Iothalamate sodium has an MW of 637 d. Iothalamate has been used as ^{125}I -radiolabeled or without radioactive label, its plasma concentration being then assessed by x-ray fluorescence or by HPLC, or, more recently, by capillary electrophoresis (135). A recent study showed an excellent correlation between the clearance of ^{125}I -iothalamate and cold iothalamate, as assessed by capillary electrophoresis (136). Critical studies have, however, unequivocally demonstrated that iothalamate is actively secreted by renal tubular cells, and perhaps also undergoes tubular reabsorption in human and animal species (137). The urinary clearance of iothalamate significantly exceeds that of inulin in patients with normal renal function (138). When present, the agreement of iothalamate clearance with inulin clearance appears to be a fortuitous cancellation of errors between tubular excretion and protein binding (139). The use of iothalamate as a glomerular marker is presently not recommended.

Renal Functional Reserve

It has been considered for a long time that GFR in healthy individuals is remarkably stable from day to day over a period of years (121). This concept has been challenged by the observation that GFR in normal subjects could vary with their diet protein content (140). Alterations in protein intake thus result in variations in GFR that are independent of changes in renal mass. Patients with renal disease on a low-protein diet may thus have a reduction of GFR unrelated to the progression of renal disease (140). Variations in GFR also occur during the circadian rhythm, and upsurges in GFR are observed in patients with burns, women during pregnancy, and patients infused with amino acids (67).

The baseline or “resting” GFR theoretically depends on the working level of the intact nephrons and is the consequence, in part, of the amount of proteins ingested per day. The renal functional reserve represents the potential of the kidney to increase GFR from a baseline or resting value to a maximal one (the so-called maximal filtration capacity) in response to increased physiologic demands. Depending on the daily protein intake, GFR may vary from 30 to 143 mL/min/1.73 m² in normal individuals (140).

The maximal filtration capacity can be measured in patients undergoing inulin clearance studies before and after an oral load of proteins, during the infusion of amino acids, or during the combined administration of amino acids and dopamine (see section Protocol for Measuring the Functional Reserve Capacity). The maximal filtration capacity in young adults has been shown to reach values close to 160 mL/min/min (140,141).

The renal functional reserve represents the difference between the resting GFR and the maximal GFR. The magnitude of the renal functional reserve obviously depends on the resting GFR (142). Normal individuals with the lowest protein intake have the highest renal reserve. In patients with renal disease, the maximal filtration capacity decreases as the disease progresses. The resting GFR is insensitive as an indicator of renal damage. On the contrary, the filtration capacity is a good indicator of renal damage as it decreases proportionally to the extent of injury to the kidney. In patients with GFR below 40 mL/min/1.73 m², the renal functional reserve is usually negligible or absent, indicating that at this level of function, all nephrons are working maximally at all times. In most conditions, the increase in GFR observed after protein loading or i.v. amino acid infusion is associated with a parallel increase in RBF. The increase in RBF is probably the consequence of decreased intrarenal vascular resistance, mainly at the level of the afferent and efferent arterioles.

Several mechanisms may play a role in mediating the renal response to protein loading or amino acid infusion, including a number of circulating or locally acting hormonal factors and intrinsic intrarenal mechanisms (143).

Experimental data suggest that growth hormone and atrial natriuretic peptide are not involved in the response to protein or amino acid administration, but that prostaglandins, nitric oxide, and the kallikrein-kinin system could play key roles (143). Intrinsic renal mechanisms, namely, tubular transport and tubuloglomerular feedback mechanisms, could also play key roles in mediating the amino acid or the protein-stimulated renal vasodilatation and hyperfiltration. Amino acids could cause a primary stimulation of proximal tubular sodium reabsorption and in turn cause renal vasodilatation and hyperfiltration (144). The finding that the response to a meat meal is inhibited by acetazolamide, an inhibitor of sodium transport in the proximal tubule, but not by amiloride provided strong support for the hypothesis that normal proximal tubular sodium

reabsorption capacity is required for protein-stimulated renal vasodilatation and hyperfiltration (145).

Protocol for Measuring the Functional Reserve Capacity

The functional reserve is assessed during a standard clearance test, using inulin and *p*-aminohippuric acid (PAH) as markers of GFR and effective renal plasma flow (ERPF), respectively. After a priming dose of inulin 25% [64 mg/kg body weight (BW)] and PAH 20% (9 mg/kg BW), a continuous infusion of 1 to 2 mg/kg/min inulin and 0.15 to 0.30 mg/kg/min PAH is given intravenously. Water diuresis is induced by an oral ingestion of 20 mL/kg BW (maximum, 1200 mL) during the first hour, and then 5 mL/kg BW (maximum, 300 ml) every 30 minutes. Urine samples are collected by spontaneous micturition at 30-minute intervals and blood samples drawn midway through each urine collection period. After an equilibration period of 60 minutes and 3-minute baseline periods, an oral protein load of 1.5 mg/kg BW (mixed meal containing meat with milk protein as a supplement) is given within 30 minutes. After the meal, the creatinine test is continued for an additional 3-hour period (6 periods of 30 minutes each).

The baseline GFR and ERPF corresponds to the mean values of the three periods before the protein-rich meal. The *maximal filtration capacity* is defined as the peak values observed after the protein-rich meal. The functional reserve is calculated by subtracting the baseline GFR and ERPF from their maximal values observed after the protein-rich meal. The renal function reserve is also expressed as fractional increase (%) from the baseline values. Another method for assessing the functional reserve consists of an i.v. infusion of a 7.5% solution of amino acids at a rate of 0.08 mL/min/kg. Dopamine (2 µg/kg BW/min) can be infused concomitantly to the infusion of amino acids.

RENAL BLOOD FLOW

Physiology

RBF approximates 20% of resting cardiac output—that is, 1200 mL/min/1.73 m². Most of this flow supplies the metabolic active renal cortex, whereas 10% of RBF is directed toward the outer medulla and only 1 to 2% into the capillary tissue. A small part goes to the capsule and perirenal fat. Several factors, such as a high-protein diet, can increase RBF both acutely and chronically. RBF also increases during pregnancy under the influence of gestational hormones.

RBF is proportional to the pressure gradient across the renal vasculature (renal artery pressure minus renal vein pressure) and inversely proportional to the total renal vascular resistance. Most of the resistance resides in three major segments: (a) the intralobular arteries, (b) the afferent arterioles,

and (c) the efferent arterioles. The renal vascular tone is affected by neural impulses and by circulating intrarenal vasoactive compounds such as angiotensin II, prostaglandins, nitric oxide, endothelin, bradykinin, and adenosine.

RBF is autoregulated by an intrinsic myogenic mechanism. The vessels have the capacity to constrict when blood pressure rises and to vasodilate when it decreases. RBF is thus independent of the perfusion pressure over the range of autoregulation (~80 to 180 mm Hg).

The major role of blood supply to the kidney is to provide blood for filtration. The fraction of plasma that is filtered through the glomeruli, the so-called filtration fraction, approximates 20% in normal conditions. When RBF is reduced, GFR is usually maintained by angiotensin II-induced efferent arteriolar vasoconstriction. This is evidenced by an increase in the filtration fraction.

Measurement of Renal Blood Flow

Measurement of RBF is based on the Fick principle. According to this principle, any substance completely extracted from the blood during a single pass through the kidney would allow the measurement of true RBF. In addition to being completely extracted from the blood, the substance should not be metabolized by the kidney, not bound to proteins, and accurately measurable in blood and urine. PAH is the only known compound that meets the required properties. It has an MW of 194 d, is filtered through the glomerular capillaries, and is secreted by the proximal tubular cells (146). It is almost completely removed from the plasma by a single pass. At low arterial plasma concentrations (~20 mg/L) the concentration in the renal vein is negligible. The plasma perfusing the kidney being completely cleared of PAH and the extracted PAH quantitatively excreted in the urine, the clearance of PAH can be used to estimate renal plasma flow (RPF). By measuring the hematocrit, RBF can be derived from RPF by the formula $RBF = RPF/1 - \text{hematocrit}$.

The clearance of PAH underestimates slightly the true RPF, as PAH extraction is only approximately 90% complete because part of the blood delivered to the kidney goes to sites not available for secretion in the proximal tubule (medulla, capsule, perinatal fat). The PAH clearance thus assesses cortical plasma flow more than true total RPF. The term *effective renal plasma flow* is often used to describe the value derived from PAH clearances. The extraction ratio can vary in disease states or under the influence of certain drugs, thus making the measurement of renal vein concentration necessary for accurate determination of RPF.

Because PAH undergoes acetylation by the liver, its clearance estimated by the constant infusion technique without urine collection or by the plasma disappearance curve significantly overestimates the urinary clearance. The clearance of PAH can be affected by drugs, such as penicillin, salicylates, or sulfapyrazone, that compete for the same secretory passage-

way. The extraction efficiency of PAH may also be depressed by drugs commonly used in renal patients (i.e., angiotensin-converting enzyme inhibitors and cyclosporine) (147,148).

Measurement of p-Aminohippuric Acid Clearance

The clearance of PAH is usually measured concomitantly with that of inulin. A priming dose of PAH is given at a dose of 9 mg/kg BW, followed by a continuous infusion of 0.15 to 0.30 mg/kg/min to maintain plasma concentration between 10 and 20 mg/L. Water intake is administered as for the inulin clearance test (20 mL/kg BW during the first hour, and then 5 mL/kg BW every 30 minutes). Urine and blood samples are collected as described for the inulin clearance test.

Determination of p-Aminohippuric Acid

PAH in plasma and urine can be measured by the classical colorimetric reaction of Bratton and Marshall (149). Several compounds interfere with the reaction, in particular those with a para-amino ring, including acebutolol, sotalol, procaine, cotrimoxazole, and furosemide (62). PAH can be measured more accurately by HPLC (150).

Adverse Effects of p-Aminohippuric Acid

The administration of PAH is usually well tolerated but may be associated with nausea, vomiting, vasomotor disturbances, flushing, tingling, cramps, and a feeling of warmth, and sometimes the urge to urinate or defecate.

Drawbacks in the Interpretation of C_{PAH}

The main drawbacks in the use of PAH clearance to assess RPF resides in the fact that the extraction of PAH is not complete and that it can vary under the influence of disease states, drug administration, and age. Newborn infants have low extraction ratios that limit the usefulness of PAH in the first month of life (151).

Other Cold Markers of Renal Plasma Flow

5-Hydroxyindoleacetic acid (5-HIAA) is the major metabolite of serotonin. Its renal elimination, analogous to that of PAH and other weak organic acids, is achieved by glomerular filtration and by probenecid-sensitive active secretion in the proximal tubule (152). A renal extraction ratio of 78% has been measured in hypertensive adult patients with normal renal function (153). This ratio is lower than the PAH extraction ratio measured in human subjects at plasma PAH concentrations below the maximum transport. The efficient renal tubular secretion of 5-HIAA is further illustrated by the 5-HIAA to inulin ratio as high as 6.3 ± 0.66

(SEM) in healthy subjects and in patients with reduced GFR (153). Plasma levels of 5-HIAA have been shown to correlate inversely ($R = 0.85$) with the PAH clearance.

The extraction of 5-HIAA in newborn animals, like that of PAH, is well below its level in mature subjects. The low extraction of PAH in neonates has been ascribed to the shunting of blood to the nonextracting renal tissues, to the relative decrease in tubular mass, and to the immaturity of the renal tubular secretory passageways (154). This endogenous marker, easily assayed in plasma by using liquid chromatography and electrochemical detection (155), may prove useful for a quick orientation on RPF in clinical practice (153).

Radionuclides as Markers of Renal Plasma Flow

Orthoiodohippurate (Hippuran)

Hippuran is eliminated by the kidney in a way similar to PAH. Its extraction ratio is, however, significantly lower than that of PAH (70 to 85% as compared to 90%) (156). Protein binding of Hippuran is not negligible. The urinary clearance of Hippuran underestimates RPF more than does that of PAH (157). Hippuran can easily be labeled by a simple iodine exchange reaction; most often it is labeled with either ^{131}I or ^{123}I . ^{123}I -Hippuran can be used in children in larger doses than ^{131}I -Hippuran, while still imparting a lower radiation burden to the patient. Its short half-life and greater cost limit its widespread use.

$^{99\text{m}}\text{Tc}$ -Mercaptoacetyl triglycerine

In spite of early claims, mercaptoacetyl triglycerine (MAG-3) is not a marker of RPF. In normal volunteers, $^{99\text{m}}\text{Tc}$ -MAG-3 and ^{123}I -Hippuran showed comparable image quality, renal extraction, blood clearance, and time to peak height of the renogram curve. Overall, the clearance of $^{99\text{m}}\text{Tc}$ -MAG-3 is, however, approximately only 80% of the simultaneous clearance of ^{131}I -Hippuran (158).

Newer Imaging Techniques for the Assessment of Renal Perfusion

Newer promising imaging techniques have been developed in the last years, both in animals and humans (159). None can be a substitute to the clearance of PAH to precisely assess RPF. These techniques may, however, provide reliable estimates of total renal or regional renal blood perfusion.

Contrast-Enhanced Ultrasound

An excellent correlation has been found in dogs between cortical nutrient blood flow using microbubbles and ultrasonic flow probe-derived RBF values ($R = 0.82$; $p < .001$) over a wide range of flows (160). A similar correlation ($R = 0.84$)

has been found in dogs when blood flow calculated from contrast ultrasonography was compared with direct measurement obtained with an electromagnetic flow probe (161).

Quantification with Color Flow and Pulsed Doppler Ultrasound

Estimates of total RBF have been produced in neonates by estimating the vessel diameter from color flow diameter and flow velocity from pulse Doppler ultrasound measurements (162).

Electron-Beam Computed Tomography

From studies in anesthetized dogs, comparing data from electron-beam computed tomography with those of electromagnetic flow probe, Lerman et al. (163) concluded that electron-beam computed tomography could provide credible quantification of RBF.

Dynamic Magnetic Resonance Imaging and Gadolinium-DTPA

By the use of a T1-weighted fast gradient sequence after an i.v. bolus injection of gadolinium-DTPA, dynamic images of the kidney have been obtained in patients presenting with well-functioning native or transplanted kidneys, patients with significant artery stenosis, or patients with renal failure (164). The authors concluded that realistic quantitative data on renal perfusion could be obtained by standard magnetic resonance imaging sequence after injection of a contrast medium. This method awaits confirmation.

TESTS TO ASSESS TUBULAR FUNCTION

Functional tests explore specific aspects of renal function under conditions in which the tubule must develop an adaptive response aimed at preserving body homeostasis. The use of functional tests often allows nephron disorders not apparent or hardly recognizable under basal conditions to be disclosed. Some tests are cumbersome, thus limiting their use in the clinical setting.

Description of the tests includes (165) (a) the function that is tested, (b) the rationale of the test, (c) the method and normal results, and (d) the indications for and limitations of the test.

Glucose Titration Test

Function tested: Characteristics of glucose tubular reabsorption.

Rationale: The amount of glucose filtered per minute is a linear function of its plasma concentration provided that GFR remains steady (Fig. 21.1). Below a threshold level, all

filtered glucose is reabsorbed, and no glucose is detected in the urine. When the load of filtered glucose saturates the mechanism of transport in all nephrons, the maximum tubular reabsorption is achieved. From then on, the urinary elimination of glucose runs parallel to the filtered glucose. The same rationale may be applied to other substances with an active and saturable mechanism of proximal tubular reabsorption (Fig. 21.1).

Method and normal results: Starting from a plasma concentration below the threshold—that is, when glucosuria is negative—3 mL/min/1.73 m² of i.v. 5% dextrose is infused. Dextrose solution concentration is increased by 5% each 30 minutes until glycemia reaches 350 to 400 mg/dL (19 to 22 mmol/L). The maximal concentration of dextrose that can be infused in a peripheral vein is 35%. Urine samples collected during the last 15 minutes of each 30-minute period and plasma samples drawn in the midpoint of each urine collection period are used for calculation. Normal plasma threshold is approximately 180 mg/dL (9.9 mmol/L). Mean reference values of the maximum tubular reabsorption are 375 and 303 mg/min/1.73 m² (2.1 and 1.7 mmol/min/1.73 m²) for males and females, respectively.

Indications and limitations: The test may be used for diagnostic classification of renal glucosurias. In some cases, the renal threshold for glucose is so low that it cannot be achieved without risk to the patient. Accurate collection of frequent and timed urine samples may require bladder catheterization in young children.

Bicarbonate Loading Test

Function tested: Characteristics of tubular reabsorption of bicarbonate (HCO₃⁻) and hydrogen ion (H⁺) distal secretory capacity in the face of a favorable chemical gradient.

Rationale: The test assesses the tubular reabsorption of HCO₃⁻ on the basis of a theoretical background similar to that described above for glucose. The difference between filtered and excreted HCO₃⁻ accounts for the HCO₃⁻ reabsorbed along the renal tubule, mostly in the proximal tubule. In addition, HCO₃⁻ loading will give rise to alkaline urine with pH higher than that of blood. This stimulates H⁺ secretion by alpha-intercalated cells of the collecting duct. Hydrogen ions so secreted combine with HCO₃⁻ anions to form carbonic acid. As at this level of the nephron, there is no carbonic anhydrase in the luminal side of the tubule; carbonic acid dehydrates very slowly into carbon dioxide (CO₂) and water. The medullary trapping of CO₂ and the unfavorable surface-to-volume relationship in the lower urinary tract limit the diffusion of CO₂ out of the tubular lumen. As a result, the measurement of the partial pressure of CO₂ (PCO₂) in alkaline urine can be used as a reliable index of distal H⁺ secretion (166).

Method and normal results: An i.v. solution of 0.3 to 0.5 mol/L of NaHCO₃⁻ is infused at a rate calculated to increase bicarbonatemia by 2 to 3 mmol/L/hr in a subject

with spontaneous or induced metabolic acidosis. For diagnostic purposes, the calculation of the plasma threshold for HCO₃⁻ is seldom required. It is usually sufficient to calculate FE_{HCO₃⁻} in the presence of normal bicarbonatemia—that is, 20 to 22 mmol/L in infants and 22 to 24 mmol/L in older children—and to measure the PCO₂ in alkaline urines (pH above 7.45 to 7.60 and bicarbonaturia higher than 80 mmol/L) induced by a single oral dose of 3 to 4 mmol/kg of NaHCO₃⁻ (1 g = 12 mmol). Normal values are FE_{HCO₃⁻} less than 5% and urinary PCO₂ above 70 mm Hg, which is equivalent to a urine minus blood PCO₂ difference (Δ PCO₂) greater than 20 to 30 mm Hg. Urine HCO₃⁻ can be calculated by the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK} + \log (\text{HCO}_3^- / \text{H}_2\text{CO}_3)$$

Knowing that

1. $\text{H}_2\text{CO}_3 = \text{CO}_2 + \text{H}_2\text{O} = 0.03 \text{ PCO}_2$, where PCO₂ is the partial pressure of CO₂ measured in mm Hg, as determined by a pH/blood gas analyzer in urine collected and processed in anaerobic conditions, and 0.03 is the solubility constant of CO₂ in aqueous solutions.
2. The pK of the NaHCO₃⁻ buffer system in urine is 6.33 – 0.5 multiplied by the square root of the sum of the urine sodium and potassium concentrations expressed in mol/L.

Indications and limitations: The test may be used in the differential diagnosis of the types of RTA. FE_{HCO₃⁻} is below 5% in type I distal RTA, above 15% in type II proximal RTA, and between 5% and 15% in type IV RTA. ΔPCO₂ is well below 20 mm Hg in children with primary forms of type I RTA. Calculation of FE_{HCO₃⁻} in the face of normal bicarbonatemia may give a clue to the dose of alkali to be recommended in recently diagnosed RTA children. The measurement of PCO₂ in alkaline urine has been proposed as a sensitive method to detect subtle defects of distal acidification (167,168). An accurate assessment of FE_{HCO₃⁻} requires a nonexpanded extracellular fluid volume. Otherwise, proximal tubular reabsorption is inhibited, giving rise to high values of NaHCO₃⁻ excretion. Because of the massive bicarbonaturia, normal bicarbonatemia is hard to achieve and maintain in children with proximal RTA.

Phosphate Loading Test

Function tested: Secretory capacity of H⁺ by the distal nephron in the face of large availability of intraluminal buffer. The use of phosphate infusions to assess phosphate tubular reabsorption has largely been replaced by the indices described above.

Rationale: A high luminal concentration of phosphate stimulates H⁺ secretion. When urine pH is close to the urinary pK of the phosphate buffer system, disodium phosphate combines with the secreted H⁺ to form acid

phosphate that, in turn, reacts with NaHCO_3^- to form H_2CO_3 and to increase PCO_2 in the final urine. Measurement of urinary PCO_2 reflects distal H^+ secretion.

Method and normal results: Concentrations of urinary phosphate greater than 20 mmol/L can usually be induced by oral administration of 50 mg/kg/day of elemental phosphorus given as a mixture of monosodium and disodium phosphate salts over a 3-day period. Alternatively, 0.6 mmol/kg of neutral sodium phosphate diluted in 180 mL of normal saline may be infused at 1 mL/min for 3 hours. Urinary PCO_2 measured in urine samples with pH of approximately 6.80 should normally exceed blood PCO_2 by 20 to 25 mm Hg (169).

Indications and limitations: The test may be used to explore the mechanism of defective acidification in patients with distal type I RTA. A normal ΔPCO_2 in individuals with distal RTA suggests that the acidification defect is due to back-leak of secreted acid.

Acidification Test

Minimal Urinary pH and Net Acid Excretion

Function tested: Secretory capacity of H^+ by the distal nephron in the face of metabolic acidosis.

Rationale: Metabolic acidosis stimulates distal secretion of H^+ . The secreted H^+ will be found in the urine in free form, estimated by the urinary pH, and will be bound to the two major urinary buffers, phosphate, and, mainly, ammonia generated by the proximal tubule. Net acid excretion is equal to the sum of titratable acid plus NH_4^+ minus bicarbonate. *Titratable acid* refers to the amount of alkali needed to bring the pH of an acid urine back to a value of 7.4.

Method and normal results: The measurements are done in situations of spontaneous or exogenously induced metabolic acidosis. Ammonium chloride is the agent of choice for inducing metabolic acidosis. It is given at a dose of 75 to 100 mmol/m² (1 g = 18.7 mmol) either intravenously over 4 to 6 hours in a 0.9% solution, or by oral route in enteric coated capsules given over 1 hour. Ammonium chloride is an irritating agent and may produce vomiting. To avoid this effect, 1.9 mmol/kg/day of ammonium chloride may be given in a 3- to 5-day period, which, in addition, represents a much more potent stimulus of ammonia production than the short test. A state of moderate metabolic acidosis (blood pH less than 7.33 and bicarbonatemia below 16 to 18 mmol/L) is usually sufficient to assess urine acidification. Normal individuals lower urine pH below 5.5 and increase net acid excretion above 70 $\mu\text{mol}/\text{min}/1.73 \text{ m}^2$.

Indications and limitations: The test is useful in the differential diagnosis of RTA. Patients with type I distal RTA are unable to both maximally decrease urinary pH and increase net acid excretion up to normal values. In type II proximal RTA, minimal urinary pH and normal net acid excretion are achieved once plasma bicarbonate falls below the renal

threshold. Subjects with type IV RTA show normal ability to decrease urinary pH and defective excretion of ammonium. A urine pH equal to or below 6.0 in the second morning urine in fasting conditions has been proposed as a reliable screening tool to exclude incomplete or minor forms of distal RTA. However, the range of urine pH determined in the early morning urine in normal children ranges from 5.16 to 7.07 (170). As pH is a measurement of free H^+ concentration, patients unable to properly concentrate urine may in turn be unable to decrease urine pH to normal minimal values. Similarly, in subjects with contracted extracellular volume, the urinary acidification defect may be a result of the lack of sodium at the lumen of the distal nephron. Accordingly, a proper evaluation of urinary acidification requires the measurement of urinary sodium and urine osmolality as well as the simultaneous determination of urine pH and NH_4^+ because a low pH associated with reduced ammoniuria does not exclude a defective distal acidification, and, on the contrary, a high ammoniuria may be responsible for the fact that pH does not decrease below 5.5.

Furosemide Test

Function tested: Secretory capacity of H^+ by the distal nephron in the presence of large amounts of sodium delivered to the distal nephron and a favorable electronegative lumen potential.

Rationale: Furosemide inhibits reabsorption of sodium chloride in the thick ascending limb of the loop of Henle. Early distal reabsorption of sodium cation leaves behind the chloride anion, enhancing the electronegativity of tubular lumen, which stimulates H^+ secretion.

Method and normal results: Furosemide is given at a dose of 1 mg/kg, orally or intravenously. In normal subjects, a minimal urine pH below 5.5, associated with a kaliuretic response, is usually found within 3 to 4 hours after furosemide administration. Mean (SD) values of minimal urinary pH and maximal FE_K reported in 20 normal children, aged 2 to 14 years, given 1 mg/kg of i.v. furosemide are 4.96 (0.32) and 34.4% (8.9%), respectively (171). The H^+ secretion stimulated by furosemide also increases ammoniuria above 30 $\mu\text{mol}/\text{min}/1.73 \text{ m}^2$ (172).

Indications and limitations: The test is used in the differential diagnosis of RTA. Type 1 distal RTA patients with an intrinsic defect in the proton pump cannot maximally decrease urine pH in response to furosemide. Subjects with type IV RTA and those with subnormal distal H^+ secretion secondary to low distal delivery of sodium (i.e., nephrotic syndrome) or reversible impairment of sodium distal reabsorption (i.e., sickle cell anemia or lithium administration) respond normally.

Acetazolamide Test

Function tested: Ability of distal nephron to secrete H^+ in the face of a favorable chemical gradient.

Rationale: By inhibiting carbonic anhydrase, acetazolamide reduces proximal tubular reabsorption of bicarbonate and causes bicarbonaturia and alkaline urine. Measurement of PCO_2 in urine samples with pH above that of blood reflects the ability of the distal nephron to secrete H^+ .

Method and normal results: Oral acetazolamide is given at a dose of 0.5 to 1.0 g/1.73 m². A normal response is characterized by urinary PCO_2 above 70 mm Hg or ΔPCO_2 above 20 to 30 mm Hg.

Indications and limitations: The test is used to explore the mechanism of defective acidification in distal type I RTA. Children with primary defects of the distal proton pump do not increase urine PCO_2 . Alon et al. found similar response to oral bicarbonate (2.5 mmol/kg) or acetazolamide (17 ± 2 mg/kg) in terms of urine bicarbonate concentration and PCO_2 (173).

Concentrating Ability

Urinary Concentration during Hydropenia

Function tested: Ability to concentrate urine in response to fluid suppression.

Rationale: Fluid restriction increases blood tonicity, thus stimulating vasopressin secretion. As a result, free water is reabsorbed, and the urine becomes concentrated.

Method and normal results: Urinary osmolality is measured at the end of a 12- to 16-hour period of fluid deprivation. During this period, children are allowed to eat solid foods except those having a high content in salt and water. In healthy children older than 2 years of age, mean (SD) values of urinary osmolality in the second and third urine voided in the morning during fluid suppression since noon have been reported to be equal to 1035 and 1127 (128) mOsm/kg H₂O (174,175). When fluid intake is suppressed since 5 or 6 p.m., the urinary osmolality measured in the second urine of the following morning is normally higher than 725 mOsm/kg H₂O. If the determination of osmolality is not available, urinary density values above 1025 are usually indicative of normal renal concentration capacity.

Indications and limitations: The test is used to investigate the origin of polyuric states as well as to disclose subclinical defects of urine concentrating ability. Prolonged fluid restriction may be harmful in infants and poorly tolerated in subjects with chronic primary polydipsia. In addition, these patients have a hypotonic medullary interstitium and may require much longer periods of hydropenia to maximally concentrate the urine. In these cases, a progressive reduction in fluid intake over days or weeks is necessary before exposing the child to a thirst test.

Vasopressin Administration

Function tested: Ability to concentrate urine in response to vasopressin administration.

Rationale: As urinary osmolality is strongly influenced by plasma concentrations of vasopressin, administration of pharmacologic amounts of a vasopressin analogue results in maximally concentrated urine even in the absence of fluid restriction.

Method and normal results: The compound most often used is the 1-desamino-8-D-arginine vasopressin (DDAVP). It can be given intranasally at doses of 10 μg in infants and 20 μg in children (175). In infants, usual fluid intake must be restricted to 50% in the 12 hours after DDAVP administration because of the risk of overhydration and hyponatremia. Osmolality is measured in individual urine samples collected over a 6- to 8-hour period after DDAVP administration. Normal values of maximal urine osmolality are shown in Table 21.5 (172,176). Recently, it has been proposed that assessment of renal concentrating capacity by administration of DDAVP at bedtime and measurement of osmolality in one urine sample taken the following morning may be reliable and easy to perform in children (177).

Indications and limitations: The DDAVP test represents a good alternative to thirst stimulus in infants and polyuric subjects in whom, as stated above, fluid suppression is hardly feasible. The test may also be used in moderately polyuric subjects sequentially after a period of fluid restriction when maximal urine osmolality obtained by hydropenia has not achieved normal values. In these cases, a DDAVP-induced increment of urine osmolality below 10% suggests tubular resistance to antidiuretic hormone, whereas a 40 to 60% increment in urinary osmolality indicates defective vasopressin release or primary polydipsia. In these sequential tests, a correct interpretation of the results requires that after DDAVP administration the child be allowed to drink an amount of fluid similar to that of urine voided. Thus, the degree of plasma hypertonicity induced by hydropenia remains unchanged.

Dilution Ability (Free Water Clearance)

Hypotonic Saline Loading

Function tested: Chloride, sodium, and potassium handling along the nephron under conditions of maximal urinary dilution and in the absence of hormonal influences.

Rationale: Maximal urine dilution and suppression of aldosterone and antidiuretic hormone are induced by extracellular volume expansion with hypo-osmolar fluid loading. Under these conditions, maximal excretion of electrolyte-free water is generated in the diluting segments of the tubule. An indirect estimate of solute reabsorption in the different segments of the nephron may be obtained by calculation of several urinary indices, as shown in Table 21.9.

Method and normal results: After oral administration of 20 mL/kg of water, a constant i.v. infusion of 2000 mL/1.73 m² of 0.45% saline is administered over 2 hours. Cal-

TABLE 21.9. NORMAL VALUES OF MAXIMAL FREE WATER CLEARANCE INDICES DURING HYPOTONIC SALINE DIURESIS

	Infants (n = 22)	Children (n = 17)
Urine osmolality (mOsm/kg)	51.8 ± 12.8	54.1 ± 13.3
Urine volume (mL/dL GF)	22.8 ± 3.6	17.2 ± 2.7 ^a
Osmolar clearance (C _{osm}) (mL/dL GF)	4.3 ± 1.3	3.2 ± 0.7 ^a
Free water clearance (C _{H₂O}) (mL/dL GF)	18.5 ± 2.9	14.0 ± 2.6 ^a
Sodium clearance (C _{Na}) (mL/dL GF)	1.9 ± 0.8	1.4 ± 0.4 ^a
Potassium clearance (C _K) (mL/dL GF)	19.9 ± 12.0	12.9 ± 5.2 ^a
Chloride clearance (C _{Cl}) (mL/dL GF)	2.7 ± 1.1	2.1 ± 0.7 ^a
Percentage of distal sodium reabsorption: $100 \times C_{H_2O} / (C_{H_2O} + C_{Na})$ (%)	90.8 ± 4.5	90.9 ± 3.3
Percentage of distal chloride reabsorption: $100 \times C_{H_2O} / (C_{H_2O} + C_{Cl})$ (%)	87.2 ± 5.3	86.7 ± 4.1
Creatinine clearance (mL/min/1.73 m ²)	88.5 ± 27.1	124.8 ± 25.2 ^a

GF, glomerular filtration (values are $\times \pm$ SD).

^aSignificantly different from infants.

C_{H₂O} + C_{Na}: Sodium delivery to the distal nephron. C_{H₂O} + C_{Cl}: Chloride delivery to the distal nephron. C_{H₂O}: Reabsorption of sodium chloride in the distal nephron. C_{H₂O} / (C_{H₂O} + C_{Na}): Fraction of sodium reabsorbed in the distal nephron. C_{H₂O} / (C_{H₂O} + C_{Cl}): Fraction of chloride reabsorbed in the distal nephron.

Adapted from Rodríguez-Soriano J, Vallo A, Castillo G, Oliveros R. Renal handling of water and sodium in infancy and childhood: a study using clearance methods during hypotonic saline diuresis. *Kidney Int* 1981;20:700–704.

culations are made in maximally diluted urine samples, those with urinary osmolality below 70 mOsm/kg and the highest free-water clearance. Normal results of the test are given in Table 21.9. Sodium and chloride FC are calculated as explained above. C_{H₂O} is calculated as follows: C_{H₂O} = V – C_{osm}, where V is the volume of urine eliminated per 100 mL of GFR and C_{osm} is the osmolar fractional clearance.

$$V = (P_{Cr}/U_{Cr}) \times 100 \text{ and } C_{osm} = (\text{Urine osmolality/Plasma osmolality}) \times V$$

Indications and limitations: The test is used to localize the site of defective reabsorption in tubular disorders, such as Bartter syndrome, with exaggerated loss of chloride, sodium, or potassium. The various indices, based on theoretical assumptions, should be interpreted with caution, but can provide valuable information in conditions associated with tubular reabsorption defects.

EVALUATION OF GROWTH AND DEVELOPMENT

SANDRA L. WATKINS
GAIL E. RICHARDS

NORMAL GROWTH

Growth is such a valuable biologic indicator of health during childhood that careful assessment of growth should be a routine part of initial and ongoing care of children with documented or suspected renal disease. To appreciate the implications of growth perturbation caused by renal disease, it is necessary to understand normal growth and the uses and limitations of methods of growth evaluation.

MEASUREMENT OF GROWTH

Linear Growth

The growth charts that are commonly used in clinical settings are derived from cross-sectional data and are useful to determine how the growth of an individual compares to age- and gender-matched peers (Fig. 22.1). To see the impact over time of both normal physiology and superimposed growth abnormalities, it is crucial to have accurate longitudinal data. The importance of accurate measurements cannot be overemphasized. Accurate measuring equipment and accurate measuring technique are crucial. Inaccurate positioning of a child on an infant-measuring board or stadiometer can lead to significant misinterpretation of growth trends. Figure 22.2 demonstrates proper positioning of an infant (Fig. 22.2A) and an older child (Fig. 22.2B). Special attention should be paid to positioning of the feet and head. Feet must be flat and positioned against the same board as the head. Usually an assistant should hold the feet in position to assure that the patient does not rise as the measurement is being taken. Buttocks and shoulder blades should be touching the back board. For infants, it is usually necessary for an assistant to hold the knees down and hold the feet flat against the end board. The head should be in the Frankfurt plane, with the outer canthus of the eye and the external auditory

meatus describing a line that is perpendicular to the back board of the stadiometer of the infant-measuring board. For standing measurements, the neck should be gently stretched while being sure that feet remain flat on the ground. Socks and shoes should be removed so that any lifting of the feet can be seen and corrected. Balance beam scales should not be used for the assessment of height, as the measurements are not accurate owing to the flexibility of the measurement arm.

Inaccurate plotting of measurements can lead to significant misinterpretations of growth data. It is crucial to plot the height as close to the fractional age as possible rather than plotting on the nearest year or half-year. Use of a growth chart appropriate to the measurement technique is also important. Standard charts for infants that often extend to 36 months are meant to be used with supine measurements taken on an infant-measuring board. Use of standing heights on these charts can lead to an erroneous conclusion that growth has slowed, because standing heights are shorter than recumbent lengths. Similarly, growth charts that include 2 years to 18 years or more are meant to be used for standing heights only and should not be used to plot recumbent lengths.

Most growth charts are expressed in terms of percentiles for a reference population. This is useful if a child's measurement lies within the percentiles. If, however, height is below the percentiles, an alternative method of height quantitation is needed. The SD score (SDS or Z score) is the number of SDs below or above the age- and gender-appropriate mean for a given height measurement. The concept of SDS is useful for most biologic variables and can be used for weight and body mass index (BMI) as well as for height and height velocity to compare individuals to the reference population and to follow change accurately. To use SDS accurately, a computer program is required that will convert height, weight, birth date, and measurement date to SDS scores. These programs are readily available and should be part of the standard armamentarium of pediatric nephrologists.

Growth Velocity

Growth velocity is an extremely useful tool for assessing health and for determining the effectiveness of various therapies. The accuracy and interpretation of growth velocity calculations depend on the accuracy of the underlying measurement and on the choice of an appropriate interval for a velocity calculation. Growth velocity varies throughout the year in healthy children; thus, the most accurate calculation of growth rate is that done with measurements that are exactly a year apart. Sometimes practical considerations, such as availability of measurements and the need to make therapeutic decisions in a timely manner, preclude using measurements over a complete year. Because multiplying the time over which two measurements were taken by the appropriate factor to calculate an annual growth rate necessarily multiplies any measurement inaccuracy, extreme cau-

tion should be used in interpretation of growth rates calculated over less than a 6-month period. It is crucial when plotting growth velocities on charts to draw bars around the midpoint of the growth velocity as plotted to indicate the time over which the velocity was calculated. It is also important, especially when assessing therapies, to choose time intervals for growth velocity calculation that represent significant events. For example, the expectation and interpretation for a growth velocity in the first year of growth hormone (GH) treatment is different from the expectation for the second year of treatment and so forth. Intervals of treatment should not be mingled with intervals without treatment in calculation of growth velocities.

Growth velocity data that correspond to the height standards shown in Figure 22.1 are not available. Thus, standards for growth velocity that were derived from longitudinal data should be used (Fig. 22.3).

Interpretation of growth velocities differs from interpretation of absolute height. Because a growth velocity of around the fiftieth percentile is required to maintain an absolute height around the fiftieth percentile, a growth velocity that is consistently at the tenth percentile over years cannot be considered normal. That differs significantly from an absolute height that could be considered quite normal if it remained at the tenth percentile over years. A child who has a growth velocity at the tenth (or even twenty-fifth percentile) over many years will gradually fall lower on the percentiles for absolute height.

Sitting Height

Measurement of sitting height can be helpful when there is reason to suspect that the patient has a condition or disease that differentially affects either the spine or the long bones. Examples might be hypophosphatemic rickets or a patient with scoliosis or those who have had irradiation of the spine or spina bifida. Sitting height is best measured with a device specifically constructed for this purpose consisting of a box of appropriate width for comfortable sitting of a precise height. The patient can then sit on the box and position the upper body and head as for a standing measurement. The height of the box is subtracted from the stadiometer measurement. Standards for sitting height are provided in Figure 22.4. In circumstances in which it is informative to separately assess growth of the spine and long bones, height and sitting height can be measured. The difference between the two can be used to assess growth of long bones in conjunction with measurement of arm span.

Other Measurements of Linear Growth

To assess very small changes in growth over short periods of time, very precise methods have been devised for measurement of the lower leg. This technique is referred to as *kne-mometry*. Although the precision of the technique is very

high, and significant advance in growth can be detected over time periods as brief as a single day, in practice, this technique is not widely applied in clinical settings and is mainly reserved for research use (1–3).

Head Circumference

Occipitofrontal circumference is an important measurement in young children up to about 3 years while brain size is increasing. Occipitofrontal circumference is affected by nutritional conditions and chronic illness only in extreme situations and generally does not give much insight into either the presence or progression of renal disease. As occipitofrontal circumference reflects brain growth, which is generally independent of somatic growth, it is an independent marker of whether an insult or multisystem disease that may have caused renal disease has also affected central nervous system development.

Body Mass Index

Weight is commonly measured, and the measurement is usually quite precise if care is taken to weigh the patient in a standard and minimum amount of clothing, such as a light hospital gown (or diaper for a young infant). Weight can be plotted for age and compared to height. Generally, it is thought to be optimum if the weight and height percentiles are the same. This is not the case for most patients, so an alternative measure of the weight to height relationship is needed to determine whether a patient is at risk from either too much or too little body mass (weight). BMI is calculated as weight in kg/height in m². Children who have a BMI higher than the seventy-fifth percentile or lower than the fifth percentile have increased health risks, which will be additive to any underlying renal disease (4–6). Thus, calculating BMI and either plotting or determining BMI SDS is another valuable health indicator. Standards for BMI percentiles are provided in Figure 22.5.

BMI is generally perceived to be a proxy for body composition, but there is significant variation in the weight of bone and muscle among individuals, making the correlation between BMI and other determinations such as fat mass are not precise. If techniques such as isotope dilution or quantitative dual-energy x-ray absorptiometry are not practical, a good approximation of fat mass can be determined by bioelectrical impedance. If it is important to document whether changes in weight are due to fat or fat-free mass, bioelectrical impedance can be quite helpful. It is important to use regression equations derived specifically for children, however, rather than relying on the immediate output of commercial machinery.

Bone Age

Physiologic maturity of the skeleton can be estimated by assessing specific radiologic findings that progress in an orderly fash-

ion in specific bones. In clinical practice, the atlas by Greulich and Pyle is almost universally used (7). This method displays a series of standards for boys and girls at various ages. An accompanying text describes the changes in specific bones because the last standard is provided. The *bone age* is reported as the standard that looks most like the radiograph of the patient. To use this information appropriately, it is important to recognize that the standards were derived approximately 50 years ago and may not entirely reflect current secular trends. There are often gaps of an entire year between standards, making it difficult to assess less dramatic changes in bone maturation. Finally, this system does not take into account that not every bone in every patient matures at the same pace as the radiographic standards. It is quite common to find a significant discrepancy among the maturity of the bones of the hand and wrist.

A more precise and useful method for bone age assessment requires 20 bones to be scored into one of (usually) eight categories of maturity and a score given for each of the categories (8). The numerical sum of the scores for each of the 20 bones is translated to a bone age. This method has the first advantage of a validated weighting system to account for the fact that some bones are more reliable predictors of maturity than others. A second advantage is the ability to assess the bone age as an almost continuous variable of 0.1-year increments. Using this system, it is possible to detect more subtle changes in maturation. When applied by very experienced interpreters, these two methods give quite comparable results. In situations of discordant clinical and radiologic findings, it is sometimes advantageous to use both methods. The 20-bone method can be much more time consuming, however, and is unlikely to be commonly used by radiologists.

The issue of what a bone age means is both intuitively obvious, yet potentially open to misinterpretation. On the one hand, a delay in bone age can imply that the individual in question has more potential for growth than would be assumed by plotting a height measurement alone. On the other hand, the tendency of films to be interpreted as either *normal* or *abnormal* based on whether they fall within two SDs of a mean reading can cause unwarranted consternation. It is perhaps more helpful to think of a bone age as a descriptor of maturation that cannot be abnormal in and of itself. A bone age is only one clue contributing to a decision about whether a growth pattern is indicative or a consequence of an underlying abnormality or treatment.

Pubertal Stages

Just as accurate assessment of height and growth velocity informs assessment of health, accurate staging of the pubertal process and monitoring of the progression of pubertal development can be a good indicator of general health and adequacy of treatment for underlying renal disease. Figure 22.6 describes the pubertal staging method of Tanner that is the accepted method to quantify pubertal development. It should be noted that pubertal stage is not described in one number,

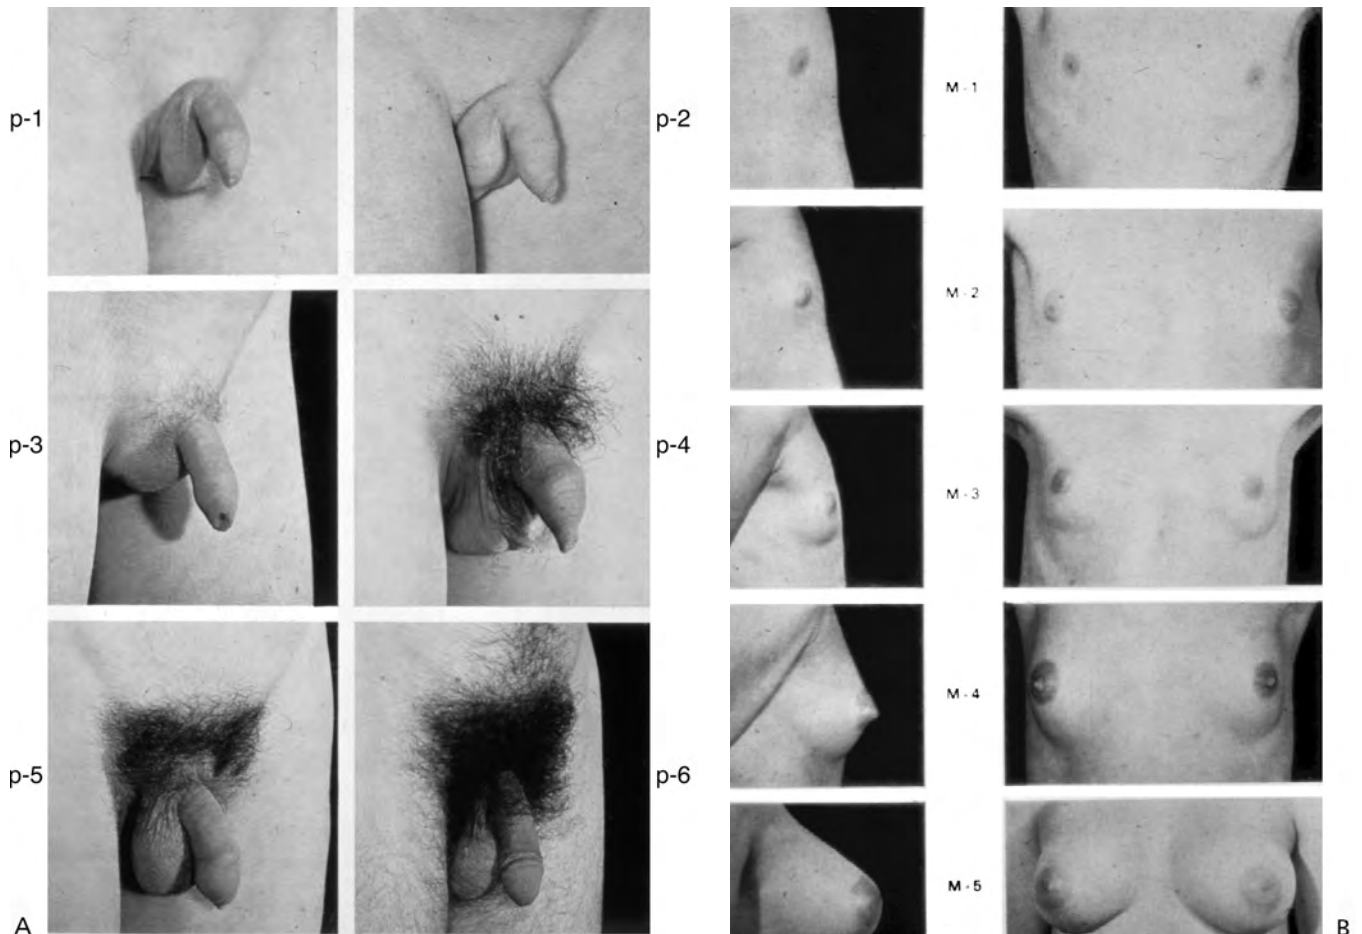

FIGURE 22.6. Stages of pubertal development for boys and girls (A–C). Stages of genital development for boys (A): (1) Preadolescent—testes, scrotum, and penis are of about the same size and proportions as in early childhood. (2) Enlargement of scrotum and of testes—the skin of the scrotum reddens and changes in texture; little or no enlargement of penis at this stage. (3) Enlargement of penis, which occurs at first mainly in length—further growth of testes and scrotum. Increased size of penis with growth in breadth and development of glans; further enlargement of testes and scrotum; increasing darkening of scrotal skin. Stages of breast development for girls (B): (1) Preadolescent—elevation of the papilla only. (2) Breast bud stage—elevation of papilla as a small mound; enlargement of areolar diameter. (3) Further enlargement and elevation of breast and areola, with no separation of their contours. (4) Projection of areola and papilla to form a secondary mound; the development of the areolar mound does not occur in all girls; in one-fourth it is absent and in a further one-fourth relatively slight. (5) Mature stage—projection of papilla only, caused by recession of the areola to the general contour of the breast. Stages of pubic hair development for boys and girls (A,C): (1) Preadolescent—the vellus over the pubes is not developed further than over the abdominal wall. (2) Sparse growth of long, slightly pigmented downy hair, or only slightly curled, appearing chiefly at the penis or along the labia. (3) Considerably darker, coarser, and more curled; the hair spreads sparsely over the junction of the pubes. (4) Hair now resembles adult in type but the area covered is still considerably smaller than in the adult; no spread to the medial surface of the thighs. (5) Adult in quantity and type with distribution of the horizontal (classically feminine) pattern; spread to the medial surface of thighs but not up linea alba or elsewhere above the base of the inverse triangle. (From Tanner J. *Growth at adolescence*. Oxford: Blackwell, 1962, with permission.)

but, rather, a separate stage should be given for pubic hair development and breast or genital development. In some situations, these numbers are discordant. It is particularly important to accurately assess testicular size by comparison to a standard orchidometer with a gradation of sizes from 1 to 25 mL. This volume should be recorded in addition to the pubic hair stage and the genital stage. A description of pubertal stage should be part of every physical examination.

NORMAL GROWTH—PHASES AND DRIVERS OF GROWTH

The first phase of growth is intrauterine growth. Although prenatal growth can be influenced by factors such as chromosomal constitution and fetal hormone production, the single most significant contributor to adequate fetal growth seems to be adequate nutrition. Adequate nutrition, in turn, depends on adequate maternal nutrition and adequate delivery of nutrients through a competent placenta. If either of these aspects of nutrition fails, intrauterine growth retardation or restriction (IUGR) results. Approximately 85% of children with intrauterine growth retardation or restriction exhibit catchup growth in the preschool years and ultimately achieve normal adult stature. The observation that approximately 15% of intrauterine growth retardation or restriction babies do not catch up has led to the hypothesis of intrauterine growth programming. This hypothesis and the mechanisms that might be responsible for it are under active investigation (9).

The second phase of growth is the rapid growth in both length and weight that occurs during the first 2 years or so after birth. Through mechanisms that are poorly understood and may be related to nutritional programming of growth, this infantile growth also seems to be driven to a significant extent by intrauterine nutrition. During this phase of growth, a healthy baby would be expected to grow approximately 25 cm/year. During the later part of this growth phase, most commonly between approximately 9 and 24 months, many children who were well nourished *in utero* but whose genetics suggest they are likely to be shorter children cross percentiles in a downward fashion to bring their length more in line with genetic expectations. This is a normal growth adjustment in this phase and does not necessarily indicate an abnormality of growth.

There have been a number of studies associating growth during this phase with plasma growth factors, such as insulin-like growth factor (IGF)-1, IGF-2, IGF-binding protein (IGFBP) 3, and IGFBP1 (10–12). It is not clear, however, that these associations reflect a causative influence of the growth factors or a common driver of both growth and the growth factors, such as nutrition or programming of the growth factors by either nutrition or other unknown factors.

The third phase of growth lasts from approximately 2 years until the time of the pubertal growth spurt. During this phase, growth is driven by genetics with the permissive input

of the child's own normal endocrine system. The growth velocity curves demonstrate well that growth velocity is constantly declining during this phase. Growth velocity for any given child is not always in a consistent percentile. In fact, a healthy child with a growth velocity with a negative SDS (i.e., below the mean) in 1 year is statistically most likely to have a growth velocity with a positive SDS (i.e., above the mean) in a subsequent year. Thus, in addition to the usefulness of calculating growth velocities over a full year, additional conclusions about the normality or abnormality of a growth pattern can require reliable data over several years.

The fourth phase of growth is the pubertal growth spurt. The time of onset of the pubertal growth spurt varies between genders but also among individuals of the same gender. Growth velocity increases dramatically and more in girls than in boys before declining as pubertal development is complete. Because the timing of the onset of puberty is variable, it is appropriate to take pubertal stage into consideration when assessing growth rate. If puberty has not begun, growth velocity will continue to decline until pubertal onset. Thus, growth velocity can be quite low in a child who has delayed onset of puberty at an age when most of his or her peers are having a pubertal growth spurt. This “dip before the spurt” phenomenon can be differentiated from a significant abnormality of growth by assessing pubertal stage and possibly bone age (see later).

After several years of exposure to sex steroids, the epiphyses of the long bones fuse, and linear growth is no longer possible. This effect on bones is believed to be mediated by estrogen in both boys and girls (13). It is this maturational effect that is responsible for the decline in growth velocity after the peak of the pubertal growth spurt and for the ultimate cessation in growth. Thus, individuals who have significant delay of their bone maturity (bone age) also have residual growth potential. If the delay in bone maturity is due to either the effect of serious illness or due to treatment with glucocorticoids or other medication, the growth potential inherent in a delayed bone age is not always completely achieved (14).

DETERMINATION OF GENETIC TARGET RANGE AND CORRECTION OF GROWTH EXPECTATIONS FOR PARENTAL HEIGHTS

In the third or childhood phase of growth, height is significantly impacted by genetics. Any assessment of absolute height must take into account the target height range, which is best estimated statistically by parental heights. To plot a genetic target range, the height of the same sex parent should be plotted on the right edge of the growth chart. The height of the opposite sex parent should be plotted either by transferring the percentile on the appropriate sex chart to the child's chart (i.e., plotting a twenty-fifth percentile mother at the twenty-fifth percentile on a boy's

FIGURE 22.7. Normal physiology of the somatotrophic axis. GHRH, growth hormone-releasing hormone; IGFBP, insulin-like growth factor-binding protein; SMS, somatostatin. (From Rosenfeld R, Rosembloom A, Guevara-Aguirre J. *Endocrine Reviews* 1995;15:369–390, with permission.)

chart) or by adding 13 cm to the mother's height and plotting it on a boy's chart or subtracting 13 cm from a father's height and plotting it on a girl's chart. Next, the midpoint of these two parental heights should be calculated and plotted. A range of 10 cm above and below this midpoint will include the fifth to ninety-fifth percentiles of the target range for that set of parents.

Further use can be made of these data to calculate a Z score adjusted for parental height. For example, if a child has a height Z score of -2 and the midpoint of the genetic target range has a Z score of -1.5 , the child has a Z score of -0.5 when adjusted for genetic target range.

PHYSIOLOGY OF GROWTH HORMONE SECRETION

Although a comprehensive discussion of the physiology and pathophysiology of GH secretion is beyond the scope of this text, it is useful to bear in mind current understanding of the regulatory mechanisms of the somatotrophic axis when assessing the growth of children with renal dysfunction.

A diagram of the functioning of the somatotrophic axis is shown in Figure 22.7 (15). Multiple inputs from a variety of neurotransmitters and neuropeptides influence the hypothalamic output of GH releasing hormone, which stimulates, and somatostatin, which inhibits GH release from the pituitary. A newly described hormone, ghrelin, appears to be an additional stimulant to pituitary release of GH, but its role in physiologic regulation of growth is not yet clear (16).

GH combines with a specific GH receptor to initiate a signal transduction cascade in multiple tissues that leads to synthesis of IGF-1. IGF-1 in turn interacts with multiple IGFBPs and the type 1 IGF receptor to affect multiple other signal transduction cascades that ultimately lead to tissue growth and other metabolic effects of IGF-1. Thus, it is possible for perturbations in this axis at any point to cause an abnormality of growth. Increasing understanding of the complex interrelationship of nutrition and the somatotrophic axis makes a clear distinction between primary nutritional abnormalities and primary abnormalities of the somatotrophic axis very difficult. A recent review of the regulation and abnormalities of the somatotrophic axis outlines the many subtleties of the interpretation of hormone levels in the context of nutritional perturbation (17).

GROWTH IN CHRONIC RENAL INSUFFICIENCY

Growth failure has long been recognized in children with chronic renal failure (18). Recent advances in dialysis and transplantation offer the potential for the child with end-stage renal disease to live well into adulthood. This magnifies the problem of growth failure, as they are unlikely to reach normal adult stature, leading to the need for investigation of the etiology of growth delay and development of strategies to overcome short stature in children with decreased renal function. The need for adequate, sustained growth is the single most important element that sets children apart from adults with chronic renal failure.

Most children with renal insufficiency exhibit profound growth retardation. The classic depiction of a typical growth pattern in a child with renal failure is shown in Figure 22.8 (19). Infants demonstrate severe statural height failure, whereas older children parallel the growth curve of the normal child but remain below it, and the adolescent again falls away from the curves demonstrating an attenuated pubertal growth spurt (19,20). The Growth Failure in Children with Renal Diseases Study looked at children with renal failure from 23 centers, grouped by degree of insufficiency and age (Table 22.1). Children with more severe renal failure and those with congenital disease and early onset of renal failure tended to have more growth delay (21).

In a study of children requiring dialysis (22), Fine found severe height delay with 70% of children below the age of 5 years more than 2 SD below the mean for age (Fig. 22.9). The effect of long-term dialysis on the growth of children with chronic renal failure was studied by Kleinknecht et al. in

FIGURE 22.8. Schematic representation of growth in children with renal insufficiency. A represents the first 2 years of life. B represents 2 years of age until onset of puberty. C represents the pubertal period. (From Betts P, Magrath G. Growth pattern and dietary intake of children with chronic renal insufficiency. *BMJ* 1974;2:189–193, with permission.)

the 1970s (23). Seventy-six children were followed for 12 to 111 months (mean 30 months) on their individualized dialysis regimens (23). In the 50 prepubertal children there was a mean height loss of 0.38 SD/year. The mean height gain during puberty in 11 pubertal children was only 2 cm/year in girls and 2.7 cm/year in boys, although some subjects exhibited a prolonged growth period (up to age 21 years in one child). A more recent study by van Diemen-Steenvoorde and Donckerwolcke of 35 prepubertal children receiving hemodialysis for more than 1 year (mean, 2.5 years) revealed a loss of 0.31 SD/year (24). The pubertal growth spurt was 3.2 cm/year for boys and 2.1 cm/year for girls at this center. The multicenter report from the European Dialysis and Transplant Association in 1978 of prepubertal children followed for more than 4 years on hemodialysis cited a loss of 0.43 SD/year in height (25). More recent data from the North American Pediatric Renal Transplant Cooperative Study (26), a registry of children with renal failure in North America, continues to demonstrate a loss of 0.32 height SDS over a 2-year period in children receiving dialysis (27).

TABLE 22.1. GROWTH FAILURE IN CHILDREN WITH CHRONIC RENAL FAILURE

Category	No. of patients	Height SD score
Age (yr)		
1–3	31	–1.4
4–6	23	–1.0
7–10	28	–0.7
Disease		
Acquired	23	–0.9
Congenital	59	–1.1
Renal failure ^a		
Mild	34	–0.9
Moderate	29	–1.2
Severe	12	–1.1

^aMild, creatinine clearance 50–75 mL/min/1.73 m²; moderate, creatinine clearance 30–49 mL/min/1.73 m²; severe, creatinine clearance <30 mL/min/1.73 m².

Adapted from Abitbol C, Warady B, Massie M, et al. Linear growth and anthropometric and nutritional measurements in children with mild to moderate renal insufficiency: a report of the growth failure in children with renal diseases study. *J Pediatr* 1990;116:S46–S62.

Several studies indicate that children on chronic ambulatory peritoneal dialysis grow better than those receiving chronic hemodialysis or transplantation (28–34). However, these studies show little, if any, statistical significance of the data and are not controlled for age, underlying disease, nutritional intake, and other factors affecting health and growth. Often, the hemodialysis data are derived from historical controls. This can be misleading, as studies have shown general improvement in SD scores on hemodialysis when comparing successive time periods (35). Some of the children had experienced failure of peritoneal dialysis before the institution of hemodialysis, further confounding the analyses. Even under optimal conditions, children on peritoneal dialysis still do not exhibit catchup growth, with several studies showing more than one-half of the children continue to lose growth percentiles while on dialysis (30,36–38).

Transplantation remains the ultimate goal for the pediatric end-stage renal disease patient. Recent data from the North American Pediatric Renal Transplant Cooperative Study show a mean standardized height of –2.16 SDS in nearly 400 transplant recipients (26). Younger children tend to be more severely growth retarded, reflecting the impact of chronic renal failure during the early growth spurt. After transplantation, children younger than 5 years demonstrate some catchup growth, but children older than 6 years have no acceleration of growth rate and may even continue to lose ground, becoming more growth retarded (26,34,39). Thus, it is clear that growth failure cannot be corrected by transplantation and must be addressed earlier in the course of renal failure.

Final adult height is greatly affected by the growth failure seen with chronic renal failure in children. The European Dialysis and Transplant Association found in 1981 (40) that the mean height of adults who had suffered from

FIGURE 22.9. Relationship between degree of growth retardation and age at onset of renal insufficiency. (From Fine R. Growth in children with renal insufficiency. In: Nissenson AR, Gentile DE, eds. *Clinical dialysis*, 2nd ed. Norwalk, CN: Appleton & Lange, 1990:667-675, with permission.)

chronic renal failure during childhood was 3 SD below the mean (-3.0 SDS). In 1985, the European Dialysis and Transplant Association (35) further reported 62% of men and 41% of women who had renal replacement therapy before the age of 15 had final adult heights below the normal range. This confirms the expectation that children with renal failure at an early age never demonstrate catchup growth and thus reach adulthood significantly height compromised.

ETIOLOGY OF GROWTH DELAY IN CHRONIC RENAL FAILURE

Many factors, listed in Table 22.2, are thought to contribute to the growth failure associated with chronic renal insufficiency, but the mechanisms responsible for their effects are

TABLE 22.2. FACTORS CONTRIBUTING TO GROWTH FAILURE IN CHILDREN WITH RENAL INSUFFICIENCY

Age at onset of primary renal disease
Etiology of primary renal disease
Degree of renal impairment
Inadequate caloric and protein intake
Renal osteodystrophy
Metabolic acidosis
Tubular defects
Polyuria
Salt wasting
Potassium depletion
Other losses (calcium, phosphorous, etc.)
Corticosteroid administration
Anemia
Infection
Psychosocial factors
Uremic inhibitors of growth hormones and related proteins

Growth and endocrine function in children with chronic renal failure. *Acta Paediatr Scand* 1990;370:S20-S27; and French C, Genel M. Pathophysiology of growth failure in chronic renal insufficiency. *Kidney Int* 1984;30:S59-S64.

poorly understood (41-43). As noted in Figure 22.9, children with onset of renal failure earlier in life have more severe growth impairment than those diagnosed later. Figure 22.10 depicts the severe growth failure of a group of children with obstructive uropathy, which is usually congenital, thus exerting an influence on growth from birth (22).

A correlation between degree of renal failure and growth dysfunction has been reported, although this correlation has not been demonstrated in all studies (21,35,42,44). Poor nutritional intake can certainly influence growth in any setting, and chronic renal failure is no exception (45). Some authors report improvement in height SD scores with nutritional intervention (42,46-48).

Renal osteodystrophy, intercurrent infections, metabolic acidosis, and tubular defects have been correlated to poor growth, and specific therapy for these defects can be growth enhancing (21,44,45,49). Corticosteroids are well known to inhibit statural growth, but are not usually required therapeutically once dialysis is initiated (50). Although chronic anemia was long thought to be a contributing factor to growth failure, early reports of correction of anemia with recombinant erythropoietin have been disappointing regarding improvement in nutrition or growth (51-54). Psychosocial factors have also been shown to affect the growth of children with impaired renal function (35).

EFFECTS OF UREMIA ON GROWTH HORMONE/INSULIN-LIKE GROWTH FACTOR AXIS

It was thought that abnormalities of GH and IGF-1 played no role in the pathogenesis of growth failure in renal insuf-

FIGURE 22.10. Relationship between degree of growth retardation and primary renal disease. (From Fine R. Growth in children with renal insufficiency. In: Nissenson AR, Gentile DE, eds. *Clinical dialysis*, 2nd ed. Norwalk, CN: Appleton & Lange, 1990:667-675, with permission.)

fiency. However, recent studies have begun to elucidate perturbations of the GH axis in chronic renal failure, which brings this aspect of growth failure into focus and lays the groundwork for therapeutic interventions (55-64).

GH functions by stimulating production and release of IGF-1 as well as by more direct effects on target tissues (64,65). Early reports indicated reduced (66) or high (62) IGF-1 levels in uremia when measured by radioimmunoassay. Bioassays have also found reduced activity of IGF in uremia, with some investigators finding a slight rise in activity after a dialytic session and others demonstrating higher levels with transplantation, raising the possibility of

uremic inhibitors (66-68). More recent reports, using improved extraction techniques, indicate that IGF-1 activity is near normal in uremia (64,69-71).

Current research is focusing on the physiology and pathophysiology of GH-binding proteins and IGFBPs in normal and abnormal growth (71-77). Uremic children have been shown to have a low serum level of GH-binding protein (75). This may play some role in end-organ effect. At least six IGFBPs have been identified and characterized (55,78). IGFBP1, IGFBP3, and IGFBP4 have been shown to be elevated in uremic children and the excess binding protein, especially IGFBP3, acts as an IGF-1 inhibitor (55,72,73,76,79).

TREATMENT OF THE GROWTH FAILURE OF CHRONIC RENAL INSUFFICIENCY

The alterations in GH-binding proteins and IGFBPs in chronic renal failure provide a rationale for the use of recombinant human growth hormone (rhGH) to treat the growth failure in prepubertal uremic children. Theoretically, excess ligand might be expected to overcome any inhibitory effect of increased binding. Landmark studies by Mehls and colleagues demonstrated a stimulatory effect of growth hormone on chondrocytes and longitudinal growth in uremic rats (80-82). Several other investigators confirmed the growth-enhancing effects of GH in this animal model (83-86). These studies also provided reassurance regarding stability of renal function and serum lipids (83,84,86), although concern has been raised regarding a trend toward reduced survival and glomerular hypertrophy with glomerulosclerosis in treated animals (83).

The favorable results of the use of rhGH in the rat model led to subsequent trials in uremic children. In 1988, Lippe et al. reported a twofold increase in height velocity in five growth-retarded, uremic children given rhGH (87). This center has since reported growth data from nine patients followed for up to 36 months on GH therapy (88-90). SD scores in these nine patients improved from mean -3.18 to -2.50 at 12 months, whereas the four subjects treated for 36 months improved from -2.78 to -1.29. The individual growth chart of a typical subject is shown in Figure 22.11. Bone age did not advance disproportionately to chronologic age in these patients. There were no significant changes in serum chemistries, calculated creatinine clearances, thyroid function tests, or glucose tolerance. IGF-1 levels increased in all patients (90).

These encouraging preliminary results have been supported by Tönshoff and the German Study Group who have now studied 61 uremic children (20 predialysis, 24 dialysis, 17 transplanted) receiving daily subcutaneous rhGH for 1 to 2 years (91,92). The 17 prepubertal, predialysis subjects improved from a pretreatment median SDS of -3.0 to -2.0 after 1 year of therapy. This study reports a

FIGURE 22.11. Growth of individual patient before and during treatment with recombinant human growth hormone (rhGH). ↓, rhGH thrice weekly; ↑, rhGH daily; D, dialysis initiated; D/C, rhGH discontinued. [From Fine R, Pyke-Grimm K, Nelson P, et al. Recombinant human growth hormone treatment of children with chronic renal failure: long-term (1- to 3-year) outcome. *Pediatr Nephrol* 1991;5:477-481, with permission.]

significant improvement in height in all patient groups with no untoward effects, except an elevation in insulin levels. This has been found to be a transient abnormality in the longer-term study (90). Mehls et al. also found an increase in IGF-1 after treatment, with no further rise in IGFBP3 concentration (55). Johansson et al. and Van Es and the European Study Group have followed 94 prepubertal children (41 predialysis and 53 transplanted) for up to 2 years of rhGH therapy (93,94). In children treated for 2 years, height SDS was improved from -2.8 to -1.8 in predialysis patients. No significant side effects were reported.

Multiple other reports have confirmed the effect of rhGH in overcoming the short stature associated with uremia in the pediatric population (95-101), including two reports of improved height in children with nephropathic cystinosis (100,101). Encouraging data exist about improvement in height SDS and head circumference in infants treated with GH. The role of the GH/IGF-1 axis in this age group still requires more clarification, especially whether treatment could relate to improved neurodevelopment (98,99). Although more difficult to assess, pubertal uremic children are also believed to respond favorably to GH treatment (92-95,97,102,103).

Concerns regarding potential long-term side effects have not been borne out by experimental data. Fine and colleague's randomized, placebo-controlled study should provide excellent data on both long-term effectiveness and adverse effects (99). Specific concerns raised regarding avascular necrosis of the femoral head, progression of renal failure, and lipid and insulin abnormalities have not been borne out in subsequent investigations (104-109).

Reports of the use of rhGH in growth-retarded children with renal allografts are encouraging with some improvement in height SDS despite the concomitant use of corticosteroids to suppress allograft rejection (92-95,110-114). However, concerns about a deleterious effect on the allograft demand caution in this patient population (115,116). Further randomized, controlled studies are necessary to determine the safety of treatment in this setting. Until then, the best approach appears to be normalization of height using growth hormone before transplantation, as final adult height is best predicted by height achieved before transplantation (39,117).

Many of the above studies included patients receiving dialysis. Fine et al. reported five children undergoing chronic cycling peritoneal dialysis who received rhGH (118). Only three showed improvement in height SDS, but length of treatment was less than 1 year in the other two. Tönshoff et al. found improvement in the height velocity SDS in eight children undergoing dialysis treated with rhGH (1 hemodialysis, 7 peritoneal dialysis), but the change was not as marked as in a single predialysis patient (91). This trend continued in the larger German study, with improvement in SDS from -3.2 to -2.7 in ten dialysis patients treated for 1 year (96). However, in Hokken-Koeliga and colleagues' placebo-controlled, double-blind, crossover trial there was no difference found in the response of dialysis patients compared to conservatively managed predialysis patients, with mean increases in height velocity of 2.9 cm/6 months versus 3.0, respectively (96). An encouraging report by Tom et al. demonstrates some catchup growth in children on maintenance hemodialysis with increased intensity of hemodialysis and closely monitored nutritional intake, raising the possibility of overcoming the poor growth response in the dialysis population (119).

Significant controversy exists regarding the safety and efficacy of rhGH after transplantation. Thus, it remains to be seen whether any height deficit remaining after successful transplantation will be amenable to rhGH therapy.

Children treated with GH may have their growth limited by fusion of the epiphyses as a result of normal pubertal development. Because of some evidence that delaying puberty in children with GH deficiency can increase height prognosis (17), such therapy might be considered for children undergoing GH treatment for chronic renal insufficiency. The benefit to be derived from such treatment in patients with chronic renal insufficiency has yet to be documented.

There are early indications that therapy with GH can have a positive effect on ultimate adult height. Recently, the German

Study Group for Growth Hormone Treatment in Chronic Renal Failure demonstrated that mean final adult height for children with chronic renal failure treated with growth hormone was 1.6 SD below normal, a marked improvement over historical controls who were untreated (120).

CONCLUSION

The growth retardation of children with chronic renal failure is a major problem for the pediatric nephrologist. With the current success of dialysis and transplantation in minimizing the mortality of early-stage renal disease, these children should live well into adulthood. Allowing them to appreciate their full adult height potential is a realistic goal. The use of rhGH to enhance growth during the early years of renal insufficiency and during dialysis has been shown to be effective. Further long-term studies are needed to determine whether growth will continue and genetic potential for ultimate adult height will be attained. Potential long-term side effects also need to be continually monitored in a rigorous fashion. Concern still exists regarding growth and the use of rhGH after transplantation to maximize growth. Thus, preventing growth retardation and recovering lost growth during early renal insufficiency and the dialytic period may be the best way to maximize adult height in this population.

DIAGNOSTIC IMAGING

FRED E. AVNI
MICHELLE HALL

Imaging the urinary tract (UT) plays a significant role in the work-up of many nephropathies (1,2). The numbers of techniques that are available to image the UT are numerous; each has its advantages and drawbacks. The work-up must be tailored to every patient taking into account the type of disease, clinical data, and questions to be answered. Hazards related to the use of a specific technique, such as radiation hazards, allergy, or postprocedural infection, should also be taken into account. Whatever technique is chosen, a decision tree must be applied in accordance with the ALARA principle (*as low as reasonably achievable*). This concept implies that imaging techniques have to be chosen to provide the most accurate diagnosis using the most adequate and safest technique in a specific indication. Whenever possible, a radiating technique should be replaced by a nonradiating one (3).

DIAGNOSTIC PROCEDURES

Ultrasound

Ultrasound (US) is the central imaging modality for assessing the UT in children. It is easy to perform. The examination is very accurate in assessing the presence of a kidney and the degree of dilatation. It should include evaluation of the bladder and ureters (not visible under normal conditions) (4,5). Kidney size should be compared to normograms; established according to age, weight, or height; and expressed in standard deviation (6). On US, the kidneys appear with a corticomedullary differentiation (CMD); the cortex is relatively echogenic and the medulla appears hypoechoic (Fig. 23.1). In the newborn, the cortex is hyperechoic compared to the liver; this is more pronounced in the premature newborn.

Pulsed Doppler analysis provides information about the venous and arterial vascularization of the kidneys. Spectral analysis demonstrates the degree of renal vascular impedance by means of the resistive index (RI) and blood velocity (Fig. 23.2). Color Doppler and Doppler energy allow the mapping of renal vascularization (5) (Fig. 23.3).

The bladder shape, wall, and content are evaluated as well. The wall thickness should be inferior to 3 mm. The volume can be evaluated using the following formula (7):

$$0.6 \times \text{bladder height} \times \text{width} \times \text{transverse diameter}$$

US can be used as an alternative method to detect vesicoureteric reflux (VUR) with sonicated contrast media (Fig. 23.4). There is a good correlation with classic voiding cystogram for demonstrating reflux (8).

Voiding Cystourethrogram

Voiding cystourethrogram (VCUG) remains the best imaging technique to detect VUR (Fig. 23.5). It also allows an evaluation of the urethra. It can be performed by catheterizing the bladder or through suprapubic puncture. The procedure should be explained in detail to the parents and to the patient. It should be performed in a strictly sterile manner. To minimize radiation, pulsed fluoroscopy may be used. Repeated filling of the bladder (cyclic VCUG) increases the rate of detection of VUR, especially in infants. VUR is graded according to the international reflux study group (grades I to V) (Fig. 23.5). Prophylactic antibiotherapy given 2 days before and 2 days after the examination is controversial, but the examination should be performed only when the urine has been tested sterile. Postprocedural infection occurs in 1 to 3% of patients, and hematuria may develop (9).

Intravenous Pyelography

The use of intravenous pyelography (IVP) has markedly decreased in recent years (Fig. 23.6A). The technique is progressively replaced by US, nuclear medicine, magnetic resonance (MR) imaging (Fig. 23.6B), and even computed tomography (CT). Known allergic disease and renal failure are the main contraindications (10).

Computed Tomography

CT has gained popularity since the development of helical CT that allows very rapid assessment of the UT. It provides exquisite cross-sectional anatomic and functional details. Two- and three-dimensional reconstruction helps to better visualize various anomalies. Yet, it is a radiating technique and it necessitates contrast injection. Still, the method is

FIGURE 23.1. Normal ultrasound of the kidney in a child. Sagittal scan of the right kidney; the pyramids (*arrows*) are hypoechoic compared to the cortex. Cortical echogenicity is similar to that of the liver (L).

helpful in several conditions (tumors, urolithiasis, or abscess) (see below). Known allergic disease and renal failure are contraindications for contrast injection (11,12).

