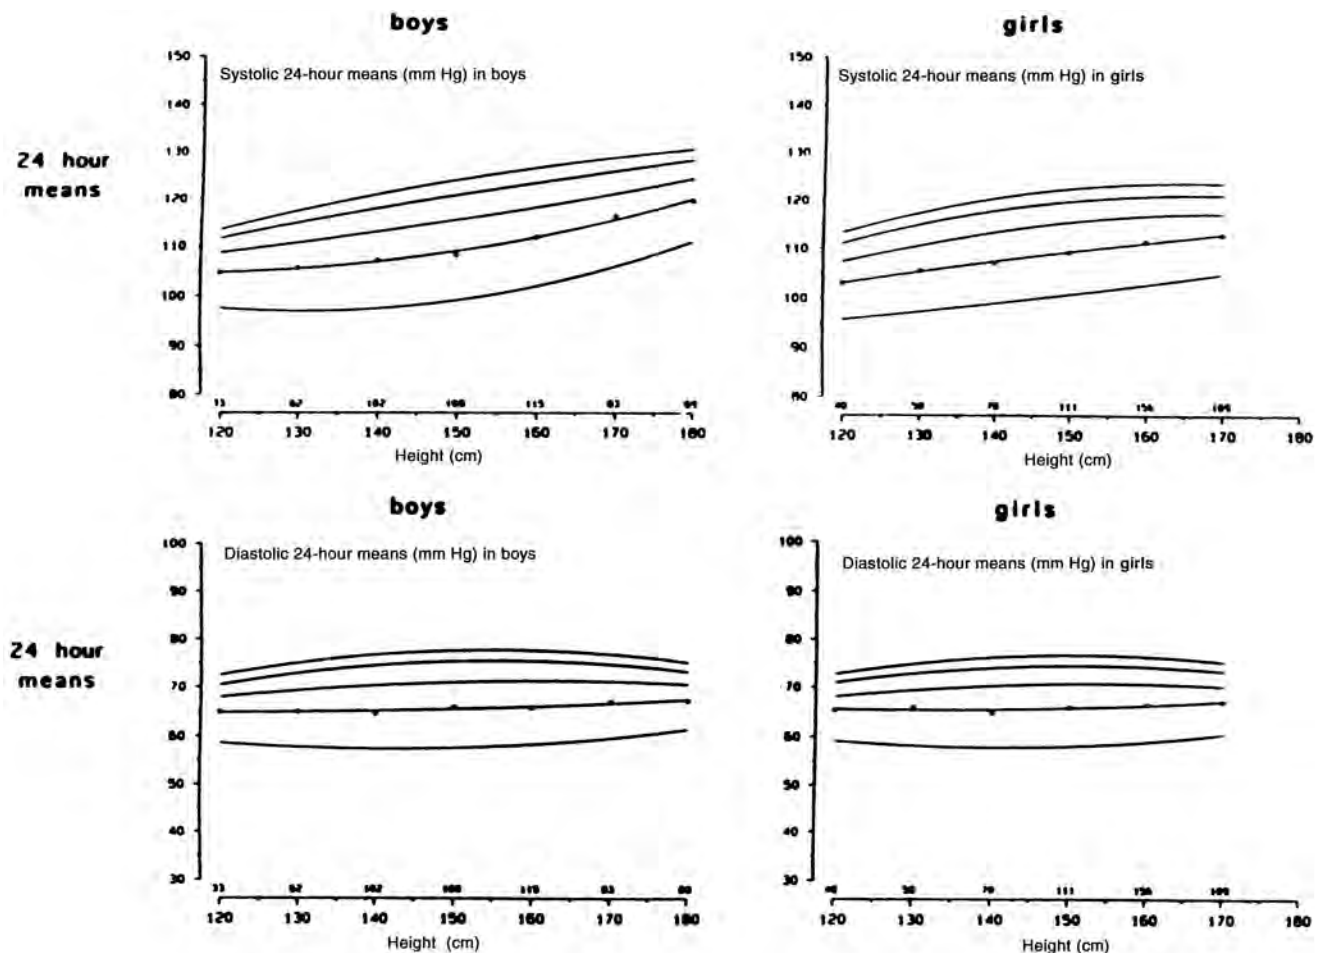

FIGURE 59.1. Twenty-four-hour mean BP values for 1141 children related to height, with systolic blood pressure in the upper two graphs and diastolic in the lower two. Values for boys are on the left side and girls the right. The points show the raw median values for each height group. The lines represent the fitting polynomials for the tenth, fiftieth, ninetieth, and ninety-fifth percentiles. The numbers along the x-axis indicate the number of subjects in each height group. (From Soergel M, Kirschstein M, Busch C. Oscillometric twenty-four-hour ambulatory blood pressure values in healthy children and adolescents: a multicenter trial including 1141 subjects. *J Pediatr* 1997;130:178–184, with permission.)

size-specific normal values for ABP. There have now been several studies in the United States, United Kingdom, Spain, Germany, Italy, and Brazil attempting to establish normal ABPM values for children. However, in none of these studies is the population of sufficient size in each age, size, and ethnic category and the measurements of BP performed with the same techniques and equipment so as to provide true normal data. The International Pediatric Hypertension Association is in the process of combining these studies to develop more generalizable normative data. Future studies examining ABPM will need to incorporate measures of EOD in the definition of HTN. The largest multicenter study, reported by Soergel et al. (36) in central Europe, provides the best available data (Fig. 59.1). The normative data were based on the child's height (115 to 185 cm). Findings show a moderate increase in fiftieth-percentile SBP with increasing height from 103 to 113 mm Hg in girls and from 105 to 120 mm Hg in boys. The fiftieth percentile for DBP was 66 ± 1 mm Hg regardless of gender or height. A new statistical approach to ABPM normalizes data, which permits the use of an SDS score for the purposes of diagnosis (37). Importantly, no statistical technique can really diagnose true HTN, which is the BP that can predict the presence of EOD. The report of the Ambulatory Blood Pressure Monitoring Task Force II (38) stated that, although it is difficult to validate diagnostic reference values based on morbidity and mortality because of low incidence rates in children, functional rather than distribution-based definitions of ambulatory HTN must be developed. This point is critical because most studies of adults and children have shown a better correlation of ABP to EOD than for CBP measures.

DEFINITIONS OF HYPERTENSION

Casual Blood Pressure

HTN is a leading risk factor for CVD, renal disease, and stroke. In addition, it is believed that primary HTN has its roots in childhood. Thus, accurate definition and early identification of HTN risk is imperative but, as yet, not possible. Ideally the definition of HTN would identify individuals at risk for adverse outcomes when BP level exceeds a determined threshold; subjects with BP levels lower than the definition would be at little or no risk for adverse outcomes related to BP. Because no such dividing line exists in the continuum of BP, arbitrary levels (based on CBP) have been established to define persons who are at risk for morbid cardiovascular events and who will benefit from therapy.

The literature for adult patients is replete with studies correlating HTN with various adverse outcomes (39). Information from such studies linking BP elevations to outcomes of mortality, nonfatal myocardial infarction, congestive heart failure, stroke, renal failure, LVH, and advancement of ath-

erosclerosis has been instrumental in guiding expert committees in efforts to reduce the morbidity of HTN. Based on these outcome studies, definitions of HTN have changed, becoming ever lower so that 130/80 is the currently recognized upper limit of normal. In contrast to the situation for adults, BP levels considered to be hypertensive in children have yet to be fully correlated with cardiovascular morbidity and mortality, as they occur infrequently in children. However, convincing evidence has been reported that pediatric HTN is not benign and that many cardiovascular risk factors found in adults begin in childhood. Hypertensive EOD damage is discussed later in the chapter. Although other large studies have been published with somewhat different results, the *Update on the 1987 Task Force Report on High Blood Pressure in Children and Adolescents* (3) is probably the most widely used source of information on BP in children and provides us with statistical definitions of HTN. The Task Force Report is a compilation of data from 10 studies and includes data for more than 60,000 white, African American, and Hispanic children. From these studies, age-specific percentile curves of BP measurements for boys and girls ranging in age from birth to 18 years have been developed with the inclusion of BP tables adjusted for height (Tables 59.2 and 59.3) for children older than 1 year of age. By using these curves, one can compare measured BP levels to age-, gender-, and height-specific norms. To use these tables, a child's BP is measured and the height percentile is calculated using standard growth charts. The measured BP and age-specific height percentile are compared with the values on the gender-specific tables. If the BP is below the ninetieth percentile, the child is normotensive. If the measured BP is between the ninetieth and ninety-fifth percentiles, the patient is considered to have high-normal BP, and observation and consideration of risk factors for HTN are initiated. Measurements higher than the ninety-fifth percentile may indicate a diagnosis of HTN, and repeated measurements are indicated. A new updated Task Force report is expected in the near future that will publish norms based on the latest Centers for Disease Control and Prevention data on height in children as well as more information on oscillometric, ambulatory, and home monitors. No changes in the standards for SBP and DBP for infants younger than 1 year were reported in the 1996 update (3); data for healthy subjects published in the Task Force report of 1987 (40) should be used.

No recommendations on the timing of BP measurement are included in the Task Force recommendations, although repeated measurements over time are encouraged (3). Future Task Force recommendations may include advice such as more information about the 24-hour pattern of BP in children as it becomes available. It is critical to recall that these data are from the *first* measure obtained for each child in each study. It is well recognized, however, that with repeated measurement there is regression to a lower average value. The pediatric definition of HTN, therefore, is arbi-

TABLE 59.2. BLOOD PRESSURE LEVELS FOR THE 90TH AND 95TH PERCENTILES OF BLOOD PRESSURE FOR BOYS AGED 1 TO 17 YEARS BY PERCENTILES OF HEIGHT

trarily higher than the true ninety-fifth percentile for the pediatric population. With repeated measurement, the Task Force (40) and others (41) estimate that only approximately 1% of children and adolescents will ultimately prove to have HTN. However, these estimates of the prevalence of pediatric HTN must be balanced against the observation that the epidemiology of cardiovascular risk factors in children is changing for the worse. In the United States, the prevalence of obesity among children increased from 5 to 11% in national surveys from the 1960s to the 1990s. Current estimates of the prevalence of obesity among school-aged children are even higher. Because the Task Force data were collected primarily in the 1970s and 1980s the current pediatric 95th percentile would almost certainly be higher than in previous decades. More recent studies place the prevalence of HTN much higher than previously

reported (42), particularly among ethnic minority adolescents. Sorof et al. (42) reported an estimated prevalence of HTN of 17% after one measurement, comparable to the Task Force data; subsequently the prevalence was reduced to 7% after three measurements were taken. Thus, the current prevalence of pediatric HTN is likely to be greater than the 1% quoted in the Task Force report. One possible explanation for this variance could be that the oscillometric method of BP measurement was used for the Sorof et al. study whereas the auscultatory method was used to collect the data for the Task Force. Oscillometric methods, as noted previously, can yield a higher SBP than auscultatory methods, but even this could not fully explain a sevenfold increase in HTN prevalence. The prevalence of EOD of 47% in a similar group of our patients suggests that the diagnosis is valid. A more likely explanation is the fact that

45% of the population was either Hispanic or African American and that 38% of the population was overweight or obese. Figure 59.2 shows that the prevalence of HTN increases as body mass index increases (42).

Ambulatory Blood Pressure Monitoring

The interpretation of the ABPM data should be based on the BP levels that are associated with EOD rather than on an epidemiologic definition of HTN. There are numerous studies of adults and now several of the pediatric population demonstrating that various ABPM parameters have an excellent correlation with EOD, whereas correlation with CBP is weaker or absent. As stated in the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC

FIGURE 59.2. Hypertension prevalence by body mass index (BMI) percentile. NML, normal; HTN, hypertension.

VI) (18), "Among persons with HTN, an extensive and very consistent body of evidence indicates that ABP correlates more closely than clinic BP with a variety of measures of target organ damage such as left ventricular hypertrophy." The definitions take into account distributions of ABP in normal and hypertensive populations, and validation of diagnostic thresholds in terms of LVH and in terms of morbidity and mortality (Table 59.1) (43). A meta-analysis of 18 studies demonstrated that CBP measurements were higher than 24-hour, wake or sleep ABP measurements (19). ABPM data can be analyzed by a number of different statistical approaches. Which of these is the superior and most clinically applicable is still unanswered. Most observers use the 24-hour mean SBP and DBP and also separate the 24-hour period into day-night or the more appropriate sleep-wake periods (44). Others choose to separate the waking BP periods into 8-hour segments: those of stress such as work or school, those of other activities, and sleep. The first 2 hours of any ABPM may be excluded as an accommodation period during which time BP levels are higher than in the rest of the readings (45).

The BP load for adults is defined as the number of SBP or DBP measurements during the wake period exceeding 135/85 plus the number of BP levels during sleep exceeding 120/75 divided by the total number of measurements during 24 hours times 100 (46,47). For pediatric patients, it is defined as the percentage of total BP measurements exceeding the upper limit of normal for age, size, and time of day. The BP load represents the summation of the peaks of BP and is believed to measure the maximal stress on the heart and other organs. As discussed later, increased BP loads have an excellent correlation with EOD. An advantage of this concept is that BP load can be influenced not only by the mean BP but also by its variability. Thus, a patient with high-amplitude swings in BP can be diagnosed as hypertensive even if the mean BP is near normal. Because the BP load is determined by comparison with age- and size-related normal values, one can compare the BP challenge of diverse patient groups. It is generally accepted that BP loads of 25% or more constitute HTN for a given time period and that BP loads above 40% in adults and 50% in children (48) are strongly associated with EOD. Analysis using BP load data is limited by a ceiling value of 100%. A patient with all BP levels mildly elevated would not be at the same risks as those with more severe BP elevations. A new concept called the BP index (48) can serve as a quantitative assessment of the degree the BP exceeds the upper limit of normal for a given time period. In early studies, it has been demonstrated to have a strong correlation with EOD in children. The index is calculated by dividing the patient's BP by the ninety-fifth percentile. For example, a BP index of 1.2 would be 20% higher than the ninety-fifth percentile for an individual measurement or for a specific time period.

As mentioned previously, mean BP tends to fall by 10 to 20% during sleep periods relative to waking levels. A dip-

per is a person who has a minimum of a 10% fall in mean BP. Nondippers have been found to have an increased incidence of EOD including LVH, stroke, and cardiovascular events. The status of dipping may be less important than the diagnosis of HTN within the period. A patient with severe HTN may have more than a 10% fall in sleep BP but have significant HTN during sleep. Conversely, 30% of children may not be dippers but may have perfectly normal sleep BP levels. In adults, age, clinic BP, diabetes, duration of sleep, smoking habits, and work activity are the most important determinants in attenuation of the nocturnal BP drop in patients with essential HTN (49). Numerous studies demonstrate very strong association between sleep period HTN and EOD. Conversely, excessive dipping ("super dipping"), especially in the elderly, can be associated with silent cerebrovascular lesions such as lacunar infarcts (50).

These abnormalities observed during the sleep period may occur secondary to a lack of physical and emotional activity, which permits less variability and therefore a heightened sensitivity for the detection of abnormal BP. Alternatively, there are specific changes that occur during sleep that may cause abnormalities not observed during the waking period.

There is a considerable list of conditions associated with sleep-related HTN or nondipper status in adults, including abnormalities of the SNS (diabetes, pheochromocytoma, dysautonomias) and renin system [chronic kidney disease (CKD), end-stage renal disease, renovascular diseases], glucocorticoid therapy or Cushing's syndrome, solid organ transplantation, sleep apnea, and preeclampsia. In particular, a blunted fall in BP appears to be a ubiquitous finding in renal diseases (51). Farmer et al. demonstrated a rise in nondipping prevalence with worsening renal function (Fig. 59.3) (52). Almost 80% of adult patients with sleep apnea syndrome are both obese and hypertensive (53); conversely, 22 to 30% of adult hypertensive patients have sleep apnea. In pediatric patients, a similar phenomena has been observed in, for example, transplant, dialysis, African American, and diabetic patients as well as in those with secondary forms of HTN (48).

The most commonly implicated potential mechanisms of sleep-related HTN in children with CKD are increased activity of the SNS, insulin insensitivity, decreased antidiuretic hormone excretion during sleep, sleep apnea, and, the most often reported, volume overload with decreased sodium excretion. Evidence for the latter also comes from a return to a dipper status when sodium restriction and/or diuretic therapy is instituted (51). Stolarz et al. (33) reviewed the Osahama study and the predictive value of sleep-related HTN with CVD. In that study, a linear and inverse relationship was demonstrated between cardiovascular mortality and the nocturnal decline in BP. Overall, each 5% increment in the systolic or diastolic night-to-day ratio was associated with a 20% rise in the risk of CVD,

FIGURE 59.3. Blunting of the diurnal blood pressure rhythm of predialysis patients is more severe as renal failure worsens. HTN, hypertension. (From Farmer CKT, Goldsmith DJA, Cox J, et al. An investigation of the effect of advancing uraemia, renal replacement therapy and renal transplantation on blood pressure diurnal variability. *Nephrol Dial Transplant* 1997;12:2301–2307, with permission.)

even when 24-hour ABP was within the normotensive range. Patzer (37) published a paper examining the diagnosis of HTN in the sleep period in children with CKD due to renal scarring. The diagnosis of HTN was more specific using ABPM than CBP and it was the nocturnal BP changes that were most specific. New techniques for examining the BP challenge may come from the rate-pressure product (HR BP) \times over the 24-hour period. The standard deviation of the BP measurements is considered an excellent measure of variability of BP and has also been considered a separate risk factor for HTN-induced EOD (54).

White-Coat Hypertension

WCH is a conditioned, transient, elevation of BP in a medical setting when the BP is normal at other times. Its reported prevalence as measured by ABPM is 20 to 60% in adults and 28 to 88% in children. The mistaking of WCH for persistent HTN may lead to unnecessary diagnostic studies and medication use. ABP has been most useful in making this diagnosis (55). A meta-analysis by Appel et al. (19) found that the prevalence of WCH was approximately 20% in the population of adults diagnosed as hypertensive by CBP. Too few studies were available to determine the reproducibility of this classification. Under standardized conditions, SMBP is also effective in identifying WCH. There is debate in the literature regarding the question of whether WCH is an intermediate state between normotension and HTN, or a prehypertensive state. The Ambulatory Blood Pressure Monitoring Task Force (56) determined that event-based studies of hypertensive patients have convincingly demonstrated that the risk of CVD is lower in patients with properly defined WCH than in those with higher ABP levels, even after controlling for concomitant risk factors. Based on prognosis in adults, WCH can be defined as a CBP that is persistently 140/90 mm Hg or higher with an average daytime ABP of below 135/85 mm

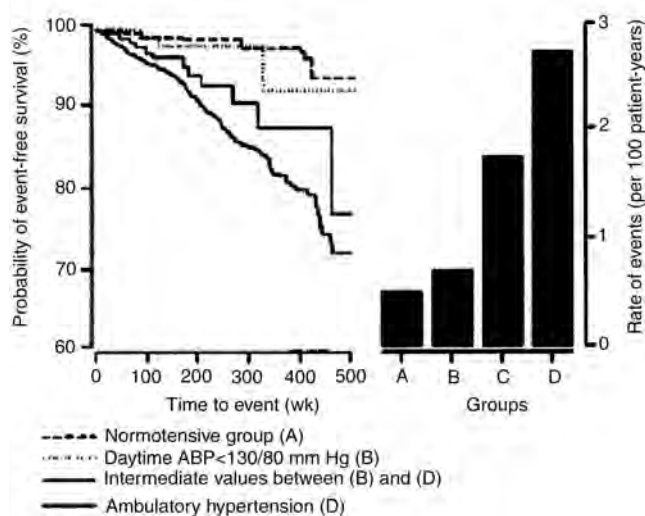

FIGURE 59.4. In the Hypertension and Ambulatory Recording Venetia Study of 942 patients with stage 1 hypertension (HTN), patients with white-coat HTN (WCH) had significantly lower left ventricular mass and microalbuminuria than did patients with established HTN, and there was no difference in end-organ damage between WCH patients and normotensive controls. ABP, ambulatory blood pressure. (From Palatini P, Mormino P, Santonastaso M, et al. Target organ damage in stage 1 hypertensive subjects with white coat and sustained hypertension. Results from the HARVEST study. *Hypertension* 1998;31:57–63, with permission.)

Hg (56). Individuals with WCH were found to have a lower risk of CVD than those with sustained HTN, although the authors concluded that no prospective study adequately compared the risk of those having WCH with that of normotensive patients (55). The finding that patients with WCH have significantly less EOD than those with persistent HTN and the same as control subjects is noted in the Hypertension and Ambulatory Recording Venetia Study (HARVEST) (57) (Fig. 59.4).

We studied 350 pediatric patients younger than 18 years of age with persistently elevated BP who were not taking concurrent antihypertensive medications or other medications that could affect BP levels. Seventy-one patients met these criteria and were studied with ABPM. Over half of these patients (55%) had WCH by ABPM as judged from mean BP; 21% had WCH when a normal BP load was required as well (58). Adult studies suggest that, the higher the JNC VI grade of HTN, the lower the prevalence of WCH. This is also true in children, as seen in Figure 59.5, which shows that the likelihood of diagnosis of WCH is 90% for patients with a BP index of 1.0 (on the 95th percentile) but less than 15% for those with a BP index of 1.2 (20% over the 95th percentile). The prevalence of WCH in patients CKD has not been determined reliably. WCH is more prevalent in patients with milder HTN in both adults and children. Thus, the prevalence of WCH might be lower in patients with CKD.

FIGURE 59.5. Blood pressure (BP) index versus probability of white-coat hypertension (WCH). DBP, diastolic blood pressure; SBP, systolic blood pressure.

Ambulatory Blood Pressure Monitoring in Chronic Kidney Disease

The emphasis of this text is pediatric nephrology, and thus the issue of BP in CKD should be carefully examined. Both JNC VI and JNC VII recommend ABPM for specific circumstances, including diagnosis of suspected WCH and evaluation of patients with apparent drug resistance, hypotensive symptoms while taking antihypertensive medications, episodic HTN, and autonomic dysfunction. The Kidney Disease Outcomes and Quality Initiative Hypertension Work Group has suggested that ABPM is valuable in patients with CKD because of the close correlation of the data with EOD and because of the alterations in circadian BP rhythms noted in CKD patients but has stopped short of recommending it for routine use. Authoritative reviews suggest that ABPM has advantages in evaluation of essential HTN (19). ABPM has been widely used for the past decade, but its use has been limited because of the expense of the equipment, the time involved in patient training and data analysis, and, until recently, the lack of consistent insurance reimbursement.

Level of BP and abnormal patterns as measured by ABPM show a high correlation with EOD, such as cardiovascular mortality and events, abnormal LV mass and function, cerebrovascular events, and glomerular and tubular proteinuria, and is capable of identifying abnormal circadian BP rhythms such as nocturnal HTN. ABP is also important in demonstrating the rapid rise in early morning BP that is associated with a high risk for cardiovascular events. There is a growing body of evidence showing that nondipping is associated with a worse prognosis, irrespective of whether nighttime dipping is studied as a continuous or a categorical variable (59). A metaanalysis of 25 studies of the relationship of ABP levels with EOD showed

that LV mass was positively associated with ABP (19). In ten studies, at least one dimension of ABP predicted subsequent clinical events prospectively. The metaanalysis agreed that a nondipping or reverse dipping pattern was associated with an increased risk of adverse events. The international conference on ABPM in 2001 agreed that, although the incidence of cardiovascular events has some correlation with CBP, the use of ABPM significantly refined the prediction. In the large Systolic Hypertension in Europe Trial, 24-hour SBP measurements were found to be a significant predictor of cardiovascular risk (60). Some but not all studies have reported an independent and positive relationship between measures of *variability* of daytime and nighttime BP and cardiovascular outcome. Finally, it has been suggested that ABP patterns can be predictive of preeclampsia early in pregnancy and that intervention with aspirin may prove beneficial in prevention (61).

Insufficient evidence exists to conclude that adjusting medications using ABP is superior to adjustment using CBP measurements. The metaanalysis (19) concluded that ABP has not been studied adequately to assess its role in antihypertensive therapy.

The most common circadian rhythm abnormalities seen in CKD patients is sleep-associated HTN and a nondipping BP pattern. Among such patients the prevalence of a nondipping pattern is high (67%) (62–64). These patterns are reproducible, with 67% of CKD patients maintaining their diurnal rhythm and 82% having a predictable pattern on repeated monitorings. The patterns were even more reproducible in transplant and dialysis patients (59). The mechanisms for this pattern have not been carefully elucidated (65). It was also demonstrated that the prevalence of nondipping patterns increases as GFR decreases (Fig. 59.3). Fifty-three percent of CKD patients with a serum creatinine level of 400 mmol/dL had a nondipping pattern; the proportion progressed to 75% for those with a creatinine level of above 600 mmol/dL (66). The nondipping pattern observed in those with type 1 and 2 diabetes (67) has also been related to the presence of microalbuminuria. CKD patients, particularly kidney transplant patients, may have a reversed BP pattern of higher BP during sleep than waking.

Children with CKD have altered patterns of BP that make the diagnosis of HTN in the normal clinic setting difficult. Lingens et al. (68) examined 31 children with CKD of whom 62% were diagnosed as hypertensive by CBP, 38% by home BP measurements, and 26% by ABPM. One-quarter of the patients had abnormal BP rhythms. The primary rhythm abnormality was a blunted sleep-related fall in BP; that is, nondipping status, which was commonly associated with sleep-related HTN. In several studies, isolated sleep-related HTN has been observed with normal wake pressures in unilateral renal dysplasia (69) and in polycystic kidney disease (70). The abnormal patterns increase as GFR declines (71,72). They are also more prevalent in dialysis patients and renal transplant

FIGURE 59.6. Followed from the time of enrollment, nocturnal ambulatory blood pressure elevations predated the development of microalbuminuria in patients with type 1 diabetes.

patients (73–75). Up to 78% of transplant patients have been reported to have a nondipping pattern and 24% to have a reversed BP pattern (73). It has been suggested (76) that ABPM can aid in differentiating primary from secondary HTN in children. A combination of daytime DBP load greater than 25% and nocturnal SBP load of greater than 50% was very specific for secondary HTN.

Abnormal ABP patterns have been shown to be related to varying degrees of abnormal protein excretion. Abnormal or nondipping pattern in ABPM measurements is strongly correlated with microalbuminuria and proteinuria, and this correlation is superior to that found with CBP measurement. This has been shown in studies of patients with type 1 diabetes (77,78), type 2 diabetes (67,79), type 1 and type 2 diabetes combined (80–82), and essential HTN (57,83–85). In the few studies examining possible mechanisms, autonomic dysfunction has been implicated (78,82).

Importantly, it has been shown in a landmark article that ABPM can identify individuals at risk for development of CKD. In type 1 diabetes, nocturnal BP elevations determined by ABPM predated the development of microalbuminuria (Fig. 59.6) (77). Identifying individuals at risk for development of microalbuminuria provides an important window of opportunity for primary prevention.

The correlation of EOD with cardiovascular end points is similar in patients with CKD to that reported in hypertensive patients. There are few studies of patients with CKD that examine the relationship of ABP to morbid or mortal events. Three hundred and twenty-five patients with non-insulin-dependent diabetes mellitus (NIDDM) were studied, with ABP circadian rhythm assessed by cosinor analysis (86). After an 8-year follow-up 201 patients had a normal circadian rhythm and 87 a reversed one. Twenty subjects in group 1 (9.9%) had nonfatal (cerebrovascular, cardiovascular, peripheral vascular, or retinal events) or fatal events versus 56 patients (64.4%) in the reversed group. Circadian pattern of BP and age had the greatest effect on adverse events in a Cox proportional hazards model. The same correlation between ABP and measures of LV mass is seen regardless of the cause of CKD: autosomal dominant polycystic kidney disease (87), kidney failure (88,89), glomerulonephritis (90), HTN with

albuminuria (91,92) immunoglobulin A nephropathy (93), NIDDM (86), and renal transplantation (64,94). The recurring theme in these articles is positive correlation of LV mass with ABP parameters, most commonly a nondipping pattern or sleep-related HTN. In each of the studies there were either weak or, more commonly, no correlations between CBP and these outcomes. Combining the 24-hour SBP with a measure of dipping, the night to day ratio, was a strong predictor of cardiovascular end points in the Systolic Hypertension in Europe Trial.

Abnormal ABP patterns have been related to more rapid progression of kidney disease. There are five studies that examine the association of ABP with renal disease progression. In 126 patients with immunoglobulin A nephropathy, those who had ambulatory HTN developed higher creatinine values, whereas the normotensive patients, with or without antihypertensive therapy, had stable serum creatinine. Nondippers made up 93% of the hypertensive patients. The normotensive patients who were nondippers also had higher creatinine values than dippers (95). In a 3-year case-control study, 48 patients with CKD were studied: 28 dippers and 20 nondippers (96). Nondippers had a faster decline in GFR (4.4 mL/min/yr) than dippers (3.2 mL/min/yr) and a higher mean protein excretion. In a similar study of diabetic patients, nondippers had a 7.9 mL/min/yr decline compared to 2.9 for nondippers (97). Finally, Nakano et al. (98) examined 257 NIDDM patients with normal circadian rhythms (194 patients) or reversed patterns (63 patients). More patients with a reversed pattern (23.5%) than patients with a normal rhythm (3%) progressed to dialysis (86). Jacobi et al. (99) demonstrated the relationship between creatinine levels 6 months after transplantation and ABP levels.

Due to these abnormal patterns, the correlation between CBP and ABP is poor, as is the relationship of CBP to EOD. A poor correlation ($R = 0.61$) was found between office BP measurements and ABP measurement in kidney transplant patients (100). Three studies of diabetic patients all showed a significant association between ABP and urinary albumin excretion in cases in which CBP failed to do so. Once again, SBP and nocturnal elevations had the clos-

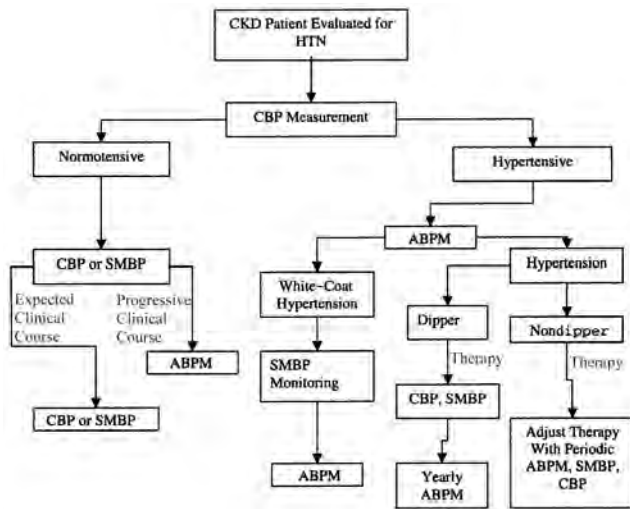

FIGURE 59.7. Proposed paradigm for use of ambulatory blood pressure monitoring in evaluation of hypertension in patients with chronic kidney disease (CKD). ABPM, ambulatory blood pressure monitoring; CBP, casual blood pressure; HTN, hypertension; SMBP, self-measurement of blood pressure.

est correlation to this measure of EOD. In nondiabetic CKD patients, five studies have demonstrated the same finding. McGregor et al. found a nondipping pattern in renal transplant patients. This pattern was associated with LVH, whereas CBP did not show such an association (64). Tucker et al. demonstrated that casual SBP and DBP had a weak correlation of 0.25 to 0.22 with LVH in 16% of his CKD patients, whereas systolic ABP had a correlation of 0.52 and diastolic ABP had a correlation of 0.42. Nocturnal BPs showed an even better correlation (88).

Cardiovascular mortality is rare in pediatric patients, although it is much more common in CKD patients than in the general pediatric population. Thus, determination of more subtle hypertensive damage is critical to an assessment of the effects of HTN or therapy for HTN. ABP correlates better with measures of LVH than does CBP in pediatric CKD patients (101–104). HTN determined by ABPM has also been shown to correlate with evidence of LV dysfunction and increased intimal-medial thickness (105). There have been no long-term studies of the treatment of HTN in children with CKD using ABPM.

The diagnosis of nocturnal HTN could affect the requirement for antihypertensive therapy in CKD patients. The concern in CKD patients who have altered patterns of BP and a nondipping BP pattern is that (a) measuring CBP may not correctly represent BP burden and risk, and (b) confining the definition of WCH to the daytime BP comparison may include patients with sleep-related HTN in the WCH category.

Insufficient evidence exists to determine whether ABPM is a better monitoring tool than CBP for assessing the effect of antihypertensive treatment and outcomes of antihyper-

tensive therapy. LVH was found to be present only when CKD patients were noted to have persistently abnormal ABP, not abnormal CBP. When treatment decisions were made on the basis of CBP, 13% of patients had LVH, compared with none of the patients whose treatment decisions were controlled by ABP criteria (91). A comparison of lisinopril with nisoldipine showed a decrease in microalbuminuria with no differences between albuminuria groups as measured by CBP; however, there were differences between groups in nighttime SBP when measured by ABP (106). A potential paradigm for the integration of various BP measurement technologies in HTN evaluation in CKD patients is presented in Figure 59.7.

PEDIATRIC STUDIES

Epidemiology of Hypertension

Age

BP levels are closely related to growth and maturation (107). Children have lower BP levels than adults, but the levels progressively increase as the child ages. At birth, a term infant has a SBP of close to 70 mm Hg (108). During the first week of life BP increases at a rate of approximately 1 mm Hg/day. After the first week the rise in BP continues at a fairly rapid rate, although slightly slower than in the first week, and then rises more slowly throughout the remainder of the first year of life. DBP begins at approximately 40 mm Hg at birth for a term infant. It also increases during the first week of life but then falls to a nadir at approximately 3 months of age. It then increases in parallel to the SBP throughout the remainder of the first year of life (109). From ages 1 to 13 years, a linear rise in BP is observed. This seems to be the result more of an increase in body size than an increase in age. From childhood to adolescence, SBP rises 1 to 2 mm Hg per year. The rise in DBP is slower (110).

The increase in SBP and DBP during the first year of life occurs at a faster rate in premature infants than in term infants (111). Among groups of premature infants, very-low-birth-weight infants have a more dramatic increase in BP than do larger preterm infants. By approximately 4 months of age, BP levels for both groups of preterm infants are similar to those of term infants.

Gender

Gender plays an important role in BP variability. Not only are there differences in BP levels between the genders, but changes in the pattern of development of BP are also observed from an early age. In girls, SBP rises more rapidly between 6 and 11 years of age than it does from 12 to 17 years of age. In boys, the opposite is seen; a more rapid rise in BP is observed from 12 to 17 years than from 6 to 11

years of age. Although not universal, by the age of 12 to 14 years boys tend to have higher mean BP levels than do girls. These changes probably reflect the gender-specific differences in rates of growth and maturation. Male predominance of higher BP levels lasts until approximately 50 years of age, when women's BP levels once again exceeds men's (109,111,112).

Race

The African American population has an incidence of HTN that is at least twice that among whites for nearly every age- and sex-matched group (113). These racial differences can be observed from childhood (114,115). Not only are CBP levels altered, but the circadian rhythm of BP in African Americans is also different from that in whites, with a blunted nocturnal BP dip (116). Those of African descent living in the Western hemisphere, including African Americans, have BP levels and 24-hour patterns of BP that are different from those of African natives (117,118). This finding suggests that, in addition to genetic factors, the environment plays a key role in BP determination.

HTN in the African American population seems to be sodium mediated. Based on these observations, the potential role of genes encoding for proteins involved in the renin-angiotensin system has been studied in African American populations. Serum levels of angiotensinogen are higher in African American than in white children (119). A higher frequency of a deletion polymorphism in the angiotensin-converting enzyme (ACE) gene has been observed in African Americans with HTN. This suggests a potential role for a salt sensitivity phenotype mediating HTN in blacks (120).

Racial differences in BP levels between African American and white children are not observed until approximately age 12 years. By this age small differences have been reported in some epidemiologic studies. Interestingly, although African American children generally demonstrate higher DBP levels from age 12 years, white children of both genders generally have higher mean SBP levels than do African American children. Some studies report that these differences disappear when socioeconomic status is considered (112). African American adults have a higher incidence of HTN than whites.

Berenson et al. have shown that African American male children have higher supine BP levels than whites and there is little relationship of HR to BP levels or body weight (121). In this same group of children, higher cardiac outputs were demonstrated in white children than in African American children after adjustment for body size. African American children also were noted to have higher peripheral vascular resistance than white children (122). Not surprisingly, BP in African American children was more sensitive to sodium (114,123,124). In addition, greater cardiovascular reactivity has been described in African

American children (115,125–127). Higher cardiovascular reactivity to stress, especially in African American patients, may lead to misclassification because of higher office BP measurements. African American children exhibited higher 24-hour mean ABP than white children, and there was a good correlation between BP during stress and mean ABPM results (128).

No dramatic differences in BP levels have been identified among other racial groups. Data from six European studies have been pooled to provide specific percentile values for children in northwest European countries (129). A comparison of the results of this European study to those of the Task Force reveals lower BP means and percentiles in the Task Force results (North American children). The average difference in systolic measurements between the two studies is approximately 6 mm Hg for both genders; the difference in DBP for both genders is approximately 3 mm Hg. The reasons for this difference are unknown but might include methodologic differences as well as actual population differences.

Body Mass

Mechanisms proposed to explain the relationship of obesity and higher BP, none of which has been proven, include increased cardiac output in an arterial tree that is of normal size, expansion of the blood volume, increased sodium intake with increased caloric intake, increased steroid production, and alteration of receptors for pressor substances (130). More recently, leptin has been implicated as a potential factor linking body mass with HTN. Animal and human data suggest that leptin is involved in BP regulation through the leptin receptor (131). Regardless of the cause, weight reduction is associated with a decrease in BP (109,132–137). HTN has been found to be more common in obese children. In a study of 2460 adolescent students (49% Hispanic, 31% African American, 13% white) 17% were found to have HTN after one measurement and 23% were obese (138). Of the HTN students, 88% had isolated systolic HTN. HTN was more prevalent in obese students (33%) than in nonobese students (11%) ($p < .001$). Obese students also had a higher resting HR (85.9 vs. 79.6 beats/min, $p < .001$) consistent with other studies, which suggests a higher activation of the SNS (139). Among those patients studied with ABPM, isolated systolic HTN was found in 51% by CBP and in 62% confirmed by ABPM. BP variability was greater during wake and sleep periods in obese patients ($p < .05$). Sorof and Daniels have reviewed this topic in detail (140).

In addition to weight, height appears to be an independent predictor of BP. Portman et al. (141) and Voors et al. (142) have reported stronger correlation of BP with height than with weight in adolescents. This effect is independent of the level of maturation (143,144). Data suggest that some of the racial differences in BP levels could be

explained by differences in body mass index (145). If white and African American populations with low body mass indices are compared, BP levels are higher in blacks. However, at the highest levels of body mass indices, high BP levels and HTN (systolic or diastolic) are more common in whites (146).

Physical Activity

The level of fitness has a significant but variable effect on ABPM profiles, particularly in African American subjects (147). Although exercise is generally promoted to improve overall cardiovascular fitness, its role as an independent factor decreasing BP levels is less clear (132). The effect on BP level may depend on the type of exercise performed. Dynamic (isotonic or aerobic) exercise decreases BP in hypertensive adolescents (148,149) and is generally recommended as part of an overall healthy lifestyle (109,132). In contrast, during static (isometric) exercise, there is a marked increase in DBP due to muscular contraction. The resultant increase in muscle mass leads to an increase in CBP (109,132). Programs emphasizing aerobic forms of exercise can be recommended to improve physical conditioning, whereas those emphasizing isometric exercise should be avoided.

A common area of concern for adolescents and parents of children with HTN is participation in various kinds of sports. Sports that feature dynamic exercise appear to improve overall cardiac fitness; the long-term effect of sports programs that feature static exercise remains less clear. Before embarking in competitive sports and highly static activities, children with cardiac symptomatology should undergo exercise stress testing to identify arrhythmias, ST-segment depression, or excessive BP increases. This may preclude some from participation in sports until clarification of the condition. Patients who have uncontrolled HTN and who have not yet responded to therapy should wait before starting sport activities (149). Once BP is under control, dynamic exercise training should be encouraged for better control of HTN and overall cardiovascular conditioning. Children with controlled HTN should not be restricted from sports participation (149).

Role of Sodium

The relationship between salt intake and BP remains controversial. Although several epidemiologic studies have shown that BP levels are significantly higher in societies with high salt intake, the results from clinical trials involving children and adults have been far less impressive (150–160). It is likely, however, that some people are genetically susceptible to the effects of salt and that at least some of the variability in BP is due to salt intake (161). Salt sensitivity is defined as an elevation in BP during high salt intake. Approximately 50% of patients with essential HTN are salt sensitive (162). Although this phenomenon is more com-

monly observed in hypertensive subjects, it has been documented in normotensive subjects as well. It is more prevalent among older patients and patients with low plasma renin activity (PRA), or low renin HTN (162).