Magnetic Resonance Imaging

Thanks to the development of faster sequences, the use of MR imaging for the evaluation of the UT in children has rapidly extended. Structures are defined as appearing hyper- (white) or hyposignal (black). T2-weighted sequences (the so-called uro-MR sequences), allow the visualization of the collecting system. T1-weighted sequences provide more

FIGURE 23.2. Duplex Doppler evaluation of normal renal vessels. Measurement of the resistive index (IR). The sample is measured at the level of the renal hilum. IR equals 0.68 (normal), maximum systolic velocity is 0.25 m/sec, and minimum diastolic velocity is 0.08 m/sec. CAL, calibration; S/D, systolic/diastolic.

FIGURE 23.3. Power Doppler ultrasound of a normal kidney vascularization. Lack of vascularization of the upper pole is related to a rib artefact (*asterisk*).

information on the renal parenchyma, especially after a gadolinium injection. The measurement of parenchymal enhancement provides information about the glomerular filtration (Fig. 23.6B).

MR imaging is progressively replacing IVP for the assessment of dilated UT, particularly for the evaluation of abnormal duplex systems or suspicion of ectopic extravascular ureteral insertion. Evaluation of tumoral extension or reflux nephropathy (RN) is another good indication. Another promising field is vascular investigation through MR angiography of the renal arteries, particularly in patients with hypertension (Fig. 23.7). The drawbacks of the method are its poor accessibility and the need for sedation in infants (13,14).

Nuclear Medicine

Recent progress in nuclear medicine techniques includes production of new tracers, new applications of known tracers, development of various algorithms to determine renal function, and increased quality of instrumentation (15–18).

FIGURE 23.4. Sonographic voiding cystourethrogram. Sagittal scan of the right kidney before (*left*) and after (*right*) instillation of sonicated albumin. The contrast distends the renal pelvis (*arrows*) indicating vesicoureteric reflux. (Courtesy of K. Darge, M.D., Heidelberg, Germany.)

FIGURE 23.5. Radiologic voiding cystourethrogram. Bilateral vesicoureteric reflux [grade II (*right*) and grade III (*left*)] with intrarenal reflux enhancing the right upper and left upper parenchyma (*arrows*).

Renal Tracers

Chromium isotope–ethylenediaminetetraacetic acid, which is eliminated exclusively through glomerular filtration without tubular secretion or reabsorption, is a good tracer for the determination of glomerular filtration rate (GFR) using blood sampling.

Technetium 99m (^{99m}Tc)–diethylenetriamine pentaacetic acid is exclusively eliminated by glomerular filtration without tubular secretion or reabsorption. The energy of ^{99m}Tc –diethylenetriamine pentaacetic acid is adequate for gamma camera studies and allows studies of individual kidney renographic curves, relative and absolute GFR, determination of renal transit times, and furosemide-augmented tests.

Iodine 131– or iodine 123–hippurate is secreted mainly by the tubular cells and by the glomerular filtration (5 to 10%). Hippurate clearance is considered to reflect the renal plasma flow and is therefore called the *effective renal plasma flow*.

^{99m}Tc –mercaptotriglycylglycine (MAG-3) is eliminated almost completely by tubular secretion. The advantages of MAG-3 compared to ^{99m}Tc –diethylenetriamine pentaacetic acid are its higher extraction rate, higher signal to noise ratio, and better reproducibility for separate renal clearance measurements. ^{99m}Tc –MAG-3 offers the advantage of combining image with information about renal excretion (Fig. 23.7).

^{99m}Tc –dimercaptosuccinic acid (DMSA) is taken up by the proximal tubular cells and is only slightly excreted in the urine. DMSA provides interesting morphologic information in diseases affecting the renal cortex (Fig. 23.8).

By means of bladder instillation, ^{99m}Tc –pertechnetate anion can be used for direct cystography and detection of VUR (18).

Indications

Common indications are unilateral or bilateral hydronephrosis, UT infections with or without associated vesicoureteral reflux, small kidney, single kidney, urethral valves, pre- and postoperative follow-up, and follow-up of known VUR (15–21).

Study of Urinary Tract Obstruction (Standard and Diuretic Renography)

Two aspects of renal function are assessed: renal clearance and excretion of the tracer. Estimation of relative clearance (differential renal function) requires the measurement of GFR by injection of chromium isotope–ethylenediaminetetraacetic acid using a simple plasma sample technique. The most accurate method for evaluation of GFR is based on the plasma disappearance curve after a single bolus injection of a glomerular tracer.

The second parameter that may be obtained from a renographic curve is the evaluation of tracer molecule transport through the entire nephron, known as the *transit time*. A normal transit time (approximately 3 minutes) excludes renal obstruction. Abnormal transit time indicates urine stasis. It is not possible on the basis of a prolonged transit time to differentiate obstruction from simple dilatation of the collecting system.

The response to intravenous injection of furosemide provides additional information in cases of renal stasis. In cases of nonobstructive dilatation, the retained radioactivity in the UT is washed out rapidly by increased urine flow, whereas renal emptying is slow or nonexistent in the case of obstruction. However, the degree of washout depends on the degree of uptake of the tracer by the kidney. Poor response to furosemide may be observed in kidneys with impaired renal function in the absence of any obstruction (17).

Tubular tracers with a high extraction (e.g., iodine 123–hippurate, ^{99m}Tc –MAG-3, or ^{99m}Tc –ethylene dicysteine) are recommended. The response depends on the rate of tracer extraction. Postmicturition images should be acquired. During the first months of life, the response to furosemide is often equivocal despite the absence of obstruction because of the low extraction (low clearance values). In the presence of a full bladder, drainage from the kidney may be delayed even in the normal individual.

The interpretation of drainage in the presence of marked hydronephrosis is more difficult. Only good drainage is easily defined. The definitions of obstruction and risk factors of renal deterioration are still controversial.

FIGURE 23.6. Bilateral urinary tract dilatation. **A:** Intravenous pyelography showing poor visualization of the right urinary tract. **B:** Magnetic resonance imaging showing uro-magnetic resonance sequence. There is good visualization of both ureters.

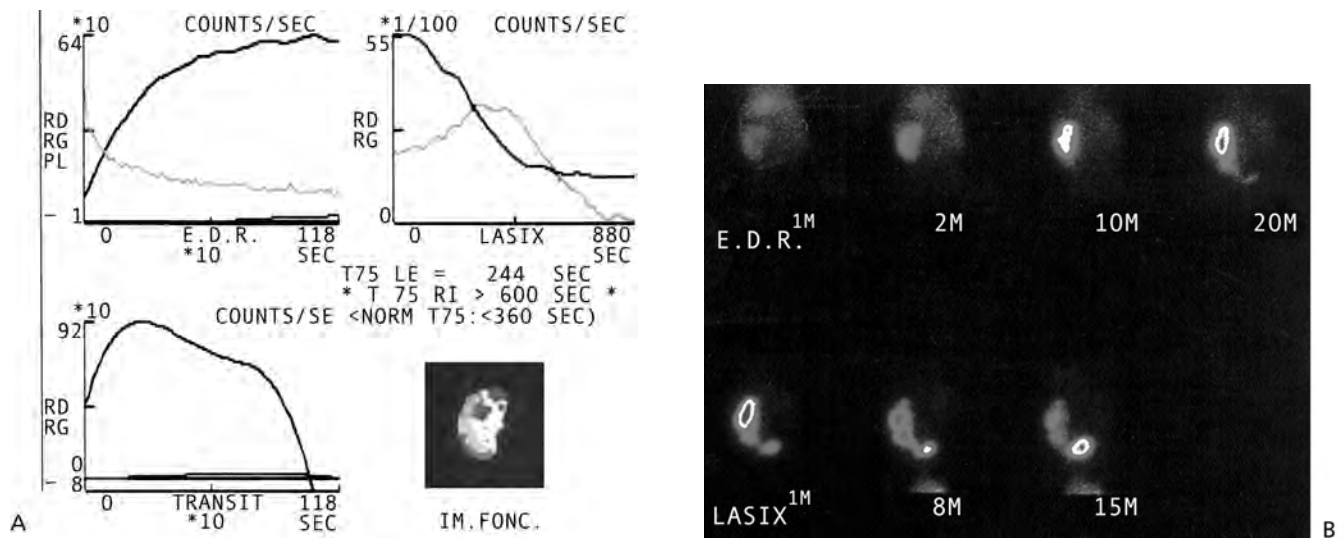

FIGURE 23.7. Mercaptotriglycine renogram in a 1-month-old boy with antenatal diagnosis of right hydronephrosis and left small cystic kidney. The renogram confirms a nonfunctioning left kidney and a ureterohydronephrosis with response to furosemide (megaureter on magnetic resonance). **A:** Curves corresponding to the function of the right kidney. **B:** Morphologic appearance of the dilated right urinary tract. (See Color Plate 23.7.)

FIGURE 23.8. Technetium 99m-DMSA scan in a girl with acute pyelonephritis. There are defects in the upper pole of the right kidney (arrow).

Renal Morphology

^{99m}Tc -DMSA is the best agent for the demonstration of focal renal abnormalities because the tracer is retained mainly in the tubular cells. DMSA scintigraphy is the technique of choice for the detection of acute pyelonephritis (APN) and renal sequelae (Fig. 23.8). The DMSA technique is also indicated for the evaluation of small, ectopic, dysplastic, or infarct kidneys and for the confirmation of nonfunctional multicystic kidneys (19,21). Indirect cystogram is highly valuable for the follow-up of known VUR or in screening siblings (18).

IMAGING CONGENITAL URONEPHROPATHIES

Antenatal diagnosis has markedly modified the time of discovery of nephrouropathies. More and more cases are

FIGURE 23.9. Ureteropyelic junction obstruction *in utero* (ultrasound). Transverse scan of the fetal abdomen at 34 weeks' gestation. Marked dilatation of the left renal pelvis and calyces (4 cm between crosses). Sp, fetal spine.

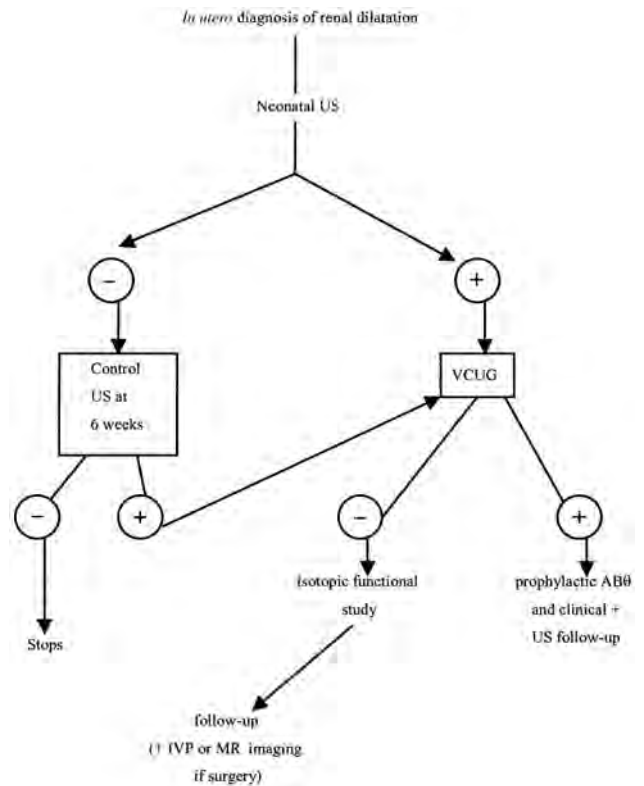

FIGURE 23.10. Neonatal work-up of *in utero* dilatation. +, normal US; -, abnormal US; AB, antibiostherapy; IVP, intravenous pyelography; MR, magnetic resonance; US, ultrasound; VCUG, voiding cystourethrogram.

diagnosed *in utero* and evaluated at birth in asymptomatic patients. Obstetric US is able to diagnose accurately many uronephropathies. In some specific indications (maternal obesity, oligohydramnios, complex malformations), fetal MR imaging provides supplementary information (22,23).

Neonatal Period

Because of the wider use of obstetric US, the evaluation of UT dilatation discovered *in utero* has been standardized (Figs. 23.9 and 23.10).

US is performed first—very rapidly if there is evidence of bilateral obstructive uropathy (i.e., pneumothorax, oligoanuria) or at the end of the first week in all other cases. If US examination is abnormal (Fig. 23.11 and Table 23.1), a VCUG is performed. If US is normal, a control examination is performed at 6 weeks. In the absence of VUR but with persisting dilatation, the degree of obstruction is evaluated with isotopes. Whenever surgery is elected, IVP or, rather, MR imaging should be performed to assess the morphology of the UT. When a conservative, nonsurgical approach is preferred, US allows the follow-up of the dilatation, which spontaneously resolves in many cases (22,24–26).

FIGURE 23.11. Ureteropyelic junction obstruction in a newborn (ultrasound). Marked dilatation—transverse scan 30 mm between crosses. The calyces (*asterisks*) are also dilated.

Urinary Tract Dilatation

The role of imaging is to determine the level and degree of obstruction. Ureteropelvic junction (UPJ) obstruction is the main cause of UT dilatation *in utero* (Fig. 23.12) and at birth (Fig. 23.13). US shows a dilated renal pelvis above 7 mm (on a transverse scan of the kidney) (Figs. 23.12 and 23.13). Dilatations can be classified as mild (7 to 10 mm), moderate (10 to 15 mm), and marked (greater than 15 mm). Thinned, echogenic or cystic cortex suggests associated dysplasia. The degree of functional impairment is evaluated by isotopic studies. IVP or better MR imaging helps to demonstrate the degree of dilatation and the status of the remaining parenchyma (Fig. 23.14). On US, UPJ obstruction should be differentiated from multicystic dysplastic kidney (see later), ureterovesical junction obstruction, or dilating VUR.

A ureterovesical junction obstruction is characterized by the presence of a visible ureter (above 3 mm diameter). This dilatation is best evaluated behind a filled bladder (Fig. 23.12). The anomaly may be confirmed using MR imaging (Fig. 23.13).

The presence on US of a large bladder (above 6 cm height) suggests a bladder outlet obstruction. The main cause in boys is posterior urethral valves. The bladder is enlarged, its wall is thickened, and bilateral ureterohydronephrosis may be present already *in utero*. After birth, the anomaly is best dem-

TABLE 23.1. ULTRASOUND CRITERIA OF ABNORMAL URINARY TRACT POTENTIALLY ASSOCIATED WITH VESICoureteric REFLUX

Renal pelvis dilatation >7 mm
Ureteral dilatation >3 mm
Calyceal dilatation >2 mm
Pelvic wall thickening >1 mm
Dysplasia (small kidney, echogenic irregular cortex, cortical cysts)
Enlarged bladder >6 cm

FIGURE 23.12. Dilated ureter (u) at ultrasound. Sagittal scans of the bladder (B). A dilated ureter is visible behind the bladder. Its caliber varies a few seconds apart, due to peristalsis.

onstrated on the micturition phase of a VCUG (Fig. 23.14). Isotopes evaluate the degree of renal functional impairment. Other causes of bladder outlet obstruction include megalourethra, anterior valves, and urethral polyps, which are evaluated by a VCUG during the micturition phase (27,28).

Duplex kidneys are commonly found in newborns. On US, a band of parenchyma separates the two pelvic complexes. A nondilated duplex kidney should be considered as a normal variant. Complications may occur at the upper or lower poles and consist of obstruction or VUR. An extravesical ectopic insertion or ureterocele is classically found in rela-

FIGURE 23.13. Magnetic resonance imaging of a left mega-ureter. Sagittal view. Uro-magnetic resonance sequence.

FIGURE 23.14. Posterior urethral valves in a neonate—voiding cystourethrogram. Distended posterior urethra (*asterisk*) and narrow anterior urethra (*arrow*). Megabladder with diverticular wall.

tion to a dilated upper pole. The VCUG is performed after birth to visualize the ureterocele, which may prolapse within the urethra and induce bladder outlet obstruction. MR imaging has proved useful in the morphologic evaluation of complicated duplex systems (29,30) (Fig. 23.15).

In cases of nonsurgical management of urogenital uropathies, imaging allows a close follow-up. US confirms resolution of the dilatation and sufficient renal growth. Isotope techniques assess renal function.

Abnormal Kidney Number or Location

The role of imaging is either to confirm renal agenesis or to demonstrate an ectopic location. ^{99m}Tc -DMSA scanning is indicated when only one kidney has been identified. US can demonstrate pelvic ectopia. In the case of horseshoe kidney, a DMSA scan might better define the isthmus. In the case of cross ectopia and fusion, IVP or, rather, MR imaging is helpful to assess the exact anatomy and the potential complications (Fig. 23.16). US can find associated genital malformations in girls (31,32).

Kidney Dysplasia and Hypoplasia (Hypodysplasia)

US signs of hypodysplasia include small size, hyperechogenicity of the cortex, cysts within the parenchyma, and thinned parenchyma.

Cystic Renal Diseases

Cystic renal diseases discovered *in utero* or in the neonatal period encompass a large panel of diseases and US patterns (see the section Imaging of Renal Failure and Renal Graft).

Unilateral solitary cortical cyst is an uncommon finding. US follow-up is usually sufficient to exclude a cystic renal tumor.

In the case of unilateral multiple cysts, a multicystic dysplastic kidney is the most frequent finding (Fig. 23.17). In most cases, the US diagnosis is straightforward: a mass containing multiple cysts of varying size, without communication between them and without normal renal parenchyma. Contralateral anomalies are frequent, especially VUR. A ^{99m}Tc -MAG-3 diuretic renogram may assess the nonfunctioning multicystic dysplastic kidney and exclude an anomaly in the remaining functioning kidney. Involution may occur *in utero* or after birth (Fig. 23.17).

Bilateral cysts have to be separated between cases with medullary cysts and those with cortical cysts. In the case of medullary cysts, autosomal-recessive polycystic kidney disease is the first diagnosis to suspect. Affected kidneys are usually markedly enlarged (+2 to +4 standard deviation). The US pattern may be much more heterogeneous (Fig. 23.18A). Liver involvement is difficult to demonstrate in the neonatal period (33). Other causes of medullary cysts include many syndromes (e.g., Bardet Biedl syndrome).

The finding of bilateral cortical cysts is in favor of autosomal-dominant polycystic kidney disease (34). Yet, it is unusual to find significant cysts in the neonatal period (see below). Other causes of (large) neonatal bilateral renal cysts are tuberous sclerosis and von Hippel–Lindau disease.

Renal cystic disease is often detected *in utero* in fetuses with bilateral hyperechoic kidneys. Large (+4 standard deviation), poorly differentiated kidneys may correspond to autosomal recessive polycystic kidney disease (Fig. 23.18B) or autosomal dominant polycystic kidney disease. Hyperechoic kidneys with persisting CMD suggest autosomal dominant polycystic kidney disease and congenital nephrotic syndrome (35,36). US examination of the parents' and grandparents' kidneys may help with the diagnosis (37).

Congenital Nephrouropathies in Older Children

Some nephrouropathies are discovered later in childhood due to complications (infections, lithiasis, trauma, increasing obstruction) (see below). They are usually detected on US. CT, MR imaging, or VCUG is performed according to US findings and the complication. For instance, UPJ obstruction may be discovered after a trauma or lithiasis may develop in a previously unrecognized primary megaureter (38) (Fig. 23.19).

A dysplastic upper pole of a duplex system with an ectopic extravascular insertion may be discovered because of urinary

FIGURE 23.15. Complicated duplex kidney. **A:** Ultrasound of the left kidney. Sagittal scan showing significant dilatation of the upper pole (*arrow*). The lower pole (LP) is not dilated. **B:** Ultrasound of the bladder. A lobulated ureterocele (Uc) is visible within the bladder. **C:** Voiding cystourethrogram, showing intravesical Uc and vesicoureteric reflux into the left lower pole. Right grade II vesicoureteric reflux. **D:** Magnetic resonance imaging. Magnetic resonance urography sequence (coronal view). Dilated upper pole (*asterisk*) in relation to an intravesical ureterocele (*arrows*).

dribbling in a toilet-trained girl. The dysplastic upper pole may escape the US examination. An MR imaging examination (or a CT when MR imaging is not available), presently the most accurate technique for this indication (39) (Fig. 23.20), confirms the clinical suspicion.

INFECTIONS OF THE URINARY TRACT

The role of imaging in the case of UT infection is to determine whether there is an underlying favoring condi-

tion, whether the kidney is affected, and whether there is a VUR (Table 23.2). The US allows the detection of a congenital anomaly or a lithiasis. DMSA scintigraphy evaluates kidney involvement, and VCUG detects a VUR (40–42).

Acute Pyelonephritis

The main role of US is to detect a congenital anomaly. In addition, several features indicate acute renal infection: The main sign is an increased renal length or, more accurately, an

FIGURE 23.16. Intravenous pyelography of a right crossed fused ectopia of the left kidney.

increased renal volume (Fig. 23.21). Another sign is a thickening (above 1 mm) of the renal pelvis wall with a hyperechogenicity of the perihilar renal fat. These signs suggest pyelitis and ureteritis. The renal parenchyma may also show

areas of increased or decreased echogenicity corresponding to an inflammatory edema and (hemorrhagic) necrosis. Such areas are typically undervascularized. This can be shown using color or power Doppler (Fig. 23.22). Echogenic urine with echogenic fluid level may correspond to pyonephrosis. It should be stressed that a normal US examination does not exclude APN (42,45–47).

Renal cortical lesions are detected by ^{99m}Tc -DMSA scintigraphy (Fig. 23.8). Decreased uptake is seen in areas of APN (47). The presence of a renal abnormality during the acute phase of infection seems to be the best predictor of renal sequelae. Conversely, the risk of developing scars is low when early scintigraphy is normal.

CT demonstrates very accurately renal involvement in cases of APN. It shows an increased renal volume and, after contrast enhancement, affected parenchymal areas. Yet, it is an irradiating technique, and it should not be used routinely (48) (see below). MR imaging has similar diagnostic performances to CT or DMSA scanning (Fig. 23.23).

A VCUG is performed to detect a VUR. Indirect cystography may be obtained by injecting contrast intravenously. It is also a valuable technique for detecting VUR under physiologic conditions without using a bladder catheterization. Children who are not toilet trained (younger than 3 years of age) may not be able to undergo this examination. The main indication is the follow-up of patients with known VUR.

Evolution of Acute Pyelonephritis

When treatment is adequate, the inflammatory infiltrates resolve progressively without sequelae; in such cases, the renal volume as measured on US returns to normal within 4 to 6

FIGURE 23.17. Involution of a multicystic dysplastic kidney (K). A: At birth; sagittal scan of the right kidney. Four cysts are visible (C). B: At 1 year of age, only one cyst has remained (arrow).

FIGURE 23.18. Neonatal autosomal-recessive polycystic kidney disease. Two different patterns at ultrasound. **A:** Sagittal scans of the left kidney (K) showing multiple medullary cysts. **B:** Left kidney in another patient. The pyramids appear hyperechoic (arrows).

weeks. This delay should be taken into account for planning follow-up examinations intended to assess renal growth (49).

In cases of late or inadequate treatment or resistance to anti-biotherapy, the renal lesions may coalesce and form an abscess. US demonstrates the abscess as an inhomogeneous mass within the parenchyma; CT or MR imaging seems to be a better technique to demonstrate abscess formation, especially for bilateral lesions. These techniques better evaluate the extrarenal extension of the abscess than does US (46) (Fig. 23.21).

The rationale for early work-up and treatment of APN is to prevent recurrence and permanent lesions. Scintigraphy is performed at least 6 months to 1 year after the acute episode to detect renal scarring. Six months is the minimal time before one can consider a lesion as permanent (49,50) (Fig. 23.24A). US and IVP underestimate the number of scars. MR imaging is a promising technique for the evaluation of permanent renal damage and chronic renal scars (RN or chronic pyelonephritis) (Fig. 23.24B) (13,14).

Cystitis and Urethritis

The bladder is more commonly affected by infection than the kidneys; findings on US are not specific. The bladder wall may be thickened (above 3 mm), and urine may appear with echogenic debris. Of note, these findings may be present without infection (43,44). Urethritis is uncommon in children. On VCUG, during the micturition phase, the urethral lumen appears irregular.

FIGURE 23.19. Horseshoe kidney with left ureteropyelic junction obstruction in a 9-year-old boy with acute left flank pain. Typical findings on an intravenous pyelography.

FIGURE 23.20. Four-year-old girl with urinary dribbling. Magnetic resonance imaging. Frontal view showing a right duplex kidney with dilated upper pole (arrow) associated with a dilated ectopic ureter (U).

Specific Organism Infections

Candidiasis

Candidiasis develops in immunocompromised patients, premature infants, and patients under chronic antibiotherapy. Candidiasis infection should be suspected on US case of: global renal hyperechogenicity, sludge distending the renal cavities, or the presence of fungus balls (echogenic masses partially filling the renal cavities) (51).

FIGURE 23.21. Acute right pyelonephritis. Sagittal scan of the right kidney that appears swollen, with patchy hyperechoic areas corresponding to inflammatory changes (asterisks).

Tuberculosis

The most typical features have been described on IVP: “drooping Lily” appearance of the pyelocalyceal system. In more advanced cases, the kidney is completely destroyed, small, and calcified (52).

VESICoureTERIC REFLUX

Primary VUR is a frequent cause of *in utero* dilatation of the UT (19). The most severe cases are detected in males. VUR may be associated with various congenital uropathies. Voiding dysfunction is another circumstance in which VUR is detected; in such cases, VUR is secondary to the bladder dysfunction. Although the relationship between UT infection and VUR is still debated, VUR is found in approximately 45% of cases with UT infection (53,54). Radiologic VCUG is the best method for the first assessment. VCUG confirms

TABLE 23.2 IMAGING IN URINARY TRACT INFECTION: RELATIVE CONTRIBUTION OF IMAGING EXAMINATIONS

Question	Ultrasound	Computed tomography	Magnetic resonance imaging	Intravenous pyelography	Voiding cystourethrogram	Dimercaptosuccinic acid

the VUR (including intrarenal VUR) and shows the morphology of the lower UT (including the urethra) (Fig. 23.5). It may also show bladder diverticula, reflux into ectopic ureters, or ureteroceles. Cyclic filling of the bladder has been shown to improve the rate of detection of VUR by 10 to 15%, especially in newborns. Tailored pulsed fluoroscopy and adapted filtration material (55) reduce radiation hazards. VUR is graded according to the international grading system. Higher grades of VUR are less likely to resolve spontaneously and are more often associated with dysplastic kidneys (56). Isotopic direct or indirect VCUG and cystosonography (using sonicated contrast media) are better suited for the follow-up of patients with known VUR or for screening siblings of patients with VUR (18,57,58). US is a poor predictor of a VUR. Yet, a completely detailed normal US examination of the UT is rarely associated with high-grade VUR (59). The parenchymal damage, the so-called RN, is best assessed by isotopes and MR imaging (Fig. 23.24B). It is present at birth

FIGURE 23.23. Acute pyelonephritis. Demonstration of a perirenal abscess on computed tomography (after contrast injection). A necrotic abscess has developed in the posterior surface of the left kidney and has extended into the posterior abdominal wall (arrows).

in 20 to 30% of the cases (associated VUR and hypodysplasia), and acquired renal damage seems less frequent (60–62).

VOIDING DISORDERS

Voiding disorders are associated with a wide spectrum of anomalies. The role of imaging is to differentiate between organic and functional diseases.

Plain film of the abdomen evaluates constipation or associated vertebral malformations. US can exclude UT malformations and measure the bladder wall thickness and the vesical content pre- and postvoiding. VCUG is performed in the case of persisting symptoms. It detects a VUR and shows the bladder volume at maximum filling, the bladder contours, the type of micturition, and the appearance of the urethra. It may show a cause of obstruction in boys.

On VCUG, a transient opening of the bladder neck and opacification of the urethra up to the external sphincter, along with cessation of contrast material dripping, suggest an uninhibited detrusor contraction. A spinning-top urethra or a wide bladder neck anomaly suggests a bladder instability (63,64) (Fig. 23.25).

In the case of neurologic symptoms, MR imaging of the conus medullaris is helpful for the demonstration of a tethered, low-positioned cord; MR urography is efficient to demonstrate ectopic ureteral insertion associated with urinary dribbling (65).

A particular circumstance of voiding dysfunction is associated with neurogenic bladder. This anomaly is related, in most cases, to an open spina bifida. Typically, a neurogenic bladder has a pear-shape appearance, irregular diverticular margins, and a thickened wall (Fig. 23.26) (66).

IMAGING OF RENAL FAILURE AND RENAL GRAFT

In most patients with renal failure, US is important for diagnosis and follow-up. The contribution of US varies greatly from patient to patient. In some cases, US is insufficient and complementary examinations are necessary (e.g., obstructive tumoral infiltration of the ureters is evaluated with CT or MR imaging). All imaging findings must be analyzed according to the clinical findings and familial history.

Acute Renal Failure

Imaging is helpful in determining postrenal obstructive causes of acute renal failure; it is often informative for renal causes but seldom contributive for prerenal causes. The main US feature is an increased renal echogenicity (67). A completely normal US examination does not exclude renal lesions.

FIGURE 23.24. Pyelonephritic scars. **A:** Dimercaptosuccinic acid scan showing small, irregular kidneys. **B:** Magnetic resonance imaging showing bilateral small, irregular, scarred kidneys.

Hemolytic-Uremic Syndrome

During the acute phase, the renal cortex appears hyperechoic with increased CMD. During the oligoanuric phase, Doppler spectral analysis shows a high RI (approximately

1) (Fig. 23.27) that decreases with recovery. At a later phase, sequelae may appear as areas of medullar or cortical calcifications (related to necrosis), and global renal growth may be impaired (68). US examination helps to assess extrarenal lesions (digestive wall thickening, hemobilia). In

FIGURE 23.25. Spinning-top urethra on voiding cystourethrogram, typical for vesicourethral dysynergia.

FIGURE 23.26. Neurogenic bladder on voiding cystourethrogram. Filling phase: trabeculated, diverticular bladder.

patients with neurologic symptoms, MR imaging of the brain may be necessary.

Medullar or Cortical Necrosis and Shock Kidneys

Medullar and cortical necrosis occur mainly in premature infants and are related to reduced arterial renal perfusion; during the acute phase, the renal cortex appears hyperechoic with persisting CMD, and spectral Doppler analysis demonstrates a high RI. In the case of medullar necrosis, calcifications may develop within the pyramids. In the case of severe cortical necrosis, the renal parenchyma shrinks, whereas in less severe cases, calcifications develop within the parenchyma. These conditions must be differentiated from the transient acute tubular blockade of a dehydrated neonate (Tamm-Horsfall proteinuria). The latter appears on US with hyperechoic pyramids, resolving within 2 to 3 days (69).

Renal Vein Thrombosis

Renal vein thrombosis most often occurs in the neonatal period and may develop *in utero*. At US, kidneys are enlarged and CMD is absent with hyperechoic streaks. Color Doppler may show the thrombus within the renal vein or the inferior vena cava (70).

Obstructive Uropathies

Several forms of obstructive uropathies may be associated with acute renal failure: the urethral prolapse of an ectopic ureterocele; congenital uropathy of a single kidney; and tumoral infiltration of the kidneys, ureters, or bladder neck. Bilateral urolithiasis are all circumstances that may lead to acute renal failure.

Chronic Renal Failure

Chronic renal failure (CRF) interferes with statural and bone growth. Skeletal x-rays allow the evaluation of bone

age. X-rays include (a) anteroposterior view of the hands and chest, including the clavicular, pelvis, long bones; and (b) dental view. Anomalies suggesting renal osteodystrophy include poor mineralization of the bones, osteolysis at the clavicular ends, phalangeal resorptions, and long bones with cortical thinning.

Renal Dysplasia and Hypoplasia

Renal dysplasia and hypoplasia may coexist, but dysplasia is only demonstrated on renal histology. At US, kidneys are small usually without CMD. Small cysts may be present within the parenchyma (71).

Cystic Renal Diseases

Among the diseases without genetic transmission, only bilateral obstructive uropathies may lead to CRF. In such conditions, on US, the kidneys are small, with a thin and hyperechoic cortex without CMD, and the renal cavities are dilated. Several cysts of varying sizes are visualized within the parenchyma.

Among the hereditary cystic diseases, some display characteristic patterns, and others are difficult to recognize (72). In autosomal recessive polycystic kidney disease, kidneys are enlarged, and the cystic lesions are mainly located in the medulla. The medulla may show macrocysts or may be hyperechoic due to multiple microcysts. With time, the cysts increase in size; some hyperechoic spots may appear and correlate with the development of CRF (Fig. 23.28). The periportal hepatic fibrosis may progress with periportal hyperechogenicity, and inhomogeneous liver echogenicity and signs of portal hypertension can be observed as well. In the case of autosomal dominant polycystic kidney disease, macrocysts are most often observed. In nephronophthisis, US changes are observed at approximately 10 to 12 years with the development of macrocysts (73). Peripheral cortical cysts

FIGURE 23.28. Autosomal-recessive polycystic kidney disease in a 10-year-old boy. The kidney (K) has a heterogeneous echogenicity. Some macrocysts have developed (arrows).

can be found in glomerulocystic kidneys (Fig. 23.29). This entity can be isolated or part of syndromes (72). It is noteworthy that cysts may appear in patients on chronic dialysis.

FIGURE 23.29. Glomerulocystic kidney. Sagittal scan of the left kidney (K). The parenchyma is hyperechoic without corticomedullary differentiation and with small peripheric cysts (between crosses).

FIGURE 23.30. Congenital nephrotic syndrome of the Finnish type in a newborn with proteinuria. Enlarged kidney (6 cm between the crosses) with hyperechoic cortex and preserved corticomedullary differentiation.

Chronic Pyelonephritis or Reflux Nephropathy

The relationship between chronic pyelonephritis, RN, and CRF is controversial, as many parenchymal lesions may preexist already at birth. Whatever the cause of the lesions, the role of imaging is the detection of an underlying favoring condition. US may detect UT malformation, but the technique is less accurate for the demonstration of parenchymal lesions, which are best visualized on DMSA scans or MR imaging (74).

Congenital Nephrotic Syndromes

US shows enlarged kidneys with small hyperechoic pyramids in newborns with Finnish-type nephrotic syndrome. With time, the kidney size and echogenicity decrease and the pyramids disappear (Fig. 23.30). In patients with diffuse mesangial sclerosis, the US may show as diffusely heterogeneous with a patchy appearance. Other congenital nephrotic syndromes do not have typical US appearances (75).

Congenital Tubular Syndromes

Congenital tubular syndromes are numerous renal diseases that include primitive or secondary tubulopathies. Hypercalciuria is often present and is responsible for nephrocalci-

nosis that is detected by US (see below). US is also helpful in type I hyperoxaluria (see below) (76).

Renal Transplant

The renal transplant is easily evaluated by US. The kidney is very close to the abdominal surface; therefore, US is able to demonstrate its anatomy with good details. A CMD is always present. Examination includes an evaluation of the transplant volume ($L \times l \times W \times 0.52$) and an analysis of the kidney echogenicity. Spectral analysis of the intrarenal vessels allows the evaluation of vascularization (77,78).

Complications may occur after surgery, during the first days, or later during follow-up. In the early posttransplant period, the role of imaging (mainly US) is to differentiate between postsurgical complications and early acute rejection (79).

Postsurgical Complications

US may demonstrate a fluid collection around the kidney. MR imaging is useful to differentiate a lymphocele, a hematoma, or a urinary leak. Doppler (duplex and color) is able to diagnose renal artery or vein thrombosis and, later, a renal artery stenosis (Fig. 23.31). Urologic complications may develop secondary to ureteral stenosis. An opacification may be necessary to show the exact site of obstruction (79).

Acute Rejection

In the case of acute rejection, the transplant volume is increased, echogenicity may become heterogeneous, and

FIGURE 23.31. Aneurysm (arrow) on the vascular anastomotic site demonstrated by angio-magnetic resonance imaging.

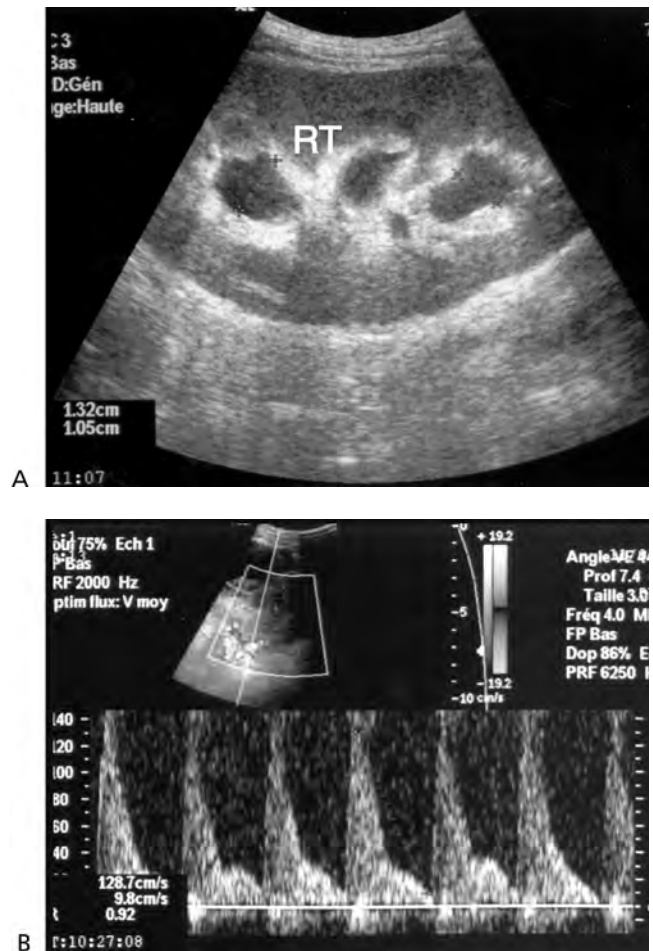

FIGURE 23.32. Acute rejection. **A:** Ultrasound. The renal transplant (RT) is swollen, the collecting system is distended, and there is perihilar hyperechogenicity. **B:** Doppler analysis. Increased vascular resistance (resistive index equals 0.85).

intrarenal RI may increase dramatically. In some cases, renal hilum becomes markedly hyperechoic, and the pelvic walls thicken (Fig. 23.32).

Other Complications

Other complications include infection and, rarely, calculi. Classical US signs usually accompany these complications. Lymphomas developing in immunocompromised patients may appear either as localized nodules or as an echogenic enlarged transplant.

UROLITHIASIS AND NEPHROCALCINOSIS

Urolithiasis

US is effective in detecting lithiasis, even tiny (2 to 3 mm), located in the kidney or the bladder. Urolithiasis determines, in most cases, a characteristic acoustic shadowing (Fig. 23.33). The role of imaging is to detect the lithiasis, to demonstrate a favoring underlying condition

FIGURE 23.33. Urolithiasis—ultrasound. Sagittal scan of the left kidney (K). A lithiasis (arrow) is visible within the dilated collecting system.

(congenital malformation, nephrocalcinosis), and to follow the lithiasis under treatment. Plain film of the abdomen is helpful to demonstrate ureteral calcified stones that may be difficult to detect on US (80–82). In the case of renal colic, it might be useful to perform unenhanced CT with two- or three-dimensional reconstruction; this has been shown to be effective in demonstrating obstructive (multiple) ureteral stones (Fig. 23.34). Urethral stones may be more difficult to demonstrate; retrograde urethrography should be used to confirm the urethral stone. Whenever extracorporeal lithotripsy is applied, US

FIGURE 23.34. Urolithiasis—computed tomography: Reformatted two-dimensional images without contrast demonstrating multiple lithiasis (arrows) within the kidney and dilated ureter. The inset box indicates the scan plan.

FIGURE 23.35. Cortical nephrocalcinosis. Highly echogenic kidney (between crosses) in a case of primary hyperoxaluria of type I. L, liver.

and plain film of the abdomen can be used to follow the effects of treatment (83).

Nephrocalcinosis

Ultrasound Patterns

Nephrocalcinosis is suspected when hyperechogenic areas disturb the appearance of the kidney. Most cases of nephrocalcinosis are bilateral (84).

Cortical Nephrocalcinosis

Cortical nephrocalcinosis is rare in children. It can be extensive and determine acoustic shadowing behind the kidney as in neonatal hyperoxaluria of type I, or it can be more localized within areas of the parenchyma and correspond to sequelae of cortical necrosis or renal vein thrombosis (Fig. 23.35). In the case of vascular calcifications, the nephrocalcinosis can be unilateral.

Medullar Nephrocalcinosis

On US, medullar nephrocalcinosis (MNC) can be graded into three stages: diffuse and homogeneous, diffuse and inhomogeneous, or limited to the tip of the pyramids (Fig. 23.36). Grading helps to evaluate the effect of treatment in specific diseases. US is the best way to detect medullar nephrocalcinosis. Medullar hyperechogenicity is not always due to nephrocalcinosis. The differential diagnosis must, therefore, include the US features as well as clinical, biochemical, and genetic data (85,86).

Imaging Features of Specific Diseases

MNC is present and may be associated with urolithiasis and medullary cysts in patients with distal tubular acidosis (87). The severe neonatal form of primary hyperoxaluria

FIGURE 23.36. Medullary nephrocalcinosis. Sagittal scan of the kidney (K). Diffuse medullary, hyperechogenicity (arrows).

type I is associated with a cortical nephrocalcinosis that induces a markedly increased cortical echogenicity determining an acoustic shadowing. In later childhood, MNC is observed. Urolithiasis and renal colic are common complications demonstrated by US (88). Renal calcifications and skeletal lesions may be impressive (Fig. 23.37). The relationship between furosemide and MNC is unclear. The MNC is inhomogeneous and persists for a long period of time (89).

TRAUMA TO THE URINARY TRACT

Kidney Trauma

Imaging, especially US and CT, has greatly modified the management of abdominal trauma in children. It allows more conservative, nonsurgical attitudes (90–92). US shows major renal damage and fluid collections (Fig. 23.38A). Color and duplex Doppler allows the evaluation of the vessels. Yet, the method has several limitations; because intestinal air may limit renal visibility, a normal US does not exclude parenchymal damage. Therefore, CT may be more suited for the first evaluation of children with suspected renal damage (Fig. 23.38B). CT is performed after contrast injection to demonstrate urinary leakage. CT angiography two-dimensional reconstruction allows an accurate evaluation of the renal vessels. A control examination may be useful if clinical evolution is unsatisfactory, suggesting

A

B

FIGURE 23.37. Primary hyperoxaluria of type I. **A:** Plain film of the abdomen. Impressive bilateral renal calcifications. **B:** Pelvic girdle. Densification and coarse trabeculation of the bones due to renal osteodystrophy.

persistent bleeding. Angiography must be limited to cases for which therapeutic intervention is likely.

Lower Urinary Tract

Bladder laceration is associated with bony pelvis fractures. Such laceration of the bladder should be suspected on US when large amounts of fluid are visualized in the cul-de-sac. VCUG can be performed if necessary to visualize the leakage site. The same mechanism explains the lesions to the urethra. Demonstration of the lesion may be difficult,

FIGURE 23.38. Left renal trauma. **A:** Ultrasound. Sagittal scan of the kidney (K). A renal fracture is visible (arrows). **B:** Computed tomography after contrast enhancement. Left perirenal hematic collection. The renal fracture is also visible (arrow). S, spleen.

and a retrograde urethrogram should be performed very cautiously (93).

RENAL AND URINARY TRACT TUMORS

Role of Imaging

Imaging allows the detection and localization of the tumor, the analysis of its content and appearance, and the evaluation of the extent. Evaluation must be performed in conjunction with clinical and biologic data. It also has to fit into therapeutic protocols.

US easily localizes small tumors (Fig. 23.39). Large tumors are more difficult to delineate (Fig. 23.40). The technique easily differentiates cystic from solid-type tumors. CT and MR imaging are better suited for the evaluation of large tumors. Both are able to assess the tumor's relationship with the retro-

FIGURE 23.39. Renal tumors: small right Wilms' tumor in a case of hemihypertrophy. **A:** Ultrasound of echogenic area (arrow) in the upper pole of the right kidney (K). **B:** Computed tomography after contrast enhancement. The mass is less dense than the rest of the kidney (arrow) L, liver.

peritoneal vessels (Figs. 23.39 and 23.40). CT is performed without and with contrast enhancement. CT without contrast demonstrates the presence of calcifications within the tumor. Contrast enhancement is aimed to define the limits between normal parenchyma and tumor. Urographic-type images can be obtained at the end of the examination to visualize the ureters. During the same examination, an evaluation of the lungs can be obtained to exclude metastasis. A disadvantage of the technique is the irradiation hazards that can be associated. MR imaging may provide the same information as CT about the tumor without using x-rays (94–96).

Imaging of Specific Renal Tumors

Wilms' Tumor or Nephroblastoma

At diagnosis, the tumor is large but well demarcated from the normal parenchyma. On US, the tumor is echogenic

FIGURE 23.40. Renal tumors: large Wilms' tumor. **A:** Ultrasound. The tumor (between crosses) is difficult to delineate. **B:** Magnetic resonance imaging transverse scan after gadolinium. The mass (M) is better delineated.

with a solid content (Figs. 23.39 and 23.40). Areas of necrosis or hemorrhage are visible within the mass, especially after chemotherapy. Adenopathies can be seen next to the mass; extrarenal metastatic extent can be seen within the vena cava. The contralateral kidney should be checked for bilateral tumors. On CT or MR imaging, the tumor is more clearly delineated than with US, and bilateral tumors are easier to demonstrate (Figs. 23.39 and 23.40). The tumor appears heterogeneous due to areas of necrosis, but the solid content is enhanced after contrast injection. The tumor rarely contains calcifications or fat. It may appear partially or completely cystic.

The main differential diagnosis is neuroblastoma, Wilms' tumor tends to displace the abdominal vessels,

FIGURE 23.41. Renal lymphoma. Computed tomography with contrast. There is a bilateral nodular (n) involvement of both kidneys. The pancreas (p) was also affected.

whereas neuroblastoma tends to encase them; calcifications are more frequent in neuroblastoma.

Nephroblastomatosis

There is a loss of CMD on US in the diffuse form. On CT or MR imaging, the kidneys are large and there is a rim of thick cortical parenchyma that does not enhance after contrast injection. In the focal nodular form, one or more nodules are present; they do not enhance after contrast injection. They are more homogeneous than Wilms' tumor (97,98).

Lymphoma

Renal involvement occurs mainly in Burkitt's lymphoma and is usually bilateral. Other sites are often affected (e.g., ovaries, testicles). On US, lymphomatous nodules are hypoechoic compared to normal parenchyma; they enhance poorly on CT after contrast injection (99) (Fig. 23.41).

Other Malignant Tumors

Other malignant tumors are rare in children; their diagnosis is usually performed at histology rather than on imaging. Their rate of metastasis, particularly to the skeleton, is higher (100).

Screening Patients at Risk

As several syndromes (Denys-Drash, Beckwith-Wiedemann, Perlman, aniridia) are associated with a higher risk of Wilms' tumor, patients affected should be screened regularly by US (101) (Fig. 23.40).

Benign Renal Tumors

Mesoblastic nephroma is the most common tumor in the newborn and fetus. On imaging, the mass is well defined

FIGURE 23.42. Hypertension in an 18-month-old boy with severe left renal artery stenosis. **A:** Doppler ultrasound. Increased resistive index and increased velocity at the ostium of the left renal artery. **B:** Angiography. Complete occlusion of the left renal artery (arrow). (Courtesy of F. Brunelle, M.D.)

from the normal parenchyma and is generally of solid type (102). Multilocular cystic nephroma appears as a cystic, septated mass on imaging; it cannot be differentiated from cystic nephroblastoma (103). Angiomyolipoma in children is invariably associated with tuberous sclerosis. The lesions are small and diffuse in early childhood, with a high fatty content; they are larger and fewer in adolescents and appear heterogeneous on US or CT (104).

Bladder Tumors

US is the easiest imaging method for the demonstration of a bladder tumor. Yet the method is unable to differentiate malignant from benign or inflammatory pseudotumors unless the tumor has extended beyond the bladder wall and metastases are present. CT and MR imaging are performed to evaluate the spreading of a malignant tumor (105–107).

RENOVASCULAR HYPERTENSION

Imaging may show scars, diffuse nephropathy, or diffuse sequelae of a vascular disease. Doppler US may show signs of renal artery stenosis (i.e., increased blood velocity at the renal artery ostium). A normal US examination does not exclude an anomaly. MR angiography has great potential for demonstrating renal vessel anomalies; the method is not yet standardized, and its accuracy has to be confirmed. ^{99m}Tc -MAG-3 or -DMSA before and after captopril stimulation can be a sensitive screening method for renovascular disease.

As fibromuscular hyperplasia and ostial stenosis are the most common causes of hypertension in children, arteriography remains the method of choice whenever the renal vascular origin of hypertension is highly probable. When a stenosis is present, an angioplasty can be performed immediately (108–110) (Fig. 23.42).

In a case of pheochromocytoma, metaiodobenzylguanidine scan, CT, or MR imaging should be performed to localize and delineate the mass.

INTERVENTIONAL IMAGING AND POSTOPERATIVE STUDIES

Interventional Imaging

Nephrostomy (Fig. 23.43) is the main interventional procedure in children. Pyonephrosis in a dilated collecting system is an indication (111).

Specific Postoperative Findings

US is the main imaging technique for the follow-up of surgical procedures (112). Isotopic evaluation allows detection of progression renal impairment.

Ureteropelvic Junction Obstruction

Nephrostomy of a very dilated congenital UPJ obstruction allows assessment of kidney function and helps the physician decide whether pyeloplasty or nephrectomy should be performed. Dilatation of the pelvicalyceal system may increase slightly after surgery due to edema; it decreases slowly thereafter within 6 to 8 weeks. Isotopic evaluation 6 months after surgery enables assessment of the evolution of renal function (113,114).

Ureterovesical Junction Obstruction

Leakage due to necrosis can occur at the site of the vesical reimplantation, and a hematoma or a urinoma may develop. The resolution of the ureteral dilatation can be monitored on US. At the level of the bladder, a characteristic posterior wall thickening can be observed at the level of the reimplantation (112,115).

FIGURE 23.43. Right nephrostomy and opacification of the urinary tract in a case of ureteral stenosis (arrow).

Vesicoureteric Reflux

In cases of ureteral reimplantation, a thickening of the posterior bladder wall can be observed. Whenever the sub-ureteric injection of Teflon (STING procedure) or other material is chosen, a small hyperechoic mass with acoustic shadowing can be seen at the level of the ureterovesical junction (Fig. 23.44). Transitory UT dilatation can also be observed. A control VCUG is useful 6 months after surgery to confirm the disappearance of the VUR (112,116).

FIGURE 23.44. Bilateral Teflon injection. Transverse scan of the bladder (B). Teflon appears hyperechoic (arrows).

Duplex Collecting System

Unroofing of ectopic intravesical ureterocele during endoscopy has been advocated to relieve obstruction and to allow functional improvement of the affected upper pole. The ureterocele collapses and appears as an intravesical pseudomass. The dilatation resolves and can be monitored by US. Secondary VUR may develop (112,117).

RENAL PATHOLOGY

AGNES B. FOGO

This chapter reviews the usual circumstances in which biopsies are obtained, methods of obtaining the biopsy material and analyzing the tissue, and the distinct characteristic morphologic findings in various diseases. Finally, current experimental techniques that may provide important pathogenic, prognostic, or diagnostic information are discussed.

RENAL BIOPSY INDICATIONS

The indications for renal biopsy vary according to the ethnic and age characteristics of the population studied and the geographic location because these factors influence the incidence of various renal diseases. The indications discussed below present the most common settings in children for which renal biopsy is undertaken.

Hematuria

Isolated hematuria (i.e., without proteinuria and with normal function of the kidney) may be due to hypercalciuria, familial, or urologic disease (1–3). Once these disorders are ruled out, a glomerular origin of persistent isolated hematuria should be considered. When present, red blood cell casts or dysmorphic red blood cells indicate glomerular origin of hematuria. Renal biopsy may define the underlying abnormality in these patients. The most common findings are mesangial proliferative disease or immunoglobulin (Ig) A nephropathy (Berger's disease). Less common disorders include hereditary nephritis (Alport's syndrome) and thin basement membrane lesion. The latter may be familial (benign familial hematuria) or sporadic. One-fourth to nearly one-half of the patients with isolated hematuria have normal biopsies (1–4). Renal biopsy may, therefore, define the pathology and provide assurance of a benign prognosis in some patients or diagnose a possible hereditary disease, which initiates screening of other family members. Finally, the information obviously is of importance in avoiding further repeated invasive evaluation in the patient.

Proteinuria

Isolated proteinuria may be postural or due to tubulointerstitial disease. These possibilities should be evaluated completely over time before renal biopsy is considered. Any glomerular disease may cause mild to moderate proteinuria as the only manifestation, and biopsy may yield the diagnosis even at an early stage.

Nephrotic Syndrome

Numerous children with nephrotic syndrome (NS) were studied when renal biopsy first became available. The biopsies showed so-called minimal change disease (MCD) in the vast majority of cases. The efficacy of corticosteroids in this setting has obviated the need for renal biopsies in most of these cases. Therefore, young children with NS typically undergo a therapeutic trial of corticosteroids without a biopsy. However, in infants with NS, in older children, or in those with evidence of nephritis (hypertension, hematuria, low C3, or decreased renal function) or who do not respond to corticosteroid therapy, renal biopsy is often performed. In these patients, a disease other than MCD [e.g., focal segmental glomerulosclerosis (FSGS), membranoproliferative glomerulonephritis (MPGN), IgA nephropathy, membranous glomerulonephritis, or, more rarely in infants, Finnish-type NS or diffuse mesangial sclerosis] is often present (4–9).

Acute Nephritis

The child with acute glomerulonephritis may need a biopsy when the course is not typical of acute poststreptococcal disease or if urinary abnormalities persist. Although the primary disease process may be evident in systemic conditions [e.g., Henoch-Schönlein purpura or systemic lupus erythematosus (SLE)], renal biopsy often is indicated to assess severity of injury and to guide therapy and prognosis. Differentiation of specific types of proliferative lesions (e.g., MPGN type I and dense deposit disease) is made by renal biopsy. This distinction has important implications for eventual treatment because the morphologic lesions of dense deposit disease invariably recur in transplants, although the clinical course is less severe than in the native kidney (10,11).

Acute Renal Failure

The cause of acute renal failure may be clinically obvious, or there may be multiple potential culprits. When prerenal and obstructive causes are not apparent, renal parenchymal disease should be considered. When acute renal failure is associated with nephritis, NS, or evidence of vasculitis or systemic diseases, biopsy is usually performed. Other common causes include acute tubular necrosis or injury, often caused by drug or ischemic injury, vascular disease, and interstitial nephritis. These conditions can often be diagnosed without renal biopsy. However, when the cause remains uncertain after complete evaluation, renal biopsy may be necessary for diagnosis (12).

Rapidly Progressive Glomerulonephritis

Renal biopsy may be considered an urgent procedure in the patient with rapidly progressive glomerulonephritis. Various systemic vasculitides that may be distinguished only by specific serologic studies (see below) or renal biopsy must be treated urgently to avoid severe chronic renal damage. Although anti-glomerular basement membrane (GBM) antibody or antineutrophil cytoplasmic antibody (ANCA) titers may provide useful information, the ANCA test in particular is not diagnostic of a specific condition; rather, it is a screening test for necrotizing vasculitides (13,14). ANCA positivity, whether in a perinuclear ANCA or cytoplasmic ANCA pattern, was present in approximately 60% of patients with immune-complex glomerulonephritis with crescents in a study of more than 200 renal biopsies (15). Furthermore, these specialized assays may have a longer turn-around time than the renal biopsy, from which preliminary information from immunofluorescence (IF) and light microscopy (LM) studies can be available within hours after biopsy.

Chronic Renal Insufficiency

Patients with renal insufficiency of uncertain etiology are candidates for renal biopsy. Although renal biopsy of the small, shrunken kidney is riskier because of the greater incidence of bleeding complications, the diagnosis of primary disease can be important. This information allows assessment of existing severity of morphologic lesions, determination of risk of recurrence in eventual renal transplant, and suitability of cadaveric versus living-related donor transplantation. If the disease has a familial basis or recurs frequently with resultant graft loss, cadaveric transplantation may be preferable to living-related donor transplant (11).

Systemic Diseases

The severity of renal involvement in systemic disease [e.g., hemolytic-uremic syndrome (HUS)], Henoch-Schönlein purpura, diabetes mellitus, or SLE may not be apparent without renal biopsy. The trend is now toward early biopsy in patients with diabetes and renal abnormalities. Severity of lesions and stage of chronicity and activity impart prognostic information and may affect therapeutic decisions (see below). The most extensively studied disease in this regard is SLE. Differentia-

tion of specific lupus nephritis World Health Organization (WHO) class (see below) may be difficult without renal biopsy (16,17). Overall, evidence indicates that renal biopsy findings may be more sensitive than clinical assessment alone in evaluating the severity of renal involvement in SLE (18,19).

Follow-Up of Disease

With improved therapeutic modalities available for intervention in chronic progressive renal disease, sequential or follow-up biopsies become increasingly necessary to evaluate therapeutic efficacy. On the other hand, additional cytotoxic therapy with its side effects may be withheld if the biopsy shows end-stage histology. Intervention with, for example, low-protein diets, angiotensin-converting enzyme inhibitors, or angiotensin type 1 receptor blockers has been shown to alter the course of chronic progressive renal disease (20).

Transplantation

Renal transplant biopsies are useful in assessing episodes of clinically suspected rejection, investigating the cause of decreased renal function or urine output, and detecting the development of *de novo* or recurrent disease. Occasionally, infection may be diagnosed by renal biopsy. Drug toxicity may be diagnosed by morphologic findings. The absence of lesions in a patient with a rise in creatinine supports cyclosporine toxicity because this drug commonly causes a decline in the glomerular filtration rate by vasoconstriction and not overt structural lesions. The absence of findings of acute rejection in renal biopsy or by needle aspiration (see below) can assist in avoiding unnecessary immunosuppressive therapy with its potential for increased morbidity and mortality. Even a diagnosis of chronic rejection, which is not amenable to therapy, has important therapeutic implications for the patient.

Diseases that recur in the transplant with high frequency include IgA nephropathy, MPGN type I, dense deposit disease (also known as *MPGN type II*), FSGS, HUS, and membranous glomerulonephritis. The latter two can occur *de novo* in the transplant. Metabolic diseases (e.g., oxalosis and diabetic nephropathy) can also cause recurrent disease in the renal transplant if liver or pancreas transplantation does not cure the primary abnormality (11). Alport's syndrome is caused by mutation in one of the type IV collagen genes, resulting in abnormal GBM assembly and structure. Patients may develop anti-GBM antibody disease in the transplant because of antibodies against its normal type IV basement membrane collagen (21,22).

OBTAINING TISSUE

General Considerations

Percutaneous renal biopsy is the most common method for obtaining tissue for the kidney. In large series, major complications are rare. The technique, first done in 1951 by Iverson and Brun, allows tissue yield in 93 to 95% of biopsies, with more than 87% of these being adequate (23–25). The biopsy

TABLE 24.1. DEFINITIONS OF COMMON MORPHOLOGIC TERMS

Term	Definition
Light microscopy	
Focal	Involving some glomeruli
Diffuse	Involving all glomeruli
Segmental	Involving part of glomerular tuft
Global	Involving total glomerular tuft
Lobular	Simplified, lobular appearance of capillary loop architecture (membranoproliferative glomerulonephritis)
Nodular	Acellular areas of mesangial matrix (diabetic nephropathy)
Sclerosis	Collapse and scarring of capillary loop
Crescent	Proliferation of parietal epithelial cells
Spikes	Projections of GBM intervening between subepithelial immune deposits (membranous glomerulonephritis)
Endocapillary proliferation	Increase in mesangial or endothelial cells
Hyaline	Descriptive of glassy, smooth-appearing material
Hyalinosis	Hyaline appearing insudation of plasma proteins (focal segmental glomerulosclerosis)
Mesangium	Stalk region of capillary loop with mesangial cells surrounded by matrix
Subepithelial	Between visceral epithelial cell and GBM
Subendothelial	Between endothelial cell and GBM
Tram-track	Double contour of GBM due to deposits or CMIP (see below)
Wire loop	Thick, rigid appearance of capillary loop due to subendothelial deposits
Activity	Score of possible treatment-sensitive lesions (e.g., based on extent of crescents, cellular infiltrate, necrosis, proliferation)
Chronicity	Score of probable irreversible lesions (e.g., based on extent of tubular atrophy, interstitial fibrosis, fibrous crescents, sclerosis)
Immunofluorescence	
Granular	Discontinuous flecks of staining along capillary loop producing granular pattern
Linear	Smooth continuous staining along capillary loop
Electron microscopy	
Foot process effacement	Flattening of foot processes so that they cover the basement membrane
Microvillous transformation	Small extensions of visceral epithelial cells with villus-like appearance
CMIP	Extension of mesangial cell cytoplasm with interposition between endothelial cell cytoplasm and basement membrane and underlying new basement membrane formation
Reticular aggregates	Organized arrays of membrane particles within endothelial cells
Immunotactoid GP	Large, organized microtubular deposits, >30 nm in diameter
Fibrillary GP	Fibrils 14–20 nm in diameter without organization

CMIP, circumferential mesangial interposition; GBM, glomerular basement membrane; GP, glomerulopathy.

findings altered diagnoses in half of the cases in one series, indicating different therapeutic approaches in approximately one-third of those cases (26). Although some renal diseases show diagnostic features by LM (Table 24.1), special studies add to the sensitivity of the study. For the renal biopsy to be most useful, it must be evaluated appropriately by an experienced renal pathologist. Biopsies must be examined by special LM, IF microscopy, and electron microscopy (EM) for the most accurate diagnosis (27). If the nephrologist's hospital does not provide these services, arrangements must be made to send tissue in appropriate fixatives (see below) to a reference laboratory with these capabilities. If such services cannot be provided, it is doubtful whether the institution should be undertaking renal biopsies.

Contraindications

Contraindications to percutaneous biopsy are solitary, ectopic, or horseshoe kidney; bleeding diathesis; abnormal renal vascular supply; and uncontrolled hypertension (23–25,28). Relative contraindications include obesity; uncooperative patients; hydronephrosis; ascites; and small, shrunken

kidneys—all are associated with greater risk for complications. Open biopsy is preferable if the biopsy information is crucial in these conditions. Percutaneous biopsy is contraindicated if the kidney has tumors, large cysts, abscesses, or pyelonephritis because the needle track may facilitate spread of malignant cells or infection. Open biopsy allows selection of specific areas for biopsy in these situations.

Biopsy Technique

The patient may be admitted on the day of the biopsy. Before biopsy is done, ultrasound examination must confirm that there are two kidneys in normal position. Laboratory evaluation must include a complete blood cell count with normal platelet count, partial thromboplastin and prothrombin times, fibrinogen level, and bleeding time. The blood bank should type and hold one unit of blood. The biopsy optimally is timed so that an experienced technician or pathologist can attend to ensure prompt processing of the biopsy tissue.

Food and drink should be withheld for at least 6 hours before biopsy, and the child should be lightly sedated but

still able to cooperate during the biopsy. The child lies in the prone position with a sandbag or rolled sheet under the abdomen, and the skin of the flank is prepped and draped in sterile fashion. Although the left kidney is usually preferred, either side can be chosen for biopsy. The lower pole of the kidney is marked on the skin with a pen after localization by any of several imaging techniques (e.g., fluoroscopy, radionuclide scanning, intravenous urography, computed tomography, or ultrasound—the last being the most commonly used method). Local anesthetic is infiltrated first in the skin and then in deeper tissues, taking care not to enter the kidney. A small incision is made through the skin and a spinal needle stylet inserted into the depth of the kidney while the patient holds his or her breath in midinspiration. When the kidney capsule is punctured, a loss of resistance can be felt. The needle moves with inspiration when the child is asked to breathe, confirming that it is within the renal parenchyma. Arterial pulsations can also be seen when the needle is within the kidney. The exact depth of the kidney and position of the needle are noted by ultrasound and marked on the stylet at the point where these respiratory movements are no longer transmitted to the stylet as it is slowly removed. Conventional or spring-loaded needles are used for renal biopsies. Most now use the spring-loaded, so-called biopsy gun. For conventional needles, the biopsy needle is inserted to the desired position as the patient again holds his or her breath, advancing the cannula over the obturator once the needle is in correct position. The entire needle with the core of tissue is then removed.

An automatic spring-loaded biopsy system has been used widely in the last several years because of the simplicity and ease of the technique (29,30). The kidney is localized with ultrasound guidance, and the depth of the kidney as judged by ultrasound and the spinal needle is used to place the biopsy needle to reach the kidney capsule. The patient holds his or her breath for only a few seconds while the spring-loaded needle is activated, causing the obturator to automatically advance into the kidney, and the entire needle is then removed with the tissue core. It is important to note that the caliber of the needle used with any of these techniques directly impacts the adequacy of the specimen (31). When 18-gauge needles are used with this method, the resulting cores are very small and there is artifact along the edges. The use of a 16-gauge needle, thus, is more likely to provide an adequate tissue sample without distortion and with fewer passes necessary to obtain adequate tissue.

Usually, two cores of tissue are necessary for optimum evaluation, or three cores if 18-gauge needles are used. If tissue cannot be obtained after several passes, the biopsy should be attempted on another day. After biopsy, a firm dressing is applied, and the child is kept supine in bed for 24 hours and monitored with frequent checks of vital signs and urine for hematuria. The hematocrit should be rechecked at 4 and 24 hours after the biopsy. The child may

be discharged the next day if no complications arise (28). An evaluation of the impact of earlier discharge showed that observation for 8 hours or less after renal biopsy missed more than 20% of complications (32).

Open biopsy can be performed under local or general anesthesia. The kidney can be directly visualized even through a small incision. Although a larger sample may be obtained with a wedge biopsy, it is preferable to also perform a needle biopsy to sample deeper cortex and medulla for assessment of diseases that preferentially involve juxtamedullary glomeruli (see below).

Aspiration Biopsy

Fine-needle aspiration (FNA) biopsy technique is used most often in the transplant setting for analysis of immunologically activated cells. FNA is especially useful in evaluating acute rejection (33). FNA can also obtain material for culture. A modified FNA technique has been described for collection of glomeruli from either native or transplant kidneys to analyze glomerular lesions. This technique has limitations in sample size and is obviously not suitable for study of vascular, tubular, or interstitial processes. The less invasive nature of the procedure makes it amenable to serial monitoring of diffuse glomerular lesions in native or transplanted kidneys (34).

Complications

Important complications occur in 5 to 10% of patients (23,35–43). Major complications, usually bleeding, leading to nephrectomy occurred in five patients in a review of 8081 biopsies (41) and one patient in a series of 5120 biopsies. In a series totaling 1820 biopsies in children, one nephrectomy resulted (35–40). Transient microscopic hematuria is universal after biopsy, although macroscopic hematuria is seen in only 5.0% and requires transfusion in up to 2.3% of patients. Perirenal hematoma is most often asymptomatic and can be seen by computed tomography in up to 85% of biopsies. Symptomatic hematoma is rare, occurring in less than 2%. Arteriovenous fistulae are symptomatic with hematuria, hypertension, or cardiac failure in only 0.5% of biopsies, although bruits may be detected in as many as 75% of patients. Most fistulae heal within a few months. Other complications have been reported, including inadvertent puncture of other viscera or major renal vessels, sepsis, renal infection, and seeding of cancer. Death is rare, occurring in less than 0.1% in reviews of large series. Complication rates appear to be slightly higher in less developed countries (35,37). Complications for the spring-loaded needle biopsy system appear to be similar to conventional needles if the same gauge is used (44). Complications relate in part to the number of passes made to obtain tissue. Therefore, the lower rate of complication with an 18-gauge, spring-loaded needle in some studies is offset largely by the need for more passes for adequate samples and the

distortion of tissue and edge artifact with use of an 18-gauge needle (see above).

ASSESSMENT OF THE RENAL BIOPSY

Adequacy of Sample

Cores of fat and connective tissue float when placed in saline, but a core of renal parenchyma sinks. The biopsy sample should also be visually inspected with a dissecting microscope or hand lens. Glomeruli are visualized as small red dots in the biopsy core. Scarred glomeruli may be difficult to identify because they are not perfused. In a diffuse disease, such as membranous glomerulonephritis, one glomerulus may be adequate for diagnosis. However, in other conditions (e.g., crescentic glomerulonephritis, FSGS, or lupus WHO class III glomerulonephritis), the lesions may be focal. The greater the number of glomeruli sampled, the lower the probability of missing a focally distributed lesion (45). If only 10% of glomeruli in the kidney are involved by the focal process, a biopsy sample of only ten glomeruli has a 35% probability of missing the lesion, decreasing to 12% if the biopsy contains 20 glomeruli. When one-fourth of glomeruli are involved in the kidney, there is only a 5% chance of missing the abnormal glomeruli in a biopsy of ten glomeruli. A biopsy of 20 to 25 glomeruli is sufficient to distinguish between mild disease (less than 20% of glomeruli involved), moderate disease (20 to 50% of glomeruli involved), or severe disease (more than 50% of glomeruli involved). However, the widespread use of small-gauge, spring-loaded biopsy needles often results in smaller samples, which make the above assessments of severity and extent of lesions difficult or impossible. The sample site must also be considered in evaluating the adequacy of tissue. Even a large biopsy consisting only of superficial glomeruli cannot exclude the presence of early FSGS in which the initial involvement is in the juxtamedullary glomeruli. Likewise, although nephronophthisis is most often diagnosed clinically, a juxtamedullary biopsy would be necessary for morphologic diagnosis.

Allotment of Tissue

Renal tissue should be studied by LM techniques with special stains [hematoxylin and eosin, modified silver stain (periodic acid and methenamine or Jones' stain), periodic acid-Schiff (PAS), IF, and EM] (26,27,46). The tissue is divided so that glomeruli are present in each portion of the sample. Optimally, the pathologist or an experienced histotechnologist attends the biopsy and inspects and allots tissue for each study. If this is impossible, tissue may be placed in saline and brought directly to the laboratory for prompt processing. It is important to handle the tissue gently so that artifacts do not occur. The fresh tissue must not be picked up with forceps because this crushes and distorts the morphology. The core can be handled carefully with a wooden stick or pipette. The core should not be placed on

a sponge or gauze pad because this may cause a divot-like artifact as the unfixed tissue molds to the holes of the underlying surface. The biopsy specimen is therefore placed on a clean smooth surface, such as a wax board, for cutting.

It may be difficult to identify the cortical end of the specimen even after inspection with a hand lens or dissecting microscope when scarring or severe injury is present. Therefore, we recommend cutting two 1-mm pieces with a sharp blade from each end of the core for EM studies. The remaining core is then divided into specimens for IF and LM. Of note, use of an 18-gauge needle yields tissue cores that are too thin to divide lengthwise, leading to a greater chance of problems in allocation of tissue for each method of study. This tissue should be cut across into two pieces for IF and LM. When two cores are obtained, we prefer to duplicate this process, rather than allocating one complete core to one study to maximize chances of adequacy of tissue for each study. When the tissue sample obtained is very small, the nephrologist and the pathologist should consider the differential diagnosis and allocate tissue accordingly. For example, in a case of suspected IgA nephropathy, tissue for IF is most important. Although EM studies can be done on other portions of tissue (as long as mercury-based fixatives have not been used), IF studies cannot be done reliably on fixed tissue. When tissue for EM is inadequate, portions of the paraffin-embedded tissue left after LM examination may be cut out from the block and processed for EM. Although the quality is not optimal, diagnostic findings can still be discerned. In special circumstances, when no tissue remains in the paraffin block and a focal lesion in one section must be studied, one may attempt to process the tissue section from a glass slide for EM.

Light Microscopy

Numerous fixatives are used for LM examination, and they vary from institute to institute. Satisfactory results may be obtained with Zenker's, Bouin's, formalin, Carnoy's, or paraformaldehyde. Material for IF studies may be snap frozen immediately at 20°C in solutions of isopentane, dry ice, acetone, or freon and embedded in Tissue-tech, OCT, or other compounds for frozen sections. If tissue cannot immediately be snap frozen, it may be placed in Michel's tissue media, where it may be stored for up to 1 week before freezing. This allows tissue to be sent to reference laboratories for appropriate processing. Tissue for EM may be fixed in glutaraldehyde, formaldehyde, or other appropriate fixatives. Tissue placed in glutaraldehyde should be promptly processed or, if stored for future possible processing, should be transferred to an appropriate buffer solution within 1 week to avoid artifacts. Tissue for LM is routinely processed, embedded in paraffin, and cut into 2- to 3- μ thick sections and stained. Serial sections with multiple levels are then prepared for examination.

If water-soluble compounds are expected (e.g., as urate or uric acid), the tissue should be fixed in ethanol. Lipids

are best detected in frozen sections because they are extracted during xylene processing for paraffin sections. Hematoxylin and eosin stains are most useful for overall assessment of the interstitium, allowing particularly good visualization of infiltrating cells, especially eosinophils. In addition, fibrin may be easily visualized by this stain. PAS stain accentuates basement membranes and matrix material and allows definition of the brush border of proximal tubular cells. Areas of hyalinosis and protein precipitation, including cryoglobulin, are also accentuated with PAS stain. The basement membrane and areas of deposits are best visualized by silver stain, usually the Jones' stain. Masson's trichrome stain may be used to accentuate areas of fibrosis and stains areas of collagen deposition bluish. Other special stains may be indicated. These include Congo red stain for amyloidosis and special stains for bacterial or fungal organisms and acid-fast bacilli. Special techniques may also be used on the LM material. These include polarization to detect crystals or foreign bodies and morphometry to assess glomerular size (see below) and severity of interstitial fibrosis quantitatively.

Immunofluorescence

IF studies are most commonly done by direct IF on frozen tissue sections, with application of fluorescein-conjugated antibodies directed against IgG, IgA, IgM, and complement component C3. Additional antisera may be used as clinically indicated. These include antisera to κ or λ light chain, antisera to hepatitis B antigen, thyroglobulin, fibrinogen, C1q, antisera to type IV collagen chains, and C4d. Some of these antigens are recognized by antisera even after fixation and can be detected by immunohistochemical techniques (e.g., immunoperoxidase) on the formalin-fixed tissue sections and then studied with a light microscope. This technique requires enzyme pretreatment of tissue, which must be tailored exactly depending on length and type of fixation, section thickness, and antigen one wishes to study. Direct observation of the digestion process, stopping when all plasma is removed from capillary loops, has been used to achieve reliable results (47). These challenges have prevented widespread use of this technique.

Frozen tissue sections stained by the commonly used method of fluorescein-conjugated antibodies are viewed by IF microscopy, evaluating staining in glomeruli, vessels, tubules, and interstitium. The pattern of glomerular staining is assessed to define granular or linear capillary basement staining or mesangial deposits. Arteriolar staining, especially with C3 in patients with hematuria, may be of diagnostic significance. Tubules may show deposits in lupus nephritis or light chain deposition disease. Nuclear staining can be seen in lupus or lupus-like diseases as a tissue manifestation of the patient's positive antinuclear antibodies. IF is more sensitive than EM in identifying immune deposits; however, EM provides more detailed information on the

exact localization of those deposits (27,46). Lesions of interest should be photographed because fluorescence fades on storage and with light exposure.

Electron Microscopy

Tissue for EM is processed with postfixation in 1% osmium tetroxide, which enhances contrast of the tissue, and then dehydrated and embedded. With new, more rapidly polymerizing embedding media (e.g., Spurr), tissue may be ready for examination within 1 day. EM study was found to add information in 6 to 11% of renal biopsies in a study from 1983 (24). A more recent study showed that EM was needed to make a diagnosis in 21% of cases and provided important confirmatory data in approximately 20% of cases (27). EM showed diagnostic pathologic abnormalities in 18% of patients with normal LM findings. Larger, so-called thick sections (1 μ) are stained with toluidine blue to select smaller areas for thin sectioning for the electron microscope. Usually, the glomerulus containing the most representative lesion is chosen. If there are irregular or focal lesions, several glomeruli may be sampled. The 60- to 90-Å thin sections are stained with uranyl acetate and lead citrate before viewing to enhance contrast.

The characteristic immune deposits are denser than basement membrane or matrix materials. In specific diseases, such as cryoglobulinemia, amyloid, immunotactoid or fibrillary glomerulopathies, or lupus nephritis, specific substructure of deposits may be seen. Specific localization of immune complexes is done by EM examination, indicating whether deposits are subendothelial, subepithelial, mesangial, or in all of the above compartments. In some diseases, such as light chain deposition disease or lupus nephritis, deposition may also be seen in vessels and tubules. So-called fingerprint deposits, with substructures reminiscent of fingerprinting, are present in some cases of lupus nephritis. Reticular aggregates (or so-called tubular arrays) of membrane material in endothelial cell cytoplasm throughout the body are characteristically seen in large numbers in patients with SLE or human immunodeficiency virus (HIV) infection and are believed to reflect a response to high levels of interferon (46,48).

EM also delineates specific basement membrane abnormalities. For instance, small subepithelial deposits without surrounding new basement membrane material do not result in spikes and, therefore, cannot be visualized by Jones' stain on LM but can still be detected directly by EM. The lamina densa of the GBM is markedly thickened in diabetic nephropathy. Circumferential mesangial interposition is defined by extension of monocytes and mesangial cell cytoplasm into the subendothelial space, with newly formed basement membrane interpositioning between the advancing mesangial cells and the endothelium, thus providing the classic double contours with silver stain seen by LM in MPGN. Increased lucent material is present in the

lamina rara interna in transplant glomerulopathy, HUS, toxemia, and other diseases presumed to involve coagulopathy. In these conditions, deposition of fibrin, fibrinogen, and their degradation products may also occur. Fibrin is recognizable by its dense, coarse, sheaf-like structure, with periodicity observed in favorable sections. Morphometry of the GBM from EM prints is used to diagnose thin basement membranes in hereditary nephritides. EM also allows structural assessment of changes of specific cells (see below). Diagnostic inclusions are seen in various storage or metabolic diseases (e.g., Fabry's disease).

BASIC RENAL LESIONS

Normal

The normal glomerulus consists of a complex branching network of capillaries originating at the afferent arteriole and draining into the efferent arteriole. The glomerulus contains three resident cell types: mesangial, endothelial, and epithelial cells (Fig. 24.1). The epithelial cells cover the urinary surface of the GBM with pseudopod-like extensions called *foot processes* with intervening filtration slits.

Endothelial cells are opposed to the inner surface of the GBM and are fenestrated. At the stalk of the capillary, the endothelial cell is separated from the mesangial cells by intervening mesangial matrix. Because the endothelial cell nucleus most often lies in this stalk region, it may be difficult to distinguish from the mesangial cell nucleus by LM. The term *endocapillary* is used to describe proliferation filling up the capillary lumen, contributed to by proliferation of mesangial, endothelial, and infiltrating inflammatory cells. In contrast, *extracapillary proliferation* refers to proliferation of the parietal epithelial cells that line Bowman's capsule.

The mesangial cell is a contractile cell that also has phagocytic properties. It lies embedded in the mesangial matrix in the stalk region of the capillary loops, attached to anchor sites at the ends of the loop by thin extensions of its cytoplasm. Normally, up to three mesangial cell nuclei per lobule are present. The basement membrane consists of three layers distinct by EM, the central broadest lamina densa, and the less electron-dense zones of lamina rara externa and interna. Thickening occurs with maturational growth. Most investigators have found thicker basement membranes in boys, with normal range from 220 to 260

FIGURE 24.1. Schematic illustration of glomerulus with glomerular capillary attached to a mesangial stalk area. The glomerular endothelium (E) is fenestrated and lines the glomerular basement membrane (GBM), which covers the mesangium. The outside of the GBM is covered by the epithelial cell and its foot processes (Ep). The mesangial cell (M) is embedded within the mesangial matrix (MM), with processes connecting to the GBM. Boston: Little, Brown and Company, 1992:1:35, with permission.)

FIGURE 24.2. Immature glomerulus with plump, dark epithelial cells from biopsy of a baby at 29 weeks' gestation (periodic acid-Schiff stain, $\times 670$).

nm at 1 year of age, 280 to 327 nm at 5 years of age, 329 to 370 nm at 10 years of age, and 358 to 399 nm at 15 years of age (49,50). In our laboratory, we found a range of GBM thickness in children with normal kidneys from approximately 110 nm at 1 year of age to 222 ± 14 nm at 7 years of age.

The glomerulus is surrounded by Bowman's capsule, which is lined by parietal epithelial cells. These are continuous with the proximal tubule, identifiable by its PAS-positive brush border. The efferent and afferent arterioles can be distinguished morphologically in favorably oriented sections or by tracing their origins on serial sections. Segmental, interlobular, and arcuate arteries may also be present in the renal biopsy specimen. The cortical biopsy also allows assessment of the tubulointerstitium. Proximal tubules are readily identified by their PAS-positive brush border lacking in the distal tubules. Collecting ducts show cuboidal, cobblestone-like epithelium. The medulla may also be included in the biopsy.

During fetal maturation, the glomerular capillary tufts are initially covered by large, cuboidal, darkly staining epithelial cells with only small lumina visible (Fig. 24.2). The cells lining Bowman's space undergo a similar change from initial tall columnar to cuboidal to flattened epithelial cells, except for those located at the opening of the proximal tubule, where cells remain taller. Immature nephrons may occasionally be seen in the superficial cortex of children up to 1 year of age. Glomerular growth continues until adulthood, with average normal glomerular diameter approximately 95μ in a group of patients younger than 5 years of age (average age, 2.2 years) and 140 to 160 μ in adulthood (51,52).

Overall Pattern

Assessment of the biopsy specimen must include inspection of all sections from different levels because additional glomeruli may be sampled on deeper cuts of the biopsy core

and many diseases are characterized by focal lesions. Assessment of severity and patterns of lesions is made, and normal and affected glomeruli are counted. Lesions are classified as focal if only some glomeruli are involved, diffuse if all glomeruli are involved, segmental if only portions of glomeruli are involved, and global if entire glomerular tufts are involved. Characteristic glomerular disease patterns include lobular proliferation in MPGN, nodular proliferation of mesangial matrix material with paucicellular areas in characteristic Kimmelstiel-Wilson lesions, focal and segmental sclerosis, and crescent formation (Table 24.1). The *crescent*, or proliferation of parietal epithelial cells, owes its name to its shape in well-established lesions. Fibrin and thrombosis are best assessed by Jones' stain.

Glomeruli are assessed for alterations in size (see below). It is important to compare with a normal control for a given age group because glomerular maturational growth is rapid in children. Glomerular hypertrophy may be an important predictor of increased risk of FSGS in children with apparent MCD (see below). Maturational pattern of glomeruli (see above) should be noted.

Glomeruli are assessed for glomerulosclerosis (i.e., the presence of segmental obliteration and scarring of glomerular capillary tufts). Sclerosis may be in a segmental or global pattern (Table 24.2). Previous studies suggested that up to 10% of glomeruli are normally globally sclerosed in people younger than 40 years of age (53). More recent work suggests that this number may be even smaller in children, with less than 1 to 3% global sclerosis expected normally up to age 40 or 56 years, respectively (54,55). These occasional globally sclerotic glomeruli are believed to represent errors of nephrogenesis. The incidence of global sclerosis increases with aging, up to half the patient's age minus 10 (55). Globally sclerotic glomeruli in a greater percentage indicate the possibility of renal disease (focal global sclerosis) (56).

The pattern of tubulointerstitial fibrosis, whether proportional to glomerular sclerosis, whether diffuse or present in a striped pattern after the medullary rays or in broad patchy zones, has diagnostic significance (see below).

Specific Glomerular Cells

Podocytes

The podocytes (glomerular visceral epithelial cells) may show vacuolization in various diseases with severe proteinuria. Although more extensive vacuolization of podocytes has been seen in FSGS compared with patients with MCD (57), these changes are seen only after established sclerotic lesions are identifiable by LM and do not permit distinction of these two disease processes in the early phase in which segmental sclerosis may be undetected. Hypertrophy of podocytes is prominent in MCD and FSGS. Effacement of the foot processes of the podocytes by EM is common to any disease with marked proteinuria, and the podocyte may also show microvillous transformation with long, attenuated pseudo-

TABLE 24.2. CHARACTERISTIC ABNORMALITIES OF GLOMERULAR DISEASES

Disease and typical clinical presentation	Light microscopy pattern	Immunofluorescence staining			EM, other findings
		Mesangial	Subepithelial	Subendothelial	
Hematuria/nephritis					
Alport's syndrome	Early: normal Late: sclerosis	–	–	–	Thin, split GBM
Lupus WHO class II (mesangial)	Normal or mesangial proliferation	+	–	–	Immune deposits by EM, reticular aggregates in endothelial cells
Lupus WHO class III (focal proliferative)	Proliferative, <50% of glomeruli	+	+ (few) All Igs, C3, C1q	+ (scattered)	Immune deposits by EM, reticular aggregates in endothelial cells
Lupus WHO IV (diffuse proliferative)	Proliferative, >50% of glomeruli	+	+	+ (wire loop) All Igs, C3, C1q	Immune deposits by EM, reticular aggregates in endothelial cells
IgA nephropathy	Mesangial proliferation	+	–	–	Immune deposits by EM
Henoch-Schönlein purpura	Mesangial proliferation, crescents	+	+/- Predominantly IgA	+/-	Immune deposits by EM
Postinfectious GN	Hypercellular, PMNs, endocapillary proliferation	+/-	+	–	Irregular, hump-like deposits on top of GBM by EM

Pods. Podocytes are limited in their ability to proliferate. However, the early sclerotic lesion of FSGS is characterized by prominence and apparent increase of the overlying podocytes often associated with endocapillary foam cells. The collapsing variant of FSGS or HIV-associated nephropathy both show prominent hyperplasia and protein droplets of the podocytes overlying segmental collapse of the glomerular capillary tuft. In the situation of recurrent FSGS in the renal transplant, NS and foot process effacement may be seen within weeks after biopsy, with sclerosis becoming apparent at a later date (58). In Fabry's disease, there is accumulation of glycosphingolipid because of deficiency of α -galactosidase. Podocytes show marked vacuolization by LM with characteristic whorled, laminated, electron-dense myelin bodies by EM. In Fabry's disease, these inclusions may also be present in endothelial cells, tubular epithelial cells, and some interstitial cells (24,46).

Mesangial Cells

Hyperplasia of mesangial cells is recognized by LM when more than three mesangial cell nuclei are present per mesangial region. Increased mesangial prominence may be due to increased cellularity, increased matrix, deposits, or a combination. Large mesangial deposits appear on Jones' stain as pinkish areas surrounded by the light silver-staining areas of mesangial matrix. So-called mesangial interposition results when the monocyte or mesangial cell cytoplasm extends outward between basement membrane and endothelial cells and new matrix accumulates between the mesangial and endothelial cell bodies.

Endothelial Cells

Extreme proliferation and swelling of endothelial cells can obliterate capillary lumina in conditions characterized by abnormalities of coagulation. Endothelial cells usually contain characteristic reticular aggregates in lupus nephritis and HIV-associated nephropathy (46,48). Endocapillary cell proliferation is characteristic of, for example, diffuse proliferative lupus nephritis and MPGN type I.

Crescents

Crescents consist primarily of proliferating parietal epithelial cells with some infiltrating macrophages and are a manifestation of severe glomerular injury. The name reflects the often crescent-shaped sheet of cells filling up part or nearly all of Bowman's space. Crescents result from injuries that break the GBM, leading to exudation of plasma protein and formation of fibrin within Bowman's space, which then induces proliferation of the parietal epithelial cells and infiltration of macrophages. When crescents are a prominent histologic feature, the patient most often presents clinically with a rapidly progressive glomerulonephritis.

Crescents may occur in a variety of diseases. Diseases with crescents as a primary manifestation include antibody-mediated injury (anti-GBM antibody disease), immune-complex diseases (e.g., lupus nephritis), and nonimmune diseases. The latter are often, but not invariably, associated with positive ANCA tests and may be associated with systemic disease or be renally limited. The perinuclear ANCA pattern is most often associated with microscopic polyangiitis, whereas the cytoplasmic ANCA pattern is typical in Wegener's granulomatosis. Of note, positive ANCA tests are not sensitive in distinguishing these categories (13–15). Renal biopsy is, therefore, critical for accurate diagnosis. Diagnosis and appropriate treatment must occur rapidly in this clinical situation to optimize chances of recovery of renal function. The early lesion of cellular crescents is responsive to cytotoxic therapy. Biopsy indications of irreversible renal damage include breaks of Bowman's capsule and fibrous transformation of the cellular crescents, periglomerular fibrosis, and scarred glomeruli and tubulointerstitium.

Glomerular Basement Membrane

GBM abnormalities are best evaluated by EM. The basement membrane is abnormally thick in diabetic nephropathy (46). Diffuse, abnormally thin GBMs, less than 250 nm in adults, are seen in familial hematuria (49–50). In children, the diagnosis of thin basement membranes is more difficult than in adults because GBM increases in thickness with normal maturation. GBM thickness should be compared with normal for age and sex (see above) (49,59,60). In Alport's syndrome, the basement membrane is characterized by irregular thickness, either very thin or very thick, with splitting and splintering of the basement membrane (22,61). The GBM in nail-patella syndrome is irregular, thickened, and split, with electron-lucent areas containing banded collagen type I fibers (46).

Immune deposits may localize on either side of the GBM. Subepithelial immune deposits are characteristically seen in membranous glomerulonephritis. Subendothelial immune deposits are seen, for example, in lupus proliferative nephritis or MPGN type I.

The basement membrane may appear split by LM in diseases other than MPGN type I or dense deposit disease. In transplant glomerulopathy, the split appearance results from varying degrees of mesangial interposition and widening with increased lucent material in the lamina rara interna. This is also a characteristic finding in preeclampsia, transplant glomerulopathy, and chronic HUS (46).

Tubules

Morphologically evident tubular necrosis correlates poorly with the clinical extent of acute tubular necrosis. The changes vary from nondiagnostic vacuolization to frank necrosis with sloughing of tubular epithelial cells and flat-

tened epithelium characteristic of regeneration (24). In cortical necrosis, zones of cortex, including glomerular structures, are necrotic. Tubules are atrophied with dilation and flattened epithelium in chronic renal disease, presumably secondary to lesions affecting the glomerulus, although inherent interstitial factors may also be involved in these changes. Tubular atrophy is also present in primary tubulointerstitial diseases. Tubulointerstitial fibrosis is an important manifestation of cyclosporine toxicity. The fibrosis occurs along the medullary rays, resulting in a striped, rather than diffuse, pattern of fibrosis, with intervening preserved tubules.

Nonspecific casts of Tamm-Horsfall protein are seen in chronic renal disease. Other casts may have a diagnostic appearance, such as the giant cells surrounding tubular casts in light chain cast nephropathy (so-called myeloma kidney). Casts of myoglobin with characteristic reddish-brown appearance are seen in rhabdomyolysis, often with associated acute tubular necrosis. Crystals (e.g., oxalate) may be identified by examination under polarized light. Tubules contain characteristic inclusions in Fabry's disease.

Polymorphonuclear neutrophils within collecting ducts and proximal tubules are diagnostic of acute pyelonephritis. In chronic pyelonephritis, there is tubular atrophy and interstitial fibrosis, characteristically in a patchy, regional distribution. The combination of segmental glomerular sclerosis with ischemic changes of corrugation and thickening of the GBM and periglomerular fibrosis and patchy, regional interstitial fibrosis and tubular atrophy is characteristic of reflux nephropathy (62).

Cysts may be demonstrated by biopsy, although the diagnosis of specific cystic diseases is usually made by combination of clinical and ultrasound findings. The segment of the nephron giving rise to the cysts can be identified by histochemical stains (63). Areas of low cuboidal epithelial-lined structures surrounded by a cuff of immature mesenchyme are present in the dysplastic kidney, often with cartilage, fat, or abnormal blood vessels in the interstitium. The deep medullary cystic dilation characteristic of nephronophthisis can be identified with a deep biopsy. Dilation of proximal tubules with microcyst formation in conjunction with sclerosis is characteristic of congenital NS of Finnish type. FSGS in a collapsing pattern with podocyte hyperplasia, numerous reticular aggregates by EM, and tubular cystic dilation and interstitial fibrosis out of proportion to the severity of glomerular lesions is highly suggestive of HIV-associated nephropathy (48).

Interstitialium

Interstitial edema is a nonspecific change present, for example, in early acute transplant rejection, renal vein thrombosis, or inflammatory processes. Identification of eosinophils in an infiltrate is suggestive of drug-induced interstitial nephritis, although eosinophils are also present in some

cases of idiopathic interstitial nephritis (64). Eosinophils can also be part of acute cellular rejection in the transplant. Nonnecrotizing granulomas, with or without eosinophils, most often reflect drug-induced hypersensitivity reaction. Fibrosis results in increased spacing of tubules because of the accumulation of PAS-positive collagenous material. The connective tissue also stains specifically blue with Masson's trichrome stain. Fibrosis in a striped pattern suggests chronic cyclosporine toxicity (65,66). Occasionally, the interstitium is infiltrated by malignancy. Hematopoietic neoplasms are especially prone to involve the kidney.

Vessels

Arterioles and larger segmental and interlobular arteries are evaluated for changes in the intima and media; the presence of deposits, fibrin, hyalin, amyloid, or other material; or the presence of vasculitis. Larger vessels typically are not sampled by a biopsy, and diseases that affect these large vessels (e.g., classic polyarteritis nodosa) are, therefore, best evaluated by other methods (e.g., arteriography). Intimal fibrosis and medial thickening with hyperplasia and hypertrophy of media are characteristic of hypertensive injury. Specific eccentric patterns of medial necrosis with nodular protein deposition suggest acute cyclosporine nephrotoxicity (66). Fibrin thrombi, when present in glomeruli or arterioles, are the essential lesions of the thrombotic microangiopathies (e.g., HUS) (46). Fibrin localizes predominantly within glomerular lumina in disseminated intravascular coagulation and hyperacute rejection.

CLINICAL PATHOLOGIC CORRELATIONS

After evaluation of the structural changes of the renal biopsy in conjunction with the clinical history, a diagnosis may be obvious. In some cases, the biopsy specimen may show overlap features, or there may be elements that do not correlate clearly with the clinical setting. Close collaboration by nephrologists and pathologists is essential in arriving at the diagnosis. The pathologist must be familiar with clinical manifestations of renal disease, and the nephrologist should be familiar with the terminology used by the pathologist to describe the biopsy findings (Table 24.2).

When lesions are evaluated, the balance of all elements must be considered. When a typical disease pattern is not present, one must consider whether more than one process is taking place. For instance, drug-induced interstitial nephritis may be superimposed on other glomerular disease. This is especially true in the transplant setting in which multiple disease processes may occur at one time. In some instances, the biopsy findings do not correlate with the patient's renal function. When such apparent discrepancies are found, one possibility is that the biopsy specimen is not representative of all the nephrons of the kidney. The

number of glomeruli necessary to estimate the severity of diseases that show focal distribution has been discussed above. However, the extent of glomerulosclerosis may in and of itself not correlate with renal function. Tubulointerstitial atrophy and fibrosis may be more closely correlated with extent of renal damage and renal function (67–69). One must also consider the elements other than structure that influence the patient's renal function (i.e., blood pressure, filtration properties of the GBM, and the glomerular filtering surface area). Patients with enlarged glomeruli, either caused by compensatory hypertrophy or by a primary pathologic process, may show less deterioration of renal function than expected based on the extent of glomerular scarring. Similarly, treatment of the patient with anti-hypertensive agents that affect glomerular filtration rate (e.g., angiotensin-converting enzyme inhibitors, which preferentially dilate efferent arterioles) may actually increase serum creatinine levels in the short term. Compensation by remaining nephrons may mask ongoing severe disease processes such that creatinine levels may remain near normal until late in the course of disease when therapy is less likely to have an impact on chronic progressive injury.

Diagnostic Findings in Selected Renal Diseases

Minimal Change Disease and Focal Segmental Glomerulosclerosis

MCD is diagnosed only after the exclusion of abnormal findings at the LM level, with diffuse foot process effacement as the only abnormality by EM. The disease is characteristically sensitive to glucocorticoid therapy. However, repeated renal biopsies in patients with apparent MCD initially have shown progression to FSGS, which has a high incidence of progression to end-stage renal disease (70,71). As discussed above, a small sample may not include the segmentally sclerotic glomerulus diagnostic of FSGS. In FSGS, there is often also hyalinosis, an insudation of plasma proteins and lipids with a glassy, smooth (hyaline) appearance on LM. There are no immune deposits, and foot process effacement is present in all glomeruli by EM (Fig. 24.3). Mesangial expansion in the native kidney biopsy may be associated with increased risk for recurrence in the transplant (72).

The presence of IgM in a biopsy that otherwise appears to be MCD (so-called IgM nephropathy) does not have prognostic value (73). Some variants of FSGS may have prognostic value (74). A recently proposed working classification of FSGS aims to examine whether morphologic patterns of FSGS have prognostic implications (Table 24.3) (75). The usual type is diagnosed when no special features are present. The collapsing type of FSGS—characterized by collapse of the glomerular tuft, either segmental or global with associated podocyte hypertrophy and/or hyperplasia—shows a rapid progression to end-stage disease (76).

FIGURE 24.3. Minimal change disease. The foot processes are flattened and appear fused ($\times 11,000$).

The cellular lesion, with endocapillary proliferation with frequent foam cells and often with podocyte hyperplasia, may represent an early stage of FSGS (77). The tip lesion (i.e., sclerosis localized to the proximal tubular pole) may have a better prognosis (78). The perihilar variant, with sclerosis and hyalinosis localized to the vascular pole, likely more often represents a secondary sclerosing process.

C1q nephropathy is characterized by either no sclerosis or segmental glomerulosclerosis by LM, with mesangial C1q deposits and lesser Ig components without dominant or codominant IgA (79). EM shows mesangial and paramesangial dense deposits but a lack of reticular aggregates. Patients typically are adolescents, have steroid-resistant NS, and do not have clinical evidence of SLE. Although these

TABLE 24.3. WORKING CLASSIFICATION OF FOCAL SEGMENTAL GLOMERULOSCLEROSIS (FSGS)

Type	Key histologic feature	Possible prognostic implication
FSGS, not otherwise specified	Segmental sclerosis	Typical course
Collapsing FSGS	Collapse of tuft, GVEC hyperplasia	Poor prognosis
Cellular FSGS	Endocapillary proliferation, often GVEC hyperplasia	?Early stage lesion
Tip lesion	Sclerosis of tuft at proximal tubule pole	?Better prognosis
Perihilar variant	Sclerosis and hyalinosis at vascular pole	?May reflect a secondary type of FSGS

GVEC, glomerular visceral epithelial cell.

findings suggest a distinct clinicopathologic entity, the prognostic significance of these lesions has not yet been established. Progression to end-stage renal disease has occurred in some patients with sclerosis at biopsy, but long-term outcome of those without sclerosis at presentation has not yet been established.

Because therapy and prognosis are different for MCD versus FSGS, early distinction of these two entities is of primary interest. We studied pediatric patients with steroid-resistant NS and MCD on renal biopsies and compared them to patients with apparent MCD on biopsy who subsequently progressed to overt FSGS (51). Morphometric analysis of initial biopsies showed that glomerular size at the onset of disease, before sclerosis was apparent, was remarkably larger in patients who subsequently progressed to FSGS (Fig. 24.4) (80,81). There was a higher risk for development of FSGS in patients younger than 5 years of age with glomerular area greater than 1.5 times that of normal age-matched controls. On the other hand, glomerular size equal to or less than normal controls in this group of patients indicated a good prognosis. Calculated glomerular diameter for increased risk of FSGS in these patients younger than 5 years of age was more than 118 μ versus 95 μ glomerular diameter in age-matched controls. Depending on processing and fixation, these values may vary (our values are based on paraffin-embedded tissue fixation in formalin or Zenker's fixative). Normal ranges should be established in each laboratory assessing glomerular size.

From these studies, abnormal glomerular enlargement suggests a high probability of development of FSGS in pediatric patients with apparent MCD. Causes of abnormal glomerular enlargement other than idiopathic FSGS (e.g., diabetes mellitus, cyanotic cardiovascular disease, and massive obesity) must be excluded before such inferences can be made. It is interesting to note that the incidence of FSGS may be increased in these diseases. The association of abnormal glomerular growth with development of glomerulosclerosis may reflect a pathogenic linkage in that processes leading to excess matrix and sclerosis may be manifested as glomerular growth. This view is supported by the coexistence of these two processes in many other diseases, including sickle cell diseases, HIV infection, and reflux nephropathy (82).

Recently, specific gene mutations of podocyte-specific genes have been identified in some forms of familial FSGS. A gene for autosomal dominant FSGS has now been localized to ACTN-4 at chromosome 19q13. ACTN-4 encodes alpha-actinin-4, and a gain-of-function mutation with possible altered actin cytoskeleton interactions has been proposed (83). The prognosis of this form of familial FSGS has been poor, with progression to renal disease in 50% of patients by age 30 years. Recurrence in the transplant has been very rare in autosomal dominant forms of FSGS. Autosomal recessive FSGS with early onset and rapid progression to end stage is caused by mutations in NPHS2, which encodes podocin (84). Podocin is expressed only in

FIGURE 24.4. Apparent minimal change disease (MCD) with subsequent progression to focal segmental glomerulosclerosis (FSGS). The first biopsy from this 5-year-old girl (**middle**) was indistinguishable from MCD, except for marked glomerular hypertrophy versus age-matched typical MCD with subsequent benign clinical course (**top**). The patient's later biopsy (**bottom**), 50 months later, showed segmental sclerosis, diagnostic of FSGS (Jones' stain, $\times 160$).

podocytes and is an integral stomatin protein family member. Its function is not determined. Mutations in NPHS2 have been described in sporadic steroid-resistant FSGS. In both autosomal dominant and autosomal recessive forms of FSGS, there is genetic heterogeneity. These familial forms do not have specific morphologic features of the segmental sclerosis.

In contrast, congenital NS of Finnish type shows mesangial hypercellularity or no glomerular lesion, along with dilated proximal tubules by LM. The gene, NPHS1, also located in the 19q13 region, codes for nephrin and is mutated in this disease (85). Nephrin localizes to the slit diaphragm of the podocyte and is tightly associated with CD2-associated protein. Nephrin is believed to function as a zona occludens-type junction protein. CD2-associated protein plays a crucial role in receptor patterning and cytoskeletal polarity, and its absence resulted in sclerosis and foot process effacement in mice, supporting a role for CD2-associated protein in the function of the slit diaphragm. The slit diaphragms are crucial for regula-

FIGURE 24.5. Arteriolar fibrin thrombi with minor areas of thrombi in capillary loops in hemolytic uremic syndrome (Jones' stain, $\times 270$).

tion of permselectivity and are decreased in density in proteinuric conditions.

FSGS associated with mitochondrial cytopathy, due to a mutation of mitochondrial DNA in tRNA^{Leu}(UUR), may show multinucleated podocytes and have abnormal mitochondria by EM examination. Patients also have unusual hyaline lesions in the arterioles. Some patients with FSGS without full-blown features of mitochondrial cytopathy (e.g., myopathy, stroke, encephalopathy, occasionally diabetes mellitus, hearing problems, and cardiomyopathy) have also been reported to have this mitochondrial mutation (86).

Hemolytic-Uremic Syndrome

HUS is the most common disease in children that is manifested by injury to the microvasculature. In adults, thrombotic thrombocytopenic purpura and postpartum renal failure may produce similar morphologic changes. By LM, thrombi in glomeruli and arterioles are present (Fig. 24.5). The renal biopsy findings, rather than clinical parameters, have recently been found to best predict long-term prognosis (87). Patients with cortical necrosis have a particularly ominous prognosis. The extent of glomerular versus arteriolar involvement is also of prognostic significance. Generally, both the long-term prognosis and the clinical presentation are more severe if larger vessels are involved. Arterial involvement was not seen in biopsies performed during the first 2 weeks of hospitalization (88). The glomerular endothelium is markedly swollen, nearly occluding capillary lumina. Fibrin thrombi are visualized easily. With chronicity, these areas may progress to segmental collapse with sclerosis, especially when arterioles are involved. The arterioles can become completely occluded by thrombi, with necrosis of vessel walls. IF shows occasional nonspecific entrapment of C3 and IgM in collapsed areas with fibrin and fibrinogen. EM shows extreme swelling of the glomerular endothelium with increased lucent material in the lamina rara interna of the base-

FIGURE 24.6. Hemolytic uremic syndrome. The lamina rara interna (endothelial side of the glomerular basement membrane) is widened with increased lucent material. No immune deposits are present ($\times 3300$).

ment membrane with entrapped platelets, fibrin, and red cell fragments without immune deposits (Fig. 24.6). *De novo* thrombotic microangiopathy in the renal transplant is indistinguishable morphologically from HUS in the native kidney. Cyclosporine and FK506 have both been implicated in its pathogenesis (89,90). For further discussion of HUS, see Chapter 47.

Henoch-Schönlein Purpura and Immunoglobulin A Nephropathy

Henoch-Schönlein purpura is often viewed as the systemic variant of IgA nephropathy (Berger's disease) (4,91). The glomerular manifestations are similar, with mild to moderate mesangial proliferation with predominance or codominance of mesangial IgA by IF studies. IgG, IgM, and C3 deposits may also be detected. The Ig deposits are present diffusely, even in glomeruli that appear normal by LM.

FIGURE 24.7. Mesangial prominence, segmental sclerosis, and small organizing crescent with adhesion in Henoch-Schönlein purpura. Immunofluorescence demonstrated immunoglobulin A mesangial deposits (Jones' stain, $\times 430$).

FIGURE 24.8. Dense deposits surrounding mesangial cell in Henoch-Schönlein purpura ($\times 3400$).

Early lesions show predominantly mesangial hypercellularity, with more prominence of matrix and even segmental sclerosis with progressive disease (92) (Fig. 24.7). In severe cases, there may be necrosis of glomerular tufts with crescents in Bowman's space. By EM, electron-dense mesangial deposits are present, with occasional spillover of deposits to subendothelial regions in the regions adjacent to the mesangium (Fig. 24.8). Deposits are decreased when clinical remission occurs (93). In Henoch-Schönlein purpura, deposits are often present in subepithelial areas as well as associated with more severe glomerular lesions, including crescents, and worse outcome (92). Classification schemas analogous to those for lupus nephritis have been proposed (94,95). For further discussion of Henoch-Schönlein purpura and IgA nephropathy, see Chapters 31 and 45.

Membranoproliferative Glomerulonephritis Type I

Type I MPGN is characterized by the tram-track appearance of the GBM on silver stain because of duplication around intramembranous and subendothelial deposits and interposition of mesangial cells and macrophages (Fig. 24.9). The glomeruli are enlarged and hypercellular with a lobular appearance by LM (Fig. 24.10). There is marked mesangial hypercellularity and occasional polymorphonuclear neutrophils, and mononuclear cells may be present. By IF, C3 predominates in a coarse granular pattern along basement membranes with moderate amounts of IgG and IgM. Subendothelial and occasional mesangial immune deposits are seen by EM (4,46). MPGN may be idiopathic or secondary to any of numerous chronic infections. Hepatitis C positivity, often with associated cryoglobulins, was present in approximately one-fourth of adult cases of MPGN type I in adults in Japan and the United

FIGURE 24.9. Split basement membrane (tram-tracking) in membranoproliferative glomerulonephritis type I caused by subendothelial/intramembranous deposits and mesangial interposition (Jones' stain, $\times 1125$).

States (96,97). This association has not been demonstrated in a study of children with apparent idiopathic MPGN (98). MPGN type I recurs in 20 to 30% of grafts and may lead to graft loss (11). Secondary MPGN more often demonstrates a focal segmental pattern of proliferation, contrasting the more diffuse involvement seen in idiopathic MPGN.

Dense Deposit Disease

In dense deposit disease (also called *type II MPGN*), the glomeruli may appear similar by LM to those of type I MPGN. However, the pathogenesis is entirely different. These patients show circulating IgG autoantibodies, also known as *C3 nephritic factor* (10,99,100). The basement membranes are deeply eosinophilic, often with a ribbon garland or sausage-shaped contour. By IF, smooth linear deposits of C3 are found, typically without Ig staining. The disease is named *dense deposit disease* because of the characteristic appearance by EM with strongly electron-dense deposits underlying the basement membrane. Studies of the dense deposits indicate that these are

FIGURE 24.10. Lobular appearance of glomeruli in membranoproliferative glomerulonephritis type I ($\times 430$).

FIGURE 24.11. Lupus nephritis, diffuse proliferative with massive dense mesangial and subendothelial deposits and fewer deposits in subepithelial areas ($\times 5600$).

likely an alteration of basement membrane material and not deposition of circulating immune complexes. Although less specific than EM diagnosis, deposits can also be identified by their staining with the fluorescent dye thioflavin T in cases in which EM examination cannot be performed (100). Renal survival may be worse than in type I MPGN (median survival, 8.7 vs. 15.3 years) (101). The distinction between these two diseases is also important because dense deposit disease invariably recurs in renal transplantation, although loss of graft is not always the outcome (10).

Lupus Nephritis

Lupus nephritis is not a single disease but rather a spectrum of severity of involvement of the kidney by the immune complexes characteristic of SLE. Most patients with SLE have morphologic manifestation of renal immune deposition. However, patients who undergo renal biopsy most often have clinical renal manifestations and have more pronounced changes. Lupus nephritis is characterized by deposits in all anatomic

FIGURE 24.12. Membranous glomerulonephritis with subepithelial deposits and intervening lamina densa (seen as spikes by silver stain on light microscopy) ($\times 15,580$).

FIGURE 24.13. Immunofluorescence of granular capillary and small mesangial immunoglobulin G deposits in diffuse proliferative lupus nephritis. The larger segments of capillary loop staining correspond to subendothelial deposits, with a smooth outer edge where deposits are molded underneath the glomerular basement membrane ($\times 250$).

compartments of the glomerulus (i.e., mesangial, subepithelial, and subendothelial regions) (17,18) (Figs. 24.11 and 24.12). All Ig classes, C3, and smaller amounts of C4 are usually found in lupus nephritis deposits (Fig. 24.13), and dense immune-complex deposits are seen by EM. Reticular aggregates (see above) are typically seen in endothelial cells in any class of lupus nephritis (4,46) (Fig. 24.14).

The WHO classifications, either the original or modified, are most commonly used (16,17). A recent meeting sponsored by the International Society of Nephrology and the Renal Pathology Society has put forth a revised lupus nephritis classification to clarify some areas of difficulty in the previous versions. In this new classification, class I has minimal mesangial deposits with normal LM. Class II is characterized by mesangial expansion and deposits with only scattered peripheral loop deposits. In class III, focal proliferative lupus nephritis, deposits are present in mesangial areas, focal endocapillary proliferation, and subendothelial deposits, with or without scattered subepi-

FIGURE 24.14. Endothelial cell containing tubular-shaped reticular aggregates in lupus nephritis ($\times 20,000$).

thelial deposits. The process, by definition, involves less than 50% of glomeruli. There is wide heterogeneity in the severity and activity of lesions, with varying amounts of proliferation. Foci of necrosis, cellular crescents (indices of activity), and cellular adhesions may be present, which over time may evolve to sclerosis and fibrous crescents (indicators of chronicity). The subendothelial deposits result in thick, rigid-appearing capillary basement membrane by LM, the so-called wire-loop lesions.

When lesions affect more than 50% of glomeruli, lupus nephritis is characterized as class IV diffuse proliferative glomerulonephritis. Findings are similar to those in class III but with more endocapillary proliferation and other active lesions. Hyaline thrombi (aggregates of immune complexes) may fill capillary lumina. IF demonstrates widespread distribution of immune complexes. EM confirms the massive and extensive immune complex deposition (Fig. 24.11). For classes III and IV, the extent of active versus chronic lesions is specified. Evidence indicates a particularly poor prognosis of segmental necrotizing lesions in class IV lupus nephritis; thus, the presence of these lesions versus global endocapillary proliferation is noted (102).

Class V membranous lupus nephritis is characterized by predominance of subepithelial deposits in a pattern similar to that of idiopathic membranous glomerulonephritis with added mesangial deposits (Fig. 24.12). Subendothelial deposits are minor components in class V. When there are superimposed focal or diffuse proliferative lesions in addition to membranous changes, both processes are diagnosed (e.g., combined diffuse proliferative and membranous lupus nephritis, WHO classes IV and V). Widespread chronic sclerosing lesions in a nonspecific pattern in a case of lupus nephritis are defined as *class VI*. Tubular basement membrane deposits can occur in any class of lupus nephritis and may account in part for the tubulointerstitial injury. Vascular lesions include immune deposits or thrombotic microangiopathy, often related to antiphospholipid antibodies. For further discussion of lupus nephritis, see Chapter 46.

Anti-Glomerular Basement Membrane Antibody Disease

LM examination shows crescentic glomerulonephritis with focal necrotizing lesions. Patients may not always show detectable serum levels of anti-GBM antibodies, especially after the acute phase of illness. Serology is positive in 95% of patients in the first 6 months after onset. However, in all patients, even those with negative serology, linear IgG staining by IF of capillary basement membrane is present (Fig. 24.15). EM shows no immune deposits. Patients with more than 50% crescents have a worse prognosis (103). For further discussion of anti-GBM antibody disease, see Chapter 34.

Wegener's Granulomatosis

By LM, the appearance of Wegener's granulomatosis is the same as for other crescentic necrotizing glomerulonephritides

FIGURE 24.15. Antiglomerular basement membrane antibody disease with linear staining by immunofluorescence for immunoglobulin G. A crescent is present in the glomerulus on the right ($\times 125$).

(e.g., microscopic polyangiitis or anti-GBM antibody disease) (Fig. 24.16). The lesions are focal and segmental. Granulomas are rare in the kidney, and arteritis is rarely found in the small sample inherent to the renal needle biopsy. IF studies allow differentiation of the lesion from anti-GBM antibody disease. It shows fibrin and fibrinogen in areas of necrosis and nonspecific trapping of Ig, especially IgM. By EM, immune deposits are not identified. Distinction from microscopic polyangiitis cannot usually be made by renal biopsy findings. Clinical manifestations must be used to distinguish between these two disorders. For further discussion of Wegener's granulomatosis, see Chapter 34.

Postinfectious Glomerulonephritis

Patients with typical poststreptococcal glomerulonephritis do not usually undergo renal biopsy. When the diagnosis remains in question, when abnormalities persist, or when the initial dis-

FIGURE 24.16. Segmental necrosis and crescent in Wegener's granulomatosis. Immunofluorescence was negative (Jones' stain, $\times 430$).

FIGURE 24.17. Postinfectious glomerulonephritis with endocapillary proliferation and polymorphonuclear neutrophil infiltration (arrows) (periodic acid-Schiff stain, $\times 430$).

ease is severe, renal biopsy may be done. Glomeruli are enlarged and hypercellular with prominent endocapillary proliferation and infiltration by neutrophils and mononuclear cells (Fig. 24.17). In severe disease, crescents are present. Occasionally, large subepithelial deposits can be visualized by LM. These differ from those typical of membranous glomerulonephritis in being more unevenly distributed along the capillary basement membrane and larger in size. The deposits lie on top of the basement membrane, rather than being embedded within it (as in membranous glomerulonephritis); therefore, spikes are not usually present. By IF, there are coarsely granular, discontinuous areas of IgG and C3 along the capillary basement membrane. The capillary lumina can be obliterated by infiltrating mononuclear cells, swollen endothelial cells, and polymorphonuclear leukocytes. Electron-dense subepithelial deposits are large, variegated, dome-shaped or haystack-shaped, and irregularly spaced (Fig. 24.18). Occasional mesangial deposits are present in many biopsies. For further discussion of postinfectious glomerulonephritis, see Chapter 30.

FIGURE 24.18. Electron micrograph of subepithelial large, irregularly spaced, dome-shaped subepithelial deposits in postinfectious glomerulonephritis. The deposits are variegated and lie on top of the glomerular basement membrane (short arrows). There is endocapillary proliferation with polymorphonuclear neutrophil (long arrow) infiltration ($\times 7000$).

Diabetic Nephropathy

Diabetic nephropathy affects 30 to 40% of patients with diabetes mellitus, either type 1 or type 2, with overt clinical nephropathy manifest 15 to 20 years after onset of diabetes. Therefore, diabetic nephropathy has been considered a disease of adults. However, recent studies in adolescents demonstrate that diabetic lesions may be present even after short duration of disease (104). In addition, obesity and type 2 diabetes mellitus are increasing in children. These structural changes included GBM thickening and mesangial expansion and were associated with proteinuria, hypertension, and decline in glomerular filtration rate. Overt diabetic nephropathy with nodular glomerulosclerosis and afferent and efferent arteriolar hyalinization was present in several of these patients. For further discussion of diabetic nephropathy, see Chapter 49.

Alport's Syndrome and Thin Basement Membrane Lesion

Early in life, in boys with Alport's syndrome and in female carriers, the renal biopsy may show no significant LM abnormalities. At later stages, glomerulosclerosis, interstitial fibrosis, and prominent foam cells are typical. These foam cells are not specific for this disease and are found in numerous proteinuric states. Glomeruli show varying stages of matrix expansion and sclerosis. IF may show nonspecific trapping of IgM. By EM, the diagnostic lesion consists of irregular thinned and thickened areas of the GBMs with splitting and irregular multilaminated appearance of the lamina densa, so-called basket weaving. In between these lamina, granular, mottled material is present. At early stages of disease (i.e., in children or women), the basement membrane may show only thinning. Some male patients with classic Alport's syndrome only have basement membrane thinning even at advanced clinical stages (22,105).

Immunostaining for type IV collagen chains can aid in the interpretation of thin basement membranes (105). Heterotrimers of α_3 , α_4 , and α_5 type IV collagen are normally present in the GBM. Mutation of α_5 type IV collagen in X-linked Alport's syndrome prevents incorporation of the other chains into the heterotrimer. In kidney biopsies, approximately 70 to 80% of male patients with X-linked Alport's syndrome lack staining of GBM; distal tubular basement membrane; and Bowman's capsule for α_3 , α_4 , and α_5 (type IV) chains. In autosomal recessive Alport's syndrome, due to mutations of either α_3 or α_4 , the GBMs usually show no expression of α_3 , α_4 , or α_5 type IV collagen; however, in contrast to X-linked cases, there is strong expression of α_5 and α_6 type IV collagen in Bowman's capsule, distal tubular basement membrane, and skin. Female patients who are heterozygous for X-linked Alport's syndrome frequently show mosaic staining of GBM and distal tubular basement membrane for α_3 , α_4 , and α_5 type IV collagen chains and skin mosaic staining for α_5 type IV collagen. Patients with autosomal dominant Alport's syndrome have not been studied immunohistochemically. Of note, occasional cases with Alport's syndrome clinically and by renal

biopsy showed apparent normal α_5 type IV pattern of skin IF staining, and approximately 20% of male X-linked Alport's syndrome patients and affected homozygous autosomal recessive Alport's syndrome patients show faint or even normal staining of the GBM for α_3 and α_5 , likely because the antigenic site recognized by the antibody has not been altered by the mutation.

Thinning of the GBM is the characteristic finding in benign familial hematuria (59,60). The diagnosis of thin basement membranes is based on morphometric measurements from EM prints, revealing marked thinning of the lamina densa of the GBM. LM and standard IF are normal. The GBM thickness normally increases with age. Normal thickness in adults in one series was 373 ± 42 nm in men versus 326 ± 45 nm in women. GBM thickness less than 250 nm has been used as a cutoff in many series (106). In children, the diagnosis of thin basement membranes must be made with caution, establishing normal age-matched controls within each laboratory. In our laboratory, we found a range of GBM thickness in normal children, from approximately 110 nm in 1-year-olds to 222 ± 14 nm in 7-year-olds. As mentioned above, thin GBM (without lamellation) may also be an early or only manifestation in some kindreds with Alport's syndrome. Thus, the presence of thin GBM cannot per se be taken to categorically indicate a benign prognosis. Some patients with benign familial hematuria clinically have mutations of α_4 type IV collagen, suggesting a continuum of autosomal recessive Alport's syndrome with benign familial hematuria (107). The immunostaining patterns in such benign familial hematuria patients have not been established.

PROGNOSTIC IMPLICATIONS OF BIOPSY FINDINGS

When the biopsy sample is adequate, extensive, severe, and irreversible lesions signify a dismal prognosis for the patient. Globally sclerotic glomeruli are not amenable to treatment, although evidence from human diabetic nephropathy and animal studies indicates that the earlier stages of sclerosis may be affected by some therapeutic interventions and may even be reversible (108–110). Similarly, active lesions with ongoing cellular crescents, necrosis, and inflammatory infiltrate are potentially dramatically modulated by therapy, allowing subsequent healing. There may be minimal irreversible damage to glomerular structures when intervention occurs early.

Although the renal biopsy may yield a diagnosis, there is less information of prognostic indicators in diseases that have a variable course. Extensive analysis aimed at determining histologic features associated with poor prognosis has been done in some diseases discussed below.

Classification schemes, especially for lupus nephritis and membranous glomerulonephritis, imply progression from one stage of disease to the next. Although sequential biopsies have illustrated progression from focal to diffuse proliferative glomerulonephritis in lupus nephritis, there is no clear-cut evidence that progression occurs among all WHO

classes (16–18). In lupus nephritis, patients with less severe proliferative disease, especially segmental necrotizing lesions, appear to have better prognoses.

Although the presence of cellular crescents is associated with activity of disease clinically, the renal biopsy offers additional prognostic information beyond that gleaned from the clinical presentation (111). Focal and diffuse proliferative lesions (WHO classes III and IV) may present very similarly clinically, but only the latter appears to require intense, long-term immunosuppression. Lesions of activity in lupus nephritis include endocapillary proliferation, necrosis, cellular crescents, interstitial inflammatory cells, and acute tubular necrosis. Lesions that indicate chronicity include tubular atrophy, interstitial fibrosis, glomerular sclerosis, and fibrous crescents.

Although assessment of activity and chronicity indices is useful for population groups, these appear to have less absolute information to guide assessment in individual patients. Nonetheless, in large series, assessment of indices of activity and severity in patients with lupus nephritis or other diseases has shown some correlation with prognosis and response to therapy. Diffuse proliferative lesions, extensive crescents, segmental necrosis, and tubulointerstitial fibrosis are associated with progression to end-stage renal disease (111,112). The best prognostic indicator in a recent study was the proportion remaining of intact glomeruli (113).

IgA nephropathy was previously believed to have a benign prognosis. In a large series of adult patients with IgA nephropathy, poor prognosis was indicated by segmental glomerulosclerosis, adhesions or crescents, and tubulointerstitial fibrosis (114). Progression occurs in 11 to 15% of pediatric patients (4,92,115). Scoring of activity and chronicity of lesions has been correlated with clinical course. Activity is assessed by degrees of crescent formation, mesangial proliferation, and interstitial infiltrate. Chronicity is scored by degrees of fibrous crescents, segmental and global sclerosis, tubular atrophy, and interstitial fibrosis (116). High indices of chronic injury and focal segmental glomerular changes were associated with a worse prognosis (117,118). Histologic features that predicted progression in a recent multicenter study in children were crescents, tubulointerstitial fibrosis, and glomerulosclerosis in 20% or more of glomeruli (115). Predominance of matrix expansion appears to be a later stage of injury associated with a higher percentage of sclerosis and persistent proteinuria (93). Extension of deposits to glomerular basement areas has also been reported as a poor prognostic indicator (116).

Focal glomerulosclerosis superimposed on membranous glomerulonephritis has been associated with more severe tubulointerstitial nephritis and a worse outcome. This lesion was present in 20% of children with hepatitis B-associated membranous glomerulonephritis (119).

Renal Transplant Biopsy

The primary use of biopsy in the renal transplantation is to uncover the reason for altered renal function. Causes of renal dysfunction in the transplant can be broadly divided

FIGURE 24.19. Acute rejection, classified as type I by Cooperative Clinical Trials in Transplantation criteria. There is interstitial lymphocytic infiltrate with tubulitis, activated lymphocytes, tubular cell injury, and interstitial edema (Jones' stain, $\times 220$).

into (a) those related to rejection, drug toxicity, recurrent or *de novo* disease; and (b) those related to the procedure itself (e.g., acute tubular necrosis).

Rejection

Acute rejection is diagnosed by the presence of either interstitial inflammation with lymphocytes and plasma cells infiltrating tubules (tubulitis, the hallmark of acute interstitial type rejection) (Fig. 24.19) or, when more severe, by extension of this process to vessels, with subendothelial arterial or arteriolar infiltration by lymphocytes (endothelialitis, the hallmark of acute vascular rejection) (Fig. 24.20). The interstitial changes of acute rejection are not pathognomonic. In contrast, the finding of endothelialitis is highly specific for acute vascular rejection. Appropriate stains (e.g., PAS) must be used to allow visualization of the tubular basement membrane and identification of tubulitis. An adequate specimen for evaluation of possible rejection should contain at least two cores with at least seven glomeruli and two arteries (120).

FIGURE 24.20. Acute vascular rejection, classified as type II by Cooperative Clinical Trials in Transplantation criteria. There is subendothelial infiltration by lymphocytes in this artery, so-called endothelialitis (Jones' stain, $\times 220$).

Several schemes have been used to diagnose and classify rejection: the Banff scoring system, based on detailed scoring of various components of injury; and the Cooperative Clinical Trials in Transplantation criteria (120,121). In both classification schemes, acute rejection is based on the presence of tubulitis or endothelialitis (i.e., lymphocytes in the tubule under the tubular basement membrane or underneath the endothelium of arteries). Other inflammatory cells (e.g., eosinophils, neutrophils, and plasma cells), although much fewer in number than T lymphocytes, may also contribute to the infiltrate in acute rejection. Type I rejection in both schemas is diagnosed when interstitial lymphocytic infiltrate and tubulitis are present (greater than 25% of parenchyma infiltrated in Banff; greater than 5% in Cooperative Clinical Trials in Transplantation criteria) (Fig. 24.20). Infiltrate and tubulitis less than specified for type I is called borderline by Banff criteria (126). Acute vascular rejection is classified in the same manner in both schemas. Type II acute vascular rejection is diagnosed when there is mild or moderate endothelialitis (arteritis), and severe acute vascular rejection (type III) is diagnosed when there is transmural vascular inflammation or fibrinoid necrosis. These types are differentiated not only based on histologic pattern, but also on differences in underlying mechanisms and response to therapies; types I and II are T-cell dependent processes and are separated based on the likely greater severity of any rejection with endothelialitis, whereas antibody-mediated mechanisms contribute to type III changes.

Identification of acute rejection at earlier stages and, thus, initiation of treatment at milder levels of injury appear to be clinically important. Thus, mild tubulitis that is borderline by Banff criteria, even in normally functioning grafts, was found to be predictive of higher serum creatinine at follow-up. In contrast, treatment of such subclinical rejection in the early time period after transplantation resulted in better preserved renal function at 24 months (122).

There are no specific IF or EM immune complexes associated with acute rejection. The recent surge of exciting molecular studies indicates the possibility of earlier, more sensitive, and specific diagnosis of acute rejection using these techniques (see below) (123). In particular, the presence in peritubular capillaries of C4d, a complement breakdown product that binds covalently to tissue, is highly associated with antidonor antibodies (humoral rejection) (124). Diagnosis of humoral antibody-mediated rejection has important therapeutic and prognostic implications. C4d staining can be done on frozen tissue and, most recently, also on fixed paraffin-processed tissue (125).

The changes of chronic rejection include intimal fibrosis of arteries, interstitial fibrosis, and transplant glomerulopathy (121,126). A previous or baseline biopsy is necessary to prove that intimal fibrosis is *de novo* and potentially represents chronic rejection rather than a preexisting, nonspecific change in the graft. Interstitial fibrosis is also a nonspecific finding and may result from various injuries.

Transplant glomerulopathy is a more specific lesion indicative of chronic rejection. By LM, the glomeruli show basement membrane splitting, corrugation, and even segmental sclerosis with hyalinosis. The latter lesion likely resulted in erroneous reports of *de novo* idiopathic FSGS in the transplant. However, in transplant glomerulopathy, there is widening of the lamina rara interna of the GBM with mesangial cell interposition and new basement membrane formation by EM. Reduplication of basal lamina of peritubular capillaries is suggested to be more specific of transplant glomerulopathy but may also occur in some other glomerular diseases and HUS (127).

Cyclosporine and FK506 Toxicity

Cyclosporine toxicity may manifest in various ways. Tacrolimus (FK506) has much the same spectrum of toxicity as cyclosporine (126,128). The most common morphologic lesion in patients with a clinical diagnosis of cyclosporine toxicity, as verified by clinical follow-up, is that of a normal kidney biopsy morphologically. In these patients, renal dysfunction is due to reversible, cyclosporine-induced vasoconstriction and hypofiltration. Morphologic changes of cyclosporine toxicity include arteriolopathy with injury to the endothelium and vascular smooth muscle cells. In its classic form, this injury results in nodular IgM IF positivity along the apical side of the arteriole, with necrosis and smooth muscle cell injury demonstrated by EM (126,128). By LM, concentric hyalinosis is present, whereas typically eccentric, more segmental hyalinosis is associated with hypertension. Isometric tubular vacuolization in a patchy distribution, although not specific, is also indicative of cyclosporine toxicity. Chronic cyclosporine toxicity results in a striped distribution of interstitial fibrosis caused by injury along the medullary rays (126). This pattern often cannot be gleaned by small needle biopsies. FSGS with ischemic, corrugated GBMs in remaining glomeruli may also result from cyclosporine toxicity and can be associated with significant proteinuria (128).

Cyclosporine has also been associated with thrombotic microangiopathy lesions (see above) (126,128). Of note, thrombotic microangiopathy can occur in patients who are recipients of transplants of kidneys or other organs and after radiation, with or without cyclosporine treatment. In some patients, collapsing-type glomerulosclerosis may be associated with cyclosporine toxicity, likely representing a response to severe vascular injury and ischemia (129).

Recurrent and De Novo Disease

Recurrent and *de novo* diseases are important causes of renal allograft injury, affecting approximately 10% of renal allografts (126). Of all graft loss, 2 to 4% is due to recurrence of disease. IF microscopy should be performed in all transplant biopsies to rule out this possibility. When IF or LM findings in conjunction with the clinical setting

indicate an undetermined lesion, EM study should also be performed.

In children, the most common recurrent diseases include, notably, IgA nephropathy, Henoch-Schönlein purpura, MPGN, dense deposit disease, and FSGS (130). Although SLE has been reported to recur only rarely, our experience indicates a recurrence rate of approximately 30% (131). However, morphologic recurrence of disease does not necessarily lead to graft loss (126,130). Dense deposit disease recurs morphologically in nearly all patients but with only 10 to 20% resultant graft loss. Although classic diarrhea-associated HUS recurs only very rarely, atypical HUS (which includes familial forms) has a recurrence rate of 15 to 25%, with 40 to 50% graft loss. Although IgA nephropathy recurs in approximately 50% of patients, only 10% of grafts with recurrent disease are lost. MPGN type I recurs in 20 to 30%, with 10 to 40% graft loss. FSGS recurs in 20 to 30% of cases, resulting in graft loss in 30 to 50% of these. Of note, in recurrent FSGS, the only morphologic change found in the first weeks after recurrence of proteinuria is foot process effacement, with early segmental sclerosis detectable at 6 to 8 weeks.

De novo disease may also affect the transplant. Membranous glomerulonephritis is the most common *de novo* glomerulonephritis in the transplant. The etiology remains unknown (126). Glomerulonephritis related to infections (e.g., hepatitis C-related MPGN) also can occur in the transplant. Early changes of diabetic nephropathy develop much more rapidly in the transplant than in the native kidney and may occur within a few years, whether diabetes preexisted or is corticosteroid induced. Thrombotic microangiopathy may be related to drug toxicity (see above) or be idiopathic in the transplant.

Posttransplant lymphoproliferative disease (PTLD) is due to the unrestrained proliferation of B lymphocytes, most often because of transformation by Epstein-Barr virus, and is an aggressive process, which if untreated, disseminates and may cause death (132). PTLD may respond to decreased immunosuppression. An expansile lymphoid infiltrate with atypical, transformed lymphocytes and serpinginous necrosis are features suggestive of PTLD (132).

Immunohistochemical studies can be used to detect Epstein-Barr virus to further support this diagnosis. Typing studies of the lymphocytic infiltrate are not often helpful because most PTLD is polytypic, rather than clonal. Of note, acute rejection and PTLD may be present concurrently.

Polyoma (BK) virus nephropathy has increased in the last years in the transplant and is perhaps related to increased immunosuppression (133). The biopsy shows a pleomorphic infiltrate with lymphocytes, plasma cells, and polymorphonuclear neutrophils and eosinophils, with enlarged tubular cells with smudgy nuclei. BK infection is confirmed by immunostaining. The prognosis is poor, although there may be some response to decreased immunosuppression and antiviral therapy.

NEW METHODS FOR THE FUTURE

With the recent surge of application of molecular biology techniques to the study of renal disease, candidate factors involved in pathogenesis and progression of disease are being studied in animal models. Studies in human beings have also commenced. With further development of such studies, we may identify specific abnormal processes and, thus, target therapy more specifically. Research techniques that have been advantageously applied to elucidate pathogenesis of disease include immunostaining; identifying specific antigen in deposits of membranous glomerulonephritis in some patients (thyroglobulin with Hashimoto's disease; hepatitis B, C antigen); identifying light chains or paraproteins in plasma cell dyscrasia-associated diseases; identifying specific type IV collagen abnormalities in Alport's syndrome and C4d as a marker of humoral rejection; and elucidating the pathogenesis of specific *Escherichia coli*-associated toxins in some forms of HUS.

Current studies are aimed at understanding disease etiologies and mechanisms at a molecular level and studying renal biopsies by laser capture microdissection, with real time or standard reverse transcription polymerase chain reaction (RT-PCR), and *in situ* hybridization techniques (134–136). Recent efforts have expanded use of these techniques to study mechanisms of injury and progression. Competitive RT-PCR has been used successfully on even single, isolated glomeruli from human biopsies (134). Modulation of growth factors, collagens, cytokines, chemokines, and their receptors have been investigated molecularly in renal biopsies. Cytokines and chemokines and their receptors were upregulated in diseases with macrophage influx and mesangial cell proliferation, supporting an important role in initiating and perpetuating injury. Such approaches can offer exciting new mechanistic insights into renal diseases.

In parallel, genetic studies are targeted at identifying patients at risk for progression in diseases with a variable course, such as diabetes and IgA nephropathy. Polymorphisms of the renin-angiotensin system genes have been implicated as risk factors for progression and also as indices for response to therapies that target this system (137,138).

Diagnostic use of RT-PCR and *in situ* hybridization has focused on detection of viruses, including hepatitis B and C, cytomegalovirus, polyoma virus, and Epstein-Barr virus. Increased expression of various immune-activated genes (e.g., perforin, granzyme, and fas ligand) quantified by competitive RT-PCR showed initial high predictive value for acute rejection, but subsequent studies have not been as clear cut (123).

Together, these approaches promise to map risks and mechanisms of disease initiation and progression and point to targets to achieve resolution of injury. Sequential biopsies with evaluation of changes in structure and patterns of abnormal factors and modulation by therapy may be neces-

sary to fully understand pathogenesis. Instead of diagnoses of morphologic patterns recognized by current techniques in the renal biopsy specimen, molecular techniques may allow more precise diagnosis of the specific diseases and identification of injury mechanisms.

ACKNOWLEDGMENTS

The author wishes to thank Drs. Tina Kon and Aida Yared, for their suggestions, and the late Dr. Alan Glick, for his advice and photographic assistance.

V

GLOMERULAR DISEASE

CONGENITAL NEPHROTIC SYNDROME

**CHRISTER HOLMBERG
KARL TRYGGVASON
MARJO K. KESTILÄ
HANNU J. JALANKO**

Renal diseases associated with nephrotic syndrome (NS) in the first year of life are uncommon and make up a heterogeneous group of disorders with different proposed causes, courses, and prognoses. *Congenital NS* (CNS) is defined as proteinuria leading to clinical symptoms soon after birth. An arbitrary age limit of 3 months has been proposed to separate CNS from “infantile” NS, which becomes manifest later during the first year of life (1). Although this age limit is useful for statistical purposes, it is not sufficient for the classification of early-onset NS (Fig. 25.1). The most common type of CNS is CNS of the Finnish type (CNF), with a clinical onset before the age of 1 month. The other early-onset NSs have a more widespread age of onset, from the first days of life to several months of age. The diagnosis of a patient with early manifestations of NS must be based on several criteria, including clinical presentation, family history, laboratory findings, and renal histology. In the coming years, the classification will be modified by the use of molecular genetics.

CNS and early-onset NS can be classified into primary and secondary or acquired forms (Table 25.1). CNF is considered the prototype of CNS, and in recent years progress has been made in the knowledge of the genetics, pathophysiology, and clinical aspects of CNF (2–4). In this chapter, management of CNF is presented more thoroughly.

PRIMARY NEPHROTIC SYNDROME

Congenital Nephrotic Syndrome of the Finnish Type

CNF originally referred to a severe form of CNS typically seen in Finnish newborns (5,6). After the gene (named *NPHS1*) responsible for this disorder was isolated in 1998, it became clear that not all cases of “typical” CNF are caused by mutations in *NPHS1* and, on the other hand, mutations in *NPHS1* may sometimes cause atypical (mild) forms of NS. This has led to some confusion in the nomen-

clature; both CNF and *NPHS1* are used as abbreviations for the same disorder. In this text, CNF is used to denote the clinical entity. The term *NPHS1* can be used to refer to cases known to be caused by *NPHS1* mutations.

Epidemiology

CNF is an autosomal recessive disease first described by Hallman et al. (5). The disease is more frequent in Finland, the incidence being 1 in 8200 live births (7). However, patients with CNF have been reported all over the world among various ethnic groups (8–12). A high incidence of *NPHS1* has been reported among the Old Order Mennonites in Lancaster County, Pennsylvania (9). In a subgroup of “Groffdale Conference” Mennonites, the incidence is 1 in 500, which is almost 20 times greater than that observed in Finland.

Clinical Features

The basic problem in CNF is severe loss of protein, beginning during the fetal period (7). The signs and symptoms are believed to be secondary to this protein deficiency (7,13,14). In a recent survey, more than 80% of the children were found to be born prematurely (before the thirty-eighth week), with a mean birth weight of 2600 g (1500 to 3500 g). However, only 2 of the 46 newborns were small for gestational age (14). Amniotic fluid is often meconium stained, but most neonates do not have major pulmonary problems. The placenta is larger than normal and almost invariably weighs more than 25% of the baby’s birth weight. The mean ratio of placental to infant weight is 0.38 in babies with CNF, compared with 0.18 in normal babies. The reason for this is not known.

In typical CNF, edema and abdominal distention become evident soon after birth. NS was diagnosed within the first week in 82% of the Finnish patients and within 2 months in the remaining cases (14). In contrast to most

FIGURE 25.1. Schematic presentation of the age at presentation for 178 children with nephrotic syndrome detected in the first year of life. CNS, congenital nephrotic syndrome; DMS, diffuse mesangial sclerosis; MCNS, minimal-change nephrotic syndrome. (From Mauch TJ, Vernier RL, Burke BA, et al. Nephrotic syndrome in the first year of life. In: Holliday MA, Barratt TM, Avner ED, eds. *Pediatric nephrology*, 2nd ed. Baltimore: Williams & Wilkins, 1994:788–802, with permission.)

other CNS, the protein loss in CNF leads to severe hypoalbuminemia, and the serum albumin concentration is typically less than 10 g/L before protein substitution (15). Without albumin substitution and nutritional support, the classic picture of CNF develops: generalized edema, abdominal distention, ascites, umbilical hernias, and widened cranial sutures and fontanelles (5).

Infants with CNF do not have extrarenal malformations. Minor functional disorders in the central nervous system and heart, however, are quite common during the course of the disease. Most children have muscular hypotonia, and computed tomography or magnetic resonance imaging showed mild atrophic changes in the brain in a third of the Finnish patients (14). Dystonic cerebral palsy has been diagnosed in 8% of the Finnish patients; the etiolo-

gy of this manifestation is not known. Minor cardiac findings, such as hypertrophy and mild functional pulmonary stenosis, have been reported in one-fourth of the Finnish patients (14). In a recent report from Malta, pulmonary valve stenosis was found in three cases and a subaortic stenosis in one patient (16).

Laboratory Findings

In CNF, the first urine analysis already shows proteinuria, microscopic hematuria, and, often, some leukocyturia. The magnitude of proteinuria depends on the serum albumin concentration. The urinary protein concentration exceeds 20 g/L when the serum albumin concentration is above 15 g/L (15) and no medication reducing filtration pressure has been given. This is in contrast to CNS associated with diffuse mesangial sclerosis (DMS), in which patients usually have less severe proteinuria (Table 25.2). In addition to albumin, many other proteins are lost in the urine: immunoglobulin G (IgG), transferrin, apoproteins, lipoprotein lipase, antithrombin III (ATIII), ceruloplasmin, vitamin D-binding protein, and thyroid-binding globulin (17). The serum levels of these proteins and their ligands (e.g., thyroxine) are low, leading to secondary metabolic disturbances. The low thyroxine concentration leads to an increase in thyroid-stimulating hormone (TSH) (18). Low serum albumin and postheparin plasma lipoprotein lipase activities and high free fatty acid concentrations lead to hypertriglyceridemia. Total and low-density lipoprotein cholesterol levels are high, but high-density lipoprotein levels are low, and the low-density lipoprotein and high-density lipoprotein particles are enriched with triglycerides (17). These lipid abnormalities and arteriolar changes are seen already during the first year of life and may lead to an increased risk of arteriosclerosis (19). The characteristics of CNF are given in Table 25.2. Today, the diagnosis can be confirmed by the analysis of the *NPHS1* gene.

TABLE 25.1. CLASSIFICATION OF CONGENITAL AND EARLY-ONSET NEPHROTIC SYNDROME (NS)

Primary NS	
	Congenital nephrosis of the Finnish type
	Isolated diffuse mesangial sclerosis
	Denys-Drash syndrome
	Congenital NS with brain and other malformations
	Minimal-change NS
	Focal segmental glomerulosclerosis
	Membranous glomerulopathy
	Unclassified
Secondary NS	
	Infections
	Congenital syphilis
	Toxoplasmosis, rubella, cytomegalovirus
	Hepatitis, human immunodeficiency virus
	Malaria
	Systemic lupus erythematosus

Radiologic Findings

Saraga et al. reported ultrasonographic measurements in 20 children with CNF (20). Kidney size was normal in most patients during the first 2 months. The renal cortex was hyperechogenic, and the medullary pyramids were echolucent in two-thirds of cases. Corticomedullary differentiation was preserved. The central echo was merged with the surrounding cortical echoes in most kidneys, and the pelvic areas were normal.

Between 2 and 12 months, the size of the kidneys was above two standard deviations in all children, but with a normal outline. The renal cortex was hyperechogenic, corticomedullary differentiation had mostly disappeared, and the medullary pyramids were still echolucent. After 12 months, there was a decrease in kidney size, and the parenchyma was hyperechogenic, with loss of corticomedullary differentia-

TABLE 25.2. TYPICAL FEATURES OF CONGENITAL NEPHROSIS OF THE FINNISH TYPE (CNF) AND DIFFUSE MESANGIAL SCLEROSIS (DMS)

Features	CNF	DMS
Proteinuria, onset	Starts intrauterinely	Can start at birth, but mostly during first year of life
Amniotic fluid alpha-feto-protein	Always increased	Usually normal
Placenta	>25% of birth weight	Usually normal
Proteinuria, magnitude	Severe (>20 g/L with a serum albumin >15 g/L)	Usually less severe
Glomerular filtration rate	Normal during the first 6–12 mo	End-stage renal disease within months after presentation
Histology	Radial dilation of proximal tubules after 3 mo	Mesangial sclerosis contracting the glomerular tuft; tubular atrophy; interstitial fibrosis
DNA analysis	Mutations in the <i>NPHS1</i> gene	Mutations of the <i>WT1</i> gene in Denys-Drash syndrome and some cases of isolated DMS

tion. These findings correlate with the histologic changes showing increased dilation of proximal tubules at first and interstitial fibrosis and glomerular sclerosis later on.

Pathology

CNF kidneys are smooth surfaced, and the renal cortex is somewhat thicker than normal. In an autopsy series, the mean kidney weight was almost twice that of age-matched control children (21). Older patients had smaller, “normal-sized” kidneys, probably because of atrophy and scarring of the renal parenchyma. Pathologic findings are confined to the renal cortex without medullary lesions. The changes are progressive with age, from occasional dilated tubules in the fetal kidneys to severe tubulointerstitial and glomerular abnormalities at the age of 1 to 2 years (21,22).

In the fetal period, the CNF kidneys develop quite normally. At 16 to 22 gestational weeks, the glomeruli show few changes by light microscopy, but occasional dilated tubules are seen in most cases (23,24). The dilations contain bright, eosinophilic, colloid material, and the epithelium is low and cuboidal. By electron microscopy, the mature glomeruli show effacement of podocyte foot processes and irregular foot processes. The slit pores between the foot processes are of various sizes, and the filamentous image of the slit diaphragm is completely missing in cases with severe *NPHS1* mutations (25). It is remarkable that also carriers of *NPHS1* mutations can have these “proteinuric” changes, making the pathologic diagnosis difficult (26).

The pathologic changes are subtle by light microscopy during the first month. The glomeruli show a slight to moderate mesangial cell proliferation. Irregular microcystic dilatations of proximal tubules are inconstantly found on renal biopsy specimens (Figs. 25.2 and 25.3). Thick-walled small arteries and fetal glomeruli are present, but they are also seen in normal kidneys of this age group. Electron microscopy shows effacement of foot processes (Fig. 25.4)

and a thin glomerular basement membrane (GBM), which is already evident in the fetal kidneys (27).

Biopsies taken 3 to 8 months after birth usually show the most characteristic changes of CNF. Numerous radial dilations of the tubules are the most obvious feature (Fig. 25.2B). The glomeruli show moderate mesangial hypercellularity, but some degenerative changes, such as shrinking of the glomerular tuft, fibrotic thickening of the Bowman’s capsule, and glomerular sclerosis, become evident (Fig. 25.3A). Interstitial fibrosis and scattered lymphocyte infiltrates begin to develop (14). The proportion of sclerotic and ischemic glomeruli increases. Some tubular dilatations increase in size, and their epithelium becomes atrophic. Interstitial fibrosis and inflammation increase.

Genetics

NPHS1 and Nephtrin

CNF is inherited as an autosomal recessive trait (6). The gene responsible for most CNF cases has been localized to chromosome 19q13.1 (28) and named *NPHS1* (2). It has a size of 26 kb and contains 29 exons. *NPHS1* codes for nephtrin, which is a 1241-residue, cell adhesion protein of the Ig family (Fig. 25.5). The extracellular part of nephtrin contains eight Ig-like modules and one fibronectin type III domain. The intracellular domain has no significant homology with other known proteins but it has nine tyrosine residues, some of which may become phosphorylated during ligand binding. The expression of nephtrin was first reported to be restricted to glomerular podocytes (2). Recent studies on the *NPHS1* promoter have confirmed this localization (29,30). The data obtained from mice, however, suggest that nephtrin is also expressed in some areas of the central nervous system (e.g., cerebellum and spinal cord) and in pancreatic beta cells (31). The tissue expression of nephtrin in humans is not clear. Pancreatic expression of nephtrin has been reported (32), but our

results suggest that nephrin expression in humans is restricted to the glomerulus (33).

NPHS1 Mutations

Sequencing the *NPHS1* coding region has revealed two important mutations in more than 90% of the Finnish CNF patients (2). The first mutation, a 2-base pair deletion in exon 2, causes a frame shift resulting in a stop codon within the same exon (Fin-major mutation). The second is a nonsense mutation in exon 26 (Fin-minor). Fin-major leads

No SD or nephrin is seen.

to a truncated 90-residue protein, and Fin-minor leads to a truncated 1109-residue protein. In addition to Fin-major and Fin-minor, a few missense mutations in the Finnish patients have been found (8). The uniform mutation pattern seen in the Finnish population can be explained by the founder effect.

Several reports on *NPHS1* mutations in non-Finnish patients have been published (8–12). The patients come from Europe, North America, North Africa, the Middle East, and Asia. In contrast to the Finnish patients, most non-Finns have “individual mutations.” These include deletions, insertions, nonsense, missense, and splicing mutations spanning over the whole gene. For the moment, more than 60 mutations in *NPHS1* have been identified (Fig. 25.6). Missense mutations are all located within the extracellular part and cluster to exons coding for the Ig-like motifs two, four, and seven (8,11,12). The Fin-major and

FIGURE 25.5. The structure of nephrin. The protein is a transmembrane cell adhesion receptor with small intracellular and a larger extracellular domain. The extracellular domain contains eight immunoglobulin-like modules (circles) and one fibronectin type III-like domain (hexagon) adjacent to the transmembrane domain. Nephrin is a major component on the podocyte slit diaphragm.

Fin-minor mutations are rare outside Finland. Enrichment of other mutations has been reported also in non-Finns. In Mennonites, the 1481delC mutation is common and leads to a truncated protein of 547 residues (9). On the other hand, a homozygous nonsense mutation R1160X in exon 27 has been found in all Maltese cases (12). Importantly, 6 of the 16 cases with this mutation had an atypically mild disease. The same mutation has been reported in six French CNF patients, and two of them had mild disease (34).

Congenital Nephrotic Syndrome of the Finnish Type Not Caused by *NPHS1* Mutations

In the report of Lenkkeri et al. (8), no mutations in *NPHS1* were found in 7 out of the 35 patients (20%) with classical CNF. Mutations may lie on important regulatory elements, which are not known yet, but it seems that *NPHS1* mutations are not the only cause of CNF. Koziell et al. (12) found no *NPHS1* mutations in 8 of 37 CNF cases. In two of these eight patients, mutations were found in the *NPHS2* gene, coding for another podocyte protein, podocin. Mutations in *NPHS2* normally lead to a recessive form of focal segmental glomerulosclerosis (FSGS) appearing later in life (35). Koziell et al. also reported three cases of CNS patients who had mutations both in *NPHS1* and *NPHS2*, indicating a functional interrelationship between the two genes (12). These patients showed FSGS on renal biopsy.