The BP response to sodium intake seems to be genetically determined. The cross-transplantation experiments of Dahl et al. in 1974 demonstrated that sodium sensitivity was determined largely by the genotype of the donor kidney rather than by that of the recipient (163). Transplantation of a sodium-sensitive kidney to a sodium-resistant rat resulted in sodium sensitivity in the latter, and vice versa. Normotensive first-degree relatives of hypertensive subjects have lower urinary sodium excretion after a saline load than do relatives of nonhypertensive subjects (164). The average U.S. diet contains an overabundance of sodium. Therefore, modest reductions in salt intake may be advisable as a general good health practice for hypertensive patients. However, severe reduction in salt intake may be inappropriate for rapidly growing children and adolescents.

Nephron Number

The idea that HTN is programmed by an adverse environment *in utero* was first proposed by Barker, who reported a strong association between HTN in adult life and retarded growth in fetal life (165,166). The relation between BP and birth weight becomes stronger as the patient ages. At 7 years of age SBP increases by 1.3 mm Hg and DBP by 0.6 mm Hg for each 1-kg decrease in birth weight (167). By age 64 to 71 years, the effect is more marked, with a decrease in SBP of 5.2 mm Hg for every 1-kg increase in birth weight (168). In humans low birth weight, length at birth, and small body in relation to placental size have been related to the development of HTN and coronary heart disease. It has been proposed that undernutrition during fetal life may stimulate an elevation in BP, which is amplified during time and results in HTN in adult life. This suggests that HTN is initiated in fetal life (169). Using ABPM, Lurbe et al. examined 332 children 6 to 16 years of age who were stratified by birth weight tertiles and age. Birth weight was inversely related to daytime SBP and BP load when current height, ponderal index, and age were controlled (170).

Brenner and colleagues have elaborated this hypothesis, suggesting that the relationship between HTN and low birth weight is the result of low nephron number in low-birth-weight infants. This directly relates birth weight to nephron mass at birth and suggests an inverse relationship between nephron number and risk of HTN (171–173). Impaired fetal growth results in a permanent decrease in nephrons. Subsequent accelerated growth leads to excessive metabolic demands for the limited renal mass. Specifically, a decreased ability to handle sodium load results in excessive sodium retention and systemic HTN. In addition, glomerular HTN causes progressive nephron loss and worsening of systemic HTN and renal function (172,173).

TABLE 59.4. GENES RESPONSIBLE FOR SELECTED MONOGENIC VARIANTS OF HYPERTENSION-CAUSING DISORDERS

Syndrome	K ⁺	pH	Renin	Aldo	Specific treatment	Gene loci	Gene
GRA	↓	↑	↓	↑	Spironolactone (amiloride, triamterene)	8q	Chimeric gene (<i>CYP11B1/CYP11B2</i>)
Liddle's syndrome	↓	↑	↓	↓	Amiloride, triamterene	16p	β and γ subunit of ENaC
AME	↓	↑	↓	↓	Spironolactone (amiloride, triamterene)	16q	11β-HSD

↑, increase; ↓, decrease; Aldo, aldosterone; AME, apparent mineralocorticoid excess; GRA, glucocorticoid-remediable aldosteronism; HBS, hypertension brachydactyly syndrome; K⁺, potassium; MR, mineralocorticoid receptor; N, normal.

^aContrary to the rest, HBS is not a salt-sensitive condition and is characterized by normal values for the parameters shown.

From Toka HR, Luft FC. Monogenic forms of human hypertension. *Semin Nephrol* 2002;22:81-88, with permission.

This hypothesis seems to be supported in a number of clinical instances. In low-birth-weight infants, for instance, reduced nephron number seems to translate into a more rapid rise in BP than in weight gain and a higher incidence of essential HTN later in life.

GENETICS OF HYPERTENSION

Essential HTN is a complex disease that is influenced by both genetics and the environment. Although Robert Platt believed that BP was inherited in a simple autosomal dominant manner, he was one of the first to recognize the influence of genetics on HTN (174). George Pickering proved this theory wrong and suggested that HTN was caused by multiple genes (174a). Although multiple genes are suspected to cause the variation in BP, no one knows exactly how many genes are involved or how much effect each gene has (175). The heritability of HTN is 30 to 40%, which implies that only 30 to 40% of the interindividual difference in BP is due to genetics (176). Identifying these genes is daunting. One of the challenges is the difficulty in defining the phenotype for HTN. Potential influential genes are discovered usually by genome scans or search for candidate genes. A big advancement in the genetics of HTN is the identification of genes responsible for some of the monogenic variants of HTN (Table 59.4). Understanding the genetics of HTN is beneficial not only in identifying those at risk but also in better predicting the response to treatment and developing new therapies.

Familial Aggregation

Given that HTN is more common and more severe in particular ethnic groups, genes likely play an important role (177). HTN is also known to aggregate in families. Longini et al. studied families from Tecumseh, Michigan, and determined heritabilities of 0.42 and 0.30 for SBP and DBP, respectively (178). Early twin studies have confirmed the

heritability of BP variation (179). Adoption studies have also been performed to study the heritability of HTN. Biron et al. performed an adoption study of French-Canadian families. After studying families with adopted children, natural children, and with both adopted and natural children, Anest et al. concluded that 34% of the variability in BP is genetically determined, 11% is due to the environment, and the remaining 55% is due to random factors (176a).

Genome Scans

Identifying the genes influencing BP is a formidable task. Currently, there are three main techniques (180). One way is to perform a genome scan to try to find regions that are similar for patients with HTN. Another method is to look at candidate genes, which are genes whose product is suspected of influencing BP based on its physiologic function. A third method is to identify genes that cause HTN in rare monogenic types of HTN and determining if these genes are altered in essential HTN.

Rice and his colleagues performed a genome scan on patients in the Quebec Family Study. They investigated 206 patients and used 420 polymorphic markers. Although they identified no site with a lod score higher than 3, they did find some peaks on chromosomes 1, 2, 5, 7, 8, and 9 (181). Another design using genome scanning is the study of highly discordant siblings. Krushkal and her group did a genome scan on discordant siblings. She performed a genome scan of 359 polymorphic markers on 427 participants, consisting of 69 discordant sib pairs. Her group identified four regions (on chromosomes 2, 5, 6, and 15) that showed significant results and eight regions that were suggestive. Some of these regions have been identified as containing candidate genes that are known to contribute to BP variation (182). Levy and his group performed a genome scan on 1702 subjects in the Framingham Heart Study and was able to identify a maximum lod score of 4.7 on chromosome 17; interestingly, this chromosome con-

tains the gene responsible for Gordon's syndrome (180). Because HTN is a complex polygenic disorder, genome scans are a difficult way to identify new genes accounting for the variation in BP.

Candidate Genes

Evaluating candidate genes is a popular tool in molecular genetics. Although several genes have been studied, five are most promising at this point. These include angiotensinogen, ACE gene, β_2 -adrenergic receptor, α -adducin gene, and G-protein β_3 subunit.

Angiotensinogen Gene

The angiotensinogen gene was the first gene to be associated with high BP (183). Genetic linkage analysis performed on populations from Utah and Paris identified the substitution of methionine by threonine at position 235 to be associated with BP. This 235T variant was associated with higher levels of circulating angiotensinogen and higher BP. Other studies, however, have not been able to replicate these findings. Brand and her colleagues conducted a large European study involving 630 affected sib pairs and were not able to show an association between angiotensinogen levels and the 235T variant (184). A meta-analysis performed by Kunz et al. did find a small association between the 235T variant and HTN (odds ratio 1.2) (185). Therefore, the discrepancy in these studies is most likely due to the fact that, although the angiotensinogen gene does influence BP, its effect is small.

Angiotensin-Converting Enzyme Gene Polymorphism

ACE gene polymorphisms have also been studied for their role in HTN. Although such polymorphism has been associated more with myocardial infarction than with BP, several studies have linked polymorphism to BP in particular groups (186). Busjahn et al. has shown that the D allele is associated with ACE plasma levels and cardiac posterior wall thickness by echocardiography (187). Another study showed a positive association between BP and the ACE gene. Fornage and her group looked at a population from Rochester, Minnesota, and found an association between ACE alleles and variation in DBP for males but not for females (188). O'Donnell et al. also found increased DBP to be associated with the D allele in their male but not in their female subjects (189). Turner et al. determined that the effect of I/D polymorphism on BP was dependent on gender, age, height, and weight (190). Several studies have focused on the influence of genetic differences in the ACE gene in determining the responsiveness to a particular therapy. Jacobsen et al. showed that possessing the deletion polymorphism for the ACE gene resulted in a decrease in

response of BP and proteinuria to therapy in diabetic patients (191). Although it exhibits a small effect, the ACE gene is likely to be one of the many genes influencing BP.

β_2 -Adrenergic Receptor Gene

Polymorphisms in the β_2 -adrenergic receptor gene have been associated with HTN. Kotanko et al. studied 136 hypertensive and 81 normotensive people of African Caribbean descent and detected an association between HTN and a variant in the β_2 -adrenergic receptor gene involving a substitution of glycine for arginine at position 16 (192). Busjahn et al. looked at the β_2 -adrenergic receptor gene in twins and found that four single nucleotide polymorphisms in the β_2 -adrenergic receptor gene were associated with BP levels (193). Bray and her colleagues identified several polymorphisms in the ADRB2 gene that were associated with HTN (194). However, Herrmann et al. conducted a large European study looking at the relation between polymorphisms in the β_2 -adrenergic receptor gene and outcome, and did not find an association with HTN or risk for myocardial infarction (195).

α -Adducin Gene

Findings regarding the role of the α -adducin gene in HTN have been conflicting. Glorioso et al. genotyped 490 hypertensive and 176 normotensive people from Sassari, Italy, and 468 hypertensive and 181 normotensive people from Milano, Italy. His group detected an association of the Gly460Trp variant with HTN in the Milano group but not in the Sassari group (196). Province et al. identified an association between the α -adducin gene Gly460Trp variant and HTN in whites but not in African Americans. They genotyped 822 white subjects and 572 African American subjects as part of the HyperGEN study and found an odds ratio of 1.73 [95% confidence interval (CI), 1.17 to 2.54] for whites for the development of HTN. Interestingly, the Gly460Trp variant was actually protective against the development of HTN in African American patients, with an odds ratio of 0.48 (95% CI, 0.25 to 0.90) (197). Bray et al. could not find an association between the α -adducin gene and BP when performing a linkage analysis on sib pairs from Rochester, Minnesota (198). However, Psaty et al. showed that patients possessing the Gly460Trp variant of the α -adducin gene had a decreased risk of myocardial infarction or stroke when their BP was controlled by diuretic therapy versus nondiuretic therapy (odds ratio, 0.49; 95% CI, 0.32 to 0.77) (199).

β_3 Subunit of G Proteins

Siffert et al. identified a polymorphism (C825T) in the β_3 subunit of G proteins that was significantly associated with HTN (200). Turner et al. evaluated the ability of the T

allele of the C825T polymorphism from the β_3 subunit of G proteins to predict the response to diuretic therapy. One hundred ninety-seven hypertensive African American adults and 190 hypertensive non-Hispanic whites were genotyped for the β_3 subunit of G proteins. After a 1-month washout period, all participants received hydrochlorothiazide for 4 weeks. The TT patients had the greatest response to the diuretic followed by the TC patients; the CC patients had the smallest response. The investigators predicted that the TT polymorphism accounted for 3.1% and 4.5% of interindividual variation in SBP and DBP response, respectively (201).

Monogenic Hypertension

HTN secondary to specific monogenic mutations, including those causing Liddle's syndrome, glucocorticoid-remediable aldosteronism, and apparent mineralocorticoid excess syndrome (Table 59.4) are described in Chapter 60.

Autosomal Dominant Hypertension with Brachydactyly

Autosomal dominant HTN with brachydactyly is a very rare monogenic hypertensive syndrome that has been identified in only three kindreds, one in northeastern Turkey, one in Canada, and one in the United States (202,203). This syndrome is characterized by severe, salt-insensitive HTN. Although the gene has been mapped to the short arm of chromosome 12, it has not yet been cloned (202,203). Frequently multiple antihypertensive medications are required to control the BP in this disease (204).

TRACKING OF BLOOD PRESSURE

BP tracking refers to the maintenance of one's position in the percentile distribution for BP levels over time. The prevalence of HTN is much higher in adults whose BPs during childhood were in the top quintile. The risk of becoming a hypertensive adult is 3.6 times higher if a child has a SBP in the top quintile and 2.6 times higher if the DBP is in the top quintile. Conversely, almost half of the adults with HTN had elevated BP during childhood (205). If a child has a BP level in the ninetieth percentile, the risk of becoming a hypertensive adult is 2.4 times higher (206). However, although many children and adolescents maintain their BP rank in the population as they mature into adults, there is considerable variability (207,208). It is currently impossible to identify with confidence which children with primary HTN are destined to become hypertensive adults and in whom modification of BP in childhood will alter risks for later coronary artery disease. The correlation seems to be much better in adults; that is, once an adult is identified as hypertensive, he or she will probably remain hypertensive for the remainder of his or her life (132,209).

During the first 6 months of life BP does not track (112). Children followed from birth have low correlation of SBP levels and no correlation of DBP levels by 7 years of age (210). In children beyond the first year of life, tracking correlations range from 0.2 to 0.5 for SBP and from 0.2 to 0.3 for DBP levels (206). These tracking correlations were compiled from several studies and demonstrate that, although some children maintain their rank order for BP over time, others do not track well. Although the predictive value of high BP early in life for future HTN is low, the actual level of a child's BP remains the single best predictor of future BP (211). The variability in the degree of tracking reported by different studies is the result of differences in the analytic methods used and the population studied. The age of the subjects at initial observation, number and spacing of observations longitudinally, and duration of the observation period play an important role. Other factors that might directly affect the BP level could influence the degree of tracking, including body mass, sexual maturation, and family history (208). It has been shown that family history and excessive weight gain in adolescence substantially increase the risk of HTN in adulthood (211).

Improved predictive value can be achieved when serial measurements over time are considered. In the Bogalusa Heart Study, Shear et al. found the predictive value for future hypertensive readings based on a single previous measurement to be only 41.4% for SBP and 34.4% for DBP (212). When three serial measurements over an 8-year period were considered, however, the predictive value of a child's remaining in the upper quartile increased to 68.4% and 62.0% for SBP and DBP, respectively. In addition, when three previous BP measurements were considered, the probability that children could be identified who would not be in the high-BP group in the future was 96.8%. Similarly, Gillman et al. found improved correlation coefficients for both SBP and DBP in children whose BP levels were measured weekly for four visits in each of 4 years (213). In this study, correlation coefficients were 0.69 for SBP levels and 0.54 for DBP levels at the end of the 4-year follow-up. The multiple measurements available with ABPM allow for better predictive values. Twenty-four-hour mean SBP measurements track better than casual SBP readings (214).

END-ORGAN DAMAGE

HTN is associated with an increase in cardiovascular morbidity and mortality in adults. Although cardiovascular mortality is rare in children, those with end-stage renal disease are 1000 times more likely to die of CVD than the general pediatric population (215). The impact of elevated BP alone in children is not as clearly delineated. In contrast to HTN in adults, which is defined by the level of BP associated with an increase in morbidity and mortality, HTN in children is defined by population normative values (3). Studies do show that elevated

BP in children, especially as determined by ABPM, is also associated with EOD. The commonly studied surrogate markers for target organ damage are LVH, carotid intimal-medial wall thickness and radial artery compliance, microalbuminuria, and retinopathy. In adults, the effect of HTN on the central nervous system is evidenced by ischemic stroke, cerebral hemorrhage, and central nerve palsy. Although these events are rare in children, extremely elevated BP can present with seizures (216). Because morbidity and mortality are not usually seen in the pediatric hypertensive patient, it is important to identify surrogate markers for EOD and treat BP aggressively to decrease disease progression in adulthood.

Left Ventricular Hypertrophy

Although many organ systems, such as the brain, eyes, kidney, and blood vessels, are affected by elevated BP, the heart is the most studied of the target organs. LVH is associated with HTN and is an independent predictor of CVD in adults (217–219). Brown et al. showed that, even in the absence of HTN, LVH is a harbinger of coronary heart disease (220). Treating HTN in adults decreases the morbidity and mortality from CVD (221,222). In children there is no clear threshold in LV mass or LV mass index (LVMI) to predict LVH (223–226). Due to the difficulty in defining LVH in children, its prevalence is difficult to predict and has been reported to range from 16 to 51% (102,223,225). In 1981, Laird and Fixler sought to determine the prevalence of LVH in hypertensive children. They evaluated 50 hypertensive and 50 normotensive children. LV mass was indexed by body surface area, and LVH was defined as more than 2 standard deviations above the mean. They identified 16% of hypertensive children and 4% of normotensive children as having LVH (225). Daniels et al. have proposed indexing LV mass by height cubed when controlling for size and gender (227). LVH can then be defined as LV mass greater than either the ninetieth or ninety-fifth percentiles for LVMI. Before this recommendation was made, Daniels et al. indexed LV mass by height when defining LVH. They studied 104 children aged 6 to 23 years and found that 51% were considered to have LVH when LVMI was greater than 90% according to normative values and 38.5% were considered to have LVH when LVMI was greater than 95% (223). Belsha performed ABPM and echocardiography in 33 normotensive and 29 untreated hypertensive children. By defining LVH as LV mass indexed for height cubed, his group identified LVH in 34% of the hypertensive children and none of the normotensive children (102). To control for differences in body size, de Simone and his group recommend indexing LV mass by height to the power of 2.7. Using a 97.5 percentile cutoff of normative values for LV mass divided by height to the power of 2.7, his group detected a fourfold increase in the presence of designated cardiovascular end points in adults (228). The same group documented left atrial enlargement in children with essential HTN. Those with left atrial enlargement had a higher body mass than those without (229).

Many studies show an association between LVMI and BP in children (102,223,224). Burke et al. in the Bogalusa Heart Study examined data for 654 children aged 7 through 22 years who had stable BPs over a 2- to 3-year period and showed that LV wall thickness was correlated with SBP ($R = 0.21$, $p < .001$) (229). Even in normotensive children, there is a correlation of age, body size, and BP to LV mass (226). Treiber and his group evaluated normotensive children with a family history of essential HTN and showed an association of LV mass with SBP but not with DBP (230). Although these studies reveal an association between LV mass and BP in children, they do not provide a threshold in LV mass that predicts LVH.

Elevated BP, as determined by CBP readings and by ABPM, has been found to be positively associated with LVMI in children (102,231). Sorof et al. showed that ABPM was a better predictor of EOD than clinic BP readings (104). His group correlated the findings of ABPM and echocardiography for normotensive and hypertensive children. They found that only systolic parameters and not diastolic parameters were associated with LVMI. In defining LVH, LV mass was indexed by height to the power of 2.7 and defined as the LVMI higher than 51 $\text{g}/\text{m}^{2.7}$ that corresponds to greater than the ninety-ninth percentile for children. LVMI was significantly greater in the hypertensive groups than in the normotensive groups (41.5 ± 12.0 vs. 32.5 ± 8.1 , $p < .001$), even when controlled for age, gender, weight, and height. The LVMI showed highest correlation with ambulatory SBP index, the average 24-hour SBP divided by the pediatric 95th percentile for ambulatory 24-hour SBP ($R = 0.43$, $p = .008$). This correlation was better than the correlation with SBP load ($R = 0.38$, $p = .020$). By assigning ABPM threshold parameters to determine LVH, his group found that, when SBP load is greater than 50% and the SBP index is higher than 1, LVH is present 47% of the time. If neither condition is met, LVH is present only 10% of the time. Therefore, ABPM is a better method to use in determining which children likely have EOD from their elevated BP and need aggressive treatment.

Microalbuminuria

During the mid-1980s the Framingham study reported the association between proteinuria and an increase in morbidity and mortality (232). Since then many studies have concentrated on the early detection of proteinuria by studying microalbuminuria, defined as 30 to 300 mg of albumin/24 hr or 30 to 300 mg of albumin/g creatinine. The Heart Outcomes Prevention Evaluation (HOPE) study of diabetic and nondiabetic adult patients showed that microalbuminuria is an independent risk factor for future cardiovascular events and is probably a signal of vascular damage (233). Treatment with the ACE inhibitor ramipril reduced CVD risk by 26% (233). Other studies have also shown microalbuminuria to be more prevalent in hypertensive patients than in normotensive patients. Jones et al. of

the National Health and Nutrition Examination Survey III studied 22,244 people aged 6 years and older to determine the prevalence of microalbuminuria and its association with other diseases such as diabetes and HTN. They identified microalbuminuria in 16% of the hypertensive participants but in only 5.1% of the participants without diabetes, HTN, or CVD (234). However, the sample size for hypertensive children was too small to be reported. The prevalence of persistent microalbuminuria is unknown because the National Health and Nutrition Examination Survey III examined only one urine sample from each participant. Pontremoli et al. evaluated the association between microalbuminuria and early EOD in adults with essential HTN. Although their sample size was small (17 hypertensive participants with microalbuminuria, 16 without microalbuminuria, and 20 controls), they showed that the hypertensive participants with microalbuminuria had significantly higher LVMI than the hypertensive participants without microalbuminuria and the controls ($167 \pm 7 \text{ g/m}^2$ vs. $139 \pm 9 \text{ g/m}^2$ vs. $118 \pm 5 \text{ g/m}^2$, respectively) (235). There are few studies evaluating microalbuminuria in hypertensive children. Belsha and his group looked at 24-hour urinary albumin excretion rates in normotensive and hypertensive adolescents and did not find a difference between the groups (236). Interestingly, normotensive children of hypertensive parents have been shown to have greater amounts of microalbuminuria than the control children who did not have hypertensive parents (3.1 mg/min vs. 2.1 mg/min , $p < .05$) (237). More studies are needed to determine the role of microalbuminuria in non-diabetic hypertensive children.

Vascular Changes

The vascular system is another "organ" often affected by HTN that has been evaluated in children as evidence of EOD. Two surrogate markers for vessel involvement are a decrease in vascular compliance and an increase in intimal-medial wall thickness of the carotid artery (cIMT). Arnett et al. evaluated arterial compliance by examining radial artery waveforms with an arterial tonometer device (pulse contour analysis). They studied 179 young normotensive adults who had been followed since childhood as part of the Minnesota Children's Blood Pressure Study. Both SBP and DBP were inversely related to large artery compliance ($p < .001$ and $p < .02$, respectively). Small artery compliance was inversely related to DBP, but not to SBP ($p < .005$) (238). Swinford et al. demonstrated markedly decreased compliance in children treated with hemodialysis, with the lowest compliance occurring middialysis (239). Bennett et al. performed studies of middle school children documenting vascular compliance that is lower than that in normal older teens and young adults. Hypertensive children in the screening population were also noted to have decreased compliance compared to normotensive children (240).

Elevated BP is also associated with cIMT. Sass et al. studied 369 men and women aged 10 to 54 years to deter-

mine the influence of age, gender, morphologic status, and BP on carotid and femoral intimal-medial wall thickness. They showed that cIMT was not affected by age or gender up to 18 years of age. However, cIMT was correlated with body mass index and BP in children (241). Sorof studied cIMT in hypertensive children. His group determined the prevalence of elevated cIMT to be 28% among hypertensive children with a mean age of 13.9 ± 2.7 years. Those with elevated cIMT also had higher LVMI than did the hypertensive children with normal cIMT ($46.8 \text{ g/m}^{2.7}$ vs. $31.4 \text{ g/m}^{2.7}$, $p < .001$) (104). Like LVH, radial artery compliance and cIMT can be used to assess the presence of EOD in children.

Retinopathy

There are only a few studies of children showing the association between elevated BP and retinal changes. Daniels and his group evaluated 88 children to determine the prevalence of target organ damage in essential HTN. They identified LVH in 36%, glomerular hyperfiltration in 49%, and retinal vascular changes in 50% of the children (242). Daniels examined retinal photographs in 97 children with essential HTN to determine the presence of arteriolar narrowing, tortuosity, and arteriovenous nicking. Forty-one percent of the children had arteriolar narrowing, 14% had tortuosity, and 8% had arteriovenous nicking; overall, 51% of the children had at least one eye abnormality (243). EOD of the eye can occur in children with HTN.

SUMMARY

The prevalence especially of essential HTN is increasing in children and adolescents parallel to the increase in obesity and the proportion of minorities making up the population in the United States. We anxiously await further population genetic studies that may provide tools to predict which patients will develop HTN. Nonetheless, secondary forms of HTN are also more prevalent in pediatric patients than in adults. The diagnosis of HTN remains an epidemiologic one and is complicated by the continued inability to clarify the optimum method of BP measurement: the more commonly and easily used oscillometry or the more accepted but difficult auscultatory technique. How do we best use these various technologies? Comparison of oscillometric results with standards obtained using auscultatory methods also confuses the diagnosis. ABPM has been well tested in children. The procedure is well tolerated and gives a clearer picture of the BP situation than CBP alone. It is now clear that HTN even during childhood leads to EOD, and ABPM measurements have been documented in children with all forms of HTN to have a superior correlation with EOD. Because the "hard" end points of mortality or cardiovascular events are rarely seen in children, more subtle

measures of EOD must be used. There is great hope that new techniques to study the vasculature such as cIMT measurement, vascular profiling, and flow-mediated dilation can identify those patients at risk before damage occurs. Thus future definitions of HTN must take into account the development of EOD damage.

PATHOPHYSIOLOGY OF HYPERTENSION

JOSEPH T. FLYNN
ROBERT P. WORONIECKI

Fundamentally, blood pressure is a function of cardiac output and total peripheral resistance. Cardiac output depends on cardiac stroke volume and heart rate. Stroke volume in turn depends on myocontractility and preload. Total peripheral resistance is dependent on vessel elasticity, myocontractility, and afterload. Thus, any factor influencing vessel wall tension or lumen size, extracellular fluid volume, autonomous cardiac rhythm, or cardiac pump function has an impact on blood pressure regulation and thereby can lead to the development of hypertension.

Research has begun to unravel relationships at the cellular and molecular levels that have important effects on blood pressure. The endothelium, intima, vascular smooth muscle, and extracellular matrix interact with each other and with vasomotor, growth, transcriptional, hormonal, and neuronal factors that affect signal transduction, gene transcription, ion transport, tissue remodeling, and cellular response, all in the context of the patient's genetic background.

MECHANISMS OF BLOOD PRESSURE REGULATION

Cardiac Output

Because the mean arterial blood pressure is a function of cardiac output and total peripheral resistance, hypertension is fundamentally a hemodynamic disorder that indicates a disturbance in one of these elements. Cardiac output is a function of stroke volume and heart rate. The preload of cardiac myocytes determines stroke volume, and heart rate is regulated by the sympathetic nervous system (SNS) as well as by the cardiac autonomic pacemaker. The SNS receives homeostatic feedback from baroreceptor-chemoreceptor reflexes and regulates the distribution of cardiac output over the short term. Increased SNS activity is most likely responsible for the mild tachycardia seen in many patients with primary hypertension (1).

Cardiac index (CI) is a function of cardiac output and body surface area. Young patients with mild hypertension have significantly higher cardiac output, CI, and sympa-

thetic nerve burst frequency than age-matched controls (1). In borderline hypertension, CI and heart rate are higher, and calculated total peripheral resistance is normal (2). In nearly all forms of established hypertension, however, total peripheral resistance is increased and cardiac output is reduced. Moreover, in progressive hypertension, a further increase in total peripheral resistance occurs, and cardiac output continues to fall, which indicates reduced vascular compliance (3).

It is clear, however, that not all hypertensive patients start out with a state of increased cardiac output. In some patients, hypertension may develop because of increased total peripheral resistance. In addition, as is discussed later in the chapter, some patients may develop hypertension because of primary renal disease or a genetic defect that increases circulating blood volume through sodium retention.

Total Peripheral Resistance and the Vascular Wall

Because resistance increases as vessel cross-sectional area decreases, total peripheral resistance is mainly a function of small, peripheral resistance vessels. This physical property makes arterioles important regulators of blood pressure. The earliest structural change observed in the arterioles of experimental animals after the onset of hypertension is thickening of the media due to matrix deposition, smooth muscle cell hypertrophy (increase in cell size without division), and hyperplasia (increase in cell number) (4). The medial smooth muscle cells then rearrange themselves to create a smaller lumen without change in cell number or size, a process that has been termed remodeling. Later, a neointima may develop with the appearance of smooth muscle cells inside the internal elastic lamina. There are also local areas of endothelial cell denudation and inflammatory cell infiltration, which can progress to atherosclerotic plaque formation (5). Finally, resorption and loss of blood vessels may occur in the periphery—a process termed *rarrefaction*, which has been found in both the early and later stages of hypertension (6).

In larger vessels, the content of elastin and collagen in the media increases and the number of smooth muscle cells decreases (via medial atrophy, necrosis, or apoptosis) (7), which leads to a loss of elasticity and the development of vessel "stiffness." Significant increases in the size and number of vasa vasorum (tiny vessels in the adventitia that supply nutrients and oxygen to the deeper layers of the media) can be observed in larger conduit vessels, which is probably an adaptive process in the sense that the increased smooth muscle cell mass in the hypertensive vessel wall requires more oxygen and nutrients. In summary, the hypertensive vessel wall is generally characterized by increased medial thickness or an increased media/lumen ratio of the resistance arterioles. This structural change is biomechanically adaptive because wall stress is normalized as defined by Laplace's law, but functionally this means that there is greater resistance for a given contractile stimulus (8).

Altered vascular structure in hypertension is also accompanied by functional changes in the cellular components of the vessel wall, specifically decreased relaxation and increased contraction (8). Decreased relaxation has been attributed primarily to endothelial dysfunction, and increased contraction has been attributed to enhanced smooth muscle cell vasoactivity. Sensitivity to vasoconstrictors may also be increased (6). Decreased relaxation is an effect of impaired endothelial production of vasodilating substances [mainly nitric oxide (NO) and prostacyclin] or increased production of vasoconstricting substances [endothelin, platelet-derived growth factor (PDGF)], or both.

Increased smooth muscle cell responsiveness is caused by alterations in the ability of vasodilating substances to exert their effects, changes in the ability of smooth muscle cells to respond to vasodilators, increased responsiveness to vasoconstrictors because of increased numbers of receptors or an augmented contractile machinery, or all of these. Moreover, vasoconstrictors frequently stimulate smooth muscle cell growth and, conversely, many growth factors have vasoconstrictor activity [e.g., PDGF is a vasoconstrictor (9) and angiotensin II is a potent smooth muscle cell growth factor (10)]. These functional alterations act in concert with the structural changes discussed earlier to perpetuate hypertension, which emphasizes the importance of the vasculature in blood pressure regulation.

Sympathetic Innervation/ Central Nervous System

Renal vessels, tubules, and the juxtaglomerular apparatus are innervated by the renal sympathetic nerves (11). Renal sympathetic nerve activity (RSNA) influences renal hemodynamics, solute and water handling, and hormonal release. Increased RSNA is found in animal models of hypertension and in hypertensive humans (12). SNS activation, as confirmed by increased circulating noradrenaline, muscle sympathetic nerve traffic, and systemic noradrenaline spillover, is

almost universally present in essential hypertension (13,14) and has been demonstrated in patients with renovascular hypertension (15). It appears to be particularly pronounced in young and middle-aged patients (14). Renal denervation prevents or alleviates hypertension in virtually all animal models of hypertension.

Increased RSNA constricts the renal vasculature and decreases glomerular filtration rate (GFR) and renal blood flow (16). The hypertensive response to chronic renal adrenergic stimulation is associated with a sustained increase in plasma renin activity and is dependent on an increase in plasma angiotensin II concentration (17). Renin release and increased circulating angiotensin II results in enhanced tubular water and sodium reabsorption throughout the nephron (18). The effect of angiotensin II to raise proximal tubular chloride and water reabsorption is decreased by 75% in animals after experimental renal denervation. Thus, only approximately 25% of the effect of angiotensin II is mediated directly by type 1 angiotensin receptors; the majority of the effect is dependent on intact renal innervation. In experimental renal sympathetic nerve stimulation, angiotensin II enhanced renal venous outflow of norepinephrine, an effect that was blocked by an angiotensin II receptor antagonist (19). This clearly demonstrates the connection between RSNA and angiotensin II, and suggests that angiotensin II exerts a peripheral, presynaptic action on renal sympathetic nerve terminals in renal tubular epithelial cells and vessels to enhance the release of norepinephrine (20).

Studies indicate that angiotensin II also acts centrally on brainstem nuclei that are important in the control of peripheral sympathetic vasomotor tone, for example, the rostral ventrolateral medulla of the hypothalamus (RVLM) (21). Because circulating angiotensin II is not able to cross the blood-brain barrier, it acts on circumventricular organs in which the normal blood-brain barrier is lacking. Those consist of the subfornical organ, the organum vasculosum of the lamina terminalis, the median eminence, and the area postrema (22). Activation of the area postrema by circulating angiotensin II may in turn increase peripheral sympathetic nerve activity via a direct excitatory connection from the area postrema to the RVLM. Experimental microinjection of angiotensin II into the RVLM results in increases in arterial pressure (23) and peripheral sympathetic nerve activity (24), and facilitates arterial baroreflex modulation of RSNA (25). All these effects are blocked by antagonists for angiotensin type 1 (AT1) receptors but not by antagonists for angiotensin type 2 (AT2) receptors (26). Moreover, the RVLM contains angiotensin II immunoreactive nerve terminals, AT1 receptor messenger RNA, and AT1 receptor binding sites (27). These findings suggest that angiotensin peptides of brain origin may have a local paracrine or autocrine action on the RVLM that regulates RSNA and its arterial baroreflex control.

Circadian Rhythm

The circadian rhythm is an intrinsic 24-hour cycle that affects numerous physiologic processes. Vascular tone, total peripheral resistance, heart rate, and blood pressure increase in the early morning hours in both normotensive and hypertensive subjects. This rise corresponds to increased plasma renin activity and a surge in secretion of catecholamines. Blood pressure reaches its peak at approximately 9 a.m. and falls to its lowest level at 3 a.m. A significant rise in blood pressure occurs before awakening. Although environmental factors (especially light-dark cycles) have a significant impact on the circadian variation in blood pressure, some aspects appear to be genetically determined (28). Diurnal variation of blood pressure has been clearly demonstrated in normotensive children (29); in hypertensive children, data suggest that diurnal variation is preserved in children with primary hypertension but is abnormal in those with secondary forms of hypertension (30). (See Chapter 61.)

The central pacemaker in mammals is located in the suprachiasmatic nucleus (SCN) of the brain, which is found in the anterior hypothalamus, immediately above the optic chiasm (31). It receives input about light-dark cycles from the retina via the retinohypothalamic tract and produces several neuropeptides, including vasopressin and vasoactive intestinal peptide (VIP), that appear to have diurnal peaks of expression and release (32). Animal experiments have demonstrated that the SCN is linked to multiple sympathetic pathways that control the cardiovascular system (33). It plays a crucial role in synchronizing the peripheral oscillators that are found in all tissues, including vascular smooth muscle cells and the aorta, and in the execution of rhythmic behavior. The primary mediator of SCN action appears to be melatonin, which is secreted by the pineal gland under control of the SCN (31). Melatonin appears to transmit information about light-dark cycles from the SCN to the peripheral oscillators (28) as well as to other centers in the hypothalamus that regulate cardiovascular activity (33).

Supporting evidence for the role of the SCN and melatonin in blood pressure regulation comes from studies demonstrating that melatonin levels are decreased in hypertensive individuals and that administration of melatonin lowers blood pressure (33). In addition, autopsy studies of patients with primary hypertension have demonstrated that SCN neuronal populations responsible for producing vasopressin and VIP are reduced, which suggests that, in at least some individuals with hypertension, normal function of the intrinsic biologic clock is impaired (34).

Fluid and Electrolyte Balance

The kidneys of an adult with free access to water and salt filter approximately 125 mL/min of plasma containing 140 mEq/L of sodium and 105 mEq/L of chloride. Approximately 100 mEq of sodium and chloride are excreted daily

in the urine. The kidneys have the ability to respond to changes in arterial pressure by altering the renal excretion of salt and water; increases in renal perfusion pressure lead to decreases in sodium reabsorption and increases in sodium excretion (pressure natriuresis) (35).

The intrarenal mechanism of pressure natriuresis is related to medullary blood flow, renal interstitial hydrostatic pressure, and renal autoids (NO, prostaglandins, kinins, and angiotensin II). Increased renal perfusion pressure is associated with increases in renal interstitial hydrostatic pressure and levels of NO, prostaglandin E₂, and kinins, and a decrease in angiotensin II (35–38). Increased blood flow to the renal medulla, which normally receives only 5 to 10% of the total renal blood flow, contributes to washout of the urea gradient. This results in an increase in renal interstitial fluid pressure, which in turn reduces tubular reabsorption of sodium and water; the result is natriuresis and diuresis, which lowers blood pressure (39). Infusion of norepinephrine into the renal medulla results in a pressure natriuresis and lowering of arterial blood pressure (40). This depressor response is abolished by chemical medullectomy (41). This finding suggests the presence of an as-yet-to-be-characterized depressor hormone in the renal medulla (42).

Regulation of the number and function of critical renal sodium transporters and channels is another important means by which the kidney controls salt and water balance. Expression of many of these proteins is influenced by aldosterone and other hormones that affect blood pressure (43,44). As discussed later in this chapter, all monogenic forms of human hypertension described thus far can be characterized by alterations in renal ion channels that lead either to increased sodium reabsorption or to decreased excretion. Similarly, in an animal model of essential hypertension, the Dahl salt-sensitive hypertensive rat, AngII/arginine vasopressin receptor dysfunction produces hypertension through increased tubular sodium and fluid reabsorption (45).

Renal Autoregulation

Renal autoregulation, or the kidney's intrinsic ability to maintain constant renal blood flow and GFR despite changes in renal perfusion pressure, serves to protect nephron function. However, major variations in renal perfusion can still influence renal excretory functions, renin release, and arterial blood pressure. Autoregulation occurs in interlobular arteries, side branches of arcuate arteries, and afferent and efferent arterioles. It depends on myogenic mechanisms present in those vessels and is blocked by the smooth muscle relaxant papaverine (46) and by calcium-channel blockade (47). Tubuloglomerular feedback also plays an important but not essential role in autoregulation (48).

Renal autoregulation is reset in animal models of spontaneous hypertension (49). Angiotensin II plays an important role in the resetting of the autoregulation limits (50).

Higher pressures are needed to trigger the vasoconstrictive response in the afferent arteriole (51), but in the intermediate portion of the interlobular artery of the spontaneously hypertensive rat, a lower threshold pressure stimulates a greater myogenic response (52). In the Dahl salt-sensitive hypertensive rat, both the afferent arterioles and the interlobular arteries have reduced myogenic responsiveness to increases in perfusion pressure (53). Studies demonstrating that abnormalities in renal autoregulation are more pronounced in patients with severe hypertension than in those with moderate hypertension (54) suggest that disturbed renal autoregulation can be induced by chronic hypertension. Thus, disturbed renal autoregulation may contribute to the perpetuation of blood pressure elevation in patients with established hypertension.

Renin-Angiotensin System

Renin is secreted from the juxtaglomerular apparatus of the kidney in response to glomerular underperfusion or reduced sodium intake, or in response to stimulation from the SNS. Except for renin, all the components of a local vascular wall renin-angiotensin system appear to be present in normal vessels (55), and their activity is dynamically regulated. In the classic renin-angiotensin system, circulating renal-derived renin cleaves hepatic-derived angiotensinogen to form the decapeptide angiotensin I, which is converted by angiotensin-converting enzyme (ACE) in the lungs to the active component of the renin-angiotensin system, angiotensin II (angiotensin II). ACE exists in plasma, in the interstitium, and within the cell. Tissue ACE is present in all major organs, including the heart, brain, blood vessels, adrenals, kidney, liver, and reproductive organs (56) and is already functional *in utero* (57).

Angiotensin II is a potent vasoconstrictor and thus causes a rise in blood pressure. It also stimulates the release of aldosterone from the zona glomerulosa of the adrenal gland, which results in a further rise in blood pressure from aldosterone-mediated sodium and water retention. In addition, it plays an important physiologic role in the regulation of sympathetic nervous activity (see preceding discussion of the SNS) and the thirst response (58). The effects of angiotensin II are mediated primarily by the plasma membrane receptors AT1 and AT2. Other angiotensin receptors have been described but are not yet fully characterized (59,60).

The AT1 receptor is composed of 359 amino acids and belongs to the seven-membrane-spanning G-protein-coupled receptor family (61,62). In rodents, the AT1 receptor has two functionally distinct subtypes, AT1A and AT1B, with greater than 95% amino acid sequence homology (63). The human AT1 receptor gene has been mapped to chromosome 3 (64). Expression of the AT1 receptor is a subject to negative feedback by angiotensin II (65). AT1 receptor activation stimulates vasoconstriction, vascular cell hypertrophy

and hyperplasia, sodium retention, reactive oxygen species generation via induction of nicotinamide adenine dinucleotide phosphate (reduced form) (66), and induction of inflammatory (67), thrombotic (68), and fibrotic processes (69). Some of the pathophysiologic effects of angiotensin II may be mediated through activation of the transcription factor nuclear factor- κ B (NF- κ B) (70), which participates in a variety of inflammatory responses (71). Many polymorphisms of the AT1 receptor gene have been identified, but the A1166 \rightarrow C polymorphism has been the most extensively studied. It has been associated with the development of primary hypertension in various populations (72).

The AT2 receptor is a seven-transmembrane-type, G-protein-coupled receptor comprising 363 amino acids. It has low amino acid sequence homology (approximately 34%) with AT1A and AT1B receptors (61,62). The expression of the AT2 receptor is upregulated by sodium depletion (73) and is inhibited by angiotensin II and growth factors such as PDGF and epidermal growth factor (74). Under physiologic conditions, AT2 receptor antagonizes AT1-mediated actions (75) by inhibiting cell growth and by inducing apoptosis and vasodilatation (76,77). Cardiovascular effects of the AT2 receptor appear to be opposite to those of the AT1 receptor (78). Other physiologic effects attributed to the AT2 receptor include modulation of thirst, behavior, and locomotor activity (79). It also has proinflammatory effects, via induction of NF- κ B (70), and trophic effects leading to vascular (80) and cardiac (81) hypertrophy. The functions of the AT1 and AT2 receptors are summarized and compared in Table 60.1.

Hypertension is associated with remodeling of the left ventricle, alterations in the morphology and mechanical properties of the vasculature, and the development of endothelial dysfunction (82,83). Angiotensin II is capable of mediating these changes, independently of its effect on blood pressure, via its interaction with the AT1 receptor (84). These varied effects of angiotensin II in hypertension provide the physiologic foundation for the use of ACE inhibitors and angiotensin II receptor antagonists in the treatment of patients with hypertension.

TABLE 60.1. COMPARISON OF THE EFFECTS OF ANGIOTENSIN TYPE 1 (AT1) AND ANGIOTENSIN TYPE 2 (AT2) RECEPTORS

AT1	AT2
Vasoconstriction	Vasodilatation
Cell proliferation	Apoptosis
Cell hypertrophy	Growth inhibition
Antinatriuresis	Natriuresis
Superoxide production	Nitric oxide production
Endothelin release	Collagen synthesis
Lipid peroxidation	
Adhesion molecule expression	
Vascular matrix expansion	

Aldosterone

Aldosterone is produced by the mitochondrial enzyme CYP 11B2 (aldosterone synthase) encoded by the *CYP11B2* gene (85). This enzyme is expressed in the zona glomerulosa of the adrenal glands, aorta, endothelial cells and vascular smooth muscle cells, hypothalamus, hippocampus, amygdala, cerebrum, and cerebellum (86,87). Aldosterone and its precursors, 18-hydroxycorticosterone, corticosterone, and deoxycorticosterone, are synthesized from cholesterol. Angiotensin II and III induce aldosterone synthesis. Potassium and adrenocorticotropic hormone (ACTH) stimulate its secretion (88). Atrial natriuretic peptide (ANP) inhibits aldosterone secretion by interfering with extracellular calcium influx (89).

Aldosterone acts via an intracellular, high-affinity type I glucocorticoid receptor. The postreceptor mechanisms of rapid aldosterone action appear to involve protein kinase C, calcium, cyclic adenosine 3',5'-monophosphate and inositol 1,4,5-triphosphate, with downstream effects on a variety of ion pumps and channels (90). Aldosterone induces retention of sodium and potassium excretion. It also activates the SNS by preventing the uptake of norepinephrine by the myocardium and causes baroreceptor dysfunction (91,92) and eventually myocardial and vascular fibrosis (93). The importance of aldosterone in hypertension is highlighted by studies demonstrating that the aldosterone receptor antagonist spironolactone improves endothelial dysfunction, increases NO bioactivity in chronic heart and renal failure, and prevents the development of nephrosclerosis and cerebrovascular lesions (94,95).

Dopamine

Dopamine is an important modulator of systemic blood pressure with direct actions on the heart, arteries, and veins. Dopamine is synthesized in noradrenergic and dopaminergic nerves, and also in nonneural tissues (e.g., kidney, gastrointestinal tract) (96). Dopamine modulates renal epithelial transport, and gastrointestinal sodium uptake (97). It can indirectly modulate blood pressure via release of hormones and humoral agents such as aldosterone, catecholamines, endothelin, prolactin, proopiomelanocortin, renin, and vasopressin (98). Dopamine modulates fluid and sodium intake via "appetite" centers in the brain (99) and, in addition, controls blood pressure by direct action on neuronal cardiovascular centers.

Dopamine increases cardiac output by stimulating myocardial β -adrenergic receptors and plays an important role in modulating vascular smooth muscle tone by a complex series of interactions with various dopamine receptors. Stimulation of D1 and D5 dopamine receptors can cause vasorelaxation, whereas stimulation of D3 receptors produces vasoconstriction. At extremely high concentrations, dopamine produces vasoconstriction by occupation of α_1 -adrenergic receptors (100). Dopaminergic blockade is asso-

ciated with the development of hypertension in rats and potentiates the renal effects of NO inhibition in humans (101).

Moreover, dopamine also regulates the expression of other receptors involved in blood pressure regulation (e.g., endothelin-B, AT1). Both D1- and D2-like receptors downregulate AT1 receptor expression and function (102). Disruption of the D3 receptor gene in mice is associated with renin-dependent hypertension and a decreased ability to excrete an acute saline load (103). Aberrant dopaminergic regulation of aldosterone secretion (via D3 receptors) may be involved in some forms of hyperaldosteronism and hypertension (104,105).

Interindividual variation in systolic blood pressure has been shown in one study to be influenced by the activity of the gene that encodes the type 1A dopamine receptor (106). However, no mutations have been found in the coding region of the D1 receptor in patients with essential hypertension or in genetically hypertensive rats (107). A polymorphism in the noncoding region of the D1 receptor has been reported to be associated with human essential hypertension; however, the mechanism by which this polymorphism induces hypertension remains to be determined (108). Several D2 receptor polymorphisms have been reported, one of which is associated with hypertension (109). It is likely that as molecular genetic and population genetic studies progress, the role of dopamine in the pathogenesis of human hypertension will be further elucidated.

Atrial Natriuretic Peptide

ANP belongs to a family of natriuretic peptides that also includes the B-type and the C-type natriuretic peptides (110). The biologic functions of B-type and C-type natriuretic peptides do not differ from those of ANP. ANP is involved in regulation of salt and water balance and blood pressure homeostasis, and has an antiproliferative effect at the cellular level in the cardiovascular system (111–113). ANP is primarily expressed in cardiac myocytes but is also found in brain, vessels, and kidneys. ANP has potent diuretic, natriuretic, and vasorelaxant effects. In the kidneys, ANP increases GFR through vasodilatation of the afferent arterioles and vasoconstriction of the efferent arterioles (114). Natriuresis occurs by several mechanisms, including inhibition of sodium reabsorption in both the proximal and the distal tubule (115,116) and inhibition of both renin and aldosterone biosynthesis (117,118).

The combined systemic hemodynamic effects of ANP result in reduction of both preload and afterload (119,120). Administration of endogenous ANP results in a significant decrease of blood pressure in humans and in animal models of hypertension by reducing systemic vascular resistance (121,122). The blood pressure-lowering effect of ANP is enhanced in models of renovascular hypertension (123) and in conditions of volume expansion (124). At high

plasma levels, ANP decreases heart rate, central venous pressure, and stroke volume (125).

Mutations in the ANP gene have been described in both hypertensive and healthy individuals (126,127). A significant association has been demonstrated between an intronic variant of the ANP gene (HpaII) and salt-sensitive hypertension in African Americans (128). A mutation located within the 5' untranslated region of the ANP gene has been reported to show a marginally significant association with occurrence of hypertension in a Japanese population (129). In a population drawn from the Physicians' Health Study, carriers of a mutation in exon 1 of the ANP gene showed a twofold higher risk of stroke than noncarriers, an effect that was independent from other conventional risk factors such as obesity and diabetes, and occurred in spite of lower blood pressure levels (130). These studies suggest a potentially important role for variants of the ANP gene in the development of hypertension and other cardiovascular disease, although, as with other genetic influences on hypertension (see later), much more research must be done to elucidate exactly how these genetic variants produce blood pressure elevation.

Endothelin-1

Endothelin-1 (ET-1) is an endothelial cell-derived, potent vasoconstrictive peptide containing 21 amino acids (131). Three isopeptides of endothelin (ET-1, ET-2, and ET-3), encoded by separate genes, have been identified (132). Endothelial ET-1 synthesis is activated by vasoactive hormones, growth factors, hypoxia, shear stress, lipoproteins, free radicals, endotoxin, and cyclosporine, and is inhibited by NO, natriuretic peptides, heparin, and prostaglandins (133). Apart from endothelial cells, ET-1 is also produced by the heart, kidney, posterior pituitary, central nervous system, and vascular smooth muscle cells (133). ET-2 is produced in endothelial cells, heart, and kidney (134), but it has not been detected in human plasma. ET-3 is selectively expressed in the endocrine, gastrointestinal, and central nervous system, but not in endothelial cells (135).

ET-1 appears to be primarily a locally acting paracrine substance. Endothelin receptor-binding sites have been identified throughout the body, with the greatest number of receptors in the kidneys and lungs (136). Endothelin signals through two receptor subtypes, ETA and ETB. The ETA receptor is preferentially activated by ET-1 but not by ET-3, whereas the ETB receptor is activated equally by ET-1 and ET-3 (137,138). The vasoconstrictor effects of endothelin are mediated primarily by ETA receptors, but ETB receptors located on vascular smooth muscle also contribute to the vasoconstrictor effects of this peptide (139). ETB receptors located on the endothelium are thought to stimulate release of NO and prostacyclin.

ET-1 closes membrane K⁺ channels (140), which prevents efflux of K⁺ from the cell and thereby favors depolar-

ization of membrane and contraction of smooth muscle. ET-1 also activates production of prostacyclin and thromboxane A₂ (141). In the kidney, ET-1 contracts afferent and efferent arterioles equally (142) and thus reduces both renal plasma flow and GFR (143,144). It blocks reabsorption of sodium by inhibiting tubular Na⁺-K⁺-adenosine triphosphatase activity in the proximal tubule and collecting duct (145). ET-1 inhibits release of renin from isolated rat glomeruli (146) but stimulates release of aldosterone from isolated cortical zona glomerulosa cells (147). ET-1 also stimulates production and release of ANP by cultured atrial myocytes (148).

The overall cardiovascular effect of endogenous ET-1 depends on the balance between ETA- and ETB-mediated effects. Activation of vascular smooth muscle ETA receptors causes vasoconstriction and tends to elevate blood pressure, whereas activation of endothelial and renal ETB receptors promotes vasodilatation and natriuresis and tends to decrease blood pressure (149). ETB "knock-out" mice have hypertension secondary to renal retention of sodium, and there is evidence of marked enhancement of vascular expression of ET-1 in salt-sensitive hypertensive rat models (150). ET-1 appears to potentiate sympathetically mediated vasoconstriction only in hypertensive and not in normotensive subjects (151).

Hypertensive patients with normal renal function have concentrations of immunoreactive E-1 similar to those in normotensive patients (152); however, plasma concentrations of ET-1 are raised in patients with accelerated hypertension, and these levels are positively correlated with creatinine clearance (153). Plasma concentrations of ET-1 in patients with chronic renal failure are onefold to twofold greater than normal, whereas values in those undergoing hemodialysis are twofold to fourfold greater than normal (154). In renal transplant patients, production of ET-1 is stimulated by cyclosporine A (155), which also increases the number of renal ET-1 binding sites (156). Tacrolimus also appears to increase secretion of ET-1 *in vitro* (157). These findings suggest that endothelin may be involved in the pathogenesis of calcineurin-induced hypertension.

Genetic variation in ET-1 expression may be involved in the pathogenesis of essential hypertension. African Americans with hypertension have much higher concentrations of immunoreactive endothelin than do whites (158). There is also strong correlation between diastolic blood pressure and polymorphisms of the ET-1 precursor pre-proendothelin-1 between patients with essential hypertension and normotensive controls (159).

Nitric Oxide and Adenosine

Nitric oxide is endothelium-derived gas, synthesized from the amino acid L-arginine by the endothelial isoform of NO synthase (NOS) (160). NO is extremely labile, with a half-life of less than 4 seconds in biologic solutions. It is

rapidly oxidized to nitrite and then nitrate by oxygenated hemoglobin before being excreted into the urine (160). Synthesized NO diffuses across the endothelial cell membrane and enters the vascular smooth muscle cells. It activates guanylate cyclase, which leads to production of a second messenger, cyclic guanosine-3',5'-monophosphate (cGMP) (160). The cGMP mediates control of vascular tone and platelet function.

NO is a vasodilator, and the balance between NO and various endothelium-derived vasoconstrictors and the SNS maintains physiologic blood vessel tone (161). In addition, NO suppresses platelet aggregation, leukocyte migration, and cellular adhesion to the endothelium. It attenuates vascular smooth muscle cell proliferation and migration, as well as inhibiting activation and expression of certain adhesion molecules, and has an influence on production of superoxide anion.

Endothelium-dependent relaxation is decreased in patients with essential hypertension (162) who have impaired generation of NO (163). Treatment with inhibitors of NO synthesis induces a hypertensive response, whereas L-arginine treatment prevents the development of hypertension in animals prone to this disease (164) and also causes a rapid reduction in systolic and diastolic pressures when infused into healthy humans and patients with essential hypertension (165). Methylated L-arginine derivatives, including NG-NG-dimethylarginine (asymmetric dimethylarginine), an inhibitor of NO synthase, and symmetric dimethylarginine, its inactive isomer, are present in human plasma and urine. These compounds accumulate in the plasma of patients with renal failure (162,166).

Cardiovascular homeostasis is also influenced by neuronal production of NO within the autonomic nervous system. Acting by central and peripheral mechanisms, NO has been shown to have sympathoinhibitory and vagotonic effects. Experiments in hypertensive rats indicate that neuronal NO production is impaired at a number of key central sites concerned with autonomic cardiovascular regulation (167). Because sympathetic overactivity may play a role in the genesis of human hypertension, these experiments suggest that defects in central nervous system neuronal NO production may be an initiating step in this process.

Adenosine is produced from the hydrolysis of adenosine 5'-monophosphate by 5'-nucleotidase (168,169). In the kidney, it regulates GFR, tubuloglomerular feedback, tubular reabsorption, and renin secretion. Adenosine acts via several cell surface receptors that have been designated A1, A2A, A2B, A3, and A4, all of which differentially stimulate or inhibit the production of cyclic adenosine-3',5'-monophosphate. Sites of A1 gene expression include glomeruli, proximal tubule, thick ascending limb of the loop of Henle, juxtaglomerular apparatus, collecting ducts, and microvessels (170). Selective A1 antagonists lead to diuresis and natriuresis and uncouple glomerular filtration and tubular reabsorption (171). A2A and A2B receptors have been described on vascular smooth muscle cells and the endothe-

lium, where they are associated with vasodilatation (171). A2A "knock-out" mice have increased blood pressure and heart rate, and increased platelet aggregation (172).

Other Regulatory Hormones

Thyroid hormone plays an important role in the regulation of blood pressure. Administration of exogenous thyroid hormone results in a decrease in systemic vascular resistance, which in turn results in renin release, activation of the angiotensin-aldosterone axis, increase in renal sodium reabsorption, increase in intravascular volume, and increase in cardiac output and cardiac contractility. Thyroid hormone also stimulates erythropoietin secretion (173). Triiodothyronine (T_3) acts directly on arterioles (vascular smooth muscle cells) and promotes relaxation and vasodilatation by local heat production, and β_2 receptor stimulation (174).

T_3 enters the cell by a specific transporter and forms a complex with nuclear T_3 receptors. This complex binds to thyroid hormone response elements of several genes and regulates their transcription. Genes upregulated by T_3 include those for adrenergic receptors, Na^+K^+ -adenosine triphosphatase, and voltage-gated potassium channels, among others. Genes downregulated by T_3 include those for the Na^+Ca^{2+} exchanger, adenylyl cyclase types V and VI, and the T_3 nuclear receptor. In the short term, T_3 modulates sodium, potassium, and calcium-channel activities in the heart that lead to changes in intracellular calcium and potassium with subsequent increase in inotropy and chronotropy (175). Increased heart rate, widened pulse pressure, and increased cardiac output despite normal or low-serum concentrations of catecholamines is a characteristic feature of patients with hyperthyroidism (176).

Adrenomedullin peptide (ADM), a 52-amino-acid peptide, has been found in the adrenal medulla, cardiac atrium, lung, and kidney. In the kidney, ADM is found in glomeruli, cortical distal tubules, and medullary collecting duct cells (177,178). ADM is also secreted from endothelial cells and vascular smooth muscle cells (179). ADM leads to vasodilatation, natriuresis, diuresis, inhibition of aldosterone production, and enhancement of tumor cell growth (180,181). Increased levels of ADM have been documented in patients with essential hypertension and chronic renal failure (182).

PRIMARY HYPERTENSION

Most hypertension in adults is of unknown cause; therefore, the term *essential hypertension* has been applied as a catch-all diagnosis in individuals in whom an underlying cause for their hypertension cannot be identified. However, because the word *essential* implies that the patient's level of blood pressure is necessary in some way to maintain normal func-

FIGURE 60.1. Multifactorial model of blood pressure determination, demonstrating the potential influence of genes, environmental factors, and demographic factors on blood pressure. The potential interaction of these determining factors is represented by arrows linking different determinants. (From Lifton RP. Genetic determinants of human hypertension. *Proc Natl Acad Sci U S A* 1995;92:8545–8551, copyright 1995, National Academy of Sciences, USA, with permission.)

tion, this term is misleading and should be abandoned in favor of *primary hypertension*. It is likely that, as our unraveling of the human genome progresses and more genetic forms of hypertension are identified (see later), fewer and fewer patients will be diagnosed with primary hypertension; for now, however, primary hypertension remains an important entity and accounts for most human hypertension.

In children, primary hypertension has long been considered an uncommon form of hypertension and accounted for fewer than 25% of cases of childhood hypertension in series from referral centers published through the mid-1990s (183). As studies from less specialized centers and more recent series from referral centers have demonstrated (184,185), however, primary hypertension in children is likely more common than previously thought and is probably also increasing in prevalence, with many children developing hypertension as a manifestation of obesity (see the following discussion), which is also becoming increasingly prevalent in childhood (186).

Primary hypertension is a multifactorial disorder in which elevated blood pressure is caused by different combinations of factors in different individuals (Fig. 60.1). Advances in molecular genetics have caused a great deal of attention to be focused on determining how genetic variation may explain blood pressure elevation in some individuals (187). Although genes are likely to be involved to some extent in nearly every hypertensive individual, however, the genetic contribution to an individual's hypertension may not be as significant as that of other factors, such as body habitus or environment. Although a detailed discussion of every factor possibly involved in the pathogenesis of primary hypertension is beyond the scope of this chapter, some of the more important mechanisms likely to contribute to the development of primary hypertension in children are highlighted.

Genetic Influences on Primary Hypertension

Substantial evidence exists for genetic influence on blood pressure. Twin studies document greater concordance of

blood pressures among monozygotic than among dizygotic twins (188), and population studies demonstrate greater similarity of blood pressure within families than between families (189). Studies demonstrating a lack of correlation of blood pressure between parents and their adoptive children would also support the contention that blood pressure is genetically determined (190). Despite intensive efforts over nearly three decades, however, the genetic basis of hypertension has not been fully elucidated thus far.

Studies applying new molecular biologic techniques to the problem of hypertension have focused on identifying candidate genes involved in the pathogenesis of hypertension. To date, however, with the exception of the single-gene forms of hypertension described later in this chapter, most of these studies have failed to demonstrate how the various genetic mutations identified lead to elevated blood pressure. For example, although the studies of Jeunemaitre et al. (191) and Inoue et al. (192) have identified a link between polymorphisms of the angiotensinogen gene and hypertension, and although other studies have shown that angiotensinogen levels are higher in individuals with higher levels of blood pressure (193), how these variations cause hypertension still is not known (187). The same holds true for all of the many other allelic variants identified to date in individuals with primary hypertension.

Studies have demonstrated that, in some people, blood pressure elevation may be not the result of a single mutation but rather the product of multiple genetic variants interacting with each other (194). Similarly, it is probable that the role of some genetic variants in the pathogenesis of primary hypertension may be not to increase blood pressure in and of themselves, but rather to increase the susceptibility of an individual to environmental factors that can elevate blood pressure (195). This would be consistent with the scheme illustrated in Figure 60.1.

Clearly, the delineation of the pathogenesis of primary hypertension from the genetic standpoint is in its early stages. Mapping of the rat genome and the development of new strategies and technologies in molecular genetics, including differential gene expression, expressed sequence tags, and DNA biochips, provide hope that the challenge of elucidating the genetic basis of primary hypertension will be met (196). This in turn should result in improved therapies for the millions of Americans with primary hypertension.

Influence of Birth Weight and Perinatal Factors on Primary Hypertension

The influence of prenatal and postnatal events on future blood pressure has been a topic of great interest to researchers over the past 15 years. Proponents of the "fetal origins" hypothesis maintain that low birth weight is a risk factor for the subsequent development of primary hypertension in adulthood. This hypothesis is based on the findings of large population studies that demonstrate an inverse correlation

between birth weight and adult blood pressure (197,198). Proposed explanations for this effect include deficient maternal nutrition (197,199), which possibly leads to acquisition of a reduced number of nephrons *in utero* (200). Other investigators have demonstrated that maternal smoking during pregnancy and bottle-feeding of newborns also may lead to hypertension later in life (201,202), which widens the spectrum of possible influences on later blood pressure from *in utero* factors to postnatal factors as well.

Animal studies have generally supported the epidemiologic evidence cited earlier. Pregnant rats fed low-protein diets bear young that are small at birth and later develop hypertension (203). Maternal diets low in protein result in decreased nephron number as well as suppression of the renin-angiotensin system (204), which leads to elevated blood pressure and reduced GFR. In addition, various pharmacologic manipulations of the fetal milieu also result in changes in fetal renal development that promote the appearance of hypertension after birth (205), which lends further credence to the theory that perinatal events have an important influence on later blood pressure.

Despite the epidemiologic and experimental evidence cited earlier, the effect of perinatal factors on later blood pressure does not appear to be completely straightforward. In contradiction to the studies demonstrating an inverse relationship between birth weight and adult blood pressure, other epidemiologic studies have found that adult blood pressure is more closely related to gestational age at birth (206) or to childhood growth (207) than to birth weight. In addition, studies have shown that twins have lower systolic blood pressures than singletons despite their lower birth weights (208). These challenges to the fetal origins hypothesis not only indicate that further research is needed to determine the effects of prenatal and perinatal factors on future blood pressure but also support the concept illustrated in Figure 60.1 that the development of primary hypertension depends on multiple factors that vary among different individuals.

Activation of the Sympathetic Nervous System in Primary Hypertension

The role of the SNS in blood pressure regulation has been discussed in detail earlier. Many lines of evidence suggest that SNS activation or overactivity is the primary mechanism by which blood pressure elevation is initiated in young individuals with otherwise unexplained primary hypertension. For example, children with primary hypertension have long been known to have higher resting heart rates than normotensive children (209). This has been confirmed by large epidemiologic studies such as the Bogalusa Heart Study, in which resting heart rate was found to correlate with blood pressure (210). Although this characteristic has now been “rediscovered” in obese adolescents with primary hypertension (211), there is a large, established body

of literature that links tachycardia not only with elevated blood pressure but also with increased cardiovascular risk in general (212).

Another notable manifestation of SNS activation in hypertensive children is heightened cardiovascular reactivity to stress. Early studies by Falkner demonstrated that hypertensive adolescents had significantly greater increases in heart rate, systolic blood pressure, and diastolic blood pressure during mental stress (performance of difficult arithmetic problems) than did normotensive adolescents (209). Increased cardiovascular reactivity to the cold pressor test has also been shown to predict the subsequent development of hypertension (213). An interaction between genetic factors and SNS activation is suggested by differences in the cardiovascular response to stress in children with different racial backgrounds or family histories of hypertension (214).

Laboratory studies confirm the SNS activation in primary hypertension suggested by the aforementioned clinical and epidemiologic data. Measurement of plasma catecholamine levels demonstrates that both children and young adults with primary hypertension have higher plasma norepinephrine levels than normotensives (13,14). The importance of this as a mechanism in the development of hypertension is highlighted by the fact that elevated catecholamine levels are more commonly found in younger individuals with primary hypertension than in older individuals (14), and also by the fact that such elevations are commonly seen in young individuals with borderline hypertension who later develop more significant blood pressure elevation (215). This phenomenon is also true of the tachycardia described earlier (209). Furthermore, abnormalities in the SNS have recently been demonstrated in normotensive children of hypertensive parents (216), which suggests that SNS activation not only is present in prehypertensives but may also be genetically determined.

Further laboratory evidence for SNS activation in primary hypertension can be found in studies that have demonstrated increased SNS activity by direct recordings of nerve activity. Increased SNS activity has been found in recordings from both peripheral and renal sympathetic nerves in hypertensive individuals (1,217). Taken together, these changes in SNS activity would then lead to the development of hypertension through a rise in cardiac output, with increased peripheral vascular resistance and volume expansion from increased renal sodium and water retention both playing a role. There is also evidence to suggest that the increased circulating levels of catecholamines may be involved in the development of the vascular hypertrophy that is a hallmark of established hypertension (218), which thereby perpetuates increased peripheral resistance. In sum, although it is likely that SNS activation may not be present in later stages of hypertension (2), there is strong evidence that abnormalities of SNS activity are involved in the pathogenesis of primary hypertension, at least in the early

phases of blood pressure elevation, which is clearly significant as far as pediatric hypertension is concerned.

White-Coat Hypertension

Individuals with *white-coat hypertension* (WCH) would be considered to have hypertension if the diagnosis were based on casual blood pressure readings obtained in the office setting, but actually have normal blood pressure except for their office readings (219). The diagnosis is best made by ambulatory blood pressure monitoring, a procedure that has become increasingly available in pediatric referral centers over the past several years. WCH is most likely a manifestation of the flight or fight response. Individuals with WCH are typically anxious and demonstrate a mild resting daytime tachycardia (219). Although the role of SNS activation has not been extensively investigated in individuals with WCH, it is a plausible underlying mechanism.

More important, WCH may represent a prehypertensive state, at least in some individuals. Long-term follow-up of adults with WCH has demonstrated a higher left ventricular mass index and greater incidence of cardiovascular events than in normotensive persons (220). This finding suggests that patients with WCH should be followed periodically for the later development of sustained hypertension, probably with serial ambulatory blood pressure monitoring.

Obesity Hypertension

Although a relationship between obesity and the development of hypertension has been recognized for many decades, the exact mechanisms by which obesity causes hypertension remain incompletely understood. In addition, there has been debate over whether obesity hypertension represents a secondary form of hypertension or a variant of primary hypertension. Because many of the mechanisms likely to be operative in individuals with obesity hypertension are similar or even identical to factors already discussed as being present in young individuals with primary hypertension, and given the absence of specific renal or other major organ system diseases in the vast majority of children with obesity hypertension, we have chosen to discuss obesity hypertension in the context of primary hypertension.

The two major hormonal abnormalities in obesity hypertension are hyperinsulinemia, a consequence of peripheral insulin resistance, and hyperleptinemia, a consequence of the increased mass of adipose tissue. It is likely that either insulin or leptin or both is fundamentally involved in the development of hypertension in most, if not all, hypertensive obese individuals.

One of the first investigators to propose that the link between obesity, insulin resistance, and hypertension was SNS activation was Landsberg, who stated "insulin resistance in the obese is a mechanism evolved for limiting fur-

ther weight gain. Like any compensatory mechanism, however, there is a price to pay. In this situation, that price is the hyperinsulinemia and sympathetic activation which, via effects on the blood vessels, the heart and the kidneys, exerts a pro-hypertensive effect that, in susceptible individuals, causes hypertension" (221). Although the issue of whether the hyperinsulinemia causes the SNS activation or vice versa remains unresolved, most of the experimental evidence supports the presence of SNS activation in obesity hypertension (221,222).

Insulin resistance has been linked to several physiologic mechanisms that can elevate blood pressure. First and foremost among these mechanisms is likely to be an altered renal handling of sodium, which leads to hypertension through an expansion of plasma volume. Insulin increases renal sodium reabsorption, possibly in the distal nephron, although this is not completely certain (223). It is likely that increased activity of renal sympathetic nerves is responsible at least in part for this effect (224). Elevated circulating levels of aldosterone, which have been demonstrated in salt-sensitive obese adolescents, may also be involved (225). Importantly, these effects of hyperinsulinemia on renal sodium handling can be reversed with weight loss (225).

The second major mechanism by which hyperinsulinemia may elevate blood pressure is through effects on vascular structure and function. Although insulin acts as a vasodilator when infused directly into local vascular beds (226), in hypertensive subjects this effect is probably offset by vasoconstriction mediated by increased sympathetic nervous activity (222,226). In addition, impaired vasodilation in response to insulin infusion has been demonstrated in obese individuals (227). Alternatively, insulin may act to stimulate vascular smooth muscle proliferation in resistance vessels (228), thereby leading to increased peripheral vascular resistance due to vascular medial hypertrophy. In this way, hyperinsulinemia would lead to hypertension by increasing total peripheral resistance.

Leptin is a peptide hormone encoded on chromosome 7 in humans and primarily produced by adipose tissue whose major function seems to be regulation of energy stores. Circulating leptin crosses the blood-brain barrier and binds with receptors in the hypothalamus. In leptin-deficiency states or after weight loss, leptin levels are decreased; this stimulates secretion of neuropeptide Y, which leads to increased food intake and decreased energy expenditure. Conversely, with weight gain, the resulting increase in leptin (caused by the increased mass of adipose tissue) leads to release of melanocyte-stimulating hormone; this hormone in turn binds to and activates the melanocortin-4 receptor, which induces physiologic changes that counteract obesity (229).

In obese hypertensive individuals, leptin levels are elevated and correlate with both blood pressure and heart rate (230). The mechanism by which hyperleptinemia results in hypertension appears to be increased SNS activity. Evidence in support of this hypothesis comes from animal

studies, several of which have demonstrated that intravenous leptin infusions increase RSNA and that intravenous leptin infusions increase blood pressure and heart rate (230,231). However, it is unknown at present whether the same hypothalamic pathways involved in leptin's regulation of energy stores is also involved in the development of hypertension (230). Leptin also has significant intraglomerular effects, including increased synthesis of transforming growth factor β , increased production of type IV collagen by glomerular endothelial cells, and stimulation of type I collagen synthesis by mesangial cells. This, in turn, may lead to glomerular sclerosis via extracellular matrix deposition (232), perhaps contributing to or even accounting for the secondary focal segmental glomerulosclerosis that can be seen in obesity. The role of leptin in the pathogenesis of obesity hypertension has been discovered relatively recently and is likely to be more complex than described here.

Insulin Resistance in Nonobese Hypertensive Individuals

Not all hypertensive individuals with insulin resistance are obese (222,233), which suggests that insulin resistance is a primary mechanism in the development of primary hypertension. Supporting this hypothesis are studies demonstrating a significant inverse relationship between insulin-mediated glucose uptake and blood pressure levels in lean normotensive and borderline hypertensive individuals (234). The mechanisms responsible for the development of elevated blood pressure in lean individuals with insulin resistance are most likely similar to those discussed earlier. What remains unknown at this point is what causes insulin resistance in nonobese hypertensive individuals (222).

Dietary and Environmental Influences on the Development of Primary Hypertension

Numerous dietary constituents have been examined as possible contributors to the development of primary hypertension. Of these, the two that have received the most interest have been sodium and potassium. Population studies of sodium consumption have demonstrated that populations with lower sodium intake have lower blood pressures than those with higher sodium intake (235,236). It is noteworthy that, typically, populations with high sodium intake also demonstrate lower potassium intake (235,237), which suggests a potential pathogenic role for potassium as well. Interventional studies of sodium restriction have generally shown that reducing sodium intake lowers blood pressure in both adults (238) and children (239), whereas the data for potassium supplementation are less clear (239,240). Recently, a diet low in sodium and saturated fats and high in potassium and calcium [the Dietary Approaches to Stop Hypertension (DASH) diet] was shown to be able to substantially lower blood pressure in hypertensive adults (241);

this diet has also been advocated as a method of hypertension prevention.

These dietary influences on blood pressure, however, although present when large populations are studied, may not apply to the individual patient (235,242). This is because some hypertensive patients are salt sensitive and others are not. Understanding the mechanisms responsible for salt sensitivity has been a subject of much research (242). What is true is that the mechanisms may vary from individual to individual: in obese hypertensive persons, for example, salt sensitivity is likely related to insulin resistance (see earlier discussion), but in hypertensive individuals with reduced nephron mass, salt sensitivity may simply represent a compensatory mechanism to maintain pressure natriuresis (200). Whatever the mechanism, one cannot ignore the public health implications of dietary sodium restriction: a modest reduction in sodium intake resulting in a 3-mm Hg reduction in systolic blood pressure has been calculated to have significant potential to reduce the incidence of stroke and other cardiovascular disease in the population at large (238).

The other environmental factor felt to play a role in the development of primary hypertension is stress. As noted earlier, stress has been shown to increase blood pressure in experimental settings, most likely through activation of the SNS (209,213,214). At the population level, stress has also been advanced as an explanation for the higher incidence of hypertension among African Americans than among whites (243). An individual's reaction to stress may lead to other changes in the environment that are themselves related to blood pressure (244), such as obesity from increased caloric intake, which would then cause hypertension by the mechanisms discussed earlier.

SECONDARY HYPERTENSION

Mendelian Forms of Blood Pressure Elevation

Molecular genetic studies have now identified mutations in eight genes that affect blood pressure. Common to all of the resulting disorders is altered renal handling of sodium. Mutations that increase renal salt reabsorption raise blood pressure; conversely, those that diminish salt reabsorption lower blood pressure (Fig. 60.2). In this chapter, we focus on the hypertensive syndromes: apparent mineralocorticoid excess (AME), Liddle's syndrome, glucocorticoid-remediable aldosteronism (GRA), and Gordon's syndrome. For a full discussion of the hypotensive syndromes, the reader is referred to the reviews of this topic (196).

The syndrome of *apparent mineralocorticoid excess* is an autosomal recessive disease characterized by early-onset hypertension with hypokalemia and metabolic alkalosis accompanied by suppressed plasma renin activity and the virtual absence of circulating aldosterone. In this disease, steroids other than aldosterone activate the mineralocorti-

FIGURE 60.2. Single-gene mutations altering blood pressure. A diagram of a nephron, the filtering unit of the kidney, is shown. The molecular pathways mediating NaCl reabsorption in individual renal cells in the thick ascending limb of the loop of Henle (TAL), distal convoluted tubule (DCT), and the cortical collecting tubule (CCT) are indicated, along with the pathway of the renin-angiotensin system, the major regulator of renal salt reabsorption. Inherited diseases affecting these pathways are indicated, with hypertensive disorders in gray and hypotensive disorders in black. 11 β -HSD2, 11 β -hydroxysteroid dehydrogenase-2; ACE, angiotensin-converting enzyme; AI, angiotensin I; AII, angiotensin II; AME, apparent mineralocorticoid excess; DOC, deoxycorticosterone; GRA, glucocorticoid-remediable aldosteronism; MR, mineralocorticoid receptor; PHA1, pseudohypoaldosteronism type 1; PT, proximal tubule. (From Lifton RP, Ghavari AG, Geller DS. Molecular mechanisms of human hypertension. *Cell* 2001;104:545–556, with permission of Elsevier Science.)

coid receptor (MR). Affected patients have a lack-of-function mutation in the gene encoding the renal isoenzyme of 11 β -hydroxysteroid dehydrogenase (11 β -HSD), which results in impaired conversion of cortisol to cortisone (245). *In vitro*, cortisol activates MR with potency similar to aldosterone; however, *in vivo* almost all activation of MR is mediated by aldosterone despite its low plasma concentration. The specificity of MR for aldosterone *in vivo* is mediated indirectly by 11 β -HSD activity; this “protects” the MR from cortisol by metabolizing it to cortisone, which does not activate the MR (246). In AME, the absence of this enzyme allows cortisol to activate the MR, which results in hypertension mediated by increased sodium retention. Confirmation of the pathogenesis of AME came with the cloning of 11HSD-2; this gene, expressed in the same cells of the nephron that express the epithelial Na⁺ channels (ENaC), shows homozygous loss-of-function mutations in AME patients (245).

Liddle's syndrome is an autosomal dominant, low-renin form of hypertension characterized by constitutively elevated renal sodium reabsorption that results from activating mutations in the β or γ subunit of the ENaC. These mutations result in an increase in the number of channels at the cell surface (247). The increased number of channels is due to reduced clearance of ENaC from the cell surface with dramatically longer half-life (248). The clearance of the

normal channel from the membrane is dependent on the sequence PPPXY in the cytoplasmic C terminus of both the β and γ ENaC subunits. Loss of this sequence from either subunit in Liddle's syndrome results in prolongation of the cell surface half-life and increased channel numbers, attributable to loss of interaction with WW domain-containing proteins and loss of clearance through clathrin-coated pits. The genetic defect has been localized to a single segment of chromosome 16 that encodes the ENaC subunits. Several different mutations have been described, all of which either cause a frame-shift mutation or introduce premature stop codons (249).

Glucocorticoid-remediable aldosteronism is an autosomal dominant disease characterized by early onset of hypertension with normal or elevated aldosterone levels despite suppressed plasma renin activity (187). GRA is caused by a chimeric gene that results from unequal crossing over of the aldosterone synthase and 11 β -hydroxylase genes on chromosome 8. Aldosterone synthase is the rate-limiting enzyme for aldosterone biosynthesis in the adrenal glomerulosa and 11 β -hydroxylase is an enzyme involved in cortisol biosynthesis in the adrenal fasciculata whose expression is regulated by ACTH. The resulting chimeric gene is expressed in the adrenal fasciculata and encodes a protein product with aldosterone synthase enzymatic activity whose expression is regulated by ACTH. Consequently, aldosterone synthase activity is ectopically expressed in the adrenal fasciculata under control of ACTH rather than of angiotensin II. Aldosterone secretion becomes linked to cortisol secretion, and maintenance of normal cortisol levels results in constitutive aldosterone secretion, which leads to expanded plasma volume and hypertension (250). The expanded plasma volume suppresses secretion of renin, but this fails to diminish secretion of aldosterone.

The final Mendelian form of hypertension is *Gordon's syndrome*, also known as pseudohypoaldosteronism type II. This is an autosomal dominant disorder characterized by hypertension, increased renal salt reabsorption, and impaired K⁺ and H⁺ excretion. It has been linked to mutations of genes on chromosome bands 1q31-42 and 17p11-q21 that encode the WNK kinases, a family of serine-threonine kinases (251). These mutations lead to increased expression of WNK1 and WNK4 in the distal nephron. An additional mutation at 12p13 has also been described that produces a similar phenotype (252).

Other Genetic Forms of Hypertension

Hypertension exacerbated in pregnancy by mutations in the MR is an autosomal dominant form of hypertension that is markedly accelerated in pregnancy (253). A systematic screening of patients with early-onset hypertension detected a missense mutation in the ligand-binding domain of the receptor MR S810L. S810L carriers all developed hypertension before age 20, a finding absent in their relatives with

wild-type receptors. Steroids lacking 21-hydroxyl groups (progesterone, spironolactone) that normally bind but do not activate MR are all potent agonists of the mutant receptor. Because progesterone levels rise 100-fold during pregnancy, all pregnancies among patients harboring this mutation have been complicated by dramatic acceleration of hypertension associated with complete suppression of the renin-angiotensin system (253).

Hypertension with brachydactyly is characterized by severe hypertension and abnormal skeletal development in the hand and wrist. There are no associated distinguishing biochemical features. This syndrome has been mapped to chromosome band 12p12.2-11.2 (254), but the responsible gene has not yet been identified.

Hypertension in Renal Parenchymal Disease

Hypertension resulting from renal parenchymal disease is multifactorial in origin. Volume expansion secondary to reduced sodium excretion increases cardiac output and activates the renin-angiotensin-aldosterone axis (255). Abnormal activation of the adrenergic system and baroreceptor dysfunction are also present (256). Chronic renal insufficiency leads to accumulation of the NOS inhibitors asymmetric and symmetric dimethylarginine (257) and endothelial dysfunction (258). Decreased production of vasodilators, including kinin and prostaglandins, and increased production of the vasoconstrictor ET-1 are also seen (259). Finally, recombinant human erythropoietin treatment and abnormal parathyroid-calcium homeostasis with elevated intracellular calcium concentrations in the myocardium and platelets is associated with hypertension (260).