Pathogenesis

Normal Glomerular Filter

Sieving of the plasma occurs in kidney glomeruli through the capillary wall (glomerular filtration barrier). This barrier is composed of three layers: a fenestrated endothelium, the GBM, and visceral epithelial cells (podocytes) (3,36). The podocytes enclose the capillaries in a comb-like fashion, where the adjacent “spikes” (foot processes) form an interrupted sheet around the capillaries. The foot processes are connected just above the GBM by an extracellular structure, the slit diaphragm (Fig. 25.7). This structure bridges the filtration pores between the adjacent podocyte foot processes, and, by electron microscopy, it is seen as a

FIGURE 25.6. The *NPHS1* gene contains 29 exons (bars) at a size of 26 kb. For the moment, 65 different mutations have been reported in congenital nephrotic syndrome of the Finnish-type patients. These include 32 missense mutations, 11 deletions or insertions, 14 nonsense mutations, and eight splice-site mutations. In addition, nine amino acid changes without known phenotype effect and nine polymorphic changes have been detected. See text for references. [■], missense; [▼], deletion/insertion; [●], polymorphism; [↑], splice site; [★], nonsense; [◆], amino acid change without known phenotype effect.

thin line connecting the cell membranes. The filter serves both as a size-selective and a charge-selective sieve. It is believed that the GBM restricts the passage of macromolecules especially according to the charge, whereas the slit diaphragm forms a size-selective filter (36,37).

Immunoelectron microscopy revealed that nephrin was localized at the slit diaphragm area of human kidney glomerulus (38). Later, this localization was confirmed in mouse and rat (39–41). A hypothetical model was presented in which nephrin molecules from adjacent foot processes show a head-to-head assembly through homophilic interactions and form a backbone of the slit diaphragm (3,38). Recently, this model has been modified with other molecules such as NEPH1 and FAT interacting with nephrin in the slit diaphragm (42–44).

Slit Diaphragm in Congenital Nephrotic Syndrome of the Finnish Type

The Fin-major and Fin-minor mutations of the *NPHS1* gene lead to a complete absence of nephrin in the CNF kidney glomerulus (14). These kidneys also totally lack the filamentous image of podocyte slit diaphragms as studied by electron microscopy (Fig. 25.4). Similarly, nephrin knock-out mice, dying of severe proteinuria soon after birth, lack the slit diaphragm filaments by electron microscopy (31). These findings indicate that the absence of nephrin leads to distortion of the slit diaphragm and the leakage of plasma proteins into urine through the “empty” podocyte pores. Liu et al. (45) have shown that many missense *NPHS1* mutations seen in non-Finnish CNF patients lead to misfolding of the nephrin molecule and a defective intracellular nephrin transport in the podocyte. This most probably explains why even “mild” (missense) mutations cause heavy proteinuria and a typical clinical disease (12).

Role of Podocytes

It has become evident that podocytes play a crucial role in glomerular filtration (37,46,47), and mutations in genes coding for the other podocyte proteins probably lead to disorders resembling CNF (Fig. 25.7). Mutations in the gene coding for alpha-actinin-4 cause NS in humans (48), and

lack of CD2-associated protein causes NS in neonatal mice (49,50). Nephrin, podocin, NEPH1, and CD2-associated protein are known to interact with each other and the actin cytoskeleton of the podocyte foot process, and defects in this interplay may cause proteinuria (37,43,51,52). Under-

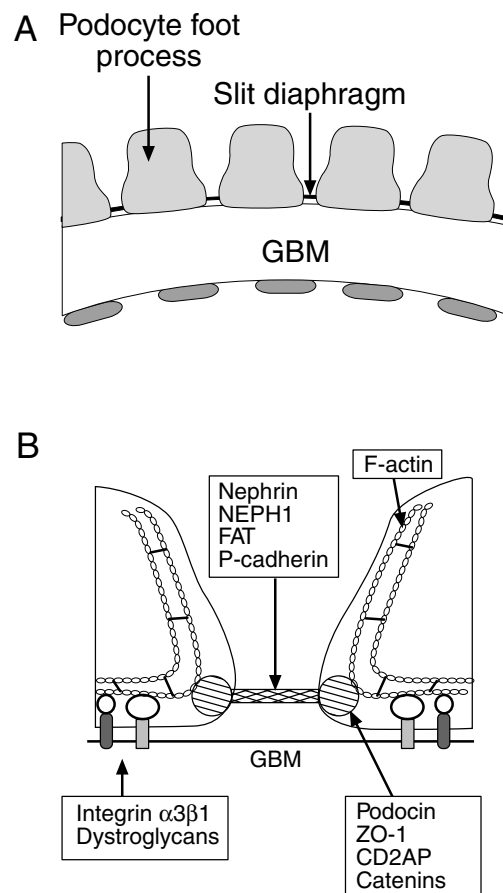

FIGURE 25.7. **A:** The structure of the glomerular capillary wall. The podocyte foot processes are connected by slit diaphragms. **B:** A model of the podocyte foot processes showing some of the known components of the slit diaphragm and the intracellular attachment proteins. The interplay between the different components is important in restricting the passage of plasma proteins into urine. GBM, glomerular basement membrane.

standing of the glomerular filtration barrier and its components is increasing rapidly, and it is to be expected that new “NS genes” will be identified in the near future.

Prenatal Diagnosis

Proteinuria in CNF starts *in utero*, and the measurement of alpha-fetoprotein (AFP) in the amniotic fluid and maternal serum has successfully been used for prenatal screening for CNF and in families with a previous CNF diagnosis (53,54). Fetal serum contains high levels of AFP, and leakage of fetal plasma proteins into amniotic fluid and further to maternal serum occurs in CNF as well as in neural tube defects. Elevated AFP levels and normal ultrasonographic findings of the fetus are considered diagnostic for CNF.

Amniotic fluid AFP levels exceeding five multiples of the normal median have traditionally been regarded as pathologic. The problem, however, is that heterozygous fetus carriers of *NPHS1* mutations may have elevated values (up to 50 multiples of the normal median) and a false-positive result in the AFP test (26,55). This may lead to termination of pregnancy on false grounds. The temporary proteinuria in carrier fetuses is also associated with tubular microcysts and podocyte foot process effacement (26). Thus, the differentiation of affected and carrier fetuses is quite difficult. In affected cases, the amniotic fluid AFP levels stay highly elevated, and repeated measurements of AFP levels during the second trimester are strongly recommended before making the diagnosis.

Analysis of *NPHS1* from placental biopsies or amniotic fluid cells is the method of choice for a precise diagnosis of CNF (2). In the Finnish population, analysis of the two major mutations is feasible. This is the case also when the disease-causing mutations are known in a family and can be specifically searched. If a fetus (without a family history of CNF) is suspected to have CNF based on elevated AFP values, sequencing of *NPHS1* is also possible, but due to the large size of the gene (29 exons) the analysis of the whole gene is time consuming and may not be done fast enough. *NPHS1* is mutation-rich and in almost all families, individual mutations have been found. In a case of missense mutation, a large number of control samples must be analyzed to find out if the amino acid substitution is a polymorphic change or a disease-causing mutation.

Management of Congenital Nephrotic Syndrome

The therapeutic decisions should usually aim at renal transplantation, which today is the only “curative” therapy in most cases (56). Immunosuppressive therapy with steroids or cyclophosphamide is not effective (1,57). The goals are to provide good nutrition, control edema, and prevent thrombosis and infections, allowing the child to reach a weight and body size allowing a successful kidney trans-

plantation (58–60). With optimal therapy, growth and development are satisfactory, and after the first months patients can spend the daytime at home and receive their nightly albumin infusions in the hospital.

Antiproteinuric Medication

A clear reduction of protein excretion with captopril and indomethacin in CNF patients has been reported (61–63). On the other hand, Birnbacher et al. found that captopril had no effect on protein excretion in their patients (64). In our experience, patients with the Fin-major and Fin-minor mutations do not respond to captopril or indomethacin. Both of these mutations, as well as many of the missense mutations, lead to a situation in which no nephrin is expressed on the podocyte surface (14,45). In such cases, this therapy is probably not effective. On the other hand, if an *NPHS1* mutation leads to a single amino acid change and quite normal nephrin expression, a reduction in the protein excretion may be observed (14). Thus, treatment with angiotensin-converting enzyme inhibitor and indomethacin is worth trying in cases in which the *NPHS1* mutations or their biologic effect are not known. A kidney biopsy with immunohistochemistry of nephrin and electron microscopic evaluation of the podocyte slit diaphragm may help in making the decision of the treatment strategy.

Albumin Substitution

Proteinuria without substitution leads to protein malnutrition, reduced growth, and secondary symptoms of hypoproteinemia (15). Mahan et al. (56) first reported good results in CNS with a high-energy (120 kcal/kg/day), high-protein (3 to 4 g/kg/day), and low-sodium diet. Diuretics were given daily and intravenous albumin occasionally. Although this treatment substantially improved outcome, developmental delay and neurologic abnormalities were observed in 93% of the children, and all exhibited growth retardation. Broyer et al. (65) demonstrated substantial catch up growth with aggressive tube feeding in CNS, but their patients never reached the fourth percentile in growth.

Since the mid-1980s, we have adopted a more aggressive approach (15,17). Parenteral albumin infusions, 3 to 4 g albumin/kg/day, are started at birth. Indwelling deep-vein catheters are used from the age of 3 weeks. Albumin is given as a 20% solution together with intravenous furosemide (0.5 mg/kg). It is first divided into three or four 2-hour infusions, and after 1 month of age given as one infusion (over 6 to 8 hours) during the night. With this substitution, patients do not have substantial edema (15,17).

Nutrition

Patients with CNF should receive enterally 130 kcal/kg of energy and 4 g/kg of protein per day (in addition to paren-

teral albumin). Calorie intake is composed of 10 to 14% protein, 40 to 50% fat, and 40 to 50% carbohydrate. Rape-seed oil (10 to 15 mL) and fish oil (2 mL) are added to increase the ratio of monounsaturated and polyunsaturated fatty acids and the polyunsaturated to saturated ratio of the diet. The excess protein is given as a casein-based protein product and additional energy as glucose polymers. The daily water intake is 100 to 130 mL/kg (15). Many patients need a nasogastric tube to guarantee their energy intake. The children should also receive vitamin D₂ (2000 IU/day), vitamin E from the rapeseed oil (2.5 to 3.0 mg/day), and water-soluble vitamins, according to the recommended dietary allowances for healthy children of the same age. Supplementary magnesium (40 to 60 mg/day) and calcium (500 mg/day for patients younger than 6 months, 750 mg/day for patients 6 to 12 months, and 1000 mg/day for patients older than 12 months) are also given.

Additional Medication

Patients with CNF often have low levels of serum thyroid-binding globulin and thyroxine (66,67). McLean et al. (18) reported an increase in TSH in four of five patients with CNS and a positive response to thyroxine substitution. We have had a similar experience. Although serum thyroxine concentration is always low, TSH may be normal in the beginning but increases in most patients during the first months. Thus, we have adopted a policy of routinely giving thyroxine from birth, adjusting the dosage according to TSH.

Urinary excretion of plasminogen and ATIII is accompanied by increased levels of macroglobulin, fibrinogen, thromboplastin, and factors II, V, VII, X, and XII, contributing to hypercoagulopathy (68). Thromboses and severe coagulation problems have been reported in children with CNS (15,56,69), and the use of low-dose aspirin and dipyridamole therapy has been recommended (56). Our CNF patients are treated with sodium warfarin from 4 weeks of age, and no severe thrombotic complications have occurred since this therapy was commenced. Before surgical or vascular procedures, warfarin is stopped, and ATIII (50 IU/kg) is given to temporarily correct the ATIII deficiency.

Bacterial infections are a major complication in infants with CNF (7,56). Because of urinary losses of gamma globulin and complement factors B and D (70,71), nephrotic children are especially prone to infections caused by capsular bacteria, such as pneumococci, and prophylactic use of penicillin has been recommended (56). Ljungberg et al. retrospectively analyzed the incidence and type of infection in 21 infants with CNF during the first year of life (72). The infants had 63 verified and 62 suspected episodes of sepsis. The use of central venous lines had no effect on the incidence, and the prophylactic use of antibiotics or immunoglobulins did not reduce the incidence. Thus, we do not recommend prophylactic medication, but a high degree of suspicion of septic infections is warranted. The symptoms

are often vague and masked by signs of focal infections occurring at the same time. Antibiotic therapy should be started promptly on suspicion and should cover the major hospital strains of bacteria. Response to treatment is usually excellent. Because of the urinary loss of IgG, no vaccinations are given.

Unilateral Nephrectomy

Some centers have adopted a routine of performing unilateral nephrectomy to reduce protein losses (73,74). This decreases the need and frequency of the albumin infusions and may help in the everyday management. We propose bilateral nephrectomy and peritoneal dialysis at an early age to avoid the many problems encountered during the nephrotic stage. Prolonged NS is also accompanied by lipid abnormalities, which leads to vascular changes already during infancy (19).

Dialysis and Transplantation

Although normal growth can be achieved with optimal therapy during the nephrotic stage, the patients are still malnourished and hypoproteinemic (15,17). To optimize treatment, we perform bilateral nephrectomy and commence continuous cyclical peritoneal dialysis when the weight reaches 7 kg. The aim is to improve the child's nutritional state before kidney transplantation (56,75). While receiving continuous cyclical peritoneal dialysis, the patient's general condition improves, muscle mass increases, and catch up growth can be documented (75–77). Transplantation can be performed also preemptively, and the results are satisfactory (78,79).

The first report of successful kidney transplantation in CNF dates back to 1973 (80), and in 1984 Mahan et al. reported excellent results with kidney transplantation in 17 children with CNS (56). Two-year patient and graft survival was 82 and 71%, respectively. Twelve of 15 surviving children had normal school and social performances, although two attended special education classes. Since 1987, 56 CNF patients have received a transplant kidney in Finland. Patient survival at 5 years is more than 90%, and graft survival is approximately 80%, with a mean glomerular filtration rate of 67 mL/min/1.73 m². Mean height standard deviation score was –1.4 at transplantation and improved to –0.9 after 5 years. Less than 20% of the patients are receiving growth hormone therapy. A great majority (72%) of those who have reached school age attend a normal class. The early patients who experienced thrombotic complications have neurologic handicaps (81–84).

Recurrence of Proteinuria

In CNF patients, a special risk after kidney transplantation is the recurrence of NS, which may lead to graft loss

(85–89). Recent findings indicate that at least half of the patients with recurrence have circulating antinephrin antibodies, which most probably react against the glomerular filter and induce protein leakage (89). Recurrence of NS has occurred in 13 Finnish patients, and all of them have a severe Fin-major/Fin-major genotype. These infants produce antibodies against the “novel antigen” in the graft. Treatment of recurrence with steroids, cyclophosphamide, and plasmapheresis often leads to remission (85,86,89).

Isolated Diffuse Mesangial Sclerosis

The term *diffuse mesangial sclerosis* denotes NS associated with the histologic change of DMS of the renal glomeruli (90,91). DMS can be isolated (IDMS) or associated with additional anomalies, especially Denys-Drash syndrome (DDS). In Habib's material, 26 patients with DMS were isolated, and 14 were associated with DDS (91). IDMS often occurs in females, but male patients have also been described (92,93). An autosomal recessive inheritance has been suggested in some cases (91,94,95). Mutations in the Wilms' tumor gene (*WT1*) have been described in children with IDMS (92,96). Recently, Yang et al. (97) described decreased podocyte expression of *WT1* and strong expression of *PAX2* in most IDMS patients, suggesting that one of the genes implicated in the cascade of *WT1* regulation (e.g., *PAX2*) could be involved in IDMS.

Pathology

The pathologic changes of DMS are characteristic (98). In the early phase, the glomeruli show increase of the mesangial matrix and podocyte hypertrophy. Then, the GBM becomes thickened, and the expanded mesangium shows a delicate PAS-positive mesh with embedded mesangial cells. The mesangial expansion and sclerosis causes obliteration of the capillary lumens and, finally, the contraction of the glomerular tufts. There is no cellular proliferation during the progression of IDMS, but a single layer of large podocytes often covers the sclerotic tufts (Fig. 25.3). A corticomedullary gradient of affected glomeruli is often present, the deepest glomeruli being the least affected. Tubulointerstitial lesions include atrophic tubules and interstitial fibrosis. Dilated tubules are also seen, but this feature is not as pronounced as in CNF.

By electron microscopy, the abundant mesangial matrix often contains filaments and collagenlike fibrils, and the GBM is thickened (98,99). Immunohistochemical analysis of DMS glomeruli shows deposits of disorganized collagen components and heparan sulfate proteoglycan, and absence of laminin and collagen IV in the hyalinized glomerular segments (100). There are no significant immune deposits, although some studies have shown variable amounts of

IgM, C1q, and C3 in the mesangium or in the periphery of the glomeruli (91,94).

Clinical Features and Management

The pregnancy and delivery are usually normal, and the size of the placenta, when recorded, has been normal with rare exceptions (101). Proteinuria can manifest in the first 3 months of life, but it is more often detected later in infancy (96,101). Proteinuria is often moderate, and in contrast to CNF, the patients develop progressive renal insufficiency and end-stage renal disease (ESRD) within a few months or years (Table 25.2). A large proportion of patients develop hypertension.

Steroids and other immunosuppressive drugs are ineffective in IDMS. Early treatment is similar to that which has been outlined for CNF, but with less aggressive protein substitution. Renal transplantation is the only curative treatment of this disease.

Denys-Drash Syndrome

The triad of Wilms' tumor, male pseudohermaphroditism (XY), and progressive glomerulopathy is known as *DDS* (102,103). It often presents as congenital or early-onset NS, but the onset may range from the newborn period to childhood (91,104,105). The characteristic glomerular lesion is DMS.

Genetics

DDS is caused by mutations in the *WT1* gene, which is located at chromosome 11p13 and encodes a transcription factor of the zinc-finger family (106,107). Alternative splicing produces four transcripts of *WT1*. *WT1* expression is important for normal fetal differentiation of the kidney and urinary organs (108,109). Heterozygous, *de novo* germline mutations in *WT1* are observed in nearly all patients with DDS. More than 60 mutations have been reported. Most are missense mutations in exons 8 and 9, encoding zinc-fingers 2 and 3 (110,111). The most prevalent is R394W located at zinc-finger 3. Also, deletions, insertions, and nonsense mutations that lead to a truncated protein have been described in DDS patients (93,111). Frasier syndrome, which is characterized by focal glomerular sclerosis, delayed kidney failure, and male pseudohermaphroditism with complete gonadal dysgenesis, is caused by point mutations in the donor splice site in intron 9, resulting in the loss of the +KTS isoform (112).

Clinical Features and Management

DDS can be divided into three clinical categories: (a) genotypic males with all three abnormalities, (b) genotypic males with nephropathy and ambiguous external and/or

internal genitalia only, and (c) genotypic females with nephropathy and Wilms' tumor only (111,113). Male pseudohermaphroditism characterized by ambiguous genitalia or female phenotype with dysgenetic testes or streak gonads is observed in all 46,XY patients. By contrast, all 46,XX children reported had a normal female phenotype with normal ovaries when the information was available. The nephropathy may precede the tumor (104,113,114).

The nephropathy begins with proteinuria and NS. In contrast to CNE, renal failure is often observed at presentation (111). Progression to ESRD before the age of 4 years is the rule. No correlation between the genotype and the severity of renal disease has been observed (115). Kidney transplantation remains the only therapeutic alternative, and favorable results without recurrence of DMS have been reported (97). Because of the risk of developing Wilms' tumor, prophylactic nephrectomy at the time of ESRD or transplantation is usually performed (113).

Other Primary Nephrotic Syndromes

In 1968, Galloway and Mowat (116) described two siblings showing congenital microcephaly, NS, and hiatus hernia. Several subsequent reports showing various brain malformations and congenital or early-onset NS have been called *Galloway-Mowat syndrome* (117). The classic Galloway-Mowat syndrome is an autosomal recessive disorder, but the disease-causing gene has not been isolated (118). In patients with CNS and brain malformation, the histologic finding may be DMS (119). In several reports, the renal histology is not fully described, but pathologic changes other than DMS have been reported (119–121). A wide variety of additional anomalies have also been reported in patients with CNS and brain malformation, including dysmorphic facial features (122–124). Other defects include ocular, limb, cardiac, and diaphragmatic anomalies (121,125). Ocular abnormalities have also been described in siblings with DMS (93,101). Oculocerebrorenal (Lowe) syndrome (126) and the nail-patella syndrome (osteochondrodysplasia) (127) have been shown to be associated in rare cases with CNS.

Idiopathic NS in the newborn is rare but becomes more common during the first year of life. Minimal changes or FSGS are more common (58,59,90,128) than diffuse mesangial hypercellularity or membranous glomerulonephritis (90,129). Diagnosis of minimal-change nephrotic syndrome (MCNS) in the very young infant may be difficult but is important because immunosuppressive treatment may be effective (130). MCNS in very young infants often carries a worse prognosis and shows more familial cases than MCNS in the older age groups (131). In some reports (132), clinicopathologic classification of congenital or infantile nephrosis has been difficult.

SECONDARY NEPHROTIC SYNDROMES

NS has been described secondary to some congenital and infantile disorders. Syphilis, toxoplasmosis, some viral infections, and the infantile form of systemic lupus erythematosus (SLE) are the most important secondary causes of congenital and infantile NS.

Infections

Congenital syphilis has long been known to cause CNS. It may cause a nephritic or nephrotic syndrome in the newborn (57). Proteinuria is common, but full-blown NS is less common. Hematuria is often present (133). NS may manifest in the newborn but is more often seen between 1 and 4 months of age (57,134). Syphilis causes a combination of glomerulonephritis and interstitial nephritis. Membranous glomerulonephritis appears to be common (135) and is a rare example of an immune complex-mediated glomerulonephritis in the newborn. Interstitial lymphocyte and plasma cell infiltration usually accompanies the glomerulonephritis. Antimicrobial therapy, usually penicillin, is curative, provided that irreversible renal lesions have not developed (136).

Toxoplasmosis has been associated with CNS in a few cases (137,138). Congenital rubella has been reported to cause CNS with membranous glomerulonephritis (139). An association of neonatal cytomegalovirus infection and CNS has also been reported (140,141). In these infections, manifestations other than NS lead to the correct diagnosis. Acquired immunodeficiency syndrome caused by the human immunodeficiency virus is associated with nephropathy, including NS (142). This disease usually affects children older than 1 year, but infants with nephropathy have been reported (143). Hepatitis B virus may cause membranous glomerulonephritis, and infants with NS associated with hepatitis B infection have been described (144).

Infantile Systemic Lupus Erythematosus

Although SLE is rarely diagnosed before 5 years of age, an infantile form of SLE has been reported (145–148). NS was the major clinical finding in five infants aged 6 weeks to 6 months with SLE. These patients had elevated antinuclear antibody titers, hypocomplementemia, and diffuse proliferative glomerulonephritis. Response to the immunosuppressive therapy was poor in many cases.

CONCLUSION

Congenital and early-onset NS forms a group of severe diseases, which so far have been mainly classified according to histology. The isolation of the *WT1*, *NPHS1*, *NPHS2*, and other podocyte genes will most probably lead to a new

CNS classification in the near future. If a child has proteinuria from birth and no signs of renal failure or extra renal malformations, the diagnosis of CNF is likely and can be confirmed by the analysis of *NPHS1*. If mutations in *NPHS1* are not found, sequencing of *NPHS2* may be indicated. On the other hand, analysis of *WT1* and *NPHS2* are indicated in infants with proteinuria and renal failure, especially if renal histology shows DMS or FSGS. Newborns and small infants with heavy proteinuria should have nutritional support and albumin substitution to guarantee normal growth and development. Antiproteinuric therapy with an angiotensin-converting enzyme inhibitor and indomethacin can be tried, especially in cases with CNF-type disease. In most CNS patients, renal transplantation is the only curative treatment, and patient and graft survival, as well as the quality of life of these patients, have greatly improved.

INHERITED GLOMERULAR DISEASES

MARIE CLAIRE GUBLER
LAURENCE HEIDET
CORINNE ANTIGNAC

Inherited glomerular disease encompasses a large number of various unrelated disorders. A tentative classification may be suggested, taking into account clinical, morphologic, pathogenetic, and genetic features (Table 26.1), but it is of limited value because of our incomplete knowledge of basic defects and pathogenesis of conditions. Glomerular involvement may appear as the primary defect, either isolated, as in the congenital nephrotic syndrome of the Finnish type, or as part of a genetically determined syndrome, as in Alport's syndrome. Glomerular lesions may develop secondarily as a consequence of inherited metabolic diseases such as diabetes mellitus or familial amyloidosis.

The incidence of hereditary glomerulopathies is probably under evaluated because of diagnostic difficulties. In fact, the differences in the observed incidence of hereditary nephropathies between groups probably depend on the extent of family investigations. In the pediatric series of Necker-Enfants Malades Hospital, inherited glomerulopathies are responsible for approximately 6.5% of end-stage renal failure (ESRF) occurring before the age of 16 years (1). According to the European Dialysis Transplantation Association registry, 15% of ESRF are due to hereditary glomerulopathies. Familial occurrence of glomerulopathies was observed by Waldherr in 7 to 8% of patients with biopsy-proven glomerulonephritis (2).

Since 1990, dramatic advances in molecular biology technology have led to an explosive growth in our knowledge of inherited disorders. New DNA-based diagnostic tests are possible when the disease genes have been localized or cloned. Recognition of the genetic nature of a given disease and its precise identification have become essential in offering patients and families the possibilities of accurate genetic counseling, presymptomatic testing, and prenatal diagnosis. However, in nephrology, and especially in pediatric nephrology, the gene defects responsible for several inherited conditions remain to be identified. The goal is now to precisely define the orphan syndromes on clinical, morphologic, and genetic criteria, this delineation being the first and obligatory step for further molecular genetic investigations and continuing progress.

STRUCTURE OF THE GLOMERULAR BASEMENT MEMBRANE

The glomerular filtration barrier consists of three layers: the fenestrated vascular endothelium, the glomerular basement membrane (GBM), and the podocyte slit diaphragm. The GBM is a highly specialized type of basement membrane (BM) (or basal lamina), between 310 and 380 nm in thickness in the mature human kidney, with a trilamellar structure composed of a thick lamina densa between two thin lamina rara. It plays an important role as a selective size and charge filtration barrier for macromolecules during the formation of primary urine.

As in every BM in the body, the major components of the GBM are type IV collagen, laminin, nidogen, and proteoglycans (3). Type IV collagen provides the structural framework and is responsible for the mechanical resistance of the BM and attachment of other glycoproteins. Laminin is involved in cell attachment, cell growth, and differentiation. Nidogen, which is always associated in equimolar proportion with laminin, seems to act as a connecting protein between laminin and type IV collagen. Heparan sulfate proteoglycans, the major proteoglycans present in the GBM, are characterized by strongly anionic heparan sulfate chains and are implicated in the charge-controlled macromolecular filtration through the GBM. Minor constituents found in the BM are osteonectin (BM-40, secreted protein, acidic and rich in cysteine), fibronectin, and amyloid P. In the mesangial matrix, the major BM components are associated with type VI collagen, chondroitin sulfate proteoglycan, fibronectin, and tenascin.

The structure of type IV collagen, the scaffold of the GBM, is interesting because of its implication in acquired and hereditary glomerular diseases. Type IV collagen belongs to the large collagen family, comprising 21 different types of molecules encoded by at least 32 genes. Each collagen molecule is formed of three α -chains folded together to form a triple helix. Specific features of type IV collagen are its length, 400 nm, and the persistence at its C-

TABLE 26.1. CLASSIFICATION OF INHERITED GLOMERULOPATHIES

1. Hereditary disorders of the glomerular basement membrane
 - Alport's syndrome and variants
 - Familial benign hematuria
 - Collagen type III glomerulopathy
2. Hereditary disorders of the podocyte
 - Finnish-type nephrotic syndrome
 - Familial steroid resistant idiopathic nephrotic syndrome
 - Familial focal and segmental glomerulosclerosis
 - Diffuse mesangial sclerosis
 - Hereditary onychoosteodysplasia: the nail-patella syndrome
 - Epstein/Fechtner syndromes
3. Hereditary metabolic disorders with primary glomerular involvement
 - Adolescent-type cystinosis
 - Fabry disease
 - Other lysosomal diseases with glomerular involvement
4. Hereditary metabolic disorders with secondary glomerular involvement
 - Diabetes mellitus
 - Sickle-cell disease
 - Familial amyloidosis
 - Alpha-1 antitrypsin deficiency
 - Various hereditary complement defects/factor H deficiency
 - Alagille syndrome
 - Lecithin cholesterol acyltransferase deficiency
 - Lipoprotein glomerulopathy
 - Type III hyperlipoproteinemia
 - Familial juvenile megaloblastic anemia
5. Other hereditary diseases associated with glomerular involvement
 - Charcot-Marie-Tooth disease
 - Cockayne syndrome
 - Hereditary acroosteolysis
 - Bardet-Biedl syndrome
 - Alström syndrome
 - Familial dysautonomia
6. Hereditary glomerulopathies without extrarenal symptoms
 - Familial lobular glomerulopathy/familial glomerulopathy with giant fibrillar deposits; "fibronectin glomerulopathy"
 - Other familial glomerulopathies
7. Mitochondrial cytopathies with glomerular involvement
8. Rare and "bizarre" syndromes
 - Hirooka disease
 - Galloway syndrome
 - Hunter disease
 - Barakat disease
 - Edwards disease
 - Matteo disease, etc.

terminal end of a noncollagenous (NC) 26- to 28-kDa globular domain, called NC (or NC1), which is a binding site between two type IV molecules. The other terminal domain, 7S, at the N terminus is the aggregation site for four molecules. In addition, frequent short interruptions in the repeated collagen-specific Gly-X-Y sequence are present in the type IV collagen chains and are responsible for the flexibility of the molecule. These features are the structural basis for the specific network organization of type IV collagen (3).

Six type IV collagen subunit components, the chains α_1 - α_6 (IV), have been identified, and their primary structure has been determined in human and for most of them in mouse (4,5). *COL4A1* and *COL4A2* genes coding for α_1 (IV) and α_2 (IV) have been cloned and mapped to the long arm of chromosome 13 as a contiguous group (6). They are the most abundant, have a ubiquitous distribution, and form heterotrimers consisting of two α_1 (IV) chains and one α_2 (IV) chain. Subsequently, two other chains, α_3 (IV) and α_4 (IV), have been identified, and their genes, *COL4A3* and *COL4A4*, have been located to chromosome 2 (7). Their complete sequence has been determined (8,9). The antigenic determinants responsible for autoimmunization in the Goodpasture syndrome have been localized to the 28-kDa NC domain of α_3 (IV) (10,11). The *COL4A5* gene was mapped to the Xq22 region, the locus previously assigned to the X-linked Alport's syndrome, making it a good candidate gene for Alport's syndrome (12-14). Subsequently, the gene *COL4A6* was assigned to the same region and shown to be located head-to-head to *COL4A5* (Fig 26.1) (15,16).

Immunohistochemical studies have shown that the α_1 and α_2 (IV) chains are present in nearly all BM. By contrast, the α_3 to α_6 (IV) chains have a selective distribution within specialized BM of the kidney, eye, inner ear, choroid plexus, and lung (17). Within the kidney, mesangial areas, Bowman's capsules, and extraglomerular BM are strongly stained with antibodies to the α_1 and α_2 (IV) chains, whereas restricted labeling of the GBM and of the distal tubular BM is obtained with anti- α_3 , - α_4 and - α_5 (IV) antibodies (18,19). The α_6 (IV) chain is absent in the GBM but is co-distributed with the α_5 (IV) chain in distal tubule and collecting duct BM and in Bowman's capsules (20,21). The

**FIGURE 26.1.** Schematic representation of the distribution of type IV collagen gene on chromosomes 13, 2, and X. bp, base pair.

FIGURE 26.2. Immunofluorescence microscopy. Normal distribution of the α (IV) chains in renal and epidermal basement membranes. (See Color Plate 26.2.)

α_5 and α_6 (IV) chains are co-distributed with the α_1 and α_2 (IV) chains in epidermal BM (Fig. 26.2). In the GBM, the α (IV) chains are organized into two separate networks, one containing α_1 (IV), and α_2 (IV) is restricted to the sub-endothelial side of the GBM, and the other, the major one, consisting of α_3 , α_4 , and α_5 (IV) chains, is distributed throughout the thickness of the GBM (17,18,22).

HEREDITARY DISORDERS OF THE GLOMERULAR BASEMENT MEMBRANE

Alport's Syndrome: A Hereditary Disorder of Basement Membrane Collagen

Classic Alport's syndrome (23) is an inherited renal disorder characterized by familial occurrence in successive generations of progressive hematuric nephritis, with ultrastructural changes of the GBM and sensorineural hearing loss. Ocular defects are commonly associated. Usually male patients have severe renal disease leading to ESRF before the fourth decade, whereas most female patients have a normal life span. Alport's syndrome has been reported in kindreds of all ethnic and geographic origins. Alport's syndrome is considered the cause of approximately 0.6 to 2.3% of ESRF in Europe and the United States (24–26). This proportion is probably underestimated because of diagnostic difficulties. The Alport's syndrome gene frequency is estimated to be 1 per 5000 to 1 per 10,000 (24).

Over the last 20 years, successive observations and findings have led to better comprehension of the renal and extrarenal manifestations of Alport's syndrome and to the identification of the new collagen IV genes, mutations of which are responsible for the disease. Questions raised by the phenotypic heterogeneity of the syndrome are partly explained by the genetic and molecular heterogeneity of the condition.

The mode of transmission of Alport's syndrome has long been debated, as shown by the many hypotheses pro-

posed to explain the transmission of the disease in the large Mormon family initially reported by Perkoff. The difficulty was essentially related to the insufficiency of the criteria accepted to identify affected subjects in the families. This problem has in large part been resolved because hematuria is considered an indispensable diagnostic criterion. With this condition, it has become clear that the disease was transmitted as an X-linked dominant trait in the "P" family (27).

Further family analyses have demonstrated the genetic heterogeneity of Alport's syndrome (24,28,29), with a particularly high frequency of dominant X-linked transmission (24). Autosomal dominant transmission confirmed by father-to-son transmission has been reported in some families with classic Alport's syndrome (28–30) or with progressive hematuric nephritis without deafness (31,32). Autosomal recessive transmission has been observed, especially in families with parental consanguinity and in which several siblings are affected and, regardless of gender, present severe Alport's syndrome, whereas parents are clinically unaffected (29). Last, in families having juvenile Alport's syndrome, the frequent absence of descendants from affected males makes it impossible to specify the exact mode of inheritance. Linkage studies using polymorphic markers situated on chromosome X have confirmed the frequency of X-linked dominant transmission and have allowed localization of the gene of the Alport's syndrome at Xq22 (33,34). Finally, identification of mutations in the *COL4A3* and *COL4A4* confirmed the genetic heterogeneity of the disease (see later).

X-Linked Alport's Syndrome

Clinical Presentation

First symptoms usually occur early in life, especially in males (35–38). In a group of 58 patients observed in a pediatric department, symptoms were detected before the

age of 1 year in 14% of the children and before the age of 6 years in 72% (38). In childhood, macroscopic or microscopic hematuria is the major presenting symptom (35–40) and may be observed at birth (38). However, the disease may be first discovered in adulthood in patients presenting with proteinuria-microscopic hematuria, with or without hypertension or renal failure. Alport's syndrome may be revealed by routine urinalysis or by family screening in mildly affected female patients.

Clinical and Laboratory Findings

Renal Disease

Microscopic hematuria is present in all patients and is usually persistent. It may be intermittent in some girls and in younger boys (38). Single or recurrent episodes of macroscopic hematuria are observed in approximately one-half of the patients, often within the 2 days after an upper respiratory tract infection. In our experience, these episodes are common during the first years of life and disappear after the age of 10 to 15 years. The duration of macroscopic hematuria usually varies from 1 to 10 days but in some instances may persist for months. Proteinuria is a common finding in males (36,38,41) but is not necessarily present in younger patients. It increases progressively with age, often exceeding 1 g/24 hours after 10 to 15 years, with development of nephrotic syndrome in approximately 40% of cases. Proteinuria is often absent, mild, or intermittent in affected females. Leukocyturia and pyuria are incidental findings.

Long-term follow-up varies according to the gender of affected patients and to genetic factors. Male patients progress to terminal renal failure. They follow a similar pattern of evolution: mild and intermittent proteinuria during childhood, then persistent and increasing proteinuria with possible development of nephrotic syndrome, hypertension, and renal failure. Depending on the rate of progression to ESRF, two types of the syndrome have been distinguished: (a) a progressive or "juvenile" type in which ESRF occurs around the age of 20 years, always before 31 years according to Atkin et al. (24), and the course is highly stereotyped within a given family (24,38); and (b) a "nonprogressive" (42) or "adult" type (24) in which age at ESRF is around 40 years, and the course is much more diverse, making individual prognosis impossible. By contrast, most female carriers have mild disease. Some of them progress to ESRF but usually at a slower rate than males (26,28).

Hearing Defects

Sensorineural hearing loss is bilateral. It is never congenital. In our experience, the initial hearing defect, at 2000, 4000, or 8000 Hz, is recognized by audiometry before the age of 15 years in 85% of boys and in 18% of girls (38). Serial audiologic studies of young males often demonstrate pro-

gression of hearing loss and extension to other frequencies. Involvement of the conversational zones leads to hearing difficulties necessitating hearing aids. In female patients, but also in some of the males affected with the "adult" type Alport's syndrome, stable and mild hearing defect is detected only by audiometry. The progression of hearing loss roughly parallels that of renal impairment (42). Partial hearing improvement reported after transplantation might be due to the suppression of the superimposed consequences of uremia on hearing.

Ocular Defects

Various types of ocular defects involving the lens, retina, and cornea have been described (44–48). The anterior lenticonus is a regular, conical protrusion on the anterior aspect of the lens. This lesion is not detected at birth and develops progressively over the years, almost exclusively in male subjects (38,46). With the exception of traumatic lenticonus, it is specific to Alport's syndrome. It has been observed in 25% of patients examined in a pediatric series (38) and in 33% of cases in an adult series (46). Lenticonus can be complicated by subcapsular cataract, without diagnostic significance, but possibly leading to loss of visual acuity. The microspherophakia reported by Sohar was in fact anterior lenticonus, as revealed by histologic examination of the lens (49).

Retinal changes are asymptomatic but more frequent, observed in 37% of patients (46). They are always present when there is anterior lenticonus. They consist of bilateral, densely packed whitish-yellow granulations surrounding the foveal area. They are superficially located in the retina. The fovea itself, whose reflection is suppressed, is dark red. These lesions are also specific. In the child, they can be difficult to identify because changes in pigmentation of the macula and disappearance of the foveola reflex precede the appearance of perimacular granulations (38). The anterior lenticonus and macular lesions, although inconstant, are reliable diagnostic criteria for Alport's syndrome. They are observed in juvenile forms of Alport's syndrome and seem to portend poor prognosis (46).

Nonspecific corneal lesions have been recently described in Alport's syndrome patients. They consist in posterior polymorphic dystrophy (47) and in recurrent corneal ulceration (48).

Clinical Variants of X-Linked Alport's Syndrome

Associated changes, including platelet abnormalities, esophageal leiomyomatosis, cerebral dysfunction, polyneuropathy, hyperproliferation, ichthyosis, and thyroid and parathyroid involvement, have been reported. They affect only a minority of kindreds. Except for two X-linked contiguous gene deletion syndromes, one resulting in esophageal leiomyomatosis, the other in the AMME (Alport syndrome, mental retardation, midface hypoplasia, and elliptocytosis) syn-

drome (50), most of these anomalies seem to be coincidental associations or complications of renal failure. On the other hand, the syndromes characterized by the association of platelet disorder and nephritis are not caused by type IV collagen deficiency.

Diffuse Esophageal Leiomyomatosis and Alport's Syndrome

The association of esophageal, tracheobronchial, and genital leiomyomatosis (with vulvar and clitoral enlargement), first described by Garcia-Torrès et al. (51), has now been reported in more than 30 families (52–54). These patients have typical X-linked Alport's syndrome, often of juvenile type, in which a notable factor is the frequent association of bilateral congenital cataract of particular severity and type. Esophageal involvement is responsible for dysphagia and may be recognized by radiologic investigations. Accidental deaths caused by tracheobronchic lesions occurring during surgical operations have been reported. Interestingly, diffuse leiomyomatosis is fully penetrant and completely expressed in females (52). Approximately 20% of children with esophageal leiomyomatosis should be affected with Alport's syndrome.

Hereditary Nephritis without Deafness

In some families, hematuric nephritis resembling adult-type Alport's syndrome progresses to ESRF without sensorineural hearing loss (even at the audiometric level) or any other extrarenal symptom (24,55). Whether these observations constitute a different entity or a variant of Alport's syndrome has been debated. Genetic studies have provided new criteria for classifying these syndromes.

Pathology

By *light microscopy*, renal findings are not specific. In young children, renal biopsy specimens show no abnormalities, although an increased number of immature glomeruli have been reported (35). With increasing age, the mesangium shows a mild and irregular excess in matrix with areas of segmental proliferation, and the capillary walls may appear thickened and irregular. Advancing glomerular disease is characterized by increasing mesangial enlargement and occurrence of segmental sclerosis and hyalinosis. Tubulointerstitial changes appear early. The presence of interstitial foam cells has often been considered as suggestive of Alport's syndrome, but these cells are seen in most types of chronic glomerulonephritis.

Conventional *immunofluorescent studies* of renal tissue are usually negative. However, granular deposits of C3 or traces of immunoglobulin M (IgM) may be observed in the glomeruli of some patients (38). In advanced cases, deposits of immunoglobulins along some GBM segments and deposits of IgM and C3 within segmental glomerular lesions are present.

FIGURE 26.3. Electron micrograph. Lead citrate and uranyl acetate stain ($\times 11,250$). Alport's syndrome. Thickened glomerular basement membrane showing splitting of the lamina densa and presence of granulations.

The characteristic lesions of the GBM were demonstrated by *ultrastructural studies* (41,56,57). These lesions associate irregular thickening of the GBM with splitting and splintering of the lamina densa, thus delimiting clear zones containing microgranulations (Fig. 26.3). The external aspect of the GBM is irregularly festooned and bordered by hypertrophied podocytes. GBM thickening is usually diffuse in the adult, whereas in the child it is segmental and a second anomaly—thinning of the GBM with occasional ruptures—is associated and may be predominant (Fig. 26.4) (37,38,58,59). Segmental thickening occurs early as it has been observed in renal biopsy specimens from children 1 to 5 years old (31,37,38,40,57). Semiquantitative studies have shown that the percentage of thick segments is higher in boys than in girls, and in boys it progressively increases with age and level of proteinuria (60). Thick and split GBM has been observed in patients with classical Alport's syndrome and with Alport's syn-

FIGURE 26.4. Electron micrograph. Lead citrate and uranyl acetate stain ($\times 4800$). Alport's syndrome. Thin and regular glomerular basement membrane (*arrow*) with attenuated lamina densa. Epithelial foot processes are extensively fused.

drome associated with leiomyomatosis (50,51). They have also been found in a few patients having progressive hereditary nephritis without deafness (31,40,56,60). In a family of Samoyed dogs, an animal model of Alport's syndrome, the GBM is normal at birth; thickening of the GBM and splitting of the lamina densa appear in the first weeks of life in the males, encompassing the whole GBM around the age of 3 months, whereas in the females the lesions remain segmental (61). Similar GBM changes were found in another canine family of Alport's syndrome (62).

The thick and split GBM lesion is specific (63). Its finding in children who have sporadic hematuria helps identify Alport's syndrome. However, this lesion can be absent, with the GBM appearing normal or presenting only nonspecific lesions (42,56,60,64) or uniformly thin (39,58,59,64,65). The GBM lesion can also appear late as reported in a family with progressive hematuric nephritis without deafness, in which lesions were observed in two brothers aged 19 and 21 years, 8 years after an initial renal biopsy that had shown normal GBM (32). Last, excessive thickening of the lamina rara interna without any change in the structure of the lamina densa has been reported in one of the families first described by Perkoff (66).

Concordance of ultrastructural lesions within families is usual. The lesion-associating thickening of the GBM and fragmentation of the lamina densa is both a marker in certain families and an index of severity (42,59). A few discordances have been reported. In a study of 100 patients—88 children and 12 adults belonging to 85 families with progressive hematuric nephritis with or without deafness—we found ultrastructural alterations of the GBM in all of them. The GBM was thickened and split in most of the patients having classic Alport's syndrome and thin in 10 of 14 patients having progressive hematuric nephritis without deafness. In 18 patients with classic Alport's syndrome, the GBM was uniformly thin (Fig. 26.3). In three of them, renal biopsy of another member of the family disclosed a thick and split GBM. On the contrary, in a large family in which seven affected members, aged 10 to 47 years, had been biopsied, the only GBM lesion observed was thinning. Thus, the existence of uniformly thin GBM in both the child and the adult is not always synonymous with benign familial hematuria and should be considered as a possible morphologic variant of Alport's syndrome (65).

In addition to GBM changes, focal thickening of Bowman's capsules and tubular BMs are observed. They are characterized by a marked bulging and splitting of the BMs delineating clear areas containing osmiophilic granules, lipid droplets, or vesicular formations. They are usually associated with the more severe GBM changes.

BM of retina and cochlea have not been studied by electron microscopy. Streeten et al. (67) demonstrated thinning and many dehiscences of the anterior lens capsule of patients with lenticonus. Epidermal BM was found to be

multilamellated in one family, but this anomaly has not been confirmed by other investigators.

Immunohistochemical and Immunochemical Anomalies

In 1976, McCoy described the lack of fixation of an anti-GBM alloantibody developed in a transplanted Alport's syndrome patient on the GBM of Alport's syndrome patients (68). This observation was confirmed by other investigators using the same type of serum or serum from Goodpasture patients. The anomaly suggested the absence or the modification of GBM structural antigen(s). This hypothesis was confirmed by biochemical and immunochemical studies of GBM prepared from Alport's syndrome end-stage kidneys showing the absence of NC peptides that were targets for anti-GBM antibodies (69–70). The Goodpasture epitopes were subsequently localized to the 28-kDa NC domain of the α_3 chain of type IV collagen (10,11).

Parallel to the studies on the α_3 (IV) chain, the Minneapolis group showed that the serum of one of their transplanted Alport's patients who had developed anti-GBM antibodies recognized a 26-kDa NC peptide different from the 28-kDa Goodpasture antigen and from the NC domain of the α (IV) collagen chains so far identified. This antigen had the same renal distribution as the α_3 and α_4 (IV) chains but was also present in the epidermal BM (EBM) of normal subjects (71). They suggested that this antigen would correspond to the NC domain of a fifth type IV collagen chain, α_5 (IV), and that anomaly in this chain would be the biochemical substrate of the Alport's syndrome (72), a hypothesis further confirmed by the identification of the *COL4A5* gene (12–14).

The distribution of α_1 – α_6 chains of type IV collagen in X-linked Alport's syndrome has been studied by several groups (19,20,43,73–77). In most, but not all male patients, no expression of α_3 (IV), α_4 (IV), α_5 (IV), and α_6 (IV) is detected in renal BMs, whereas the distribution of the chains is discontinuous in female patients, a finding consistent with the random inactivation of one X in each female cell. In contrast, α_1 (IV), α_2 (IV), and collagen type VI are overexpressed in the GBM (78). Both α_5 (IV) and α_6 (IV) are also absent from the EBM in males and have a segmental distribution in females (Fig. 26.5) (19,71,73,76,78) providing a simple approach for the diagnosis of X-linked Alport's syndrome. In a series of 78 patients—mostly children—with Alport's syndrome, the distribution of the α_3 – α_5 (IV) chains was abnormal in two-thirds of the patients with classic Alport's syndrome. On the contrary, in one-third of them and in eight patients who had hereditary nephritis without deafness, the distribution of the chains was normal in the GBM and/or the EBM. Two patients were studied in each of eight families, and the immunohistochemical results were concordant (43). Abnormal distribution of the α_3 , α_4 , and α_5 (IV) chains has been observed

FIGURE 26.5. Immunofluorescent microscopy. Distribution of the α (IV) chains in renal and epidermal basement membranes of male (A–C) and female (D–F) patients affected with X-linked Alport's syndrome. C: Absence of epidermal basement membrane labeling (arrow). F: Discontinuous epidermal basement membrane labeling (arrows). (See Color Plate 26.5.)

in anterior lens capsules of one of the two patients with Alport's syndrome and anterior lenticonus who underwent capsulectomy for cataract extraction (79). The group of patients with abnormal distribution of the α_3 – α_5 (IV) chains is of particular interest. This anomaly appears to be a marker of severe juvenile forms of Alport's syndrome because: (a) the thickened and split GBM indicating poor prognosis was observed in 36 of the 37 α_3 – α_5 (IV)–negative patients studied, and (b) all males belonging to α_3 – α_5 (IV)–negative families progressed to ESRF before the age of 30 years (43).

Affected animals in both models of canine X-linked Alport's syndrome display the same immunohistologic anomalies as in humans (61,62). In addition, in dogs without any clinical evidence of extrarenal involvement, antigens were absent from the specialized membranes of the eye and internal ear.

Mutations in the COL4A5 Gene: Molecular Heterogeneity of X-Linked Alport's Syndrome

As soon as it was identified, the *COL4A5* gene, localized at Xq22, became the candidate gene for the Alport's syndrome and, a few months later, the description of the first mutations confirmed this hypothesis (80). Thus far, more than 300 different mutations have been identified by different groups, corresponding to a detection rate of 40 to 80% according to the screening method.

Deletions or other major rearrangements (duplication, insertion/deletion, inversion) of *COL4A5* have been detected by Southern blot analysis in 5 to 15% of cases (81–83). Deletions vary in size and location, ranging from

the absence of a few exons to the complete absence of the gene, and involve various parts of the gene. They can result in total loss of expression of the gene, in a shortened α_5 (IV) chain, or in an aberrant gene product, within all cases a major effect on the organization of the collagen IV molecule and thus on the GBM structure.

All types of small mutations, distributed throughout the *COL4A5* gene, have been observed (80,84–94). Various consequences at the protein level may be expected from resulting changes in amino acid residues. The most common mutation found is glycine substitution by bulkier amino acid in the collagenous domain. It creates an interruption in the repeated collagen-specific gly-X-Y sequence and affects the formation of the triple helix. Removal of highly conserved cysteine in the NC domain could affect the correct conformation of the NC1 domain and influence the formation of the triple helix and of the intermolecular crosslinks (84). Nonsense mutations and small deletions or insertions resulting in a frame shift at the RNA level and in a premature stop codon lead to the synthesis of a putative truncated α_5 (IV) chain often lacking the NC domain. Splice site mutations are expected to alter the conformation of the protein or result in premature termination of the translation.

As indicated earlier, heterogeneity in the X-linked Alport's syndrome male phenotype has been documented widely. They are partly explained by the molecular heterogeneity of the disease. As shown in a European collaborative study, large deletions, nonsense mutations, or small mutations changing the reading frame confer to affected males a 90% probability of developing ESRF and hearing loss before 30 years of age, whereas the same risk is approx-

FIGURE 26.6. Immunofluorescent microscopy. Distribution of the α (IV) chains in renal and epidermal basement membranes of patients affected with autosomal recessive Alport's syndrome. (See Color Plate 26.6.)

imatively 50% for ESRF and 60% for hearing loss in patients with missense mutations (91).

At the protein level in most patients with a *COL4A5* mutation, there is a loss of the α_5 (IV) chains in BMs. A striking feature is the co-absence of the α_3 and α_4 chains of type IV collagen. The mechanisms resulting in such a configuration are controversial. It is now established that α_3 (IV) and α_4 (IV) mRNA are expressed in male patients affected with X-linked Alport's syndrome, and thus *COL4A5* mutations probably result in defective molecular assembly and subsequent proteolysis of the chains (95,96).

Deletions of *COL4A5* and *COL4A6* Genes in Alport's Syndrome Associated with Diffuse Esophageal Leiomyomatosis

No isolated *COL4A6* mutation has been found in Alport's syndrome patients. But deletions removing the 5' end of both *COL4A5* and *COL4A6* genes are observed in all patients with Alport's syndrome associated with diffuse esophageal leiomyomatosis (51–54). Interestingly, in all cases, the deletion involves only the first two exons of *COL4A6*, whereas its extent in *COL4A5* is variable. In contrast, patients with *COL4A5* deletions associated with a larger deletion in *COL4A6* are affected with Alport's syndrome without diffuse esophageal leiomyomatosis (53,54). Dramatic changes in the composition of myocyte extracellular matrix was observed in the tumoral tissue. They include the co-absence of the α_5 and α_6 (IV) chains contrasting with the high level of *COL4A6* transcripts, raising the question of a potential role for this RNA in the tumoral process (97).

Autosomal Recessive Alport's Syndrome

It is now recognized that 10 to 20% of Alport's syndrome patients are affected with the autosomal recessive form of the disease (29). Most features of the disease are identical to those observed in X-linked families. The nephritis usually progresses to early-onset ESRF, sensorineural hearing loss is often present, and ocular lesions, identical to those in X-linked families, may or may not be associated. Ultrastructural changes of the GBM in homozygotes are not distinguishable

from those seen in classic Alport's syndrome. By contrast, some features suggest autosomal recessive inheritance—consanguinity, severe disease in affected females, and mild or no symptoms in the parents. As in X-linked Alport's syndrome, the GBM antigenicity is normal in a minority of patients and abnormal in most of them (98). A peculiar pattern of α_3 – α_5 (IV) distribution has been identified: It is characterized by the co-absence of the 3 chains in the GBM and the presence of the α_5 (IV) chain in collecting ducts and EBM at places where the α_5 (IV) chain is not associated with the α_3 (IV) and α_4 (IV) chains (Fig 26.6) (98). Mutations of the *COL4A3* or *COL4A4* genes have been identified in autosomal recessive Alport's syndrome (8,9,88,99–102). The status of heterozygote carriers is highly variable. Most of them are asymptomatic or have isolated microscopic hematuria with thin GBM, which are typical features of familial benign hematuria (8,9). In rare cases, heterozygotes have a slowly progressive nephritis. Murine models of autosomal recessive Alport's syndrome have been developed by knock-out of the *COL4A3* gene (103,104).

Autosomal Dominant Alport's Syndrome

A few cases of autosomal dominant Alport's syndrome with or without deafness have been reported (28–32). The renal prognosis in male patients is significantly better than in X-linked Alport's syndrome (28). In 2000, a *COL4A3* splice site mutation was identified in a large Irish family with autosomal dominant inheritance. This finding completes the spectrum of type IV collagen mutations in all genetic forms of Alport's syndrome (105). An autosomal dominant nephropathy with GBM changes similar to those occurring in Alport's syndrome has been described in bull terrier dogs (106).

Kidney Transplantation in Alport's Syndrome Patients and Anti-Glomerular Basement Membrane Nephritis

Favorable long-term results have been observed in most Alport's syndrome patients who have undergone kidney transplantation (107–109). However, approximately 3% of transplanted males affected with Alport's syndrome develop anti-GBM glomerulonephritis (88,91,110). This

complication occurs within the first year after transplantation and leads to severe crescentic glomerulonephritis and subsequent graft loss. Patients are usually male and are affected with early-onset Alport's syndrome and deafness, progressing to ESRF before or around the age of 20 years. A few female patients, all affected with recessive Alport's syndrome, also developed anti-GBM nephritis (68,88,99,101,102), but this complication has not been reported in females with X-linked disease. Recurrence of anti-GBM nephritis on a second transplant is common (111–113).

Nearly all patients who developed anti-GBM nephritis carry large deletions of the *COL43* or *COL4A5* genes or premature stop codon predicted to result in absent or truncated proteins without the NC domain of the molecule (88,91,99,101,102,114,115). The risk for these patients of developing anti-GBM nephritis reaches 15% (91).

The production of anti-GBM antibodies after kidney transplantation is induced by the exposure of GBM antigens for which the patient has not established immune tolerance. These antibodies recognize the NC domain of type IV collagen chains (72,116). Several types of specificities have been observed. Most patients with the *COL4A5* mutation develop antibodies against the 26-kDa NC domain of $\alpha_5(\text{IV})$ (118), but antibodies against the $\alpha_3(\text{IV})$ NC domain have also been observed (116,117,120). The serum of patients with the *COL4A3* mutation recognizes the NC domain of the $\alpha_3(\text{IV})$ chain (102,118). In addition, transient linear IgG fixation along the GBM has been observed in approximately 15% of transplanted patients in the absence of crescentic glomerulonephritis (119). More recently, this abnormal fixation has been shown to be associated with the presence of circulating anti-GBM antibodies with a wide spectrum of reactivity to the α_3 , α_4 , and $\alpha_5(\text{IV})$ chains (120).

Factors other than the genetic defect are probably implicated in the occurrence of immunization, as suggested by the absence of anti-GBM posttransplant glomerulonephritis in most patients with major *COL4A5* mutations (43,88,91) and the intrafamilial discordance, with regard to the occurrence of GBM alloimmunization, observed in one family with a *COL4A5* deletion (82,113).

Diagnosis and Genetic Counseling

Diagnosis of Alport's syndrome is based on the finding of hematuria with or without proteinuria, hypertension, and renal failure in association with the following features: (a) familial hematuria, (b) sensorineural hearing loss present either in the proband or in one of the affected relatives, and (c) progression to renal failure occurring in at least one affected subject. Flinter et al. require one additional criterion—ocular changes or ultrastructural lesions of the GBM—for the diagnosis of Alport's syndrome (121). Diffuse esophageal leiomyomatosis and abnormal expression of

the α_3 , α_4 , and $\alpha_5(\text{IV})$ chains are other criteria (91). All hematuric patients fulfilling four criteria are actually affected with Alport's syndrome, but, from a practical point of view, diagnosis of Alport's syndrome is not always that easy. It has to be considered in every child who has persistent hematuria of glomerular origin, even in the absence of proven familial disease. The investigations to be performed are Addis counts in parents and siblings, regular audiograms, and ocular examinations seeking incipient anomalies (extrarenal symptoms are absent in very young children). Before performing renal biopsy, skin biopsy showing the absence or focal distribution of the $\alpha_5(\text{IV})$ chain in the EBM can be used for rapid identification of X-linked Alport's syndrome (78). Renal biopsy with immunohistochemical and ultrastructural studies of the renal specimen allows one to exclude glomerulonephritis and especially IgA nephropathy, another frequent cause of microscopic and macroscopic hematuria, in children. Thick and split GBM, and abnormal GBM distribution of type IV collagen chains, are specific markers of the disease. However, normal immunohistochemistry of the GBM and/or the finding of thin BMs do not eliminate the diagnosis of Alport's syndrome. We never observed normal GBM ultrastructure in children affected with Alport's syndrome. Transmission of the disease by asymptomatic female carriers in X-linked Alport's syndrome or autosomal recessive transmission may explain the absence of evident family history. Another possibility is the occurrence of a neo-mutation, which accounts for up to 18% of patients with the syndrome.

Correct identification of the mode of inheritance is necessary for genetic counseling. Affected and unaffected subjects should be identified, making it crucial to detect asymptomatic carriers. In X-linked dominant Alport's syndrome, affected fathers will transmit the disease to all their daughters and to none of their sons. Half of the children—of either sex—of affected mothers will be affected. In autosomal dominant Alport's syndrome, affected parents transmit the disease to 50% of their offspring; father-to-son transmission is characteristic for this mode of inheritance.

Presymptomatic and prenatal diagnosis by linkage analysis or by direct *COL4A5* study are now possible in previously tested and informative families. In these families, DNA testing may allow the precise identification of asymptomatic female carriers, which is important in view of possible kidney donation and for genetic counseling.

Prognosis and Treatment

The prognosis of Alport's syndrome nephropathy is poor: All males progress to ESRF. Hearing impairment, ocular changes, and family history of juvenile-type Alport's syndrome have an ominous significance. In an individual male or female patient, regular increase in proteinuria is the most accurate clinical symptom indicating a poor prognosis. The presence of glomerular, tubular, and interstitial changes by

light microscopy; the degree of GBM thickening and splitting; and the defect in GBM antigenicity are also indicative of severe disease. Severe *COL4A5* rearrangements are associated with juvenile-type nephritis.

The renal disease is progressive. However, recently, it has been shown that cyclosporin A could delay progression of ESRF (122). Angiotensin-converting enzyme inhibition decreases proteinuria and could also slow the rate of progression (123,124). Prospective controlled trials based on the precise clinical and genetic definition of the disease should be undertaken among larger series of patients to allow definitive conclusions. Also, therapeutic trials on animal models are now possible. Regular dialysis does not raise specific problems in Alport's syndrome patients. Most results indicate that posttransplant survival and renal function are as good as, or better than, in other groups of patients. The question of the selection of heterozygotes—asymptomatic or having isolated hematuria—as possible kidney donors is strongly debated (110). The development of anti-GBM glomerulonephritis in the transplanted kidney remains a rare possibility, but anti-GBM antibodies have to be sought in cases of rapid deterioration of kidney function.

Hearing loss has to be detected early and treated by hearing aid for a better comfort of the child and for preventing further degradation of the auditory center.

Familial Benign Essential Hematuria

Familial benign essential hematuria (FBEH) is defined by familial occurrence of persistent hematuria without proteinuria and without progression to renal failure or hearing defect. Diffuse attenuation of the GBM is usually considered the hallmark of the condition. However, thin GBM is not pathognomonic for familial benign hematuria. The incidence of this hematuric disorder has not been clearly evaluated. Recent data have shown that, at least in some families, type IV collagen is involved in the pathogenesis of the disorder (8,9,125).

Clinical and Laboratory Findings

Hematuria is often detected in childhood by routine urinalysis (58,59,126–128), but it may also be discovered in adults (129–131). It is usually microscopic and persistent. Episodes of gross hematuria have been reported, but we have never observed them in our series of patients. Clinical and laboratory investigations fail to disclose any other symptom: proteinuria is absent, there is no progression to renal failure, and no extrarenal manifestation.

Pathology

Few renal biopsies have been performed in this benign disease. By *light microscopy*, the renal tissue appears normal, except for the occasional presence of red blood cells within

tubular lumens. No specific deposits are detected by *immunofluorescence*; small granular C3 deposits may be seen on the flocculus or the arteriolar wall. Diffuse and extreme attenuation of the GBM was first described by Rogers et al. in a well-documented family; it was the only lesion detected at the *ultrastructural level* in the five biopsied patients aged from 19 to 51 years (132). This finding has been confirmed by further observations (2,58,65,126–128,130,131), but, in some patients belonging to families affected with FBEH, the GBM has been found normal (2,128). Thinning of the GBM is usually regular and diffuse, but focal attenuation, involving at least 50% of capillary walls, may be observed. The structure and contours of the GBM are normal.

There is a wide discrepancy among investigators concerning the mode of identification of “thin” GBM. It may be based on subjective evaluation of GBM thickness followed by measurements of representative GBM segments or on systematic, numerous, random GBM measurements leading to the establishment of average values. The definition of thin GBM also varies among groups. In the first study by Rogers et al., the average thickness of the GBM was 150 nm (132). GBM thickness was between 100 and 200 nm in most pediatric series (65,127,128). In adult series, the mean GBM thickness values leading to the diagnosis of thin GBM varied from 206 to 319 nm. Overlaps between “abnormal” values and normal values measured in controls are observed in some series. Immunohistochemical studies of the GBM gave normal results in all patients tested (46,65,130,134).

Genetic Transmission

FBEH is usually considered to be transmitted as an autosomal dominant trait. In the family extensively studied by Rogers et al., in which eight members with persistent hematuria have been identified in four generations, the disease is clearly inherited as a dominant trait, but the autosomal dominant inheritance proposed by the authors is not demonstrated in the absence of father-to-son transmission (132). Male-to-male transmission was observed in two out of ten families in our series and in some kindreds in the series recently reported (130,135). Recent data have demonstrated that some patients with “familial benign hematuria” have *COL4A3* or *COL4A4* mutations and consequently are heterozygotes for autosomal recessive Alport's syndrome (8,9,136,137). However, genetic linkage to these genes has been excluded in some kindreds (138,139).

Sporadic cases of benign hematuria with thin GBM have been reported by different groups. Further analyses are still necessary to elucidate their relationship to FBEH.

Diagnosis and Prognosis

FBEH, when diagnosed in hematuric children, implicates a favorable short-term and long-term prognosis. Diagnosis is

based on a series of negative symptoms (absence of proteinuria and of extrarenal involvement), on the results of family investigations demonstrating the absence of progression of the disease in adult males, and if necessary, on renal biopsy findings showing thin GBM with normal antigenicity. However, the distinction between FBEH and Alport's syndrome may be difficult, especially in young children. In both conditions, hematuria may be the only symptom. Thinning of the GBM is often prominent in children affected with Alport's syndrome and may constitute the only lesion, even in adulthood. Normal antigenicity of the GBM is observed in approximately 30% of Alport's syndrome patients. It is impossible to determine whether the course of the disease will be progressive or not when only adult females are affected in a kindred. In the absence of a pathognomonic marker, diagnosis of FBEH should be made with caution and reconsidered if proteinuria or extrarenal symptoms are detected in the proband or in family members during the follow-up.

Thin Basement Membrane Nephropathy

Thin GBM is frequently found in patients with FBEH, but the lesion that seems to represent approximately 11% of nontransplant renal biopsies in some groups (130) is not specific and is not the guarantee of benign disease. However, in recent years, various terms based on the ultrastructural finding of thin GBM have been used to describe, mostly in adults, the heterogeneous conditions characterized by hematuria and attenuation of the GBM (130,131,133) sometimes associated with proteinuria and progression to renal failure. The terms *thin glomerular basement membrane disease*, *thin basement membrane nephropathy*, *thin membrane nephropathy*, and *familial thin basement membrane nephropathy* are ambiguous because they suggest that the finding of thin GBM is a marker for a specific and common disorder with a uniformly good prognosis. In our opinion, thin GBM has to be viewed as a lesion and not a clinicopathologic entity. In children with this lesion, the diagnosis of Alport's syndrome has to be considered before any other possibility. The same ultrastructural lesion found in late adulthood in association with isolated microscopic hematuria probably has an overall favorable prognostic significance. However, substantial proteinuria and progression to ESRF have been reported in adult patients with thin GBM (131).

Hereditary Osteo-Onychodysplasia (Nail-Patella Syndrome)

Hereditary osteo-onychodysplasia (HOOD), or *nail-patella syndrome* (NPS), is a rare autosomal dominant disorder defined by the association of nail dysplasia, bone abnormalities, and renal involvement. Since the first description of the disease (140), more than 500 cases have been reported

in kindreds from all geographic origins. This curious association and the presence of fibrillar collagen within the GBM have suggested that HOOD could be an inherited connective tissue disorder. However, recently, *LMX1B*, a transcription factor involved in limb and renal development has been shown to be the NPS protein.

Dysmorphic Syndrome

The dysmorphic features were first described in 1897 by Little, who reported on a family of 18 members in whom nails and patellae were absent (140). Several reports followed, and the typical, bilateral, and symmetric involvement of the nails, knees, elbows, and pelvis were put forth by Mino et al. (141).

Nail involvement is almost constant: It has been found absent in only 6 of 147 patients, despite the presence of other elements of the tetrad (142). It predominates on the hands, where the thumb and the index finger are more severely affected. Lesions range from hemidysplasia to total nail aplasia. Common features are longitudinal pterygium and absence or triangular appearance of the lunulae. Nail dysplasia is usually visible from birth.

The *knees* are abnormal in 95% of cases. The patellas are hypoplastic or even absent. They have a tendency to dislocate laterally, producing difficulties in learning to walk in children and in climbing stairs in adults (143). In fact, the functional disability is usually limited, and the most frequent complications are knee pains, recurring patella dislocations, and early onset of arthrosis. The dysplasia may also involve other structures of the knee.

Elbow dysplasia was mentioned in 94% of cases. The radial head may be small and dislocated in a posterolateral position. Associated anomalies include deformities of the distal humeral extremity, hypoplasia of the olecranon, and elongation of the radial neck. These anomalies may lead to mild to severe limitation of extension, pronation, and supination of the forearm, especially in cases of webbing of the skin at the anterior aspect of the elbow joint.

The presence of *iliac horns*, usually discovered on plain film or intravenous pyelogram, was reported in 70.7% of cases. They are asymptomatic, bilateral, triangular, and symmetric formations arising from the posterior aspect of the ilium (143). In some cases, they may be detected by palpation through the buttock muscles.

Various other bone abnormalities have been described but are not contributive to diagnosis. According to the severity of the dysmorphic syndrome, HOOD may be discovered at various ages, but the notion of family history strongly contributes to its early recognition. Some severely affected neonates with clubbed feet are misdiagnosed as arthrogryposis. Mild forms of the disease may remain undetected over decades.

Abnormal pigmentation of the inner margin of the iris is seen in approximately 50% of patients, and recently open-

angle glaucoma has been recognized as an additional feature of the disorder (144).

Renal Involvement

Renal involvement was first reported in 1950 (145,146). Curiously enough, renal symptoms are not found in all patients or in all families. They seem to develop in approximately 30 to 40% of cases (142,147), but this evaluation is perhaps overestimated. Both genders are equally affected. The most common presenting feature is proteinuria with occasional nephrotic syndrome sometimes associated with microscopic hematuria.

Progression to ESRF occurs in approximately 30% of patients with renal symptoms. Cases of rapid evolution to renal failure have been observed in the pediatric population. In fact, we lack precise knowledge of the long-term renal outcome in HOOD. A surprising evolution has been observed in a neonate with typical deformities belonging to a severely affected family: Nephrotic syndrome was present at birth, but proteinuria disappeared within 2 weeks and was still absent 8 months later (147). A striking feature of the disease is the total unpredictability of renal prognosis, even within a given family. It is illustrated by a personal observation in which a child developed ESRF at 15 years of age, whereas his monozygote twin had only intermittent proteinuria at 27 years. This suggests that superimposed factors, which remain to be identified, may be implicated in the rapid progression of the glomerulopathy in some patients. Goodpasture syndrome, membranous nephropathy, necrotizing angitis, and IgA nephropathy have been observed in HOOD patients (142).

Pathology

Light microscopy is poorly contributive. The lesions of focal-segmental sclerosis, when present, are nonspecific and correlate with the severity of renal insufficiency. *Immunofluorescence* may show focal deposits of IgM and C3.

The specific glomerular lesion has been identified by *electron microscopy* (148). It is characterized by the presence of clusters of fibrillar collagen irregularly distributed within thick GBM segments and within the mesangial matrix. With standard staining techniques, the GBM and the mesangial matrix often have a “moth-eaten” appearance (149). Staining with phosphotungstic acid often is necessary to disclose the collagen bundles (Fig. 26.7). They have a fibrillar structure with a major periodicity of 40 to 60 nm, but, in some instances, no periodicity can be detected. The width of individual fibrils varies considerably. These lesions have been found within the GBM in all patients studied, mostly within the lamina densa (148,150–154). However, we could not detect any GBM collagen fiber in the first biopsy specimen from a child affected with HOOD and presenting with

FIGURE 26.7. Electron microscopy. Phosphotungstic acid stain ($\times 10,500$). Nail patella syndrome. Irregular distribution of fibrillar collagen within the glomerular basement membrane. Inset shows the typical periodicity of interstitial collagen ($\times 48,000$).

infantile nephrotic syndrome. The lesions were evident on the second renal specimen obtained 3 years later. By contrast, in the 2-year-old child reported by Browning et al. (154), diffuse thickening of the GBM was associated with focal sub-endothelial accumulation of fibrillar collagen. No tubular BM involvement has been described.

There is a curious lack of correlation between the severity and the extension of ultrastructural GBM lesions on one hand, and the patient's age, the severity of proteinuria, or even the degree of renal failure on the other. Typical lesions have been found in patients who were not proteinuric (162,164).

Immunohistochemical studies of the GBM using antibodies against the NC domain of $\alpha_3(\text{IV})$ gave conflicting results—normal labeling in three patients and no GBM labeling in two others (119). We detected type III collagen with an irregular mesangiocapillary localization and observed abnormal distribution of type VI collagen in glomeruli from several patients confirming the abnormal biochemical composition of the glomerular extracellular matrix.

Genetic Transmission: Mutations in the Gene LMX1B

HOOD is transmitted as an autosomal dominant trait. The gene located at 9q34 is closely linked to those coding for ABO blood groups and for adenylate kinase (155,156). Taking into account the absence of nephropathy in some kindreds, Lommen et al. suggested that there are two allelic mutations of the HOOD locus, one causing HOOD without nephropathy and one associated with the possible occurrence of nephropathy (157). The risks for affected parents of having a child with nephropathy, eventually leading to ESRF, should be different in these two types of families.

In 1998, *LMX1B* was shown to be the NPS gene by two groups using two different approaches. Positional cloning,

candidate gene approach, and identification of mutations were used by the first group (158). For the second group, the resemblance between the phenotypes in mice inactivated for the *Lmx1b* gene and in NPS patients suggested that *LMX1B* might be the NPS gene (159). Further studies confirmed this finding, and more than 100 *LMX1B* mutations have now been reported in NPS patients (160–164). *LMX1B* is a transcription factor belonging to the LIM homeodomain protein family playing an important role during development. It establishes dorsoventral patterning of the limb in which it is expressed in a temporally and spatially restricted manner (165). Mice with a homozygous deletion of the gene exhibit nail and skeletal defects similar to those observed in patients and GBM abnormalities and die within 24 hours after birth (165). The previously known function of *LMX1B* provides a satisfactory explanation for the occurrence of nail and skeletal anomalies in NPS patients (159). On the other hand, the recent demonstration of the early and persistent expression of *lmx1b* in the podocyte, and the role of the protein in the regulation of the expression of type IV collagen $\alpha 4$ chain and other podocyte proteins opened new avenues for the understanding of the NPS nephropathy (166–168). The expression of the $\alpha 3$ and $\alpha 4$ chains of type IV collagen is strongly reduced in the GBM of *Lmx1b*^{-/-} mice (166,168). Similarly, decreased expression of CD2AP and podocin—two markers of podocyte differentiation, responsible when mutated of proteinuria and nephrotic syndrome—was observed in *Lmx1b* null mice (167). Moreover, binding sites for *Lmx1b* were identified in both podocin and Cd2ap promoters and in an enhancer sequence in *COL4A4* intron 1 (166–168). These findings strongly suggest that defects in GBM type IV collagen and changes in podocyte phenotype contribute to glomerular disease in NPS. However, no renal symptom and no defects in the expression of these proteins were found in heterozygous mice.

Diagnosis and Treatment

As seen earlier, clinical diagnosis of nail-patella syndrome is easy and based on identification of the elements of the classic tetrad. At the ultrastructural level, the finding of collagen fibers within the GBM of nonsclerotic glomeruli is quite specific for the condition. One exception is the detection of similar lesions in a few patients without extrarenal anomalies of the HOOD series (see Collagen Type III Glomerulopathy).

Evolution of renal symptoms is unpredictable. No specific treatment is available. No recurrence of GBM lesions and no anti-GBM glomerulonephritis have so far been reported after kidney transplantation.

Collagen Type III Glomerulopathy

Massive accumulation of collagen fibers within the glomerular tuft has been reported in 22 patients with proteinuria

unassociated with extrarenal symptoms (169–177). The glomerulopathy has been termed *primary glomerular fibrosis* (172), *collagenofibrotic glomerulonephropathy* (174,177), or *collagen type III glomerulopathy* (173,175,176). The glomerular involvement was initially considered as being an incomplete, purely renal form of HOOD (169). However, analysis of morphologic, clinical, and genetic data strongly suggests that they represent a new type (or new types) of glomerulopathy.