Hypertension in Renovascular Disease

In the classic Goldblatt model of hypertension (261), the one-clip one-kidney or two-kidney two-clip model (analogous to renal artery stenosis in a solitary kidney or to bilateral renal artery stenosis in humans), hypertension is sodium and volume dependent. In the one-clip one-kidney or two-kidney two-clip hypertensive model, ACE inhibition has little effect on blood pressure unless the animal has been sodium depleted (262). However, in humans with bilateral renal artery stenosis, both renin and volume factors are involved.

Hypertension in the one-clip two-kidney model (analogous to unilateral renal artery stenosis in humans) is renin dependent (263). Two-kidney one-clip animals also have increased norepinephrine release and SNS activity (264), which implicates the SNS in the development of renovascular hypertension. This has been disputed in animal models (263), but as mentioned previously, studies in humans with renovascular hypertension have clearly demonstrated elevated sympathetic nerve activity (15).

Renal perfusion pressure starts to be affected when renal artery stenosis reaches 50%. The stenosis needs to occlude at

least 70% of the lumen, however, before it begins to reduce renal blood flow and raise arterial pressure (265). In the late phase, hypertension persists despite removal of the stenosis or ischemic kidney due to damage to the contralateral kidney (266). In fact, in the one-clip two-kidney model of renovascular hypertension, the vascular, glomerular, and tubulointerstitial damage is greater in the unclipped kidney than in the clipped kidney. The clipped kidney is exposed to elevated angiotensin levels but is protected from hypertension (267). Activation of the renin-angiotensin system also results in an increase in oxidative stress and accelerated atherosclerosis (268).

Hypertension in Acute and Chronic Renal Failure

Acute and severe insult to the kidneys impairs excretion of salt and water, reduces renal blood flow, or both. Dysregulation of salt and water excretion leads to volume expansion, whereas reduction in renal blood flow activates the renin-angiotensin-aldosterone axis. Hypertension in chronic renal failure is primarily volume and salt dependent and results from impaired sodium excretion. Salt plays a crucial role by causing an increase in interchangeable (269) and vascular wall sodium (270), which leads to an expansion in the intravascular volume. The renin-angiotensin system is also stimulated, which in turn produces sodium retention and an increase in total peripheral resistance.

Sympathetic tone increases, as expressed by an increase in plasma noradrenaline, which contributes to increases in total peripheral resistance and cardiac output (256). As discussed previously, ET-1 and ANP are elevated and associated with high blood pressure in chronic renal failure (154,271). Administration of nonsteroidal antiinflammatory drugs in chronic renal failure produces an increase in arterial pressure and a reduction in renal prostaglandins (272), which suggests an important role for prostaglandins in hypertension associated with chronic renal failure. Patients with uremia secondary to impaired renal clearance also have elevated levels of NOS inhibitor (166).

Posttransplantation Hypertension

Hypertension is a common phenomenon after renal transplantation, with up to 70% of pediatric transplantation patients requiring antihypertensive medications in the first month after transplantation (273). The major contributing factors include history of pretransplantation hypertension, persistent native kidney hypertension, the effects of immunosuppressive medications, transplant renal artery stenosis (TRAS), and chronic allograft dysfunction (see Chapter 73).

As can be deduced from the preceding sections, pretransplantation hypertension causes chronic vascular changes that increase peripheral vascular resistance. Although such vascular remodeling can be reversed with effective antihyperten-

sive treatment (274), many patients come to transplantation hypertensive despite therapy, so the same mechanisms that were operative in perpetuating their pretransplantation hypertension will still be at work. In addition, if the patient's native kidneys are still in place, they may continue to release renin (275), thereby further contributing to posttransplantation hypertension.

Immunosuppressive medications, particularly glucocorticoids and calcineurin inhibitors, contribute to posttransplantation hypertension in several ways. Although prednisone may be a significant contributing factor to the development of hypertension in the immediate posttransplantation period, most pediatric immunosuppression protocols try to reduce the dosage of prednisone as far as possible to maximize posttransplantation growth, so that prednisone is a much less important contributing factor later on (275,276). Calcineurin inhibitors affect blood pressure in a variety of ways, including increasing production of the vasoconstrictor endothelin (155,157), decreasing production of vasodilatory substances (276), and activating the SNS (277).

TRAS has been reported to occur in up to 20% of hypertensive pediatric renal transplant recipients (275), although improved surgical techniques have probably decreased its incidence somewhat (276). Causes may include surgical trauma, prolonged ischemia, suturing technique or reactions to suture material, and atheromatous plaques in the donor kidney (276). Elevated renin secretion has been seen in patients with TRAS (278), which suggests that the mechanisms responsible for hypertension in TRAS are similar to those discussed elsewhere in this chapter for renovascular hypertension.

Allograft dysfunction has long been recognized as a significant cause of hypertension in both children and adults with posttransplantation hypertension (275,276). Whether it results from the sequelae of rejection or from calcineurin nephrotoxicity, the primary mechanism of hypertension related to allograft dysfunction appears to be renal sodium retention (276,279). Other mechanisms seen in patients with renal insufficiency of other causes may also be responsible.

Hypertension in Dialysis Patients

Children receiving long-term dialysis have a significant incidence of hypertension: of the children in the North American Pediatric Renal Transplant Cooperative Study dialysis database, 53 to 63% of those receiving hemodialysis and 43 to 56% of those receiving peritoneal dialysis were also receiving antihypertensive medications at the time of the 2002 study annual report (273). The major pathophysiologic mechanism in most dialysis patients seems to be volume overload related to sodium and water retention. This may be more significant in peritoneal dialysis patients than in hemodialysis patients (280). Evidence in favor of fluid overload as the major mechanism can be found in the many studies that demonstrate correction of

hypertension after increased fluid removal in both peritoneal dialysis and hemodialysis patients (281,282).

Numerous other factors have been implicated, however, including overactivity of the SNS, activation of the renin-angiotensin system, erythropoietin, parathyroid hormone, and nocturnal hypoxemia (283). Studies have also implicated NO and endothelin in the pathogenesis of dialysis hypertension (283,284). Endothelin and other vasoconstrictive factors have also been shown to be involved in the pathogenesis of erythropoietin-related hypertension (285). Postdialysis hypertension in hemodialysis patients is likely renin mediated and responds to administration of an ACE inhibitor after dialysis (286).

Hypertension in Coarctation of the Aorta

Hypertension associated with aortic coarctation may occur in three clinical settings: before surgical repair, in the immediately postoperative period after surgical repair, and long after surgical repair. Prerepair hypertension is the result of renal hypoperfusion and activation of the renin-angiotensin system. The activity of the SNS may also be increased (287). In the immediately postsurgical period, paradoxical hypertension may be seen, which is probably the result of increased activity of the renin-angiotensin system and the SNS (288).

Despite surgical repair of coarctation, many patients are found to have abnormal blood pressure at rest. Ambulatory blood pressure monitoring is probably superior to casual blood pressure measurement for detection of hypertension in this population (289). Proposed mechanisms for this late or persistent hypertension include altered baroreceptor function, thickening of blood vessels below the site of the coarctation, and elevation of plasma adrenaline and aldosterone levels (290,291). Renal structural changes have also been demonstrated in animal models of coarctation (292). Recoarctation should also be investigated in any patient with the development of late postrepair hypertension.

Hypertension in Vasculitis

Due to the numerous vessels within the renal parenchyma, the kidneys are frequently targeted by systemic vasculitides. Glomerular inflammation, with cellular infiltration, proliferation, and immune complex deposition resulting in nephritis and renal failure, has been well described in systemic lupus erythematosus, microscopic polyarteritis, Wegener's granulomatosis, Schönlein-Henoch purpura, and cryoglobulinemic vasculitis (see Chapters 44 through 46). Takayasu's arteritis, an inflammatory process associated with stenosis and obliteration of the aorta and its primary branches, induces hypertension by mechanisms that are similar to those seen in coarctation of aorta, renovascular hypertension, or ischemic kidney disease as discussed earlier. Necrotizing vasculitides, such as classic polyarteritis nodosa and Kawasaki disease, may lead to hyperten-

sion secondary to thrombosis of inflamed major extrarenal and intrarenal arteries with resulting local (intrarenal) renin-angiotensin system activation and infarction of the renal parenchyma (293).

Hypertension in Endocrine Diseases

Adrenocortical Hypertension

Although an excess of exogenous or endogenous glucocorticoids (Cushing syndrome) has long been known to cause hypertension, the exact mechanism or mechanisms that result in blood pressure elevation remain unknown. The hepatic synthesis of angiotensinogen, which stimulates the renin-angiotensin system, is activated, and phospholipase A₂, which releases arachidonic acid from phospholipids and plays an important role in the synthesis of vasodilatory prostaglandins, is inhibited (294). Glucocorticoids also reduce the activity of the depressor kallikrein-kinin system, enhance pressor sensitivity to endogenous vasoconstrictors (epinephrine and angiotensin II) (295,296), and promote sodium influx into vascular smooth muscle cells (297). High levels of cortisol exert mineralocorticoid effects, and in adrenal carcinomas, deoxycorticosterone and aldosterone levels may also be elevated (298).

Hyperaldosteronism may result from either an aldosterone-producing adrenal adenoma or, more commonly, from adrenal hypertrophy (idiopathic hyperaldosteronism). Aldosterone-producing adenoma and idiopathic hyperaldosteronism both produce excess aldosterone secretion and both result in hypertension with similar clinical features: hypokalemia, renal potassium wasting, suppressed plasma renin activity, and increased plasma and urinary levels of aldosterone (299). The blood pressure elevation due to aldosterone excess results from an increase in systemic vascular resistance due to aldosterone-mediated increased plasma sodium concentration, which leads in turn to a rise in the intracellular calcium content. Increase in intracellular calcium results in impaired left ventricular diastolic relaxation (300) and enhanced contractility with reduced vascular compliance (301). The increased aldosterone production in idiopathic hyperaldosteronism reflects increased activity of a rate-limiting mitochondrial cytochrome P-450 isoenzyme, the aldosterone synthase gene CYP 11B2 (302). Polymorphisms of the CYP 11B2 gene determine interindividual variations in aldosterone activity and response to antihypertensive treatment (303,304).

Pheochromocytoma

Pheochromocytomas are catecholamine-secreting tumors of chromaffin cells that may arise from cells of neural crest origin, either in the adrenal glands themselves or in extraadrenal sites. Sustained or paroxysmal hypertension is the most common clinical sign, although it may be less common in children than in adults (305). Although most pheochromocytomas are spo-

radic, there is a familial predisposition in patients with multiple endocrine neoplasia type 2, von Hippel–Lindau disease, neurofibromatosis type 1, and familial carotid body tumors (306). Pheochromocytoma in multiple endocrine neoplasia type 2 is associated with a germline mutation of the proto-oncogene RET (307) and pheochromocytoma in von Hippel–Lindau disease results from germline mutation of the von Hippel–Lindau gene (308).

Hypertension in pheochromocytoma results from the direct effect of high circulating levels of catecholamines, primarily noradrenaline, adrenaline, and dopamine (305). Some tumors produce the catecholamine precursor L-dopa. Pheochromocytomas also secrete numerous other peptide hormones, among which are renin, VIP, neuropeptide Y, somatostatin, and ET-1. These substances are responsible for many of the nonhypertensive symptoms seen in patients with pheochromocytoma, including flushing, sweating, and diarrhea (305).

Thyroid Disorders

Hypothyroidism produces a reduction in renal blood flow and GFR, as well as decreased cardiac output (309). Compensatory mechanisms, primarily increased peripheral resistance mediated by increased responsiveness to adrenergic stimulation and increased SNS activity (310), lead to diastolic hypertension. Treatment with thyroid hormone corrects the hypertension.

Hyperthyroidism, on the other hand, is associated with activation of the renin-angiotensin-aldosterone axis and increased sodium reabsorption, which leads to expansion of plasma volume (172). There is also β_2 -receptor stimulation, which in turn results in vasodilatation, increased cardiac output, and cardiac contractility (173). These physiologic changes result in isolated systolic hypertension (175).

Renin Overproduction

Juxtaglomerular cell tumors of the kidney or ectopic tumors secrete renin and induce hypertension associated with hypokalemia, as well as hyponatremia and other features of renin-angiotensin-aldosterone system activation (311).

Hypertension in Pulmonary Diseases

Hypertension in children with chronic lung disease is most commonly seen in infants with bronchopulmonary dysplasia. Although the pathophysiology of bronchopulmonary dysplasia-associated hypertension is not completely understood, it is likely to be multifactorial in origin. Corticosteroids, especially dexamethasone, when used for prolonged periods elevate blood pressure in such infants, but with withdrawal the hypertension resolves (312). Because the development of hypertension has been correlated with the severity of lung disease, chronic hypoxia may also be an important mechanism (313).

Obstructive sleep apnea, characterized by episodic upper airway obstruction during sleep despite persisting respiratory efforts, leads to asphyxia, hypoxia, hypercapnia, and disruption of sleep architecture. Obstructive sleep apnea is a risk factor for systemic hypertension, myocardial infarction, stroke, and sudden death (314). Acute episodes of hypoxia result in stimulation of peripheral chemoreceptors and increased sympathetic outflow with subsequent activation of the renin-angiotensin system (315). These events lead to cyclic or episodic hypertension that later evolves into sustained hypertension if the sleep apnea remains untreated.

Hypertension in Neurologic Disorders

Systemic hypertension can be seen in a variety of neurologic disorders, including seizures, poliomyelitis, hydrocephalus, head trauma, pseudotumor cerebri (idiopathic intracranial hypertension), Guillain-Barré syndrome, and space-occupying lesions (tumor, bleeding, and abscess). Many of these are associated with increased SNS outflow, which leads to peripheral vasoconstriction and renal sodium retention (see earlier sections).

In Guillain-Barré syndrome, for example, microneurographic studies have demonstrated increased SNS activity in the acute phase of the illness (316). Increased levels of circulating renin and catecholamines have also been reported (317). These abnormalities, and the hypertension, resolve as the neurologic abnormalities subside. Increased sympathetic activity is also seen in patients with spinal cord injury. In familial dysautonomia, hypertension is caused by increased levels of circulating catecholamines and increased responsiveness to circulating catecholamines (318).

Increased intracranial pressure causes systemic hypertension that can be quite labile. The mechanism of hypertension is believed to be the stretching of receptors located under the floor of the fourth ventricle (319). Sympathetic nervous outflow is increased in most patients, and baroreceptor function is disrupted. Circulating levels of catecholamines may be increased. Hemodynamically, hypertension is primarily due to increased total peripheral resistance. In many instances, especially when intracranial pressure is elevated due to trauma, systemic hypertension is an important compensatory mechanism for the maintenance of normal cerebral perfusion (320).

Pregnancy-Induced Hypertension and Preeclampsia

Pregnancy-induced hypertension may affect up to 10% of all first pregnancies in the United States (321). As with many of the forms of hypertension discussed in this chapter, pregnancy-induced hypertension is most likely a multifactorial disorder with many contributing mechanisms. However, because the hypertension associated with preeclampsia develops during pregnancy and remits after

TABLE 60.2. MECHANISMS OF DRUG-INDUCED HYPERTENSION

Drug	Potential mechanism(s) (references)
Caffeine	Vasoconstriction, increased SNS activity, decreased baroreceptor sensitivity (328,329)
Calcineurin inhibitors	SNS activation (277), increased ET-1 secretion (155–157)
Cocaine	Increased heart rate and myocardial oxygen demand, direct vasoconstriction, increased matrix synthesis, glomerular inflammation, and glomerulosclerosis (330)
Erythropoietin	Increased erythrocyte mass, changes in production or sensitivity to endogenous vasopressors, dysregulation of production or responsiveness to endogenous vasodilatory factors, a direct vasopressor effect, arterial remodeling through stimulation of vascular cell growth (285,331)
Ethanol	Abnormal response of blood pressure and plasma renin activity to variations in salt intake (332)
Glucocorticoids	Stimulation of the renin-angiotensin system, inhibition of phospholipase A ₂ , reduced activity of the kallikrein-kinin system, enhanced pressor sensitivity to endogenous vasoconstrictors, mineralocorticoid effects (295–298)
NSAIDs	Prostaglandin inhibition, decrease glomerular filtration rate, salt and water retention, tubulointerstitial injury (333)
Oral contraceptives	Alteration in sodium balance and the renin-angiotensin-aldosterone system (334,335)
Tobacco	Increased SNS outflow, attenuated endothelium-dependent vasodilatation, increased arterial wall stiffness (336–338)

ET-1, endothelin-1; NSAID, nonsteroidal antiinflammatory drug; SNS, sympathetic nervous system.

delivery, the placenta is thought to play a central role in the disease development. Abnormal cytotrophoblast invasion of spiral arterioles leading to reduced uteroplacental perfusion and ischemia appears to be the initiating event (322).

Placental ischemia results in activation or dysfunction of the maternal vascular endothelium that in turn increases the formation of endothelin and thromboxane, increases vascular sensitivity to angiotensin II, and decreases formation of vasodilators such as NO and prostacyclin (323,324). There is also increased synthesis of inflammatory cytokines such as tumor necrosis factor- α , interleukin-1, and interleukin-6, which is activated by tumor necrosis factor- α (325). Those cytokines, in turn, induce structural and functional alterations in endothelial cells, enhance the formation of endothelin, and reduce acetylcholine-induced vasodilatation (325).

Another important mechanism may be defective production of NO. During normal pregnancy, maternal cardiac output and blood volume increase by 40 to 50%, whereas total peripheral resistance and blood pressure tend to decrease. In addition, GFR and renal plasma flow increase 30 to 40%. There is substantial evidence that NO plays an important role in mediating those changes. Plasma and urinary levels of cGMP, the second messenger of NO, increase during pregnancy in rats, and urinary nitrate and nitrite excretion have also been reported to be increased. Chronic NOS inhibition in pregnant rats produces a hypertension associated with peripheral and renal vasoconstriction, proteinuria, intrauterine growth retardation, and increased fetal morbidity, a pattern that closely resembles the symptoms of human pregnancy-induced hypertension (326,327).

Drug-Induced Hypertension

Numerous therapeutic and illicit drugs, as well as various other consumed substances, may influence blood pressure significantly, especially in individuals whose blood pressure regulation is already disturbed. A detailed discussion of the many substances with effects on blood pressure is beyond the scope of this chapter. However, some of the more common mechanisms of blood pressure effects due to drugs are summarized in Table 60.2.

EVALUATION OF HYPERTENSION IN CHILDHOOD DISEASES

EILEEN D. BREWER

Evaluation of hypertension in the pediatric age group should be guided by how old the child is at presentation, how severe the hypertension is, and whether the hypertension is sustained or transient. The most common causes of hypertension differ by age group (Table 61.1). Hypertension is more likely to be secondary and sustained in younger age groups, whereas essential hypertension and white-coat hypertension are more likely to be the cause in adolescents (1–3). The current epidemic of childhood obesity has been associated with an increase in the incidence of essential hypertension in adolescence (1,4). Obese children have a threefold higher risk of developing hypertension than nonobese children (4). The increased incidence of essential hypertension in obese adolescents dictates an entirely different evaluation for this group than for younger or nonobese children. Renal disease must be considered in every child with hypertension, because of the prevalence of renovascular and renal parenchymal disorders as a cause of hypertension in any age group. Secondary hypertension from renal disorders is more likely to be severe at presentation than is essential hypertension. Endocrine causes of hypertension are rare, so special diagnostic studies for these disorders should be reserved for those patients whose history, physical examination, and preliminary evaluation indicate that further specific investigation is warranted. This chapter outlines the steps in evaluation of childhood hypertension, starting with the confirmation of the diagnosis of high blood pressure and evaluation of its duration and severity.

CONFIRMATION OF THE DIAGNOSIS OF HYPERTENSION IN CHILDREN AND ADOLESCENTS

Recommended techniques for measuring blood pressure in children are discussed in detail in Chapter 59. A few points are reemphasized here, because confirming the diagnosis of hypertension is the first step in the evaluation. Standards for

blood pressure measurement in children and adolescents were revised in 1996 to include assessment of height as well as age and gender to determine normative data for children 1 to 17 years old (1). The new approach minimizes misclassification of children as hypertensive when they are very tall or very short for age. In addition, the fifth Korotkoff sound (point at which the sound disappears) is used to determine diastolic blood pressure in all age groups, even though in some young children no fifth sound can be heard because sounds are still audible at 0 mm Hg. In these children only the systolic measurement can be used to assess hypertension. In infants younger than 1 year of age, the use of systolic blood pressure to define hypertension is recommended, because few data exist for normal diastolic blood pressures (1–2). However, the report of the 1987 Second Task Force on Blood Pressure Control in Children (2) includes standards for both systolic and diastolic blood pressure for awake infants, aged birth to 12 months, based on measurements obtained using either Doppler instruments or sphygmomanometers and the fourth Korotkoff sound (point at which the sound muffles) to determine diastolic blood pressure (2). Blood pressure is lower in sleeping infants, so correction factors of 7 mm Hg for systolic and 5 mm Hg for diastolic blood pressure are recommended when measurements taken during sleep are used to assess for hypertension (2). Standards for adolescents 18 years of age and older are included in those for the adult age group and do not take into account age, gender, or height. In 2003, the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (5) revised adult blood pressure standards. This report set the guidelines for the upper limit of normal blood pressure for all adults, aged 18 years or older, at 120/80 and classified blood pressures between 120/80 and 139/89 as prehypertension.

Tables of normal blood pressure for children and adolescents (1,2) or adults (5) are based on measurements made manually with a sphygmomanometer and auscultation using a stethoscope. Few data are available for normal blood pressures measured with an automatic oscillometric device, such

TABLE 61.1. MOST COMMON CAUSES OF HYPERTENSION BY AGE AT PRESENTATION

Age group	Cause
Newborn	Renal artery thrombosis or embolus (umbilical artery catheter) Renal vein thrombosis Congenital renal malformations Coarctation of aorta Renal artery stenosis Bronchopulmonary dysplasia
Infancy to 6 yr	Renal parenchymal disease Renal artery stenosis Coarctation of the aorta Medications (corticosteroids, albuterol, pseudoephedrine) Endocrine causes
6–10 yr	Renal parenchymal disease Renal artery stenosis Essential hypertension Endocrine causes
Adolescence	Essential hypertension White-coat hypertension Renal parenchymal disease Substance abuse (cocaine, amphetamines, methamphetamines, phencyclidine, methylphenidate, caffeine) Endocrine causes

as the Dinamap. Although oscillometric devices are in widespread use in pediatric hospitals in North America, especially for neonates, infants, and toddlers, no established reference standards exist for normal blood pressure in children using these devices (1,6). In practice, values obtained with automatic oscillometric devices are treated as if they were obtained manually and compared with the standard blood pressure tables. In the few studies comparing measurements with oscillometric devices to those with conventional manual sphygmomanometry in children, the blood pressures were not equivalent, and the errors were not systematic for all ages (6–8). In addition, few of the oscillometric devices on the market were actually found to fulfill strict criteria for accuracy (9). Therefore, in instances of borderline or mild hypertension, manual sphygmomanometry should be performed as part of the evaluation to confirm that the diagnosis of hypertension is appropriate.

The conditions under which blood pressure is measured are also important, but sometimes these are not able to be standardized in a busy outpatient clinic or emergency room. The Second Task Force on Blood Pressure Control in Children (1) and the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (5) recommend that blood pressure be measured at least twice in a controlled environment, preferably in the right arm with the cubital fossa at heart level and the patient in a seated position after the patient has rested for 3 to 5 minutes. The bladder of the cuff, not the entire cuff, should be an appropriate size for the patient (1). The blad-

der width should be approximately 40% of the arm circumference midway between the acromion and olecranon; the length of the bladder should cover 80 to 100% of the circumference of the arm without overlapping. Cuff sizes are not standardized, so determination of the appropriate cuff size should be made according to these guidelines and not according to the name written on the cuff; for example, a small adult cuff might be just the right size for a tall or obese 7-year-old. Measuring blood pressure accurately may be difficult in a severely obese adolescent, unless a large leg cuff is used on the arm. Sometimes, particularly in a small or ill child, blood pressure is most conveniently evaluated using a leg measurement. When the leg blood pressure is abnormal, the value should be compared to values measured in the right arm to be certain of the diagnosis of hypertension. If a patient has coarctation of the aorta, blood pressure may be greatly reduced in the legs and possibly in the left arm, depending on the location of the coarctation, but will still be high in the right arm.

High blood pressure readings may be transient. A blood pressure reading taken in a crying, moving, or anxious child is likely to be high and is not reliable for diagnosing hypertension. Blood pressure measurement should be repeated several times when the child is calm. If blood pressure is not severely high, it should be measured on repeated visits over days to weeks before one diagnoses primary hypertension or embarks on a detailed diagnostic evaluation (1). Blood pressure tends to decrease on subsequent visits as anxiety subsides and the patient becomes more accustomed to the environment and technique of measurement. If white-coat hypertension is suspected after focused detailed history taking and physical examination and minimal screening laboratory tests, ambulatory blood pressure monitoring (ABPM) may be the next step in the evaluation (1,10). ABPM requires a wearable oscillometric blood pressure device, usually placed on the nondominant arm, that automatically measures and records blood pressure at prescribed frequent intervals (e.g., every 20 minutes during awake time and every 30 minutes during sleep) over an entire 24-hour period (10). ABPM allows evaluation of blood pressure throughout the day in the patient's own environment to reduce anxiety-induced elevations in blood pressure. Frequency of hypertension throughout the day (blood pressure load) and changes in the normal circadian pattern of blood pressure are also assessed, which cannot be done by casual blood pressure measurements in the clinic or at home. ABPM is discussed in detail in Chapter 59.

ASSESSMENT OF SEVERITY AND DURATION OF HYPERTENSION

When repeated blood pressure measurements taken under appropriate conditions satisfy the definition of hypertension (1,2,5), the severity of hypertension must be deter-

mined to direct further evaluation (Fig. 61.1). Guidelines for assessment of the severity of hypertension by age, gender, and height percentile are given in Table 61.2. If hypertension is mild or moderate (intermediate between mild and severe), diagnostic evaluation may continue before treatment is instituted. If hypertension is severe, emergent treatment should be undertaken to reduce the level of hypertension before further diagnostic evaluation (Fig. 61.1). If possible, laboratory tests that might be affected by treatment, such as peripheral plasma renin levels, should be performed before therapy is initiated.

The nature of the hypertension—acute or chronic, transient or sustained, or episodic—helps direct further evaluation. Transient or unsustained hypertension may need only clinical follow-up to be sure it does not recur. Episodic hypertension is best evaluated at the time of an occurrence, because evaluation may be unrevealing between attacks. Acute hypertension is often secondary to other diseases, which may have distinct signs and symptoms that direct specific evaluation at the time of presentation.

Duration of hypertension is first assessed by taking a thorough hypertension-oriented history and performing a physical examination (1,3). Headaches, blurred vision, seizures, chest pain, and frequent epistaxis may be associated with acute onset of hypertension. Episodic symptoms and hypertension are associated with pheochromocytoma or autonomic nervous system dysfunction. A detailed medication history for both prescription and over-the-counter medications, including herbal medicines, may help identify the cause of acute, transient, or episodic hypertension. Recent introduction of medications for which hypertension is a known side effect, like high-dose corticosteroids (11) or albuterol for asthma, large (adult) doses of pseudoephed-

rine for cold symptoms, or phenylephrine eye or nose drops, may be the cause of new-onset but transient hypertension. Adolescents are at risk for substance abuse and should be interviewed in private to maximize the chance of obtaining a history of the use of illicit drugs, tobacco, or high-caffeine or guarana-containing drinks, all of which can cause or contribute to hypertension (1,12,13). Restless sleep, irritability, anorexia, and poor school performance are subtle signs of chronic hypertension and should be specifically elicited in the history. Poor growth may also be a sign of chronic hypertension or underlying chronic renal disease. Obesity with body mass index higher than the 95th percentile for age and gender is often associated with chronic essential hypertension (1,4). The presence of peripheral edema, pleural effusion, rash, or swelling and tenderness of joints suggest acute onset or exacerbation of underlying renal or systemic disease. Retinal changes usually indicate long-standing untreated hypertension and include arteriolar narrowing or tortuosity, arteriovenous nicking, and hemorrhages and exudates (Fig. 61.2).

SCREENING EVALUATION OF HYPERTENSION

Episodic or sustained, acute or chronic hypertension, whether mild or severe, merits further screening and specific detailed evaluation. A convenient algorithm for evaluation of pediatric hypertension is given in Figure 61.1. The direction of further detailed laboratory and radiographic or biopsy evaluation of hypertension should become apparent after taking a detailed personal and family history, performing a careful physical examination, and ordering a few simple laboratory tests.

The personal history taking should include specific questioning regarding the presence of headaches, visual distur-

bance, nosebleeds, palpitations, episodic rapid pulse, pallor or flushing, joint pains, rash, edema, gross hematuria, excessive weight gain or loss, or decreased height growth. Neonatal history of low birth weight or the use of umbilical artery catheters may provide clues to the diagnosis of essential hypertension in an adolescent (14,15) or hypertension from renal artery thrombosis or emboli in an infant, respectively. Detailed dietary history may reveal excessive intake of sodium or caffeinated beverages, especially soft drinks. Taking a medication history should include specific questions about over-the-counter drugs like pseudoephedrine or herbal preparations like ephedra, St. John's wort, or licorice (16,17), as well as prescription drugs. Adolescents should be questioned in private to obtain a history of substance abuse or the possibility of pregnancy. Identifying a family history of hypertension, heart attacks, or stroke is particularly important for children with essential hypertension. Over 50% of children with essential hypertension have a relative with the same disease (1,2,4,18).

Physical examination may reveal specific signs of genetic disease, such as the elfin facies of Williams syndrome, the café-au-lait spots and small skin neurofibromata of neurofibromatosis type 1, the physical features of Cushing syndrome, or ambiguous genitalia associated with congenital adrenal hyperplasia or Denys-Drash syndrome. Rarely, unilateral facial paralysis (Bell's palsy of the seventh cranial nerve) can be the initial presentation of severe hypertension in a child (19,20). Careful auscultation of the abdomen may reveal a bruit suggestive of renovascular disease, but a bruit is audible only approximately 50% of the time in these patients (21). Femoral pulses may be diminished in patients with coarctation of the aorta or middle aortic syndrome. Determination of height, weight, and body mass index with comparison to percentiles for age and gender should always be included as part of the screening physical examination.

Screening laboratory evaluation should be minimally invasive and cost effective. Screening for rare endocrine causes of hypertension should not be done initially in every pediatric patient with hypertension. Screening studies for all patients should include complete blood count, urinalysis, and levels of serum electrolytes, creatinine, and blood urea nitrogen (BUN) (1–3). In adolescents with suspected essential hypertension for whom there is no suspicion of endocrine abnormalities, measurement of serum electrolytes may not be useful. However, a low potassium concentration with metabolic alkalosis may indicate a rare but treatable disorder, such as primary or secondary hyperaldosteronism or Liddle's syndrome. Elevated serum potassium level in conjunction with metabolic acidosis may suggest chronic renal disease, which is confirmed by the presence of an increased serum creatinine concentration. Creatinine clearance can be estimated from serum creatinine level (Schwartz formula) (22) or measured directly with a 24-hour urine collection. Because renal disease is the

most common cause of hypertension in children and the kidney is also a target organ for damage from untreated hypertension, urinalysis is an important screening test. Hematuria and the presence of red cell casts with or without proteinuria suggests glomerular disease. Isolated hematuria also may be associated with dilatation of the urinary tract or trauma. Proteinuria may be seen in nonglomerular conditions such as reflux nephropathy, obstructive uropathy, or interstitial nephritis, as well as glomerular diseases like focal segmental glomerulosclerosis or membranoproliferative glomerulonephritis. Proteinuria alone may be a sign of end-organ damage from hypertension but must be distinguished, especially in adolescents, from orthostatic (postural) proteinuria, which is a benign condition.

A renal ultrasonographic examination is a simple, noninvasive test that is appropriate to perform early in the evaluation of any hypertensive child (3). Although it may not provide much information in the adolescent in whom essential hypertension is strongly suspected, a renal ultrasonogram helps exclude congenital anomalies that have previously gone undetected. The renal ultrasonogram provides information about the size and architecture of each kidney and the lower urinary tract. Abnormal kidneys may be small or asymmetric (renovascular disease, vesicoureteral reflux, or dysplasia); hyperechoic, symmetric, and normal or large (renal parenchymal disease); or large with or without cysts (polycystic kidney disease, multicystic dysplasia). Hydronephrosis and/or hydroureters may be associated with congenital obstructive uropathy or vesicoureteral reflux.

The addition of color-coded Doppler analysis to B-mode ultrasonography is termed *duplex ultrasonography* (23) and provides information about the patency and flow within the main renal vessels to help diagnose renovascular hypertension. Better hardware, software, and transducer technology have improved visualization and evaluation of the more distal segments of the main renal artery (23). During Doppler evaluation care should be taken to scan the entire artery from origin at the aorta to renal hilum to improve sensitivity and accuracy. Obtaining measurements in two views, both anterior and oblique, improves identification of fibromuscular dysplasia in the middle to distal segments of the main renal artery. The limited amount of body fat in many children and the proximity of renal vessels to the skin surface allow the use of high-frequency transducers to improve the technical quality (24). Ultrasonography in obese patients may provide a technical challenge. Color Doppler images can demonstrate global perfusion as well as patency of flow through large renal arteries and veins. Turbulence at a stenotic site alters peak-systolic and end-diastolic blood flow velocities and creates a characteristic pattern of flow detected by the spectral Doppler waveform (Fig. 61.3). The sensitivity of the Doppler flow study is limited for detection of stenosis in accessory renal arteries, intrarenal arteries, or mildly stenotic arteries (24,25). A positive result on a Doppler flow study is helpful in direct-

ing further evaluation, but a negative result does not rule out significant renovascular disease.

DIRECTED SPECIFIC EVALUATION OF HYPERTENSION AFTER SCREENING

Specific Evaluation 1

If the screening evaluation described earlier is normal or positive only for obesity or a family history of essential hypertension, detailed evaluation should be directed toward the diagnosis of essential hypertension (Fig. 61.1). Because essential hypertension is largely a diagnosis of exclusion and is less common in young children, renovascular disease must always be ruled out if the child is younger than 10 years of age.

Essential Hypertension

The specific evaluation of essential hypertension is directed primarily at determining the presence of cardiovascular risk factors, such as hyperlipidemia, and assessing any end-organ damage to the heart or kidneys (1). In children elevation of serum uric acid level may help distinguish essential from secondary hypertension. Increased serum uric acid concentrations were noted in children with essential hypertension many decades ago (26) but were largely ignored until reports appeared that serum uric acid level is significantly higher at presentation in children with essential hypertension than in children with secondary hypertension (27). Elevated uric acid levels may play an early pathogenetic role in childhood hypertension by activating cellular pathways that lead to increased renovascular tone, fibrosis, and irreversible arteriosclerosis (28). ABPM may also help distinguish essential from secondary hypertension, the latter of which is more likely to manifest greater daytime diastolic blood pressure load, greater nocturnal systolic blood pressure load, and blunted nocturnal dipping (29). ABPM is useful to differentiate white-coat hypertension from essential hypertension as well (10).

End-organ damage may already be evident at presentation of essential hypertension in adolescents. An echocardiogram is the best way to screen for left ventricular hypertrophy and also serves as a baseline study for comparison later in the course of therapy (2,30). APBM may also be useful to identify which children may be at greatest risk for developing end-organ damage from hypertension (10,31,32).

Renovascular Disease

Renovascular disease is the cause of hypertension in approximately 10% of children referred for diagnosis (33,34). Children with renovascular hypertension are frequently asymptomatic (35). Hypertension is often severe and may be hard to control with medication before proceeding with spe-

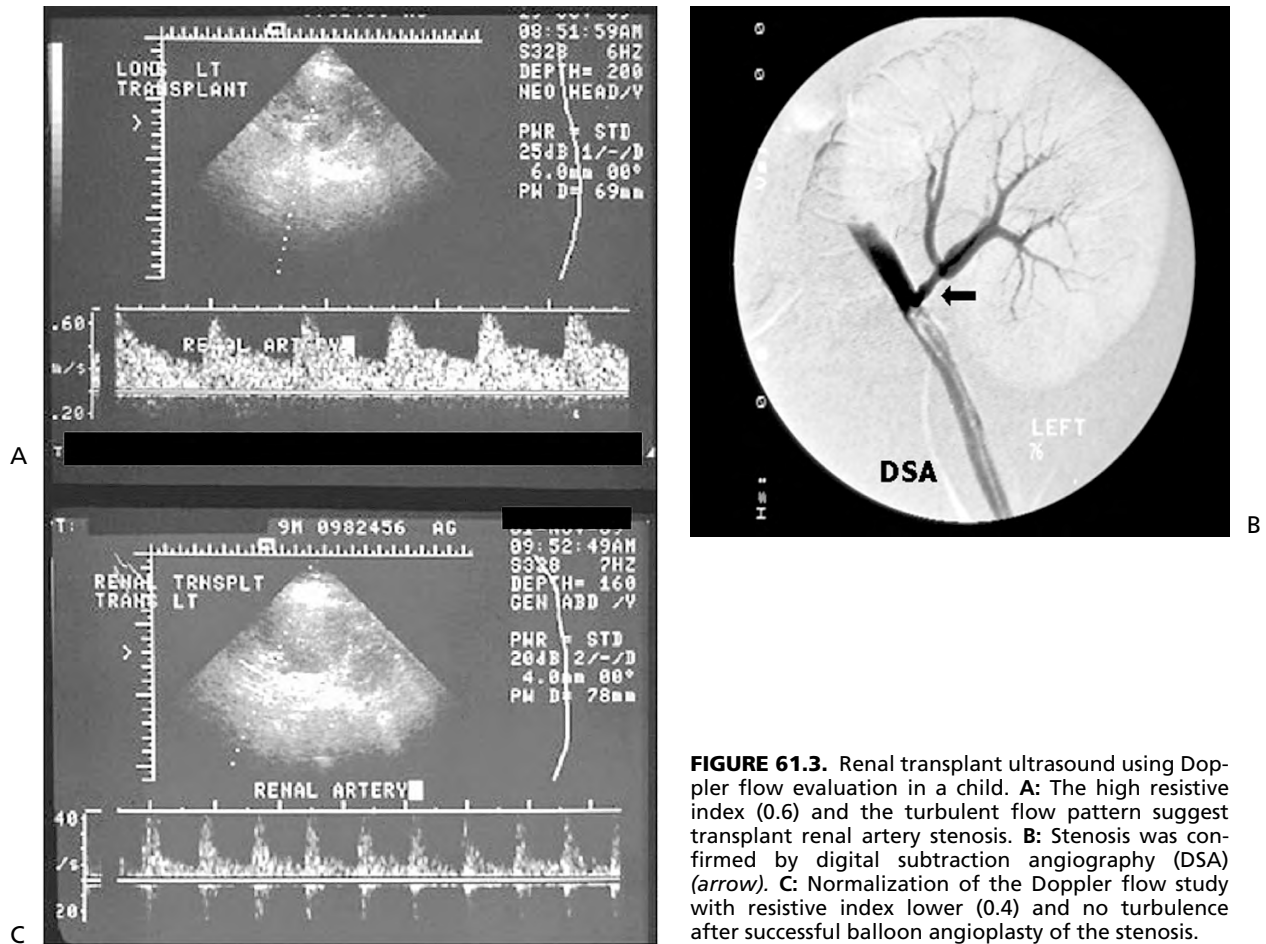

FIGURE 61.3. Renal transplant ultrasound using Doppler flow evaluation in a child. **A:** The high resistive index (0.6) and the turbulent flow pattern suggest transplant renal artery stenosis. **B:** Stenosis was confirmed by digital subtraction angiography (DSA) (arrow). **C:** Normalization of the Doppler flow study with resistive index lower (0.4) and no turbulence after successful balloon angioplasty of the stenosis.

cific evaluation (35). An angiotensin-converting enzyme (ACE) inhibitor may provide the best control, but with prolonged use can also lead to loss of function in the affected kidney from reduced arterial flow in an area of severe stenosis (Fig. 61.4). Some patients with bilateral renal artery stenosis may develop acute renal failure at the onset of ACE inhibitor therapy. A child's response to an ACE inhibitor during radionuclide imaging with either diethylenetriaminepenta-acetic acid (DTPA), mercaptoacetyltriglycine (MAG-3), or dimercaptosuccinic acid (DMSA) can be used in the evaluation for renal artery stenosis and is often referred to as a captopril renal scan (36–38). Although a captopril renal scan may help lead to a diagnosis, the test is invasive and only moderately sensitive (50 to 70%), especially if disease is bilateral (37,38). Because a renal arteriogram is both diagnostic and potentially therapeutic when coupled with balloon angioplasty, a captopril renal scan may not be a reasonable step in the evaluation of children with a high likelihood of renal artery stenosis at centers with skilled pediatric interventional radiologists.

A renal perfusion scan with DTPA or MAG-3 may be useful to identify segmental areas of hypoperfusion or infarction, especially those associated with an embolus from an umbilical artery catheter used in the neonatal

period (39,40). Intravenously administered MAG-3 is initially filtered by the glomerulus, then taken up into the kidney primarily by proximal tubular secretion, so MAG-3 can be used for estimation of tubular function as well as renal plasma flow.

Selective renal arteriography with or without digital subtraction angiography enhancement is the gold standard for diagnosis of renal artery stenosis. In a retrospective review of 15 years' experience with renal arteriography in pediatric hypertensive patients, Shahdadpuri and colleagues (41) showed that renal arteriography had a high positive yield, providing diagnostic findings in 40% of cases when performed for the indication of severe hypertension or inability to control hypertension effectively with one drug. Renal arteriography has the added advantage that therapeutic transluminal balloon angioplasty (42–46) or placement of bridging stents (47) can be performed during the same procedure. Balloon angioplasty may be possible even in small children using balloon catheters designed for coronary artery angioplasty (47). The disadvantage of renal arteriography is that it is invasive, exposes the child to nephrotoxic radiocontrast agents, and usually requires general anesthesia for small or uncooperative children (35). Deep conscious

FIGURE 61.4. sedation may be effective for cooperative older children and adolescents. If performed by an experienced interventional radiologist, renal arteriography can be performed safely as a 1-day outpatient procedure for most children. The incidence of severe complications, such as intimal tear or injury, renal artery thrombosis, or branch embolus, is very low in experienced hands. Patients must be observed for 4 to 6 hours after the procedure for possible complications. Arterial puncture carries the risk of hematoma formation at the site and vascular compromise to the extremity.

Magnetic resonance angiography (MRA) is emerging as an accurate and sensitive alternative to renal arteriography for evaluation of renovascular disease in adults, especially those with significant renal failure or heart disease (48–50). Unfortunately, published experience of MRA in pediatric hypertensive patients is limited to studies using technology available in the early 1990s, which is now out of date (51). Current three-dimensional (3D) contrast-enhanced MRA technology allows faster scans of higher resolution within a 20- to 30-second breath hold (49). MRA has the advantages of being minimally invasive (requires only a peripheral intravenous line), avoiding ionizing radiation, and using a nonnephrotoxic contrast agent, gadolinium, which provides excellent imaging of the abdominal vasculature. Direct comparison of MRA results with those of conven-

tional angiography shows that MRA has 100% sensitivity and 95 to 98% specificity for detecting greater than 50% renal artery stenosis in adults (48) and children (51). MRA is not yet as good as conventional angiography for delineating the architecture of accessory renal arteries and distal renal artery fibromuscular dysplasia (23,49), but the technology is still evolving. MRA has been a useful evaluation technique at our center for neonates or infants too small to undergo balloon angioplasty and for children and adolescents in whom the indication for invasive renal angiography is not clear-cut.

MRA has a distinct advantage over spiral computerized tomographic renal angiography (CTRA), which can produce excellent images of the renal vasculature but uses ionizing radiation and requires nephrotoxic radiocontrast agents (23,52). Like MRA, CTRA requires only a peripheral intravenous approach and allows 3D visualization with appropriate software (52). A limited computed tomographic (CT) scan of the abdomen may be performed before CTRA to provide additional information about the anatomy of the kidneys, adrenals, and surrounding structures (23). If MRA and conventional renal angiography are not available or possible, spiral CTRA may be a useful alternative (52).

Plasma renin activity measured in samples from peripheral veins or especially from selective renal veins may provide additional useful information for evaluation of renovascular disease (35,53). Selective sampling of renal vein renins may be done conveniently at the time of renal arteriography to provide supporting evidence for unilateral or bilateral disease. The inferior vena cava above and below the renal veins should be sampled at the same time as the renal veins. If the selective renal vein renin concentration is at least 1.5 times greater than the concentration in the contralateral kidney, the result is diagnostic of renin-mediated hypertension from that kidney (35,53). If the contralateral kidney is normal, renal vein renin concentration should actually be decreased due to downregulation of renin production in the normal kidney from increased circulating angiotensin II (54,55). If the ratio between renal vein renin concentration in the contralateral kidney and that in the caudal inferior vena cava is less than 1.3, then renin production is suppressed in the contralateral kidney (53). The combination of results may be useful to determine whether a patient might benefit from or be cured by surgery (53), in the event that angioplasty is only partially successful or not able to be performed.

Peripheral vein renin levels obtained before initiation of antihypertensive therapy may also be useful in evaluation of renovascular hypertension, if they are abnormal (35). Levels must be interpreted within the age-specific normal values for the laboratory performing the test and in light of estimated sodium intake at the time the sample was drawn. Furthermore, the levels may be adversely affected if the blood is not handled properly after the blood draw. The specimen should be drawn into an ethylenediaminetetraacetic acid tube, immediately placed on ice, spun in a

refrigerated centrifuge, and then kept frozen for later assay. A peripheral renin level that is elevated for age suggests renovascular or renal parenchymal hypertension. A normal level, however, does not exclude significant renovascular hypertension. Low levels of plasma renin in the presence of hypokalemia and elevated plasma and urinary aldosterone levels suggest primary aldosteronism or one of the forms of congenital adrenal hyperplasia as the cause of the hypertension (see the section on endocrine abnormalities later).

Specific Evaluation 2

When the history, physical examination, or screening laboratory evaluation is abnormal, further evaluation should be directed by those results. If the history, physical examination, urinalysis, and other laboratory test results suggest renal artery stenosis or other vascular disease (Table 61.3) or renal parenchymal disease (Table 61.4), evaluation should proceed along the lines outlined in the algorithm presented earlier (Fig. 61.1). If initial screening rules out renal disease but suggests a rare endocrine cause (Table 61.5), evaluation should proceed accordingly (Fig. 61.1).

The need for evaluation for other causes of childhood hypertension, such as neurologic abnormalities, teen pregnancy, drugs, or other illnesses (Table 61.6), should become apparent after a detailed screening history taking and physical examination. The rest of the discussion in

TABLE 61.6. MISCELLANEOUS CAUSES OF HYPERTENSION

Neurologic abnormalities
Elevated intracranial pressure (associated bradycardia)
Recent seizure, status epilepticus
Familial dysautonomia (Riley-Day syndrome)
Quadriplegia with autonomic nervous system dysfunction
Femoral nerve traction
Cyclic vomiting syndrome
Polycythemia; recombinant erythropoietin therapy
Anesthetic drugs
Ketamine
Naloxone
Drug abuse
Cocaine
Amphetamines
Methamphetamines (e.g., ecstasy)
Phencyclidine (PCP)
Methylphenidate
Oral contraceptive use
Teen pregnancy

this chapter is divided into evaluation of hypertension by disease category.

RENOVASCULAR AND CARDIOVASCULAR DISEASE

Renovascular Disease

Multiple types of renovascular abnormalities can lead to hypertension (Table 61.3), but fibromuscular dysplasia is the most common, occurring in approximately 70% of pediatric cases (33,56,57). Most often, the medial layer of the artery is affected, although rarely the intima may be involved, especially in the case of neurofibromatosis type 1 or Williams syndrome (35). Disease may be bilateral or unilateral, but if unilateral, may manifest itself with hypertension from the other kidney at a later date. Multiple stenotic lesions followed by poststenotic aneurysms can resemble a string of beads on a selective angiogram (Fig. 61.5). Branch vessels, as well as peripheral intrarenal vessels, may be involved. Other vessels, including the abdominal aorta, may be stenotic or hypoplastic, especially in association with neurofibromatosis type 1 (Fig. 61.6) or Williams syndrome (58,59). Typically, the lesions of neurofibromatosis are near the origin of the renal arteries (Fig. 61.6), whereas the lesions of fibromuscular dysplasia are often more distal (Fig. 61.7) (33,42). Duplex ultrasonography with color Doppler flow may suggest the diagnosis of these disorders, but renal arteriography is needed for diagnosis and delineation of the extent of the renovascular disease. If the lesion is in the main renal artery and does not involve a long segment of the vessel, transluminal balloon angioplasty may be performed at the same time (Fig. 61.7) (42–44). If the child is too small for

FIGURE 61.5. Renal arteriogram showing typical “string-of-beads” appearance (*arrow*) of fibromuscular dysplasia in the left main renal artery.

balloon angioplasty, hypertension may be controlled with medical therapy, especially ACE inhibitors. Then, a radio-nuclide renal scan is a useful tool to sequentially evaluate the growth and function of the affected kidney during long-term follow-up (Fig. 61.4).

Duplex ultrasonography with color Doppler is a good screening evaluation test for renal transplant artery stenosis (60,61), which usually occurs at or near the surgical anastomosis (60) (Fig. 61.3). The incidence is as high as 10% in

FIGURE 61.6. Abdominal arteriogram in a child with neurofibromatosis type 1 showing long segment tubular stenosis of the aorta with collateral flow as well as severe stenosis of the left main renal artery near its origin (*arrow*). Poststenotic dilatation of the renal artery and delayed uptake of contrast in the left kidney compared to the right are present.

FIGURE 61.7. Renal angiogram for a child showing right main renal artery stenosis from fibromuscular dysplasia pre- and posttransluminal balloon angioplasty. The image after angioplasty shows residual stenosis, but considerable improvement in flow of radiocontrast. DSA, digital subtraction angiography.

children and adults (60,61). Confirmatory arteriography is always necessary (Fig. 61.3), and therapeutic balloon angioplasty may be performed at the same time if indicated. Duplex ultrasonography also may be useful for follow-up to determine continued success or the recurrence of stenosis after balloon angioplasty or surgical intervention (60,61) (Fig. 61.3). MRA may be helpful in equivocal cases (49). However, the presence of metallic surgical clips adjacent to the anastomosis may cause MRA artifacts that mimic stenosis and render the test unreliable.

Mild to severe hypertension is associated with chronic renal allograft nephropathy, the term now used to describe the various processes, including chronic rejection, donor vascular disease, and chronic calcineurin inhibitor nephrotoxicity, that lead to arterial fibrous intimal thickening, interstitial fibrosis, tubular atrophy, and glomerulosclerosis late in the course after renal transplantation (62). The small arteries are affected, so imaging is not useful for diagnosis (60). The diagnosis is made by renal transplant biopsy.

Rarely, hypertension in a child results from extrinsic compression of a renal artery or segment by an extrinsic mass, such as a tumor or traumatic perirenal hematoma. Renal ultrasonography may identify the mass, but MRA technology allows visualization of extensive 3D detail to establish the diagnosis (Fig. 61.8) and direct corrective therapy (49). More than half of patients with Wilms' tumor have concomitant hypertension secondary to either intrarenal vessel compression or renin production by the tumor (63).

Cardiovascular Disease

Coarctation of the aorta accounts for 2% of secondary hypertension in childhood and adolescence but is the underlying disorder in approximately one-third of patients

with hypertension seen in the first year of life (64,65). Aortic coarctation may be focal (juxtaductal), diffuse (hypoplastic aortic isthmus), or complete (aortic arch interruption) (66). Screening evaluation of the hypertensive child suggests coarctation when blood pressure is at least 10 mm Hg higher in the right arm or in both arms than in the legs, and the femoral pulses are diminished. A systolic ejection murmur of low intensity may be heard over the base of the heart and precordium and radiates into the left interscapular region. The murmur may be louder over the back. The older child who has developed collateral circulation may have a continuous murmur over large collateral intercostal arteries. When coarctation is suspected on the basis of screening evaluation, the patient should be referred to a pediatric cardiologist for further evaluation.

Echocardiography with color Doppler flow may identify a characteristic wedge-shaped band of tissue to confirm the diagnosis and measure any gradient across the coarcted segment (67–69). The transverse aortic arch also should be imaged to evaluate for hypoplasia. Magnetic resonance imaging (MRI) and MRA are being used increasingly for primary evaluation of thoracic coarctation in children over 4 or 5 years of age or for follow-up after angioplasty or surgical correction (66,70–73). Echocardiography is difficult after surgical repair because of the presence of scar tissue and thorax deformities, which limit the acoustic window. MRI technology, including 3D gadolinium-enhanced MRA, allows excellent visualization of the anatomy of the aorta, estimates the pressure gradient based on peak flow velocity across the stenosis, assesses collateral aortic circulation, and permits a 3D view of the full extent of the aorta (66,71). Conventional angiography still remains the gold standard and allows direct measurement of the pressure gradient across the coarctation, but MRI technology may

FIGURE 61.8. Images from a three-dimensional gadolinium-enhanced magnetic resonance angiography (MRA) for a teenager with new-onset severe hypertension. MRA shows that each kidney is supplied by two renal arteries (**A**). The right kidney and left upper pole kidney provide prompt nephrograms, but perfusion of the lower two-thirds of the left kidney is delayed (**A,B**) secondary to compression of the left lower renal artery by a 4-cm paraspinous soft tissue mass (*arrow*) (**C**).

become an adequate replacement in the near future, especially with new technology (66,72).

Other uncommon forms of cardiovascular disease lead to hypertension in infants and children (Table 61.3). Middle aortic syndrome, a rare entity that may be congenital, acquired from aortitis or vasculitis, or associated with genetic diseases such as neurofibromatosis (Fig. 61.6) or Williams syndrome, may lead to severe life-threatening hypertension as well as lower extremity claudication and mesenteric ischemia (20, 33,74–78). Diagnosis is made by conventional abdominal angiography, which shows tubular stenosis of the aorta and its visceral branches. MRA with gadolinium enhancement may eventually replace angiography in the initial evaluation of middle aortic syndrome, because MRA is much less invasive and gives excellent 3D detail.

Williams syndrome or Turner syndrome should be suspected during screening evaluation because of typical physical findings, including the elfin facies of Williams syndrome and the short stature and webbed neck of Turner syndrome. A variety of cardiovascular abnormalities that can cause hypertension are associated with Williams syndrome, includ-

ing supravalvular aortic stenosis and thoracic coarctation (58,76,79). Patients with Turner syndrome have a high incidence (20 to 50%) of cardiovascular malformations, including coarctation of the aorta, bicuspid aortic valve, and aortic root dilatation, as well as a high incidence of cardiovascular disease morbidity and mortality as adults (80–83). Hypertension per se may contribute to cardiovascular disease as adults (81–83). ABPM in 75 girls with Turner syndrome revealed abnormal blood pressure circadian rhythm in 50%, suggestive of secondary hypertension (83).

RENAL PARENCHYMAL DISEASE

Most children with secondary hypertension (60 to 80%) have renal parenchymal disease (84,85). A variety of glomerular and a few tubular or interstitial renal disorders may cause hypertension in children and adolescents (Table 61.4). The most common renal parenchymal disorders associated with hypertension are glomerulonephritis and reflux nephropathy (85,86). Further evaluation for renal parenchymal disease is

FIGURE 61.9. Dimercaptosuccinic acid (DMSA) radionuclide scan for evaluation of renal scars. **A:** Technetium 99m-DMSA radionuclide scan for a 9-year-old who presented with hypertension and Bell's palsy, showing right upper pole renal scar (arrow) and poorly functioning smaller left kidney (relative activity 29%) from vesicoureteral reflux. **B:** Kidney from a different patient showing an upper pole scar from vesicoureteral reflux.

dictated by findings of the screening history and physical examination or abnormal complete blood count, urinalysis, or levels of BUN, serum creatinine, or electrolytes (Fig. 61.1). Hematuria, proteinuria, red blood cell casts on urinalysis, and edema suggest glomerulonephritis. Other systemic signs and symptoms, such as purpuric or malar rash, arthritis, and abdominal pain, are suggestive of systemic vasculitis. Anemia and short stature for age in the presence of elevated BUN and serum creatinine levels are characteristic of chronic renal failure, which can result from most of these diseases. Additional laboratory studies, including serum levels of C3 and C4, anti-glomerular basement membrane antibody, antinuclear antibody, anti-double-stranded DNA, and antineutrophil cytoplasmic antibody, may help make the diagnosis of a specific glomerulonephritis or systemic vasculitis, but a renal biopsy is almost always needed for definitive diagnosis. The diagnosis of hemolytic uremic syndrome may be made clinically, if microangiopathic hemolytic anemia, thrombocytopenia, and uremia are present. These diseases are all discussed in detail in other chapters of this book.

Some hereditary diseases are frequently associated with hypertension. These include autosomal recessive and dominant polycystic kidney disease, medullary cystic disease, juvenile nephronophthisis, Denys-Drash syndrome, and sickle cell disease. Diagnostic evaluation of these disorders is discussed in detail in other chapters of this book. Liddle's syndrome (pseudoaldosteronism) is a familial syndrome characterized by

severe hypertension, hypokalemia, metabolic alkalosis, and decreased plasma renin activity and aldosterone levels (87–89). Originally thought to be an endocrine disorder, Liddle's syndrome is known now to result from a primary defect in renal tubular sodium handling that can be suppressed by amiloride therapy with dietary sodium restriction. A mutation in the renal epithelial sodium channel located in the luminal membrane of the collecting duct leads to avid unregulated sodium reabsorption, volume expansion, hypertension, and renal potassium wasting. The gene has been mapped to locus 16p13-p12. The precise mechanism of the abnormal activation of the sodium channel is still under investigation.

Hypertension associated with congenital renal anomalies, especially vesicoureteral reflux, typically presents in late childhood or early adolescence and may be the first sign of disease (19,86). Screening renal ultrasonography may be diagnostic but at least will direct further specific evaluation. Specific evaluation for vesicoureteral reflux should include taking a detailed history to identify undiagnosed fevers or documented urinary tract infections in early childhood and obtaining a voiding cystourethrogram, which can both diagnose and grade reflux. The absence of reflux does not negate the possibility that reflux was present in infancy and early childhood and then spontaneously resolved, but left the child with renal scars and reflux nephropathy. Results of a urinalysis and urine culture should be negative for urinary tract infection before one proceeds with a voiding cystourethro-

FIGURE 61.10. Ask-Upmark kidney. **A:** Technetium 99–diethylenetriaminepenta-acetic acid (DTPA) radionuclide scan showing right kidney smaller than left. **B:** Selective right renal arteriogram showing no filling of lower pole of right kidney; left kidney with late nephrogram of previous radiocontrast injection. **C:** Intraoperative photograph showing small lower pole of right kidney (*arrow*). **D:** Light microscopy of the junction of the normal portion of the kidney with the hypoplastic lower pole segment (periodic acid–Schiff stain).

gram. Children previously diagnosed with vesicoureteral reflux or other congenital anomalies, such as unilateral multicystic dysplastic kidney found in the neonatal period, may be normotensive at diagnosis and may develop hypertension later in life. Unfortunately, no test is available to predict the risk for developing hypertension, so regular follow-up of blood pressure is recommended (86). To detect the presence of renal scars, a DMSA radionuclide scan is preferred over conventional urography or ultrasonography (90,91). DMSA is filtered and then reabsorbed by the renal tubule to become fixed in the parenchyma, which provides a static image of functional renal tissue (92). Absence of uptake is consistent with a nonfunctioning scar as illustrated by Figure 61.9.

Segmental hypoplasia with atrophy, known as the Ask-Upmark kidney (Fig. 61.10), is a scarred, shrunken segment of the kidney characterized histologically by the presence of colloid-filled tubular microcysts and few or absent glomeruli (93,94). Whether this defect is congenital or the result of injury from vesicoureteral reflux or urinary tract infection is uncertain (94). Partial nephrectomy cures the associated hyper-

tension. Renal arteriography with selective renal vein renin sampling is helpful to identify the exact location and extent of the hypoplastic segment before surgery is undertaken (95).

ENDOCRINE ABNORMALITIES ASSOCIATED WITH HYPERTENSION

Endocrine causes of hypertension in childhood are rare but usually treatable and often curable (96). Specific evaluation should be directed by the suspected disorder (Fig. 61.1). The combination of a good history taking and physical examination, accurate interpretation of screening laboratory data, and sequential ordering of diagnostic tests leads to a diagnosis and is still efficient and cost effective.

Pheochromocytoma

Pheochromocytoma is quite rare in all age groups (96,97) and accounts for fewer than 1% of the cases of secondary

FIGURE 61.11. Diagnostic imaging for pheochromocytoma. **A:** Abdominal computed tomographic scan showing a 3-cm mass with central calcifications (*arrow*) located superior to the left kidney in the left adrenal gland. **B:** Iodine 123 meta-iodobenzyl guanidine (MIBG) scan showing uptake in right adrenal mass (*arrow*).

hypertension in childhood (64). Children are more likely to have multiple tumors, recurrence of tumors, and a positive family history of related tumors (96). Pheochromocytomas are chromaffin cell tumors that arise from the adrenal gland. When they arise in extra-adrenal positions in the autonomic nervous system of the abdomen, thorax, neck, or head, they are more specifically termed *paragangliomas* but are often referred to as extra-adrenal pheochromocytomas (97). Children with pheochromocytomas may present with the classical clinical triad of episodic hypertension, headache, and sweating, but hypertension is sustained approximately 80% of the time in children (96). Other symptoms include pallor, flushing, visual disturbances, abdominal pain, nausea, vomiting, and weight loss. Physical examination may reveal hypertensive retinopathy, features of associated syndromes such as the café-au-lait spots of neurofibromatosis, or rarely an abdominal mass, the palpation of which may lead to an abrupt increase in blood pressure and other symptoms of catecholamine release (96).

Pheochromocytomas in childhood may be sporadic but are familial approximately 30% of the time (96). Advances in genetic mutation analysis have improved identification of familial disease, which allows detection of affected children at an early age, before typical signs and symptoms occur (97). Familial disease is seen mainly in patients with von Hippel–Lindau disease, multiple endocrine neoplasia type 2, neurofibromatosis, or familial carotid body tumors. If pheochromocytoma is the primary manifestation of the family disease, a von Hippel–Lindau gene mutation is the most likely cause, whereas most of the patients with multiple endocrine neoplasia type 2 have medullary thyroid carcinoma.

Pheochromocytoma is a potentially curable cause of severe and sometimes life-threatening bouts of hyperten-

sion (96,99), so a thorough evaluation to make the diagnosis is important. Specific evaluation for pheochromocytoma (Fig. 61.1) should start with measurement of plasma metanephrine levels, which are elevated in 80% of patients even when the individuals are asymptomatic (98). Periodic screening with this test can lead to early diagnosis in children with familial disease (97). If the levels are normal, the diagnosis may be excluded. If the levels are only marginally increased, further evaluation with repeated measurement of plasma metanephrines plus plasma catecholamines, or a clonidine or glucagon test should be performed by a clinician experienced with these tests. Plasma concentrations of normetanephrine greater than 2.5 pmol/mL or plasma concentrations of metanephrine greater than 1.4 pmol/mL indicate the presence of pheochromocytoma with 100% specificity and warrant proceeding directly to imaging studies to locate the tumor (97).

The first step in imaging should be a CT or MRI scan of the abdomen (97). CT detects adrenal pheochromocytomas with 93 to 100% sensitivity (Fig. 61.11A) but has only 90% sensitivity for extra-adrenal tumors. MRI has high sensitivity for detecting both. CT and MRI cannot delineate whether a mass is a pheochromocytoma or another adrenal or soft tissue tumor. As an example, the paraspinal tumor depicted by MRA in Figure 61.8 was unexpectedly identified as a paraganglioma histologically after surgical removal. To identify pheochromocytomas preoperatively, the next step should be meta-iodobenzyl guanidine (MIBG) scanning (Fig. 61.11B). MIBG, which localizes in storage granules in adrenergic tissue of neural crest origin, is very specific (95 to 99%) for pheochromocytoma and neuroblastoma in children (100,101). Iodine 123 MIBG offers better imaging quality than iodine 131 MIBG (97). False-negative MIBG results can occur, particularly if tumors are small or in the

thorax, neck, or head. Repeated examinations may be necessary to finally localize small tumors. Once localized, the pheochromocytoma may be surgically removed and cures hypertension in 90% of cases (96). Only approximately 10% of childhood pheochromocytomas are malignant (96).

Renin-Producing Tumors

The possibility of a renin-secreting tumor, such as a juxtaglomerular cell tumor (102,103) or Wilms' tumor (63,104), should be entertained in a hypertensive child with hypokalemia, elevated plasma renin activity, and absence of other obvious renal or renovascular disease. For juxtaglomerular cell tumors, abdominal CT or MRI imaging identifies small masses better than does selective renal arteriography, the results of which are normal in approximately 50% of reported cases (103).

Thyroid Disorders

Mild hypertension may be associated with hyperthyroidism from Graves' disease or rarely thyroid adenoma (96). Acquired hypothyroidism in adults is associated with hypertension and is reversible with thyroid replacement therapy in approximately 50% of cases (105). The first step in specific evaluation of thyroid disease is assessment of serum thyroxine and thyroid-stimulating hormone concentration to make the diagnosis of hyperthyroidism or hypothyroidism (Fig. 61.1). Further evaluation is probably best accomplished by referral to a pediatric endocrinologist.

Cushing Syndrome

Exogenous glucocorticoid or adrenocorticotrophic hormone (ACTH) therapy, including that used for treatment of asthma, renal disease, rheumatologic disease, neurologic disorders, and cancer or transplantation immunosuppression, is the most common cause of Cushing syndrome and endocrine-associated hypertension in pediatric patients (96). On the other hand, excess endogenous production of glucocorticoids or ACTH from an adrenal or pituitary tumor is unusual in childhood. Obvious physical changes of glucocorticoid excess, including round facies, plethora, truncal obesity, acne, easy bruisability, and abdominal striae, may direct the physician to the diagnosis. If the patient is receiving no glucocorticoid medications, screening by measurement of an 8 a.m. plasma cortisol level, ACTH level, and 24-hour urinary excretion of 17-hydroxycorticosteroids and free cortisol may be appropriate, if referral to a pediatric endocrinologist is not readily available.

Hyperaldosteronism

Hypertension associated with adrenal tumors or idiopathic adrenal hyperplasia is usually mediated by aldoster-

one or other compounds with mineralocorticoid effects (96). Mineralocorticoid excess leads to salt and water retention, volume expansion, and renal potassium wasting. Hypertension in the presence of hypokalemia and metabolic alkalosis found on screening evaluation should direct the specific evaluation to that for hyperaldosteronism (Fig. 61.1). If plasma renin activity is low, plasma and 24-hour urinary aldosterone levels should be measured. Urinary aldosterone level is elevated in the presence of high plasma aldosterone concentration and decreased in the presence of other compounds with mineralocorticoid effect. Imaging of the adrenal glands with CT or MRI should be the next step for diagnosis and localization of adrenal adenoma or carcinoma in patients with hyperaldosteronism (96).

Congenital Adrenal Hyperplasia

Only two enzyme deficiencies in the cortisol pathway are associated with hypertension, 11 β -hydroxylase (96,106) and 17 α -hydroxylase (96,107). Deficiency of 11 β -hydroxylase is the second most common cause of congenital adrenal hyperplasia but accounts for only approximately 5% of cases (96). Deficiency of 11 β -hydroxylase is an autosomal recessive disorder caused by mutations of the CYP11B1 gene located on chromosome band 8q21-q22 (106). An 11 β -hydroxylase deficiency results in decreased conversion of 11-deoxycortisol to cortisol and 11-deoxycorticosterone (DOC) to corticosterone, and excess production of androgens from precursors more proximal in the pathway. Decreased cortisol production stimulates secretion of pituitary ACTH, which results in adrenal stimulation and excess production of DOC. DOC has mineralocorticoid effects at high concentration. The excess androgen production results in virilization and ambiguous genitalia in female infants and penile enlargement in males. Hypertension, hypokalemia, and low plasma renin activity are present in most, but not all, affected patients. Referral to a pediatric endocrinologist for more extensive laboratory evaluation is an appropriate next step. Characteristic findings are elevated plasma concentrations of 11-deoxycortisol and DOC and the androgens dehydroepiandrosterone (DHEA) and testosterone, as well as increased urinary excretion of 17-hydroxycorticosteroids, tetrahydro-11-deoxycortisol, and 17-ketosteroids (108). ACTH stimulation testing may be needed to make or confirm the diagnosis, especially in adolescents.

Deficiency of 17 α -hydroxylase is very rare, occurring in less than 1% of cases of congenital adrenal hyperplasia (96). The trait is autosomal recessive and caused by mutations in the CYP17 gene on chromosome band 10q24-q25 (107). This enzyme has both 17 α -hydroxylase and 17,20-lyase (desmolase) activity (109,110). The enzyme 17 α -hydroxylase normally facilitates conversion of progesterone to 17-hydroxyprogesterone and conversion of pregnenolone to

17-hydroxypregnenolone, which lead to the production of cortisol. The enzyme 17,20-lyase is required for the synthesis of androgens and estrogenic C18 steroids. Deficiency of the enzyme limits synthesis of cortisol as well as androgens and estrogens. Unlike patients with 11 β -hydroxylase deficiency, patients with 17 α -hydroxylase deficiency are not virilized and thus may not be diagnosed before discovery of their hypertension, hypokalemia, and hypogonadism in adolescence. Girls have primary amenorrhea and absent secondary sexual characteristics. Boys usually have complete male pseudohermaphroditism with female external genitalia, a blind vagina, absent uterus, and intraabdominal testes. Laboratory evaluation reveals increased serum progesterone and DOC levels and reduced plasma cortisol, 11-deoxycortisol, DHEA, testosterone, and estradiol concentrations. These cases are very rare and are best evaluated by referral to a pediatric endocrinologist.

Hypercalcemia

Hypercalcemia is well known to cause hypertension as well as polyuria, constipation, abdominal pain, anorexia, and mental status changes. In pediatric cases, the cause is most often vitamin D intoxication, Williams syndrome, or malignancy, and rarely primary hyperparathyroidism (96). Evaluation should include measurement of serum levels of total and ionized calcium, phosphorus, parathyroid hormone, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D (Fig. 61.1).

MISCELLANEOUS CAUSES OF HYPERTENSION

Table 61.6 lists a number of miscellaneous causes of hypertension, including some drugs that should be considered in the evaluation of the hypertensive child. In all adolescents or younger children at high risk for drug abuse, a urine drug screen should always be performed as part of the initial evaluation. A few of the other causes of hypertension in children are discussed in more detail here.

Neurologic Abnormalities

A variety of neurologic disorders give rise to hypertension (Table 61.6). In the critically ill child with rising blood pressure and falling heart rate, evolving increased intracranial pressure should always be suspected. The incidence of intracranial pressure is especially high with acute meningitis or encephalitis (111). Children with seizures and status epilepticus may present with hypertension (112). If blood pressure in the postictal period is high but is less than 4 standard deviations above the mean, hypertension is more likely to be transient and seizure induced rather than caused by hypertensive encephalopathy with seizures (112). Disorders of the autonomic nervous system may also lead

to hypertension. Familial dysautonomia is the best known of these disorders (113–115). Clinical features include paroxysmal hypertension, swallowing difficulties, speech and motor incoordination, and pain insensitivity. Clinical diagnosis is based on the findings of Ashkenazi Jewish heritage, diminished tear production, lack of an axon flare after intradermal histamine, lack of lingual fungiform papillae, and decreased deep tendon reflexes. The gene for this disorder, IKBKAP, has been isolated and mapped to chromosome band 9q31.

Teen Pregnancy

Pregnant teenagers are at high risk for developing hypertension, which increases their risk for poor outcomes for the baby, including low birth weight, preterm delivery, and congenital malformations (116–118). When hypertension occurs early in gestation, hospitalization with strict supervision and control of blood pressure may be required. Ultrasonographic imaging for evaluation of hypertension is acceptable, but conventional radiographic studies and radioisotopic scans should be avoided because of potential adverse effects on the fetus. ACE inhibitors and angiotensin receptor blockers are teratogenic, and their use in pregnancy is contraindicated (119,120). Pubertal and postpubertal girls with antecedent hypertension should be advised to protect against pregnancy while taking these medications for control of hypertension (120). When preeclampsia or severe hypertension occurs after 36 weeks' gestation, delivery is the therapy of choice. If a teenager with known hypertension becomes pregnant, evaluation should always include serial reassessment of maternal renal function throughout pregnancy.

TREATMENT OF HYPERTENSION

BETH A. VOGT
IRA D. DAVIS

This chapter reviews nonpharmacologic and pharmacologic interventions used to treat hypertension. Therapeutic plans for various causes of hypertension are also discussed.

NONPHARMACOLOGIC TREATMENT OF HYPERTENSION

To the physician, nonpharmacologic therapy of hypertension is appealing. Interventions such as dietary salt restriction, mineral supplementation (potassium, calcium, magnesium), weight loss, exercise, and lifestyle modification (alcohol, cigarettes, stress) are inexpensive, provide health benefits in addition to their blood pressure (BP)-lowering effects, and can delay or prevent the need for antihypertensive medications.

Is there any value in using nonpharmacologic therapies as first-line treatments for mild or moderate hypertension (or as an adjunct to medications in more serious forms of hypertension), when effective, safe, and well-tolerated medications exist? For most children and adolescents, the long-term complications of hypertension have little relevance to their daily life. It is difficult to predict which patients and families will embrace lifestyle modifications necessary for successful nonpharmacologic BP reduction. Currently, the National High Blood Pressure Education Program Task Force report on high blood pressure in children and adolescents recommends the introduction of nonpharmacologic interventions to all children with high-normal BPs (ninety to ninety-fifth percentile for age and height) and those with documented hypertension (1).

Dietary Salt Restriction

There is ample evidence from studies of adults demonstrating that high salt intake adversely affects BP. Observational studies of diet and BP have shown that populations with high dietary salt intake have higher BPs than those with lower salt intake (2,3). In addition, multiple clinical trials have shown that reduced salt intake lowers BP (4–6). It is clear that certain subpopulations, including African Ameri-

cans; the elderly; and individuals with obesity, diabetes, or renal dysfunction, tend to be more *salt-sensitive* than other populations.

The mechanisms by which excess dietary salt intake may contribute to hypertension are not well understood. One theory suggests that kidneys of hypertensive individuals may have a physiologic defect in their ability to excrete sodium (7). Normally, renal sodium excretion increases when there is an acute increase in BP; in individuals with hypertension, the BP required to excrete a given sodium load is higher and is described as a rightward shift in the pressure-natriuresis curve. The mechanisms leading to this shift in the curve remain uncertain, but may involve (a) a congenital reduction in the number of nephrons limiting sodium filtration (8), (b) genetic alterations in the expression of vasoactive mediators involved in renal sodium handling (9), or (c) a reduction in renal medullary blood flow, leading to local tissue ischemia and sodium retention (10).

Many pediatric intervention studies, in which patients receive a low-salt diet, have failed to demonstrate a diet-specific reduction in BP (11–14). However, several pediatric studies have demonstrated small but measurable reductions in BP (15–17), and a number of interventional trials suggest a beneficial effect of a low-sodium diet in hypertensive adults (4–6).

In the future, research may improve our ability to identify those children and adolescents most likely to benefit from dietary salt restriction. Because dietary salt intake is generally so high in Western countries (average adult intake = 150 mEq Na or 3500 mg Na/day), we currently recommend daily intake of no more than 2400 mg sodium for all children and adolescents with high-normal BP or hypertension (18). Families must be educated that added salt represents only a small proportion of total daily dietary salt intake. Prepared foods, breads, and fast food restaurant items tend to contain large amounts of salt added during food processing. Families should be encouraged to read food package labels, which in the United States and Western Europe contain extensive information about sodium content. Health care providers should provide guidance in

interpreting those labels to families interested in reducing sodium intake. Initial consultation and longitudinal follow-up with a qualified dietitian may be particularly beneficial.

Mineral Supplementation

Observational and interventional studies suggest that the adequate mineral content of the diet may be linked to BP variability, in particular salt sensitivity. Therefore, there have been attempts to improve BP control using oral potassium, calcium, and magnesium supplements.

In epidemiologic studies, high dietary potassium intake has been found to be associated with lower BP (19). The mechanisms by which potassium exerts its antihypertensive effects include induction of natriuresis, decreasing urinary calcium excretion, and altering systemic vascular and renal resistance (20). There is evidence of a BP-lowering effect of oral potassium supplementation in adults (21); however, there are no reports to date of a beneficial effect in hypertensive children or adolescents.

Dietary calcium intake has also been found to be inversely related to BP (22). Increased calcium intake may impact BP through a variety of mechanisms, including alteration of vascular smooth muscle tone and cardiac muscle contractility. Dietary calcium supplementation in hypertensive adults yields minimal reductions in BP (23). Although some individuals may benefit more than others, there is currently no way to identify which individuals with hypertension might respond to dietary calcium supplementation. There is no clinical evidence to support dietary calcium supplementation in the pediatric hypertensive patient.

Epidemiologic studies examining dietary magnesium intake (24), as well as the clinical efficacy of magnesium in the treatment of preeclampsia-associated hypertension, suggest that magnesium supplementation may be of benefit in the treatment of chronic hypertension. However, trials of magnesium supplementation have demonstrated minimal (25) or no effect (26) on decreasing BP in adults. There is currently no indication for dietary magnesium supplementation in hypertensive adults or children.

The most compelling evidence supporting a beneficial effect of increased mineral intake comes from the DASH (*Dietary Approaches to Stop Hypertension*) clinical trial (27). In the DASH study, adults consumed a healthy diet that was rich in fruits, vegetables, and low-fat dairy products. The DASH diet provided intake of potassium, calcium, and magnesium at the seventy-fifth percentile of U.S. consumption, while maintaining daily sodium intake at 3 g. In hypertensive adults, the systolic BP was reduced by 11.4 mm Hg and the diastolic BP by 5.5 mm Hg. It is theorized that the increased intake of all three minerals provided by the DASH diet led to an additive effect on BP reduction not previously seen in clinical trials involving supplementation of individual nutrients. On the basis of these data, we recommend that children and adolescents with hypertension consume a

healthy diet, rich in fruits, vegetables, and low-fat dairy products similar to the DASH diet, rather than recommending specific nutritional supplements.

Weight Loss

The prevalence of childhood obesity has increased worldwide, particularly in developed nations, as a result of easy access to calorically dense foods and an increasingly sedentary lifestyle (28). Obese children have increased rates of hypertension, as well as other adverse cardiovascular risk factors, including hyperlipidemia and insulin resistance (29).

The mechanisms by which excessive body fat increases BP are complex and likely multifactorial. There is general agreement that obesity-associated hypertension is associated with excessive fluid retention (30), possibly caused by increased sympathetic nervous system activity (31,32), insulin resistance (33), or increased activity of the renin-angiotensin-aldosterone system (34).

Traditionally, obesity has been defined as a weight in excess of 120% of the median weight for a given height or a weight for height greater than the ninetieth percentile on the growth charts from the National Center for Health Statistics. Recently, the body mass index [BMI; weight (kg)/height (m)²] has been added to the revised 2000 pediatric growth charts and become a useful tool in assessing pediatric obesity (35). A child with a BMI greater than the ninety-fifth percentile for a child of the same age and gender is defined as obese, whereas a child with a BMI greater than the eighty-fifth percentile and less than or equal to the ninety-fifth percentile is considered at risk for obesity.

Reduction of body fat through diet and exercise is an effective way to reduce BP (36–38). Strategies for weight reduction should include counseling regarding the benefits of healthy eating habits and less sedentary lifestyles. In addition, population-based approaches should be initiated, as even small reductions in the percentage of obese patients would significantly lower the incidence of adult cardiovascular disease. In addition, Rocchini (30) has outlined a treatment plan for obese children that recognizes the importance of family participation in an exercise program (Fig. 62.1). The clinician should stress that weight loss is important in obese children, not only to reduce BP, but also to decrease the risk of other obesity-associated complications, including type II diabetes, obstructive sleep apnea, orthopedic complications, cholelithiasis, hepatic steatosis, pseudotumor cerebri, polycystic ovary disease, and psychological consequences, including depression and behavioral problems.