Pathology

By *light microscopy*, glomerular lesions are peculiar, contrary to the lesions observed in most patients affected with HOOD. The glomerular tuft is significantly enlarged because of both expansion of the mesangial matrix and thickening of the capillary walls owing to accumulation of poorly stained subendothelial material. There is no significant increase in the number of mesangial cells. Conventional *immunohistologic studies* are negative or show segmental and focal deposits of various immunoglobulins and complement factors. Expansion of the mesangial matrix and of the subendothelial aspect of the GBM by a heterogeneous electron-lucent material is confirmed by *electron microscopic studies*. The most characteristic finding is the detection (after selective stainings) of bundles of collagen fibers accumulated within the expanded mesangium and the subendothelial space of the GBM. The lamina densa is usually normal. Thus, changes in the glomerular structure and distribution of the collagen fibers are different from those observed in HOOD. Antibodies to type III collagen are strongly positive on the glomerular tuft.

Clinical Data

The disease has been described in both genders and in patients aged from 1 to 70 years. Persistent proteinuria with or without nephrotic syndrome is observed in all cases and is often the presenting symptom. Microscopic hematuria and hypertension are inconstant. Anemia has been noted in several patients (174–177).

Concerning the progression of the disease, a striking difference appears between adult and pediatric series. Stable renal function or slow progression to renal failure is observed in most adult patients (174,175), whereas a protracted course to ESRF is frequently described in children (171,179).

Genetic Data

Family investigations were negative in most patients reported to date. In two adult patients (170,171), the family history of renal disease is consistent with dominant transmission of the condition (170). By contrast, autosomal recessive transmission of the disease was suggested in

the pediatric series on the finding of parental consanguinity, involvement of several siblings of both genders, and absence of renal and extrarenal symptoms in parents (171,175).

Further studies are necessary to clarify the actual incidence, the long-term evolution, and the basic mechanisms responsible for the massive overproduction of type III collagen. Of interest, in one young boy, collagen type III glomerulopathy was associated with autosomal recessive factor H (FH) deficiency (176), an inherited disorder possibly associated with the occurrence of glomerular lesions (see Factor H Deficiency). From a practical point of view, the typical ultrastructural and immunohistochemical anomalies have to be sought in proteinuric patients with atypical glomerular lesions that could mimic thrombotic microangiopathy of the glomerular type. Evaluation of C3 and factor-serum levels has to be systematically performed.

Hereditary Nephritis with Thrombopenia and Giant Platelets: Epstein/Fechtner Syndromes

The association of hereditary nephritis with macrothrombocytopenia (MTCP), first reported by Epstein et al. (178), has long been regarded as an Alport's syndrome variant. These authors studied two families with MTCP, deafness, and nephritis, a syndrome that appeared to be autosomal dominant. In Fechtner syndrome, patients are affected with nephritis and MTCP as well. However, they also display cataracts and small, pale blue cytoplasmic inclusions within the neutrophils and eosinophils that were not described in Epstein families (179). Leukocyte inclusions are also observed in two other autosomal dominant MTCPs without renal, ocular, or hearing defects: Sebastian syndrome and May-Hegglin anomaly.

The Epstein and Fechtner syndromes appear heterogeneous because of the variable severity of hematologic, renal, and auditory symptoms. Thrombopenia may be asymptomatic or responsible for hemorrhagic complications. Progression to ESRF is variable and does not generally occur before the fourth or fifth decade of life. It is absent in some families. On the contrary, rapid progression to ESRF during childhood has been reported (180). Early occurrence of deafness, particularly in females, is commonly observed. In addition, dissociation between the renal disease and the thrombopenia has been reported. Some males, both thrombopenic and deaf, who are obligatory transmitters of Alport's syndrome have no renal impairment (181), which is never observed in classic Alport's syndrome.

Renal histology shows variable and nonspecific abnormalities, including variable degrees of mesangial cell proliferation and mesangial matrix expansion and some tubular atrophy. Electron microscopy shows mesangial alterations, focal or diffuse effacement of podocyte foot processes, and alterations of the GBM. GBM lesions reminiscent of ultrastructural

GBM lesions observed in Alport's syndrome have been reported. However, GBM alteration in Fechtner and Epstein syndrome have mostly a focal distribution and, except from rare cases (180), are not specific of Alport's syndrome.

In 1999, the May-Hegglin anomaly, the Sebastian syndrome, and the Fechtner syndrome were shown to be genetically linked to chromosome 22q (182,183) suggesting that these three dominant MTCPs were allelic. Indeed, mutations in the *MYH9* gene, encoding the nonmuscle myosin heavy chain IIA, were subsequently identified in patients affected with one of these three diseases as well as in Epstein syndrome (184–186). This gene is expressed in the kidney from the early stages of nephrogenesis to adulthood, mainly in the podocytes and peritubular capillaries (186).

HEREDITARY METABOLIC DISORDERS WITH PRIMARY GLOMERULAR INVOLVEMENT

Fabry Disease

Anderson-Fabry disease is a rare X-linked recessive disorder of glycosphingolipid metabolism resulting from deficiency of the lysosomal hydrolase, α -galactosidase A (187). Clinical aspects of this disease are discussed in Chapter 50.

Characteristic glycolipid accumulation within every glomerular, vascular, and interstitial cell and within distal tubular cells has been observed in renal tissue from all hemizygous patients irrespective of their age at renal biopsy. In heterozygous females, a peculiar feature is the presence of two intermingled cell populations, one normal and one massively involved by the storage disease. Degenerative renal changes develop with age. They first affect vessels and are characterized by the presence of round fibrinoid deposits resulting from necrosis of smooth muscle cells. They are secondarily associated with nonspecific vascular, glomerular, and tubulointerstitial lesions (188). Of interest, the reported beneficial effect of enzyme replacement therapy seems to be linked to decrease glycolipid accumulation in the vascular endothelium (189).

Other Glomerular Lipidoses

Nephrosialidosis is a rare and severe form of oligosaccharidosis, or glucoproteinoses (previously classified as mucopolipidosis type I). The condition is inherited as an autosomal recessive trait and is caused by neuraminidase deficiency. The clinical and radiologic features of the disease include dysmorphic facies, visceral storage disease, severe mental retardation, skeletal abnormalities, foam cells in the marrow, and cherry red spot on funduscopy. A specific feature is the early occurrence of progressive glomerular symptoms leading to ESRF in the first years of life (190). Podocytes and proximal tubular cells show severe vacuolization. At the electron microscopic level, membrane-bound vacuoles look empty because of the loss of the stored material during fixation.

Glomerular symptoms are rare in other lipidoses (191). They usually are mild or absent in patients affected with *Gaucher disease*, an autosomal recessive condition in which the accumulation of glucosylceramide within monocytes-macrophages results from deficient activity of the lysosomal enzyme glucosylceramidase. Severe symptoms, proteinuria, and progressive renal failure have been described in only a few adult patients, most often after splenectomy. Large “Gaucher” cells with abundant, pale, faintly fibrillar cytoplasm have been observed in endothelial and mesangial position within glomeruli and also in the interstitium.

In *Niemann-Pick disease*, *I-cell disease*, and *GMI gangliosidosis*, silent accumulation of glycolipids or mucopolysaccharides within glomerular cells has been detected by examination of autopsy material (191).

HEREDITARY METABOLIC DISORDERS WITH SECONDARY GLOMERULAR INVOLVEMENT

Familial Amyloidosis

Hereditary amyloidosis encompasses a group of autosomal dominant disorders characterized by the extracellular accumulation of protein fibrils having β -pleated sheet conformation. They are now classified according to the type of protein composing amyloid fibrils and for some of them according to the type of mutation detected in the corresponding gene. Transthyretin variants have been found in most affected families, but systemic hereditary amyloidosis may be associated with variants of cystatin C, gelsolin, apolipoprotein A1, fibrinogen, or lysozyme (192). In hereditary amyloidosis, symptoms, usually of the neurologic series, develop during adulthood. Except for a few families with apolipoprotein A1, fibrinogen, or lysozyme variant, renal symptoms are not a prominent and early feature, but severe renal involvement may be observed in all types of familial amyloidoses and has an ominous significance.

Familial Mediterranean fever, an autosomal recessive disorder common in Mediterranean and Middle Eastern populations, especially in Sephardic Jews and Armenians, is characterized by recurrent episodes of fever, abdominal pain, joint pain, and less frequently, pleuritis or pericarditis. The prognosis of the disease depends on the development of amyloidosis of the AA type with prominent renal involvement. The gene involved in familial Mediterranean fever, designated *MEFV*, has been identified by positional cloning (193,194). Colchicine administration has been shown to reduce the number of attacks and to prevent amyloidosis (195).

Development of amyloid of the AA type occurs in other types of inflammatory disorders also characterized by recurrent attacks of fever with visceral, synovial, muscular, or cutaneous inflammation—the *Muckle-Well syndrome* and the *TRAPS syndrome* both transmitted on the autosomal dominant mode (196).

Alpha-1 Antitrypsin Deficiency

Alpha-1 antitrypsin (α 1AT) is a major serine protease inhibitor synthesized by the liver. The gene responsible for α 1AT deficiency has been localized on chromosome 14. α 1AT deficiency, phenotype ZZ, may result in emphysema in adults (review in 197). Renal complications are rare in these patients. Conversely, approximately 25 cases of glomerulonephritis have been described in α 1AT-deficient children with severe chronic liver disease (198–200), another possible and early complication of this autosomal dominant biochemical defect. Diffuse or focal segmental type I membranoproliferative glomerulonephritis was present in most cases, but diffuse endocapillary glomerulonephritis has also been observed. Immunofluorescence revealed the presence of immunoglobulins, often including IgA and complement components. The co-localization of PiZ protein with immunoproteins has been observed (200,201), but is not a constant finding (199). Expression of glomerular involvement varies from no disease to proteinuria, hypertension, and renal failure. Its severity roughly parallels that of renal lesions. A direct pathogenic link with α 1AT deficiency has been suggested based on the presence of granular α 1AT or PiZ subendothelial deposits and on the increased incidence of glomerular lesions in α 1AT-deficient patients compared with a controlled cirrhotic population (200). Regression of nephrotic syndrome and glomerular lesions has been observed after liver transplantation (201). In adults, association of α 1AT deficiency and systemic vasculitis, especially Wegener syndrome, has been described, suggesting involvement of the gene in the pathogenesis of these diseases (202).

Factor H Deficiency

Homozygous deficit in FH, a 150-kDa glycoprotein controlling the alternative pathway of complement activation, is usually responsible for increased susceptibility to infections. In several families, renal involvement consisting of atypical dense deposit disease, hemolytic uremic syndrome, or collagen type III glomerulopathy has been reported (203).

Dense deposit disease, observed in two brothers, was characterized by the early onset of glomerular symptoms, with recurrent macroscopic hematuria and the abundance of mesangial and parietal granular C3 deposits (204). FH deficiency has been shown in piglets with autosomal recessive dense deposit disease. The disease develops early after birth and progresses rapidly to ESRF. Transfusion of normal porcine plasma or injection of FH into affected pigs increases survival, demonstrating the role of FH deficiency and alternative complement activation in the pathogenesis of the disease (205).

Low C3 level has been described in several atypical, recurrent, and/or familial cases of *hemolytic uremic syndrome* and, recently, the role of FH deficiency and the identification of mutations of the FH gene have been reported by several groups (206–213). It appears now

that FH deficiency is one major cause of familial hemolytic uremic syndrome associated with a high risk of recurrence in renal allografts. Within families, a striking feature is the absence of correlation between the degree of FH deficiency and the presence and severity of renal disease.

Extensive deposition of *type III collagen* has been identified in a young patient with progressive glomerulopathy and FH deficiency; the relationship between the two abnormalities is still unclear (181).

Alagille Syndrome

Alagille syndrome, or *syndromic paucity of interlobular ducts*, is an autosomal dominant disorder with variable penetrance, recognized as a common cause of severe cholestasis in children. Liver abnormalities are associated with a peculiar facial appearance, cardiovascular malformations, butterfly-like vertebral arch defect, embryotoxon, hypogonadism, growth retardation, and high-pitched voice. The disease is caused by mutations in *Jagged1*, which encodes a ligand for the Notch1 receptor, implicated in cell differentiation (214,215). Glomerular lesions of variable severity have been observed in some patients (216). They are characterized by the presence of clear vacuoles containing osmiophilic material within the mesangial matrix and sometimes within the GBM. Mesangial foam cells may be associated (Fig. 26.8). The extent of mesangio-lipidosis is related to the degree of cholestasis and is probably a consequence of the resulting abnormal lipid metabolism. A striking feature is the early occurrence of these lesions during the first years of life in some patients contrasting with the paucity of renal symptoms. Progression to renal failure in adulthood may be a major complication for patients with this syndrome.

FIGURE 26.8. Electron microscopy. Lead citrate and uranyl acetate stain ($\times 8600$). Alagille syndrome. Massive accumulation of lipid vacuoles within mesangial cells and matrix. Irregular distribution of lipid vacuoles within the glomerular basement membrane.

Hereditary Lecithin-Cholesterol Acyltransferase Deficiency

Hereditary lecithin-cholesterol acyltransferase (L-CAT) deficiency, first described in Norway, is a rare autosomal recessive disorder characterized by an inability to esterify plasma cholesterol and by abnormal deposition of unesterified cholesterol in tissues, including the kidney (217,218). Progression to ESRF usually occurs in the fourth or fifth decade. Glomerular lesions resemble those seen in Alagille syndrome. They include accumulation of foam cells of endothelial and mesangial origin and massive deposition of lipids within the mesangial matrix and along the subendothelial aspect of the GBM (217). The *L-CAT* gene has been localized on chromosome 16, and different point mutations spread in all exons of the gene have been described in families of various geographic origins (218).

Lipoprotein Glomerulopathy

Lipoprotein glomerulopathy is a new type of renal disease characterized by intraglomerular lipoprotein thrombosis and high plasma concentration of apolipoprotein E. Since the first publication by Saito et al. in 1989 (219), numerous cases have been observed mostly, but not exclusively, in Japan (220–224). The disease, observed in both genders, usually is detected in adulthood; however, in some cases, first symptoms occurred in childhood (224). All patients have persistent proteinuria resulting in nephrotic syndrome in most of them. Some have mild to moderate proteinuria for a long period, whereas progression to ESRF has been observed. Transplantation has been followed by the recurrence of glomerular lesions (221,223). Curiously, systemic manifestations of lipidosis are consistently absent. The familial occurrence observed in some kindreds suggested a genetic basis for the disease, involving perhaps the isoform E₂ of apolipoprotein E. Actually, a variant of apolipoprotein E, apolipoprotein E Sendai, characterized by a missense mutation resulting in arginine-145 to proline substitution appears to be the most frequent mutation in the patients (222), but other mutations have been described (223).

Glomerular lipidosis has also been observed in patients with *familial hypercholesterolemia* resulting from defect in the receptor for low-density lipoproteins, in *type III hyperlipoproteinemia*, and in the rare cases of *cholesterolic polyco-ria*. In these diseases, clinical symptoms usually develop in adulthood.

Familial Juvenile Megaloblastic Anemia

Familial juvenile megaloblastic anemia, or *Imerlund-Gräsbeck syndrome*, is a rare autosomal recessive disorder caused by primary and selective vitamin B₁₂ malabsorption. Anemia appearing in infancy or early childhood is nearly always associated with mild and nonprogressive proteinuria, usually considered of glomerular origin. Minor and nonspecific

glomerular changes have been described by electron microscopy (225).

OTHER HEREDITARY DISEASES WITH GLOMERULAR INVOLVEMENT

Charcot-Marie-Tooth Disease

Charcot-Marie-Tooth (CMT) disease is a familial peripheral neuropathy resulting in progressive symmetric atrophy and weakness of distal muscles and sensory loss. Various clinical forms of the disease have been described according to nerve morphology and nerve conduction velocity, age at onset of symptoms, and presence or absence of associated symptoms. This clinical heterogeneity is explained by the genetic heterogeneity of the condition: Autosomal dominant, X-linked dominant, and X-linked recessive modes of inheritance have been described (226,227). In 1993, mutations in the myelin protein zero gene on chromosome 1, peripheral myelin protein 22 gene on chromosome 17 and connexin 32 on chromosome X were identified (228–230). Renal symptoms with focal glomerular sclerosis have been reported in a few patients and seem to segregate with the neuropathy in some families (231). They consist of long-standing proteinuria occurring in childhood or in adolescence, followed by rapid progression to ESRF. Because some of these patients are also deaf, CMT disease with renal involvement could have been considered a variant of Alport's syndrome. Deafness is a possible manifestation of peripheral involvement in CMT disease, and, except in one family with co-segregation of AS and CMT disease (232), no specific ultrastructural changes of the GBM have been observed in patients with CMT disease.

Cockayne Syndrome

Cockayne syndrome is an unusual autosomal recessive disorder. Characteristic symptoms are poor growth, neurologic abnormalities, premature aging, senile face, sensorineural hearing loss, cataracts, pigmentary retinopathy, sun sensitivity, and dental caries, as reported in a comprehensive review of 140 patients by Nance and Berry (233). Death occurs in most cases during the first or second decade. Increased cell sensitivity to the killing effect of ultraviolet radiation has been observed, caused by a specific defect in the DNA repair system. Renal symptoms consisting of hypertension, mild proteinuria, or renal insufficiency develop in approximately 10% of patients. The basic lesion seems to be diffuse and homogeneous thickening of the GBM (234,235). The syndrome is clinically and genetically heterogeneous (236).

Hereditary Acro-Osteolysis with Nephropathy

Hereditary acro-osteolysis is a rare disorder characterized by arthritis-like episodes and progressive resorption of carpal

and tarsal bones. Inherited, dominant or recessive, and sporadic cases have been reported. Hypertension, proteinuria, and progressive renal failure may occur in some patients (237). Arteriolar thickening and sclerosis and focal glomerulosclerosis are the usual histopathologic findings.

Other Syndromes with Renal Involvement

Renal involvement is nearly constant in *Biedl-Bardet syndrome* (BBS), an autosomal recessive disorder, the cardinal features of which are obesity, polydactyly, mental retardation, retinal dystrophy, and hypogonadism (238). The disease is genetically heterogenous. Six genes have been localized, and the first one has been identified (239). BBS is responsible for severe renal disease in 15 to 55% of patients, according to different series. Glomerular symptoms, such as proteinuria, as well as questionable glomerular changes, have been described in only a few patients. Actually, tubular dysfunction and abnormal kidney structure detected by urography are the main renal symptoms in BBS. Cystic kidney dysplasia and/or tubulointerstitial lesions seem to be the most consistent lesions in this disease (240,241).

Alström syndrome is a rare autosomal recessive disorder, the gene of which has been recently identified. It is characterized by the association of profound childhood blindness, nerve deafness, obesity, and diabetes mellitus and differs from BBS by the absence of mental retardation and polydactyly. It is considered a classic cause of proteinuria. However, primary glomerular involvement has not been demonstrated, and tubular dysfunction and tubulointerstitial lesions have been observed in the few patients studied (242).

In *familial dysautonomia*, an autosomal recessive neuropathy that occurs in the Ashkenazi Jewish population, renal involvement seems to be primarily vascular with secondary development of glomerulosclerosis (243).

HEREDITARY GLOMERULOPATHIES WITHOUT EXTRARENAL SYMPTOMS

Familial Lobular Glomerulonephritis/ Fibronectin Glomerulopathy: A Heterogeneous Entity?

Several familial cases of atypical lobular glomerulopathies have been reported (244–247). They were characterized by extensive subendothelial and mesangial deposits in which immunoglobulins and complement components were inconstant or lacking. Patients had persistent proteinuria, hematuria, and hypertension. Slow progression to ESRF or severe cerebral vascular complications (in one family) occurred around the third decade of life. The disease is transmitted as an autosomal dominant trait. Recently, strong reactivity of deposits to fibronectin derived from the plasma was shown in patients previously reported and in additional families (248–252). The names “fibronectin

glomerulopathy" or "familial glomerulonephritis with fibronectin deposits" were suggested for this glomerulopathy (220). However, the pathogenic significance of fibronectin deposition remains to be confirmed. It has been suggested that genetically altered fibronectin is trapped within the glomerular tuft, but fibronectin was excluded as a causative gene by linkage analysis in a large family (250). Linkage analysis of a large pedigree led to the localization of a gene at 1q32 (253).

The homogeneity of this new entity is not demonstrated. Clinical evolution varies between families with regard to the occurrence of cerebral vascular complications, progression to ESRF, evolution after transplantation, and ultrastructural appearance of deposits. One child developed nephrotic syndrome at 3 years of age (252). In some kindreds, deposits are homogeneous and granular with a restricted subendothelial and mesangial distribution (245, 248), whereas in others they are fibrillar (246,247,249) and also observed in subepithelial location (246). Of four patients from different families who were reported to have undergone kidney transplants, the disease recurred in one only (248,250).

Other Familial Glomerulopathies

A curious form of hereditary nephropathy has been described by Grottum et al. in 11 members of a large family (254). Persistent moderate proteinuria was abruptly followed by rapidly progressive renal failure, malignant hypertension, and microangiopathic anemia and thrombocytopenia occurring at the ages of 24 to 31 years (254). Diffuse vascular damages and ischemic glomeruli with IgM and C3 deposits were observed in all cases. A glomerular disease with a similar clinical course has been observed in another family. The presence of diffuse round mesangial deposits of C3 was the characteristic feature in this family (255). In both families, the disease appears to be autosomal dominant.

MITOCHONDRIAL CYTOPATHIES

Mitochondrial cytopathies are a heterogeneous group of diseases. They are due to genetic defects of one or several mitochondrial enzyme complexes that play a major role in oxidative phosphorylation and energy production. They have long been regarded as neuromuscular diseases only, but any organs dependent on mitochondrial energy supply may be affected by these disorders (256). For a long time, renal involvement was regarded as being rare, the most frequent manifestation, usually seen in children, being proximal tubulopathy manifested by a de Toni Debré Fanconi syndrome (257). More recently, several cases of glomerulopathy have been reported (257–273), and this expression is probably more frequent than initially thought.

Glomerular involvement has been initially described in three children who developed nephrotic syndrome with focal segmental glomerulosclerosis before the age of 5 years (258,259). These patients had mitochondrial cytopathies manifested by the association of myopathy, ophthalmoplegia, and deafness or pigmentary retinitis and hypoparathyroidism.

Since 1994, approximately 40 cases of glomerulopathies, initially isolated or associated with extrarenal symptoms, have been reported. The clinical presentation of the renal disease is nonspecific: occurrence of proteinuria at various ages between 1.6 and 35.0 years, progressive increase with age with eventual development of nephrotic syndrome, and variable rate of progression to ESRF. An important feature is the usual absence of hematuria. Steroid therapy is ineffective. Proteinuria was the revealing symptom of the disease in 12 patients aged 10 to 32 years who secondarily developed extrarenal symptoms. Proteinuria/nephrotic syndrome was also found in patients aged 17 to 34 years who have maternally inherited diabetes and/or deafness or, less frequently, complete or incomplete MELAS (*mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes*) syndrome. This observation led to the identification of the mitochondrial DNA MELAS mutation in most patients with mitochondrial glomerulopathy.

Focal and segmental glomerulosclerosis was observed in nearly all renal biopsies. An increased number of abnormal mitochondria of various shapes and sizes was found in podocytes by Hotta et al. (271), but in most cases, no mitochondrial lesion was seen. Mitochondrial abnormalities appear to be more frequent and prominent in proximal tubular cells despite the absence of tubular symptoms. Arteriolar deposits have been described in the five biopsies examined by Doleris et al. (269). They could result from individual myocyte necrosis and participate in the progression of glomerular lesions.

RARE AND "BIZARRE" SYNDROMES

Several curious syndromes with a glomerular component have been described in single or few families (274–280). Their basic defect and final classification have not been determined. According to recent data on mitochondrial cytopathies, some of these disorders could be caused by mitochondrial defects.

STEROID-SENSITIVE IDIOPATHIC NEPHROTIC SYNDROME IN CHILDREN

PATRICK NIAUDET

In children, the most common cause of nephrotic syndrome is idiopathic nephrotic syndrome, also called *nephrosis*. Idiopathic nephrotic syndrome is defined by the association of a nephrotic syndrome and minimal changes on renal biopsy by light microscopy with foot process fusion of epithelial cells on electron microscopy. No immunoglobulin (Ig) or complement fraction deposit is seen on immunofluorescence examination. Patients with minimal change disease most often respond to corticosteroids. As renal biopsy is not usually performed when the patient responds to corticosteroids, the term *minimal change disease* has become synonymous with steroid-sensitive nephrotic syndrome.

However, in some patients who respond to corticosteroids, histologic examination shows diffuse mesangial proliferation or focal and segmental glomerular sclerosis (FSGS). In addition, IgM deposits may be found. Several authors believe that minimal change disease is a distinct disease and that diffuse mesangial proliferation, FSGS, and IgM nephropathy are also distinct entities. There is no doubt that patients with diffuse mesangial proliferation or FSGS are more frequently resistant to corticosteroids and have a significant propensity for progression to renal failure. Conversely, patients with minimal change disease rarely progress to end-stage renal failure. However, there is an overlap between these histologic variants, and a significant proportion of patients with FSGS responds to corticosteroids, whereas some patients with minimal change disease are resistant to corticosteroids. Moreover, in the early stages, FSGS and minimal change disease are indistinguishable (1).

Experience has shown that response to steroid therapy carries a greater prognostic weight than the histologic features seen on the initial renal biopsy. Therefore, two types of idiopathic nephrotic syndrome can be described according to the response to corticosteroids: steroid-responsive idiopathic nephrotic syndrome, in which proteinuria rapidly resolves, and steroid-resistant idiopathic nephrotic syndrome (see Chapter 29), in which the nephrotic syndrome persists despite the treatment. This distinction is also more helpful for the clinician, as the therapeutic options are

more dependent on the initial response to corticosteroids than on the results of renal biopsy.

EPIDEMIOLOGY

The incidence of idiopathic nephrotic syndrome varies with age, race, and geography. The annual incidence in children in the United States has been estimated to be 2.0 to 2.7 per 100,000 (2), with a cumulative prevalence of 16 per 100,000. Geographic or ethnic differences are well known. In the United Kingdom, for example, the incidence of idiopathic nephrotic syndrome is sixfold greater in Asian than in European children (3); this is also true for Indians (4), Japanese, and Southwest Asians. Idiopathic nephrotic syndrome is rare in Africa, where most cases of nephrotic syndrome seem to be related to structural glomerular lesions unresponsive to steroids (5). Such differences underline the role of genetic as well as environmental factors in the pathogenesis of this disease.

Although idiopathic nephrotic syndrome accounts for only 25% of adult cases (6), it is by far the most common cause of nephrotic syndrome in children. Almost all nephrotic children between 1 and 6 years of age in Western countries have idiopathic nephrotic syndrome. The International Study of Kidney Disease in Children (ISKDC) found minimal change disease in 76.6% of children with primary nephrotic syndrome (7).

There is male preponderance in children, with a male to female ratio of 2:1 (7,8), but both sexes are similarly affected in adolescents. The familial occurrence of idiopathic nephrotic syndrome is well known. In a European survey, White found that 3.3% of 1877 patients with idiopathic nephrotic syndrome (excluding congenital nephrotic syndrome) had affected family members, mainly siblings (9). Nineteen of the 63 children had minimal change disease, and 18 of them had affected siblings, whereas the remaining child's father was affected with the disease. This incidence was greater than among the general population. Idiopathic nephrotic syn-

drome was also reported in identical twins (10). In one series of familial cases (11), the disease tended to develop in siblings at the same age, with the same renal histology and the same outcome. Another study reported 34 patients in 15 families; the response to corticosteroids was identical within members of individual families (12). The age and sex distribution, the relapsing course, and the absence of renal failure in 15 steroid-responsive familial cases were comparable to the sporadic cases.

ASSOCIATED DISORDERS

Idiopathic nephrotic syndrome is, by definition, a primary disease. Nevertheless, in a number of cases, an upper respiratory tract infection, an allergic reaction, or another factor may immediately precede the development or relapse of the disease.

Many agents or conditions have been reported to be associated with idiopathic nephrotic syndrome (e.g., infectious diseases, drugs, allergy, vaccinations, and malignancies) (Table 27.1). The question remains whether these factors are real causes, a simple coincidence, or precipitating agents.

Allergy is associated with up to 30% of cases (13,14). Among a list of anecdotal cases, the allergens reported include fungi, poison ivy, ragweed pollen, house dust, jellyfish stings, bee stings, and cat fur. A food allergen (i.e., cow's

milk or egg) may be responsible for relapses of steroid-sensitive nephrotic syndrome. Laurent et al. evaluated the effect of an oligo-antigenic diet given for 10 to 15 days to 13 patients. This diet coincided with improvement of proteinuria in nine, including complete remission in five (15).

The association between minimal change disease and malignancies mainly concerns lymphomatous disorders: Hodgkin's disease and non-Hodgkin's lymphomas (16). The nephrotic syndrome may be the presenting feature of the disease. It usually disappears after successful treatment of the malignancy. Other types of neoplasias that have been associated with idiopathic nephrotic syndrome include colon carcinoma, bronchogenic neoplasia, and small cell carcinoma (17).

Eosinophilic lymphoid granuloma in Asians (Kimura's disease) has also been reported in association with steroid-responsive idiopathic nephrotic syndrome. Several cases of minimal change disease have been reported in association with the onset of insulin-dependent diabetes mellitus. The disease is usually responsive to corticosteroids and follows a relapsing course.

HISTOCOMPATIBILITY ANTIGENS AND IDIOPATHIC NEPHROTIC SYNDROME

A three- to fourfold increased incidence of HLA-DR7 in children with idiopathic nephrotic syndrome has been reported (18,19). Clark et al. found a strong association between HLA-DR7 and the *DQB1* gene of *HLA-DQW2* and steroid-sensitive nephrosis and suggested that the β -chains of DR7 and DQW2 contribute to disease susceptibility (20).

An association with HLA-B8 was reported in Europe. Children with atopy and HLA-B12 have a 13-fold increased risk of developing idiopathic nephrotic syndrome.

CLINICAL FEATURES

The disease is characterized by a sudden onset, with edema being the most frequent presenting symptom. Edema increases gradually and becomes clinically detectable when fluid retention exceeds 3 to 5% of body weight. It is often initially apparent around the eyes and misdiagnosed as an allergy. Edema is gravity dependent. During the day, periorbital edema decreases while it localizes to the lower extremities. In the reclining position, it localizes to the back. It is white, soft, and pitting. Edema of the scrotum and penis, or labia, may also be observed. Anasarca may develop. Blood pressure is usually normal but sometimes elevated. The abdomen may bulge with umbilical or inguinal hernias. When ascites build up rapidly, the child complains of abdominal pain and malaise. Abdominal pain may also result from severe hypovolemia, peritonitis, pancreatitis, thrombosis, or steroid-induced gastritis. Shock is not unusual after a sudden fall of plasma albumin, with

abdominal pain and peripheral circulatory failure. Emergency treatment is needed.

The nephrotic syndrome is occasionally discovered during routine urine analysis. The disease may also be revealed by a complication. Peritonitis due to *Streptococcus pneumoniae* is a classical mode of onset. Deep vein or arterial thromboses and pulmonary embolism may also occur during the first attack or during a relapse.

LABORATORY FINDINGS

Urine Analysis

Nephrotic range proteinuria is defined as urinary protein excretion greater than 50 mg/kg/day or 40 mg/m²/hr. It is higher at onset and decreases as plasma albumin concentration falls. In young children, it may be difficult to obtain a 24-hour urine collection, and urinary protein to creatinine ratio or albumin to creatinine ratio in untimed urine specimens is useful. For these two indices, the nephrotic range is 200 to 400 mg/mmol. In most cases, proteinuria is highly selective, consisting of albumin and lower-molecular-weight proteins. The selectivity of proteinuria may be appreciated by polyacrylamide gel electrophoresis or by the evaluation of the Cameron index that is the ratio of IgG to transferrin clearances. A favorable index would be below 0.05 to 0.10; a poor index is above 0.15 or 0.20. A poor Cameron index is often associated with FSGS. However, there is a considerable overlap in results, and the test has limited value. Microscopic hematuria is present in 20% of cases and has no influence on the response to steroid therapy. Conversely, macroscopic hematuria is exceptional and, in the context of idiopathic nephrotic syndrome, may be related to renal vein thrombosis. The urine sediment often contains fat bodies. Hyaline casts are also usually found in patients with massive proteinuria, but granular casts are not present unless there is associated acute renal failure and acute tubular necrosis. Urinary sodium is low, 1 to 2 mmol/day, resulting in sodium retention and edema.

Blood

Plasma protein levels are markedly reduced, less than 50 g/L, due to hypoalbuminemia. Plasma albumin level is usually lower than 25 g/L and may be less than 10 g/L. Electrophoresis shows a typical pattern with low albumin, increased α_2 -globulins, and, to a lesser extent, β -globulins, whereas γ -globulins are decreased. IgG is considerably decreased, IgA slightly decreased, and IgM is increased. Lipid abnormalities include high levels of cholesterol, triglyceride, and lipoproteins. Total cholesterol and low-density lipoprotein cholesterol are elevated, whereas high-density lipoprotein cholesterol remains unchanged or low, particularly high-density lipoprotein 2, leading to an increased low-density lipoprotein to high-density lipopro-

tein cholesterol ratio. Patients with severe hypoalbuminemia have increased triglycerides and very-low-density lipoprotein. Apoproteins and apolipoproteins B, CII, and CIII are also elevated. The levels of lipoprotein(a) are elevated in nephrotic patients.

Serum sodium is often reduced due in part to hyperlipemia and in part to the dilution from renal retention of water due to hypovolemia and inappropriate antidiuretic hormone secretion. Hyperkalemia may be observed in cases of renal insufficiency. Hypocalcemia is related to hypoalbuminemia, and the level of ionized calcium is usually normal. Plasma creatinine is elevated in one-third of cases and returns to normal when remission occurs.

Hemoglobin levels and hematocrit are increased in patients with plasma volume contraction. Thrombocytosis is common and may reach 5×10^8 /L or 10^9 /L. Fibrinogen and factors V, VII, VIII, and X are increased, whereas antithrombin III, the heparin cofactor, and factors XI and XII are decreased. These abnormalities contribute to a hypercoagulable state.

COMPLICATIONS

Acute Renal Failure

Some patients have a reduction of the glomerular filtration rate (GFR) attributed to hypovolemia, with complete return to normal after remission. A reduced GFR may be found despite normal effective plasma flow (21,22). Bohman et al. showed a close relationship between the degree of foot-process effacement and both the GFR and the filtration fraction, suggesting that foot-process effacement leads to a reduction of the glomerular filtering area or of permeability to water and small solutes (23). This reduction is transitory, with a rapid return to normal after remission.

Marked oliguria may occur in children (24). Oliguric renal failure may be the presenting symptom. Renal failure may be secondary to bilateral renal vein thrombosis that can be diagnosed by sonography. Acute renal failure has also been reported with interstitial nephritis. Skin rash and eosinophilia are suggestive of this diagnosis, which is often associated with furosemide or other medication.

Acute renal failure is usually reversible, often with intravenous albumin and high-dose furosemide-induced diuresis (25). In some cases in which glomerular structure is normal on initial histology, renal failure may persist for as long as 1 year (21) and rarely be irreversible (26).

Infections

Bacterial infections are frequent in nephrotic children (Table 27.2). Sepsis may occur at the onset of the disease. The most common infection is peritonitis, often with *S. pneumoniae*. Other organisms may be responsible: *Escherichia coli*, *Streptococcus bovis*, *Haemophilus influenzae*, and other gram-negative

TABLE 27.2. INFECTIONS IN NEPHROTIC SYNDROME

Clinical syndrome	Risk factors
Pneumococcal peritonitis	Low immunoglobulin G
<i>Haemophilus</i> infection	Low factor B
Gram-negative sepsis	Edematous tissue
<i>Staphylococcus</i> cellulitis	Impaired lymphocyte function
	Corticosteroids
	Immunosuppressive drugs

organisms. Apart from peritonitis, children may develop meningitis, pneumonitis, or cellulitis. Several factors may explain the propensity of nephrotic children to develop bacterial infections: low IgG levels due to an impaired synthesis, urinary loss of factor B, and impaired T-lymphocyte function. Factor B is a cofactor of C3b in the alternative pathway of complement, which has an important role in opsonization of bacteria such as *S. pneumoniae*.

Viral infections may be observed in patients receiving corticosteroids or immunosuppressive agents. Varicella is often observed in these young children and may be life-threatening if acyclovir therapy is not promptly initiated. Of interest, measles infection may induce long-lasting remissions.

Thrombosis

Nephrotic patients are at risk of developing thromboembolic complications (Table 27.3). Several factors contribute to this increased risk of thrombosis: a hypercoagulable state, hypovolemia, immobilization, and infection. A number of hemostatic abnormalities have been described in nephrotic patients: an increase in platelet aggregability; an increase in fibrinogen and factors V, VII, VIII, X, and XIII, whereas the levels of anti-thrombin III (heparin cofactor), proteins C and S, and factors XI and XII are decreased; and an increase in fibrinolytic system components (e.g., tissue plasminogen activator and plasminogen activator inhibitor-1) (27). The incidence of thromboembolic complications in nephrotic children is reported to be approximately 3%. However, this percentage may underestimate the true incidence. In one series, systematic evaluation by ventilation-perfusion scans showed defects consistent with pulmonary embolism in 28% of all patients with steroid-dependent minimal change disease (28). Pulmonary embolism should be suspected in cases with pulmonary or cardiovascular

symptoms and may be confirmed by angiography or angioscintigraphy. Renal vein thrombosis should be suspected in patients with nephrotic syndrome who develop sudden macroscopic hematuria or acute renal failure. In such cases, Doppler ultrasonography shows an increase in kidney size and the absence of blood flow in the renal vein. Thrombosis may also affect the arteries (e.g., pulmonary arteries or other deep veins).

Hypovolemia

Hypovolemia is common and typically observed early during a relapse (Table 27.4). Sepsis, diarrhea, or diuretics may precipitate hypovolemia. Hypovolemic children often have abdominal pain, low blood pressure, and cold extremities. Hemoconcentration with a raised hematocrit accompanies hypovolemia.

RENAL BIOPSY

Indications

Renal biopsy is not indicated at onset in a child 1 to 8 years of age with typical symptoms of idiopathic nephrotic syndrome. Complete remission induced by corticosteroid therapy strongly supports the diagnosis. A renal biopsy is indicated at disease onset in clinical settings suggesting another type of glomerular disease. These include moderate nephrotic syndrome, a long previous course of mild proteinuria, macroscopic hematuria, marked hypertension, and persistent renal insufficiency. A decreased plasma C3 fraction is also an indication for renal biopsy. Age younger than 12 months and older than 11 years is another indication, even in patients with a typical clinical picture.

In steroid-dependent patients, the therapeutic approach is not influenced by histology. Therefore, a renal biopsy is not necessary before initiating a course of alkylating agents but is recommended before starting cyclosporine treatment to allow assessment of nephrotoxicity on a later biopsy.

Pathology

Light microscopy shows minimal changes in the majority of children with steroid-responsive nephrotic syndrome. FSGS occurs in only 5 to 10% of such patients (Fig. 27.1) (29). Mesangial proliferation is present in a small number of

FIGURE 27.1. Responses to steroids in children with idiopathic nephrotic syndrome according to histology/responders (checked bars) and nonresponders (dotted bars). DMP, diffuse mesangial proliferation; FSGS, focal and segmental glomerular sclerosis; MCD, minimal change disease.

patients. Immunofluorescence generally reveals no immune staining, but mesangial deposits of IgM and, more rarely, IgA, IgG, and C3 may be observed.

A complete description of the histopathology of minimal change disease, diffuse mesangial proliferation, focal and global sclerosis, FSGS, and IgM-associated nephropathy is presented in Chapter 29.

PATHOPHYSIOLOGY: MECHANISMS OF PROTEINURIA

In normal individuals, the clearance of albumin is approximately 1% of that of neutral proteins with similar molecular weight (e.g., polyvinylpyrrolidone or dextran). Similarly, the clearance of neutral dextran is higher than that of anionic sulfate dextran with similar molecular weight. These data indicate that the permeability of the glomerular basement membrane (GBM) is determined not only by the size but also by the charge of the protein. It is believed that the anionic charge of the GBM is responsible for the charge selectivity of filtration. The anionic (negative) charges of the GBM repulse negatively charged albumin molecules, which have an isoelectric point of 4.6.

The mechanism of proteinuria in the absence of histologic alterations on light microscopy has suggested an electrochemical disorder of the GBM. Indeed, it was shown that the glomerular K_f is diminished despite increased permeability to serum albumin. Using polyvinylpyrrolidone (30) or dextrans (31) with Einstein-Stokes radii between 2.0 and 4.8 nm as test macromolecules, the pore size of the GBM was shown to be reduced contrasting with massive albuminuria. This suggested a loss of glomerular negative charges. Kitano et al., using polyethylamine as a cationic probe, reported a decrease in the anionic charges of the GBM in minimal change disease (32). Carrie et al. studied renal biopsy sections stained by colloidal iron and showed that its glomerular uptake was mark-

edly reduced (33). They postulated a reduced sialic acid content in the GBM, as sialic acid residues are responsible for glomerular negative charges (34).

Van den Born et al. produced a mouse monoclonal antibody to partially purified heparan sulfate proteoglycan isolated from rat glomeruli (35). By indirect immunofluorescence, the monoclonal antibody bound to the GBM on rat kidney sections. By electron microscopy, a diffuse staining of the GBM was observed. After intravenous injection, the monoclonal antibody was localized along the GBM with a granular staining and 1 day later in the mesangium with a concomitant decrease in staining along the GBM. By electron microscopy, 1 hour after injection, the antibody was bound mainly to the inner side of the GBM. Intravenous injection of this antibody in rats resulted in selective proteinuria. This model shows that neutralization of heparan sulfate anionic charges may contribute to albuminuria.

Levin et al. and Boulton-Jones et al. presented data indicating that loss of negative charges was not restricted to the glomeruli in patients with idiopathic nephrotic syndrome but was also found on erythrocyte and platelet membranes, as shown by reduced binding of Alcian blue, a cationic dye (36,37). A cationic protein is found in the plasma and the urine of patients in relapse.

IMMUNE SYSTEM IN STEROID-RESPONSIVE IDIOPATHIC NEPHROTIC SYNDROME

Cellular Immunity

In 1974, Shalhoub postulated that idiopathic nephrotic syndrome might be secondary to a disorder of T-lymphocyte function (38). He hypothesized that clonal expansion of a T-lymphocyte subpopulation might result in the production of lymphokines, which increased the permeability of the glomerular filtration barrier to proteins. Data supporting this hypothesis were the response of the disease to corticosteroids and alkylating agents; the remission occurring in association with measles, which depresses cell-mediated immunity; the susceptibility of patients to pneumococcal infections; and the occurrence of minimal change nephrotic syndrome in patients with Hodgkin's disease.

Peripheral blood T-lymphocyte subpopulations have been shown to be altered in children during a relapse, with an increase in memory T-cell subsets (CD45RO⁺CD4⁺ T cells and CD45RO⁺CD8⁺ T cells) (39). Increased expression of the interleukin (IL)-2 receptor on the T-lymphocyte surface is found in patients with minimal change disease during relapse but not during remission (40).

Cell-mediated immunity is depressed in patients with idiopathic nephrotic syndrome and returns to normal with remission. Their lymphocytes have an impaired response to mitogens (41,42). This decreased response is partly reversible when normal human serum is added to the culture medium instead of autologous serum, suggesting both intrinsic

defects of the cells and the presence of inhibitory factors in the serum (43). Macrophages may be responsible for the impaired response of mononuclear cells to mitogens. The proliferative response of these cells returns to normal during remission. Therefore, a soluble factor may inhibit the proliferative response of T lymphocytes. Other abnormalities of cell-mediated immunity have been described in minimal change nephrotic syndrome. Skin reactivity to common antigens and recall response to common antigens are decreased during relapses and return to normal during remission (44).

Sahali et al. used a subtracted complementary DNA library screening to identify genes that might be differentially expressed in patients in relapse compared to those in remission (45). They found several upregulated genes, some of which are closely involved in T-cell activation. Relapsing patients display persistently high levels of nuclear factor- κ B DNA-binding activity and downregulation of I κ B α messenger (mRNA), which may account for increased production of several cytokines. In contrast, nuclear factor- κ B binding activity returns to normal during remission with concomitant upregulation of I κ B α and downregulation of most of the cytokines. An upregulation of c-maf expression and a downregulation of IL-12 receptor during relapse may suggest that T-cell activation in patients with minimal change disease evolves toward a T-helper-2 phenotype (46).

Humoral Immunity

Patients with minimal change disease have depressed serum IgG levels. This is more pronounced during relapses but persists during remission (47). Conversely, serum IgM is elevated. Altered serum levels of IgG and IgM may be secondary to abnormal T-cell regulation of Ig synthesis (48). Factors B and D are decreased during relapses but return to normal during remission. Specific antibodies to pneumococcal or streptococcal antigens are reduced in these patients up to 20 years after remission. This suggests that patients with minimal change nephrotic syndrome have a defect of the immune response that is not directly related to the nephrotic state. However, it does not imply that it is pathogenic.

Circulating Factors

Increased production of several lymphokines by activated T lymphocytes may alter glomerular permeability to albumin. Lagrue et al. described a vascular permeability factor, a lymphokine found in the supernatant of concanavalin A-activated lymphocytes from patients with minimal change disease that enhances vascular permeability when injected in guinea pigs (49,50). The vascular permeability factor is produced by T lymphocytes and is distinct from IL-2. Cyclosporine suppresses *in vitro* vascular permeability factor production. (51). Tanaka et al. found that supernatants of peripheral mononuclear cells stimulated with concanavalin injected in the renal artery of rats induced proteinuria along with reduction of the GBM anionic charges (52).

Koyama et al. found a glomerular permeability factor in the supernatant of a T-cell hybridoma derived from peripheral T lymphocytes from a patient with minimal change disease (53). The supernatant induced proteinuria when injected in the rat. Histology showed partial fusion of glomerular epithelial cell foot processes without immune deposits.

Several studies have shown increased *in vitro* production of IL-2, IL-4, and interferon- γ by lymphocytes and high plasma and urine concentrations of the soluble IL-2 receptor in patients during a relapse. The soluble IL-2 receptor suppresses lymphocyte proliferation. Patients in relapse have increased CD4⁺ and CD8⁺ IL-13 mRNA expression as compared to patients in remission or controls (54). The IL-13 and IL-4 cytokines are produced by stimulated Th2 lymphocytes. Activation of Th2 lymphocytes is known to play a key role in atopy. Glomerular epithelial cells express IL-4 and IL-13 receptors, and both cytokines increase transcellular ion transport in cultured cells as well as basolateral secretion of lysosomal proteinases (55,56). Such effects of IL-4 and IL-13 may explain an alteration of glomerular permeability.

Increased IL-2 concentrations have been found in supernatants of lymphocyte cultures from patients with idiopathic nephrotic syndrome, and IL-2 can induce proteinuria and a reduction of anionic sites of the GBM when injected into the rat kidney. Nephrotic syndrome has been observed in patients treated with recombinant IL-2 and interferon- α (57,58). Garin et al. reported an increased serum concentration of IL-8 and the presence of its mRNA in mononuclear cells from patients with minimal change disease during relapses (59). They also found that IL-8 may affect the metabolism of the GBM and postulated that it might alter glomerular permeability. Serum concentrations of tumor necrosis factor- α and its mRNA in peripheral mononuclear cells from patients with idiopathic nephrotic syndrome are increased in comparison with controls or patients in remission (60).

Schnaper and Aune (61–63) reported the presence of a lymphokine, the soluble immune response suppressor, in the urine and serum from patients with steroid-responsive nephrotic syndrome, including minimal change nephrotic syndrome and other histopathologic forms of nephrotic syndrome. The soluble immune response suppressor is produced by regulatory T lymphocytes and inhibits both delayed hypersensitivity reactions and antibody responses. The soluble immune response suppressor may contribute to the decreased immune responsiveness of patients with minimal change disease.

TREATMENT

Symptomatic Treatment

Diet

Diet includes a protein intake of 130 to 140% of the normal daily allowance according to statural age. Salt restriction is necessary for the prevention and treatment of edema. A very low salt diet is necessary in the case of edema. Fluid restric-

tion is recommended for moderate to severe hyponatremia (plasma sodium concentration less than 125 mmol/L). A reduction of saturated fat is advisable. Carbohydrates are given preferentially as starch or dextrin-maltose, avoiding sucrose, which increases lipid disturbances.

Hypovolemia

Hypovolemia, a consequence of rapid loss of serum albumin, may be aggravated by diuretics. When symptomatic, this complication requires emergency treatment by rapid infusion of plasma (20 mL/kg) or albumin 20% (1 g/kg) administered with monitoring of heart rate, respiratory rate, and blood pressure.

Diuretics

Diuretics should only be used in cases of severe edema, after hypovolemia has been corrected. Patients with anasarca may be treated with furosemide (1 to 2 mg/kg) or, if necessary, furosemide and salt-poor albumin (1 g/kg infused over 4 hours) (25). This approach is effective immediately, but it is not long-lasting. Moreover, respiratory distress with congestive heart failure has been observed in some patients (64). Spironolactone (5 to 10 mg/kg) may be effective to minimize hypokalemia in patients with normal renal function. Diuretics must be used with caution. They may induce intravascular volume depletion with a risk of thromboemboli and acute renal failure as well as severe electrolyte imbalance. Refractory edema with serous effusions may require drainage of ascites or pleural effusions. Head-out immersion has been reported to be helpful in some cases (65).

Thromboemboli

Patients with severe hypoalbuminemia are at risk for thromboembolic complications. Prevention includes mobilization, avoiding hemoconcentration, and treating early sepsis or volume depletion. Prophylactic warfarin may be given to patients with a plasma albumin concentration below 20 g/L, a fibrinogen level greater than 6 g/L, or an antithrombin III level less than 70% of normal. Patients at risk may alternatively be treated with low-dose aspirin and dipyridamole, although no controlled trials have been performed to demonstrate their efficacy in preventing thrombosis (66). Heparin is given initially if thrombosis occurs alone or with thrombolytic agents. The heparin dose necessary to obtain a therapeutic effect is often greater than normal due to decreased antithrombin III levels.

Antihypertensive Drugs

Hypertension is treated using beta-blockers or calcium-channel blockers during acute episodes. In cases of persistent hypertension, an angiotensin-converting enzyme inhibitor or an inhibitor of angiotensin receptor 2 is preferred.

Infections and Immunizations

Prophylaxis of *S. pneumoniae* with oral penicillin is often prescribed to children during initial corticosteroid treatment. Although antibody response to pneumococcal vaccine is blunted in children with steroid-responsive nephrotic syndrome, vaccination with the conjugated pneumococcal vaccine (7vPCV) is recommended (67). In cases of peritonitis, antibiotics against both *S. pneumoniae* and gram-negative organisms are started after peritoneal fluid sampling. Varicella is a serious disease in patients receiving immunosuppressive treatment or daily corticosteroids. Varicella immunity status should therefore be assessed. In the case of exposure of an at-risk patient, acyclovir therapy should be initiated. Immunization with live virus vaccines is contraindicated in immunosuppressed patients.

Specific Treatment

Corticosteroid treatment should be initiated in all cases of idiopathic nephrotic syndrome regardless of histopathology. The majority of patients is steroid responsive: 89% of children studied by White et al. (68) and 98% of the patients with minimal changes on histology. Steroid responders may relapse, but the majority still responds to steroids throughout the subsequent course. Only 1 to 3% of patients initially steroid sensitive subsequently become steroid resistant and are defined as *late nonresponders* (69).

Initial Treatment

Steroids should not be started immediately, as spontaneous remission occurs in 5% of cases within the first 8 to 15 days. Some of these early spontaneous remissions are definitive. Infection must be treated before starting steroids, not only to prevent the risk of overwhelming sepsis during treatment, but also because occult infection may be responsible for steroid resistance (3). Patients should have a tuberculin test (i.e., purified protein derivative) before initiation of immunosuppressive therapy.

Glucocorticoid therapy is started when the diagnosis of idiopathic nephrotic syndrome is most likely in a child or after renal biopsy has been performed. Prednisone remains the cornerstone of therapy. Prednisolone has the advantage of being soluble in water, making treatment easier in young children, but it may fail to induce remission in some patients who respond quickly to the same dosage of prednisone. The differences in intestinal absorption and drug interactions (e.g., with aluminium gels) may explain decreased efficacy in some children.

The ISKDC regimen consists of prednisone, 60 mg/m²/day, with a maximum of 80 mg/day in divided doses for 4 weeks, followed by 40 mg/m²/day with a maximum of 60 mg/day in divided doses on 3 consecutive days per week for 4 weeks (70). The Arbeitsgemeinschaft für Pädiatrische Nephrologie showed that an alternate-day regimen (40 mg/m² every other day for 4 weeks) after initial daily therapy

resulted in a significantly lower number of patients with relapses and fewer relapses per patient (71). It also showed that on alternate days, prednisone could be given in a single dose rather than in divided doses.

A response occurs in most cases within 10 to 15 days (median, 11 days). According to the ISKDC data, approximately 90% of responders enter remission within 4 weeks after starting glucocorticoids, whereas less than 10% go into remission after 2 to 4 more weeks of daily medication (70). A small number of patients go into remission after 8 to 12 weeks of daily steroids (6,72), but prolongation of daily steroid treatment beyond 4 or 5 weeks increases the risk of side effects. An alternative for patients who are not in remission after 4 weeks is to administer three to four pulses of methylprednisolone (1 g/1.73 m²). This additional regimen seems to be associated with fewer side effects than prolongation of daily high-dose steroids and probably produces remission more rapidly in the few patients who would have entered the second month of daily therapy (73).

The duration of initial steroid therapy influences the risk of relapse. The Arbeitsgemeinschaft für Pädiatrische Nephrologie compared a standard regimen of 4-week daily prednisone and 4 weeks of alternate-day prednisone with a shorter course comprising prednisone given at a dose of 60 mg/m²/day until the urine was protein free, followed by alternate-day prednisone until serum albumin returned to normal (74). Treatment lasted approximately 1 month in children receiving the short course. However, these children had twice the relapse rate so that, at the end of the trial, they had received an amount of prednisone significantly greater than had the standard treatment group.

After an 8-week steroid regimen, 50 to 70% of children experienced relapses. Several controlled studies have compared the 8-week regimen with longer duration of steroid regimen (3 to 7 months), including 4 to 8 weeks of daily prednisone followed by alternate-day prednisone (75–79). With a follow-up of 2 years, a significant reduction of 25 to 30% in the relapse rate was observed with a prednisone regimen of 3 months or more.

The number of children with frequent relapses is also decreased with a longer initial course of prednisone. Longer duration is more important than the cumulative dose of prednisone in reducing the risk of relapse. This relative risk decreases by 0.133 (13%) for every additional month of treatment up to 7 months (80). There are no data showing that treating for more than 7 months is beneficial. However, an alternate-day regimen over 1 year did not reduce the rate of relapse compared to a 5-month alternate-day regimen (81). Although the studies were not designed to analyze the side effects of glucocorticoids, the authors did not report increased toxicity with longer duration of treatment.

Treatment of Relapses

Approximately 30% of children experience only one attack and are definitively cured after a single course of steroids.

Persistent remission for 18 to 24 months after stopping treatment is likely to reflect definitive cure, and the risk of later relapses is low. Ten percent to 20% of patients relapse several months after stopping treatment and are most often cured after three or four episodes, which respond to a standard course of corticosteroids. The remaining 50 to 60% experience relapses as soon as steroid therapy is stopped or when dosage is decreased. In some cases, exacerbation of proteinuria is only transient, and spontaneous remissions are observed (82). The risk of relapse is greater in children aged younger than 5 years at onset and in male patients. These steroid-dependent patients often raise difficult therapeutic problems.

Steroid-dependent patients may be treated with repeated courses of prednisone, 60 mg/m²/day, continued 3 days after the urine has become protein free, followed by alternate-day prednisone, 40 mg/m², for 4 weeks as proposed by the ISKDC (70). Another option consists of treating relapses with daily prednisone, 40 to 60 mg/m², until proteinuria has disappeared for 4 to 5 days. Thereafter, prednisone is switched to alternate days, and the dosage is tapered to 15 to 20 mg/m² every other day, according to the steroid threshold (i.e., the dosage at which the relapse has occurred). Treatment is then continued for 12 to 18 months. The first approach allows better definition in terms of number of relapses but is associated with more relapses. The latter regimen is associated with fewer steroid side effects as the cumulative dosage is lower. Prolonged courses of alternate-day steroid therapy are often well tolerated by young children, and growth velocity is not affected. However, prednisone dosage must be as low as possible to minimize side effects. In adolescents, steroid therapy is often accompanied by decreased growth velocity.

A controlled trial has shown that deflazacort reduces the risk of relapse in comparison with equivalent doses of prednisone without additional side effects (83). However, deflazacort is not available in all countries.

The role of upper respiratory tract infections in exacerbating nephrotic syndrome has been highlighted in all series: 71% of relapses were preceded by such an event in a prospective study, although only 45% of respiratory infections were followed by an exacerbation of proteinuria (84). Mattoo et al. found that the risk of relapse was decreased during upper respiratory tract infections when prednisone was given daily for 5 days rather than on alternate days (85).

Leisti et al. suggested a role for postcorticosteroid adrenal suppression in triggering relapses (86), and some clinicians have suggested possible prevention by low-dose maintenance hydrocortisone (87,88) (Fig. 27.2).

Alternative Treatments

Alternative treatment is required in children who relapse on alternate-day prednisone therapy and experience severe glucocorticoid side effects (e.g., growth retardation, behavior

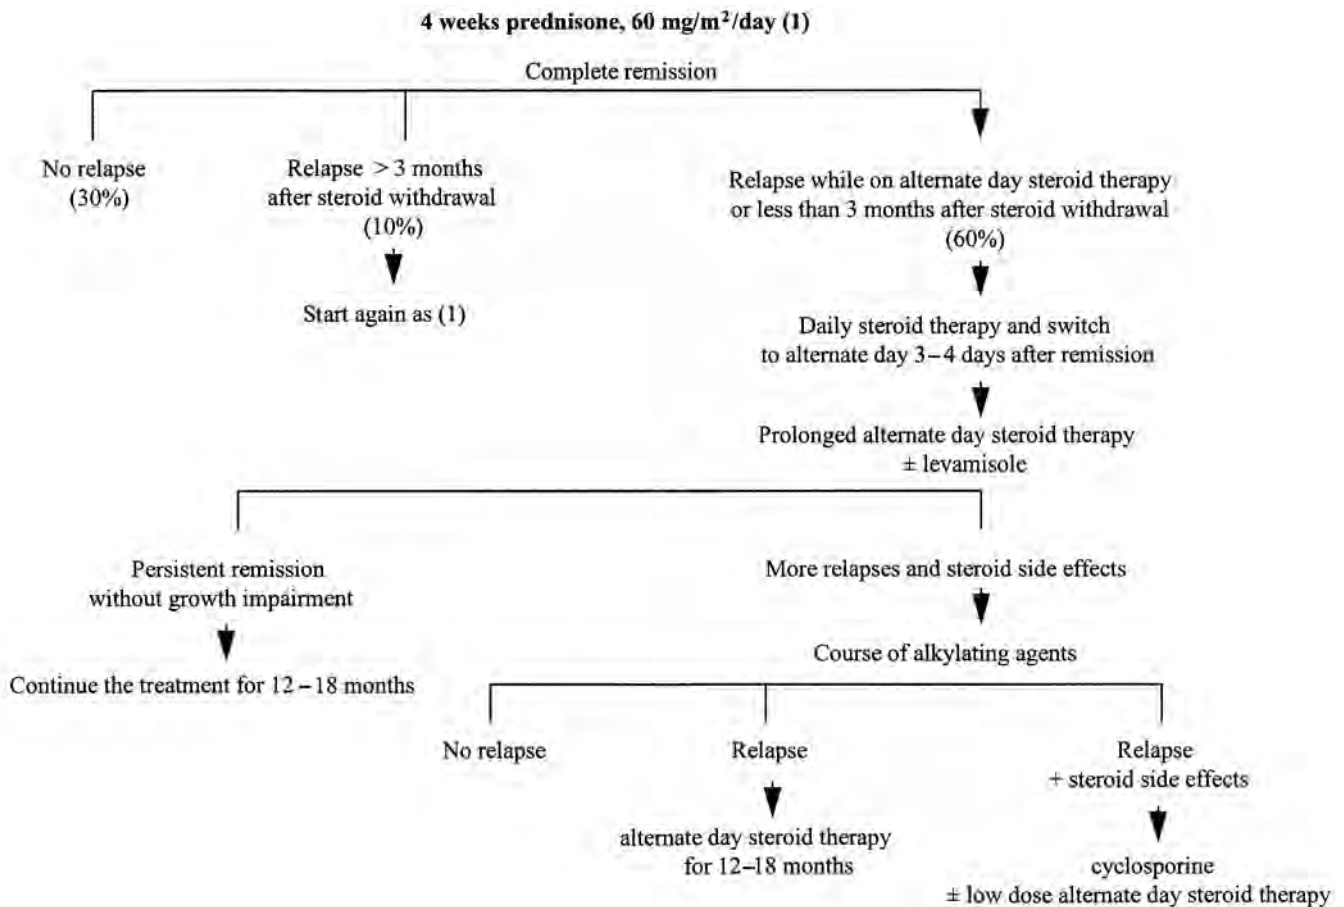

FIGURE 27.2. Treatment of idiopathic nephrotic syndrome regardless of histopathology.

disturbances, cushingoid features, hypertension, cataracts, or osteopenia). Alternative treatment is also indicated in children at risk of toxicity (e.g., diabetes or during puberty), in children with severe relapses accompanied by thrombotic complications, or severe hypovolemia and in those with poor compliance. Alternative treatments include levamisole, which has a weak steroid sparing effect, and alkylating agents (e.g., cyclophosphamide, chlorambucil, or cyclosporine).

Levamisole

The beneficial effect of levamisole was first described by Tanphaichitr et al. (89). Levamisole was subsequently reported to reduce the risk of relapse in steroid-dependent patients (90–93). A significant steroid-sparing effect at a dose of 2.5 mg/kg every other day was demonstrated in a prospective controlled trial of the British Association for Paediatric Nephrology (94). Another controlled study confirmed the efficacy of levamisole for preventing relapses (95). However, the beneficial effect of levamisole is not sustained after stopping treatment.

Levamisole given for 6 months was compared with cyclophosphamide given for 8 to 12 weeks in a retrospective study involving 51 children with steroid-dependent nephrotic syndrome (96). The relapse rate and the cumulative dose of prednisone were reduced to the same extent with both drugs.

Side effects include neutropenia, agranulocytosis, vomiting, cutaneous rash, and neurologic symptoms, including insomnia, hyperactivity, and seizures. However, levamisole is well tolerated in most children.

Alkylating Agents

Alkylating agents have been used for more than 40 years to achieve long-lasting remission in patients with idiopathic nephrotic syndrome.

Cyclophosphamide

The efficacy of cyclophosphamide for preventing relapses of idiopathic nephrotic syndrome was reported more than 20 years ago (97) and confirmed in a prospective study by Barratt and Soothill, who compared an 8-week

course of cyclophosphamide to prednisone alone (98). An ISKDC trial found a 48% relapse rate after a mean follow-up of 22 months in children treated with a combination of cyclophosphamide and prednisone compared to a 88% relapse rate in patients on prednisone alone (99).

Several studies have addressed the relationship between dose, duration of treatment, and therapeutic efficacy. Treatment for 12 weeks at a daily dose of 2 mg/kg was found to be more effective than an 8-week course, with 67% as compared to 22% remaining in remission after 2 years (100). However, a randomized trial showed that prolonging the course of cyclophosphamide from 8 to 12 weeks did not further reduce the proportion of children experiencing relapses (101).

Cyclophosphamide is less effective in patients with steroid dependency compared to patients with frequent relapses (102). The incidence of relapse after cyclophosphamide is significantly higher in patients with FSGS (73%) or mesangial proliferation compared to 22% in children with minimal change disease (103).

Cyclophosphamide toxicity includes bone marrow depression, hemorrhagic cystitis, gastrointestinal disturbances, alopecia, and infection. Leukopenia is frequently observed, but weekly hematologic monitoring may limit its severity, and concomitant steroids help blunt marrow depression. Hemorrhagic cystitis rarely occurs. Alopecia, which is variably pronounced, remits a few weeks after stopping treatment. Viral infections can be overwhelming if cyclophosphamide is not stopped in due time.

Long-term toxicity includes malignancy, pulmonary fibrosis, ovarian fibrosis, and sterility. The risk of sterility is greater in boys than in girls. The cumulative threshold dose above which the risk of oligo- or azoospermia increases is between 150 and 250 mg/kg (104–106). Azoospermia is reversible in some patients (107). In girls, the cumulative dose associated with sterility is greater but not well defined. Pregnancies have been reported after treatment courses of longer than 18 months (108).

Chlorambucil

Beneficial results have also been achieved with chlorambucil in steroid-responsive idiopathic nephrotic syndrome. In 1973, Grupe demonstrated the efficacy of chlorambucil given for 2.5 to 12.0 weeks, with a relapse rate of only 13% (109). A controlled trial of chlorambucil for 6 to 12 weeks showed prolonged remissions of 1 to 3 years (110). Baluarte et al. obtained similar results in relapsing steroid-responsive nephrosis (111). Williams et al. showed that low daily doses are preferable: 91% of patients on a dose of 0.3 mg/kg and 80% of those on 3 mg/kg were still in remission 4 years later (112).

Acute toxic effects are less frequent with chlorambucil than with cyclophosphamide. Leukopenia and thrombocytopenia may occur and are reversible within 1

to 3 weeks. Severe microbial and viral infections have been reported, including malignant hepatitis and measles encephalitis.

Long-term toxic effects include the risk of developing malignancy, which has been reported in patients with prolonged therapeutic courses. Gonadal toxicity, as with cyclophosphamide, is more common in male patients. Azoospermia is total and probably irreversible at cumulative doses above 10 to 20 mg/kg. No case of azoospermia was reported in patients given less than 8 mg/kg.

Cyclosporine

In a number of uncontrolled studies, cyclosporine has been shown to reduce the incidence of relapses in 75 to 90% of patients with steroid-dependent idiopathic nephrotic syndrome (113). However, most patients experience relapses when the dosage is tapered or when cyclosporine is withdrawn. Relapse rate usually returns to the pretreatment rate. Hulton et al. found that patients in whom cyclosporine had been discontinued and later restarted had more relapses, requiring steroids in addition to cyclosporine to maintain remission (114).

The effects of cyclosporine have been evaluated in two comparative trials in steroid-sensitive patients. Cyclosporine at a dosage of 6 mg/kg/day for 3 months then tapered over 3 months was compared with chlorambucil given for 2 months. At 12 months, 30% of patients who had received chlorambucil and only 5% of those who received cyclosporine were still in remission (115). A multicenter randomized controlled trial compared cyclosporine for 9 months and then tapered over 3 months with oral cyclophosphamide for 2 months (116). After 2 years, 25% of the patients (50% of adults and 20% of children) who had received cyclosporine had not relapsed, whereas 63% of those treated with cyclophosphamide (40% of adults and 68% of children) were still in remission. During the year after treatment, the relapse rate (1.8 vs. 0.7) and the steroid dosage required (109 vs. 23 mg/kg/yr) were significantly higher in children who had received cyclosporine.

Tejani et al. performed a randomized controlled trial comparing low-dose prednisone and cyclosporine versus high-dose prednisone for 8 weeks as initial treatment in 28 children (117). Thirteen of the 14 children receiving the combined treatment went into remission compared to only 8 of the 14 receiving prednisone alone ($p < .05$). The duration of remission after ending treatment was comparable in both groups. Ingulli and Tejani reported that severe hypercholesterolemia may inhibit cyclosporine efficacy and that patients with severe hyperlipidemia require higher doses for maximal effectiveness (118).

Considering the high rate of cyclosporine dependency as well as its nephrotoxicity, steroid-dependent patients should first be treated with alkylating agents before resorting to cyclosporine (113,119). In patients being treated with cyclosporine, it is often difficult to determine if any observed

changes in renal function are transient or due to the nephrotoxic effect of the drug. In these cases, it is advisable to reduce dosage or even stop cyclosporine treatment. Lesions of chronic cyclosporine-induced nephrotoxicity can develop without any appreciable decline of the GFR (120,121). As it is often necessary to use long therapeutic courses of cyclosporine, repeat renal biopsies are advised to detect lesions. They most often consist of tubulointerstitial injury, characterized by stripes of interstitial fibrosis containing clusters of atrophic tubules, as well as vascular lesions.

Other side effects of cyclosporine are of less concern: Hypertension, hyperkalemia, hypertrichosis, gum hypertrophy, and hypomagnesemia are common but easily manageable with standard therapies.

Azathioprine and Mycophenolate Mofetil

Abramowicz et al. (122) performed a controlled, multicenter trial in children with steroid-sensitive nephrotic syndrome that demonstrated that azathioprine had no effect in preventing relapses. Preliminary data suggest that mycophenolate mofetil treatment may have a beneficial effect in inducing and maintaining remission (123) in such patients. Such data must be confirmed in prospective clinical trials.

LONG-TERM OUTCOME

Steroid-dependent patients may have a prolonged course. However, if the patient continues to respond to steroids, the risk of progression to chronic renal failure is minimal.

Schärer and Minges found that 22% of patients had only one attack and 35% of the relapsing patients continued to relapse after 10 years (124). Trompeter et al. reported the late outcome of 152 children with steroid-responsive nephrotic syndrome after a follow-up of 14 to 19 years: 127 (83%) were in remission, 4 had hypertension, 10 were still relapsing, and 11 had died (125). The duration of the disease was longer in children who had their initial episode before the age of 6 years. Wynn et al. found that 15% of 132 patients had a persistent relapsing course with a mean follow-up of 27.5 years (126). Lewis et al. reviewed 26 patients older than age 20 years, five of whom were still relapsing during adulthood (127).

Koskimies et al. reported on the follow-up of children with idiopathic nephrotic syndrome in Finland from 1967 to 1976: 94 of 114 cases had responded to corticosteroids. Twenty-four percent of steroid responders had no relapse, 22% had infrequent relapses, and 54% had frequent relapses. More than two-thirds were in remission at time of report (128). None of these patients developed renal insufficiency, and none died from the disease.

Overall, this favorable long-term prognosis has also been observed in patients with steroid-responsive FSGS: 19 children reported by Arbus et al. remained responders, and none had renal insufficiency after a mean follow-up of 10 years (74).

Fakhouri et al. recently reported on the outcome in adulthood of 102 patients born between 1970 and 1975 (129). Forty-two percent presented at least one relapse in adulthood. A young age at onset and a high number of relapses during childhood were associated with a risk of relapse in adulthood.

STEROID-RESISTANT IDIOPATHIC NEPHROTIC SYNDROME IN CHILDREN

PATRICK NIAUDET

Idiopathic nephrotic syndrome is defined by the combination of nephrotic syndrome (proteinuria, hypoalbuminemia, hyperlipidemia, and edema) with nonspecific histologic abnormalities of the kidney, including minimal changes, focal segmental glomerulosclerosis (FSGS), and diffuse mesangial proliferation. Glomeruli show a fusion of epithelial cell foot processes on electron microscopy and no significant deposits of immunoglobulins (Igs) or complement on immunofluorescence.

Many authors consider minimal change disease (MCD), diffuse mesangial proliferation, and FSGS as separate diseases because of differences in response to corticosteroids and subsequent clinical course (1). Indeed, these various pathologic features carry prognostic significance. Patients with FSGS and those with diffuse mesangial proliferation more frequently have hematuria, are often resistant to corticosteroid treatment, progress more often to renal failure, and may have a recurrence of the nephrotic syndrome soon after transplantation. Recent data demonstrate differences between the basic pathophysiology of FSGS and MCD. FSGS appears to be a podocyte disease (2). The notion of podocyte dysregulation (3–5), the different expression of cyclin-dependent kinase inhibitors in MCD and in FSGS, the role of these cell cycle disturbances leading to podocyte proliferation and maturation (6), and the identification of parvovirus B19 in glomeruli of patients with FSGS (7,8) support the separation of minimal change nephrotic syndrome and FSGS as distinct entities. Moreover, Streulau et al. found transforming growth factor β 1 (TGF- β 1) gene expression in 18 of 20 patients with steroid-resistant FSGS and in only 3 of 14 steroid-sensitive patients (9). These data support a sequence of specific immunologically mediated events that contribute to progressive renal damage in children with FSGS.

In the early stages, FSGS and minimal change nephropathy are indistinguishable (10). A significant number of patients with FSGS respond favorably to glucocorticoid therapy (11), whereas some steroid-resistant patients have no sclerotic changes on systematic histopathologic evaluation (11,12). Therefore, some authors believe that, although his-

tologic variants of the idiopathic nephrotic syndrome carry prognostic significance, they cannot at present be considered as separate entities (13).

The term *MCD* has become synonymous with steroid-sensitive idiopathic nephrotic syndrome, although renal biopsy is usually not performed in patients who respond to steroid therapy. Indeed, in many centers, renal biopsy is recommended only for those patients who do not respond to steroids. Consequently, renal biopsy findings in recent published series are not representative of the true incidence of various histopathologic categories seen in idiopathic nephrotic syndrome. It is, therefore, more appropriate to classify the patients according to their response to steroid therapy. Response to glucocorticoid therapy has greater prognostic value than the histologic features seen on initial renal biopsy. Thus, two types of nephrosis can be defined: *steroid-responsive* (see Chapter 27) and *steroid-resistant nephrotic syndrome* (SRNS).

In this chapter, we focus on the 10% of children with idiopathic nephrotic syndrome who do not respond to corticosteroids and are at risk for extrarenal complications of nephrosis as well as the development of end-stage renal disease (ESRD). Steroid-resistant idiopathic nephrotic syndrome accounts for more than 10% of children who progress to ESRD.

SRNS is a heterogeneous entity. In some patients, particularly those who experience a recurrence after renal transplantation, the disease is probably immunologically mediated by a cytokine that increases the permeability of the glomerular basement membrane (GBM) to proteins. In other cases (e.g., familial cases), the disease is related to a primary defect of the filtration barrier. Recent studies have highlighted the roles of newly identified podocyte proteins and demonstrated that mutations of corresponding genes may be responsible for SRNS (14).

CLINICAL AND BIOLOGIC FEATURES

SRNS may occur during the first year of life, but it usually starts between 2 and 7 years of age, with a male to female

ratio of 2:1 (15). The disease is characterized by sudden onset, with edema being the major presenting symptom. Edema becomes clinically detectable when fluid retention exceeds 3 to 5% of body weight. Edema is gravity dependent and localized to the lower extremities in the upright position and to the dorsal part of the body in the reclining position. Edema is white, soft, and pitting, retaining the marks of clothes or finger pressure. Anasarca may develop with ascites and pleural and pericardial effusions. Although there may also be abdominal distention, dyspnea is rare. Periorbital edema may limit eye opening, and edema of the scrotum and penis or labia may be seen. Blood pressure is usually normal but is sometimes elevated. Rapid formation of ascites is often associated with abdominal pain and malaise, but these symptoms may also be related to concomitant hypovolemia. Abdominal pain is occasionally due to a complication such as peritonitis, thrombosis, or, rarely, pancreatitis. Cardiovascular shock is not unusual, secondary to the sudden fall of plasma albumin, with abdominal pain and symptoms of peripheral circulatory failure with cold extremities and hypotension.