Exercise

There is abundant evidence that regular exercise of mild to moderate intensity lowers BP in both children and adults (39–41). In addition, interventional trials have shown that regular exercise can lead to regression of left ventricular hypertrophy, a

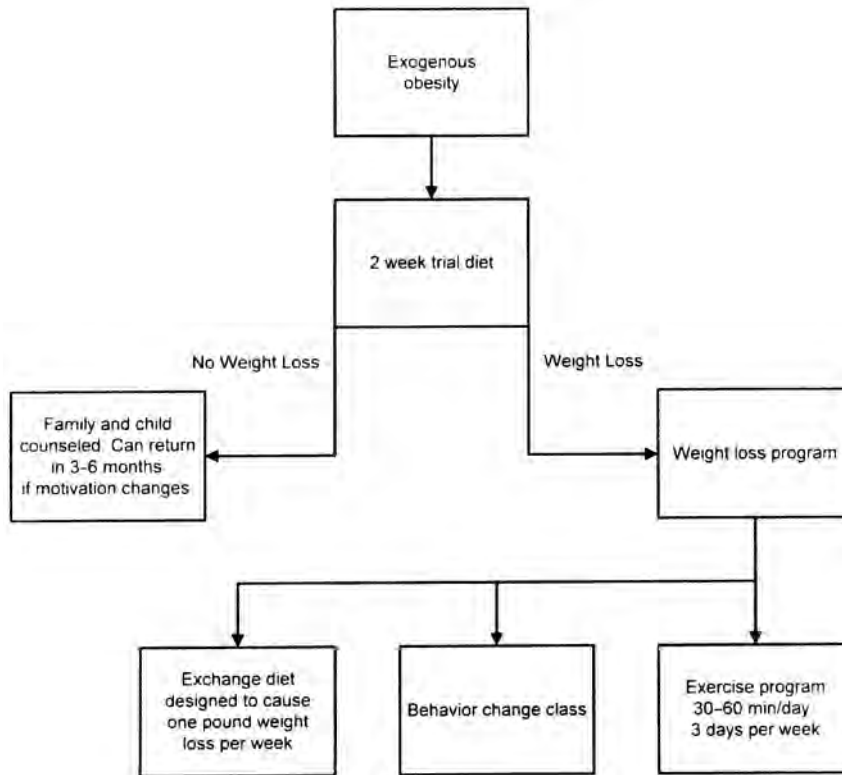

FIGURE 62.1. Suggested treatment plan for obese children. [From Rocchini AP. Adolescent obesity and hypertension. *Pediatr Clin North Am* 1993;40(1):81-92, with permission.]

finding that is recognized as an independent risk factor for cardiovascular disease (42,43). The underlying mechanisms by which exercise reduces BP are not well understood. Exercise may reduce BP by leading to weight loss, but there is general agreement that additional independent mechanisms exist. These mechanisms may include decreased sympathetic tone, decreased insulin resistance, altered baroreceptor responsiveness, increased endorphin production, decreased plasma volume, improved endothelial function, and decreased systemic vascular resistance (44).

Aerobic (dynamic) exercise involves repetitive low resistance movements over a long period of time, usually more than 10 minutes. Aerobic activities include walking, running, swimming, soccer, and basketball. These activities increase cardiac output and mean BP, but they may decrease or only slightly increase diastolic BP and decrease peripheral vascular resistance. Aerobic exercise can be characterized as low intensity [35 to 59% of age-predicted maximal heart rate (PMHR)], moderate intensity (60-79% of PMHR), and high intensity (80% or higher of PMHR). *Anaerobic* (also known as *isometric* or *static*) exercise involves high resistance, low repetition movements over short periods of time (1 to 3 minutes). These activities, which include weight lifting, are characterized by increases in both systolic and diastolic BPs, increased peripheral vascular resistance, and increased cardiac output.

Regular aerobic exercise is strongly recommended as a lifestyle modification for children and adults with hypertension (1,45). Although some studies have shown BP ben-

efits of isometric exercise (46,47), the American College of Sports Medicine does not recommend it as the only form of exercise for hypertensive patients (48).

Clinicians should advise children and adolescents with hypertension or high-normal BP to adopt an active lifestyle with regular aerobic exercise. Unfortunately, in the twenty-first century, physical activity has diminished significantly in children and adolescents, particularly adolescent girls. In all parts of the world, automobiles have replaced walking, and sedentary entertainment exceeds active leisurely pursuits (49). Clinicians should assess the amount of time spent in sedentary leisure activities (television viewing, video games) versus the amount of time spent in organized sports, outdoor play, and physical education classes. Parents should be advised to set time limits for sedentary activities and to schedule a daily time for physical activity. Optimally, all children and adolescents should participate in regular (4 to 5 times/week) activities that involve low to moderate intensity aerobic exercise to maintain optimal cardiovascular health (50).

Media reports of sudden death in competitive athletes have created unwarranted fear in active children and adolescents with hypertension. The largest theoretic risk occurs for those patients with extreme hypertension who choose to participate in weight and power lifting, bodybuilding, and strength training. To date, no episodes of sudden death in children or adolescents during exercise have been attributed to hypertension alone. The American Academy of Pediat-

rics Committee on Sports Medicine and Fitness recommends that the presence of significant hypertension in the absence of target organ damage or concomitant heart disease should not limit a person's eligibility for competitive athletics (51). Children and adolescents with severe hypertension should be restricted from competitive sports and highly static (isometric) activities until their hypertension is under adequate control and they have no evidence of target organ damage.

Hyperlipidemia

Hyperlipidemia, in particular elevated low-density lipoprotein cholesterol, is recognized as the primary target for risk factor modification in adults to prevent cardiovascular disease (52). Although routine lipid screening is recommended for all adults older than 20 years, routine screening for hyperlipidemia is not recommended in the general pediatric population. The National Cholesterol Education Program of the National Institutes of Health's National Heart, Lung, and Blood Institute National Cholesterol Education Program suggests selective screening of children whose parents or grandparents have a history of atherosclerotic disease or hyperlipidemia, as well as those children with additional risk factors, including hypertension, obesity, and smoking (53).

Because of the combined risks of hyperlipidemia and hypertension, we recommend measurement of fasting lipid profiles in all children and adolescents with hypertension. Initial treatment for children and adolescents found to have lipid abnormalities (hypertriglyceridemia, elevated low-density lipoprotein cholesterol, decreased high-density lipoprotein cholesterol) should include the American Heart Association Step I diet, regular aerobic exercise, and weight loss. Children whose lipid profiles do not improve using this approach should be changed to the American Heart Association Step II diet. Although their use is limited in the pediatric population, lipid-lowering medications may be considered in children refractory to dietary and lifestyle modification, particularly those with familial dyslipidemias or medical conditions that result in altered lipid profiles, such as nephrotic syndrome, end-stage renal disease, or renal transplantation.

Tobacco Use

Cigarette smoking remains a significant problem in adolescents. Sixty-four percent of surveyed U.S. high school students report lifetime smoking (any previous use of cigarettes), 28.5% report current smoking (smoking on 1 or more of the 30 days preceding the survey), and 13.8% report current frequent smoking (smoking on 20 or more of the 30 days preceding the survey) (54). Although these percentages suggest a continued problem with tobacco, the data actually demonstrate a steady decline in tobacco use since 1999, possibly

related to national smoking prevention campaigns, increased school-based efforts to prevent tobacco use, and a 70% increase in the retail price of cigarettes between 1997 and 2001. Tobacco use was highest among white adolescents, followed by Hispanic and African American adolescents. The putative causes of adolescent smoking include high levels of stress in individuals with deficient coping resources, peer pressure, and social factors, as well as neurochemical dependence on nicotine (55).

All children and adolescents, particularly those with hypertension, should receive preventative counseling on the health dangers of initiating tobacco use. Hypertensive adolescents who are currently smokers should be strongly urged to discontinue all tobacco use. Smoking cessation programs in adolescents have had varied success in the face of peer pressure, family influences, and social forces but should nevertheless be part of any treatment plan for hypertension.

PHARMACOLOGIC TREATMENT OF HYPERTENSION

Although nonpharmacologic therapies may be effective in reducing BP in children and adolescents with essential hypertension, antihypertensive medications are usually necessary in patients with secondary hypertension or target organ involvement. Pharmacologic therapy is also important in hypertensive patients unwilling to make lifestyle changes. Therapies most likely to be effective are those with simple dosing regimens and minimal side effects.

Pharmacologic treatment of hypertension in children is limited by a lack of controlled clinical trials to assess safety and efficacy, as well as the absence of age-specific pharmacokinetic data for most agents. Many of the reports are limited by retrospective design, small sample size, and absence of a control group. Most pediatric dosing regimens have been simply extrapolated from adult data. As a result, the U.S. Food and Drug Modernization Act of 1997 now grants patent exclusivity to pharmaceutical companies that conducted pediatric safety and efficacy studies. This has led to an increasing number of appropriate pediatric studies (56).

The following sections review the major classes of antihypertensive medications found to be useful in children and adolescents and discusses specific use in hypertensive emergencies, essential hypertension, hypertensive athletes, neonatal hypertension, and chronic kidney disease. Dosing guidelines are based on either specific pediatric data or "best practice" guidelines used by most pediatric nephrologists and cardiologists.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors are widely used in the management of both essential and secondary hypertension in pediatric patients. ACE inhibitors prevent

the conversion of angiotensin I to angiotensin II (AII), reducing AII-induced vasoconstriction and aldosterone release. In addition, ACE inhibitors indirectly reduce BP by their effects on vasopressin, atrial natriuretic factor, prostaglandins, and sympathetic nervous system activity. Finally, ACE inhibitors inhibit kininase II, which may reduce BP by increasing circulating levels of vasodilatory bradykinins.

Captopril and enalapril were the first ACE inhibitors to be widely used in children (57,58). Because of its relatively short half-life and the ability to carefully titrate dosages by grinding tablets into a powder, captopril is widely used in neonates and in younger children. Dosing every 6 to 8 hours usually results in stable BP control, although some patients may be successfully treated with twice-daily dosing. For older patients, the longer half-life and consequent once- or twice-daily dosing regimens of enalapril favor its use. Pharmacokinetic data have recently been generated for infants and children treated with enalapril (59). The only currently available intravenous ACE inhibitor with established pediatric use is enalaprilat (60). This agent should be used with great caution, as it has been associated with prolonged hypotension and oliguric acute renal failure, particularly in neonates.

Newer ACE inhibitors, formulated primarily to reduce cost, dosing frequency, and side effects, include benazepril, fosinopril, lisinopril, quinapril, and ramipril. Pharmacokinetic and pharmacodynamic studies are currently underway to determine optimal pediatric dosing recommendations for most of these agents. Fixed-dose combinations of ACE inhibitors with diuretics or calcium-channel blockers (CCBs) are now reaching the market. Although these medications may prove to offer improvements over current therapies, there is no pediatric literature to recommend their use at this time. Currently available ACE inhibitors and recommended dosages are listed in Table 62.1.

The side effects of ACE inhibitors in children do not differ from those seen in adults. Renal impairment, hyperkalemia, neutropenia, anemia, dry cough, and angioedema have all been reported in children. Adverse effects on renal function are seen primarily in patients with preexisting renal insufficiency [glomerular filtration rate (GFR) less than 30% of normal], bilateral renal artery stenosis, and renal artery stenosis in a solitary or transplanted kidney. Decreased renal function in patients with the previously mentioned conditions occurs when AII-mediated efferent arteriolar vasoconstriction, necessary for maintenance of glomerular filtration, is reversed by ACE inhibition. The resulting acute renal failure is reversible once ACE inhibitors are discontinued.

Hyperkalemia may be related to medication-induced acute renal failure but may also be seen in patients with relatively normal renal function because of diminished aldosterone levels. Many clinicians periodically measure blood urea nitrogen, creatinine, and electrolytes beginning 1 week after starting ACE inhibitors and after increases in dosage.

TABLE 62.1. SUGGESTED DOSAGES OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Drug	Infant/child	Adult
Benazepril ^a	?	10–80 mg/d PO (QD or ÷BID)
Captopril ^b	1–6 mg/kg/d (÷BID-QID)	12.5–450 mg PO (÷TID)
Enalapril ^c	0.1–0.5 mg/kg/d (QD or ÷BID)	2.5–40 mg/d PO (QD or ÷BID)
Enalaprilat ^d	5–10 µg/kg/dose IV q8–24h	1.25 mg IV q6h
Fosinopril ^e	?	10–40 mg/d PO (QD or ÷BID)
Lisinopril ^f	?	5–40 mg/d PO (QD)
Quinapril ^g	?	10–80 mg/d PO (QD)
Ramipril ^h	?	1.25–20 mg/d PO (QD or ÷BID)

?, Dosages for these age groups have not been established; ÷, divided.

^aAvailable as Lotensin, 5-, 10-, 20-, and 40-mg tablets.

^bAvailable as Capoten, 12.5-, 25-, 50-, and 100-mg tablets.

^cAvailable as Vasotec or generic enalapril, 2.5-, 5-, 10-, and 20-mg tablets.

^dAvailable as 1.25 mg/mL in 1- and 2-mL vials.

^eAvailable as Monopril, 10-, 20-, and 40-mg tablets.

^fAvailable as Prinivil or Zestril, 2.5-, 5-, 10-, 20-, and 40-mg tablets.

^gAvailable as Accupril, 5-, 10-, 20-, and 40-mg tablets.

^hAvailable as Altace, 1.25-, 2.5-, 5-, and 10-mg tablets.

Dosage reduction is indicated in the presence of hyperkalemia or a rising serum creatinine. Although hematologic complications are rare and reversible with drug discontinuation, it is prudent to periodically obtain complete blood counts in patients treated with ACE inhibitors.

The inhibition of kininase and accumulation of bradykinin produce several side effects in patients treated with ACE inhibitors. A small but significant number of patients treated with captopril (1 to 5%) report a persistent, non-productive cough. The incidence of this side effect appears to be less frequent in patients treated with newer ACE inhibitors. The cough is not dose-related and improves when medication is stopped. It is important to ask about cough when monitoring for side effects, because parents and patients may often attribute it to other causes (reactive airway disease, upper respiratory infection). Angioedema and anaphylactoid reactions are less common (0.1%) but serious side effects of ACE inhibitors.

ACE inhibitors are contraindicated during pregnancy. Maternal use of ACE inhibitors during the second and third trimesters of pregnancy has been associated with oligohydramnios, profound fetal hypotension, reversible or irreversible neonatal renal failure, hypocalvaria, and neonatal death (61,62). ACE inhibitors are also contraindicated in patients with bilateral renal artery stenosis, renal artery stenosis in a solitary kidney, and acute renal failure. The need for frequent monitoring of serum creatinine and potassium values also limits their usefulness in patients with chronic renal insufficiency with a GFR of less than 30% of normal.

ACE inhibitors have been shown to have both renoprotective and cardioprotective properties, making them particularly attractive therapeutic agents for patients with chronic hypertension (63–66). The renoprotective properties of ACE inhibitors are most likely due to reduction in AII, which has been implicated as a central effector in the progression of chronic renal injury (63). Several clinical trials have demonstrated that treatment with ACE inhibitors retards the progression of chronic renal disease in both diabetic and nondiabetic nephropathy (64–66). In addition, the HOPE (*Heart Outcomes Prevention Evaluation*) trial recently demonstrated that treatment with ramipril significantly reduced cardiovascular morbidity and mortality in adult patients with cardiovascular disease (67). These additional beneficial effects of ACE inhibitors add significantly to their value as first-line antihypertensive medications.

Angiotensin II Receptor Antagonists

AII receptor antagonists are relatively new agents in the treatment of pediatric hypertension. AII receptor antagonists block the binding of AII to the AT-1 subtype of the AII receptors in blood vessels and other tissues (68). This blockade reduces BP by inhibiting AII-induced vasoconstriction and aldosterone release.

Although AII receptor antagonists are similar to ACE inhibitors in their blockade of AII, there are several major differences that differentiate these two classes of drugs. Because AII receptor antagonists act directly at the AII receptor site, they completely block the effect of AII, including AII formed by ACE-independent pathways such as trypsin, cathepsin, and heart chymase. ACE inhibitors, on the other hand, block only the AII formed by ACE-mediated conversion from angiotensin I. Unlike ACE inhibitors, AII receptor antagonists have minimal effect on bradykinin metabolism. Finally, AII receptor antagonists, but not ACE inhibitors, lead to an exaggerated stimulation of the AT-2 subtype of the AII receptor, which may promote apoptosis and decrease fibrosis (69), possibly reducing renal scarring and cardiac hypertrophy.

Losartan was the first AII receptor antagonist approved for the oral treatment of hypertension in adults and now is increasingly used in the pediatric population (70). Irbesartan, valsartan, candesartan, and telmisartan are additional long-acting AII receptor antagonists that have been approved for the treatment of hypertension and offer the benefit of once-daily dosing (71). Pharmacokinetic and pharmacodynamic studies are currently underway to determine optimal pediatric dosing guidelines for losartan, irbesartan, and valsartan. Currently available AII receptor antagonists and recommended dosages are listed in Table 62.2.

AII receptor antagonists are generally well tolerated, with a favorable side effect profile. Adverse effects on renal function may occur, particularly in patients with preexisting renal insufficiency, bilateral renal artery stenosis, or

TABLE 62.2. SUGGESTED DOSAGES OF ANGIOTENSIN II RECEPTOR ANTAGONISTS

Drug	Infant/child	Adult
Candesartan ^a	?	8–32 mg PO QD
Eprosartan ^b	?	400–800 mg/d PO (QD or \pm BID)
Irbesartan ^c	?	150–300 mg/d PO (QD)
Losartan ^d	?	25–100 mg/d PO (QD or \pm BID)
Telmisartan ^e	?	40–80 mg/d PO (QD)
Valsartan ^f	?	80–320 mg/d PO (QD)

?, Dosages for these age groups have not been established; \pm , divided.

^aAvailable as Atacand, 4-, 8-, 16-, and 32-mg tablets.

^bAvailable as Teveten, 400- and 600-mg tablets.

^cAvailable as Avapro, 75-, 150-, and 300-mg tablets.

^dAvailable as Cozaar, 25-, 50-, and 100-mg tablets.

^eAvailable as Micardis, 40- and 80-mg tablets.

^fAvailable as Diovan, 80-, 160-, and 320-mg tablets.

renal artery stenosis in a solitary or transplant kidney. Hyperkalemia may be related to medication-induced renal insufficiency but also may be seen in patients with normal kidney function as a result of aldosterone inhibition.

Although cough and angioedema occur in patients treated with AII receptor antagonists (72,73), they are observed less frequently than in patients treated with ACE inhibitors. The difference in the frequency of these side effects is most likely due to the difference in effect on bradykinin metabolism between the two drug classes. AII receptor antagonists are contraindicated in pregnancy, as they have been associated with hypocalvaria, oligohydramnios, and fetal death (74).

Several recent large trials have demonstrated that, like ACE inhibitors, AII receptor antagonists exert renoprotective effects in patients with diabetic nephropathy (75–77). In addition, AII receptor antagonists appear to have cardioprotective effects (78–80). The additional renal and cardioprotective effects of AII receptor antagonists make them attractive as therapeutic agents for patients with chronic hypertension and cardiovascular and/or renal disease.

Because AII receptor antagonists and ACE inhibitors suppress the renin-angiotensin system by different mechanisms, they can be used together. Combination has been proven to be safe and more effective at reducing BP (81) and proteinuria (82) than single-drug therapy.

Vasopeptidase Inhibitors

Vasopeptidase inhibitors are a new class of cardiovascular drugs that may become useful in the treatment of pediatric hypertension in the future (83). Vasopeptidase inhibitors simultaneously inhibit ACE and *neutral endopeptidase* (NEP), a metalloproteinase enzyme found principally in the brush-border membrane of renal tubules. The mechanism of action of vasopeptidase inhibitors includes the previously described effects of ACE inhibition, such as reduction in AII-mediated vasoconstriction, reduction in

aldosterone synthesis, and increase in circulating bradykinins. In addition, vasopeptidase inhibitors block the effect of NEP, which catalyzes the breakdown of a variety of vasodilatory peptides, including atrial natriuretic peptide, brain natriuretic peptide, C-type natriuretic peptide, adrenomedullin, urodilatin, and bradykinin.

The vasopeptidase inhibitor at the most advanced stage of clinical development is omapatrilat. Several studies have demonstrated favorable antihypertensive effects when compared to lisinopril (84) and amlodipine (85). A large, international, placebo-controlled trial is currently assessing the effects of omapatrilat on survival and cardiovascular outcomes in elderly patients with systolic hypertension (86). Additional vasopeptidase inhibitors under early clinical development include sampatrilat, gemopatrilat, and fasidotrilat.

Flushing, transient facial redness, and dizziness have also been noted in patients treated with omapatrilat. Like ACE inhibitors, omapatrilat has been reported to cause cough and angioneurotic edema, most likely related to its inhibitory effect on bradykinin metabolism. Because ACE inhibition and NEP inhibition both produce increases in bradykinin levels, these side effects potentially may occur more frequently in patients treated with vasopeptidase inhibitors than in patients treated with ACE inhibitors. The full safety profile of vasopeptidase inhibitors remains to be determined with wider clinical development.

Calcium-Channel Blockers

CCBs are among the most commonly used antihypertensive agents in children. CCBs act as direct vasodilators by inhibiting vascular smooth muscle contraction by interfering with cellular calcium influx (87). The relative affinities of the different types of CCBs for different types of contractile tissues (vascular smooth muscle, myocardium) determine their antihypertensive efficacy and their side effect profiles. The three major classes are dihydropyridines (amlodipine, felodipine, isradipine, nicardipine, nifedipine), phenylalkylamines (verapamil), and benzothiazepines (diltiazem). Because of their relative selectivity for arteriolar smooth muscle, the dihydropyridines (particularly amlodipine and nifedipine) are the most widely used CCBs in pediatric hypertension. Because the nondihydropyridines also exert significant effects on cardiac conduction and contractility, their role in pediatric hypertension is not well defined.

One of the primary benefits of CCBs is the availability of long-acting preparations that permit once- or twice-daily administration (88). Although sustained release nifedipine (Procardia XL) was commonly used in the past, its usefulness in smaller children and infants was limited by the ability of the child to swallow the commercially available capsules and tolerate the minimum dosage available. As of 1999, amlodipine became a popular choice, as its long-acting effect is related to the drug's chemical structure rather than a slow-release pill formulation (89,90). Amlodipine tablets may be

TABLE 62.3. SUGGESTED DOSAGES OF CALCIUM CHANNEL BLOCKERS

Drug	Infant/child	Adult
Amlodipine ^a	0.1–0.6 mg/kg/d (÷QD-BID)	2.5–20 mg/d PO (QD)
Diltiazem ^b	1.5–2.0 mg/kg/d (÷TID)	120–360 mg/d PO (QD or ÷BID)
Felodipine ^c	0.1 mg/kg/d (÷QID-BID)	2.5–10 mg PO (QD)
Isradipine ^d	0.05–0.15 mg/kg/dose (TID-QID)	2.5–20 mg/d PO (QD)
Nicardipine ^e (IV)	0.5–5.0 µg/kg/min	5–15 mg/h
Nicardipine ^f (oral)	?	60–120 mg/d PO (BID)
Nifedipine ^g (extended-release)	0.25–3.0 mg/kg/d (QD or ÷BID)	30–120 mg/d PO (QD or ÷BID)
Verapamil ^h	3–8 mg/kg/d (÷TID)	120–480 mg/d PO (QD or ÷BID)

?, Dosages for these age groups have not been established; ÷, divided.

^aAvailable as Norvasc, 2.5-, 5.0-, and 10.0-mg tablets.

^bAvailable as Cardizem-SR, 60-, 90-, and 120-mg sustained-release capsules (dosed BID), and available as Cardizem-CD, 120-, 180-, 240-, 300-, and 360-mg extended-release capsules (dosed QD).

^cAvailable as Plendil, 2.5-, 5.0-, and 10.0-mg extended-release capsules.

^dAvailable as Dynacirc, 2.5- and 5.0-mg capsules, which may be made into an extemporaneous suspension stable up to 30 days.

^eAvailable as Nicardipine injection, 2.5 mg/mL.

^fAvailable as Cardene-SR, 30-, 45-, and 60-mg capsules.

^gAvailable as Procardia XL, Adalat-CC, or Nifedipine-ER, 30-, 60-, and 90-mg sustained-release tablets. Also available as Procardia and Adalat, 10- and 20-mg liquid-filled capsules. Liquid may be aspirated from the capsule with a syringe, with a concentration of 10-mg/0.34 mL, although the accuracy of dosing is not consistent. See text for concerns about the use of rapid-acting nifedipine.

^hAvailable as Calan-SR, 40-, 80-, and 120-mg capsules.

crushed and/or made into a suspension, extending the drug's usefulness to small children and infants.

In contrast to adults, nondihydropyridines (verapamil and diltiazem) are not commonly used for treatment of hypertension in children. Nondihydropyridines are contraindicated in neonates and in patients with left ventricular dysfunction, sick sinus syndrome, second- or third-degree atrioventricular block, and atrial flutter or fibrillation. Currently available CCBs and recommended dosages are listed in Table 62.3.

Nicardipine is the only CCB available in intravenous form and may have an emerging role in the emergency department and intensive care setting for treatment of hypertensive emergencies. Rapid, safe, and effective reductions in BP have been achieved with continuous infusions of 0.5 to 5.0 µg/kg/min in children and neonates, providing an alternative to nitroprusside or intravenous labetalol (91,92).

CCBs are generally well tolerated, with a low incidence of significant side effects. No routine monitoring of blood work is recommended. Headache, flushing, dizziness, and tachycardia may be seen with immediate release CCB formulations as a result of acute vasodilation. Lower extremity edema and erythema may be seen with higher doses of

long-acting CCB preparations as a result of a direct effect on local vasculature and not fluid overload. Gingival hyperplasia may occur and may be even more significant when CCBs are administered in conjunction with cyclosporine in transplant patients (93).

In adult patients, short-acting CCBs have been associated with adverse cardiovascular and neurologic sequelae, including myocardial infarction, stroke, and syncope (94). Therefore, their use in the management of acute hypertension in adults has been significantly curtailed. The safety of short-acting CCBs in children is less well defined. Although several surveys and studies suggest that CCBs are safe in the pediatric population (95,96), serious adverse events have been temporally linked to the administration of short-acting nifedipine (97–99). Some clinicians have replaced short-acting nifedipine with isradipine (0.05 to 0.15 mg/kg/dose), which offers a more gradual reduction in BP, theoretically lowering the risk of adverse events associated with abrupt decreases in BP.

CCBs appear to have some immediate and long-term renoprotective properties that have led to widespread use among renal transplant recipients. CCBs decrease mesangial cell proliferation and dilate the afferent arteriole, increasing renal blood flow and GFR. In the long-term, verapamil reduces proteinuria in patients with diabetic nephropathy; however, this beneficial effect does not appear to be uniform among all CCBs.

β -Adrenergic Antagonists

β -Adrenergic antagonists (beta-blockers) were among the first and most widely used antihypertensive medications in children. Several mechanisms for their antihypertensive effect have been proposed, including decreased cardiac output, decreased peripheral vascular resistance, inhibition of renin secretion, decreased circulating plasma volume, and inhibition of central nervous system (CNS) sympathetic activity. The relative importance of each of these mechanisms is unclear and may depend on the specific β -adrenergic agent used.

Characteristics that distinguish one β -adrenergic antagonist from another include differences in cardioselectivity, intrinsic sympathomimetic activity due to partial β -agonist activity, degree of hydrophilicity and lipophilicity, and α -adrenergic antagonism. Use of the prototypic β -adrenergic antagonist, propranolol, is limited by its lack of selectivity for cardiovascular β_1 -receptors. Because of propranolol's effects on peripheral β_2 -receptors, including bronchoconstriction, impaired glucose tolerance, and altered lipid profiles, drugs with relative cardioselectivity were developed such as atenolol and metoprolol. Intrinsic sympathomimetic activity is another characteristic that is variable among β -adrenergic antagonists. This characteristic may benefit some patients by moderating negative inotropy, bradycardia, peripheral vasoconstriction, and dyslipidemia. Many patients treated with β -adrenergic antagonists experi-

ence significant CNS side effects that are minimized by altering the hydrophilicity/lipophilicity of the drug that limits CNS absorption.

Labetalol is a β -adrenergic antagonist with peripheral α -adrenergic antagonism that produces vasodilatation of peripheral vasculature, providing a synergistic antihypertensive effect. Labetalol is not cardioselective and does not have intrinsic sympathomimetic activity. Labetalol can be given safely in children and is an effective agent when administered intravenously for the treatment of hypertensive emergencies (100).

Other cardioselective β -adrenergic antagonists without intrinsic sympathomimetic activity that have been used safely in children include atenolol and metoprolol (101). Esmolol is a short-acting intravenous β -adrenergic antagonist that has been used successfully in children with hypertension after cardiac surgery (102). A randomized double-blind, placebo-controlled trial of the combination drug bisoprolol fumarate, a selective β_1 -adrenergic antagonist, and hydrochlorothiazide has recently been shown to have modest effects on lowering BP in hypertensive children precluding its use as a first-line agent (103).

The most common side effects of β -adrenergic antagonists include (a) cardiovascular—bradycardia, fluid retention; (b) CNS—light-headedness, ataxia, dizziness, syncope, sleepiness, irritability, hearing and visual disturbances, vivid dreams/nightmares, weakness, fatigue, depression; (c) gastrointestinal—nausea, diarrhea, cramping, constipation; (d) hematologic—eosinophilia, leukopenia, thrombocytopenia; (e) genitourinary—impotence; and (f) metabolic—delayed recognition of the clinical symptoms of hypoglycemia, blunted recovery from hypoglycemia in insulin-dependent diabetics. β -Adrenergic antagonists that are nonselective or lacking sympathomimetic activity are more likely to result in increased serum triglyceride levels and reduced levels of high-density lipoproteins. β -Adrenergic antagonists are contraindicated in patients with asthma, insulin-dependent diabetes mellitus, Raynaud's phenomenon, congestive heart failure, and atrioventricular conduction disturbances other than first-degree heart block.

No direct comparisons of β -adrenergic antagonists with diuretics, CCBs, or ACE inhibitors as first-line pediatric antihypertensives have been performed. As a result, clinical practice and experience, rather than direct comparison, have relegated β -adrenergic antagonists to second or third choices for the pharmacologic treatment of essential hypertension in children. Nonetheless, β -adrenergic antagonists may be particularly useful when combined with vasodilators that produce reflex tachycardia or in patients for whom ACE inhibitors are contraindicated. Currently available β -adrenergic antagonists and recommended dosages are listed in Table 62.4.

Diuretics

Despite increasing use of ACE inhibitors and CCBs as first-line pediatric antihypertensive medications, diuretics remain

TABLE 62.4. SUGGESTED DOSAGES OF β -ADRENERGIC ANTAGONISTS

Drug	Infant/child	Adult
Atenolol ^a	1–3 mg/kg/d (\div QD, BID)	25–100 mg/d PO (QD or \div BID)
Bisoprolol ^b	?	2.5–20 mg/d PO (QD)
Labetalol ^c	1–40 mg/kg/d (\div BID, TID)	200–2400 mg/d PO (\div BID) (usual regimen 400–1200 mg/d)
Metoprolol ^d	?	Short acting: 100–450 mg/d PO (QD or \div BID) Extended release: 50–400 mg PO (QD)
Nadolol ^e	?	20–320 mg/d PO (QD)
Pindolol ^f	?	10–60 mg/d PO (\div BID, TID)
Propranolol ^g	0.5–8.0 mg/kg/d (\div BID, QID)	80–480 mg/d PO (\div BID)

?, Dosages for these age groups have not been established; \div , divided.

^aAvailable as tablets: 25 mg, 50 mg, 100 mg.

^bAdjust dose in renal failure.

^cContains α_1 blocking activity. Available as tablets: 100 mg, 200 mg,

300 mg. Available as suspension: 10 mg/mL.

^dAvailable as short-acting tablets: 50 mg, 200 mg. Available as

extended release tablets: 47.5 mg, 95 mg, 195 mg.

^eAdjust dose in renal failure. Available as tablets: 20 mg, 40 mg, 80

mg, 120 mg, 160 mg.

^fContains intrinsic sympathomimetic activity. Available as tablets: 5

mg, 10 mg.

^gAvailable as short-activity tablets: 10 mg, 20 mg, 40 mg, 60 mg, 80

mg, 90 mg. Available as extended-release tablets: 60 mg, 80 mg, 120

mg, 160 mg. Available as suspension: 20 mg/5 mL, 40 mg/5 mL, and

80 mg/mL.

important adjunctive agents. Diuretics are commonly prescribed because of their long history of safety in children, their low cost, and their effectiveness in most types of pediatric hypertension. They remain the standard by which newer medications are compared.

All diuretics act by blocking solute reabsorption in the nephron, resulting in increased distal delivery of solute, increased urine flow, and ultimately decreased intravascular volume. Some diuretics may also act directly on the peripheral vasculature as vasodilators. The different classes of diuretics are defined by their primary site of action in the nephron (104). Diuretics are secreted by organic acid transporters in the proximal tubule (105). Their secretion may be inhibited in the presence of metabolic acidosis, retained organic anions, or urates.

Quinazolones act by blocking sodium reabsorption in the proximal and distal convoluted tubules. Metolazone, the most commonly used quinazolone, is a long-acting diuretic, which results in the excretion of 5–8% of the filtered sodium load. Although rarely used alone, quinazolones may be used concurrently with diuretics acting at the loop of Henle to increase solute delivery to the distal nephron.

Loop diuretics act primarily in the thick ascending limb of the loop of Henle by binding to the bumetanide-sensitive cotransporter-1 or $\text{Na}^+/\text{K}^+/\text{2Cl}$ cotransporter resulting in the

excretion of water, sodium, potassium, chloride, magnesium, calcium, and phosphate. Common loop diuretics include furosemide, bumetanide, and ethacrynic acid. Loop diuretics are potent and effective when rapid diuresis is needed. Unlike thiazides, loop diuretics remain effective in patients with chronic renal insufficiency with GFR between 10 and 30 mL/min. Loop diuretics increase urinary calcium excretion, which may lead to nephrocalcinosis with extended use. Ototoxicity can be seen with higher dosages or when used with other ototoxic agents such as gentamicin. Loop diuretics and thiazides should be used with caution in neonates, because they displace bilirubin from albumin, which increases the risk of hyperbilirubinemia.

Thiazide diuretics, such as chlorothiazide, chlorthalidone, and hydrochlorothiazide, inhibit sodium chloride reabsorption in the distal convoluted tubule by binding to the thiazide-sensitive transporter or Na^+/Cl cotransporter. The safety and effectiveness of thiazides for the treatment of hypertension is well established in the pediatric population. Compared with loop diuretics, thiazides provide a more sustained but less vigorous diuresis. Also, they cause an increase in calcium absorption in the distal nephron, which may lead to hypercalcemia. Thiazide diuretics are relatively ineffective in patients with GFRs less than 30 mL/min.

Potassium-sparing diuretics such as spironolactone, triamterene, and amiloride, inhibit sodium reabsorption in the collecting duct. Spironolactone is a competitive inhibitor of aldosterone, whereas amiloride and triamterene act more directly by inhibiting sodium transport mechanisms. Although these medications have limited antihypertensive effects compared with loop or thiazide diuretics, spironolactone is useful in patients with states of elevated plasma aldosterone such as primary hyperaldosteronism, congestive heart failure, and liver disease, whereas amiloride is valuable in patients with glucocorticoid-remediable hypertension. Potassium-sparing diuretics can also minimize urinary potassium losses and obviate the need for potassium supplementation in patients treated with thiazide or loop diuretics.

SR121463, a selective vasopressin V_2 receptor antagonist, represents a new class of drugs called *aquaretics*, which induce free-water excretion without sodium or potassium urinary excretion (106). This drug has the potential to be therapeutically effective in dilutional causes of hyponatremia such as syndrome of inappropriate antidiuretic hormone, congestive heart failure, liver cirrhosis, and nephrotic syndrome. The potential use of this new class of drugs in patients with hypertension remains to be determined.

Dosages of commonly used diuretics are listed in Table 62.5. Although diuretics are effective, well tolerated, and inexpensive, they have largely been replaced as first-line agents for pediatric hypertension. Potential reasons for the decreasing use of diuretics include the need for monitoring potassium, magnesium, and uric acid levels in patients taking loop and thiazide diuretics; an increased risk of nephrocalcinosis in patients receiving loop diuretics; and adverse

TABLE 62.5. SUGGESTED DOSAGES OF COMMONLY USED DIURETICS

Drug	Infant/child	Adult
Amiloride ^a	?	5–20 mg PO QD
Bumetanide ^b	?	0.5–4.0 mg/d PO (QD or ÷BID)
Chlorothiazide ^c	10–20 mg/kg/d (maximum dose = 375 mg if age <2 yr, 1000 mg if age 2–12 yr)	125–500 mg/d PO (÷BID) (maximum dose, 2000 mg/d)
Furosemide ^d	0.5–4.0 mg/kg/d (QD or ÷BID)	Same as children
Hydrochlorothiazide ^e	1–3 mg/kg/d (÷BID) (maximum dose = 37.5 mg if age <2 yr, 100 mg if age 2–12 yr)	25–200 mg/d PO (QD or ÷BID)
Metolazone ^f	0.2–0.4 mg/kg/d	2.5–20 mg/d PO (QD or ÷BID)
Spirolactone ^g	3.3 mg/kg/d	25–200 mg/d PO (QD or ÷BID)

?, Dosages for these age groups have not been established; ÷, divided.

^aAvailable as 5-mg tablets.

^bAvailable as tablets: 0.5 mg, 1 mg, and 2 mg.

^cAvailable as tablets: 250 mg, 500 mg. Available as oral suspension: 250 mg/5 mL.

^dAvailable as tablets: 20 mg, 40 mg, and 80 mg. Available as oral solution: 10 mg/mL.

^eAvailable as tablets: 12.5 mg, 25 mg, 50 mg, 100 mg. Available as oral solution: 50 mg/5 mL.

^fAvailable as tablets: 2.5 mg, 5 mg, and 10 mg. Available as oral suspension: 0.1 mg/mL.

^gAvailable as tablets: 25 mg, 50 mg, and 100 mg. Tablet may be pulverized and administered in oral suspension with cherry syrup.

lipid profiles and hyperglycemia in patients taking thiazide diuretics. However, diuretics remain useful in hypertensive patients with hypervolemia.

Direct Vasodilators

Although direct vasodilators work through different mechanisms, they are discussed together because they are used similarly in hypertensive emergencies or in cases refractory to more commonly used antihypertensives. Their usefulness as first-line medications for treatment of chronic hypertension is limited by their side effects such as headache, palpitations, tachycardia, flushing, fluid and sodium retention, and exacerbation of symptoms in patients with preexisting coronary or cerebrovascular compromise. These side effects are primarily due to nonspecific vasodilation. Concurrent use of β -adrenergic antagonists or diuretics is often effective in reducing these side effects while controlling refractory hypertension in patients treated with vasodilators as first-line antihypertensive agents.

Hydralazine

Although the mechanism of action of hydralazine is not well understood, it affects primarily arteriolar resistance vessels and,

to a lesser effect, venous capacitance vessels. Hydralazine has been used extensively in pediatrics, particularly in neonates, because it is available in oral suspension, oral tablets, and intravenous preparations (107,108). Frequent side effects include reflex tachycardia, palpitations, dizziness, headaches, and gastrointestinal discomfort. With long-term use, up to 10% of patients treated with hydralazine may develop a hypersensitivity reaction that resembles systemic lupus erythematosus characterized by fever, arthralgia, splenomegaly, lymphadenopathy, myalgia, chest pain, and edema. These physical findings may be accompanied by the development of antinuclear antibodies and anti-single-stranded DNA antibodies. This syndrome resolves when hydralazine is stopped. As a result of these side effects, hydralazine use is restricted primarily to hypertensive neonates requiring parenteral antihypertensive therapy. Hydralazine is contraindicated in patients with dissecting aortic aneurysm, rheumatic valve disease, cerebrovascular disease, and coronary vascular disease. Pediatric oral dosing of hydralazine is 0.25 to 1 mg/kg per dose two to four times daily up to a maximum dose of 7.5 mg/kg/day or 25 mg per dose. Hydralazine is available as 10-, 25-, 50-, and 100-mg tablets and as a 0.2-mg/mL oral liquid. The intravenous dosage is 0.1 to 0.6 mg/kg per dose every 4 to 6 hours up to a maximum dose of 20 mg in children and 40 mg in adolescents or adults.

Minoxidil

Minoxidil acts on arteriolar resistance vessels to exert a potent antihypertensive effect possibly through inhibition of vascular smooth muscle potassium channels or through modulation of cyclic adenosine monophosphate or guanosine monophosphate-mediated vasodilation. Because of significant side effects, pediatric use usually is limited to hypertensive patients with renal disease who require multiple drugs for BP control (109,110). Fluid and sodium retention is a major problem often leading to congestive heart failure or pericardial effusion. Therefore, patients treated with minoxidil require diuretic therapy, a sodium-restricted diet, and careful attention to fluid balance. In addition, minoxidil therapy is usually associated with tachycardia, which often requires concurrent use of a β -adrenergic antagonist. Other side effects of minoxidil include hirsutism and exacerbation of angina pectoris. Contraindications to the use of minoxidil include pheochromocytoma, congestive heart failure, and recent myocardial infarction. Minoxidil is available as 2.5- and 10.0-mg tablets. Pediatric dosing is 0.2 to 5.0 mg/kg/day given once or twice daily. The maximum dose is 50 mg/day in children and 100 mg/day in adolescents and adults. Therapy is commonly initiated while patients are hospitalized to observe for evidence of congestive heart failure, pericardial effusion, or other evidence of fluid overload.