The nephrotic syndrome is occasionally discovered during a routine urine analysis. Macroscopic hematuria is observed in a few cases. SRNS may present with an infectious or thrombotic complication.

Proteinuria during the Urinalysis

Nephrotic range proteinuria is defined as urinary protein excretion greater than 50 mg/kg/day or 40 mg/m²/hr mean value. Proteinuria during the first days may be higher, as the urinary concentration of proteins also depends on the plasma albumin concentration. In young children, it may be difficult to perform accurate 24-hour urine collections, and urinary protein to creatinine ratio or urine albumin to urine creatinine ratio in untimed urine specimens is useful. For these two indices, the nephrotic range is 200 to 400 mg/mmol (16).

The amount of protein excreted in the urine does not reflect the quantity of protein crossing the GBM because a significant amount is reabsorbed in the proximal tubule. Typically, in severe nephrotic syndrome with glomerular lesions and resistance to steroid treatment, the urine contains not only albumin but also higher-molecular-weight proteins. This can be seen on polyacrylamide gel electrophoresis and can also be quantified by means of the selectivity index. The selectivity index is the ratio of IgG (molecular weight, 150 kDa) to albumin (70 kDa) or transferrin (80 kDa) clearances. A selectivity index above 0.15 or 0.20 is frequently observed in SRNS. However, the test is of limited clinical value because of its poor specificity. Some children with SRNS and tubulointerstitial lesions have both glomerular and tubular proteinuria with an increased excretion of β_2 -microglobulin, retinol-binding protein, and lysozyme due to impaired protein reabsorption in the proximal tubule.

The urine sediment of patients with idiopathic nephrotic syndrome often contains fat bodies. Hyaline casts are also usually found in patients with massive proteinuria, but granular casts are not present unless there is associated acute renal failure and acute tubular necrosis. Macroscopic hematuria is rare, occurring in 3% of patients. Microscopic hematuria is far more common and may be observed in up to two-thirds of patients, particularly those with FSGS.

Urinary sodium excretion is low (less than 5 mmol per 24 hours), associated with sodium retention and edema. Kaliuresis is usually higher than natriuresis but may be reduced in oliguric patients.

Blood Chemistry

Serum proteins are markedly reduced, and serum lipid usually increased. Plasma protein levels are below 50 g/L in 80% of patients and below 40 g/L in 40% (17). Albumin concentration usually falls below 20 g/L and may be less than 10 g/L. Electrophoresis shows not only low albumin levels but also increased α_2 -globulins and, to a lesser extent, β -globulins, whereas γ -globulins are decreased. IgG is markedly decreased, IgA is slightly reduced, IgM is increased, while IgE is normal or increased. Among other proteins, fibrinogen and β -lipoproteins are increased and antithrombin III is decreased.

Hyperlipidemia is a consequence of (a) an increased hepatic synthesis of cholesterol, triglycerides, and lipoproteins; (b) a decreased catabolism of lipoproteins due to a decreased activity of lipoprotein lipase that normally transforms very-low-density lipoprotein to low-density lipoprotein (LDL) via intermediate-density lipoprotein; and (c) decreased LDL receptor activity and an increased urinary loss of high-density lipoprotein (HDL) (18). Total cholesterol and LDL cholesterol are elevated, whereas HDL cholesterol remains unchanged or low, particularly HDL₂, leading to an increased LDL to HDL cholesterol ratio. Patients with severe hypoalbuminemia have increased triglycerides and very-low-density lipoprotein. Apoproteins and apolipoproteins B, CII, and CIII are also elevated. The levels of lipoprotein(a) are elevated in nephrotic patients, which further contributes to an increased risk of cardiovascular and thrombotic complications.

Serum electrolytes are usually within the normal range. A low sodium level may be related to dilution from inappropriate renal retention of water due to hypovolemia and inappropriate antidiuretic hormone secretion. A mild reduction of plasma sodium concentration may be an artifact related to hyperlipidemia depending on reference laboratory methodology. Serum potassium may be high in oliguric patients. Serum calcium is consistently low as a result of hypoproteinemia. Ionized calcium is usually normal but may be decreased due to urinary loss of 25-hydroxyvitamin D₃ (19) and normal but inappropriate levels of calcitriol (20). Blood urea nitrogen and creatinine concen-

trations are usually within the normal range or slightly increased, reflecting a modest reduction in glomerular filtration rate (GFR).

A few patients with FSGS and a poor subsequent outcome present with a Fanconi syndrome: glycosuria, aminoaciduria, urinary bicarbonate loss, and hypokalemia (21). A defect in urinary acidification has also been reported (22).

Hematology

Hemoglobin levels and hematocrit are increased in patients with plasma volume contraction. Anemia with microcytosis may be observed and is probably related to urinary loss of siderophilin. Thrombocytosis is common and may reach 5×10^8 or $10^9/L$.

COMPLICATIONS

Acute Renal Failure

Renal function is usually within normal limits at presentation. A reduction of the GFR, secondary to hypovolemia, is frequent (23). A reduced GFR may be found in patients with normal effective plasma flow (24,25). Bohman et al. showed a close relationship between the degree of foot-process fusion and both GFR and filtration fraction, suggesting that fusion of foot processes could lead to a reduction of glomerular filtering area or of permeability to water and small solutes (26).

Acute renal failure may be secondary to bilateral renal vein thrombosis. Interstitial nephritis is another possible cause of acute renal failure, especially in association with furosemide administration.

Chronic Renal Failure

Patients with SRNS are at major risk of developing end-stage renal failure (ESRF), which is seen in less than 3% of patients with idiopathic nephrotic syndrome who respond to glucocorticoid therapy. ESRD develops in at least 50% of patients with SRNS. As patients develop ESRD, all features of their nephrotic syndrome may improve because a decrease in urinary protein excretion parallels their decreased GFR.

We have retrospectively analyzed in the Enfants Malades series the outcome of 181 children with SRNS who have been followed for at least 5 years. Eighty-five percent were primary nonresponders, 15% were late nonresponders, and 13% had a sibling affected by the same disease. Initial renal biopsy had shown MCD in 62 cases and FSGS in 119 cases. Renal survival rates were 65% at 5 years, 50% at 10 years, and 34% at 15 years. It is interesting to note that the rate of progression to ESRF was similar in patients with minimal changes or FSGS on initial biopsy.

Data reported in other series are difficult to compare, as most of them deal with patients with FSGS. The Southwest

Pediatric Nephrology Study Group (27) reported 75 children with FSGS followed for periods of 7 to 217 months. Twenty-one percent had progressed to ESRF, 23% had decreased GFR, 37% had a persistent nephrotic syndrome, and 11% were in remission.

Progression to ESRF has been reported to be more rapid in patients of African or Hispanic descent when compared with whites. Ingulli and Tejani found that among 57 black and Mexican American children, 50% of them reached ESRF in 3 years, and 95% reached this stage after 6 years (28). In addition, among the children with idiopathic nephrotic syndrome, the proportion of those with steroid-resistant FSGS was increased in black and Mexican American children.

Growth

Growth may be severely affected in children with persistent nephrotic syndrome. Hypothyroidism related to urinary loss of iodinated proteins has been observed and may be treated. Low plasma IgF1 and IgF2 levels associated with urinary loss of carrier proteins have also been reported (29). The response of such patients to growth hormone therapy has not been studied.

Infections

Bacterial infections are frequent in nephrotic children. Sepsis may occur at the onset of the disease. The most common infection is peritonitis, often with *Streptococcus pneumoniae* (30). Other organisms may be responsible: *Escherichia coli*, *Streptococcus bovis*, *Haemophilus influenzae*, and other gram-negative organisms. Apart from peritonitis, children may develop meningitis, pneumonitis, and cellulitis. Several factors may explain the propensity of nephrotic children to develop bacterial infections: low IgG levels due to an impaired synthesis, urinary loss of factor B, and impaired T-lymphocyte function. Factor B is a cofactor of C3b of the alternative pathway of a complement that has an important role in opsonization of bacteria, such as *S. pneumoniae*.

Thrombosis

Nephrotic patients are at risk of developing thromboembolic complications. Several factors contribute to the increased risk of thrombosis: hypercoagulability state, hypovolemia, immobilization, and infection. A number of hemostatic abnormalities have been described in nephrotic patients: (a) increased platelet aggregability; fibrinogen; and factors V, VII, VIII, X, and XIII; and (b) decreased levels of antithrombin III, heparin cofactor, proteins C and S, and factors XI and XII. Furthermore, fibrinolytic system components (e.g., tissue plasminogen activator, plasminogen activator inhibitor-1) are increased (31). The incidence of thromboembolic complications in nephrotic children is close to 3%. However, this percentage

may be underestimated as shown by systematic ventilation-perfusion scans, which have demonstrated defects consistent with pulmonary embolism in 28% of patients with steroid-dependent idiopathic nephrotic syndrome (32). Pulmonary embolism should be suspected in patients with SRNS who present with acute pulmonary or cardiovascular symptoms. The diagnosis may be confirmed by angiography or angioscintigraphy. Renal vein thrombosis should be suspected in cases with sudden macroscopic hematuria or acute renal failure. Doppler ultrasonography shows an increase in kidney size and the absence of blood flow in the renal vein. Thrombosis may affect the arteries (e.g., pulmonary arteries) or other deep veins.

RENAL BIOPSY

Light microscopic analysis of kidneys from patients with SRNS demonstrates three major morphologic patterns: minimal changes, diffuse mesangial proliferation, and FSGS.

Minimal Change Nephropathy

On light microscopy, glomeruli may be normal with normal capillary walls and normal cellularity. Swelling and vacuolation of epithelial cells and a slight increase in mesangial matrix are often observed. Mild mesangial hypercellularity may be noted (17,33,34) as well as scattered foci of tubular lesions and interstitial fibrosis.

Ultrastructural changes are always present, involving podocytes and mesangial stalks. Podocyte foot-process fusion is generalized and constant; its extent is closely related to the degree of proteinuria (35). Other epithelial changes consist of microvillus formation and the presence of numerous protein reabsorption droplets. The GBMs are normal, with no parietal deposits. The endothelial cells are often swollen (36). Mesangial alterations include mesangial cell hyperactivity, increased mesangial matrix, and occasionally finely granular, osmiophilic deposits located along the internal side of the basement membrane. These ultrastructural alterations are nonspecific and are probably related to massive proteinuria.

Diffuse Mesangial Proliferation

Some patients with steroid-resistant idiopathic nephrotic syndrome show a marked increase in mesangial matrix associated with hypercellularity (Fig. 28.1) (17,23,34, 37). However, peripheral capillary walls are normal, and immunofluorescence microscopy is negative. Electron microscopy shows foot-process fusion similar to the changes observed in MCD. The presence of mesangial hypercellularity has been reported to have prognostic significance with a higher rate of progression to renal failure (37), but these findings have not been confirmed by other authors (27,38).

FIGURE 28.1. Diffuse mesangial proliferation without sclerosis. Light microscopy with trichrome light green ($\times 400$).

Focal and Segmental Glomerular Sclerosis

The glomerular lesions affect a variable proportion of glomeruli (11,17,34). The focal changes are limited to a part of the tuft, with the other capillary loops showing no modification. The lesions always predominate at the corticomedullary junction (39). The segmental lesion affects a few capillary loops that stick together either at the hilum or at the periphery of the tuft (Fig. 28.2) (40,41). The clinical course has been found to be more benign when the location of these sclerotic lesions is peripheral (the tip lesion), although such findings have not been confirmed by other authors (42,43). Hyaline material is often present within the sclerotic lesions. A clear halo zone is observed at the periphery of the sclerotic segments. The segmental lesion has a different aspect depending on whether it affects a group of capillary loops free in Bowman's space or is adherent to Bowman's cap-

FIGURE 28.2. Focal and segmental glomerular sclerosis. Obliteration of capillary lumens by a combination of sclerosis and hyalinosis. Light microscopy with trichrome light green ($\times 280$).

FIGURE 28.3. Focal and segmental glomerulosclerosis. Segmental lesion of the tuft is characterized by the obliteration of capillary lumens by granular and lipid deposits. Multilayered basement membrane material is seen around the lesion. Note the presence of focal detachment of podocytes along the adjacent capillary lumens. Electron microscopy with silver impregnation ($\times 3900$).

sule. The free sclerotic segments are always surrounded by a crown of flat or hypertrophied podocytes. The podocytes form a continuous layer overlying the damaged areas of the tuft and in close apposition to the clear halo. When the sclerotic lesion is adherent to Bowman's capsule, there is a direct synechia between the collapsed capillary loops and Bowman's basement membrane. The rest of the tuft and the nonsclerotic glomeruli show either minimal changes or diffuse mesangial proliferation, both with foot-process fusion. Glomerular hypertrophy is common in FSGS; when such hypertrophy is found in MCD, it is somewhat predictive of further development to FSGS (44,45).

Tubular atrophy and interstitial fibrosis are often present and apparently proportional to the glomerular damage (11,46). Focal glomerular lesions should therefore be suspected when focal tubular and interstitial changes are found associated with minimal glomerular changes. On immunofluorescence, the segmental lesions show strong staining with anti-IgM and anti-C3 antisera.

By electron microscopy, the lesion is characterized by the presence of paramesangial and subendothelial, finely granular, osmiophilic deposits (46–48), with either disappearance or swelling of endothelial cells, and an increase in mesangial matrix material (Fig. 28.3). Fatty vacuoles may be seen in the middle of the abnormal deposit or in the cytoplasm of endothelial and mesangial cells. The peripheral synechia, located between podocytes and basement membrane, is formed by the apposition of acellular material in which thin and irregular layers of newly formed basement membranes are visible. Modifications of the podocytes consist of focal cytoplasmic degeneration, breakdown of cell membranes, and detach-

ment of epithelial cells from basement membranes, with filling of the resulting space by cell debris and new membranes (49).

A subgroup of patients has collapsing focal segmental glomerular sclerosis characterized by a global collapse of the glomerular capillaries with marked hypertrophy of epithelial cells (Fig. 28.4) (50). These patients rapidly progress to renal failure. Such features closely resemble those observed in human immunodeficiency virus-associated nephropathy (51). Many authors consider collapsing glomerulopathy to be a distinct form of FSGS that may be idiopathic, observed in renal transplants of patients with recurrent nephrotic syndrome, or associated with human immunodeficiency virus or parvovirus infection (52,53). Idiopathic collapsing glomerulopathy predominates in blacks and has a poor prognosis (54).

Recent studies on collapsing glomerulopathy and on patients with recurrence of nephrotic syndrome after renal transplantation have shown important changes in the podocytes with major cell cycle derangement (4,5). The normal, mature podocyte does not divide and does not express proliferative markers (e.g., proliferating cell nuclear antigen and Ki-67). The podocyte expresses several cell-surface proteins (e.g., WT-1, C3b receptor, glomerular epithelial protein-1, podocalyxin, synaptopodin, and vimentin). The first stages of FSGS are characterized by the loss of cell surface proteins and the expression of macrophage markers and cytokeratin. Proliferation markers (proliferating cell nuclear antigen and Ki-67) are expressed. This "podocyte dysregulation" is accompanied by podocyte detachment from the GBM.

FSGS is an irreversible scarring process in the glomeruli, as shown by the analysis of repeat biopsies (47,48,55). Studies in experimental animals (56) as well as in nephrotic patients have shown that proteinuria precedes the development of focal sclerotic lesions. The same sequence was reported in patients with recurrence of the disease

FIGURE 28.4. Collapsing glomerulopathy. Early glomerular lesion characterized by the irregular collapse of capillary loops. Light microscopy with periodic acid-Schiff ($\times 320$).

FIGURE 28.5. Idiopathic nephrotic syndrome with minimal changes. Diffuse mesangial deposits of immunoglobulin M. Immunofluorescence ($\times 300$).

after transplantation. Within weeks after recurrence of proteinuria, podocytes appear swollen and vacuolated by electron microscopy. The podocytes exhibit strong mitotic activity, with multinucleation and expression of the proliferating cell nuclear antigen and Ki-67 proliferation markers.

FSGS is not a specific histopathologic lesion: Similar alterations may be seen in persistent idiopathic proteinuria; heroin-associated nephropathy; and, independently, in association with acquired immunodeficiency syndrome, Alport's syndrome, hypertension, pyelonephritis, and obesity. FSGS has also been reported in renal hypoplasia with oligomeganephronia, after partial nephrectomy, and in other conditions associated with a reduction in nephron number, including reflux nephropathy and obstructive uropathy.

Immunoglobulin M–Associated Nephropathy

Immunofluorescence microscopy is usually negative (57,58). However, mesangial deposits of IgM, IgG, C3, and, more rarely, IgA have been reported (Fig. 28.5). Cohen et al. found that patients with IgM deposits in the mesangium had a poor response to corticosteroids (59). Other studies have not confirmed these findings. Habib et al. reported on immunofluorescence studies in a series of 222 children with idiopathic nephrotic syndrome (60). Although IgM was the Ig most frequently present in the glomeruli (54 of 222), there was no correlation between IgM deposits, the initial response to steroid therapy, or the final outcome. IgM deposits have also been described in association with diffuse mesangial proliferation and with FSGS.

Relationship between the Different Histologic Patterns

Repeat renal biopsies in patients with idiopathic nephrotic syndrome have shown morphologic transition between the

three main histologic patterns. Some patients with clear evidence of minimal changes on initial biopsy have FSGS on a second biopsy. A high proportion of these patients are steroid resistant. Tejani found that FSGS lesions had developed in 60% of 48 patients with steroid-resistant MCD, in association with aggravation of symptoms (61). The progression to sclerosis may occur from minimal change or from mesangial proliferation (37,62). Conversely, some patients who show diffuse mesangial proliferation, regardless of whether it is associated with focal sclerosis on initial biopsy, may demonstrate minimal change or FSGS on repeat biopsy (27).

In conclusion, it may be considered that, at least in children, MCD, FSGS, and diffuse mesangial proliferation represent histologic variations of idiopathic nephrotic syndrome that may be found alone or in any combination on sequential biopsies in the same patient.

CLINICOPATHOLOGIC CORRELATIONS

The relative frequencies of the three histologic patterns differ in steroid-sensitive and steroid-resistant patients. A report of the International Study of Kidney Disease in Children showed that among 354 patients with idiopathic nephrotic syndrome who had an initial response to prednisone, 95.5% had MCD, 3.0% had FSGS, and 1.5% had diffuse mesangial proliferation. Conversely, among 55 patients who did not respond to prednisone, 45.5% had MCD, 47.5% had FSGS, and 7.0% had diffuse mesangial proliferation (63). This study also analyzed the numbers of responders and nonresponders within each histologic category. Among the 363 patients with minimal change, 193.1% were responders and 6.9% nonresponders, whereas among the 37 patients with FSGS, 29.7% responded to prednisone and 70.3% did not. Waldherr et al. found that only 2 out of 36 patients with diffuse mesangial proliferation responded to corticosteroids (37).

PATHOPHYSIOLOGY

In 1974, Shalhoub postulated that lymphokines may be responsible for the increased permeability of the GBM (64). Lagrue et al. first described the vascular permeability factor (VPF), a lymphokine found in the supernatant of concanavalin A-activated lymphocytes from patients with MCD that enhances vascular permeability when injected intradermally into the guinea pigs (65,66). Heslan et al. showed that VPF was produced by T lymphocytes and was distinct from interleukin (IL)-2 (67,68). Maruyama et al. showed that cyclosporine at concentrations ranging from 100 to 250 ng/mL was able to suppress the *in vitro* production of VPF by mononuclear cells from patients with MCD (69). VPF was also found in other diseases,

such as IgA nephropathy. Tanaka et al. found that the supernatants of concanavalin A-activated lymphocytes from patients with MCD or FSGS induced a marked proteinuria when injected in the renal artery of rats together with a reduction of the anionic charges of the GBM (70). Boulton-Jones et al. infused lymphocyte culture supernatants into the renal artery of rats and found reduced colloidal iron staining in the kidneys, suggesting a loss of negative charges of the GBM (71). Similarly, Wilkinson et al. showed that the infusion of plasma from nephrotic patients to rabbits induced proteinuria and a reduction in the number of anionic sites on the GBM (72).

Koyama et al. described a glomerular permeability factor in the supernatant of T-cell hybridoma derived from the fusion between peripheral T lymphocytes of a patient with MCD and a T-cell line, CCRF-HSB2 (73). The glomerular permeability factor was identified by the ability of the supernatant to induce a proteinuria when injected intravenously (IV) in the rat. In addition, rats injected with the supernatants show a partial fusion of foot processes of glomerular epithelial cells and no immune deposits. Glomerular permeability factor is different from the other known lymphokines. Its molecular weight is between 60,000 and 160,000.

Other lymphokines may play a pathogenic role in SRNS (74). Increased IL-2 levels have been found in lymphocyte culture supernatants from patients with idiopathic nephrosis, and IL-2 can induce proteinuria and a reduction of the anionic sites of the GBM when injected into the rat kidney (68,75). A nephrotic syndrome has been described in several patients treated with recombinant IL-2 and interferon- α .

The rapid recurrence of proteinuria after renal transplantation in 30% of patients with SRNS is a strong argument for the presence of a circulating factor that increases the permeability of the GBM. Savin et al. identified a serum factor in some patients with FSGS that increases the albumin permeability of isolated rat glomeruli. The presence of the factor was strongly predictive of the recurrence of proteinuria after renal transplantation (76). A VPF, which induces proteinuria when injected into the renal artery of rats, was found in the serum from a transplanted patient who had recurrence of the nephrotic syndrome (77). However, subsequent attempts to isolate such a factor have failed. Dantal et al. treated patients who had recurrent nephrotic syndrome with plasma protein A adsorption (78). The administration to rats of material eluted from the protein A columns increased urinary albumin excretion. The active fraction had a molecular weight below 100,000. The factor or factors that may be responsible for recurrent nephrotic syndrome after transplantation appear to be bound to an Ig (79).

The Buffalo/Mna strain of rats spontaneously develops proteinuria with FSGS at 2 months of age. Le Berre

et al. found that the nephrotic syndrome recurs when Buffalo/Mna rats receive a kidney from a healthy LEW.1W rat (80). Conversely, proteinuria and renal lesions regress when kidneys from a Buffalo/Mna rat are transplanted into normal LEW.1W rats. Although recurrence of proteinuria is not immediate after transplantation, this model may provide new insights into the pathogenesis of FSGS and the mechanisms of recurrence after transplantation in humans.

Two additional observations indicate that circulating factors, rather than innate kidney defects, render the GBM more permeable to proteins: Lagrue et al. reported the case of a woman with steroid-resistant FSGS who gave birth on two occasions to children who were proteinuric and hypoalbuminemic at birth. In both cases, proteinuria and nephrotic syndrome disappeared within 2 and 3 weeks, respectively (81). The second observation concerns the report of a 20-year-old man with MCD who died of cerebral hemorrhage and whose kidneys were transplanted into two recipients whose primary renal disease was not idiopathic nephrotic syndrome. In both cases, proteinuria and all features of MCD disappeared within 6 weeks of transplantation (82).

The pathogenesis of glomerulosclerosis is still unknown (83). Several factors, including hemodynamic factors, cytokines and growth factors, hyperlipidemia, and platelet activation, lead to an increase of mesangial matrix production by resident cells. Patients with lesions of FSGS have a significant glomerular hypertrophy. Experimental and clinical data demonstrate that abnormal glomerular growth is associated with glomerular sclerosis. Growth factors involved in the process include platelet-derived growth factor, TFG- β , angiotensin II, thromboxane A₂, macromolecule deposition, coagulation factors, and lipids (84–86). It is interesting to note that angiotensin regulates the expression of platelet-derived growth factor and TFG- β . This may explain the fact that angiotensin-converting enzyme inhibitors may prevent the decline of renal function in nephrotic patients.

Genetic Factors

In recent years, there have been several reports on the molecular basis of familial cases of idiopathic nephrotic syndrome with FSGS. Moreover, the discovery of molecular defects leading to FSGS has provided important insight in the critical role of newly identified podocyte proteins in the glomerular filtration barrier to proteins.

Mathis et al. performed linkage analysis in a large family in which FSGS followed an autosomal dominant mode of inheritance (87). Some patients developed severe proteinuria and ESRD by the fourth decade, whereas others had only mild proteinuria. The responsible gene, located on chromosome 19q13, encodes α -

actinin-4, an actin-filament cross-linking protein (88). Mutations in this gene were detected in affected patients (88). In vitro, mutant α -actinin-4 binds filamentous actin more strongly than does wild-type α -actinin-4. Regulation of the actin cytoskeleton of glomerular podocytes may be altered in this subpopulation of FSGS patients.

Another family with autosomal dominant FSGS was studied by linkage analysis (89,90). The disease was diagnosed during the third decade of life, with high-grade proteinuria progressing to ESRD in a relatively high percentage of cases. The authors detected a linkage to chromosome 11q21-q22 with a maximum lod score of 9.89. Winn et al. described another large family with autosomal dominant FSGS but no linkage to chromosome 11q21 or 19q13 (90).

Fuchshuber et al. mapped a locus to chromosome 1q25-q31 for autosomal recessive SRNS characterized by an early-onset steroid resistance, a rapid progression to renal failure, and the absence of recurrence after transplantation (91). Using a positional cloning approach, Boute et al. identified the causative gene, NPHS2, which is expressed only on podocytes and encodes an integral membrane protein, podocin (92). By immunoelectron microscopy, podocin is located at the foot processes, opposite the slit diaphragm (93). This 42-kDa protein is structurally related to human stomatin, an adapter protein that links mechanosensitive channels to the cytoskeleton on the cell surface. Podocin may link membrane proteins (e.g., nephrin) to the cytoskeleton. Ten different NPHS2 mutations comprising nonsense, frameshift, and missense mutations were found to segregate with the disease. Podocin mutations have also been identified in 15 to 30% of patients with sporadic SRNS (94,95).

CD2-associated protein (CD2AP), which anchors CD2 receptors of T lymphocytes to the cytoskeleton, is also expressed in the podocyte. Shih et al. observed that mutant mice lacking CD2AP develop proteinuria and renal failure (96). They showed that CD2AP and nephrin interact directly, suggesting an important role of this protein in the anchoring of nephrin to the slit diaphragm or into the signaling pathways (97). No mutations in the CD2AP gene associated with SRNS have been reported to date.

The Wilms' tumor suppressor gene, WT-1, encodes a transcription factor presumed to regulate the expression of numerous target genes through DNA binding. It plays a key role in renal and gonadal maturation. Mutations in WT-1 have been associated with nephroblastoma or glomerular diseases (Denys-Drash syndrome and Frasier syndrome). The WT-1 gene contains ten exons covering approximately 50 kb of genomic DNA. Exons 1 to 6 encode a proline/glutamine-rich transcriptional regulatory region, whereas exons 7 to 10 encode the four zinc-fingers of the DNA-binding domain. Two alternative splicing regions—one corresponding to the 17 amino acids encoded

by exon 5 and the other to three amino acids [lysine-threonine-serine (KTS)] encoded by the 3' end of exon 9—lead to the synthesis of four isoforms with definite and stable proportions and different functions. The target genes potentially regulated, most often negatively, by WT-1 include genes coding for transcription factors (e.g., PAX2, PAX8, NovH, and WT-1) and for growth factors or their receptors (insulin-like growth factor-2, insulin-like growth factor-R, platelet-derived growth factor-A, TGF- β , and EGFR) (98). WT-1 is strongly expressed during embryofetal life (99). In the mature kidney, WT-1 expression persists only in podocytes and epithelial cells of Bowman's capsule. WT-1 gene disruption in mice results in the absence of kidneys and gonads, suggesting a key role of WT-1 in the maturation of the genitourinary tract.

Frasier syndrome is characterized by male pseudohermaphroditism and progressive glomerulopathy (100). Proteinuria is discovered during childhood, usually between 2 and 6 years of age or later. It increases progressively with time and does not respond to corticosteroids or to immunosuppressive agents. The disease runs a slow, progressive course to ESRD. Renal biopsy shows FSGS. No recurrence is observed after transplantation. Patients have female external genitalia, and it is often the evaluation of primary amenorrhea in nephrotic females that leads to the diagnosis of 46,XY gonadal dysgenesis, which is frequently complicated by gonadoblastoma.

Barboux et al. detected point mutations in the donor splice site in intron 9 of the WT-1 gene (101). These mutations were heterozygous, and appeared *de novo* in the two patients whose parents were studied. The mutations result in loss of the +KTS isoform. Similar intronic mutations have been described by other authors (102,103). This indicates that donor splice-site mutations in WT-1 intron 9 are constant in Frasier syndrome. The former definition of Frasier syndrome included only 46,XY patients with a female phenotype. However, Frasier syndrome mutations may be responsible for isolated persistent glomerulopathy with focal sclerosis in genetically female patients and in patients with Denys-Drash syndrome (104,105).

Nephrotic syndrome with FSGS has been reported in patients with mitochondrial cytopathies (106–108). An A to G transition at position 3243 in mitochondrial DNA was reported in some of these patients who presented with isolated nephrotic syndrome or with nephrotic syndrome in association with mitochondrial myopathy, encephalopathy, lactic acidosis, stroke-like episodes, or progressive external ophthalmoplegia. Other patients develop diabetes mellitus or hearing loss.

Some familial cases of minimal change nephrotic syndrome are associated with other abnormalities (e.g., microcephaly and hiatus hernia), as in the Galloway-Mowat syndrome (109). Spondyloepiphyseal dysplasia was found in association with FSGS (110). Other syndromes, including microcephaly or disturbances of neuronal migration,

have also been reported in association with early-onset nephrotic syndrome (111).

TREATMENT

Symptomatic Treatment

Symptomatic treatment—including dietary recommendations; use of diuretics; prevention and therapy of infectious and thromboembolic complications; and treatment of hypovolemia, hypertension, and hyperlipidemia—is identical to that recommended for the glucocorticoid-responsive patient with idiopathic nephrotic syndrome (see Chapter 27).

Immunosuppressive Therapy

By definition, patients with SRNS have not responded to standard glucocorticoid regimens (see Chapter 27).

Pulse Methylprednisolone

Methylprednisolone pulse therapy has been advocated for patients with SRNS. The protocol proposed by Mendoza et al. consists of methylprednisolone (30 mg/kg IV) administered every other day for 2 weeks; weekly for 8 weeks; every other week for 8 weeks; monthly for 9 months; and then every other month for 6 months in association with oral prednisone and, if necessary, cyclophosphamide or chlorambucil (112). At an average of over 6 years of follow-up, 21 of 32 children were in complete remission, and the 5-year incidence of ESRD was approximately 5% versus 40% in historic controls (113). Side effects included nausea during the infusion of pulse methylprednisolone in almost all, slowed growth in four patients, small cataracts that did not interfere with vision in five patients, and infections in two patients. There were no cases of abdominal striae, diabetes mellitus, or aseptic necrosis of bone.

Initial enthusiasm for usage of pulse methylprednisolone in patients with SRNS has been decreased by subsequent studies that have failed to produce similar results. A preliminary multicenter report of 15 children with FSGS was unable to confirm the efficacy of pulse corticosteroids (114). A mean of 15 pulses were given, and eight patients also received an alkylating agent. At the end of the study, only four patients maintained a complete remission, whereas five patients had a poor outcome with progression to ESRD or death. Waldo et al. did not observe complete remission in ten children who were treated with this protocol (115), whereas Hari et al. reported a 65% response rate (116).

Alkylating Agents

Although alkylating agents have little therapeutic effect in patients with SRNS, they are still widely used either alone or in combination with corticosteroids. Cyclophosphamide has

been more often used than chlorambucil. The rate of full or partial remission is higher in patients with partial steroid resistance, those with late steroid resistance, or those in whom initial renal biopsy has shown MCD, by comparison with those showing initial resistance to corticosteroids or FSGS. The International Study of Kidney Disease in Children recently reported on 60 children with steroid-resistant FSGS who were randomly allocated to receive (a) prednisone, 40 mg/m² on alternate days for 12 months (control group) or (b) cyclophosphamide, 2.5 mg/kg body weight for 3 months plus prednisone, 40 mg/m², on alternate days for 12 months (117). Complete remissions were observed in 28% of children in the control group and in 25% of children who received cyclophosphamide. The authors concluded that there was no beneficial effect of cyclophosphamide in these patients. Geary et al. reported full or partial response to cyclophosphamide in 12 of 29 steroid-resistant patients with FSGS (118). Renal failure developed less frequently in partial responders (one of nine) than in those who did not respond at all (seven of eight). Siegel et al. observed complete remissions in six steroid-resistant patients with MCD, three of whom relapsed but became steroid responsive (119). Similarly, Bergstrand et al. reported that some patients with steroid-resistant nephrosis treated with cyclophosphamide had become steroid responsive (120). Conversely, White and Glasgow observed no improvement after cyclophosphamide treatment in 15 steroid-resistant children with focal sclerosis (121). Cameron et al. reported only 1 responder out of 13 children with steroid-resistant nephrosis and FSGS who received cyclophosphamide (122). Similarly, Tejani et al. reported no remission with cyclophosphamide in ten steroid-resistant children (123). In a controlled trial involving 13 children with steroid-resistant minimal change nephrotic syndrome, IV pulse cyclophosphamide was shown to be beneficial when compared to oral cyclophosphamide (124). Rennert et al. treated ten children with steroid-resistant FSGS with IV cyclophosphamide. Only two of the five patients who were initial nonresponders went into remission, whereas all five late nonresponders achieved complete remission (125).

The side effects of cyclophosphamide include bone marrow depression, hemorrhagic cystitis, gastrointestinal tract symptoms, alopecia, and infection. Hemorrhagic cystitis occurs infrequently at the doses used in these patients.

Long-term toxic effects include the risk of cancer, pulmonary fibrosis, ovarian fibrosis, and sterility. Gonadal toxicity is well established, and the risk of sterility is greater in boys than in girls. The cumulative threshold dose above which oligo- or azoospermia may occur is above 250 mg/kg (126,127). Azoospermia is reversible in some patients (128). The risk of cancer is difficult to define with the short courses used to treat idiopathic nephrotic syndrome.

Chlorambucil has been used in a few studies. Baluarte et al. described remissions in 10 of 17 cases (129). Williams et al. treated six children who all went into remission with a follow-

up of 1.3 to 9.4 years (130). We treated 74 steroid-resistant children with chlorambucil, 0.2 mg/kg, for 2 to 6 months, and only 14 (19%) achieved complete or partial remission.

Acute toxic effects are less frequent with chlorambucil than with cyclophosphamide. Leukopenia and thrombocytopenia may occur and are reversible within 1 to 3 weeks. Severe viral infections have been reported. Long-term toxic effects include an increased risk of malignancy (131). Gonadal toxicity, which predominantly affects male patients, is probably irreversible (azoospermia) at cumulative doses above 10 mg/kg.

Combined Immunosuppression

Trompeter proposed aggressive immunosuppression for a subgroup of patients with FSGS, refractory nephrotic syndrome, or rapid progression to renal failure (132). The regimen included vincristine, 1.5 mg/m²/wk in eight weekly IV doses; cyclophosphamide, 3 mg/kg/day for 8 weeks; and prednisolone, 2 mg/kg/day initially, with progressive tapering after 2 weeks. Lasting remissions were observed in 7 of 21 children, starting 6 months to 3 years from the onset of therapy. Almeida et al. observed a complete and stable remission in only two of the seven children who received this regimen (133).

Azathioprine

Azathioprine was considered to be ineffective in steroid-resistant patients after the report of Abramowicz et al., who found no difference between a 3-month course of azathioprine and placebo (134). However, Cade et al. reported complete remission in 13 adult patients with steroid-resistant idiopathic nephrotic syndrome (135).

Cyclosporine

Cyclosporine has been used to treat patients with SRNS. Initial reports showed that only 20% of 60 steroid-resistant children achieved complete remission (136–142). A partial response was observed in 13% of cases, but it was usually transient (143).

The Collaborative Study of Sandimmune in Nephrotic Syndrome analyzed the data from different clinical studies, including 226 steroid-resistant patients, adults, and children (144). The analysis demonstrated that the rate of complete remission was significantly higher when cyclosporine was given in combination with steroids: 24% compared to 14%.

The French Society of Pediatric Nephrology reported the results of a prospective trial, including 65 children treated with cyclosporine, 150 to 200 mg/m², and prednisone, 30 mg/m²/day for 1 month and on alternate days for 5 months thereafter (145). Twenty-seven patients (42%) went into complete remission and four (6%) partial remission, whereas 34 (52%) did

not respond to the combined treatment. Complete remission occurred in more than one-half of the patients within the first 2 months of this treatment, which makes it likely that the treatment was responsible for the remission, although spontaneous remission cannot be excluded. It is interesting to note that eight patients who relapsed after cyclosporine treatment subsequently responded to steroids and experienced a steroid-dependent course. Progression to renal failure was observed only in patients who had not responded (12 patients) or had only a partial response (1 patient) to the combined treatment.

Ingulli et al. reported that prolonged cyclosporine treatment in children with steroid-resistant FSGS reduced proteinuria and slowed progression to ESRF (146). The dose of cyclosporine (4 to 20 mg/kg/day) was titrated to the serum cholesterol level to achieve a remission. In this study, only 5 of the 21 treated patients (24%) progressed to ESRF compared to 42 of 54 patients from a historical control group who had not received this treatment.

Ponticelli et al. compared cyclosporine to supportive therapy in a randomized trial (147). Seven of the 22 treated patients went into complete remission, six experienced partial remission, and nine did not respond. Only 38% of the patients who responded had sustained remissions. In the control group, only 3 of the 19 patients achieved partial remission. Tejani and Liberman compared cyclosporine and placebo in 25 children with steroid-resistant FSGS (148). All 12 patients who were treated demonstrated a decrease in proteinuria compared to two in placebo-treated patients.

Gregory et al. treated 15 children with SRNS cyclosporine combined with prednisone. They observed a remission in 13 children after a mean duration of treatment of 2 months (149).

Singh et al. recently reported the effect of cyclosporine in 42 children with steroid-resistant FSGS (150). The mean proteinuria decreased from 7.1 to 1.8 g/day, whereas the serum albumin increased from 2.1 to 3.5 g/dL. The mean serum creatinine increased from 0.85 to 1.26 mg/dL. Twenty-five patients responded with a complete remission.

Patients who respond to cyclosporine often relapse when the dose is tapered or discontinued (151). Many reports indicate that the prolonged use of cyclosporine is associated with chronic nephrotoxicity. The most prominent histologic feature of chronic cyclosporine nephrotoxicity is the presence of tubulointerstitial lesions, characterized by stripes of interstitial fibrosis containing groups of atrophic tubules. Cyclosporine-associated arteriopathy is rarely observed. Classen et al. did not find significant changes on the renal biopsies of five patients treated for a mean period of 10 months (152). Habib and Niaudet performed repeat renal biopsies in 42 patients (153). There were no significant changes in 18 patients, several foci of atrophic tubules with thickened basement membranes within stripes of interstitial fibrosis in 15 patients, and extensive lesions of interstitial fibrosis with atrophic tubules in nine patients. In this study, 9 of the 15 patients with several foci of atrophic

tubules and all nine patients with severe interstitial fibrosis had MCD on pre- and posttherapy biopsies without FSGS, suggesting that the lesions were secondary to cyclosporine and not to the natural course of the disease. At the time of most recent biopsy, all children, including the nine patients with the most severe tubulointerstitial lesions, had normal renal function. Thus, morphology is a more sensitive indicator of chronic cyclosporine nephrotoxicity than GFR.

Other side effects give less cause for concern and respond to standard therapy: elevation of blood pressure, hyperkalemia, hypertrichosis, gum hypertrophy, and hypomagnesemia.

FK506

A few patients have been treated with the immunophilin modulator FK506 with poor results (154).

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs may decrease proteinuria. Several authors have used indomethacin in the treatment of idiopathic nephrotic syndrome with variable results. Donker et al. found a reduction of proteinuria in patients with focal sclerosis associated with a simultaneous reduction of GFR (155). Velosa et al. also reported a significant reduction in proteinuria in patients treated with meclofenamate (156).

The detrimental effect of nonsteroidal antiinflammatory drugs on renal function is well established, and patients with renal disease seem more vulnerable (157,158). Positive sodium balance, increased edema, and risk of arterial hypertension are recognized complications. The decreased GFR observed with nonsteroidal antiinflammatory drugs is usually reversible and marked only in salt-sodium-depleted patients. However, irreversible renal failure was reported with a high incidence in a prospective study in children with nonresponsive nephrotic syndrome and focal sclerosis (159).

Angiotensin-Converting Enzyme Inhibitors

The angiotensin-converting enzyme inhibitor captopril was reported to dramatically decrease nephrotic range proteinuria secondary to renovascular hypertension and secondary FSGS (160). A decrease in proteinuria and even complete remission have also been observed in patients with chronic glomerulopathies with or without hypertension (161). Reduction of proteinuria by 50% without a concomitant decrease in GFR was reported in children with SRNS (162). Further studies are needed to confirm these observations.

Lipid-Lowering Agents

Hyperlipidemia has been shown to accelerate the progression of glomerular sclerosis in experimental animals. Con-

trolled trials in adult patients have shown that lipid-lowering agents can prevent the decline of renal function in a variety of chronic nephropathics. No such studies have been performed in children.

RECURRENCE OF IDIOPATHIC NEPHROTIC SYNDROME IN TRANSPLANTED KIDNEYS

A major problem in patients with idiopathic nephrotic syndrome who progress to ESRF and subsequently undergo renal transplantation is the risk of recurrent disease in the graft. The overall risk of recurrence is estimated at 25%. The risk appears to be different in children and adults. Senggutuvan et al. reported recurrence in 8 of 16 children compared to 3 of 27 adults (163). In children, recurrence is more frequent when the disease is diagnosed after 6 years of age (164,165). Similarly, a rapid progression of the disease to ESRF was a major factor associated with recurrence: In most series, when the duration of disease has been shorter than 3 years, the nephrotic syndrome recurs in one-half of the patients (166,167). The histopathologic pattern observed on the first biopsy during the course of the disease is also an important predictive factor (163,165,166,168,169). Recurrence occurs in 50 to 80% of patients in whom initial biopsy showed diffuse mesangial proliferation but in only 25% of patients with MCD on initial biopsy. Most patients who experience a recurrence in a first graft show recurrence in a second graft (170–173). Conversely, when a first graft has been lost due to rejection without recurrence, a second graft can be performed safely, as no recurrence has been described in this setting.

In children, recurrence of proteinuria occurs in most cases within the first hours or days after transplantation. A high proportion of patients with immediate recurrence show delayed graft function (164,170,174). In some patients, proteinuria recurs several months later. Proteinuria is most often associated with a nephrotic syndrome. Transplant biopsy, when performed early, usually shows minimal glomerular changes with foot-process fusion (175–177). Lesions of FSGS appear after several days or weeks (176).

Graft failure occurs in approximately 60% of patients with recurrence versus 23% of those without recurrence (163,164,170,178). Some patients may maintain adequate renal function for several years despite persistent nephrotic syndrome (164,167).

The role of cyclosporine in recurrent SRNS remains unclear. There is no evidence that cyclosporine can prevent the recurrence of nephrotic syndrome after transplantation (179–184). After the introduction of cyclosporine, the incidence of recurrence did not change, but graft survival improved (164,179,180,183). In patients who have recurrent disease, high doses of cyclosporine may be effective. Mowry et al. reported on 11 children who received 12 renal transplants and who had been treated with high-dose cyclo-

sporine, plasma exchanges, or a combination of both (185). Remission was observed in 10 of the 12 recipients. Ingulli and Tejani reported two children with recurrent nephrotic syndrome who both achieved remission when cyclosporine dosage was gradually increased from 15 mg/kg/day to 27 and 35 mg/kg/day (186). A similar experience was reported by Srivastava et al. (187). In our group, 17 children with recurrence were treated with IV cyclosporine at an initial dose of 3 mg/kg/day, which was then adjusted to maintain whole blood levels between 250 and 350 ng/mL. In 14 of the 17 cases (82%), proteinuria completely disappeared after 20.8 ± 8.4 days (range, 12 to 40 days). The treatment was ineffective in the remaining three patients. Plasma exchanges were performed in four patients during the first 2 months, and proteinuria regressed in three cases and persisted in one. Persistent remission was observed in 11 patients with a follow-up of 3.7 ± 3.0 years. Actuarial graft survival was 92% and 70% at 1 and 5 years (188). We advocate the early use of IV cyclosporine as a first-line treatment in recurrent idiopathic nephrotic syndrome after renal transplantation. There is limited experience with the use of tacrolimus (FK506) in recurrent nephrotic syndrome after transplantation (189).

Plasma exchange has been performed in a number of patients and, in some cases, combined with increased immunosuppression (190–196) and associated with partial or transient remissions. Improved results were observed when the treatment was started early. Dantal et al. treated eight kidney transplant recipients with recurrent nephrotic syndrome with plasma protein adsorption (78). The treatment consistently decreased urinary protein excretion by an average of 82% at the end of a cycle. The effect of adsorption was short-lived, and protein excretion returned to pretreatment levels within a maximum of 2 months.

CONCLUSION

There is evidence to suggest that MCD and FSGS represent a spectrum of diseases (197). Indeed, it is likely that several disease entities are included in the term *steroid-resistant idiopathic nephrotic syndrome*. In many patients, circulating agents produced by immune cells increase GBM permeability to proteins. In these patients, cyclosporine may be effective. Recurrence posttransplantation is another feature of such patients. In other patients, the disease is genetically transmitted and is resistant to all treatments. Defects in podocyte proteins have been identified in some of these familial cases.

IMMUNE MECHANISMS OF GLOMERULAR INJURY

ALLISON A. EDDY

OVERVIEW

Immunologic pathways initiate and propagate glomerular injury. Over the past decade, major advances in cellular, molecular, genetic, and immunologic sciences have provided significant new insights into the pathogenesis of glomerulonephritis. For the purpose of review, the immunopathogenic mechanisms can be divided into two basic phases. Primary mechanisms of glomerulonephritis focus on those events that initiate glomerular injury. These initial events alone rarely produce significant and sustained damage. The role of the humoral immune system, dependent on B lymphocyte activation and antibody production, has been recognized for nearly a century (Fig. 29.1). Although two distinct antibody-mediated pathways have been proposed, current evidence suggests that antibody interaction with antigens *in situ* within the glomerulus (which may or may not lead to the formation of immune complexes) predominates, whereas glomerular trapping of immune complexes preformed within the circulation occurs rarely, if ever. The cellular immune system, dependent on T-lymphocyte activation, occasionally triggers glomerular injury. However, for many glomerular diseases, separation of B-cell and T-cell pathways is rather artificial as the cellular and humoral effector limbs of the immune system often collaborate.

The secondary immune mechanisms of glomerular injury implicate cascades of inflammatory mediators that are recruited to propagate renal damage after the primary glomerular attack. Some of these mediators play essential roles; others may modify disease severity, but their participation is not essential. The secondary mediators are variable depending on the nature of the primary injury, but they often include lymphohemopoietic cells [polymorphonuclear leukocytes (PMNs), monocytes, and platelets] and activated components of the complement cascade. Resident glomerular endothelial cells, mesangial cells, and epithelial cells may be activated and further contribute to the inflammatory response. Most of the secondary mediators that have been identified are products of lymphohemopoietic cells or resi-

dent glomerular cells and include cytokines and growth factors, reactive oxygen metabolites, bioactive lipids [platelet-activating factor (PAF) and eicosanoids], proteases, and vasoactive substances [endothelin (ET) and nitric oxide (NO)]. It is hoped that by understanding the immunopathogenesis of glomerulonephritis, new therapeutic strategies will emerge. Furthermore, future genetic studies may find that genotype-dependent expression and/or activity levels of certain key mediators predict risk and severity of glomerulonephritis.

STRUCTURE OF THE GLOMERULAR CAPILLARY WALL AND MESANGIUM

A basic understanding of the architecture of the glomerulus is necessary to appreciate the basis of the dynamic interactions between intrinsic components of the glomerular capillary wall and mesangium and the blood-borne mediators of glomerular injury. The *glomerular basement membrane* (GBM) is a specialized extracellular matrix lined by the endothelial and visceral epithelial cells. It acts as a filtration barrier with selective permeability, allowing passage of small plasma molecules but almost completely restricting filtration of molecules larger than albumin. It also plays a more dynamic role regulating the adhesion and behavior of adherent cells. Chemical analyses have shown the GBM to be 80% collagenous proteins, primarily collagen IV (α_3 , α_4 , and α_5 chains). A number of the other components have been identified such as laminin-11 and entactin/nidogen (1). The GBM also contains proteoglycans, the most abundant of which is agrin. Although constituting only 1% of the dry weight of the GBM, these anionic components contribute significantly to the charge-selective properties of the ultrafiltration unit. The onset of proteinuria is usually characterized by a loss of charge as well as size selectivity. At least four theories have been proposed to explain the alterations in the GBM charge: masking by immune complexes, depolymerization by oxygen radicals, alterations in proteoglycan synthesis, and proteolytic diges-

FIGURE 29.1. Immunofluorescence and electron microscopic features of three distinct patterns of immune-mediated glomerular injury. In anti-glomerular basement membrane (GBM) nephritis, immunoglobulin G (IgG) is deposited in a linear pattern along the GBM (**A**). Although dense immune deposits are not detected by electron microscopy, there may be expanded lucent subendothelial areas (**B**). Membranous nephropathy is characterized by granular deposits of IgG and C3 (**C**) along the epithelial aspect of the glomerular capillary wall, which correspond to the subepithelial deposits present on electron microscopy (**D**). Immune complex–induced glomerulonephritis, illustrated by the renal biopsy of a patient with lupus nephritis, is characterized by the deposition of immunoglobulins and complement (**E**) along the glomerular capillary wall and within the mesangium. Electron microscopy reveals electron-dense deposits in similar locations (**F**).

tion (2). On the other hand, exactly how erythrocytes traverse the GBM remains enigmatic. A recent ultrastructural study suggests that they may traverse through gaps in the GBM (3).

The *mesangium*, the region occupying the centrolobular position between the mesangial cells and the perimesangial basement membrane, is similar in composition but not identical to the peripheral GBM. It consists of a dense network of microfibrils; fibronectin appears to be the most

abundant component. During the filtration process, some plasma enters the mesangial zone, gaining access through the mesangial “waist” or “angle,” bypassing the GBM. Circulating immune complexes commonly become lodged in this area.

The intrinsic glomerular cells—specialized epithelial cells (podocytes), mesangial cells, and endothelial cells—play an active role in the regulation of both normal physiologic processes and pathologic states. *Mesangial cells* have

TABLE 29.1. GLOMERULAR MATRIX ADHESION MOLECULES

	Matrix ligand	Glomerular expression		
		Mesangial	Epithelial	Endothelial

smooth muscle cell-like characteristics and attach to the GBM at several sites. Consequently, mesangial cell contraction modifies glomerular filtration. In response to injury, these cells may change phenotypically, and presumably functionally, by expression of additional smooth muscle cell proteins such as α smooth muscle actin, desmin, and calponin and matrix-binding integrin receptors (Table 29.1) (4,5). Mesangial cells express receptors that may actively engage in antibody-mediated glomerular injury: receptors for the Fc fragment of immunoglobulin G (IgG) (FC γ RIII or CD16) and IgA.

Mesangial cell proliferation, a common feature of glomerulonephritis, may replenish cells depleted by mesangiolysis, but proliferation may also have pathologic consequences by enhancing the production of proinflammatory and profibrotic substances. Most proliferating mesangial cells are resident glomerular cells, but precursor cells may also migrate in from the extraglomerular mesangium within the juxtaglomerular apparatus and from the bone marrow (6–8). Given the close association between mesangial hypercellularity and glomerular injury, understanding the mechanisms that regulate their number is important. Proliferation is controlled at multiple levels: mitogens and their receptors, intracellular signaling pathways, and intranuclear events. Many proteins are mesangial cell mitogens including platelet-derived growth factor (PDGF)-B and -C, insulin-like growth factor-1, epidermal growth factor (EGF), transforming growth factor α (TGF α), low-dose TGF β , basic fibroblast growth factor (FGF), chemokines, insulin, interleukin-1 (IL-1), tumor necrosis factor (TNF), ET, serotonin, bradykinin, vasopressin, thrombin, fibronectin, and prostaglandin (PG)F $_2\alpha$.

Recent studies have identified several nuclear proteins that tightly regulate the mesangial cell cycle at multiple levels (Fig. 29.2). Their actions ultimately determine whether the retinoblastoma protein, a negative cell-cycle regulator, will be inactivated by phosphorylation. With retinoblastoma protein inactivation, transcription factors of the E2F family are released to promote transcription of sev-

eral cell-cycle proteins that promote mitosis (9). Cell-cycle inhibitory agents such as E2F decoy oligonucleotides and cyclin-dependent kinase inhibitors have been used experimentally to prevent mesangial cell proliferation after immunologic injury, with beneficial outcomes (10,11).

Mesangial cells may produce several products that may contribute to acute and chronic glomerular damage such as vasoactive hormones (renin, angiotensin II, vasopressin, ET), bioactive lipids (PGs, leukotrienes, PAF), peptide growth factors and cytokines (PDGF, IL-1 α , IL-1 β , insulin-like growth factor-1, IL-8), matrix proteins (mainly collagen I but also types III, IV, and V; laminin; and fibronectin), glycosaminoglycans, thrombospondin, procoagulants, fibrinolytic factors (plasminogen activators), proteinases, and reactive oxygen species (ROS). Megsin is a recently identified serine protease inhibitor that is produced primarily by mesangial

FIGURE 29.2. Cell-cycle regulatory proteins in glomerular cell proliferation. Cellular proliferation is characterized by the orderly progression of cells through sequential phases from the quiescence (G₀), resting (G₁), DNA synthesis (S), resting (G₂), and mitosis (M). Each step is regulated by cell-cycle proteins (cyclins) that bind and activate cyclin-dependent kinases (CDK). Each step may be blocked by negative cell-cycle proteins, CDK inhibitors. Recent studies indicate that the several CDK inhibitors are expressed in normal glomeruli and play a major role in the regulation of the glomerular cell proliferative responses to mitogens produced during injury. CDK inhibition has been shown to decrease mesangial cell proliferation, decrease matrix expansion, and improve renal function in rats with Thy 1 nephritis (11). (Courtesy of Dr. Stuart Shankland, University of Washington).

FIGURE 29.3. Molecular anatomy of the glomerular podocyte. The basal sole plate of the podocyte approximates the glomerular basement membrane (GBM) and is directly attached to it in areas of focal contact via $\alpha_3\beta_1$ integrin receptors and the $\alpha_4\beta_1$ dystroglycan (α -, β -DG) complex. Adjacent podocytes are joined laterally by a modified adherens junction of "slit diaphragms." Genetic mutations in several slit diaphragm-associated proteins cause inherited nephrotic syndrome, including nephrin, CD2AP, podocin, and the nephrin homologue neph-1. The apical membrane extending from the slit diaphragm into Bowman's space is covered with an anionic glycoprotein coat made predominantly of podocalyxin. Each of these domains is connected to the intracellular actin cytoskeleton that functions to maintain podocyte structural integrity. The complexity of the contractile apparatus has become appreciated with the identification of several key subcomponents that interact with actin, including myosin II, α -actinin-4 (α -act-4), talin (T), vinculin (V), and synaptopodin (synpo). MAGI-1, membrane-associated guanylate kinase inverted-1; NHERF2, NA⁺/H⁺ exchanger regulatory factor 2; P, paxillin; P-Cad, P-cadherin. (From Mundel M, Shankland SL. Podocyte biology and response to injury. *J Am Soc Nephrol* 2002;13:3005–3015, with permission.)

cells and is associated with mesangial proliferation and matrix expansion when overproduced (12).

Glomerular *podocytes* serve several functions such as pinocytosis of proteins that have leaked through the GBM, synthesis of GBM matrix proteins, and restriction of passage of proteins at the level of the slit diaphragm. Epithelial cells synthesize many biologically active products, including extracellular matrix proteins [type IV collagen, heparan sulfate proteoglycan (HSPG), fibronectin], cyclooxygenase (COX), and lipoxigenase products; urokinase-type plasminogen activator and plasminogen activator inhibitor-1; and antioxidant enzymes, IL-1, and angiotensin-1. Podocytes express C3b/C4b and Fc receptors that may interact directly with immune complexes. The outer podocyte cell membrane is differentiated into three structurally and functionally distinct regions that are illustrated in Figure 29.3 (13).

The functional hallmark of glomerular injury is proteinuria. The filtration barrier of the glomerular capillary wall is regulated at the level of the GBM and the slit diaphragm. Perturbations of podocyte slit diaphragm function underlie most if not all types of glomerulonephritis and are often associated with significant structural changes as well, namely, foot-process retraction or effacement. The cellular processes that cause foot-process effacement remain to be elucidated, but they may recapitulate embryonic development in reverse and an uncoupling of the actin cytoskeleton from membrane functional domains (13,14). Proteinuria

can be rapidly induced in animals by injection of antibodies to slit diaphragm proteins such as nephrin (15). A parallel process has been observed in some congenital nephrotic syndrome patients who develop nephrotic syndrome after renal transplantation in association with antinephrin antibody production. In many glomerular diseases, podocytes completely detach from the GBM and are shed into the urinary space (16). Unlike mesangial cells, glomerular podocytes are terminally differentiated cells that, with a few exceptions, fail to proliferate in response to injury. The reasons for this are not yet entirely clear. Highly differentiated podocytes express high levels of cyclin-dependent kinase inhibitors, p21, p27, and p57 (Fig. 29.2). A proliferative phenotype can be restored by genetic deficiency of p21 or p27 (17,18). However, the complete answer to this question is likely to be more complex with evidence that injured podocytes can enter the cell cycle but arrest at the G2/M phase. This failure to proliferate and self-replenish is problematic, as podocyte loss is now recognized as a harbinger of progressive glomerular sclerosis (19).

Glomerular *endothelial cells* line the capillary wall. These cells assume a flattened profile and are densely perforated by transendothelial pores or fenestrae, water channels that may permit direct size-dependent access of blood-borne factors to the basement membrane (20). Endothelial cells can proliferate (21). Their integrity after renal injury is partially maintained by vascular endothelial growth factor (VEGF) and angioten-

TABLE 29.2. ENDOTHELIAL LEUKOCYTE ADHESION MOLECULES IN EXPERIMENTAL GLOMERULONEPHRITIS

Family	Member	Primary cellular distribution	Ligand
Selectins	L-selectin (leukocyte)	PMN, M ϕ , lymphocytes	Mucins (e.g., addressin, CD34, Gly-CAM)

etin-1 that bind to their endothelial receptors, Flk-1 and Tie-2, respectively (22). Angiopoietin-2 also binds to the Tie-2 receptor, but it antagonizes and destabilizes capillary integrity (23). Glomerular endothelial cells appear unique in many respects compared to endothelial cells of other origin. Although less extensively studied than other glomerular cells, they also undergo specific alterations in structure, function, and metabolism during glomerular injury, making them active participants in injurious and reparative processes. Endothelial cells synthesize several coagulation proteins, growth factors, and cytokines; extracellular matrix proteins; and vasoactive molecules. The surface of endothelial cells expresses angiotensin-converting enzyme (ACE) and ET-converting enzymes that catalyze the formation of the vasoconstrictors angiotensin II and mature ET, respectively. They may express several different adhesion molecules that promote interactions with blood-borne leukocytes, platelets, and the third component of complement (Table 29.2). Other functions include synthesis of reactive oxygen metabolites and the potential to serve as antigen-presenting cells.

Cellular interactions with the GBM and extracellular matrix play an essential role in maintaining glomerular integrity and function. Among the numerous cell-matrix adhesion molecules, those of the β_1 integrin family of membrane glycoproteins (also known as *very late antigens*) have been most extensively studied in the glomerulus (Table 29.1). The β_1 chain associates with one of 12 different α chains, the most abundant glomerular isoform being $\alpha_3\beta_1$. In addition to maintaining glomerular capillary wall integrity, integrins can function as classical signal-transducing receptors to initiate a variety of cellular responses that may play a role in the glomerular response to injury: mitogenesis and synthesis of matrix proteins, reactive oxygen metabolites, and arachidonic

acid (AA) metabolites. The identification of anti- β_1 integrin antibodies in polyclonal antisera against the tubular brush-border fraction Fx1A and GBM, which induce proteinuria in experimental animals, suggests that integrins play an important role in maintaining the permselectivity of the glomerular capillary wall. Recent studies suggest the $\alpha_1\beta_1$ may also play an important role in extracellular matrix remodeling during progressive glomerulosclerosis (24,25).

HUMORAL IMMUNE MECHANISMS OF INDUCTION OF GLOMERULAR INJURY

Antibody-mediated glomerular injury is the result of a B-lymphocyte-driven immune response. B-lymphocyte activation requires T-lymphocyte participation. The fact that helper T lymphocytes recognize antigen in the context of major histocompatibility complex (MHC) class II antigens (HLA DR in humans) has led to speculation that the risk of developing immune-mediated glomerulonephritis may be linked to the inheritance of certain MHC class II genes. Although beyond the scope of this review, several studies have suggested an association between various DR antigens and the risk of developing anti-GBM nephritis, IgA nephropathy, membranous nephropathy, and lupus nephritis (26–28).

Interaction of Antibodies with Intrinsic Matrix Components of the Glomerular Extracellular Matrix

Normal structural components of the GBM may be the target of an autoantibody attack leading to the development of anti-GBM nephritis, which in humans may occur with

(Goodpasture syndrome) or without pulmonary involvement. Experimentally, anti-GBM nephritis is induced by passive administration of heterologous antibodies (nephrotoxic serum nephritis) or by active immunization with heterologous GBM in an immunologic adjuvant (experimental autoimmune glomerulonephritis).

Glomerular Basement Membrane

The GBM target antigen(s) in the classic experimental model of nephrotoxic serum (or Masugi) nephritis has not been completely elucidated and is likely multiple. In contrast, the dominant human Goodpasture antigen is known to be part of the collagen IV molecule, and it has been further localized to a conformation-dependent epitope residing within the amino-terminal noncollagenous NC-1 globular domain of $\alpha 3(\text{IV})$ collagen (29,30). The gene encoding $\alpha 3(\text{IV})$ collagen is located in the q35-37 region of chromosome 2. Immunization with antibodies to $\alpha 3(\text{IV})$ collagen or dimers of $\alpha 3(\text{IV})$ induces mild nephritis in animals. Less common, other components of the GBM may also serve as antibody targets. In general, immunization with collagen IV, laminin, fibronectin, and HSPG or administration of their specific antisera alone produces minor morphologic changes without proteinuria, although more severe disease has occasionally been reported.

Anti-GBM antibodies may play a role in other forms of glomerulonephritis. For example, patients with poststreptococcal glomerulonephritis may develop circulating antibodies to type IV collagen, laminin, entactin/nidogen, and HSPG. Anti-DNA antibodies isolated from the sera of patients with systemic lupus erythematosus (SLE) cross-react with HSPG and type IV collagen, probably via antibody-bound DNA-histone complexes. Humans with X-linked dominant hereditary nephritis lack the α_5 chain of collagen IV, a gene that is encoded in the Xq region of the X chromosome. This genetic defect results in a secondary failure of α_3 and α_4 collagen IV chains to be integrated into the GBM. Primary mutations in the genes that encode the α_3 and α_4 chains of collagen IV are responsible for autosomal recessive hereditary nephritis. After renal transplantation, approximately 2 to 4% of the Alport syndrome recipients develop anti-GBM disease in the normal renal allograft due to the formation of anti- α_3 , - α_4 , and/or - α_5 collagen IV antibodies (31).

Mesangial Matrix

The antigenic composition of the mesangial matrix is similar to that of the GBM, yet it appears to be largely protected from immune attack in anti-GBM nephritis, presumably because the nephrotoxic antibodies bind avidly to the GBM before they gain access to the mesangium. It is possible that unique mesangial matrix antigens exist and are the target of immune attack. Injection of a monoclonal antibody to a rat mesangial matrix component (81 kDa) induces mesangial

electron-dense deposit formation, although histologic changes and proteinuria do not develop. A glycoprotein [matrix metalloproteinase (MMP)-50/100] has been identified that is unique to rat glomerular mesangium, the expression of which is increased in several models of nephritis. A similar unique human mesangial antigen has been identified (32).

Antibody Interaction

After injection of heterologous anti-GBM antiserum (or nephrotoxic antiserum), the antibody binds to the GBM within minutes, gaining free access through the open glomerular endothelial fenestrae. By immunofluorescence microscopy, the antibody is observed in a linear pattern corresponding to the distribution of the GBM. Formation of electron-dense deposits along the glomerular capillary wall does not ensue (Fig. 29.1). Alterations in glomerular structure and function occur as a direct consequence of antibody binding to the GBM, leading to proteinuria and a decline in glomerular filtration rate (GFR). Ultrastructural changes include a rearrangement of GBM laminin, foot-process fusion, loss of GBM anionic-binding sites, and evidence of cellular injury. Some of these changes may be induced by the interaction of the antiserum with glomerular epithelial cell antigens such as the β_1 integrins and aminopeptidase A (33).

Secondary Mediators

Although antibody binding alone causes some alterations in glomerular structure and function, additional mediators are needed for the full expression of the injury, otherwise the initial damage subsides after 24 hours. This subsequent period of glomerular inflammation is associated with the infiltration of PMNs, chemoattracted by complement proteins C5a and C3b generated by interactions with the anti-GBM antibody. Depletion of PMNs or complement prevents proteinuria. There is some evidence that the membrane attack complex (MAC) of complement also plays a role in mediating cellular damage. In experimental models of anti-GBM nephritis induced by heterologous antiserum, a second phase of glomerular inflammation develops 5 to 7 days later as a result of the production of antibodies by the immunized animal (autologous antibodies) to the heterologous antibody, which is now acting as a foreign antigen planted along the GBM. In addition to antibody complement-induced damage, other mechanisms of injury are now recognized. T cells sensitized to GBM antigens play an important role and may even cause severe glomerulonephritis in the absence of nephritogenic antibodies (34). The complement-binding domain of IgG (as opposed to the antigen-binding domain) may also interact directly with mesangial cells, podocytes, and inflammatory cells through interactions with Fc receptors. Studies in mice demonstrated that deficiency of the γ chain (shared by Fc receptors

I, II, and III) was associated with significantly milder anti-GBM nephritis (35).

Interaction of Antibodies with Glomerular Cell-Surface Antigens

Experimental models involving the binding of antibodies to cell-surface antigens have now been described for the three cell types intrinsic to the glomerulus. Antibody attack is directed to the epithelial cells in Heymann nephritis and in glomerular diseases associated with the anti-slit diaphragm antibodies, to mesangial cells in anti-Thy 1 disease, and to endothelial cells when animals are injected with antibodies to ACE and possibly with antineutrophil cytoplasmic antibodies (ANCA). These interactions may produce glomerular injury associated with the formation of immune complexes (*in situ*) or associated with perturbations in normal cellular function but without the formation of immune complexes. Knowledge gained from investigation of these experimental models has revolutionized thinking about the immunopathogenesis of glomerular injury. *In situ* mechanisms now appear to play the dominant role in most forms of human glomerulonephritis.

Podocytes

The model of Heymann nephritis has been extensively studied because it resembles human membranous nephropathy (Fig. 29.1). Heymann nephritis can be induced in susceptible strains of rats by active immunization with the antigen. Proteinuria develops by 8 to 10 weeks in 30 to 80% of the immunized animals. A similar lesion can also be induced passively by injection of the appropriate antibody, producing proteinuria within 5 days.

Nephritogenic Antigen

Extensive work by several investigators has determined that the primary target antigen is a large 517-kDa glycoprotein named *megalyn* (previously called *glycoprotein gp330* and *gp600*) (36). Megalyn, a member of the low-density lipoprotein receptor gene family, is an endocytosis receptor for multiple ligands such as plasminogen, plasminogen activator complexes, apolipoprotein E-enriched β very-low-density lipoprotein, lipoprotein lipase, clusterin/apolipoprotein J, retinol-binding protein, insulin, β_2 microglobulin, thyroglobulin, and certain polybasic drugs, to name a few. Megalyn is also present on other epithelial cells, including the brush border of proximal tubules where it serves an important role in albumin reabsorption, pneumocytes, and ependymal cells in the brain. Mice that lack megalyn develop abnormalities in the kidneys, lungs, and central nervous system, and most die of respiratory failure shortly after birth. A second antigen is involved, a 44-kDa protein known as *RAP* (receptor-associated protein). This protein is homologous to human low-density lipoprotein receptor-related protein/ α_2 -macroglobulin receptor. *RAP* associates

with megalyn and may function in a regulatory role to control megalyn-ligand interactions. Purified antibodies to either megalyn or *RAP* induce subepithelial immune complex formation, but neither antibody alone produces the full renal disease spectrum that was first observed by Edgington and colleagues when they injected polyclonal anti-Fx1A antiserum into rats (36a). This has led to the notion that other antigen-antibody interactions may also be involved. Candidates include antibodies to dipeptidyl peptidase IV, β_1 integrin, laminin, and antibodies to complement regulatory proteins, *Crry* and *CD59*. The nephritogenic antigen(s) in idiopathic human membranous nephropathy is still unknown; megalyn is not expressed by human podocytes. There is still speculation that circulating immune complexes involving exogenous antigens may also play a role in human membranous nephropathy (37).

Antibody Interaction

The primary interaction that initiates the formation of subepithelial immune deposits in passive Heymann nephritis is the binding *in situ* of antibodies to megalyn on the foot processes of glomerular podocytes. *In vitro* studies suggest that cross linking of the antibodies redistributes the antigens into progressively larger aggregates that are subsequently shed into the subepithelial space. These complexes may then be modified by the addition of further megalyn and/or *RAP* molecules (36).

Secondary Mediators

Induction of renal injury and proteinuria depends on the activation of complement, but inflammatory cells are not required. Immunofluorescence studies reveal early and prominent participation of the complement cascade (C3 and neoantigens of the MAC of complement) in the subepithelial deposits. Rats depleted of complement fail to develop proteinuria despite antibody deposition, although perturbations in glomerular flow can be detected by micropuncture studies. Neutralization of *Crry* and *CD59*, complement regulatory proteins expressed on the surface of podocytes (by antibodies naturally present in anti-Fx1A antiserum), promotes proteinuria (38). Sublethal podocyte attack by C5b-9 has several consequences, including the production of eicosanoids and ROS and disruption of focal adhesions that link the actin cytoskeleton to extracellular matrix (39,40). Disruption of slit diaphragms and reduction of the glomerular heparan sulfate agrin are other structural consequences associated with the development of proteinuria (41). Once glomerular damage is established, ongoing complement activation appears to be unnecessary because complement depletion at this time does not abolish proteinuria. After transplantation of a kidney with active Heymann nephritis into a normal syngenic rat, complement deposits begin to disappear within 2 to 4 weeks, but proteinuria persists much longer. These studies suggest that structural alterations to the glomerular filter are long-standing once damaged by the antibody complement-dependent pathway.

Mesangial Cells

The rat Thy 1 model of glomerulonephritis has proven to be an important investigative model as so many glomerular diseases are characterized by mesangial cell proliferation. Thy 1 is an 18-kDa membrane glycoprotein most notably expressed in the thymus and brain. It is also expressed on the surface of normal rat mesangial cells; circulating rat lymphocytes are negative. Mesangial cell injury is induced by the injection of heterologous antithymocyte serum or anti-Thy 1.1 monoclonal antibody. Anti-Thy 1 nephritis is a biphasic model of glomerular disease, the first phase characterized by mesangiolysis (1 hour to 2 days) and the second phase by mesangial cell proliferation and glomerular microaneurysm formation (4 to 14 days). Despite histologic and glomerular micropuncture evidence of significant glomerular injury, proteinuria is often mild. Mesangiolysis is the consequence of antibody-directed, complement-mediated injury to mesangial cells and can be abrogated by complement depletion but not by the elimination of leukocytes. Deposition of components of the terminal complement cascade within the mesangium suggests that cell lysis is mediated by the MAC of complement. The hypercellular phase is mainly due to the proliferation of the smooth muscle-type mesangial cells. It does not occur if the mesangiolytic phase is prevented by complement depletion. Lymphohemopoietic cells—PMNs, monocytes, and platelets—also invade the glomerulus during the initial phase of mesangial injury. Several mesangial cell mitogens have been identified, and their effects on mesangial cell cycle regulatory proteins are becoming clarified and offer the possibility of future therapeutic targeting (Fig. 29.2). Integrin-dependent interactions between mesangial cells and their matrix also modulate their proliferative response (25). Platelets and PDGF-B appear to play an important pro-mitotic role in the Thy 1 model. Although antimesangial cell antibodies appear to be uncommon in humans, they have been identified in a few patients with IgA nephropathy and lupus nephritis (42,43). Nonetheless, mesangial cells respond to and elicit a large variety of pathophysiologic events, whether initiated by an antibody or another form of injury.

Endothelial Cells

The ability of antiendothelial antibodies to cause glomerular damage is best exemplified by renal allograft rejection. Several antigen families may be targeted, especially MHC class I and II antigens. Antiendothelial antibodies have also been demonstrated in patients with SLE, systemic vasculitis, and thrombotic microangiopathy, although the relationship of these antibodies to the pathophysiology of the disease remains unclear. An animal model of antibody-induced renal thrombotic microangiopathy has recently been developed and some of the mediators of injury identified, but the target antigen(s) have yet to be determined (44).

There is increasing evidence that ANCA associated with pauciimmune necrotizing glomerulonephritis are patho-

genic, although the specifics of the connection between the antibodies to the granulocyte proteins (proteinase 3 and myeloperoxidase) and endothelial injury are still unraveling. Classical “immune complexes” are not formed, but recent data support a direct link between antibody-mediated activation of neutrophils and monocytes and glomerular endothelial injury (45). Endothelial cells may also express and/or internalize proteinase 3 and become directly involved in the pathogenetic process—both ANCA-dependent and -independent (46,47). Recent studies in animal models provide convincing evidence that antimyeloperoxidase antibodies cause glomerular damage (48).

ACE present on endothelial cells has been used as an experimental target for antibody attack to induce epimembranous nephropathy in rabbits, but whether there is a human counterpart to this model is unknown. The anti-ACE antibody binds to and redistributes endothelial cell-surface ACE, followed by shedding of antigen-antibody complexes from the cell membrane in a sequence of events reminiscent of that proposed for Heymann nephritis. The reason that these complexes move from a subendothelial (days 1 to 2) to a subepithelial position (days 3 to 24) concentrated at filtration slits is not entirely clear, but it may be related to hydrodynamic factors as the plasma filtrate crosses the GBM. The glomerular lesion is characterized histologically by complement deposition and the presence of PMNs, but their respective roles in the pathogenesis of the glomerular disease remain to be defined.

Interaction of Antibodies with Exogenous Antigens Trapped or Planted within the Glomerulus

Exogenous macromolecules trapped or planted within the glomerulus may become antigenic targets for antibodies, resulting in the *in situ* formation of immune complexes. Although still unproven, this pathway may account for some forms of immune complex nephritis occurring in humans after exposure to certain drugs, toxins, or microorganisms or in association with malignancy. Endogenous antigens originating at extrarenal sites may also induce renal injury by a similar mechanism.

Antigen Candidates

Several experimental manipulations have been used to trap antigens in the glomerulus with glomerular injury ensuing as circulating antibodies bind *in situ* to the planted antigen. Several factors might promote antigen entrapment. Low (subnephritic) concentrations of antiglomerular antibodies may initially bind and serve as a magnet for further antibody recruitment (e.g., antiidiotypic antibodies, antirheumatoid factor antibodies or antiheterologous antibodies as occurs in animals injected with nephrotoxic serum produced in another animal). Other possibilities include electrostatic interactions

(cationic antigens binding to GBM anionic sites such as streptococcal proteinase) (49), glomerular carbohydrate interactions with lectins (e.g., lectin-like domains on microbial pathogens), glomerular matrix interactions (e.g., DNA-histone complexes binding glomerular heparan sulfate and fibronectin), or mesangial entrapment of a molecule of colloidal size as they percolate through normal mesangial channels.

Glomerular Deposition of Circulating Immune Complexes

Since the recognition of the *in situ* mechanism of glomerular immune complex formation, the concept of the entrapment of immune complexes preformed in the circulation has been increasingly challenged. It is now believed that most immune complexes form *in situ* even in such classical diseases as lupus nephritis. Nonetheless, the “circulating immune complex” pathway likely contributes to some extent in the pathogenesis of human glomerulonephritis, and nearly 75 years of work using animal models of immune-complex glomerulonephritis have taught us a great deal about the immunopathogenesis of glomerular injury. With rare exception, the nature of the nephritogenic antigens in human glomerulonephritis are unknown. Putative antigens include foreign serum proteins, drugs, food antigens, infectious organisms (bacteria, parasites, viruses, fungi, and mycoplasma), and certain endogenous antigens (nucleic acids, thyroid antigens, tumor antigens, nuclear non-DNA antigens, erythrocyte antigens, and renal tubular antigens).

Animal Models of Immune Complex Glomerulonephritis

The classic model of immune complex–induced tissue injury is acute serum sickness, induced in rabbits by injecting heterologous plasma proteins such as albumin or ovalbumin. The clinicopathologic features resemble those of acute poststreptococcal glomerulonephritis. Glomerular injury begins abruptly during the phase of antibody-dependent immune elimination of the antigen coincident with the appearance of circulating immune complexes. Injury resolves again in 2 to 3 weeks. The most striking and extensively studied spontaneous models of immune complex occur in certain strains of mice and resemble lupus nephritis (NZB X NZW)F1, BXSB, and MRL/lpr/lpr mice.

Glomerular Immune Complex Deposition and Injury

Multiple factors influence the capacity of a circulating immune complex to remain soluble, lodge within, and initiate glomeruli injury. First, the antigen must be immunogenic and persist in the circulation long enough to allow antibody generation and binding. The size of the immune complex that is formed, determined primarily by the antigen-

to-antibody ratio, has a major influence on its rate of clearance from the circulation (faster rates being associated with a lower risk of nephritis) and on the pattern of deposition within glomeruli. Large-latticed complexes formed near antigen:antibody equivalence are efficiently eliminated by the mononuclear phagocyte system and are minimally entrapped by glomeruli, mainly in the mesangium. The smallest immune complexes pass freely through the glomerulus without being trapped. It is the intermediate-size immune complexes (e.g., Ag₂:Ab₂) that are retained within glomeruli. In primates, soluble-circulating immune complexes are eliminated via a complement-dependent “erythrocyte shuttle” within the mononuclear phagocyte system. Within minutes of formation, circulating immune complexes bind complement and attach to the erythrocyte complement receptor 1 (CR1). This interaction protects peripheral organs such as the kidney from immune-complex deposition and injury. Erythrocytes bearing immune complexes circulate to the liver, where the complexes are transferred to Kupffer cell Fc receptors and catabolized.

Physicochemical properties such as net charge are important. Given the net negative charge of the glomerular capillary wall, cationic antigens are more nephrotoxic than neutral or anionic ones. Both size and charge also influence the location of trapping. Small highly cationic complexes (isoelectric point, 9.5 to 11.5) deposit along the glomerular capillary wall, whereas large cationic complexes tend to lodge in the mesangium. The high renal blood flow rates and transcapillary hydraulic pressure gradients are thought to explain why the kidney is particularly vulnerable to immune complex–mediated tissue injury. Alterations in glomerular hemodynamics may affect the severity of injury. For example, serum sickness is worse in hypertensive rabbits, a reduction in GFR decreases immune-complex deposition, and renal artery stenosis protects the kidney from immune-complex disease.

In Situ Modification and Damage

Trapped glomerular immune complexes are free to escape unless a series of events occur *in situ* to stabilize them. Intrglomerular immune complexes enlarge over time, the morphologic counterpart of the *in situ* interactions that rearrange, enlarge, and stabilize the lattice structure. In fact, the immune complex is in a state of dynamic equilibrium with its component parts in the circulation. The immune response typically involves polyclonal B-cell activation, involving a heterogeneous group of antibodies. The addition of antibodies of increasing affinity may provide further stability to the complex. The entire immune complex may act as a planted antigen, recruiting additional antibody systems such as rheumatoid factors (antibodies reactive with the Fc and occasionally Fab fragment of IgG), antiidiotypic antibodies binding to unique epitopes of the Fab antibody fragment, and immunoconglutinins, which are IgM anti-

bodies that react with sites on activated fragments of C3 and C4. At other times, subsequent events dissolve the complexes. The addition of nonprecipitating antibodies, excess antigen, and/or complement proteins may decrease and ultimately dissolve glomerular immune deposits. Proteolytic enzymes may also accelerate complex removal.

Once nephritogenic immune complexes stabilize within the glomerulus, they trigger a sequence of events that induce glomerular inflammation and proteinuria. Marrow-derived monocytes are the key mediators of proteinuria in experimental models of acute serum sickness.

Unique Features of Immunoglobulin A Nephropathy

New insights into the pathogenesis of experimental IgA nephropathy have been made in recent years and are further discussed in Chapter 31. Only a few unique factors will be mentioned here. It appears that many antigens may be involved, although this remains speculation. One recent study identified *Haemophilus parainfluenzae* antigens in the mesangium of 31% with IgA nephropathy and 4% with other renal diseases, illustrating one example of a possible link between microbial pathogens in this disease (50). The IgA molecule is unique in that 10 to 20% circulates in a polymeric form, with monomers linked by J chain. Humans produce two isotypes—IgA1 and IgA2—but it appears that most of the glomerular deposits are monomeric IgA1. Despite a strong clinical correlation between acute mucosal infections (respiratory and gastrointestinal), and perhaps abnormal mucosal immunity, and nephritis exacerbations, most of the data point to the bone marrow and not the mucosal immune system as the origin of the glomerular IgA1 deposits. Bone marrow transplantation data, both human anecdotes and studies in the spontaneous ddY mouse model, suggest that IgA nephropathy is a primary stem cell disorder (51).

Several recent studies have focused on the biochemical structure of the IgA molecule and have consistently reported differences in the carbohydrate structure between patients and controls (52,53). The number of O-linked galactose sugars in the hinge region of IgA1 is significantly reduced in the patients. Although the metabolic basis of this galactose deficiency is not yet known, it is thought to be of primary pathogenetic significance. Relevant observations include its delayed rate of clearance from the circulation, increased binding to mesangial cells, and recognition as an antigenic determinant by naturally occurring IgA1 and IgG antibodies.

The ability of IgA to bind to fibronectin and certain lectins may facilitate glomerular uptake. After the observation that mice lacking uteroglobin, an antiinflammatory protein with high affinity for fibronectin, spontaneously develop IgA nephropathy, additional studies have yet to confirm its role in human IgA nephropathy (54). Mesangial deposition

of IgA alone is insufficient to cause glomerular injury. IgA may also bind to mesangial cells and trigger subsequent effects, although the specific receptor involved remains to be identified—it appears to be distinct from the known receptors IgA Fc α R1 (CD89), asialoglycoprotein receptor, and the polymeric Ig receptor (55).

Whereas C3 is almost always present in association with IgA immune deposits, IgA is an inefficient activator of the alternative pathway. The recent recognition that IgA can activate complement by the third or mannan-binding lectin pathway may be relevant to IgA glomerular injury (56). Alternatively it may be the co-deposited IgG or IgM molecules that activate complement and mediate renal injury. In most experimental IgA models, hematuria is C3 dependent, but the terminal components C5b-9 are not required.

CELLULAR IMMUNE MECHANISMS OF INDUCTION OF GLOMERULAR INJURY

T lymphocytes play an intricate role in the immune responses that cause glomerulonephritis, usually culminating in the generation of nephritogenic antibodies. Considerably less common, it has long been suspected that T cells may occasionally cause glomerular injury by recruiting monocytes in the absence of antibodies. Evidence that T cells alone, working in the absence of antibodies, can induce glomerular injury, has been convincingly demonstrated in animal models of autoimmune glomerulonephritis. Transfer of GBM-sensitized CD4⁺ T cells to normal animals can induce glomerulonephritis (34,57). In a related model based on the injection of subnephritic doses of anti-GBM antibodies (that serves as the “planted” antigen for subsequent immunologic attack by the host immune system), crescentic glomerulonephritis develops even in antibody-deficient mice, whereas disease is attenuated in T-cell-depleted animals (58).

An alternative T-cell-dependent antibody-independent mechanism that may cause glomerular dysfunction involves T-cell activation and release of a “lymphokine” that alters the glomerular permselectivity barrier, causing proteinuria in the absence of glomerular inflammation (59). Such a mechanism, first proposed Shalhoub in 1974 (59a), is still the favored immunopathogenetic paradigm for idiopathic minimal change nephrotic syndrome and focal segmental glomerulosclerosis (FSGS) despite the lack of definitive evidence. The nature of the putative lymphocyte-derived glomerular permeability factor remains elusive despite several proposed candidates [reviewed in (60)]. Savin et al. identified a factor in the plasma of FSGS patients that exerts permeability changes in a rat glomerular bioassay and predicts the risk of allograft-recurrent FSGS in some patients (60a). The factor itself has not been isolated. Immunoabsorption to protein A suggests that it may circulate in association with IgG. Similar permeability activity has also been identified in the plasma of patients with

FIGURE 29.4. Antigen-dependent T-cell activation and functional polarization. When T cells encounter antigen-presenting cells (APC), at least two signals must be transmitted before an immune response is initiated. The first signal is emitted by ligation of the T-cell receptor with antigenic peptides bound to major histocompatibility complex (MHC) molecules on the APC. T-helper cells (CD4⁺) interact with MHC class II, and T-cytotoxic cells (CD8⁺) interact with MHC class I molecules. A second signal is required for full activation. It may be provided by CD28 that activates T cells after binding to its ligand, B7-1 or B7-2, on APCs. Once activated, T cells begin to express a CD28 homologue (CTLA-4) that binds B7-1 and B7-2 with higher affinity and inhibits T-cell activation. Therapeutic administration of CTLA-4 can decrease the severity of autoimmune nephritis. Two new members of the CD28 superfamily are ICOS (inducible costimulator) and PD-1 (programmed death-1) that interact with their respective APC ligands, B7RP-1, and PD-L1 or PD-L2. The second major costimulatory family is the tumor necrosis factor (TNF)-TNF-R family, which includes CD154 expressed by activated T cells and CD40 expressed by APCs, including B cells. The CD154-CD40 system appears to be particularly important in antibody-mediated diseases such as lupus nephritis. Several new TNF-TNF-R superfamily members have been identified and await investigation in glomerulonephritis (GN): 4-1BB/4-1BBL, CD134/CD134L, and CD27/CD70. Resident glomerular mesangial and epithelial cells may function as nonprofessional APCs to activate T cells, but it is unlikely that they can initiate a primary immune response. T-helper (Th) cells activated by antigen can be divided into two distinct subsets based on the cytokines they produce. Th1 cells synthesize interleukin-2 (IL-2), interferon-gamma (IFN γ), TNF, and granulocyte-macrophage colony stimulating factor (GM-CSF) and mediate delayed-type hypersensitivity reactions with monocyte and cytotoxic T-cell activation and immunoglobulin class switching to favor the production of complement-fixing immunoglobulin G (IgG) isotypes. The Th1 pathway predominates in hypercellular/proliferative forms of glomerulonephritis. In contrast, Th2 cells are characterized by the production of IL-4, -5, -10, and -13 and mediation of allergic, immediate-type hypersensitivity reactions associated with mast cells and production of IgE and the weaker complement-fixing IgG1. The Th2 cytokine profile is commonly associated with nonproliferative glomerular diseases such as minimal change nephrotic syndrome and membranous nephropathy. Cytokine therapy has been used experimentally to attenuate Th1-dependent proliferative diseases: either administration of Th2 cytokines or inhibition of Th1 cytokines/receptors. (Modified from Kitching AR. Cytokines, T cells and proliferative glomerulonephritis. *Nephrology* 2002;7:244-249.)

podocin mutations, indicating that this “factor” is not unique to idiopathic FSGS (61). Alternatively, it has been suggested that proteinuria may be the consequence of the loss of an inhibitory substance, perhaps a lipoprotein, which serves in normal individuals to block the permeability factor (62,63). Two fundamental aspects of T-lymphocyte biology have been extensively investigated in the past decade, yielding insights that bear relevance to the basic immunology and possible therapeutics of glomerulonephritis. The first is the identification of pairs of costimulatory molecules involved with MHC molecules in antigen recognition, and the second is the identification of functionally distinct subsets of T cells (64–66). These functions are reviewed in Figure 29.4.

SECONDARY MEDIATORS OF GLOMERULAR INJURY

After the primary immunopathogenic event that initiates glomerular injury, a series of secondary mediators are recruited and activated to execute the inflammatory response. Definitive proof that these pathways are involved in renal damage is usually based on the results of selective inhibition or depletion of the effector system under investigation and by studies in knock-out mice.

Polymorphonuclear Leukocytes

PMNs are present in several human and experimental glomerulonephritides in which they contribute to inflammation-associated injury. Depletion of PMNs during the heterologous phase of anti-GBM nephritis and in the Con A-anti-Con A model of immune-complex nephritis prevents proteinuria. In PMN-dependent lesions, the cells appear abruptly, and several factors may play a role in their recruitment, including chemoattraction to C3a, C5a, or alpha (C-X-C) chemokines; immune adherence to CR1 or CR3; and Fc receptor-dependent binding to antibodies. Among numerous toxic PMN secretory products, ROS and proteolytic enzymes (e.g., GBM-degrading serine proteases, neutral proteinases such as elastase and cathepsin G and matrix-degrading metalloproteinases) have been most frequently implicated in glomerular damage. Other PMN activities that may contribute include proteolytic activation of plasma protein cascades, such as the coagulation pathway; release of cationic proteins that may bind and neutralize GBM anionic charge sites; and the synthesis of phospholipid metabolites [PGs, thromboxanes (Tx), leukotrienes, and PAF], hydrogen peroxide, and vasoactive substances (histamines). Products derived from PMN granules that are targeted by ANCA have been implicated in the genesis of endothelial cell damage and focal necrotizing glomerulonephritis.

Monocytes and Macrophages

Monocytes and macrophages (M ϕ) are present in many glomerular diseases, particularly in crescentic and postinfectious

glomerulonephritis. Although most of these cells migrate into glomeruli from the circulation, they may also proliferate *in situ* (67). Beginning with landmark studies in the late 1970s, the pivotal role played by M ϕ in the genesis of primary glomerulonephritis has clearly been established by numerous studies. M ϕ may also be recruited during a secondary wave of glomerular injury, associated with disease progression, as demonstrated in the remnant kidney model and in lipid-induced glomerular disease. Although unraveling the effector pathways of monocyte-dependent glomerular damage is challenging owing to their multifunctionality, several activities appear to be involved: (a) phagocytosis, which may eliminate immune reactants but may also activate pathways that promote damage; (b) antigen presentation to T cells after induction of MHC class II surface molecules; and (c) biosynthesis of numerous proinflammatory products: cytokines, procoagulant and fibrinolytic proteases and proteins, matrix-degrading enzymes, ROS, vasoactive substances, and cationic proteins. Although M ϕ express CRs (CR1 and CR3) and are chemoattracted to C5a *in vitro*, glomerular M ϕ recruitment is usually complement-independent in experimental models. M ϕ also express receptors for antibody Fc fragments that may participate in their recruitment and activation (68). It is also quite clear that activated M ϕ and PMN represent a highly heterogeneous population of cells, and even in glomerulonephritis some of these cells are programmed to be antiinflammatory and to terminate ongoing injury.

Glomerular Leukocyte Recruitment Mechanisms

To reach a site of inflammation, leukocytes must first adhere to and subsequently emigrate through retracted endothelial junctions and the basement membrane out into the surrounding tissue [reviewed in (69)]. This is accomplished by a multistep process involving a series of leukocyte surface adhesion molecules that bind to cognate receptors on the endothelium (Fig. 29.5; Table 29.2). Leukocyte migration to sites of inflammation is directionally regulated by chemoattractant molecules, especially chemokines (chemotactic cytokines). These small proteins (8 to 10 kDa) are subdivided into four major families (already more than 50 ligands and 17 different receptors identified) based on the position of the first two cysteine residues (Table 29.3) (70). Only two of the families have been extensively investigated. The α -chemokines share a common CXC structure (X denotes any intervening amino acid), and many are involved in the recruitment of PMN. They bind to G-protein-coupled CXC receptors and activate intracellular phosphatases. Each receptor typically binds more than one chemokine making for great pleiotropy and redundancy in the system. PMN are known to express CXCR1 and CXCR2. It has recently been reported that glomerular podocytes also express CXCR1, -3, -4, and -5, although their role here has yet to be determined (71). IL-8 (that binds to CXCR1 and 2) has been implicated

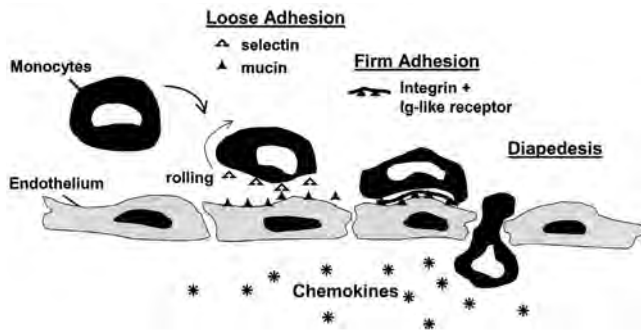

FIGURE 29.5. Mechanisms of glomerular leukocyte recruitment. The earliest and relatively transient adhesions, which cause leukocytes to “roll” along the endothelium, are mediated by surface receptors with lectin-like domains (selectins) that bind to specific glycoprotein ligands (mucins). Not expressed by normal glomeruli, P- and E-selectins have been detected in some diseased human glomeruli. Their only ligand in normal glomeruli is CD34. Selectin blocking and neutralization studies have not been shown to prevent leukocyte recruitment or proteinuria. In fact, in a study of P-selectin-deficient mice, anti-glomerular basement membrane (GBM) nephritis was more severe compared to wild-type mice (149). Once activated, leukocytes soon become firmly attached to the endothelium by engaging leukocyte integrins ($\alpha_4\beta_1$ and β_2) with their endothelial ligands, which are members of the immunoglobulin (Ig) gene superfamily: intercellular adhesion molecules (ICAM) and vascular cell adhesion molecules (VCAM) (reviewed in Table 29.2). Low-level glomerular ICAM-1 and ICAM-2 expression has been observed in some studies, whereas VCAM-1 appears limited to parietal epithelial cells of Bowman’s capsule. Thus far, interventions designed to prevent leukocyte recruitment in acute glomerular disease by selectively blocking a single leukocyte integrin ligand have generally been ineffective. Whether this is due to overlapping functions of other receptors or whether other reactions promote leukocyte adherence to the glomerular endothelium remains to be determined. Galectins, osteopontin, and CD44 may be involved, for example. In addition to recruitment, leukocyte integrin-ligand interactions may activate several intracellular signaling pathways and alter leukocyte functions. These effects may partially explain why mice with genetic ICAM-1 deficiency and nephrotoxic serum nephritis develop milder chronic renal damage (150). Directed by chemokines, leukocytes ultimately migrate between endothelial cells to the site of injury.

in PMN recruitment in some inflammatory glomerular diseases. Additional CXC chemokines are chemoattractants for other cells but not PMN. These include interferon gamma ($\text{IFN-}\gamma$)-inducible protein of 10 kDa (IP-10) and monokine induced by $\text{IFN-}\gamma$ (Mig); both have been detected in inflamed glomeruli (72).

The role of the second chemokine family in glomerulonephritis, the CC or β chemokines, has been more extensively investigated. In general, the CC chemokines recruit monocytes and other mononuclear cell lineages but not PMN. At least 10 CC receptors are known; monocytes express CCR1, -2, and -5. Monocyte chemoattractant protein-1 (MCP-1) has been most extensively investigated; MCP-2, -3, -4, and -5 also exist. MCP-1 binds to CCR2 and its expression is often detected in proliferative and crescentic glomerulonephritis. MCP-1 deficiency or neutralization usually decreases glomerular monocyte numbers and disease severity. RANTES (regulated upon activation, normal T cell expressed and secreted)

binds to monocyte CCR1 and CCR5, and its inhibition has also been protective in experimental proliferative nephritis. However, neither MCP-1 nor RANTES blockade achieves sustained reversal of monocyte infiltration and proteinuria in any model. It has become evident that several of the chemokines have other effects, including cellular activation and generation of Th1 or Th2 responses. For example, inhibition of macrophage inflammatory proteins (MIP)-1 α and -1 β (CC chemokines) decreased proteinuria without affecting monocyte numbers. Rather surprising, despite the beneficial effect reported in experimental nephritis with either antireceptor antibody therapy or inhibition of MCP-1, genetic deletion of CCR1 and CCR2 has not been protective in the same disease model (73–76). In fact, both knock-out mice develop worse anti-GBM nephritis, perhaps due to a greater Th1 polarity and more aggressive crescent formation.

Fractalkine is the only known membrane-bound chemokine. It belongs to a third chemokine class, CXXXC, and binds to its own unique receptor (CX3CR1) that is expressed on natural killer cells, T cells, and mesangial cells (77,78). Chemokine expression is primarily induced by proinflammatory cytokines such as IL-1 and TNF- α . The transcription factor NF- κ B is frequently involved, and NF- κ B inhibition may be an effective strategy to reduce glomerular inflammation (79). In addition to lymphohematopoietic cells, mesangial cells may be an important source of chemokines in glomerulonephritis. Resident glomerular cells may also respond to chemokines via specific receptors. Mesangial cells express CCR1 and CX3CR and proliferate in response to IL-10 via an unknown receptor.

Platelets and Platelet-Activating Factors

Intraglomerular platelets or their degradation products are commonly observed in diseases such as membranoproliferative glomerulonephritis and lupus nephritis. Evaluation of circulating platelets isolated from such patients often shows evidence that they have been activated *in vivo*. Although antiplatelet therapy has been advocated in the diseases discussed earlier, its efficacy has not been clearly established. The role of platelets as inflammatory mediators in experimental glomerulonephritis has been investigated for several decades now, but results have been inconsistent because of the difficulties inherent in platelet depletion and nonspecific drug inhibition studies.

Mechanisms of glomerular platelet recruitment to the kidney are poorly characterized. Complement activation is critical in a model of *in situ* immune-complex nephritis (Con A-anti-Con A) and in anti-Thy 1 nephritis, but whether this is a result of immune adherence to CR1 or of chemoattraction to C5a is unknown. Platelets may adhere to and become activated by the GBM in a reaction reminiscent of the *in vitro* effects of collagen. Other factors that have been implicated in intraglomerular adherence or activation of platelets include immune adherence to Fc recep-

TABLE 29.3. CHEMOKINES IN GLOMERULAR DISEASE

Family	Members	Abbreviation	Receptors	Primary target cells	
CXC (alpha)	Growth-related oncogene alpha	GRO- α	CXCL1	CXCR2	PMN
	Platelet factor 4	PF4	CXCL4	?	PMN, eosinophils
	Interleukin-8	IL-8	CXCL8	CXCR1, CXCR2	PMN
	Monokine induced by interferon gamma	Mig	CXCL9	CXCR3	T cells
	Interferon gamma-induced protein	IP-10	CXCL10	CXCR3	Th1 cells, NK cells
CC (beta)	Monocyte chemoattractant protein-1	MCP-1	CCL2	CCR2	M ϕ , dendritic cells, T cells, NK cells
	Macrophage inflammatory protein-1 α	MIP-1 α	CCL3	CCR1, CCR5	M ϕ , dendritic cells, Th1 cells, NK cells
	Macrophage inflammatory protein-1 β	MIP-1 β	CCL4	CCR5	M ϕ , dendritic cells, Th1 cells, NK cells
	Regulated on activation, normal T cell expressed and secreted	RANTES	CCL5	CCR1, CCR3, CCR5	M ϕ , dendritic cells, Th1 cells, NK cells
	Eotaxin		CL11	CCR3	Eosinophils, basophils, Th2 cells, dendritic cells
CX ₃ C	Fractalkine	FKN	CX ₃ CL1	CX ₃ CR1	T cells, NK cells
	Lymphotactin	LTN	XCL1	XCR1	T cells

M ϕ , monocytes/macrophages; NK, natural killer; PMN, polymorphonuclear leukocyte; Th, T helper.

Note: This is a partial listing, highlighting chemokines most frequently investigated in glomerular disease. CXCR4 is also a T-cell coreceptor for human immunodeficiency virus (HIV)-1; CCR5 is a coreceptor for HIV-1 strains that infect macrophages and activated T cells.

tors, activation of the coagulation cascade, TxA₂, and PAF. The role of platelet adhesion molecules, including P-selectin, glycoprotein Ib, platelet-endothelial cell adhesion molecule (PECAM-1), and β_3 integrins (e.g., glycoprotein IIb-IIIa) in glomerular disease has not yet been determined.

Several platelet products may be injurious to glomeruli such as bioactive lipids (PAF and TxA₂), platelet factor 4 (a cationic protein that participates in the coagulation cascade and is a CXC chemokine for leukocytes), and growth factors (PDGF, TGF- β 1). PAF has a multitude of biologic effects that may be mediated by the phospholipid itself (leukocyte chemoattraction, altered vascular permeability) or indirectly by stimulating release of substances such as Tx, PGs, leukotrienes, lysosomal enzymes, superoxide, IL-1, MCP-1, and TNF. PAF is not only produced by platelets but also in turn triggers platelet aggregation, activation, and degranulation. Antagonists to PAF or its receptor have decreased disease severity in several experimental glomerulonephritis models. Platelets may further modulate glomerular injury by activating C3 and C5 of the complement cascade, activating the intrinsic coagulation cascade, or by synthesis of β -thromboglobulin (inhibits endothelial release of prostaglandin I₂) or vasoactive amines such as histamine and serotonin.

Soluble Secreted Peptides

Growth factors and cytokines are small polypeptide messengers (most approximately 6 to 30 kDa) that bind to target cells

by specific surface receptors to initiate a variety of cellular responses (Table 29.4). Most of these factors can be produced by native glomerular cells as well as inflammatory cells.

Epidermal Growth Factor Family

One of the first circulating growth factors to be recognized, EGF was originally isolated from mouse submandibular glands and human urine. Most studies have failed to identify immunoreactive EGF in diseased glomeruli. *In vitro*, EGF stimulates mesangial cell contraction and PG synthesis; intrarenal EGF infusion decreases GFR and renal blood flow. TGF α shares 30% sequence homology with EGF and exerts its biologic action by binding to the EGF receptor. A newer family member, heparin-binding EGF-like growth factor, a mesangial cell mitogen, is expressed in disease models associated with mesangial cell proliferation (80). Heparin-binding EGF also has direct glomerular hemodynamic effects (81).

Fibroblast Growth Factor

FGF-2 or basic FGF (bFGF) is a potent angiogenic factor that also regulates matrix synthesis and is a mitogen for all intrinsic glomerular cells. FGF-2 has affinity for heparin and HSPG and may bind to basement membranes/extracellular matrix *in vivo*. In the Thy 1 nephritis model, production of bFGF increases during the phase of mesangial cell proliferation. Disease severity is enhanced by exogenous FGF and

TABLE 29.4. SOLUBLE SECRETED PEPTIDES IN ACUTE GLOMERULAR INJURY

Promotes injury	Prevents injury	Either (model-dependent)

attenuated by FGF-2 neutralization/antagonism (82). FGF may also contribute to the genesis of glomerulosclerosis as chronic administration causes podocyte damage in rats, and it enhances cytokine-induced endothelial cell apoptosis (83).

Colony-Stimulating Factors

Colony-stimulating factors (CSF) are a family of glycoproteins that not only regulate the development of hematopoietic progenitor cells but also promote the inflammatory response of mature cells such as macrophages. Increased CSF expression has been reported in several proliferative glomerular diseases. Mice deficient in granulocyte-macrophage (GM)-CSF develop less inflammation (PMN and M ϕ) after injection of nephrotoxic antiserum and membranoproliferative glomerulonephritis has been reported in a patient exposed to chronic GM-CSF treatment (84,85). The effects of G-CSF may be dose-dependent based on the observation that low-dose G-CSF promotes a Th2 response and worse nephritis in MRL-*lpr/lpr* mice, whereas high-dose therapy downregulated expression of the Fc γ receptor III and attenuated nephritis (86). Increased M-CSF has also been observed in proliferative nephritis. Macrophage migration inhibitory factor is another proinflammatory protein shown to be upregulated in glomerular diseases associated with a leukocyte infiltrate. Anti-migration inhibitory factor antibodies partially reverse glomerular injury induced with anti-GBM antiserum (87).

Interleukins

ILs are a large family of cytokines (at least 25) that play a central role in inflammatory and immunologic responses. The expression and function of several members have been examined in glomerulonephritis. In addition to the role played by ILs in the polarization and function of Th1/Th2 cells, several ILs are produced by and/or regulate the behavior of resident glomerular cells. IL-1, IL-8, and IL-18 have proinflammatory roles in most glomerular

diseases. IL-1 induces mesangial cell proliferation and promotes synthesis of a variety of substances: eicosanoids, oxygen radicals, collagenase, cytokines, chemokines, and adhesion molecules. It also enhances collagen synthesis by glomerular epithelial cells. Renal IL-1 mRNA levels are increased in several glomerular diseases, and neutralization studies with a soluble IL-1 receptor antagonist diminish inflammation and proliferation in rats with anti-Thy 1 or nephrotoxic serum nephritis (88). IL-8 is an important mediator of granulocyte chemoattraction and activation. Mesangial cells produce IL-8 when stimulated with cytokines such as IL-1 and TNF- α . IL-8 neutralization prevents neutrophil infiltration in a model of immune complex glomerulonephritis. In humans, urinary IL-8 levels are higher in patients with glomerulonephritis associated with leukocyte infiltration. IL-18 treatment has been reported to exacerbate SLE nephritis and cell-mediated crescentic nephritis (89,90).

ILs with antiinflammatory effects that have been shown to attenuate glomerulonephritis include IL-4, IL-10, and IL-11. Promotion of a Th2 response and inhibition the proinflammatory effects of macrophages are effects of IL-4. Both mesangial cells and podocytes can produce IL-4. The protective role of IL-4 has been documented in the anti-GBM nephritis model, both by studies in IL-4-deficient mice that develop worse disease and by IL-4 therapy that attenuates disease (91–93). In this model, IL-11 therapy has also been protective (94). IL-10 suppresses the nephritogenic Th1 immune responses; IL-10 $^{-/-}$ mice develop worse nephrotoxic serum nephritis than IL-10 $^{+/+}$ mice (95). In the Thy 1 nephritis and anti-GBM nephritis model, IL-10 therapy is protective (95,96).

Some ILs may have either pro- or antiinflammatory effects depending on the type of disease evaluated. For example, IL-6 is a cytokine produced by several blood-borne cells as well as glomerular endothelial and mesangial cells. IL-6 may be detectable in glomeruli and the urine in several proliferative glomerular diseases in animals and humans. Neutralizing anti-IL-6 antibodies and IL-6 receptor blockade decreased the severity of lupus nephritis,

whereas IL-6 transgenic mice spontaneously develop glomerulonephritis (97). Yet, IL-6 recombinant protein therapy reduced disease severity in rats with anti-GBM nephritis (98). Anti-GBM nephritis is less severe in IL-12-deficient mice, whereas IL-12 DNA plasmid therapy reduces the severity of immune complex nephritis associated with graft-versus-host disease (99,100).

Interferon Gamma

IFN- γ is a member of a family of glycoproteins (α , β , and γ) with immunomodulatory, antiviral, and antineoplastic activity. IFN- γ has been shown to play a key role in several autoimmune diseases including lupus nephritis. Deletion of IFN- γ or its receptor or treatment with a neutralizing antibody or IFN- γ R-Fc chimeric protein reduces renal disease in several SLE mouse models (101,102). Macrophages have been identified as an important source of IFN- γ , and IFN- γ expression regulates glomerular monocyte migration (103).

Platelet-Derived Growth Factor

PDGF is a dimeric glycoprotein of four known isoforms—PDGF-A, -B, -C, and -D. It has diverse biologic activities, including chemoattraction and activation of inflammatory cells, mitogenesis, and promotion of tissue repair. It also has vasoconstrictor properties. The mitogenic effect of PDGF on mesangial cells is especially remarkable, but it may also trigger a chemotactic and contractile response. Mesangial cells may also produce PDGF. During the mesangial proliferative phase of Thy 1 nephritis, PDGF neutralization by antibody, aptamers, PDGF receptor-IgG, or a PDGF receptor tyrosine kinase selective inhibitor is effective in blocking proliferation (104). Enhanced expression of PDGF and the PDGF-B receptor has been observed on human glomerulonephritis. The role of the more recently discovered PDGF-C and PDGF-D remains to be determined, although it has already been shown that PDGF-C can be made by podocytes and induce mesangial cell proliferation (105,106).

Transforming Growth Factor

TGF β is a family of polypeptide growth factors with at least three distinct mammalian isoforms. TGF β has diverse biologic actions that are relevant to glomerular disease, including its ability to modulate (sometimes in a dose-dependent manner) inflammatory and immunologic responses, cellular proliferation, apoptosis and differentiation, angiogenesis, and extracellular matrix metabolism. TGF β appears to be the primary mediator of glomerulosclerosis. TGF β production by resident and/or inflammatory cells may occur early in the course of glomerular injury, but its pathogenetic role in the acute phase of glomerulonephritis is still not clear. It is most commonly reported to have antiproliferative and proapoptotic effects. TGF β also has striking immunosuppressive

effects that may prove to be relevant to initiation of immune-mediated glomerular injury. Although TGF β therapy has been reported to attenuate experimental autoimmune diseases such as arthritis and encephalitis, mice overexpressing Smad7, an inhibitor of TGF β signaling, were found to have less severe anti-GBM nephritis (107).

Tumor Necrosis Factor

TNF- α is a proinflammatory cytokine primarily produced by monocytes and macrophages, although mesangial cells can also synthesize TNF- α . It is particularly important in the genesis of septic shock and the associated renal endothelial damage. TNF- α is also thought to play a role in proliferative glomerular diseases including anti-GBM nephritis, murine lupus nephritis, and serum sickness. Anti-GBM nephritis is less severe in TNF- α knock-out mice (108). TNF- α can induce mesangial cell contraction and synthesis of a variety of products such as IL-1, IL-8, GM-CSF, MCP-1, PGs, procoagulant, NO, and ROS.

Vascular Endothelial Growth Factor

VEGF, also known as vascular permeability factor, promotes capillary repair and angiogenesis through endothelial cell mitogenesis. Four isoforms have been identified: VEGF₁₂₁ and VEGF₁₆₅ (the most abundant) are soluble secreted forms, whereas the 189 and 206 isoforms are usually cell-bound. Within glomeruli, podocytes and activated mesangial cells produce VEGF, whereas its receptors, flt-1 and flk-1, are expressed on endothelial cells. Inhibition of VEGF exacerbates Thy 1 nephritis and results in the development of microaneurysms, whereas treatment with VEGF₁₆₅ promotes recovery from thrombotic microangiopathy (22,44,109).

Coagulation Cascade

The normal glomerulus is remarkably protected from the formation of thrombi, but fibrin deposition is frequently observed as a feature of three pathologic states: thrombotic microangiopathy, proliferative and necrotizing glomerulonephritis, and crescent formation. Earlier studies using anticoagulation with warfarin, heparin, or hirudin (a thrombin antagonist) yielded conflicting data on the potential for this intervention to diminish the severity of crescentic glomerulonephritis. Studies with fibrinolytic agents (anecrod, streptokinase or tissue plasminogen activator) have generally been more convincing with attenuated disease reported in models of anti-GBM nephritis, serum sickness, and lupus nephritis. The most compelling data that fibrin plays a significant role are based on a study of anti-GBM nephritis in fibrinogen-deficient mice (110). The number of intraglomerular monocytes, crescent formation, and serum creatinine levels were significantly reduced in the fibrinogen-/- mice. In proliferative glomerular diseases, fibrin's primary role may

be monocyte recruitment to the glomerular tuft and to Bowman's space to the site of crescent formation. The pathways that regulate glomerular fibrin deposition and removal are reviewed in Figure 29.6.

FIGURE 29.6. Regulation of glomerular fibrin deposition and removal. Fibrin deposition may be the consequence of intraglomerular activation of prothrombotic cascades and/or decreased endogenous fibrinolytic activity, primarily intraglomerular tissue plasminogen activator (tPA). Most of the fibrin associated with immunologic glomerular diseases is generated by activation of the extrinsic coagulation pathway that begins with the activation of factor VII by the tissue factor (TF) procoagulant to generate VIIa. TF can be produced by resident glomerular cells or monocytes/macrophages in response to several inflammatory stimuli. In addition, normal renal vessels constitutively express a TF inhibitor, tissue factor pathway inhibitor (TFPI), which is downregulated in many crescentic glomerular diseases. The importance of the TF pathway has been confirmed in experiments showing worse disease with TFPI neutralization and milder disease with recombinant TFPI therapy or TF inhibition (151). Several other factors contribute to the anti-thrombotic environment within normal glomerular such as PGI₂, nitric oxide, antithrombin III, and thrombomodulin (152,153). It is becoming apparent that certain coagulation proteins may themselves have proinflammatory effects that may contribute to glomerular injury. For example, mesangial cells express and can be activated by a thrombin receptor, protease-activated receptor-1 (PAR-1). The receptor is activated by the protease TRAP. Mice genetically PAR-1-deficient develop less severe anti-GBM nephritis, whereas PAR-1 activation by recombinant TRAP therapy causes worse disease but only in PAR-1-expressing mice (154). Mesangial cells proliferate after exposure to factor Xa, a VIIa cofactor for thrombin generation (155). Fibrin itself may also bind to cell surfaces through several potential mechanisms, especially by binding to $\alpha_v\beta_3$ integrin (156). Glomeruli produce plasminogen activators, mainly tPA, which normally protect the kidney from the damaging effects of fibrin accumulation. Mice with a genetic deficiency of tPA or plasminogen develop worse anti-GBM nephritis (157). Production of PA inhibitors, especially plasminogen activator inhibitor-1 (PAI-1) and perhaps protease nexin-1, may depress endogenous plasmin activity and promote glomerular fibrin deposition. In addition to its role in acute glomerular injury, it is now evident that the glomerular tPA/PAI-1 balance is involved in the chronic phase of injury and glomerulosclerosis through activities that regulate accumulation of not only fibrin but also extracellular matrix proteins [reviewed in (158)]. uPA, urokinase-type plasminogen activator.

Complement Cascade

Since the first description of complement proteins in diseased human glomeruli in 1956, the role of complement has been extensively investigated in experimental glomerular disease models. It is now evident that the complement cascade is multifunctional, somewhat paradoxically functioning systemically to prevent the formation and deposition of immune complexes but at a local level contributing to the inflammatory response through its intraglomerular effects. Most of the soluble complement components are made in the liver, but glomeruli may contribute to local production, especially during inflammation (111). The three pathways of complement activation are reviewed in Figure 29.7.

Complement-mediated glomerular injury may be a consequence of leukocyte recruitment, or complement itself may directly attack target cells. Complement activation generates the small chemoattractant peptides C3a and C5a that are especially effective in recruiting and activating PMN expressing C3a and C5a receptors. The latter fragment is unique for its chemotactic activity, which leads to the recruitment and activation of PMNs. Observations during the heterologous phase of anti-GBM nephritis provide the most compelling evidence for the complement PMN-dependent mechanism of glomerular injury. The MAC of complement may also activate the transcription factor NF- κ B leading to further inflammation due to IL-8 and MCP-1 production (112). The importance of this pathway is illustrated by studies in complement-depleted or -neutralized animals that are protected from the early injury induced by anti-GBM antibodies. Despite the presence of C3a and C5a receptors on several other cells, including monocytes, the glomerular recruitment of monocytes is usually complement independent. Mesangial cells also express the C5a receptor that may lead to direct cellular activation in the absence of PMN (113).

Based on important observations in the models of passive Heymann nephritis and anti-Thy 1 nephritis, it was recognized that the terminal complement components C5b-C9 that form the MAC can directly induce glomerular injury without inflammatory cells. Many subsequent studies using different strategies to inhibit or deplete complement or experiments in rodents with genetic complement deficiencies have clearly established the requirement for C5b-9 formation within glomeruli as the key event that initiates glomerular cell damage. The nature of this injury is still an area of active investigation, but several possibilities have been recognized. Multiple C9 molecules of the MAC polymerize to form ring-like structures that insert into the lipid bilayer of cell membranes, forming channels. Insertion into erythrocyte cell membranes leads to hemolysis, but nucleated cells are more resilient. C5b-9 can induce cell death by apoptosis, and such a mechanism may explain the early phase of complement-dependent mesangiolysis in rats with Thy 1 nephritis and glomerular endothelial cell loss in antibody complement-dependent thrombotic microangiopathy (114). "Sublytic" levels of C5b-9 have been shown to significantly modify the

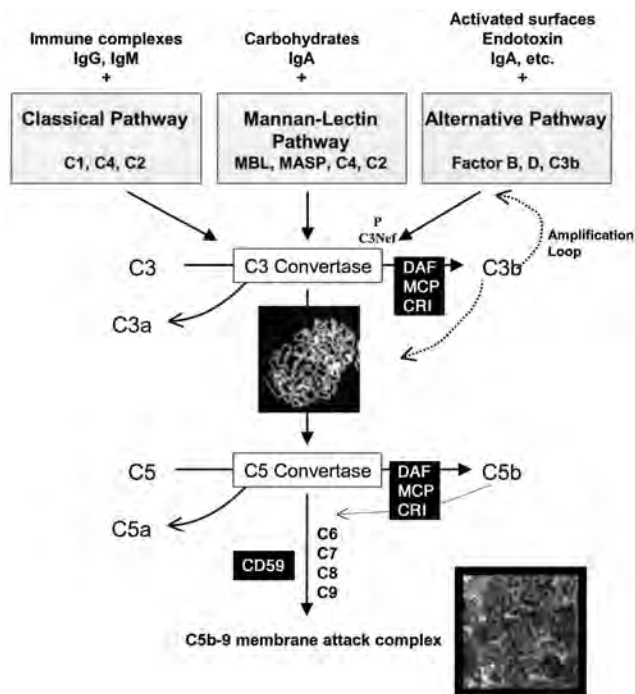

FIGURE 29.7. The complement cascade. The complement cascade is composed of at least 35 plasma proteins and several cell membrane receptors. The cascade is divided into three activation pathways: the classical, alternative, and mannan-lectin recognition pathways, which activate different early components, and a common terminal unit leading to the formation of C5b-9 and the membrane attack complex (MAC) of multiple C9 molecules. In humans, the classical pathway is activated by the binding of C1q to the Fc region of immunoglobulin G1 (IgG1), IgG2, IgG3, or IgM. The alternative pathway is usually triggered by immunoglobulin-independent interactions with substances such as damaged tissues, polysaccharides, or microorganisms. IgA may activate the alternative pathway, but it does not capture C3 molecules efficiently. GBM can also activate the alternative pathway. The recently identified lectin complement pathway leads to complement activation when the plasma protein mannan-binding lectin (MBL), which has a structure similar to C1q, binds to specific carbohydrate structures. MBL normally circulates as a complex with a family of serine protease (MBL-associated serine proteases-1, -2, -3) that becomes activated as a consequence of MBL-carbohydrate interactions. These proteases subsequently cleave C3 and C4. C3 nephritic factor (C3Nef) is an IgG autoantibody that reacts with the alternative pathway C3 convertase (C3bBb), an interaction that enhances enzyme activity leading to C3 consumption. The membrane attack complex of polymerized C9 molecules forms ring-like structures that may insert into cellular and basement membranes to cause dysfunction (illustrated within renal basement membrane in the lower-right immunoelectron photomicrograph). At least four cell surface proteins, highlighted in black boxes at their sites of action, inhibit complement activation and protect glomerular cells from complement-mediated damage: decay accelerating factor (DAF), membrane cofactor protein (MCP), complement receptor 1 (CR1), and CD59. (The MAC photomicrograph is from Falk et al. Ultrastructural localization of the membrane attack complex of complement in human renal tissues. *Am J Kidney Dis* 1987;9:121–128, with permission.)

behavior of the targeted cell. For example, several intracellular signaling pathways are activated in glomerular epithelial cells, leading to increased synthesis of eicosanoids and matrix protein; mesangial cells respond by increased synthesis of IL-

1, ROS, and PG; and endothelial cells produce MCP-1 and IL-8 (112,115). At least some of these products are coupled to alterations in the glomerular capillary permselectivity barrier that lead to proteinuria. What remains perplexing is the mechanism by which MAC causes glomerular injury and proteinuria in immunologic diseases associated with noncellular antigens. Although the GBM lacks a lipid bilayer, C5b-9 does bind to it. In factor H–deficient Yorkshire piglets that spontaneously develop membranoproliferative glomerulonephritis type II (dense intramembranous deposit disease in the absence of immune complex deposition) and factor H knock-out mice with MPGN, deposits of C5b-9 can be seen along the GBM early in the course of the disease (116).

Glomerular cells are normally protected from complement-mediated injury due to a cell-surface defense mechanism that inhibits complement activation and/or function (117). In human glomeruli, three such molecules have been well characterized, but additional molecules exist. Decay accelerating factor (DAF or CD55) and membrane cofactor protein (MCP or CD46) regulate C3 and C5 activation. CD59 inhibits at the level of C8 activation, preventing MAC formation (Fig. 29.7). In glomeruli, MCP and CD59 are expressed by all three types of intrinsic cells, whereas DAF expression is minimal, sometimes found on podocytes. Studies based on human biopsies show that MCP and CD59 expression is increased, and DAF is expressed *de novo* in the mesangium in various forms of glomerulonephritis. Crry is the rodent homolog with activities similar to DAF and MCP. Not only does blockade of complement regulatory proteins such as DC59 or Crry exacerbate complement-dependent glomerulonephritis, but also soluble Crry and CD59 can effectively inhibit complement and attenuate renal injury (118,119).

Two additional complement regulatory proteins are of interest for their potential to attenuate glomerular injury. CR1 (CD35) preferentially binds to C3b and C4b and is expressed on glomerular podocytes. CR1 also functions as a regulatory molecule to protect cells from injury, and treatment with soluble CR1 has been shown to attenuate glomerular injury. Clusterin is a plasma protein that is frequently found within glomerular immune deposits in association with vitronectin and soluble C5b-9. Clusterin depletion enhances immune complex glomerulonephritis in mice (120).

Systemically, the primary function of the complement is one of defense and protection against infectious and autoimmune disease. This role is powerfully illustrated by the observation that individuals with genetic complement deficiencies have an increased incidence of infectious diseases and SLE that is often associated with glomerulonephritis. The risk is greatest with deficiencies of the early components of the classical pathway.

The complement cascade plays a role in the normal processing and elimination of immune complexes before they can deposit in tissues such as glomeruli. *In vitro* studies have shown that components of the classical pathway help to maintain circulating immune complexes soluble by

interfering with their aggregation so that they can be eliminated by the mononuclear phagocytic system. In primates, the opsonization of immune complexes by complement facilitates hepatic elimination by the “erythrocyte shuttle.” In the lupus-prone mouse, deficiency of C3, C4, and factor B causes worse renal disease (121–123). The alternative complement pathway is able to dissolve antigen-antibody complexes by intercalating C3 molecules into their lattice structure. This activity may help to clear immune complex deposits from glomeruli. Recent observations in C1q-deficient mice, which like deficient humans develop a lupus-like syndrome, suggest that complement plays an important role in the clearance of apoptotic cells (a potential source of nuclear autoantigens) (124).

Reactive Oxygen Species

ROS are partially reduced oxygen molecules containing an unpaired electron that are generated during oxygen metabolism and are capable of an independent existence. Oxygen normally accepts four electrons to be converted directly into water. Acceptance of one electron generates superoxide anion (O_2^-), two electrons produce hydrogen peroxide (H_2O_2), and three electrons generate the hydroxyl radical ($OH\cdot$). Although H_2O_2 itself is not an oxygen radical, it is an important precursor. ROS may be generated by intrinsic glomerular cells (endothelial, mesangial, epithelial) or infiltrating leukocytes by a variety of stimuli, and they can cause glomerular damage. In experimental models of glomerular disease, alterations in glomerular permselectivity and proteinuria have been linked to ROS generation. Other effects relevant to the glomerulus include the ability of ROS to influence the susceptibility of the GBM to degradation directly or indirectly via the activation of latent proteases (collagenase, gelatinase) or by inactivation of collagenolytic enzyme inhibitors (α_1 -protease inhibitor), halogenation and damage to glomerular structures via interactions with hypohalous acid derivatives (derived from PMN), mediation of cellular toxicity, vasodilation of the microcirculation, and altered metabolic activity of intrinsic glomerular cells. ROS may also be involved in the initiation phase of glomerular damage, for example, by altering the hexameric structure of collagen IV to expose the normally “hidden” Goodpasture antigen (125).

Several different ROS may cause glomerular injury. Superoxide anions are the most abundant species produced by the respiratory burst of PMNs, but they are poorly reactive in aqueous solution and are unlikely to mediate tissue injury. It is more likely that the toxic glomerular effects of O_2^- relate to its conversion to hydroxyl radicals via the Haber-Weiss reaction. Hydrogen peroxide appears to be an important mediator of PMN-dependent models of glomerular diseases. Infusion of H_2O_2 directly into the renal artery of rats causes dose-dependent proteinuria, and depletion of H_2O_2 with catalase therapy reduces PMN-dependent pro-

teinuria. In addition to its potential role as an antigenic target in ANCA-associated vasculitis, myeloperoxidase catalyzes the formation of another toxic product by reaction of H_2O_2 with a halide, usually to produce hypochlorous acid. The role of highly toxic hydroxyl radicals in glomerular injury is less clearly defined. Both H_2O_2 and O_2^- may be converted to $OH\cdot$ via the Haber-Weiss reaction, and $OH\cdot$ scavenger therapy has been beneficial in several experimental models, but in general the agents used may have additional effects unrelated to $OH\cdot$ depletion. Analogous to atherosclerosis, lipid peroxidation products may also deposit in glomeruli with proinflammatory effects. Glomeruli are normally equipped with effective antioxidant defenses—catalase, superoxidase dismutase, and glutathione peroxidase. The response of these endogenous systems has not been extensively investigated in glomerulonephritis, but a recent study reported a decline in glomerular antioxidant activity during the phase of ROS generation in rats with Thy 1 nephritis (126).

Eicosanoids

Eicosanoids (*eicos* is the Greek word for 20 indicating their number of carbon atoms) are a family of biologically important autocoids derived from AA that are released from plasma membranes by cytosolic phospholipases (rate-limiting step). Two major pathways generate oxidized AA products of interest in glomerular disease: the COX and lipoxygenases (Fig. 29.8). Each pathway has its own receptors; some are expressed on glomerular cells. Whereas both resident glomerular cells and inflammatory cells are active in AA oxidation, most often resident cells produce COX

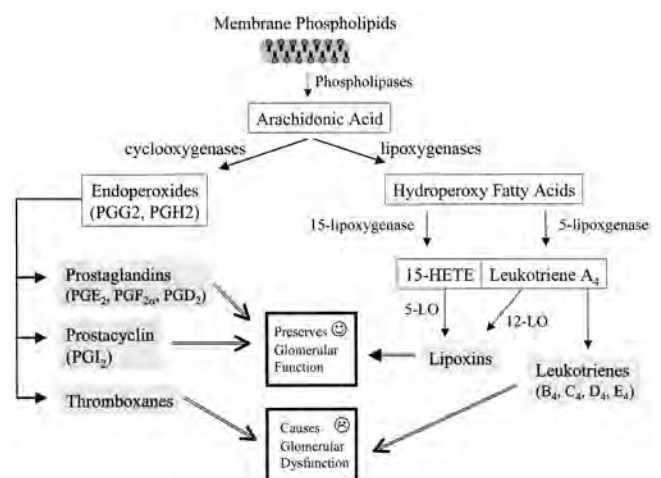

FIGURE 29.8. Glomerular effects of eicosanoids. Arachidonic acid released from plasma membranes by phospholipases is metabolized by cyclooxygenase and lipoxygenase enzymes to yield eicosanoids that can regulate glomerular hemodynamics and/or the intensity of inflammation. Some eicosanoids preserve renal blood flow and dampen inflammation, whereas others compromise glomerular blood flow and enhance inflammation. HETE, hydroxyeicosatetraenoic acid.

products, and leukocytes produce lipoxygenase products, with some overlap. Eicosanoids have profound effects on renal blood flow and leukocyte recruitment/activation that may either preserve renal blood flow and prevent inflammation (PGs and lipoxins) or decrease GFR and promote inflammation (Tx and leukotrienes).

Two COX genes have been identified that encode constitutive COX-1 (and the recently identified COX-3 splice variant) and the inducible COX-2, respectively (127). Neither isoform is easily detected in normal glomeruli, but several inflammatory stimuli induce COX-2 expression during glomerulonephritis. Mesangial cells are the most important intrinsic glomerular source of prostaglandin E₂; epithelial and endothelial cells produce some. Prostaglandin E₂ is often synthesized in response to acute glomerular injury in which it serves to preserve renal blood flow by vasodilation and mesangial cell relaxation. It may also have an antiinflammatory role, suppressing lymphocyte function and macrophage recruitment, preserving vascular permeability, and downregulating the synthesis of MCP-1, NO, and collagen (128,129). Prostaglandin I₂ or prostacyclin may also dampen the severity of acute glomerular injury through hemodynamic and antiinflammatory effects and by its ability to inhibit platelet activation.

Usually Tx are the most abundant eicosanoids produced by nephritic glomeruli. Elevated glomerular and/or urinary TxB₂ (the stable TxA₂ hydration product) levels have been reported in virtually every experimental model of glomerulonephritis examined, and inhibition therapy has been beneficial, especially in lupus nephritis. A relationship between TxB₂ and proteinuria has been proposed, but conflicting reports exist. A recent study reported that glomerular albumin permeability could be increased *in vitro* by incubation with TxA₂ (130). In addition to its ability to contract mesangial cells and to constrict blood vessels, TxA₂ also induces platelet aggregation, mediates the glomerular effects of PAF, and may stimulate matrix protein synthesis. TxA₂ may be synthesized by inflammatory cells (PMN, Mφ, and platelets) as well as intrinsic glomerular cells.

Lipoxygenase products may also be produced during acute glomerulonephritis (Fig. 29.8). The 5-lipoxygenase products (5-HETE, LTB₄, and leukotrienes C₄, D₄, E₄) appear to originate from infiltrating leukocytes, whereas 12-lipoxygenase predominates in platelets. Elevated levels of LTB₄ have been reported in several experimental models and associated with worse glomerular damage due to both hemodynamic effects (vasoconstriction) and enhancement of leukocyte recruitment and activation. Although the functional significance of all of the products of AA lipoxygenation has not yet been determined, studies using LTB₄, LTC₄, and LTD₄ receptor antagonists have reduced glomerular disease severity (131).

Lipoxins are a family of more recently described eicosanoids that undergo dual lipoxygenation by either 5- and 15- or 5- and 12-lipoxygenases (132). They have sig-

nificant antiinflammatory effects, particularly because of their ability to block leukotriene-mediated PMN chemotaxis and β₂ integrin-dependent adhesion. Within inflamed glomeruli, interaction between PMNs (a source of 5-lipoxygenase) and platelets (a source of 12-lipoxygenase) results in the generation of lipoxins. Mφ are a rich source of 15-lipoxygenase. The antiinflammatory effects of 15-lipoxygenase were nicely demonstrated in an anti-GBM nephritis model by gene transfection (133).

Two dietary manipulations that induce changes in eicosanoid metabolism have been shown to attenuate glomerulonephritis severity. First, dietary supplementation with fish oil that contains omega-3 fatty acids (especially eicosapentaenoic acids and docosahexaenoic acid) modifies both COX and lipoxygenase metabolites. Second, dietary depletion of essential fatty acids impairs renal production of a specific lipid-derived Mφ chemoattractant and eicosanoids such as LTB₄. In addition to alterations in eicosanoid biosynthesis, both fish oil supplementation and essential fatty acid deficiency have been shown to reduce macrophage production of TNF-α, ROS, and NO. Fish oil decreases mesangial cell proliferation in response to mitogens such as PDGF that have been implicated in the pathogenesis of mesangioproliferative glomerular disorders (134).

Endothelin and Nitric Oxide

ETs are a family of peptides first isolated in 1988. Three mammalian isoforms are known: ET-1, -2, and -3. ET, predominantly ET-1, is produced constitutively by intrinsic glomerular cells, most notably by endothelial cells. Several mediators of glomerular inflammation are reported to stimulate the production of ET-1 by mesangial cells *in vitro*, TGFβ, IL-1, TNF-α, PDGF, thrombin, and Tx, for example. Synthesis of ET-1 by mesangial cells and macrophages has also been documented *in vivo* in several human and animal models of glomerulonephritis. Evidence of a direct role for ET-1 in glomerular damage is based on the ability of ET-receptor blockade to attenuate experimental glomerulonephritis and the presence of glomerulosclerosis in ET-1 overexpressing mice. ET may function as a mesangial cell mitogen and a mediator of inflammation by upregulating adhesion molecules and by enhancing monocyte chemoattraction and activation. ET-1 may also stimulate matrix protein production.

Several endothelium-derived factors can mediate vascular relaxation, but the term *endothelium-derived relaxing factor* has become synonymous with NO. NO is a gaseous free radical that is liberated from the enzymatic conversion of L-arginine to citrulline by NO synthase. NO is an unstable molecule with a half-life of a few seconds; its stable oxidation products, nitrites and nitrates, or its secondary mediator, cyclic guanosine monophosphate, are used to estimate rates of NO generation. Three NO synthase isoforms have been identified: two constitutive, calcium-dependent enzymes

originally described in the brain (nNOS) and endothelium (eNOS), respectively, and an inducible, calcium-independent enzyme first described in macrophages (iNOS). In normal glomeruli low levels of eNOS and sometimes iNOS may be present, but generally these enzymes are quiescent unless stimulated. The acute phase of glomerular disease is usually characterized by increased NO production, and several inflammatory stimuli have been shown to stimulate production, endotoxin, TNF- α , IL-1, cyclic adenosine monophosphate, and IFN, for example.

Despite great interest in the biologic role of NO, it remains unclear whether its enhanced expression during glomerulonephritis serves a primary beneficial or detrimental role because it elicits multiple effects. An emerging theme suggests that the origin of NO—both cellular source and generating enzyme isoform—may determine its fate and function. Enhanced eNOS activity has many protective outcomes, including vasodilation to preserve renal plasma flow, inhibition of platelet aggregation and thrombosis, and decreased leukocyte recruitment (135). In eNOS-/- mice, anti-GBM antibodies induce severe glomerular damage with worse inflammation and fibrosis than is observed in wild-type mice (136). Experimental thrombotic microangiopathy is also worsened by inhibition of endogenous eNOS (137).

In other models of glomerular injury, NO is produced by iNOS activity of inflammatory leukocytes and, less often, of mesangial cells and is often associated with glomerular damage. NO can be oxidized to peroxynitrite, a toxic ROS (138). NO may also bind directly to iron or thiol groups on proteins and modify their function. Heme oxygenase has been recognized as an important defense against oxidative injury, and one of its activities is to down-regulate iNOS expression (139). NO has been ascribed other functions that may be relevant to glomerular injury but these still need further *in vivo* investigation—mitogenesis, apoptosis, vascular permeability changes, immune response modulation, and matrix synthesis (140). Pharmacologic blockade of iNOS using the inhibitor L-NIL has been beneficial in some but not all tested models, but genetic deficiency of iNOS does not alter the severity of anti-GBM nephritis (141,142).

RESOLUTION OR PROGRESSION OF GLOMERULAR INJURY

The immunologic events initiating glomerular injury are often self-limited. Yet, the outcome is extremely variable, ranging from the regeneration of an entirely normal glomerulus to global glomerulosclerosis. It is becoming evident that many genetic factors influence the glomerular response to injury (143). It is also clear that the events occurring simultaneously in the tubulointerstitium play a critical role in determining the long-term outcome in patients with primary

glomerulonephritis. Although a discussion of issues relevant to the resolution of glomerular injury is beyond the scope of this chapter, a few recent observations merit presentation.

The difference between recovery and progression may be determined by the duration or intensity of the initial insult. This can be shown experimentally using nephritogenic antibodies in which the injection of a single dose induces injury followed by full recovery, whereas multiple injections may cause progressive fibrosis. Glomerular sclerosis is characterized by the progressive accumulation of extracellular matrix proteins. As damaged glomeruli repair themselves, matrix protein synthesis may be transiently increased, but in the absence of ongoing injury, this phase of mesangial matrix expansion often does not progress to the destructive phase of glomerulosclerosis. Matrix-degrading enzymes are produced by glomeruli. They include serine proteases (plasminogen activators, elastase) and the MMPs (interstitial collagenase, gelatinases, stromelysin, and membrane-type MMP). Each of these enzymes has a naturally occurring inhibitor(s). An increase in proteolytic enzyme secretion or a decrease in inhibitor activity could degrade early glomerular matrix protein deposits. It is increasingly recognized that many of these proteases/inhibitors are multifunctional proteins. For example, MMP-2 is a gelatinase that also activates mesangial cells, whereas the tissue inhibitor of metalloproteinase-1 inhibits mesangial cell apoptosis (144,145).

Mesangial cell proliferation is a feature of many acute glomerular diseases that progress to chronic disease, but it is not clear that mesangial hypercellularity per se predicts progression. More important is the phenotypic transformation of mesangial cells into smooth muscle-like cells (expressing alpha smooth muscle actin, non-smooth muscle myosin, and the intermediate filament, desmin). These cells are the primary source of the sclerosing matrix proteins. Innate genetic programs within mesangial precursor cells may determine their phenotypic and functional fate (8). The contribution of podocytes to the expanding pool of matrix proteins is unclear, although *in vitro* these cells synthesize several matrix proteins. During glomerular repair, novel interstitial matrix proteins may be synthesized that further modulate the function of glomerular cells through integrin-dependent signaling mechanisms (Table 29.1).

Apoptotic programs play a critical role (146). During the recovery phase, apoptosis has been shown to be important in the reversal of mesangial cell hypercellularity and perhaps in the elimination of inflammatory cells. Programmed cell death may further deplete all lines of intrinsic glomerular cell as glomeruli succumb to destruction by sclerosis. An important area of investigation is the study of the molecular pathways that program glomerular cell death and whether different mechanisms are involved in the beneficial effects of apoptosis that terminate inflammation compared to those that lead to acellular sclerotic glomeruli.

During the evolution of glomerular injury, several soluble factors may be produced that help dampen or even terminate

disease progression. These may be products of intrinsic glomerular cells, inflammatory leukocytes, or T cells polarized to a Th2 phenotype. Examples include Th2 cytokines (Fig. 29.4), matrix-degrading proteases, fibrinolytic activity (Fig. 29.6), complement regulatory proteins (Fig. 29.7), antiinflammatory eicosanoids (Fig. 29.8) protective growth factors (Table 29.4), and NO. Some glycoproteins synthesized during the inflammatory phase may sequester and inhibit fibrosis-promoting cytokines. For example, SPARC (secreted protein acidic and rich in cysteine) binds PDGF, HSPG binds bFGF, and small proteoglycans, including decorin and biglycan, block the actions of TGF- β 1.

On the other hand, other products of glomerular inflammation have fibrogenic potential. The central role of TGF β is undisputed based on data from many studies (147). Many other factors contribute, some working via TGF β interactions and other independently such as angiotensin II and ET-1 [reviewed in (148)]. Numerous physical features associated with glomerular injury have been implicated in the genesis of glomerulosclerosis, but how they function at a molecular level is not fully understood. These include intraglomerular hypertension (which may cause glomerular mechanical stretch-induced TGF- β 1 synthesis), mesangial overload, the glomerular hypertrophic response, podocyte protein overload, podocytopenia, hyperlipidemia, and secondary cellular immune responses to cryptic glomerular antigens exposed during injury.

ACKNOWLEDGMENTS

Grants supporting the author's research and academic efforts are greatly appreciated and acknowledged, from the National Institutes of Health (DK54500 and DK44757) and the Juvenile Diabetes Foundation. ACUTE PROLIFERATIVE GLOMERULONEPHRITIS

ENDRE SULYOK

Acute proliferative glomerulonephritis (GN) includes a variety of diseases with diverse etiologies and variable morphologic appearances clinically presenting with a nephritic syndrome. These include abrupt onset, gross or microscopic hematuria, proteinuria varying from minimal to nephrotic range, casts on urinalysis, fluid overload with hypertension, and variable degree of renal insufficiency with oliguria or anuria. The term *proliferative* implies glomerular hypercellularity, whatever the origin of cells. They may invade the glomeruli from the circulation or may originate from glomerular mesangial, endothelial, or epithelial cells. Glomerular involvement may be focal or diffuse, segmental or global, according to the number of glomeruli and extent of glomerular injury.

The underlying mechanism of acute proliferative GN is immune-mediated inflammation as evidenced by glomerular deposits containing immune complexes and complement components in most cases. In pauci-immune crescentic GN, the pathogenetic role of immune mechanisms is indicated by the high rate of positivity for antineutrophil cytoplasmic antibodies.

It is important to emphasize that the morphologic patterns are not specific of a distinct clinical entity, and a specific disease may have different histologic appearances (Table 30.1). GN may be primary or secondary to a systemic process, such as vasculitis (1). As the etiology, history, clinical manifestations, laboratory findings, morphologic patterns, and clinical course may be extremely variable, an evaluation is needed for an appropriate diagnosis and adequate therapeutic interventions.

In this chapter, the acute poststreptococcal GN (APSGN) is presented in detail because it serves as a prototype of postinfectious proliferative GN. It is the most commonly encountered and the best understood form of proliferative GN. The terms *diffuse intracapillary GN*, *diffuse endocapillary GN*, and *acute postinfection GN* are also used in the text as synonyms.

ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Epidemiology

The major aspects of the epidemiology of APSGN have been summarized in comprehensive reviews by several authors (2–

4). Sporadic cases have been reported to occur in clusters, but endemic and epidemic outbreaks have also been recognized. Most often, APSGN follows upper respiratory tract infections in temperate climates or skin infections in tropic and subtropic areas caused by group A streptococci or, occasionally, groups C and G streptococci. Only certain streptococcal strains are capable of causing GN; these are called *nephritogenic streptococci*. Nephritogenic strains have the cell wall M-protein serotypes 1, 2, 3, 4, 12, 18, 25, 49, 55, 57, and 60. Postpharyngitis GN is usually associated with M types 1, 3, 4, 12, 18, 25, and 49, whereas postpyoderma GN is related to specific M types 2, 49, 55, 57, and 60. The incidence of GN after infection with nephritogenic streptococci is variable and depends on the M serotype and the site of infection. It has been reported to range from 1 to 33% of the patients, with the overall risk of approximately 15%. Clinically apparent GN occurs in less than 2% of children infected with various streptococcal strains. Seasonal variation is characteristic for APSGN in the temperate climate because streptococcal throat infections are more common in winter and early spring, whereas streptococcal pyoderma mostly occurs in late summer and early fall.

The occurrence of APSGN is influenced by certain host factors, such as age, sex, socioeconomic background, and genetic predisposition. The disease is more frequent among children between the ages of 2 and 12 years, although 5% of the patients are younger than 2 years of age. Boys are more often affected with clinically overt GN than girls, with the ratio of 2:1.

Epidemic outbreaks tend to occur in closed communities and in densely populated areas where poor hygiene, malnutrition, anemia, and intestinal parasites are common. Since the 60s of the last century, marked steady declines have been noted in the prevalence of APSGN, although cyclic recurrences have been observed in certain communities. The reason for the apparent decline in the prevalence of the disease is not clear and may be attributed to the widespread use of antibiotics, improved hygienic conditions, changes in nephritogenic potential of streptococcus strains, or altered susceptibility of the host (5). After recovery from APSGN, protective immunity is acquired against

TABLE 30.1. HISTOLOGIC CATEGORIES OF ACUTE PROLIFERATIVE (HYPERCELLULAR) GLOMERULONEPHRITIS (GN)

Histologic pattern	Causes
Diffuse intracapillary proliferative (exudative) GN (with neutrophils)	Usually postinfectious Occasionally related to SLE or vasculitis
Diffuse proliferative GN (without neutrophils)	Postinfectious GN SLE
Mesangial proliferative GN	Primary forms of GN Resolving postinfectious GN IgA nephropathy IgM nephritis Accompanying systemic disease SLE Infective endocarditis Henoch-Schönlein purpura Mixed connective tissue disease
Membranoproliferative (mesangiocapillary) GN	Idiopathic Systemic immune complex diseases Mixed cryoglobulinemia SLE Sjögren's syndrome Hereditary deficiencies of complement components Infectious diseases Bacterial Infected ventriculoatrial shunts Endocarditis Viral Hepatitis B and C Human immunodeficiency virus Protozoal: malaria, schistosomiasis Other: mycoplasma, mycobacteria Neoplasms Chronic liver diseases Miscellaneous
Diffuse extracapillary proliferative (crescentic) GN	
Diseases with crescent in majority of cases	Anti-glomerular basement membrane antibody diseases With pulmonary hemorrhage (Goodpasture's syndrome) Without pulmonary hemorrhage Antineutrophil cytoplasmic antibody-associated GN Wegener's granulomatosis Polyarteritis nodosa Hypersensitivity vasculitis Idiopathic crescentic GN
Diseases with crescent in minority of cases	Postinfectious GN SLE IgA nephropathy Henoch-Schönlein purpura Essential mixed cryoglobulinemia Membranoproliferative GN

Ig, immunoglobulin; SLE, systemic lupus erythematosus.

Adapted from Kern WF, Laszik ZG, Nadasdy T, et al. The true (hypercellular or "proliferative") glomerulonephritis. Diseases associated with the nephritic syndrome. In: Kern WF, Laszik ZG, Nadasdy T, et al., eds. *Atlas of renal pathology*. Philadelphia: WB Saunders, 1999:669–689.

the nephritogenic strains. This protective immunity is more likely related to the specificities and neutralizing capacity of antibodies rather than to the antibody titer itself (6).

Family studies have suggested genetic predisposition for APSGN by demonstrating its higher incidence in siblings

of index cases with sporadic disease (38%) than the expected attack rate of children at risk in epidemics (4.5 to 28.0%) (7). The genetic aspects of APSGN are further supported by the reports of common association of the disease with HLA-DR1 and -DRw4, whereas patients with HLA-

DRw48 and -DRw8 appear to be less susceptible to development of primary GN (8,9).

Pathogenesis

APSGN is an immune-mediated disease associated with throat or skin infections with certain nephritogenic strains of group A streptococci. Streptococcal constituents or products that may trigger pathologic processes have not been fully defined. Furthermore, the exact mechanism of renal injury remains controversial, although several theories have been proposed: (a) trapping of circulating immune complexes in the glomeruli (10,11); (b) molecular mimicry between streptococcal and renal antigens (i.e., normal glomerular tissue acting as autoantigen reacts with circulating antibody formed against streptococcal antigens) (12–14); (c) *in situ* immune complex formation between antistreptococcal antibodies and glomerular planted antigens (15,16); and (d) direct complement activation by streptococcal antigens deposited in the glomeruli (17).

Streptococcal Factors Implicated in the Pathogenesis of Acute Poststreptococcal Glomerulonephritis

The group A streptococci are covered with an outer hyaluronic acid capsule required for resistance to phagocytosis and bacterial adherence to epithelial cells. Extracellular surface molecules further consist of a group A carbohydrate polymer, a mucopeptide, and an M protein. The M protein extends from the cell surface as an alpha-helical coiled-coil dimer, which appears as hair-like projections on the surface of streptococci (18).

M Protein and M-Like Proteins

Groups A and C and human isolates of group G streptococci possess M proteins, and more than 80 serotypes have already been identified. M proteins have the variable N-terminal region projected outward and the highly conserved C-terminal part anchored in the cell membrane. The genes encoding several types of M proteins, called *emm genes*, have been cloned, and their nucleotide sequences have been established. M proteins have a common structure: the heptad-repeating amino acid sequence motifs within each region of the molecule. M proteins have been divided into two classes based on their reactivity with antibodies against the C repeat region. Class I M proteins contain a surface-exposed epitope that reacts with these antibodies and are opacity-factor negative, whereas class II M-protein serotypes do not contain the class I epitope, do not react with anti-C repeat region antibodies, and are opacity-factor positive (19).

The nephrogenicity of group A streptococci appears to be related to specific M-protein serotypes, but not all strains of the same M-protein serotype are nephritogenic.

There is an apparent difference in streptococcal strains leading to APSGN through pharyngeal or skin infection. The predominant M-protein serotypes associated with pyoderma and APSGN are M proteins 2, 42, 49, 56, 57, 60, whereas M proteins 1, 4, 12, and 25 are associated with throat infection and APSGN. In general, the pyoderma or skin strains belong to the class II M-protein serotypes with the capacity to produce opacity factor but having no reaction with antibodies against C repeat region (20).

The potential role of M proteins in inducing APSGN has been extensively studied. Markedly elevated immunoglobulin (Ig) G titers against the C-terminal region but not the N-terminal region of the M12 protein were found in patients with APSGN as compared to patients with pharyngitis or chronic GN or healthy individuals. Binding of IgG to bacteria is assumed to be of importance for the development of APSGN. Binding of IgG and IgA aggregates is frequently detected among nephritogenic streptococci. Fc regions of IgG and IgA may bind to the surface of certain group A streptococcus strains through M proteins or M-like proteins. Fc receptor-positive group A streptococci isolates elicit anti-IgG response and promote deposition of IgG and C3 in the rabbit kidney immunized with group A streptococcus. These findings suggest that Fc receptors of nephritogenic streptococci may induce anti-IgG molecules and, consequently, may contribute to the pathogenesis of APSGN by enhancing renal deposition of immune complexes (21,22).

The role of M proteins in inducing renal injury is further supported by the well-established cross-reactivity of M proteins with glomerular basement membrane (GBM) antigens. Antiglomerular antibodies have been shown to react with streptococcal M12 protein. A number of surface proteins from nephritogenic streptococci have been reported to bind constituents of GBM (e.g., heparan sulfate, laminin, and collagen IV). The streptococcal host factor-binding proteins share structural homologies with classical M proteins and are designated as *M-like proteins* (23).

Endostreptosin

Endostreptosin is a 40- to 50-kDa protein derived from the streptococcal cell cytoplasm. It was found to absorb anti-glomerular antibodies from the sera of patients after APSGN. Endostreptosin has been detected in the glomeruli in the early phase of APSGN. In the late stages of the disease, it is not detectable, but increased serum antistreptosin titers are diagnostic of APSGN. Endostreptosin deposited in the GBM is considered to be an *in situ* activator of the alternative pathway of the complement system and immunologically distinct from other streptococcal enzymes or cell wall components (24,25).