Nitroprusside

Sodium nitroprusside is a nitric oxide donor that exerts a vasodilatory effect on both venous capacitance and arteriolar

resistance vessels. Also, this drug increases renal blood flow with minimal effects on cardiac output. Sodium nitroprusside is administered as a continuous infusion and remains one of the drugs of choice for management of hypertensive emergencies. Because of its immediate onset of action and rapid metabolism, use of nitroprusside requires continuous BP monitoring, preferably with an indwelling arterial catheter. Significant side effects limit the duration of treatment. Prolonged use of nitroprusside results in the production of toxic metabolites, cyanide and thiocyanate, which accumulate in patients with renal and hepatic insufficiency. In patients requiring treatment for longer than 24 hours, concurrent infusion with thiosulfate (10:1 ratio of nitroprusside to thiosulfate) is recommended to eliminate the possibility of cyanide toxicity (111). Clinical signs of cyanide/thiocyanate toxicity include anxiety, headache, dizziness, confusion, jaw stiffness, seizures, metabolic acidosis, and hypoxemia. Other side effects include hypotension, methemoglobinemia, hypothyroidism, tinnitus, visual disturbances, and tachyphylaxis. Nitroprusside is contraindicated in patients with increased intracranial pressure and should be used with caution in patients with coarctation of the aorta. Use of nitroprusside in children is associated with fewer episodes of ischemic events secondary to hypotension compared to bolus injections of diazoxide (112).

Dosing should begin at 0.3 $\mu\text{g}/\text{kg}/\text{min}$, and is titrated to a maximum dose of 8 $\mu\text{g}/\text{kg}/\text{min}$ to achieve the desired BP. Adequate control is usually obtained with a dose of 2 to 4 $\mu\text{g}/\text{kg}/\text{min}$. If BP is not adequately controlled at a nitroprusside dose of 8 $\mu\text{g}/\text{kg}/\text{min}$, additional medications may be needed such as labetalol, calcium-channel antagonists, or diuretics.

Diazoxide

Diazoxide is a powerful arteriolar vasodilator, although its mechanism of action is not well defined. This drug is available only for parenteral use because of its rapid but unpredictable onset of action. The side effects of diazoxide are similar to other systemic vasodilators. In addition, hyperglycemia, hyperuricemia, nausea, vomiting, constipation, hypertrichosis, skin rash, fever, leukopenia, and thrombocytopenia may occur. Although slow continuous infusion of diazoxide appears to be tolerated as well as nitroprusside (113), diazoxide has been replaced by better-tolerated and safer medications, including intravenous labetalol and nicardipine in the setting of hypertensive emergencies (112). Diazoxide is contraindicated in patients with intracerebral hemorrhage, dissecting aortic aneurysm, acute myocardial infarction, and aortic coarctation. The recommended dosage is 1 to 2 mg/kg per dose via intravenous infusion over 5 to 10 minutes and may be given every 10 to 15 minutes until a response is seen. The maximal daily dose is 10 mg/kg.

Fenoldopam

Fenoldopam mesylate is the first selective peripheral dopamine-1 receptor agonist approved for parenteral use in the

treatment of hypertensive emergencies and severe perioperative hypertension (114). This drug is a direct-acting vasodilator that binds to the postsynaptic dopamine-1 receptors in renal, coronary, cerebral, and splanchnic vasculature resulting in dilation of arterial and venous capacitance vessels. Activation of dopamine-1 receptors in the renal vasculature and renal tubular epithelium leads to natriuresis, diuresis, mesangial cell relaxation, and an increase in renal blood flow and GFR.

Due to its poor oral bioavailability, fenoldopam is used exclusively as a parenteral agent to achieve rapid reduction of BP. Peak effects on BP occur within 5 to 15 minutes and steady-state serum levels are achieved by 30 to 60 minutes. In a prospective, randomized, multicenter trial of 153 adults with diastolic BPs exceeding 120 mm Hg, fenoldopam was as effective as sodium nitroprusside in reducing BP (115). A dose-dependent reduction in BP was noted up to 48 hours without evidence of tolerance or rebound on withdrawal. In a study of 107 adults with hypertensive emergencies, fenoldopam was safe and effective in lowering BP using a dose-titration regimen (116). Fenoldopam has also been effective in treating perioperative hypertension, including elevations in BP after coronary bypass surgery. Fenoldopam has been used successfully without significant side effects in four children between the ages 6 weeks and 11 years for treatment of hypertensive emergencies/urgencies and hypertension associated with extracorporeal membrane oxygenation (117). Also, fenoldopam has been used to achieve controlled hypotension intraoperatively (117).

Although fenoldopam has the potential to function as a renal protective agent, no conclusive evidence exists to support this pharmacologic effect (114). Uncontrolled studies with small numbers of patients suggest that fenoldopam may be beneficial in protecting against radiographic contrast nephropathy after percutaneous coronary intervention or angiography and renal dysfunction associated with aortic cross-clamping for repair of aneurysms (118,119).

Adverse effects of fenoldopam include headache, flushing, dizziness, and tachycardia or bradycardia. These effects usually occur within the initial 24 hours of treatment and are self-limited. A more serious adverse effect of fenoldopam is increased intraocular pressure. Therefore, this drug should be used cautiously in patients with glaucoma or high intraocular pressure. Nonspecific T-wave flattening may also be seen. Clinically significant drug interactions have not been reported. Advantages of fenoldopam over nitroprusside include absence of thiocyanate toxicity, lack of degradation on exposure to light, and lack of rebound hypertension after discontinuation.

The recommended initial infusion rate of fenoldopam should be 0.1 $\mu\text{g}/\text{kg}/\text{min}$ with increments of 0.05 to 0.10 $\mu\text{g}/\text{kg}/\text{min}$ every 15 to 20 minutes, up to a maximal dose of 5 $\mu\text{g}/\text{kg}/\text{min}$. The infusion period should not exceed 48 hours owing to the presence of tolerance beyond this time period. Fenoldopam can be slowly tapered or abruptly discontinued without complications. Oral antihypertensive therapy may be initiated at any time during the fenoldopam infusion.

Central Nervous System Sympathetic Inhibitors

CNS sympathetic inhibitors, such as clonidine, methyl dopa, guanabenz, and guanfacine, have been used successfully in children for many years. These drugs inhibit sympathetic tone through stimulation of CNS α_2 -adrenergic receptors. Unlike β -adrenergic antagonists and diuretics, these drugs exert favorable cardiovascular effects, including decreased left ventricular mass and stable or improved lipid profiles. In addition, they exert no adverse influence on renal hemodynamics or glucose metabolism. Although these drugs are excellent candidates for the treatment of chronic hypertension, unfavorable side effect profiles have relegated these agents to second or third choices in patients requiring multiple drug regimens. Patients often experience dry mouth, depression, sedation, vivid dreams, nightmares, hallucinations, impotence, decreased libido, or ejaculatory difficulty. A particularly worrisome side effect of these drugs is rebound hypertension, which may precipitate a hypertensive emergency or urgency in patients who suddenly discontinue their use. Because of the concern about rebound hypertension, these drugs should not be administered to patients at high risk for noncompliance, such as adolescents, and should be limited to those patients with a clear understanding of this risk.

Clonidine

Most pediatric experience with clonidine arises from use in children treated with this medication for behavioral problems. It is worth remembering that normotensive children treated with clonidine for behavioral modification may experience rebound hypertension if suddenly withdrawn (120). Patients treated with clonidine may experience transient elevations in liver enzymes, muscle or joint pain, weight gain, and rash, in addition to the previously mentioned side effects of central sympatholytic agents. Clonidine is available in 0.1- and 0.2-mg tablets. The oral dosage is 0.05 to 0.3 mg per dose two to three times daily. Clonidine is also available in transdermal patches, Catapres TTS-1, TTS-2, and TTS-3, which are equivalent to daily doses of 0.1, 0.2, and 0.3 mg, respectively. Patches are changed weekly. Steady-state levels are achieved after 48 to 72 hours of initial placement. Many patients prefer the transdermal patch to the tablets because of administration ease, reduced incidence of rebound hypertension, and fewer side effects due to stable steady-state drug levels. Caution should be exercised in patients with significant hirsutism, such as renal transplant recipients on cyclosporine, or patients with excess sweating due to difficulties in maintaining the patch properly applied to the skin surface.

Methyl dopa

Methyl dopa is one of the few antihypertensive medications with wide experience and proven safety in pregnancy. Unique side effects include a higher incidence of fluid reten-

tion and weight gain than that seen with the other sympatholytics, a less favorable effect on lipid profiles, and development of a positive direct Coombs' reaction in approximately 25% of patients. Five percent of patients who develop this reaction may develop hemolytic anemia or hepatitis that resolves after requiring discontinuation. Although patients may develop positive antinuclear antibodies or rheumatoid factor, overt clinical manifestations of autoimmune disease are uncommon. The pediatric dosage of methyl dopa is 5 to 20 mg/kg per dose two to three times daily, and it is available as 125-, 250-, and 500-mg tablets and as a 250-mg/5 mL oral suspension. The use of methyl dopa is restricted primarily to hypertension associated with pregnancy.

Guanabenz and Guanfacine

Pediatric experience with guanabenz and guanfacine is limited, and neither has demonstrated side effects that differ from those of the class. Guanabenz appears to have the most favorable effect on lipid profiles. Guanfacine has the longest half-life, often permitting once-daily dosing. No pediatric dosing for these medications has been determined. For older adolescents and adults, guanabenz is available in 4- and 8-mg tablets, and dosing is 4 to 16 mg per dose twice daily. Guanfacine is available as 1- and 2-mg tablets, and usual dosing is 1 to 3 mg per dose as a single daily dose.

Miscellaneous Antihypertensive Medications

Prazosin

Prazosin (along with newer agents terazosin, doxazosin, trimazosin, and indoramin) selectively antagonizes peripheral α_1 -adrenergic receptors, resulting in dilation of both arteriolar resistance and venous capacitance vessels. Although these drugs cause less reflex tachycardia, renin release, and catecholamine excretion than direct vasodilators, significant postural hypotension may occur. The safety of peripheral α_1 -adrenergic receptor antagonists has recently been questioned after the results of an adult study in which doxazosin was associated with a doubling of the risk for heart failure compared to patients on low-dose chlorthalidone (121). Pediatric experience with this class of drug is limited, and pediatric dosing has not been established. However, prazosin may be most effective when used in combination with ACE inhibitors, CCBs, labetalol, or diuretics when triple-drug therapy is needed for control of refractory hypertension. It is available in 1-, 2-, and 5-mg tablets. The usual adult dosing is 1 to 5 mg three times daily.

Phenoxybenzamine and Phentolamine

Phenoxybenzamine and phentolamine are α -adrenergic antagonists used almost exclusively in the treatment of pheochromocytoma. Phenoxybenzamine, which binds irreversibly to α_1 - and α_2 -adrenergic receptors, reduces BP and diaphoresis

From Miller K. Effects of antihypertensive agents on a variety of physiological factors. Pharmacological management of hypertension in paediatric patients: a comprehensive review of the efficacy, safety, and dosage guidelines of the available agents. *Drugs* 1994;48(6):868–887, with permission.

without blockade of β -adrenergic receptors. Phentolamine, which is a competitive antagonist of α_1 - and α_2 -adrenergic receptors, may be administered parenterally during a pheochromocytoma-associated hypertensive crisis or in the perioperative period during tumor excision. The onset of action is immediate with a duration of action of 30 to 60 minutes. Side effects related to α -blockade include tachycardia, postural

hypotension, nasal congestion, fatigue, miosis, gastrointestinal irritation, drowsiness, and inhibition of ejaculation.

Phenoxybenzamine is available as a 10-mg capsule and is used as chronic therapy at an initial dose of 2.5 mg twice daily. Dosage adjustments are made every 4 to 7 days up to a maximum dose of 20 to 25 mg/day in young children and 40 to 100 mg/day in adolescents and adults in two to three divided

doses. Phentolamine may be administered parenterally at a dose of 0.05 to 0.10 mg/kg per dose up to a maximum of 5 mg 1 to 2 hours before surgery and repeated every 2 to 4 hours as needed.

Combination Antihypertensive Products

A number of fixed-dosage combination products have been designed for the treatment of hypertension. The proposed benefit of such products is the synergistic effect of antihypertensive agents with differing mechanisms of action and the minimization of side effects with the use of lower dosages of different drug classes. Examples of categories of combination drugs include β -adrenergic antagonist-diuretic, ACE-inhibi-

tor-diuretic, AII receptor antagonist-diuretic, diuretic-diuretic, and CCB-ACE inhibitor. Only one study to date has evaluated the pharmacokinetics and efficacy of a combination drug (bisoprolol-hydrochlorothiazide; Ziac) in the pediatric population (103). The use of combination drugs in children and adolescents remains limited at present but may increase over time as pediatricians gain familiarity with these agents.

Comparison of Antihypertensive Medications

In the selection process of an antihypertensive agent, the physician must appraise the physiologic effects on systemic hemody-

TABLE 62.9. CONTRAINDICATIONS TO THE USE OF VARIOUS ANTIHYPERTENSIVE MEDICATIONS

Angiotensin-converting enzyme inhibitors/angiotensin-II receptor blockers
Pregnancy
Bilateral renal artery stenosis (or renal artery stenosis in solitary kidney)
Acute renal failure
Calcium-channel blockers
Left ventricular dysfunction (verapamil and diltiazem)
Sick sinus syndrome, second- or third-degree atrioventricular block (verapamil and diltiazem)
Atrial flutter or atrial fibrillation (verapamil and diltiazem)
Neonates (verapamil and diltiazem)
β-Adrenergic antagonists
Asthma
Insulin-dependent diabetes mellitus
Raynaud's phenomenon
Congestive heart failure
Atrioventricular conduction disturbances (other than first-degree heart block)
Diuretics
Thiazides in neonates with hyperbilirubinemia
Loop diuretics in patients with hypercalciuria/nephrocalcinosis
Potassium-sparing in patients with hyperkalemia, diabetic nephropathy
Direct vasodilators
Hydralazine—coronary artery disease, cerebrovascular disease, mitral valve disease
Minoxidil—pheochromocytoma, congestive heart failure, recent myocardial infarction
Diazoxide—cerebral hemorrhage, dissecting aortic aneurysm, acute myocardial infarction, aortic coarctation
Nitroprusside—coarctation of aorta, increased intracranial pressure
Central sympathetic inhibitors
Clonidine, Guanabenz, Guanfacine—none other than hypersensitivity to drug
Methyldopa—acute/active hepatic disease
Other drugs
Reserpine—mental depression
Prazosin—none other than hypersensitivity to drug

namics, cardiac and renal function (Table 62.6), potential side effects (Tables 62.7 or 62.8), and cost. Contraindications to the use of various antihypertensive medications is presented in Table 62.9. With attention to these details, the practitioner is able to assess the benefit:risk ratio of any antihypertensive drug.

TREATMENT PLANS FOR SPECIFIC TYPES OF HYPERTENSION

Hypertensive Emergencies

Patients who present with severe hypertension (BP greater than the ninety-ninth percentile for age, height percentile, and gender) or an acute BP elevation require immediate attention if they present with a hypertensive urgency or

emergency. A *hypertensive urgency* is a situation in which the possibility exists for progression to a hypertensive emergency requiring a decrease in BP within 12 to 24 hours (112). A hypertensive emergency is defined by elevations in systolic and diastolic BP associated with end-organ injury of the brain, heart, and/or kidneys. Clinical manifestations of hypertensive emergencies include hypertensive encephalopathy, congestive heart failure, pulmonary edema, acute renal failure, stroke, head trauma, myocardial infarction, adrenergic crisis, dissecting aortic aneurysm, or eclampsia. Hypertensive encephalopathy typically presents with a prodrome lasting for at least 12 to 48 hours consisting of headache, altered mental status, visual impairment, seizures, or focal neurologic deficits. The symptoms of hypertensive encephalopathy appear to be a result of disturbances in cerebral autoregulation, which lead to altered cerebral blood flow and perfusion pressure.

An algorithm for treating hypertensive emergencies is shown in Figure 62.2. This algorithm incorporates a 25% reduction in BP during the initial hour after presentation with a hypertensive emergency and recommends not achieving a mean arterial pressure below the ninety-fifth percentile for age and height until 24 to 48 hours after presentation. Excessive reductions in mean arterial pressure must be avoided, because this can lead to diminished cerebral blood flow and syncope that may progress to infarction of the cerebral cortex, brainstem, or retina.

Essential Hypertension

Although hypertensive children younger than 10 years are more likely to have a secondary cause for their hypertension, older children and adolescents most commonly have no identifiable etiology and are considered to have essential hypertension. All children with essential hypertension should be counseled on the nonpharmacologic lifestyle interventions previously described. Antihypertensive therapy in children with essential hypertension should be aimed at reducing BP below the ninetieth percentile and preventing or reversing target organ damage. Figure 62.3 provides a general approach to the treatment of a child with essential hypertension. The choice of antihypertensive drug should take into account the potential for adverse side effects, including hyperlipidemia, electrolyte abnormalities, glucose intolerance, sedation, and behavioral changes (Table 62.7 or 62.8), as well as contraindications of various medications (Table 62.9).

Children without target organ damage and BP between the ninety-fifth and ninety-ninth percentile should be placed on a nonpharmacologic regimen for 3 months before considering the addition of antihypertensive medication. Children with target organ damage and/or severe hypertension (BP greater than ninety-ninth percentile) should receive both nonpharmacologic interventions and antihypertensive medications.

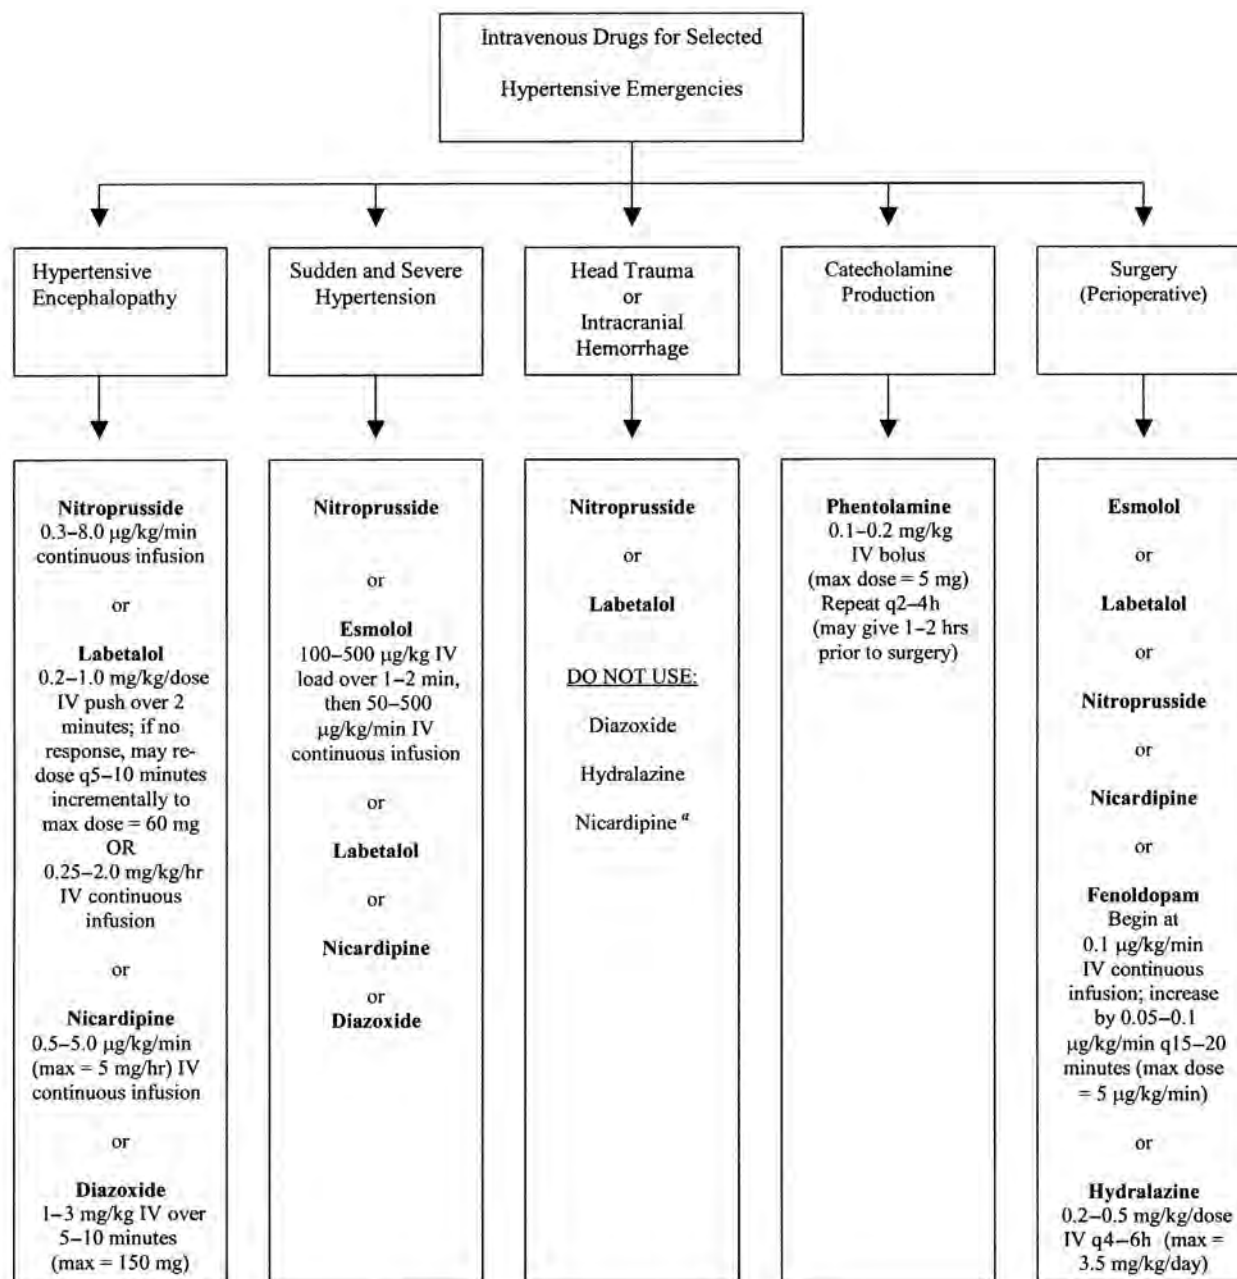

FIGURE 62.2. Suggested treatment options for hypertensive emergencies. ^aUse with extreme caution in children with space-occupying intracranial lesions and severe atelectasis or pneumonia. (Modified from Feld LG, Waz WR. Pharmacologic therapy of hypertension. In: Feld LG, ed. *Hypertension in children*. Boston: Butterworth-Heinemann, 1997:133–178.)

Hypertensive Athlete

Treatment of the hypertensive athlete presents unique issues because of the potential for medication-related side effects. Impairment in athletic performance may result from the use of β -adrenergic antagonists, which reduce cardiac contractility and cardiac output, or diuretics, which reduce intravascular volume. As a result, ACE inhibitors or dihydropyridine CCBs

are the preferred agents in hypertensive athletes requiring pharmacologic therapy, because they effectively lower BP without significant adverse effects on cardiac output, cardiac contractility, or intravascular volume that might impair athletic performance (122). Recommendations by the American Academy of Pediatrics Committee on Sports Medicine and Fitness for hypertensive pediatric patients wishing to participate in competitive sports are summarized in Table 62.10 (51).

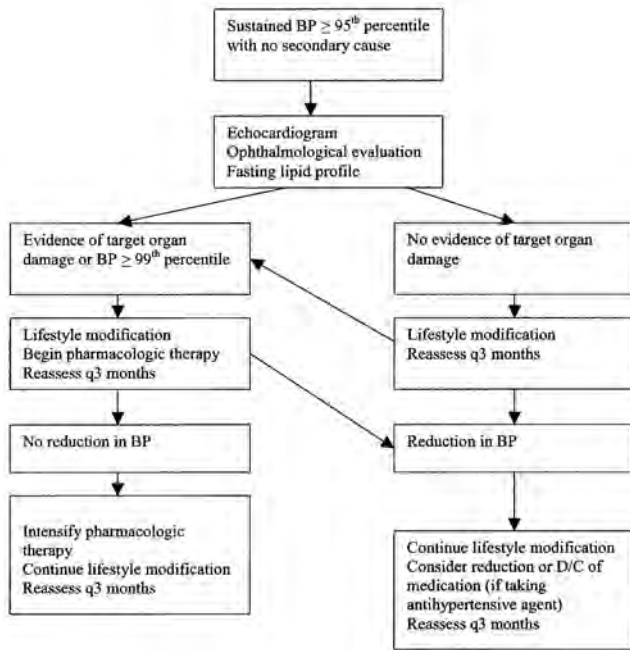

FIGURE 62.3. Suggested treatment of essential hypertension. BP, blood pressure; D/C, discontinue.

Neonatal Hypertension

Hypertension is seen in approximately 2% of term or preterm neonates (123). Premature infants; infants with acute renal failure, respiratory distress, or severe infection; and those with a family history of congenital renal or heart disease are at greatest risk for developing hyperten-

TABLE 62.10. RECOMMENDATIONS FOR PARTICIPATION IN COMPETITIVE SPORTS FOR THE HYPERTENSIVE PEDIATRIC PATIENT

1. Patients with mild to moderate hypertension (90th to 99th percentile for age and height; 1996 Task Force) and no evidence of end-organ involvement or other cardiovascular disease can participate in all competitive sports. Blood pressures should be monitored every 2 mo to monitor the impact of participation.
2. Patients with severe hypertension (>99th percentile for age and height; 1996 Task Force) but with no evidence of end-organ involvement or other cardiovascular disease should be restricted, particularly from high-static sports, until blood pressure is controlled. They may then participate as in number 1. For those patients with severe hypertension and evidence of end-organ involvement, the same recommendation may be followed as long as sports participation does not exacerbate the end-organ involvement or place the patient at risk.
3. Patients with hypertension and coexisting cardiovascular disease may require additional restrictions based on the nature of the cardiovascular disease and associated risks.

From American Academy of Pediatrics Committee on Sports Medicine and Fitness. Athletic participation by children and adolescents who have systemic hypertension. *Pediatrics* 1997;99:637–638, with permission.

TABLE 62.11. PHARMACOLOGIC THERAPY OF NEONATAL HYPERTENSION

Angiotensin-converting enzyme inhibitors	
Captopril	0.05–2.0 mg/kg/d PO (÷q6–12h)
Enalaprilat	5–10 µg/kg/dose IV (q8–24h)
Beta-adrenergic antagonists	
Esmolol	100–500 µg/kg IV load over 1–2 min, then 50–500 µg/kg/min IV continuous infusion
Labetalol	1–20 mg/kg/d PO (÷q8–12h) 0.2–1.0 mg/kg/dose IV bolus or 0.25–3.0 mg/kg/h IV continuous infusion
Propranolol	0.5–5.0 mg/kg/d PO (÷q6–12h)
Calcium-channel antagonists	
Amlodipine	0.1–0.6 mg/kg/d PO (÷q12h)
Isradipine	0.05–0.15 mg/kg/dose PO (q6h)
Nifedipine	0.125–0.5 mg/kg/dose PO (÷q6–8h) (max dose = 3 mg/kg/d)
Nicardipine	0.5–3.0 µg/kg/min IV continuous infusion
Diuretics	
Bumetanide	??
Chlorothiazide	20–30 mg/kg/d PO (÷q12h)
Furosemide	0.5–4.0 mg/kg/dose IV/PO (÷q6–8h) (max dose = 4 mg/kg/d)
Hydrochlorothiazide	2–3 mg/kg/day PO (÷q12h)
Vasodilator	
Hydralazine	0.1–0.6 mg/kg/dose IM/IV q4–6h OR 0.75–5.0 µg/kg/min IV continuous infusion
Sodium nitroprusside	0.5–8.0 µg/kg/min IV continuous infusion

÷, divided.

sion. Causes of neonatal hypertension are reviewed in Chapter 60. The choice of pharmacologic therapy of neonatal hypertension depends on the underlying cause and severity of the hypertension. Hypertension in some neonates resolves once the underlying cause is properly treated, such as obstructive uropathy, hypervolemia associated with acute renal failure, or coarctation of the aorta. The initial approach to treatment of neonates with hypertension due to thromboembolism from an umbilical artery catheter is catheter removal. Antihypertensive medication may be required for 1 to 2 years in these patients. Medications used in neonatal hypertension are listed in Table 62.11.

Chronic Kidney Disease

BP control is particularly important in the CKD population, as studies in adult and animal models of kidney disease demonstrate that effective BP control and reduction of proteinuria delay the progression of chronic renal insufficiency (63–66,75–77). Although nonpharmacologic therapies remain a critical component of the therapeutic strategy to properly control BP in patients with CKD, these lifestyle

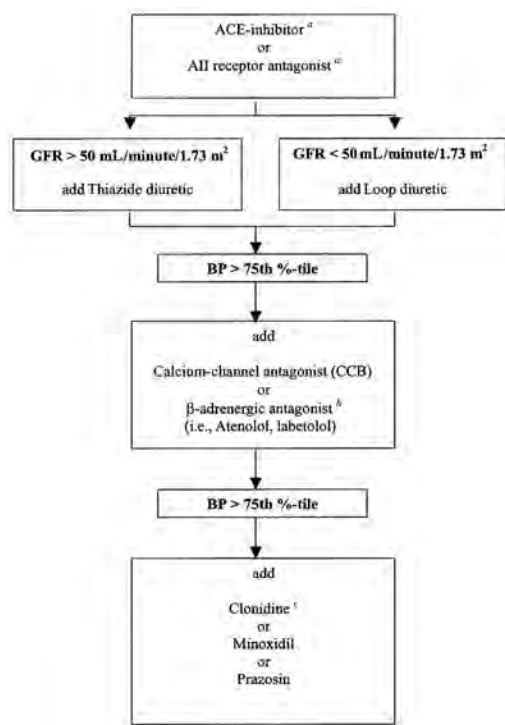

FIGURE 62.4. Suggested pharmacologic approach for treatment of hypertension in chronic kidney disease. Blood pressure (BP) goal should be below the 75th percentile for age, height, and gender. ^aUse with caution in patients with glomerular filtration rate (GFR) <50 mL/min/1.73 m² and discontinue if hyperkalemia or acute decrease in GFR. ^bAvoid if patient on β-adrenergic antagonist. ^cMay contribute to the development of hyperkalemia. ACE, angiotensin-converting enzyme; CCB, calcium-channel blocker. (Modified from Feld LG, Lieberman E, Mendoza SA, et al. Management of hypertension in the child with chronic renal insufficiency. *J Pediatr* 1996;129:518.)

modifications are rarely sufficient in achieving BP measurements below the seventy-fifth percentile.

The pharmacologic approach for treating hypertension is different in patients with CKD, compared to those with essential hypertension (124). Guidelines derived from the National Kidney Foundation Hypertension and Diabetes Executive Committees Working Group (125) for treating hypertension in CKD patients are presented in Figure 62.4. Recommended dosage adjustments for antihypertensive agents in children with CKD are outlined in Table 62.12.

The hallmark of therapy in hypertensive CKD patients with a mild impairment in kidney function is blockade of the renin-angiotensin-aldosterone pathway with ACE inhibitors or AII receptor antagonists. Importantly, dose adjustments of antihypertensive medications should not be made more frequently than every 2 to 3 days when maximal dosage effect may occur. Addition of a second antihypertensive agent should not occur until maximum dosage is achieved with the initial drug.

Another important aspect of treating hypertensive CKD patients is sodium restriction and diuretic therapy to reduce

TABLE 62.12. RECOMMENDED DOSAGE ADJUSTMENTS FOR SELECTED ANTIHYPERTENSIVE DRUGS FOR PATIENTS WITH CHRONIC KIDNEY DISEASE

Drug	Adjustment in CRI	Effect on renin
Diuretics		
Chlorothiazide	Thiazides not effective at GFR <30–40 mL/min/1.73 m ²	Increase
Hydrochlorothiazide		
Furosemide	None	
Bumetanide	Unknown	
Metolazone	Unknown	
β-Adrenergic antagonists		
Acebutolol	Decrease dose	Decrease
Atenolol	Decrease 50% at GFR <50 mL/min/1.73 m ² , give QOD at GFR <10 mL/min/1.73 m ²	
Labetalol	None	
Metoprolol	None	
Propranolol	None	
Vasodilators		
Hydralazine	None	Increase
Minoxidil	None	
Central sympatholytic		
Clonidine	None	Decrease
Angiotensin-converting enzyme inhibitors		
Captopril	Caution with all ACE inhibitors when GFR <50 mL/min/1.73 m ²	Increase
Enalapril		
Lisinopril		
Angiotensin-II receptor antagonists		
Losartan	Caution with all All receptor blockers when GFR <50 mL/min/1.73 m ²	Increase
Valsartan		
Calcium-channel blockers		
Nifedipine	May need to limit dose	None
Diltiazem	Unknown	
Verapamil	With caution	

All, angiotensin II; ACE, angiotensin-converting enzyme; CRI, chronic renal insufficiency; GFR, glomerular filtration rate. Modified from Feld LG, Lieberman E, Mendoza SA, et al. Management of hypertension in the child with chronic renal insufficiency. *J Pediatr* 1996;129:518.

the intravascular volume. Mechanisms for loop diuretic resistance in CKD include decreases in loop diuretic basal fractional NaCl reabsorption and proximal tubular secretion. Other factors for loop diuretic resistance include decreased renal clearance and enhanced distal nephron NaCl reabsorption. Strategies to overcome loop diuretic

resistance include maintaining adequate BP and intravascular volume; correction of metabolic acidosis, uremic organic acids, and hyperuricemia; avoiding the use of organic anion medications that compete for the OATs; and addition of thiazides or quinazolones. However, thiazides should be used with caution in patients with mild to moderate renal insufficiency, because they may result in significant reductions of intravascular blood volume leading to hypotension and prerenal azotemia.

ACUTE RENAL FAILURE

PATHOGENESIS OF ACUTE RENAL FAILURE

**NORMAN J. SIEGEL
SCOTT K. VAN WHY
PRASAD DEVARAJAN**

PATHOPHYSIOLOGIC MECHANISMS

Acute renal failure (ARF) is defined as the sudden loss of renal function that may result from inadequate renal perfusion associated with a decrease in effective circulation, arterial or venous obstruction, renal cell injury, or obstruction to urine flow as occurs in obstructive uropathy (see Chapters 54 and 55). Renal cell injury commonly results from an ischemic or toxic insult that causes acute tubular damage. In this circumstance, the decrease in glomerular filtration rate (GFR), an invariable component of ARF, is a successful adaptive response in that the continued filtration of plasma across the glomerular basement membrane without reabsorption of the filtrate by the renal tubules results in massive losses of salt and water (1). Thus, the decreased GFR associated with ARF prevents severe depletion of extracellular fluid (ECF). This chapter describes the pathophysiology of ARF to provide a contemporary understanding of the cellular and molecular mechanisms that are associated with epithelial cell injury.

PATHOPHYSIOLOGY OF EXPERIMENTAL ACUTE RENAL FAILURE

Initially, studies on the pathophysiology of ARF were descriptive and involved the development of experimental models. Contemporary studies have been concerned with the pathophysiology of cell injury, particularly related to renal tubule function and metabolism. This chapter addresses the cellular, molecular, and metabolic alterations associated with loss and restitution of epithelial cell integrity and functions.

Renal Hemodynamics

Renal vasoconstriction is intense in experimental and clinical ARF (2–4). Because vasoconstriction was considered to

be the dominant factor, it was suggested once that the term *vasomotor nephropathy* might be more appropriate than ARF to describe this condition (5). The hypothesis was that an insult to the renal tubular epithelium resulted in release of vasoactive compounds that increased cortical vascular resistance, thereby decreasing renal blood flow (RBF) and perpetuating injury to the tubule. Release of vasoconstrictive compounds diminished GFR by constricting the afferent and efferent arterioles, which led to a diminished urine output, or oliguria (3). Therefore, emphasis has been placed on identifying vasoactive compounds that are stimulated or induced by an ischemic or toxic insult. Candidate systems for vasoconstriction and vascular components of epithelial cell injury include angiotensin, prostaglandins, adenosine, endothelin, and nitric oxide (NO).

Renin-Angiotensin System

The renin-angiotensin system functions in a manner consistent with the renal vasoconstriction hypothesis (3,6). An injury to the more proximal portion of the nephron that impairs reabsorption results in the delivery of more solute and water into the distal nephron. This increased solute load enters the distal nephron and perfuses the macula densa of the juxtaglomerular apparatus, stimulating the intrarenal release of renin with the subsequent generation of angiotensin II, a potent renal vasoconstrictor.

Several findings suggest that this system may have a role in the pathogenesis of ARF:

1. Hyperplasia of the juxtaglomerular apparatus with increased renin granules is reported both in patients and in experimental animals with ARF.
2. Plasma renin activity is increased in patients with ARF.
3. Changing intrarenal renin content modifies the degree of renal functional impairment; for example, animals fed a high-salt diet (which suppresses renin production) before a renal injury have better preservation of

renal function than those fed a low-salt diet (which stimulates renin production).

However, other findings suggest that the renin-angiotensin system does not fully account for the changes in renal hemodynamics associated with ARF. For example, amelioration of the renal injury also follows the induction of a solute diuresis with either mannitol or loop diuretics, neither of which affects intrarenal renin. Furthermore, the degree of renal injury is not affected in animals that have been immunized against renin-angiotensin, treated with angiotensin-converting enzyme inhibitors, or infused with a competitive antagonist to angiotensin II. Therefore, the role of the renin-angiotensin system as the modulator of renal injury in ARF is uncertain.

Prostaglandins

Prostaglandins are potent renal vasodilators. Although inhibition of prostaglandin production is associated with decreased RBF and affects the severity of ARF, the precise role of prostaglandins in the induction and maintenance of acute tubular necrosis is not established (6). However, prostaglandin inhibitors, such as nonsteroidal antiinflammatory drugs, increase the risk for development of ARF and may act to synergize with other insults.

Adenosine

Adenosine, which results from catabolism of adenine nucleotides, is a potent vasoconstrictor of renal vasculature, whereas it is a vasodilator of peripheral vasculature (7). The infusion of methylxanthines, which block adenosine receptors, inhibits the tubuloglomerular feedback mechanism and the decrease in GFR that accompanies reduced tubular absorption, suggesting that adenosine may be involved in the modulation of renal vascular resistance in ARF. In some experimental models, the infusion of methylxanthines has been associated with diminished functional impairment. The proposal that adenosine is an important vasoactive compound after an acute tubule insult is attractive because it would link alterations in cell metabolism with hemodynamic changes.

However, the evidence that adenosine is a major factor in the vasoconstrictive response is inconclusive:

1. Methylxanthines have a variety of effects in addition to the inhibition of adenosine receptors.
2. Although adenosine is produced after the initiation of adenine nucleotide catabolism, it is rapidly catabolized by adenosine deaminase when released into ECF.
3. Intrarenal levels of adenosine diminish very rapidly on the establishment of reflow to the kidney, whereas renal vasoconstriction is continued through the early phases of reperfusion after an ischemic injury.
4. When tissue adenosine levels are increased by inhibition of adenosine deaminase during ischemia, postischemic recovery of renal function is enhanced (8).

Endothelin

Endothelin, a 21-amino-acid peptide, is a very potent renal vasoconstrictor that has other important biologic activities as well (9–11). It contributes to the vasoconstriction that occurs in a number of tissues and organs as a response to hypoxia. Raised endothelin levels in plasma and in both the cortex and medulla of the kidney have been demonstrated in experimental animals after the induction of renal ischemia (9). The postischemic infusion of antiendothelin antibody or endothelin-receptor antagonists provides protection from ischemic injury (9–11). This represents a very early event in the initiation of ARF and may be quite specific for only some types of injuries.

Nitric Oxide

NO is a potent renal vasodilator that is widely distributed in the kidney and is produced by constitutive and inducible synthetases located in endothelial cells and renal tubules (12). Although a specific role for these compounds in cerebral ischemia has been established (13), the effect of either stimulation or inhibition of NO synthetase (NOS) on ischemic or toxic ARF is confusing and, at times, contradictory. The rat kidney was protected from ischemic injury when inducible NOS was targeted with oligodeoxynucleotides, suggesting that NO had a direct cytotoxic effect on renal epithelia (14). A similar cytotoxic effect of NO has been documented in isolated proximal tubule cells subjected to hypoxia (15). Yet, it has been postulated that production of NO after ischemia should help alleviate the vasoconstriction that characterizes ARF, and nonselective NOS inhibition has been shown to result in worsening of renal function and profound vasoconstriction (13). Hence the enigma: Stimulation of NO in the renal vasculature via NOS will modulate vasoconstriction and lessen injury; induction of NO via NOS in renal tubules is cytotoxic (12–14). This complex biologic system may play a role in the pathogenesis of ARF, but the specificity of involvement remains to be determined.

All things considered, renal vasoconstriction is a well-documented factor in initiating ARF, but vasodilation does not consistently result in amelioration of an acute renal insult. Once ARF has been established, the infusion of potent vasodilators such as prostaglandins or dopamine does not lead to sustained improvement in GFR (16,17). The early recovery phase of ARF is associated with an increase in RBF, whereas GFR increases more slowly (18). Although renal hemodynamic factors play an important role in initiating ARF, alterations in renal vascular resistance and renal perfusion may not be the dominant determinants of epithelial cell injury.

Nephronal Factors

The term *nephronal factors* refers to the unique susceptibility of various nephron segments to injury. Best studied, in

this regard, are the S₃ segment of the proximal tubule and the medullary thick ascending limb (mTAL). Studies of cellular injury and repair in each of these segments have provided important insights into the pathophysiology of tubule cell injury.

Medullary Thick Ascending Limb

The mTAL is particularly vulnerable to hypoxia because oxygen tension in this, the medullary area, is low, and the mTAL segment has a high rate of oxygen consumption (19). Initial observations that established this relationship were made in isolated kidneys that were perfused with cell-free perfusate. Hypoxic injury to the mTAL progresses rapidly from mitochondrial swelling to nuclear pyknosis and then complete cellular disruption. These lesions in the mTAL are prevented or reversed by increasing oxygen delivery with the addition of red blood cells or hemoglobin to the perfusion media.

The degree of mTAL necrosis also is modified by the workload imposed on this segment. Inhibiting transport by infusing furosemide or ouabain significantly diminishes the degree of injury; increasing the workload has the opposite effect. It has been suggested that lesions in the mTAL may be enhanced because swelling in the S₃ segment of the proximal tubule would decrease venous return from the medullary portion of the kidney by impingement of the swollen S₃ segments on venules.

The relationship of these observations, made largely during *in vitro* studies of the isolated perfused kidney, to the pathogenesis of acute tubular necrosis in humans is controversial. Reducing the inspired oxygen content in experimental animals does not reproduce these lesions *in vivo*, and the experimental models in which the lesions occur *in vivo* are those that combine severe reductions in RBF with the administration of a nephrotoxin. The unique vulnerability of this nephron segment to hypoxia has provided new information concerning important relationships between oxygen supply, workload, and the cellular targets of an ischemic, hypoxic, or anoxic injury (20). In large measure, these pathophysiologic changes may be most pertinent in the synergistic effects of agents that would not on their own produce ARF.

Straight Segment of the Proximal Tubule

The straight segment of the proximal tubule (S₃ segment) depends on oxidative phosphorylation for the energy required for its transport functions. It is particularly susceptible to ischemia and to those nephrotoxins that disrupt energy supply or mitochondrial function (6,21). The earliest responses to ischemia are found in the brush border and consist of blebbing and internalization of the luminal membrane. Even mild and short-term (as little as 10 minutes) ischemia can result in sloughing of the brush border and other alterations in the proximal tubule histomorphology. With more prolonged ischemia, these changes progress to a lethal injury of some cells

in which the tubule epithelium is denuded from the basement membrane and a sublethal injury characterized by swelling, mitochondrial condensation, and disruption of cellular morphology in other cells. These changes in the S₃ segment result in two important pathophysiologic events.

Intratubular Obstruction and Backleak

Cell and brush-border debris become impacted in the hairpin turn of the loop of Henle and produce obstruction and backleak of tubular fluid in some nephron segments. Intratubular obstruction has been documented by determination of elevated proximal tubular pressure and by histomorphology after ischemic injury (21–23).

A loss of tubular integrity and backleak of tubular fluid have been demonstrated in both experimental animals and patients (21–24). In experimental animals, the microinjection of inulin or horseradish peroxidase into normal nephrons results in the inulin being collected only from that kidney or the staining of horseradish peroxidase only within that tubule lumen. However, microinjection into an injured nephron results in inulin being excreted by the contralateral kidney and the horseradish peroxidase being found in both intratubular and peritubular loci.

In patients with ARF, backleak has been demonstrated by the differential clearance of graded dextrans (24). These observations and an understanding of this mechanism have clinical implications. If inulin, urea, and creatinine leak back into the circulation, the renal clearances of these solutes are no longer suitable for estimating GFR in patients with ARF.

Over the past several years, the cellular and molecular basis for tubule obstruction and backleak have been documented (25,26). Integrins are proteins that are (a) located on the basal domain of epithelial cells and (b) attach tubules to ligands in the extracellular matrix. After ischemia or adenosine triphosphate (ATP) depletion, these proteins lose their attachment to the extracellular matrix, which allows both injured and viable cells to be liberated from the tubule basement membrane and float into the tubule lumen. In addition, these integrins become displaced from the basal to the luminal domain, which allows individual cells to attach via an arginine-glycine-aspartic acid (RDG sequence) adhesion mechanism (25). This RDG sequence may also promote binding of sloughed tubule cells to Tamm-Horsfall protein, which is produced in the thick ascending limb and distal convoluted tubule and contains an RDG sequence (26). The infusion of RDG peptide abolished the characteristic increase in proximal tubule pressure and substantially improved renal function (27,28).

Cellular and Metabolic Alterations

Reactive Oxygen Molecules

Reactive oxygen molecules have been implicated in a variety of kidney diseases, including reperfusion injury after

FIGURE 63.1. Schematic of adenosine triphosphate (ATP) metabolism that results from renal ischemia. Adenine nucleotide catabolism proceeds in a clockwise direction.

ischemia (29). The most highly reactive oxygen molecules are free radicals such as hydroxyl radical (OH) or superoxide anion (O_2^-). The very high reactivity and brief existence of these molecules result in injury very close to the site of free radical generation. Other oxygen species such as hydrogen peroxide (H_2O_2) and hypochlorous acid (HOCl), not being free radicals, are less reactive. However, they have longer half-lives than free radicals and in some cases may cross cell membranes to cause injury distant from their site of origin.

Reactive oxygen molecules also are generated during reperfusion of kidneys (29). Ischemia results in a rapid fall in cellular ATP levels with subsequent metabolism of the adenine nucleotides to adenosine, inosine, and hypoxanthine (Fig. 63.1). Ischemia also may cause a conformational change in xanthine dehydrogenase [which uses NAD (nicotinamide adenine dinucleotide) as an electron receptor] to xanthine oxidase, which uses oxygen (30). Once perfusion and oxygen delivery are returned, xanthine oxidase can metabolize hypoxanthine to xanthine and uric acid, generating hydrogen peroxide and superoxide anion (Fig. 63.1). Mitochondria, which produce reactive species through electron transport systems, when damaged by ischemia, may leak the injurious oxygen metabolites. The respiratory burst and myeloperoxidase released from activated polymorphonuclear leukocytes produce superoxide anion, hydrogen peroxide, and hypochlorous acid (29). Prostaglandin metabolism may also provide reactive molecules. Iron can play a significant part by donating electrons to hydro-

gen peroxide to form the highly damaging hydroxyl radical (31). In this way, iron release may be responsible for the injury resulting in hemoglobin- or myoglobin-induced ARF (32).

Once generated, reactive oxygen molecules damage cellular components and extracellular matrix (33). Many amino acid residues on cellular proteins may be oxidized, resulting in conformational changes with loss of enzymatic activity or loss of the integrity of structural proteins. Membrane lipids and lipoproteins undergo peroxidation by free radicals; these propagate and result in progressive membrane damage. Hydroxyl radicals damage DNA and oxidize matrix proteins. Reactive oxygen metabolites may contribute to ischemia by deleterious interactions with NOSs. Because of the putative effects, a great deal of attention has been paid to determining the role of reactive oxygen molecules in ischemic-reperfusion injury (29,34). The effects of enhancing endogenous antioxidants (superoxide dismutase, glutathione, and catalase) or administering exogenous free radical scavengers have been examined. Despite the large number of studies using these techniques, no final conclusion can be made as to the importance of reactive oxygen species, because strong evidence exists both for and against these compounds having a dominant role.

Adenine Nucleotide Metabolism

Energy depletion and restoration are believed to play a pivotal role in renal cell injury (33). *In vivo*, renal ischemia results in a profound fall in ATP, and, *in vitro*, metabolic inhibition of ATP production is used to induce cellular injury. Within 5 to 10 minutes of renal ischemia, nearly 90% of ATP has been consumed (8). With reperfusion, renal ATP levels recover in a bimodal fashion (Fig. 63.2). In the first few minutes of reper-

FIGURE 63.2. The course of renal adenosine triphosphate (ATP) depletion and recovery during ischemia and reperfusion. The initial rapid phase of ATP recovery represents phosphorylation of remaining AMP and ADP. Slow recovery phase occurs by resynthesis and phosphorylation of adenine nucleotides.

fusion, there is a rapid, although incomplete, recovery of ATP to 50 to 70% of normal levels, depending on the duration of ischemia (34,35). The longer the interval of ischemia, the smaller the degree of renal ATP recovery during this rapid phase. ATP recovery during this initial phase correlates highly with the total pool of adenine nucleotides (ATP + ADP + AMP) that are present in the kidney at the end of the ischemic interval. The total adenine nucleotide pool, mainly composed of AMP, decreases as the duration of ischemia increases. The catabolism of adenosine by adenosine deaminase results in depletion of the adenine nucleotide pool with extended duration of ischemia (Fig. 63.1). Thus, the predominant means of ATP recovery during the initial period of reoxygenation is through oxidative phosphorylation of the residual cellular nucleotides (AMP and ADP).

After the rapid phase, a second, slow phase of ATP recovery occurs over hours. The ATP recovery rate in this phase also depends on the duration of the preceding ischemia; longer ischemic intervals result in slower recovery rates. The second phase requires resynthesis of ATP from purine nucleotide degradation products and salvage pathways or from precursors provided during reperfusion. A primary role for ATP depletion in the cellular event that leads to epithelial cell injury is supported by several findings:

1. When ATP catabolism is inhibited during ischemia, the structural and functional consequences of renal artery occlusion are significantly ameliorated (18,21,33).
2. Graded reductions in cellular ATP either *in vivo* or *in vitro* determine the severity of cellular disruption (36,37).
3. Augmentation of recovery of ATP during reperfusion substantially enhances recovery of structure and function (33).

Consequently, alterations in adenine nucleotide metabolism are both a consequence and predictor of renal cell injury. In addition, limited cellular ATP sets in motion a sequence of events that lead to disruption of epithelial structure and function: increased intracellular calcium, activation of phospholipases, loss of polarity, and detachments of the cortical cytoskeleton.

Alterations in Intracellular Calcium

Under normal circumstances, ECF calcium concentration exceeds that of intracellular free calcium (Ca_i) by a factor of 10^4 . The remarkably low Ca_i is maintained by a variety of mechanisms that exclude calcium from the cell or sequester it within intracellular compartments. Calcium is extruded from cells by plasma membrane Ca^{2+} -adenosine triphosphatase (ATPase) and Na^+ - Ca^{2+} exchanger. Intracellular sequestration is mediated by Ca^{2+} -ATPase in the endoplasmic reticulum and by calcium uptake into mitochondria. A fall in cellular ATP will adversely effect Na^+ - K^+ -ATPase and Na^+ - Ca^{2+} transporter, which, taken together, would likely result in decreased calcium transport out of cells and a rise in Ca_i . However, a rise in mitochondrial calcium levels after

ischemic and toxic cell injury usually occurs after cell injury is lethal because mitochondrial calcium uptake is substantial only when cytosolic levels rise because even damaged mitochondria are able to actively sequester calcium (34). In addition, it has been suggested that release of Ca_i from cellular organelles contributes substantially to the rise in cytosolic Ca.

It is unclear whether high Ca_i levels play a central role in the pathophysiology of cell injury or the intracellular Ca changes are merely secondary to cell death. Increased cell and mitochondrial Ca levels are linked with cell death but are not thought to increase until irreversible changes have occurred (38,39). In light of the many ATP-dependent mechanisms responsible for Ca exclusion from the cytosol, it is surprising that only recently an increase in Ca_i has been documented early in the course of cell injury. After 5 minutes of hypoxia, rat proximal tubules developed a significant rise in Ca_i before evidence of membrane damage and the increase in Ca_i was reversed with reoxygenation (40). An increase in Ca_i could contribute to renal cell injury in several dimensions: increased activity of proteases and phospholipases; calpain activation, which would contribute to degradation of cytoskeleton; and inhibition of mitochondrial oxidative phosphorylation. Nonetheless, controversy remains about the extent to which increased Ca_i contributes to these pathophysiologic mechanisms.

Phospholipids and Phospholipases

The striking morphologic changes that occur in proximal tubules after ischemia, especially brush-border membrane blebbing, and the release of intracellular enzymes such as lactate dehydrogenase suggest that significant membrane alterations may be part of the cellular injury. Changes in intracellular calcium flux have been shown to activate endogenous phospholipase, and some phospholipase may be activated by decreased cellular ATP. Phospholipase activation results in breakdown of membrane phospholipids into products including free fatty acids and lysophospholipids, which may disrupt membranes. The accompanying lack of ATP during ischemia may prevent the synthesis of new phospholipids to replenish membranes. The result is a generalized loss of membrane phospholipids with an accumulation of degradative products that by their detergent activities further disrupt cell membranes and eventually lead to loss of membrane integrity and cell death.

Renal ischemia does indeed result in activation of phospholipase (PLA_2) and a rapid fall in cortical phospholipid levels (41). The detrimental effects of PLA_2 can be offset by unsaturated free fatty acids (42) and suggest that PLA_2 could be cytotoxic by degradation of phospholipids in cell membranes or through accumulation of lysophospholipids (43).

Cell Polarity

Renal tubules are composed of highly specialized cells whose primary function of transport depends on their polar structure (Fig. 63.3). Changes in cell polarity that occur during ARF have important effects on these functions (37). The plasma membrane of proximal tubule cells is divided into apical and basolateral domains by the tight junction that it shares with neighboring cells. The apical membrane, which faces the tubule lumen, differs from the basolateral membrane both in lipid composition and in the types of membrane proteins present. The microvilli of the apical domain are rich in sodium-dependent cotransporters and $\text{Na}^+\text{-H}^+$ antiporters, which affect reabsorption of glucose, amino acids, phosphate, and bicarbonate. The sodium gradient across the apical membrane, which drives the reabsorption of these compounds, is established and maintained by $\text{Na}^+\text{-K}^+\text{-ATPase}$, located on the basolateral membrane. Plasma membrane polarity is maintained by the tight junctions that prevent lateral diffusion of membrane phospholipids and proteins into the opposite domain. In addition, the cortical cytoskeleton anchors membrane proteins, such as $\text{Na}^+\text{-K}^+\text{-ATPase}$, in specific domains through an intricate sequence of linked proteins. The actin-based cytoskeleton is a dynamic structure that maintains cellular polarity and mediates a number of processes necessary to sustain both structure and function of renal epithelia (44). Interactions between cytoskeletal proteins and plasma membrane proteins are responsible for functions, including cell adhesion, endocytosis, signal translocation, and ion channels.

Renal ischemia *in vivo* and ATP depletion *in vitro* alter this polarity in that membrane lipids and proteins, which are highly mobile, redistribute between apical and basolateral domains (Fig. 63.3). After as little as 5 minutes of renal ischemia, there is loss, internalization, and blebbing of brush-border membranes and, shortly thereafter, basolateral $\text{Na}^+\text{-K}^+\text{-ATPase}$ migrates to the apical membranes (37). With longer ischemia, the loss of polarity worsens. Proximal tubule tight junction integrity, an obstacle to diffusion of membrane components across domains, is lost. Membrane proteins such as $\text{Na}^+\text{-K}^+\text{-ATPase}$, which normally are anchored to the actin cortical cytoskeleton, migrate when this attachment is disrupted. The actin cytoskeleton itself plays an important role in both processes because disruption of actin microfilaments results in opening of tight junctions (35,45) and loss of the polar distribution of those proteins that anchor $\text{Na}^+\text{-K}^+\text{-ATPase}$ to the plasma membrane (46). Ankyrin, which links fodrin to $\text{Na}^+\text{-K}^+\text{-ATPase}$, normally is limited to the basolateral domain. After ischemia, ankyrin migrates along with $\text{Na}^+\text{-K}^+\text{-ATPase}$ to the apical domain. After ATP depletion, spectrin, which normally links actin to ankyrin and $\text{Na}^+\text{-K}^+\text{-ATPase}$, becomes dissociated and solubilized throughout the cytosol (47). The loss of cellular polarity is a fundamental alteration in renal epithelial injury. These structural changes and the reduction in transepithelial sodium reabsorption that follows ischemia do not return to normal until membrane polarity is reestablished during reflow or ATP repletion.

FIGURE 63.3. Disruption of normal proximal tubule cell structure by ischemia includes loss of apical brush border, opening of tight junctions, and depolarization of the plasma membrane. Impairment of transepithelial solute reabsorption coincides with alterations in cell structure. Functional recovery parallels morphologic recovery. ATPase, adenosine triphosphatase.

Apoptosis

In recent years, it has been appreciated that cell death after an ischemic or toxic insult may occur by necrosis or apoptosis—a gene-directed process that results in irrevocable DNA damage (48). The characteristic biochemical marker for apoptosis is endonuclease activation, which has been documented in hypoxic and ischemic tubules (49). In the final analysis, apoptosis is the result of the dynamic interaction of an activator such as tumor necrosis factor and inhibitors such as growth factors. Apoptosis represents an important mechanism of cell death, and its role in ARF is under active investigation (48).

Factors Influencing Recovery

An understanding of factors that may influence the course of recovery from an acute insult offers an opportunity to identify mechanisms that are fundamental to cellular repair and restitution of function.

Adenine Nucleotides and Thyroxine

Because ATP depletion predicts the severity and reversibility of an ischemic injury, altering the recovery of renal ATP is a likely candidate for influencing recovery from injury. Two compounds, ATP-MgCl₂ and thyroxine, have been shown to accelerate recovery of renal ATP. In both cases, glomerular and tubular function is improved, cellular structure and polarity are stabilized, and enhanced recovery of renal function is sustained (16,32,35). Although the specific cellular mechanism by which each compound-enhanced ATP recovery is different, the end result is accelerated recovery from an ischemic or toxic insult. Adenine nucleotides-MgCl₂ provide essential precursors, particularly adenosine to the sublethally injured cells and stimulate *de novo* purine synthesis (35). Thyroxine stimulates regeneration of ATP by stabilizing the mitochondrial adenine nucleotide transporter (50).

Atrial Natriuretic Factors

Atrial natriuretic factors (ANFs), which, when infused into animals, cause a dramatic increase in salt and water excretion, also increase RBF and GFR through afferent arterial dilation and efferent arterial constriction. As is expected, ANF infusion improves overall renal function in states of volume depletion or high afferent renal artery vascular resistance. ANF is beneficial in toxin-induced renal injury, which may be attributable to its enhancement of RBF and urine flow. Of particular interest are the effects of ANF infusion after renal ischemia. When infused shortly after an interval of renal ischemia, ANF results in rapid and sustained improvement in GFR (51). Renal plasma and urine flow also are increased, as is net tubular reabsorption of sodium. Reports conflict as to whether ANF treatment improves renal histomorphology.

The mechanism of the effects of ANF is not definitively determined but is attributed to its vasodilatory properties, increased RBF, and increased tubular flow rate with concomitant relief of tubular obstruction. Thus, in established ARF, ANF may increase hydraulic pressures in obstructed nephrons sufficiently to dislodge tubule casts downstream, thereby restoring GFR (52). It has also been proposed that ANF ameliorates the ischemic injury through its initial natriuretic effect, reducing tubular reabsorptive work and thus permitting greater energy expenditure for restoring cellular integrity and polarity (51).

Leukocyte-Endothelial Adhesion

In ischemic tissues, leukocytes, particularly neutrophils, are known to adhere to the vascular endothelium and are thought to contribute to tissue injury by release of reactive oxygen species or cytotoxic enzymes (53–55) and may contribute to vascular congestion. Intracellular adhesion molecule I (ICAM-I) on endothelial cells promotes this leukocyte adhesion, and elegant studies have demonstrated that mice deficient in ICAM-I are protected against ischemic injury and that administration of ICAM-I antibody prevents ischemic ARF (54,55).

Calcium-Channel Blockers

Low-extracellular calcium levels ameliorate anoxic injury, whereas high-extracellular calcium levels enhance anoxic injury. Manipulating extracellular calcium levels to potentially ameliorate the course of ARF has obvious clinical limitations. However, calcium-channel blockers, in the setting of ARF, might alter the influx of calcium into injured cells and attenuate further cell damage or prevent cell death. The effects of calcium-channel blockers on the course and recovery from ARF are inconsistent. Specific effects have been seen in some types of injuries (34), particularly cyclosporine-related toxicity, but evidence for ubiquitous effects on basic pathophysiologic mechanisms is lacking.

Heat-Shock Proteins

Heat-shock proteins (HSPs) are a group of highly conserved proteins that are elaborated in cells and respond to injury caused by heat, anoxia, and a number of toxic agents. HSPs are present in nearly every organism studied and appear to be essential to basic cell function and survival by providing routine assistance in intracellular protein handling and trafficking (56). These stress proteins are grouped into families according to size and apparent function. Within each HSP family, certain members are constitutively expressed, and others are expressed only after injury. The pattern of HSP induction varies, depending on species, cell types, and the nature of the agent causing injury.

The loss of cell polarity and disruption of the cytoskeleton are fundamental processes that contribute to

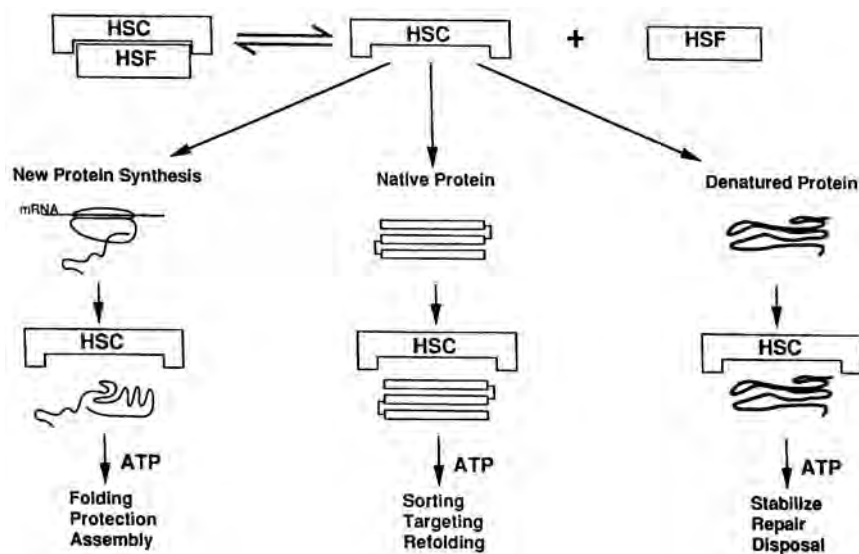

FIGURE 63.4. Known and proposed actions of 70-kDa heat-shock protein (HSP-70) system. Normal cellular protein handling accomplished by heat-shock cognate (HSC; constitutively expressed heat-shock protein). Cellular stress and increased denatured protein increases demand for HSC. Heat-shock factor (HSF; transcription factor for inducible HSP) is reversibly bound to HSC and is released with increased demand for HSC. HSF then initiates transcription of inducible HSP mRNA. ATP, adenosine triphosphate.

the pathogenesis of cellular ARF. Injured tubule cells, which have suffered loss of polarity, appear to regain their polarity through remodeling (37). The recycling of cytoskeletal and plasma membrane proteins is a primary mechanism of cellular repair after ischemia or ATP depletion (47,57).

One family of HSPs that may assist in restitution of cellular polarity and function is the 70-kDa HSP family (HSP-70). Certain members of this family are readily induced by injury and have distinctive cytoprotectant effects different from those of other HSPs. Although first identified by their ability to be induced, most of what is known about HSP-70 activity has been found by studying the constitutively expressed members. HSP-70 proteins provide various functions by their shared ability to unfold peptides and disassemble protein aggregates. These HSPs act as “chaperones” to newly formed proteins, allowing proper folding and preventing “inappropriate” peptide interactions or aggregation. In like manner, HSP-70 members assist in the translocation of proteins across intracellular membranes and assist denatured proteins in refolding or reassembling into normal configuration as part of the process of repair (Fig. 63.4).

When renal ATP levels are reduced below 50% of control values either *in vivo* or *in vitro*, heat-shock transcription factor, the most proximal component of HSP induction, is rapidly activated (36). Newly formed HSP-70/72 mRNA is found within minutes, and its rate of formation peaks within a few hours after a period of ischemia. HSP-72 protein elaboration follows shortly thereafter, accumulates in the first day after the injury, and persists for up to 5 days. HSP-72 is found in membrane protein fractions and among soluble cytoplasmic proteins, suggesting that HSP-72 is interacting with and rescuing diverse proteins (58,59). *In situ* localization of HSP-72 in proximal tubules has a specific pattern of dis-

tribution after ischemic injury (59). Within minutes of the relief of ischemia, HSP-72 appears predominantly in the apical domain of proximal tubule cells. This localization coincides with brush-border changes, apical cytoskeletal disruption, and redistribution of basolateral membrane proteins to the apical membrane (see Cell Polarity). During the recovery period, when brush-border morphology is largely restored, HSP-72 migrates away from the apical domain to cytoplasmic and basolateral domains. Thus, the course of induction, elaboration, and localization of HSP-72 coincides with repair of cell morphology, polarity, and function during recovery of the proximal tubule epithelia from ischemic injury. HSP-25, which is able to function as an actin-capping protein, has been shown to be induced after renal ischemia (60). Moreover, this protein moves from a soluble cytosolic distribution to an insoluble actin-associated state rapidly after an ischemic insult. These dynamic interactions of different classes of HSP, each with its specific functions, may be essential to reestablish cellular polarity and integrity.

Growth Factors

Several growth factors are known to bind specific receptors in renal tubules and regulate the proliferative process. After an ischemic insult, the infusion of either epidermal growth factor, hepatocyte growth factor, or insulin-like growth factor I result in (a) improved GFR, (b) diminished morphologic injury, (c) increased thymidine incorporation into tubule DNA, and (d) diminished mortality (61). Insulin-like growth factor I also diminishes loss of body weight associated with ARF in animals. In addition, growth factors may interact with other factors such as thyroxine or ADP to augment recovery from ARF (62–64).

CONCLUSION

Over the past decade, we have begun to unravel and discover the cellular and molecular mechanisms that contribute to the development of and recovery from ARF (65,66). Because ARF is a multifactorial process, it is unlikely that any single mechanism can explain the many dimensions of ARF. The processes described in this chapter and the integration of their effects provides a basis for understanding the complex pathophysiologic events that result in damage to renal epithelial cells and the acute unexpected loss of renal function—ARF.

CLINICAL EVALUATION AND MANAGEMENT

SHARON P. ANDREOLI

DEFINITION

Acute renal failure is characterized by an abrupt increase in the blood concentration of creatinine and nitrogenous waste products, a decrease in the glomerular filtration rate (GFR), and the inability of the kidney to appropriately regulate fluid and electrolyte homeostasis. Increases in the levels of serum creatinine and blood urea nitrogen (BUN) are typical in acute renal failure, but each may be affected by factors other than a decline in the GFR. Because the serum creatinine level is a reflection of muscle mass, children with decreased muscle mass may have substantial decreases in their GFR with minimal to modest changes in the serum creatinine concentration. BUN is affected by multiple factors, including the state of hydration of the child and conditions that increase urea production, such as gastrointestinal bleeding, high protein intake, a hypermetabolic state, or the administration of catabolic medications such as corticosteroids. Each of these states increase the BUN level independently of renal function. In contrast, BUN may be lower than expected in acute renal failure in a child with diminished urea production, such as in severe liver disease, or in a child with protein malnutrition.

Although a decline in urine output is a common clinical manifestation of acute renal failure, some forms of acute renal failure are associated with normal urine output. Children with acute renal failure due to hypoxic-ischemic insults, hemolytic uremic syndrome (HUS), acute glomerulonephritis, rapidly progressive glomerulonephritis, or other causes are more likely to demonstrate oliguria or anuria (urine output <400 to 500 mL/24 hr in older children or urine output <0.5 to 1.0 mL/kg/hr in younger children and infants). Children with acute interstitial nephritis or nephrotoxic renal insults, including aminoglycoside nephrotoxicity and contrast nephropathy, are more likely to have acute renal failure with normal urine output. Several studies have shown that the morbidity and mortality of nonoliguric acute renal failure are substantially lower than those of oliguric renal failure (1–8). Although nonoliguric renal failure is more commonly associated with nephrotoxic

insults, studies also suggest that the degree of oliguria or anuria is also related to the severity of the insult, with less severe insults resulting in nonoliguric acute renal failure (3,4).

EPIDEMIOLOGY OF ACUTE RENAL FAILURE

Although the precise incidence and prevalence of acute renal failure in pediatric patients is unknown, studies suggest that the incidence of acute renal failure in hospitalized children may be increasing (5–13). In a large study of adult patients, the incidence of acute renal failure was 209 per 1 million population, and the most common cause of acute renal failure was prerenal in 21% of patients and acute tubular necrosis in 45% of patients (13). Similar epidemiologic studies have not been performed in pediatric patients, but hypoxia-ischemia and nephrotoxicity have been shown to be important causes of acute renal failure in neonates, children, and adolescents (5–7,9). In a study of pediatric patients in a tertiary care center, 227 children received dialysis therapy during an 8-year interval for an overall incidence of 8 per 1 million total population (6). In one study of neonates, the incidence of acute renal failure ranged from 8 to 24% of newborns, and acute renal failure was particularly common in neonates who had undergone cardiac surgery (6–8). Neonates experiencing severe asphyxia had a high incidence of acute renal failure, whereas acute renal failure was less common in neonates with moderate asphyxia and the acute renal failure was nonoliguric, oliguric, and anuric in 60%, 25%, and 15%, respectively (6–8,11).

In addition to environmental risks factors for acute renal failure, some children may also have genetic risks factors for acute renal failure. Polymorphism of the angiotensin-converting enzyme gene or the angiotensin receptor gene with resultant alterations in activity of the renin-angiotensin system might play a role in the development of acute renal failure (14). In a study in neonates, the incidence of angiotensin-converting enzyme I/D allele genotypes or the

variants of the angiotensin I receptor gene did not differ in neonates with acute renal failure and neonates without acute renal failure (14). In other studies, polymorphisms of tumor necrosis factor- α , interleukin-1 β , interleukin-6, and interleukin-10 genes were investigated in newborns to determine if polymorphisms of these genes would lead to a more intense inflammatory response and predispose newborns to acute renal failure (15). The allelic frequency of the individual genes did not differ between newborns with acute renal failure and those without acute renal failure, but the tumor necrosis factor- α /interleukin-6 AG/GC haplotypes were present in 26% of newborns who developed acute renal failure compared to 6% of newborns who did not develop acute renal failure. The investigators suggested that the combination of these polymorphisms might lead to a greater inflammatory response and the development of acute renal failure in neonates with infection (15). Future studies of the genetic background of the child at risk for acute renal failure due to medication exposure, toxin exposure, ischemic-hypoxic insults, or other insults will likely influence the management of the child at risk for acute renal failure and the management of acute renal failure.

ETIOLOGY OF ACUTE RENAL FAILURE IN CHILDREN

There are many different causes of acute renal failure in neonates, infants, children, and adolescents. Renal failure can be divided into prerenal failure, intrinsic renal disease including vascular insults, and obstructive uropathies (Table 64.1). Some causes of acute renal failure such as cortical necrosis and renal vein thrombosis occur more commonly in neonates, whereas HUS is more common in young children and rapidly progressive glomerulonephritis generally occurs in older children and adolescents. The history, physical examination, laboratory studies, including a urinalysis, and radiographic studies can establish the likely cause(s) of renal failure. In some instances, such as in acute renal failure occurring in hospitalized children, multiple factors are likely to be implicated as the cause of acute renal failure. Tables 64.2 and 64.3 show the clinical, laboratory, and radiographic findings in the more common broad categories of acute renal failure in children.

Prerenal Failure

When a child is at risk for developing acute renal failure, appropriate therapy can prevent or decrease the extent of the injury that leads to acute renal failure. Adequate hydration of the dehydrated child, avoidance of nephrotoxic drugs when possible, and other appropriate measures can minimize or prevent acute deterioration in renal function in children. Specific measures that can help minimize or eliminate acute deterioration in renal function include hydration of the child receiving nephrotoxic drugs such as

TABLE 64.1. ETIOLOGY OF ACUTE RENAL FAILURE IN NEONATES, INFANTS, CHILDREN, AND ADOLESCENTS

Prerenal failure
Decreased true intravascular volume
Dehydration
Gastrointestinal losses
Salt-wasting renal or adrenal disease
Central or nephrogenic diabetes insipidus
Third-space losses (sepsis, traumatized tissues, nephrotic syndrome)
Decreased effective intravascular volume
Congestive heart failure
Pericarditis, cardiac tamponade
Intrinsic renal disease
Acute tubular necrosis
Ischemic-hypoxic insults
Drugs
Aminoglycosides
Intravascular contrast medium
Cisplatin
Ifosfamide
Nonsteroidal antiinflammatory drugs
Acetaminophen
Toxins
Exogenous toxins
Ethylene glycol, methanol, bromate, toxic mushrooms
Heavy metals
Endogenous toxins
Myoglobin and hemoglobin
Uric acid nephropathy and tumor lysis syndrome
Interstitial nephritis
Drug induced—antibiotics, anticonvulsants
Idiopathic
Glomerulonephritis
Postinfectious glomerulonephritis
Membranoproliferative glomerulonephritis
Systemic lupus erythematosus nephritis
Nephritis of chronic infection
Henoch-Schönlein purpura nephritis
Antineutrophil cytoplasmic antibody–positive glomerulonephritis
Anti-glomerular basement membrane glomerulonephritis
Goodpasture syndrome
Idiopathic rapidly progressive glomerulonephritis
Vascular lesions
Hemolytic uremic syndrome (HUS)
Verotoxin-producing <i>Escherichia coli</i> -associated HUS
Drug-induced HUS (mitomycin, birth control pills, quinine)
Bone marrow transplant nephropathy
Cortical necrosis
Renal artery thrombosis
Renal venous thrombosis
Infectious causes
Sepsis, with or without disseminated intravascular coagulation
Pyelonephritis
Obstructive uropathy
Obstruction in a solitary kidney
Bilateral ureteral obstruction
Urethral obstruction

amphotericin B, cisplatin, and intravascular contrast media as well as avoidance of prostaglandin synthetase inhibitors and angiotensin-converting enzyme inhibitor therapy during volume depletion and renal hypoperfusion (16–26).

TABLE 64.2. EVALUATION OF CAUSES OF ACUTE RENAL FAILURE IN CHILDREN BY SEVERITY OF INSULT

	Prerenal failure	Acute tubular necrosis	Cortical necrosis
Clinical history	Dehydration Vomiting, diarrhea Hemorrhage Diabetes insipidus Third-space losses Congestive heart failure Cardiac tamponade Hepatorenal syndrome	Dehydration, hemorrhage Hypoxia-ischemia Toxins Sepsis Hemoglobinuria Myoglobinuria Nephrotoxic drugs NSAIDs, ACE inhibitors	Hypoxia-ischemia Placental abruption Twin-twin or twin-maternal transfusion Renal artery or vein thrombosis
Urine output	Decreased	Oliguria or nonoliguria	Oliguria
Urinalysis	Normal or minor changes	Granular casts Pigmenturia Epithelial cells Epithelial casts	Gross or microscopic hematuria Proteinuria
Urine osmolality	>400–500 mOsm	<350 mOsm	
Newborn	>350 mOsm	<300 mOsm	
Urine Na	<10 mEq/L	>30–40 mEq/L	
Newborn	<20–30 mEq/L	>30–40 mEq/L	
FE _{Na}	<1%	>2%	
Newborn	<2.5%	>2.5–3.0%	
Laboratory studies	Increased BUN compared to creatinine		Thrombocytopenia Microangiopathy
Imaging studies	US: normal RS normal	US: normal or increased echogenicity with loss of corticomedullary differentiation RS: normal or slightly decreased blood flow with delayed renal parenchymal accumulation of isotope	US: normal or loss of cortomedullary differentiation RS: poor or no blood flow with no accumulation of isotope

ACE, angiotensin-converting enzyme; BUN, blood urea nitrogen; FE_{Na}, fractional excretion of sodium; NSAID, nonsteroidal antiinflammatory drug; RS, radiographic scan; US, ultrasonographic scan.

TABLE 64.3. EVALUATION OF CAUSES OF ACUTE RENAL FAILURE IN CHILDREN BY TYPE OF INJURY

	Interstitial nephritis	Glomerulonephritis	Hemolytic uremic syndrome	Obstruction
Clinical history	Drug exposure Infection Rash Fever	Previous infection Systemic symptoms Rash Fever	Diarrheal (may be bloody) prodrome	Flank masses Abdominal mass Palpable bladder Posterior urethral valve in newborn
Urine output	Variable Usually nonoliguric	Variable Usually oliguric	Variable Usually oliguric	Variable
Urinalysis	Pyuria WBC casts Eosinophiluria	Gross or microscopic hematuria RBC casts Proteinuria	Hematuria RBC casts Proteinuria	Unremarkable
Urine osmolality	<350 mOsm	>400–500 mOsm	Variable	Variable
Urine Na	>30–40 mEq/L	<10 mEq/L	Variable	Variable
FE _{Na}	>2%	<1%	Variable	Variable
Laboratory studies	Eosinophilia	Positive ANA, ANCA Low C3, C4	Thrombocytopenia Microangiopathic hemolytic anemia	
Imaging studies	US: nephromegaly and increased echogenicity	US: nephromegaly and loss of corticomedullary differentiation	US: normal or loss of corticomedullary differentiation RS: poor flow with decreased function	US: dilated pelvis, ureter, and/or bladder depending on level of obstruction RS: collection of isotope in pelvis, ureter, or bladder depending on level of obstruction

ANA, antinuclear antibodies; ANCA, antineutrophil cytoplasmic antibodies; FE_{Na}, fractional excretion of sodium; RS, radiographic scan; US, ultrasonographic scan.

The prophylactic administration of *N*-acetylcysteine has been shown to dampen the decline in GFR associated with the administration of intravascular contrast agents in adults at risk for contrast nephropathy (23). However, a separate study did not demonstrate such a benefit in adult patients undergoing cardiac angiography (24). Similar studies have not been performed in pediatric patients. The potential hazards and benefits of *N*-acetylcysteine in pediatric patients at risk for contrast nephropathy are unknown, and such studies should be performed.

In prerenal failure, renal function is decreased due to decreased renal perfusion, but the kidney is intrinsically normal. Restoration of renal perfusion results in a prompt return of renal function to normal, whereas the presence of acute tubular necrosis as described later implies that the kidney has suffered intrinsic damage. The evolution of prerenal failure to intrinsic renal failure is not sudden, however, and a number of compensatory mechanisms work together to maintain renal perfusion in the face of adverse renal hemodynamic conditions (16–22). When renal perfusion is compromised, the afferent arteriole relaxes its vascular tone to decrease renal vascular resistance and maintain renal blood flow. Decreased renal perfusion results in increased catecholamine secretion, activation of the renin-angiotensin system, and generation of prostaglandins. During renal hypoperfusion, the intrarenal generation of vasodilatory prostaglandins, including prostacyclin, mediates vasodilatation of the renal microvasculature to maintain renal perfusion (16–18). Administration of aspirin or nonsteroidal antiinflammatory drugs can inhibit this compensatory mechanism and precipitate acute renal insufficiency during renal hypoperfusion. Similarly, when renal perfusion pressure is low, as in renal artery stenosis, the intraglomerular pressure necessary to drive filtration is in part mediated by increased intrarenal generation of angiotensin II to increase efferent arteriolar resistance (19–22). Administration of angiotensin-converting enzyme inhibitors under these conditions can eliminate the pressure gradient needed to drive filtration and precipitate acute renal failure (19–22). It was originally thought that selective cyclooxygenase-2 (COX-2) inhibitors would be renal sparing, but it has been recognized that the selective COX-2 inhibitors can adversely affect renal hemodynamics in a way similar to nonselective COX inhibitors (25). In addition, clinical use of selective COX-2 inhibitors has been associated with acute renal failure (26). Thus, administration of medications that can interfere with compensatory mechanisms to maintain renal perfusion can precipitate acute renal failure in certain clinical circumstances.

Prerenal failure results from renal hypoperfusion due to true volume contraction or from a decreased effective blood volume (1,6–19). True volume contraction results from hemorrhage, dehydration due to gastrointestinal losses, salt-wasting renal or adrenal diseases, central or nephrogenic diabetes insipidus, increased insensible losses such as occur in