Cationic Antigens

Cationic proteins of group A streptococci are known to have affinity for the polyanionic GBM. Antibodies raised against

cationic proteins from nephritogenic group A streptococcus isolates were shown to bind to renal biopsy samples from patients with APSGN, and antibodies to these cationic antigens were detected in APSGN patients. Cationic antigens generate *in situ* immune complexes and initiate glomerular inflammation. As C3 deposition precedes that of IgG in APSGN, the cationic protein-related mechanisms are likely to be involved in the later phase of the disease (26).

Streptococcal Pyrogenic Exotoxin B

Streptococci isolated from patients with nephritis produce a 46-kDa extracellular protein not found in strains from patients without acute GN. This nephritis strain-associated protein was found to be a plasmin-binding protein and was later identified as *streptococcal pyrogenic exotoxin B* (SpeB) precursor, also known as the *streptococcal proteinase zymogen*. It is believed that the protease or superantigenic properties of this exotoxin/protease/plasmin binding may cause an activation of the immune system by cleaving several host factors that favor the release of active inflammatory mediators, vascular permeability factors, and biologically active fragments from the streptococcal wall (27). Antibody titers to SpeB are markedly elevated in APSGN as opposed to patients with acute rheumatic fever, scarlet fever, or healthy subjects. SpeB is detected in the glomeruli of 67% APSGN biopsy specimens as compared with only 16% of non-APSGN cases (28).

Streptokinase

Streptokinase, a 46-kDa, 414-amino acid, extracellular protein is considered to be involved in the pathogenesis of APSGN. Nine different genotypes of streptokinase have been identified, and ska-1, -2, -6, and -9 have been found to be associated with APSGN. The streptokinase genes are highly conserved, and a greater than 90% homology in the amino acid sequence is observed in nephritogenic strains as compared with less than 60% homology for nonnephritogenic strains (29). Streptokinase was found to be tightly bound to the glomeruli, and glomerular deposits of streptokinase could be detected with a highly sensitive staining technique. Streptokinase is known to form complexes with plasminogen and plasmin, and these complexes have the capacity to convert plasminogen to plasmin. Plasmin then activates the local complement cascade, causes degradation of extracellular matrix proteins, and induces the release of vasoactive bradykinin. In an experimental model, the deletion of the streptokinase gene was shown to eliminate the nephritogenic properties of the strain (30).

Neuraminidase

It has also been suggested that in APSGN, the autologous IgG becomes autoimmunogenic after being desialized by streptococcal neuraminidase. The modified antigenic IgG stimulates the anti-IgG rheumatoid factor response, which may lead to the formation of cryoglobulins. The pathogenic

role of neuraminidase is further supported by the demonstration of free sialic acid and neuraminidase activity in the serum of APSGN patients and by experimental evidence that intravenous (IV) neuraminidase administration promotes renal infiltration of leukocytes and that neuraminidase-treated leukocytes preferentially accumulate in the kidney (31,32). However, neuraminidase is also produced by non-nephritogenic streptococcus strains. It has been proposed that the formation of autoantibody to IgG could be due to its incorporation into a streptococcal antigen-antibody complex rather than to its modification by neuraminidase.

Nephritis-Associated Plasmin Receptor

A 43-kDa protein designated as *nephritis-associated plasmin receptor* (NAPlr) has been isolated from nephritogenic streptococci. This antigen is present in glomeruli in the early stage of APSGN, and antibodies to NAPlr are detected in the serum of 92% of patients within 3 months of the onset of the disease. Soluble NAPlr could bind to the glomeruli and attack activated plasmin, which has a central role in the process of local inflammation. In addition, NAPlr directly contributes to alternative complement activation (33).

Complement Cascade

Humoral immunity initiated by nephritogenic streptococcal antigens is assumed to be mediated by *in situ* formation of antigen-antibody complexes and by glomerular deposition of circulating immune complexes. These processes lead to the activation of the classical and the alternative complement pathways as evidenced by the depressed serum levels and the glomerular localization of the components of complement cascade.

The classical pathway is primarily involved in the early stage of disease and is likely activated by immune complexes when IgG has become deposited. Several observations suggest that the alternative pathway is operating as well. These include (a) the glomerular presence of properdin; (b) C3 deposition precedes that of IgG, or even C3 may be present in the glomeruli without IgG; and (c) in the acute stage of APSGN serum levels of C3 and C5 are low, whereas the levels of early components of the classical activation pathway (e.g., C1q, C2, or C4) are normal or only slightly depressed (34–36). Other studies have revealed an activation of the terminal complement pathway and the generation of the terminal C5_b-C9 complex, also designated as *membrane attack complex*, by showing its elevated plasma level and colocalization with C3 deposits in glomerular capillaries and mesangium in patients with APSGN. The potential importance of this terminal complement complex implies its capacity to stimulate the production of vasoactive substances, proteolytic enzymes, and reactive oxygen radicals—all known to damage the integrity of glomerular capillary membrane. C3_a and C5_a also appear to be involved in tissue damage, as they function as chemotactic

factors for infiltrating cells and cause histamine release and increased permeability (4). The early phase of APSGN may be associated with C3 nephritic factor and decreased plasma levels of C3. C3 nephritic factor is an autoantibody against the C3 convertase that stabilizes this inherently labile enzyme and induces a continuous activation of alternative pathways with subsequent C3 depletion (37).

During the course of GN, protective mechanisms have been identified against complement-mediated injury of glomerular cells. Surface-bound proteins expressed on glomerular cells are assumed to prevent complement activation, and soluble complement receptors and those on the glomerular visceral epithelial cells appear to attenuate glomerular injury (38).

Coagulation System

Intraglomerular deposition of fibrin or fibrinogen-related antigen is a constant finding in APSGN. The activation of the coagulation system is further indicated by the increased levels of plasma high-molecular-weight fibrinogen complexes, the development of hypo- or hyperfibrinogenemia, the depression of factor XIII, α_2 -macroglobulin, and the activation of factor XII. Fibrinolysis is increased as shown by the elevation of serum and urinary fibrinogen or fibrin degradation products. Urinary excretion of these products is believed to reflect the degradation of glomerular fibrin deposits and the beginning of the recovery phase of the disease. It is interesting to note that there is no relationship between serum levels of C3 and fibrin degradation products. The possible involvement of platelet activation has also been proposed because of the diminished platelet survival time and the presence of platelet-activating factor and platelet-derived growth factor in APSGN (39).

Cellular Infiltration and Cytokine Production

APSGN is characterized by diffuse glomerular hypercellularity, primarily as a result of accumulation of polymorphonuclear leukocytes and monocytes, an increase in intrinsic glomerular cells, and a transient pathologic expansion of mesangial matrix. Resident endothelial and mesangial cells proliferate, and macrophages are believed to induce this proliferation. Glomerular macrophage infiltration appears to be mediated by complement-induced chemotaxis and by antigen-specific T-cell activation. Streptococcal superantigens cause a selective increase in T-cell receptor β and massive T-cell activation with the release of T-cell-derived lymphokines [e.g., interleukin (IL)-1 and IL-6] (40).

Hisano et al. found more infiltrating macrophages and the four macrophage subclasses—early-, acute-, chronic-stage inflammatory, and chronic-stage mature macrophages—in the glomeruli of patients with APSGN compared to patients with IgA nephropathy (41). The proportion of

intraglomerular proliferating macrophages decreases with time during the course of the disease in APSGN, whereas it remains constant in IgA nephropathy. Infiltrating cells undergo apoptosis, which is a prerequisite for the elimination of these cells and the resolution of renal injury. Decreased apoptosis has been found to be associated with a progressive clinical course (42). In addition to macrophages, neutrophils and T lymphocytes are present in the glomeruli but not B lymphocytes (43). Recently, proinflammatory monocytes or macrophages expressing CD16 antigen have been demonstrated in the glomeruli and the urine of patients with active proliferative GN, and the number of these cells appears to correlate with the severity of acute glomerular inflammation (44). CD16⁺ macrophages produce high levels of proinflammatory cytokines [e.g., tumor necrosis factor (TNF)], whereas antiinflammatory cytokines (e.g., IL-10) are absent or produced at a low level (45). Increased local production of proinflammatory cytokines may induce the expression of adhesion molecules (intercellular adhesion molecule-1) and lymphocyte function-associated molecule-1 on endothelial cells, and these molecules may facilitate the adhesion of circulating cells to the renal endothelium and their subsequent invasion into the parenchyma (46). In response to nephritogenic glomerular antigen, two subsets of fully differentiated T helper cells are activated. T helper-1 cells produce IL-2 and interferon-gamma, activate macrophages, and induce expression of MHC antigen, whereas T helper-2 cells secrete IL-4, -5, and -6, cofactors for B-cell proliferation, and stimulants for Ig production (47). IL-1 has the potential to increase glomerular inflammation, whereas antiinflammatory cytokines (e.g., IL-4, -6, -10, -13, and transforming growth factor β) reduce IL-1 synthesis by macrophages and suppress the generation of oxygen radicals and nitrogenous intermediates, the secretion of proteolytic enzymes, and the expression of Fc receptors (48). It is of note that IL-4 ameliorates experimental GN also by upregulating the glomerular gene expression of IL-1 decoy receptor (49). IL-8 is a selective activator and chemoattractant of polymorphonuclear leukocytes secreted by monocytes and intrinsic glomerular mesangial, endothelial, and epithelial cells. Glomerular immunoreactivity for IL-8 correlates with neutrophil infiltration and clinical activity in patients with APSGN. Transforming growth factors β 1, β 2, and β 3, originating from infiltrating monocytes or macrophages or from mesangial cells, are also abundant in biopsy specimens of APSGN and appear to be responsible for the accumulation of mesangial matrix components, including collagens, proteoglycans, and fibronectin (50).

It has recently been shown that selective podocyte injury exacerbates mesangial cell proliferation and mesangial matrix expansion, which consequently contributes to the progression of experimental proliferative GN. Podocyte dysfunction is an important factor in the development of irreversible mesangial alterations. Basic fibroblast growth

factor is also released by the podocytes, and it may further amplify podocyte damage and mesangial alterations (51).

Mesangial injury or activation may also be controlled by serine protease inhibitors. Megsin, a novel member of the superfamily of serine protease inhibitors, is predominantly expressed in mesangial cells, and its expression is upregulated at the peak of hypercellularity and matrix accumulation during various glomerular diseases. Imbalance between proteinases and their inhibitors may participate in the expansion of mesangial extracellular matrix by modulating the turnover of glomerular mesangial matrix compounds (52,53).

It is generally accepted that proinflammatory cytokines and chemokines originating from infiltrating cells or from resident glomerular cells are more expressed in proliferative GN. Their expression is differentially regulated by the presence of immune complexes, and there is a relationship between cytokine gene expression and clinical manifestations (54). In patients with APSGN, plasma levels of IL-6 have been shown to parallel the clinical course, whereas TNF- α is elevated in the acute phase and variable thereafter. Levels of platelet-derived growth factor always remain normal (55).

Free Oxygen Radicals

Recent studies have revealed some major features of oxygen stress and antioxidant defense mechanisms in children with APSGN. Lipid peroxidation is enhanced, as demonstrated by increased red blood cell osmotic fragility, elevated levels of malonyl dialdehyde, oxidized glutathione, and hemoglobin. Furthermore, the activities of major antioxidant enzymes including superoxide dismutase, catalase, glutathione peroxidase, and glutathione-S-transferase are markedly depressed in children with APSGN as compared with healthy control children. As a result, the levels of reduced glutathione are significantly lower and the reduced glutathione–oxidized glutathione redox system is depleted. APSGN children, therefore, have diminished antioxidant defense capacity and may suffer from prolonged oxidative stress with increased susceptibility to lipid peroxidation and osmotic lysis of red blood cells (56,57). There is evidence for a redox-sensitive regulation of transcription factors and gene expression of prooxidant and antioxidant mediators. The genetic shifting of superoxide to nitric oxide–dominated chemistry during the course of GN may alter the self-limited inflammatory responses of glomerular mesangial and endothelial cells to tissue injury (58).

Pathologic Changes

Microscopic Findings

Microscopic findings correspond to the infiltration with professional immune cells, activation, and proliferation of resident glomerular cells and matrix expansion.

Capillary tufts are enlarged and exhibit marked lobularity and hypercellularity with global and relatively uniform

FIGURE 30.1. Acute postinfectious glomerulonephritis. The glomeruli show global intracapillary hypercellularity with large numbers of polymorphonuclear leukocytes in the glomerular capillary lumina (hematoxylin and eosin stain, $\times 400$). (Courtesy of Peter Degrell, University of Pécs Faculty of Medicine, Nephrological Center, Pécs, Hungary.) (See Color Plate 30.1.)

involvement of all glomeruli (Fig. 30.1). During the course of the disease, distinct patterns of cellular reaction can be recognized.

At the early stage of the disease, glomerular hypercellularity is due to an influx of blood-borne polymorphonuclear leukocytes and monocytes, whereas in later stages, it is mainly caused by proliferation of intrinsic endothelial and mesangial cells. T-helper and T-suppressor lymphocytes also participate at the onset of APSGN. In addition to mesangial proliferation, mesangial matrix accumulation, growing mesangial fibers, mesangiolysis, and expression of molecules mediating the cross-communication between resident and invading cells, have been noted. Mesangial hypercellularity may persist long after apparent resolution of the disease. Extracapillary proliferation (i.e., crescents) may also be present in a minority of cases. Capillary walls are not thickened, but the lumens are frequently occluded. The GBMs may be irregular due to the characteristic humps observed on electron microscopy. Renal tubules are usually not involved, although protein resorption droplets have been noted in the proximal tubular cells and erythrocytes, sometimes mixed with eosinophilic cast-like material, and neutrophils may be present in the tubular lumen. Tubular vacuolation, dilatation, or atrophy is rarely observed.

Renal arteries and arterioles are generally spared or show minimal changes. There have been occasional reports of fibrinoid necrosis and necrotizing vasculitis that are usually associated with hypertension (3). The involvement of interstitium is not remarkable; interstitial edema and scattered inflammatory cells may be present.

Immunofluorescence Microscopy

Early in the clinical course, coarse granular staining for IgG and C3 can be detected in the glomerular capillary walls; IgM is found less frequently, and IgA and early complement

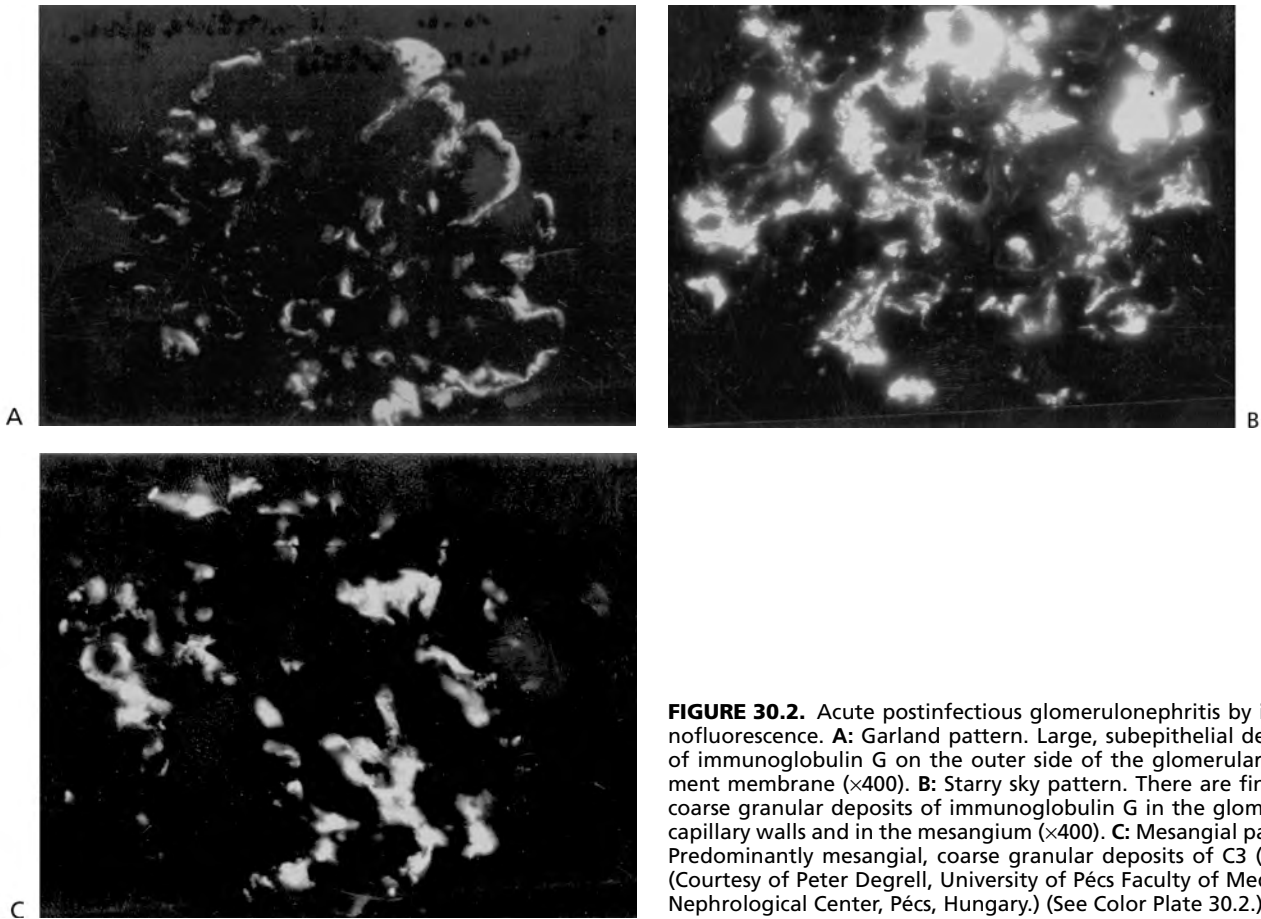

FIGURE 30.2. Acute postinfectious glomerulonephritis by immunofluorescence. **A:** Garland pattern. Large, subepithelial deposits of immunoglobulin G on the outer side of the glomerular basement membrane ($\times 400$). **B:** Starry sky pattern. There are fine and coarse granular deposits of immunoglobulin G in the glomerular capillary walls and in the mesangium ($\times 400$). **C:** Mesangial pattern. Predominantly mesangial, coarse granular deposits of C3 ($\times 400$). (Courtesy of Peter Degrell, University of Pécs Faculty of Medicine, Nephrological Center, Pécs, Hungary.) (See Color Plate 30.2.)

components (i.e., C1 and C4) are usually absent. As the disease evolves, staining for C3 predominates, whereas IgG staining becomes less apparent. Three distinct immunofluorescence patterns have been described and are designated as *garland*, *starry sky*, and *mesangial* patterns (Fig. 30.2). Garland pattern consists of discrete, densely packed, sometimes confluent capillary wall deposits often seen in patients with extracapillary proliferation and heavy proteinuria with worse prognosis. Starry sky pattern displays fine, granular IgG and C3 deposits in the capillary walls and mesangium and occurs mainly at the acute stage of the disease. The mesangial pattern is characterized by granular deposition of C3 and IgG predominantly in the mesangium, with the capillary walls being relatively spared. C3 deposits prevail over IgG, and this pattern appears to be closely related to the resolution of the disease. It is of note that although the distinct patterns of immunofluorescence staining and their clinical correlates are well established, combinations of these patterns and transitional forms are often observed (59,60).

Electron Microscopy

Ultrastructural examination shows a swelling of glomerular endothelial and mesangial cells with closure of the capillary

lumen. The most consistent finding is the presence of large, electron-dense, immune-type deposits on the subepithelial surface of the GBM, classically referred to as *humps* (Fig. 30.3). These are most abundant during the first few weeks of APSGN and tend to disappear 6 weeks after the clinical onset of disease. The electron density of the deposits is variable and diminishes with time, and the appearance of electron-lucent regions in the deposit is regarded as a sign of morphologic resolution (61,62). Subendothelial, mesangial, and membranous deposits may also be present, but they are less consistent and smaller in size. GBMs are generally normal in contour and thickness, although patchy thickening and focal disruption may occasionally be identified. The glomerular capillary endothelium may also be partially disrupted, with neutrophils directly adjacent to the denuded GBM.

It has been suggested that several morphologic alterations—including glomerular hypercellularity, crescent formation, the degree of interstitial volume, the number of glomerular humps, and the intensity of immunofluorescent staining for IgG and C3—may influence the initial presentation, clinical course, and long-term outcome of APSGN. The combination of these morphologic features is likely to have greater prognostic value than any single finding alone (3).

FIGURE 30.3. Acute postinfectious glomerulonephritis on electron micrograph. Hump-like, electron-dense subepithelial deposits (arrows) are seen in the glomerular capillary wall, with polymorphonuclear leukocytes in the capillary lumina ($\times 6000$). Clinical Presentation

Typical APSGN is characterized by the abrupt onset of hematuria and proteinuria often in association with edema, hypertension, and mild to moderate renal functional impairment. The disease is usually preceded by group A β -hemolytic streptococcus infection of the throat or skin. The long-term prognosis is generally favorable, but some patients may have life-threatening acute complications or may slowly progress to renal failure.

Acute nephritic syndrome follows throat or skin infection after a latent period of 1 to 2 weeks or 3 to 6 weeks, respectively. During the latent period, microscopic hematuria may be detected. Some patients remain asymptomatic, and the ratio of subclinical to clinically overt disease is estimated to be 4 to 5:1 (7,63,64).

The most common presenting symptoms are hematuria, edema, proteinuria, and hypertension. Gross hematuria is present in 24 to 40% of children with APSGN. The urine is smoky or coke-colored, and the patients may have dysuria, frequency, and abdominal discomfort. Macroscopic hematuria may be present for up to 2 weeks, and microscopic hematuria may remain evident for months after illness resolution. Glomerular hematuria is characterized by dysmorphic red blood cells and red blood cell casts best seen in freshly prepared urine by phase-contrast microscopy. Mild to moderate proteinuria is common in APSGN, whereas proteinuria of nephrotic range is rare in children.

Transient oliguria occurs in approximately 50% of children with APSGN, but anuria is rare. Decreased urine output is the result of markedly decreased filtration fraction and glomerular filtration rate (GFR), diminished distal delivery of the filtrate, and maintained or even enhanced sodium and fluid reabsorption in the distal nephron.

TABLE 30.2. CLINICAL MANIFESTATIONS OF ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS IN CHILDREN AND ELDERLY ADULTS

Symptom	Children (%)	Elderly patients (%)
Hematuria	100	100
Proteinuria	80	92
Edema	90	75
Hypertension	60–80	83
Oliguria	10–50	58
Dyspnea, heart failure	<5	43
Nephrotic proteinuria	4	20
Azotemia	25–40	83
Early mortality	<1	25

From Rodriguez-Iturbe B. Acute endocapillary glomerulonephritis. In: Davison AM, Cameron JS, Grunfeld J-P, et al. *Oxford textbook of clinical nephrology*. Oxford, UK: Oxford University Press, 1998:613–623, with permission.

Edema and vascular congestion results from salt and water retention. Edema may be mild and confined to the periorbital area or severe with pleural effusion, ascites, and hypertension. Periorbital edema may be apparent in the morning, but as the day progresses, edema localizes in the abdomen or lower extremities. In younger children, edema is usually generalized, whereas in adolescents and adults, it is limited to the face and legs. Congestive heart failure may complicate the clinical course of the acute nephritic syndrome presenting with orthopnea, dyspnea, cough, pulmonary crackles, and gallop rhythm.

Hypertension is observed in more than 80% patients. It is volume dependent in addition to the increased peripheral vascular resistance; plasma volume and cardiac output are invariably elevated. Hypertension can be associated with headaches, somnolence, changes in mental status, anorexia, nausea, and convulsion. Some patients present with *hypertensive emergency*, which is defined as blood pressure greater than 30% of normal for age and sex or any elevation with evidence of encephalopathy, heart failure, or pulmonary edema. Central nervous system involvement during the course of APSGN may be secondary to hypertensive encephalopathy, but it can also be attributed to cerebral vasculitis. In normotensive children presenting with severe neurologic symptoms, magnetic resonance imaging may show multiple bilateral supratentorial lesions in the white and gray matter—a finding consistent with vasculitic infarct (64–66).

Other nonspecific symptoms include nausea, vomiting, malaise, anorexia, weakness, lumbar pain, and abdominal discomfort. Clinical manifestations of APSGN in children are summarized and compared to those seen in adults in Table 30.2 (4).

Diagnostic Evaluation

Diagnostic work-up includes identification of nephritic syndrome, antecedent streptococcal infection, serologic

markers of immune-mediated inflammation, and, when needed, renal histology.

Urine analysis reveals distorted, also termed *dysmorphic* or *crenated*, red blood cells and red blood cell casts indicative of glomerular hematuria (67,68). Proteinuria, usually moderate, reaches the nephrotic range in 5 to 10% of patients with APSGN. It lasts for approximately 6 months (69,70). Leukocyte, hyaline, and granular casts are also frequently seen (7). There is a transient elevation of blood urea nitrogen and serum creatinine due to a decreased GFR with normal or low renal plasma flow and markedly depressed filtration fraction. Tubular function is usually preserved or mildly reduced (3).

Recent streptococcal infection is confirmed by the demonstration of increased titers of antibodies against antigens of cell wall and extracellular products of group A streptococci. In clinical practice, repeated measurements of anti-streptolysin, anti-deoxyribonuclease B, antihyaluronidase, antistreptokinase, and anti-nicotinamide adenine dinucleotidase are used to demonstrate streptococcal infection. The antistreptolysin and anti-nicotinamide adenine dinucleotidase titers are elevated in 80% of patients with post-pharyngitis nephritis, whereas antihyaluronidase and anti-deoxyribonuclease B titers are elevated in 80 to 90% of patients after skin infections. Antibody titers are elevated 1 to 5 weeks after infections and return to their initial levels after several months (72). Antibiotic treatment may attenuate antibody response (73,74). IgG antibodies against the C region of streptococcal M protein have been claimed to be a more reliable diagnostic marker for APSGN because they remain significantly elevated long after the other streptococcal antibodies have normalized (21).

In patients with APSGN, the complement system is activated as assessed by measurement of the total hemolytic complement (CH 50), C3, and C4. More than 90% of APSGN patients have low levels of C3 and CH 50 and normal or mildly depressed C4 levels, indicating a preferential activation of the alternative pathways (4,71,75). In most cases, C3 returns to normal within 8 weeks, although a prolonged decrease of C3 has been reported (76).

Serum levels of IgG and IgM are elevated in 90% of patients (3). Circulating immune complexes can be detected in 58% of cases as compared to 4% in normal individuals (10), and 66% of patients have cryoglobulins (77). Serum IgG levels and glomerular IgG deposits are not directly correlated. A group of APSGN patients with elevated serum IgG was identified as being unable to form glomerular IgG deposits; in these cases, the severity of disease appeared to be independent of serum IgG levels (78). Increased circulating levels and urinary excretion of some cytokines during the acute phase of APSGN are found to be correlated with the clinical course (54,55). Of interest, antineutrophil cytoplasmic autoantibodies were detected in 9% of APSGN patients, and their presence was significantly associated with a more severe glomerular disease as assessed by serum creatinine and crescent formation (79).

Because APSGN has a self-limited course with a good prognosis, renal biopsy is rarely indicated. It should be considered, however, for patients with atypical history or presentation, including nephrotic-range proteinuria in the acute stage, normal serum complement, progressively increasing serum creatinine, prolonged hypocomplementemia for more than 3 months, ongoing macroscopic hematuria, or long-lasting proteinuria (73).

Considering differential diagnosis, Figure 30.4 gives a simplified diagnostic work-up. Determination of serum complement levels has a critical role in the initial evaluation of acute nephritic syndrome and may discriminate between diseases with low or normal complement levels (80).

Treatment

The acute nephritic syndrome is treated with restricted salt and fluid intake. When significant edema or hypertension is present, furosemide or other loop diuretics should be given to initiate prompt diuresis and to correct fluid overload, volume-dependent hypertension, and cardiovascular congestion. In some patients, hypertensive emergencies may occur and antihypertensive agents are needed. Initial management of severe hypertension includes calcium-channel blockers (e.g., IV nicardipine), IV labetalol or dihydralazine followed by maintenance antihypertensive therapy with loop diuretics, and calcium-channel blockers (e.g., nifedipine). Administration of angiotensin-converting enzyme inhibitors is not recommended because they can cause hyperkalemia.

Occasionally, pulmonary edema may develop, which needs aggressive diuretic treatment, oxygen, and morphine administration. Hyperkalemia can be controlled by restriction of potassium intake, administration of potassium-binding resin, and, in more severe cases, IV salbutamol. Dialysis is indicated in cases of persistent electrolyte abnormalities, fluid overload, or severe azotemia.

Streptococcal infection has usually resolved before presentation, but patients with positive throat or skin cultures or clinical evidence of streptococcal pharyngitis should receive antibiotic therapy (e.g., penicillin or erythromycin). Preventive antimicrobial treatment is also indicated for the immediate family members and for those individuals who are in close contact with the affected persons. The spread of infection can also be limited if personal hygiene measures are taken (2,4,81).

In a subset of patients with progressive clinical course or with histologic evidence of extensive crescent formation, aggressive treatment with pulse methylprednisolone, with or without cytotoxic drugs, should be considered (82,83). The beneficial effect of this therapeutic intervention has been suggested by case reports.

Prognosis and Clinical Outcome

APSGN in children is a benign disease with an early mortality rate of less than 1%. Most children undergo complete

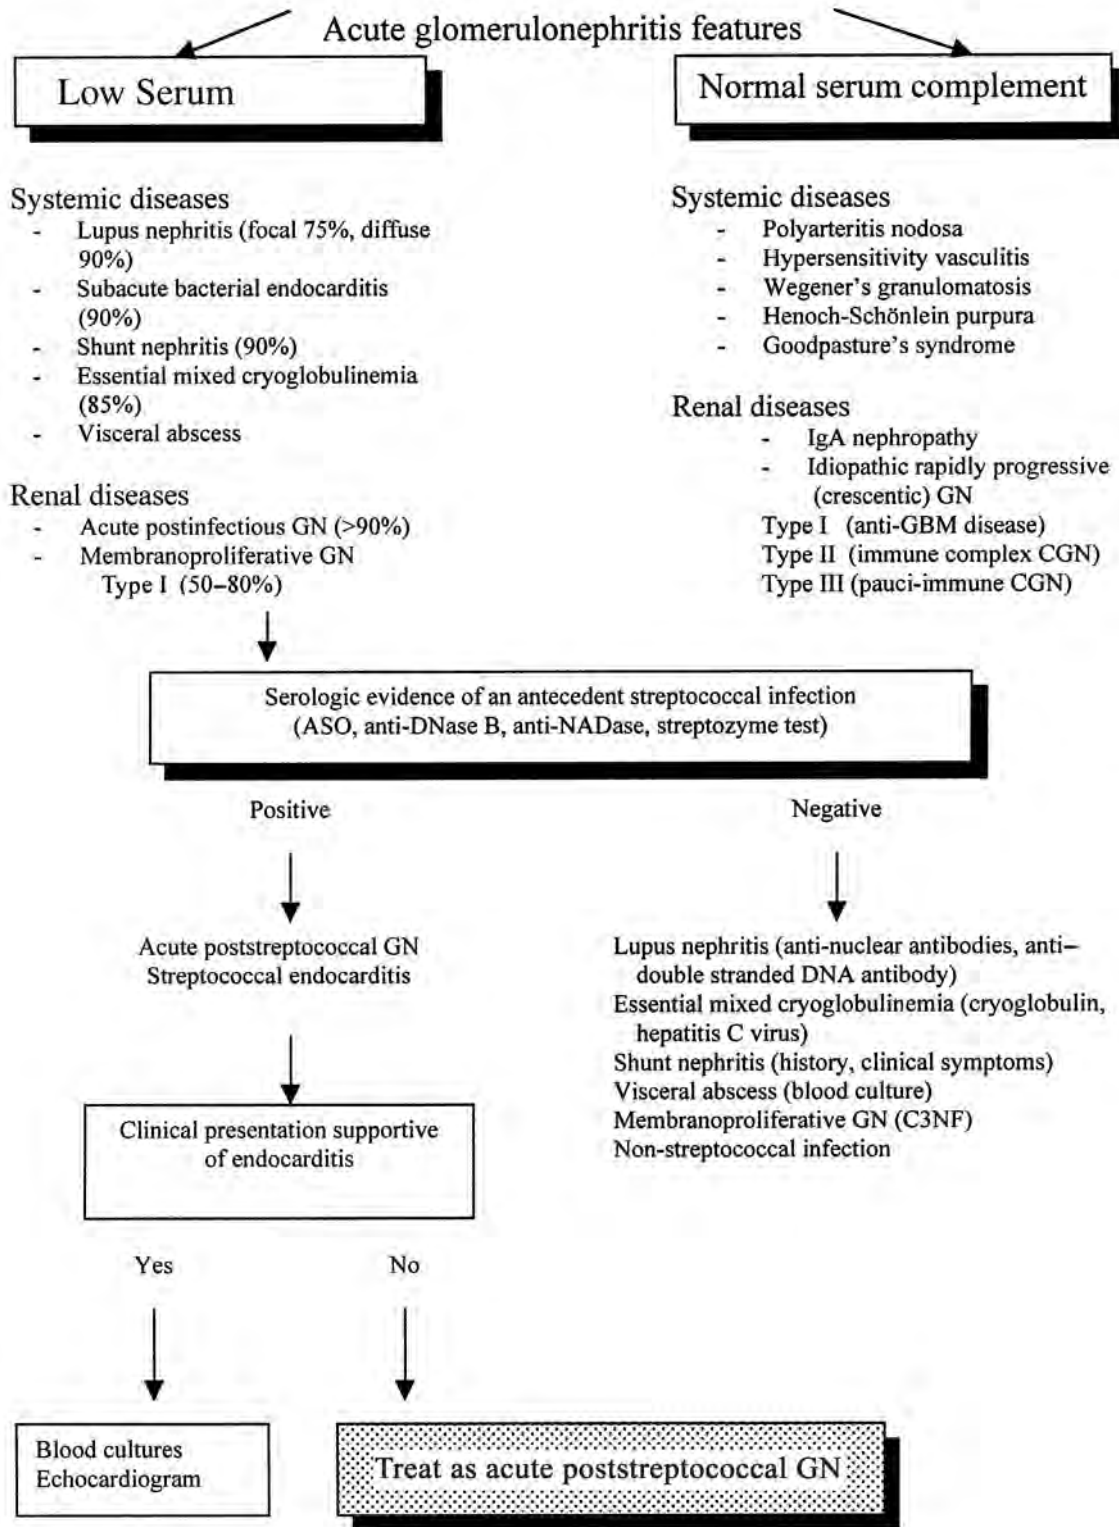

FIGURE 30.4. Diagnostic work-up and etiologic classification of acute glomerulonephritis. Number in parentheses indicates the frequency of low complement levels. CGN, crescent-forming glomerulonephritis; C3NF, C3 nephritis factor; GBM, glomerular basement membrane; GN, glomerulonephritis. (Adapted from Yoshizawa N. Acute glomerulonephritis. *Intern Med* 2000;39:687–694; and Lang MM, Fowers C. Identifying poststreptococcal glomerulonephritis. *Nurse Pract* 2001;34:37–47.)

remission; hypertension and gross hematuria usually resolve over several weeks, proteinuria may last for several months, and microscopic hematuria may persist for years. Less than 2% of the patients have been reported to progress to end-stage renal failure.

Attempts have been made to identify clinical features and morphologic markers that may serve as prognostic indicators. Nephrotic range proteinuria, persistent oliguria, and impaired renal function may have an adverse effect on clinical outcome. Similarly, morphologic changes (e.g., extensive crescent formation, atypical humps on electron microscopy, garland pattern on immunofluorescence or glomerular necroses, adhesions, thromboses, and sclerosis) have been found to be more often associated with poor prognosis (2,3). Follow-up studies have been undertaken to assess the long-term consequences of APSGN. The rate of morphologic healing increases steadily with the time elapsed from the clinical presentation of APSGN to the renal biopsy: 20% at 2 years after the onset of the disease, to 94% at 10 years after onset, and to 97% at 12 years after onset (84). There is a clear dissociation between histologic healing and clinical resolution. Despite the very low rate of histologic abnormalities, approximately 20% of the patients have persistent urine abnormalities or reduced GFR, and 8 to 13% have proteinuria and hypertension (4).

Healing, usually defined as the absence of persistent inflammation, does not exclude the fact that the reduced number of intact nephrons undergo hemodynamic changes over time, and the resulting hyperfiltration may cause further renal damage with urine abnormalities or hypertension. In fact, simultaneous measurements of GFR and effective renal plasma flow at the acute stage of the disease and at follow-up 2 to 12 years later revealed relative hyperperfusion of the kidney; the hypothesis has been put forward that in the remaining intact nephrons, significant damage may develop insidiously many years after apparent resolution of APSGN (85). This hypothesis appears to be supported by the observations that renal functional reserve, as assessed by acute protein loading test, is markedly reduced in patients who have recovered from APSGN (77,86).

APSGN is still considered a benign disease in children, with the vast majority of patients recovering without apparent long-term sequelae (87). It remains to be established whether the more severe clinical presentation and progression is related to older age or whether it may be attributed to specific *Streptococcus* strains.

Patients who have experienced APSGN have life-long protection against recurrence of the disease because of the intense immune response to nephritogenic streptococci (3). However, recurrent APSGN has been reported with an incidence of 0.7 to 7.0%. Occasional recurrence was attributed to the suppression of immune reaction due to early antibiotic therapy, although other mechanisms may also be implicated (88). NAPlr protein, a recently identified pathogenetic antigen in APSGN, is always detected in the glomerular mesangium and GBM in the early stage of the disease. Anti-NAPlr antibodies have been shown to be protective against a

second attack of APSGN in most patients. When the disease recurred, antibodies against NAPlr were not present in the sera, indicating that failure to induce this specific immune response may contribute to recurrence of APSGN (89).

IMMUNOGLOBULIN A NEPHROPATHY

NORISHIGE YOSHIKAWA

Immunoglobulin (Ig) A nephropathy was first described in 1968 by Berger and Hinglais (1) and is now recognized as a distinct clinicopathologic entity with a higher frequency worldwide than any other primary glomerulopathy (2). It was initially considered a benign condition, but extended follow-up of patients indicates that 20 to 50% of adults ultimately progress to end-stage renal failure (2,3). Likewise, the favorable prognosis initially attributed to children with IgA nephropathy must be questioned in the light of more recent studies (4–8).

EPIDEMIOLOGY

IgA nephropathy has been diagnosed all over the world, but its prevalence varies widely from one country to another. In the Pacific Rim (e.g., Japan, Singapore, Australia, and New Zealand), IgA nephropathy accounts for as many as one-half of cases of primary glomerulonephritis. In Europe, it accounts for between 20 and 30% of all primary glomerulonephritis, whereas in North America, it is responsible for only 2 to 10%. The explanation for this apparent variability in incidence is uncertain, but it may be due to a racial difference in the incidence of IgA nephropathy or to differences in biopsy selection practices (9).

Genetic factors and environmental influences could contribute to geographic differences in prevalence. A lower prevalence among blacks than whites has been reported in the United States. However, in American children, similar incidences of IgA nephropathy in white and black children from Shelby County, Tennessee, have been reported (10). In Australia (11), where the population is heterogeneous and includes many immigrants from Third World countries, all racial groups seem to be affected equally.

The high incidence of IgA nephropathy in certain countries may reflect the practice of routine urinalysis. In Japan, all children between the ages of 6 and 18 years are screened annually, and those found to have urinary abnormalities are referred for further investigation. Thus, IgA nephropathy is the most common primary glomerulopathy in children seen in Kobe University and Wakayama Medical University

Hospitals, detected in approximately 30% of biopsy specimens obtained.

ETIOLOGY

Because of the frequent association between upper respiratory tract or gastrointestinal infection and the onset of macroscopic hematuria, it has been suggested that certain viral or bacterial infections may lead to IgA nephropathy. Considerable effort has been directed toward the search for antigens and for the antibody specificity of the mesangial IgA, but it has met with limited success. Many antigens, including herpes simplex virus, cytomegalovirus, Epstein-Barr virus nuclear antigen, adenovirus, and milk antigen, have been identified. The observation of numerous antigenic substances in the glomeruli indicates that the antigenic materials in IgA nephropathy may be heterogeneous. The presence of *Haemophilus parainfluenzae* antigens in a diffuse and global distribution in the glomerular mesangium and the presence of IgA antibody against *H. parainfluenzae* in sera of Japanese patients with IgA nephropathy have been demonstrated (12,13).

Predisposing Genetic Factors

Predisposing genetic factors have been suggested as important in the development of IgA nephropathy (14). Moreover, it has been suggested that genetic factors may not only determine susceptibility to glomerulonephritis but also influence the pathologic severity and natural course of IgA nephropathy (15,16).

Evidence for genetic factors being important in IgA nephropathy is provided by family studies (15–19). Ram-bausek et al. reported that 9.6% of patients with mesangial IgA nephropathy in Germany had one or more siblings with glomerulonephritis (15). Julian et al. described kindred from eastern Kentucky in which six patients with IgA nephropathy descended from one ancestor and eight other patients belonged to potentially related pedigrees (17). Moreover, they indicated that at least 48 (60%) of 80 IgA

nephropathy patients who were born in same region were related to at least one other patient (18). Scolari et al. reported that 26 (14%) of 185 patients with IgA nephropathy investigated in Italy were related to at least one other patient with the disease (19). These family studies suggest that familial predisposition is a very common finding and genetic factors are influenced in the pathogenesis of IgA nephropathy. Recently, Gharavi et al. (20) demonstrated linkage of IgA nephropathy to 6q22-23 under a dominant model of transmission with incomplete penetrance.

Genetic factors are implicated in both disease susceptibility and disease progression (21). Polymorphisms of Ig heavy-chain switch region gene (22), I α 1 germ-line transcript regulatory region gene (23), genes of the renin angiotensin system (24,25), and platelet activating factor acetylhydrolase gene (26) have been reported. Although some associations have emerged, they have been inconsistent (27). Some of the discrepancies may be caused by different sample sizes and different geographic regions of the patients included in the studies.

PATHOGENESIS

Although the pathogenesis of IgA nephropathy remains uncertain, there is substantial evidence that it is an immune complex disease (2,28). Granular electron-dense deposits are observed in the glomerular mesangial areas by electron microscopy and confirmed as containing IgA and C3 by immunofluorescence microscopy. Circulating IgA immune complexes have been detected by several different assays often associated with IgG immune complex. Many immunologic abnormalities that may lead to the formation of IgA immune complex have been reported in patients with IgA nephropathy. Recurrence of IgA nephropathy frequently occurs in allografts (29), and a rapid disappearance of glomerular IgA deposits is observed when kidneys with mesangial IgA deposits are transplanted to patients without IgA nephropathy. Although much of this work was performed in adults, there is no evidence to suggest that the findings cannot be extrapolated to children. Moreover, glomerular IgA deposits associated with histologic lesions similar to those of human IgA nephropathy can be induced in laboratory animals by passive administration of preformed IgA immune complex or by active immunization (30–34).

Nature of Mesangial Immunoglobulin A Deposits

IgA contributes to immunity at the level of the external secretory system. IgA exists in monomeric and polymeric forms. Monomeric IgA represents approximately 90% of the serum IgA and is produced mainly by the circulating lymphocytes and plasma cells in the spleen and bone marrow. Polymeric IgA is produced mostly by lymphocytes and

plasma cells in the gastrointestinal and respiratory tracts, where it is synthesized as monomers and then secreted as dimers linked by the J-chain, which is also produced within the plasma cells. During the passage of dimeric IgA molecules through the mucosal epithelium toward the external lumen, the secretory component is attached through specific noncovalent interactions; this component appears to protect the dimeric IgA from the proteolytic enzymes present in the external secretions. IgA has two subclasses, IgA1 and IgA2. Approximately 90% of serum IgA is composed of IgA1 mostly produced in the bone marrow, whereas IgA2 is mostly derived from the local mucosa of the gastrointestinal and respiratory tracts. Both IgA1 and IgA2 are produced in the mucosa.

The most prominent finding in the glomeruli of renal biopsy specimens from patients with IgA nephropathy is mesangial IgA deposition. The majority of investigators has indicated that IgA1 is the predominant subclass present in the glomeruli (35). The J-chain has also been identified in the mesangium in patients with IgA nephropathy (36). Secretory component is not present in the mesangial deposits, but immunofluorescence studies of renal biopsy sections from patients with IgA nephropathy have indicated that it binds to the mesangial areas *in vitro* (37). These observations suggest that the mesangial IgA deposits are polymeric, a hypothesis further supported by the immunochemical characterization of IgA eluted from renal biopsy sections (38). Assessment of polymeric IgA1 production by *in situ* hybridization for J-chain messenger RNA in IgA plasma cells shows downregulation in the mucosa (39) and upregulation in the bone marrow (40). Impaired mucosal IgA responses allowing enhanced antigen challenge to the marrow shown by de Fijter et al. (41) could be the primary abnormality in IgA nephropathy, although this remains unproven (42).

A number of studies have suggested that the alternative complement pathway has a pathogenetic role in IgA nephropathy. This hypothesis is consistent with the typical immunohistologic demonstration of C3 and properdin in a pattern and distribution similar to that of IgA in the glomeruli, in the absence of C1q and C4. The detection of the membrane attack complex of complement further supports the pathogenetic role of complement activation in this disease (43). Certain types of IgA aggregates or IgA from patients with myeloma have been shown to activate complement *in vitro* (44). IgA has been reported to activate the complement system via the mannan-binding lectin pathway (45). However, there is no direct evidence that complement activation is mediated by IgA deposition in the glomeruli. Activation of C3 is observed in the majority of adult and pediatric patients with IgA nephropathy, but the mediator as well as the pathophysiologic significance of this complement activation remains to be determined. C3 is deposited in the kidney but is also produced by mesangial cells in IgA nephropathy (46).

With regard to antibody specificity, IgA eluted from cryostat sections of IgA nephropathy biopsies has been reported to react with mesangial areas of its own and other IgA nephropathy patients' biopsies, but not with normal kidney (47). Such eluates have also been shown to contain antibodies that react with tonsillar cells and cultured fibroblasts obtained from patients with IgA nephropathy (48).

In summary, the immunochemical nature of the mesangial deposits in IgA nephropathy is consistent with antigen-polymeric IgA complexes predominantly of A1 subclass and, perhaps, multispecific for ubiquitous mucosally derived antigens.

Immunoglobulin A Glycosylation

IgA glycosylation has received recent attention as a putative nonimmune feature of IgA, which may explain its abnormal behavior and glomerular deposition in IgA nephropathy (49). IgA1 subclass is prominent in IgA nephropathy. IgA1 is unique among all Igs in its possession of a hinge region rich in proline, serine, and threonine and characterized by five O-glycosylation sites (Fig. 31.1). These O-glycosylation sites consist of N-acetylgalactosamine O-linked to the serine residues of hinge region. Abnormal galactosylated IgA1 increases affinity for glomerular fibronectin, laminin, and collagen IV (50) and may lead to accumulation of IgA in the mesangium (51). Preliminary data indicate that deficient galactosylation of hinge-region glycans may be detected even in family members of patients with IgA nephropathy (52). Altered amino-acid sequence of the IgA1 hinge region is a possible mechanism to consider for abnormal galactosylation of IgA1. However, the hinge region is a highly conserved region of the IgA1 molecule. There is no evidence for any nucleotide sequence alteration or transcriptional abnormality of the hinge region in IgA nephropathy (53). It has also been postulated that altered galactosylated IgA1 in IgA nephropathy may be due to a

deficiency or structural modification of β 1,3-galactosyltransferase, the enzyme responsible for the terminal galactosylation of GalNAc on O-linked glycans (54). This structural or functional deficiency may be genetically determined. The recent sequence of β 1,3-galactosyltransferase may help us to understand the genetic basis of these abnormalities (55,56). Circulating IgA1 has reduced terminal galactose on O-linked hinge-region sugars in IgA nephropathy (57), apparently because of a B-cell defect in β 1,3-galactosyltransferase, the enzyme responsible for placing terminal galactose on O-linked sugars (58). The IgA1 O-glycan chains are truncated in IgA nephropathy (59). Circulating immune complexes in IgA nephropathy consist of IgA1 with a galactose-deficient hinge region, and the deficiency of galactose may result in the generation of antigenic determinants that are recognized by naturally occurring IgG and IgA1 antibodies (60). Sano et al. demonstrated that enzymatically deglycosylated human IgA1 molecules accumulate and induce inflammatory cell reaction (61); Amore et al. showed that glycosylation of circulating IgA modulates mesangial proliferation in IgA nephropathy (62).

Immunoglobulin A Immune System

There is a general agreement that serum levels of IgA are increased in 50 to 70% of patients with IgA nephropathy, with elevations in both monomeric and polymeric IgA. There is an increase in polymeric IgA1-producing plasma cells in the bone marrow (63) and in the tonsils (64) of patients with IgA nephropathy. The proportion of IgA- λ in serum IgA is also increased. Serum IgA is more anionic, owing to the increased anionicity of λ - compared with κ -light chain (65). The binding of IgA to mesangial cells is charge dependent, and anionic charge may play an important role in IgA1 deposition in the mesangium (66). In

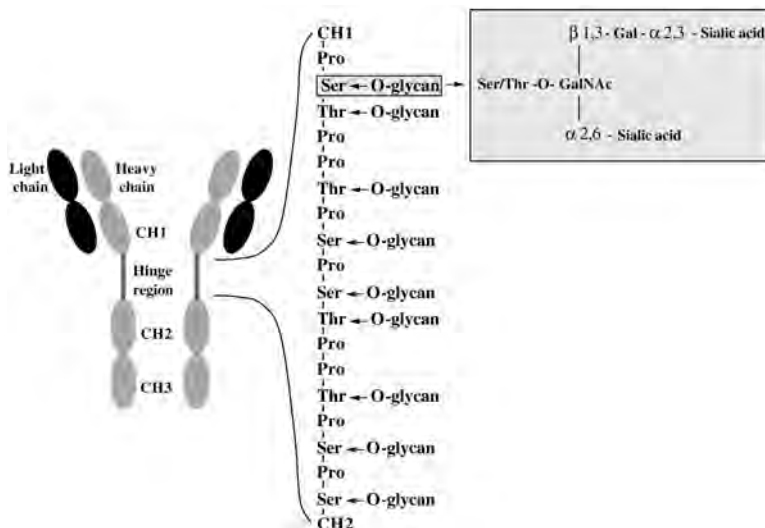

FIGURE 31.1. Immunoglobulin A1 (IgA1) molecule with hinge region O-glycosylation sites. IgA1 molecule with two heavy chains, each having three constant region domains, CH1 to CH3, and a hinge region between CH1 and CH2. Each serine (Ser) and threonine (Thr) residue is a potential site for O-glycan side chain. O-glycosylation sites consist of N-acetylgalactosamine (GalNAc) O-linked to the Ser or Thr residues of hinge region. Pro, proline.

addition to the increased levels of serum IgA, various types of autoantibodies of the IgA class have been recognized. These IgA autoantibodies include rheumatoid factor (67), antinuclear antibodies (68), and anticollagen antibodies (69). However, the IgA may be polyspecific, indicating a polyclonal increase rather than true antigen-specific autoantibodies (70). IgA immune complexes are frequently detected (71). Cultured peripheral blood lymphocytes from patients with the disease produce more IgA than do those of normal individuals, either spontaneously or after polyclonal stimulation *in vitro*. We also demonstrated an increased spontaneous and pokeweed mitogen-stimulated IgA production by peripheral blood lymphocytes in children with IgA nephropathy (72). This increased IgA production remained stable during the follow-up period in patients with persistent urinary abnormalities but decreased toward normal in patients with clinical remission.

IgA production is T-cell dependent, and the increased production in IgA nephropathy may indicate altered T-cell function. An increased circulating OKT4 to OKT8 cell ratio, due to increased OKT4 helper T lymphocytes and decreased OKT8 cytotoxic-suppressor T lymphocytes, has been reported in patients (73). Increased IgA-specific helper T-cell activity and decreased IgA-specific suppressor T-cell activity have also been reported (74,75).

Defective clearance of immune complexes from the circulation may also be important (76), but this seems more likely to be a consequence rather than the cause of the increased immune complex load.

Mechanism of Progression

IgA alone appears to be sufficient to provoke injury in susceptible individuals (77), and deposition of polymeric IgA, but not of monomeric IgA, can initiate glomerulonephritis (78). There is little to suggest that the mechanisms of mesangial proliferative glomerulonephritis, progression, and scarring are distinct in IgA nephropathy compared with other types of chronic glomerulonephritis. Studies *in vitro* and in animal models of mesangial proliferative glomerulonephritis have shown the key role of cytokines and growth factors, particularly platelet-derived growth factor and transforming growth factor β , in the induction and progression of mesangial injury, and there is evidence that these are also involved in IgA nephropathy (79–81). Studies in children with IgA nephropathy suggest that mesangial proliferation may in part be the result of local production of cytokines, interleukin-1, interleukin-6, tumor necrosis factor, platelet-derived growth factor, transforming growth factor β , vascular permeability factor, and endothelial growth factor (82–85). Although much has been learned about the basic abnormalities of IgA in IgA nephropathy, therapeutic interventions that may prevent glomerular IgA deposition or the subsequent inflammation and injury have to be found.

PATHOLOGY

Immunohistologic Findings

The diagnostic immunopathologic pattern of IgA nephropathy is the presence of IgA in the glomerular mesangium as the sole or predominant Ig. IgA deposits often extend just beyond the mesangiocapillary junctions into the adjacent capillary walls (Fig. 31.2). There are also deposits of IgG or IgM with the same staining pattern as IgA but with lesser intensity and frequency. In our series, mesangial IgA deposits were associated with IgG in 32% of patients, IgM in 8%, and both IgG and IgM in 11% (86). C3 deposits were observed in a similar distribution pattern in 64% of cases. The early components of the classical complement pathway, C4 or C1q, are absent. Fibrin- or fibrinogen-related antigens are found in a diffuse mesangial distribution in 25 to 70% of patients and are believed to be one of the injurious agents in the glomeruli (87). Although, in most patients, IgA is present only in the mesangial regions, in approximately 10% of patients it is also observed in the peripheral capillary walls. Such peripheral capillary wall deposits, whether documented by immunofluorescence or electron microscopy, have been associated with more severe clinical manifestations and a poor renal outcome (88–91).

Light Microscopic Findings

Various glomerular changes are observed. The most characteristic abnormality is mesangial enlargement, caused by various combinations of hypercellularity and increase in matrix (Fig. 31.3). Occasionally, small eosinophilic and PAS-positive fibrinoid mesangial deposits are also seen.

FIGURE 31.2. Immunofluorescence micrograph showing mesangial immunoglobulin A deposits in a patient with immunoglobulin A nephropathy.

FIGURE 31.3. Light micrograph showing mesangial proliferation in patients with immunoglobulin A nephropathy. Three types of mesangial changes are identified: **A:** Mesangial hypercellularity is more prominent than the increase in matrix. **B:** The degrees of mesangial hypercellularity and matrix increase are similar. **C1,C2:** The increase in matrix is more prominent than the mesangial cellularity.

Biopsies can be graded according to the amount of mesangial cell proliferation on the basis of the World Health Organization criteria (92).

1. Minimal glomerular lesions. The majority of glomeruli appears optically normal, although a few may show a slight increase of mesangial matrix, with or without accompanying hypercellularity. The number of mesangial cells per peripheral mesangial area does not exceed three. There are also small foci of tubular atrophy and interstitial lymphocyte infiltration in some patients.

2. Focal mesangial proliferation. Up to 80% of glomeruli show moderate or severe mesangial cell proliferation (i.e., more than three cells per peripheral mesangial area). The

degree of mesangial cell proliferation varies considerably among glomeruli as well as segmentally within individual glomeruli. The proliferation is usually associated with increased matrix. Small cellular or fibrocellular crescents are frequently found but rarely affect more than 20% of the glomeruli. Capsular adhesions are frequently seen overlying lobules showing mesangial proliferation. Segmental capillary collapse is often observed in association with crescents. A small number of glomeruli showing global sclerosis is often present. Tubular atrophy, interstitial fibrosis, and interstitial lymphocyte infiltration are frequently present but are not extensive.

3. Diffuse mesangial proliferation. More than 80% of glomeruli show moderate or severe mesangial cell prolifera-

tion, which varies in intensity in different regions of the mesangium in a given glomerulus as well as from one glomerulus to another. Mesangial cell proliferation is always accompanied by increased mesangial matrix. Cellular and fibrocellular crescents are often found, usually affecting less than 50% of the glomeruli, although in approximately 10% of patients, more than 50% are involved. Capsular adhesions are frequently seen in the absence of crescents. A small number of globally sclerosed glomeruli are often present. Tubular atrophy, interstitial fibrosis, and interstitial lymphocyte infiltration are frequently present and are extensive in 10% of patients.

Three types of mesangial changes are identified in children with IgA nephropathy (5) (Fig. 31.3): (a) Mesangial hypercellularity is more prominent than the increase in matrix, (b) the degrees of mesangial hypercellularity and matrix increase are similar, and (c) the increase in matrix is more prominent than the mesangial cellularity.

The first type of lesion is seen in biopsies in which the interval between onset of disease and biopsy is short. Serial pathologic observations reveal that prominent mesangial hypercellularity is almost exclusively seen in initial biopsies and disappears in follow-up biopsies. These observations suggest that predominant mesangial hypercellularity is characteristic of the early lesion of childhood IgA nephropathy and may disappear within a matter of months. An increase in mesangial cells, although sometimes present, is seldom striking in adult patients (93). In contrast, biopsies with a predominant matrix increase show a long interval between onset of disease and biopsy and a high percentage of glomerular sclerosis. Serial pathologic observations reveal that this type of change is usually seen in follow-up biopsies. An increase in the amount of mesangial matrix with duration of the disease has also been noted in adult patients (94). These findings suggest that progression of IgA nephropathy leads to gradual resolution of mesangial hypercellularity and an increase of matrix associated with the development of sclerosis (95).

The severity of tubulointerstitial changes usually reflects the severity of glomerular damage. Vascular lesions, such as arterial or arteriolar sclerosis, are reported to be common in adults (96) but are very unusual in children with IgA nephropathy (97). This difference may be related to the age at biopsy and the duration of disease before biopsy.

Electron Microscopy

Electron microscopic abnormalities are mainly observed in the mesangium, which is variably enlarged by a combination of increased cytoplasm and matrix. Electron-dense deposits in the mesangium are the most constant and prominent feature and are seen in almost all patients (Fig. 31.4). They are granular masses situated immediately beneath the lamina densa in the perimesangial region and expanded mesangium. The size and extent of mesangial deposits varies from patient

FIGURE 31.4. Electron micrograph showing numerous electron-dense deposits in the mesangium in a patient with immunoglobulin A nephropathy.

to patient; in some patients, they are large and produce localized protrusions. Peripheral glomerular capillary wall deposits are also found in the subendothelial and subepithelial regions. Subendothelial deposits occur most frequently in the capillary wall adjacent to the mesangium, although they are also observed in the peripheral part of the loop. Subepithelial deposits are reported to be unusual in adult patients but are frequently found in children with IgA nephropathy. They are generally small and flat and localized to a few capillary loops; the humps typical of acute poststreptococcal glomerulonephritis are never observed. Lysis of the glomerular basement membrane is also seen quite frequently in children (98). In affected areas of the glomerular capillary walls, the lamina densa is thin and irregular, and the epithelial aspect of the glomerular basement membrane shows irregular segments of low electron density with an expanded, washed-out appearance. The epithelial foot processes are generally well preserved, but diffuse foot process effacement may be seen in patients with the nephrotic syndrome.

Repeat Renal Biopsy Findings

There have been only a few reports on the results of repeat renal biopsies (99,100). We previously reported our results in children with IgA nephropathy (6). At the time of the second biopsy, 23 patients had shown *clinical remission*, defined as complete disappearance of proteinuria and hematuria with normal renal function, whereas 38 had persistent urinary abnormalities with normal renal function. There were no differences between the two groups with regard to the initial clinical findings and the pathologic findings in the initial biopsy. The second biopsy in patients who were in clinical remission showed improvement of the glomerular lesions on light microscopy, a disappearance of or a decrease in mesangial IgA deposits, and a decreased amount of electron-dense deposits. Conversely, light microscopy showed a progression of histologic lesions and the persistence of both

mesangial IgA deposits and electron-dense deposits in patients with persistent urinary abnormalities. Clinical remission and histologic regression have been reported in adults with IgA nephropathy (101).

CLINICAL FEATURES

IgA nephropathy occurs at all ages but is most common during the second and third decades of life; it affects boys more often than girls, with the reported male to female ratio varying from less than 2:1 to 6:1 (2). In a study of Japanese children (86), the mean age at presentation was 9.3 years in boys and 10.3 years in girls, and the male to female ratio was 3:2. The clinical presentation of IgA nephropathy varies. Some patients have asymptomatic microscopic hematuria with or without proteinuria. Other patients have recurrent episodes of macroscopic hematuria. Some patients present with acute nephritic syndrome and, more rarely, with acute renal failure.

Sixty-two percent of our 258 Japanese children were found to have microscopic hematuria or asymptomatic proteinuria (86). Twenty-six percent presented with macroscopic hematuria and 12% with an acute nephritic syndrome or nephrotic syndrome. Several studies from Europe and the United States reported that more than 80% of the patients have episodes of macroscopic hematuria, and recurrent macroscopic hematuria is traditionally regarded as the hallmark of childhood IgA nephropathy (102–105). However, it was the initial feature in only 26% of our series, presumably because of the school screening program that detected a high prevalence of asymptomatic urinary abnormalities rather than regional variation in the expression of IgA nephropathy. During the observation period, 60% of our patients had one or more episodes of macroscopic hematuria, whereas the other 40% remained asymptomatic.

Macroscopic hematuria often occurs in association with upper respiratory tract infections; less frequently, it occurs in association with other infections involving the mucosal system (e.g., diarrhea and sinusitis). Episodes of macroscopic hematuria are sometimes associated with loin pain. The interval between the precipitating infection and the appearance of hematuria ranges from 1 to 2 days compared with 1 or 2 weeks in acute postinfectious glomerulonephritis. Many patients have recurrent episodes of macroscopic hematuria—each often associated with the same type of infection. The number of recurrences and the intervals between different episodes are variable. The incidence of macroscopic hematuria is lower in adults (105,106).

Patients with a nephritic or nephrotic onset have the most severe glomerular damage. The most common presenting symptom is macroscopic hematuria. Hypertension is infrequent and usually mild to moderate. Nephrotic edema is reported in approximately 10% of patients. Acute renal failure is occasionally associated with episodes of macroscopic

hematuria and is usually reversible. However, a number of investigators have documented a subset of patients with IgA nephropathy that is characterized by extensive crescents and a rapidly progressive course (107–109).

LABORATORY INVESTIGATIONS

Serum IgA levels are increased in 30 to 50% of adult patients but in only 8 to 16% in children with IgA nephropathy (86). For this reason, it is seldom of diagnostic significance. Serum complement component concentrations are usually normal, but the C3 level should be measured routinely if the patient has been referred for investigation after the first attack of hematuria to eliminate a diagnosis of postinfectious glomerulonephritis or membranoproliferative glomerulonephritis. Likewise, the antistreptococcal antibody titers should be determined after initial hematuria. The serum creatinine should be measured routinely to estimate renal function; if necessary, the glomerular filtration rate should be determined. If present, proteinuria should be quantified, as proteinuria is associated with histologic lesions and a risk of progression. The plasma proteins should be measured routinely in the presence of heavy proteinuria.

DIFFERENTIAL DIAGNOSIS

The diagnosis of IgA nephropathy is based on the presence of IgA as the sole or predominant Ig in the glomerular mesangium. Because diffuse mesangial IgA deposits are observed in a variety of other disorders (Table 31.1), the diagnosis of IgA nephropathy can be made only by exclusion.

Relationship between Immunoglobulin A Nephropathy and Henoch-Schönlein Purpura

There is a close relationship between IgA nephropathy and Henoch-Schönlein purpura (110). The morphologic and immunopathologic features are similar in the two conditions (110,111), which are characterized by various degrees of focal or diffuse mesangial proliferation, the diffuse deposition of IgA in the mesangium, and electron-dense deposits in the mesangium. Elevated serum IgA levels are found in both IgA nephropathy and Henoch-Schönlein purpura nephritis, and IgA-containing circulating immune complexes have been demonstrated in both conditions. Infective episodes precede Henoch-Schönlein purpura nephritis in 30 to 50% of patients, and the presence of *H. parainfluenzae* antigens in a diffuse and global distribution in the glomerular mesangium and the presence of IgA antibody against *H. parainfluenzae* in sera of Japanese children with Henoch-Schönlein purpura nephritis have also been demonstrated (13). The two disorders have been reported to coexist in different members of

TABLE 31.1. DISEASES ASSOCIATED WITH DIFFUSE MESANGIAL IMMUNOGLOBULIN A (IgA) DEPOSITS

Mixed cryoglobulinemia
Polycythemia
Scleritis

the same family, including a pair of monozygotic twins who developed the disorders simultaneously after a well-documented adenovirus infection (112–115). Moreover, the evolution of IgA nephropathy into Henoch-Schönlein purpura nephritis in the same patient is described in both adults and children (116–118). It has been suggested that the two conditions are variants of the same process and that IgA nephropathy is Henoch-Schönlein purpura nephritis without the rash. Although there are similarities in their pathologic and immunologic features, the two conditions are clinically different, and the pathogenesis is not clear. Our study suggests that Henoch-Schönlein purpura nephritis is an acute disease, with glomerular lesions nonprogressive after the onset (119). Therefore, in most patients, the prognosis is associated with the severity of glomerular change at the onset. In contrast, IgA nephropathy is a chronic, slowly progressive glomerular lesion, which may eventually lead to chronic renal failure, whatever the presentation. A few patients with Henoch-Schönlein purpura nephritis have recurrent episodes of macroscopic hematuria and a progressive renal disease on repeat renal biopsies. Finally, Henoch-Schönlein purpura nephritis occurs mostly in young children and is rare in adulthood, whereas IgA nephropathy affects mainly older children and younger adults.

Chronic Liver Disease

Glomerular IgA deposits may be observed in patients with various types of chronic liver diseases (120–122). Mesangial

proliferation and IgA deposits are the most common findings. Most patients with chronic liver disease have clinically asymptomatic renal disease. The pathogenetic mechanisms that contribute to mesangial IgA deposition in chronic liver diseases remain unknown. Significant elevations of the serum monomeric and polymeric IgA levels have been reported. Impaired hepatic clearance and increased synthesis of polymeric IgA, abnormalities of IgA metabolism, and portosystemic shunting of antigens and immune complexes have been suggested as possible causes of mesangial IgA deposition (123).

Idiopathic Nephrotic Syndrome

A few patients with steroid-sensitive nephrotic syndrome show mesangial deposits of IgA on renal biopsy. They are classified by some as IgA nephropathy, whereas others consider that mesangial IgA in patients with minimal changes (i.e., without cellular proliferation) is coincidental. This probably applies to idiopathic nephrotic syndrome associated with mesangial IgA deposits occurring in Asians and explains a favorable response to steroids, which is not the case in true IgA nephropathy (124).

NATURAL HISTORY AND PROGNOSIS

In adult series, the incidence of renal insufficiency varies from less than 10% to as high as 45% in patients followed for more than 1 year. In long-term follow-up of adult patients, 30 to 35% have been found to develop progressive renal insufficiency 20 years after the initial discovery of disease (2,125–127). It can be estimated that 1 to 2% of adult patients will enter end-stage renal failure each year from time of diagnosis (128). The long-term prognosis of the 169 Japanese children with IgA nephropathy who were followed for more than 10 years indicates that 9% of the patients had developed chronic renal failure by 15 years (Fig. 31.5).

FIGURE 31.5. Long-term prognosis of the 169 Japanese children with immunoglobulin A nephropathy who were followed for more than 10 years.

Because of the variable rate of progression to chronic renal failure, there have been attempts to identify features present at the time of diagnosis that would predict the ultimate outcome. The following clinical findings are regarded as poor prognostic indicators in adult patients (2): persistent hypertension, persistent heavy proteinuria, and reduced glomerular filtration rate at presentation (125–127,129–134). In children, several studies have shown that the degree of proteinuria correlates with the severity of morphologic glomerular lesion (104,135–137) and heavy proteinuria at the time of biopsy predicts a poor outcome (91,138). In contrast, slight proteinuria or its absence at the time of biopsy predicts a favorable outcome. There is general agreement that hypertension and low glomerular filtration rate at presentation are significant factors in determining the outcome of adult patients with IgA nephropathy. In children, acute renal failure at onset is usually transient and associated with macroscopic hematuria and reversible tubular lesions. Male gender has also been considered an unfavorable prognostic feature by some investigators (126), but we (91) and others (89) could not confirm it in a large cohort of adult and pediatric patients. Schena et al. reported an increased risk of end-stage renal disease in familial IgA nephropathy (139).

Several pathologic features are associated with a poor outcome: diffuse mesangial proliferation; a high proportion of glomeruli showing sclerosis, crescents, or capsular adhesions; the presence of moderate or severe tubulointerstitial changes; the presence of subepithelial electron-dense deposits; and lysis of the glomerular basement membrane by electron microscopy (91). Patients with diffuse mesangial proliferation have been reported to have a significantly worse prognosis than those with focal proliferation or minimal lesions by light microscopy in adults (125,130,140). In many adult studies (89,125,133,141), glomerular sclerosis and crescents have also been associated with poor renal outcome. Levy and associates found that mesangial proliferative glomerulonephritis with crescents was associated with poor prognosis in children (135). Because the severity of the tubulointerstitial changes usually corresponds with the severity of the glomerular changes, tubulointerstitial changes in IgA nephropathy are believed to be secondary to the glomerular injury. Vascular lesions, such as arterial or arteriolar sclerosis, have been reported to play an important role in the progression of IgA nephropathy in adults. However, vascular changes are very unusual in children (5,105,108). This difference may be related to the age at biopsy and the duration of disease before biopsy.

TREATMENT

IgA nephropathy is a leading cause of chronic renal disease and end-stage renal disease in adult patients, and recent

long-term studies assessing the prognosis in children have challenged earlier views that the condition represents a benign disorder. Thus, IgA nephropathy presents a therapeutic challenge in both adults and children. Because of the variable rate of progression to renal failure, and because of the probable multifactorial pathogenesis of the disease, the effectiveness of any treatment can only be properly evaluated by means of a randomized controlled trial (142). When considering treatment protocols, an issue of great importance is the selection of appropriate patients in whom the treatment is to be evaluated. Patients with heavy proteinuria at biopsy and the most severe glomerular lesions on renal biopsy appear to be at greatest risk of progressive renal deterioration and, therefore, the most appropriate candidates for specific therapeutic interventions. Patients with long-standing disease and extensive, irreversible glomerular damage are unsuitable for such treatments.

Controlled double-blind trials in adult patients with IgA nephropathy (143–145) showed that treatment with fish oil for 2 years retarded the rate at which renal function was lost, but a meta-analysis showed that there was only a 75% probability that fish oil was beneficial (146). Recent studies have indicated that angiotensin-converting enzyme inhibitors reduce urinary protein excretion and preserve renal function in adult patients with IgA nephropathy (147,148), but there is no randomized controlled study demonstrating that angiotensin-converting enzyme inhibitors preserve renal function in IgA nephropathy. High-dose intravenous methylprednisolone was shown to delay development of renal failure in a randomized controlled trial in adult patients (149). However, no convincing evidence has been published to date to support the use of fish oil, angiotensin-converting enzyme inhibitors, or high-dose intravenous methylprednisolone for the treatment of children with IgA nephropathy; at present, there is no curative therapy for IgA nephropathy (150).

Our recent controlled trial by the Japanese Pediatric IgA Nephropathy Treatment Study Group demonstrated that treatment of children with severe IgA nephropathy with prednisolone, azathioprine, heparin-warfarin, and dipyridamole for 2 years early in the course of disease prevents immunologic renal injury and progression of the disease (151). Seventy-eight children with newly diagnosed IgA nephropathy showing diffuse mesangial proliferation were randomly assigned to receive either the combined therapy of prednisolone, azathioprine, heparin-warfarin, and dipyridamole for 2 years (group 1) or the combination of heparin-warfarin and dipyridamole for 2 years (group 2). Urinary protein excretion was significantly reduced in group 1 patients but remained unchanged in group 2 patients. Serum IgA concentration was also significantly reduced in group 1 patients but was unchanged in group 2 patients. Blood pressure and creatinine clearance were normal at the end of the trial in all but one group 2 patient who developed chronic renal insufficiency. The percentage of glomeruli showing sclerosis was unchanged in group 1

patients but significantly increased in group 2 patients. The intensity of mesangial IgA deposits significantly decreased in group 1 patients but remained unchanged in group 2 patients. The beneficial effects of prednisolone, azathioprine, heparin-warfarin, and dipyridamole treatment were accompanied by relatively few serious side effects specifically attributable to the drugs.

Progression of IgA nephropathy leads to gradual resolution of mesangial hypercellularity and an increase of matrix and is associated with the development of sclerosis (5). The majority of patients with IgA nephropathy in our series are diagnosed early in the course of the disease, and the asymptomatic period before the discovery of urinary abnormalities is short. Patients with long-standing disease and extensive glomerulosclerosis are unsuitable for treatment. In our controlled trial, the average interval between onset and discovery of disease and start of treatment was 11 months, and no patient showed predominant matrix increase or extensive glomerulosclerosis. Early diagnosis and early treatment are very important in IgA nephropathy.

Recurrence of mesangial IgA deposits is often observed in transplant recipients whose original disease was IgA nephropathy (29,152). Clinically, such recurrences are mild or even asymptomatic; despite this risk of recurrent glomerulonephritis, graft survival in patients with IgA nephropathy is considered good (29).

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

C. FREDERIC STRIFE
MICHAEL C. BRAUN
CLARK D. WEST

Membranoproliferative glomerulonephritis (MPGN) is characterized on histology by glomerular hypercellularity, increased mesangial matrix, thickening of the peripheral capillary walls, and a splitting of the glomerular basement membranes (GBMs) due to mesangial interposition in the capillary walls. The term *MPGN* was originally used by Habib et al. (1) in 1961 to describe the glomeruli in a group of patients with chronic nephritis. In 1965, this appearance was associated with hypocomplementemia (2). In 1973, a second chronic nephritis, originally called *dense deposit disease* by Berger and Galle (3), was classified as a variant of MPGN (4) and later designated *MPGN type II*. The more common type, in which subendothelial deposits predominate, was designated *type I*. The term *mesangiocapillary glomerulonephritis* has been used interchangeably with *membranoproliferative glomerulonephritis*. A nephritis morphologically similar to type I found in patients with chronic antigenemia or malignancies makes necessary the additional classification of secondary as opposed to idiopathic MPGN (Table 32.1). In the 1970s, several observers using silver-impregnated electron micrographs described a third type of MPGN with ultrastructural features distinct from MPGN types I or II (5–7). In MPGN type III, complex alterations of the GBM are revealed by the silver stain, together with deposits that are subendothelial and subepithelial as well as within the GBM. Although certain aspects of MPGN types I and III are similar, the clinical and morphologic differences between the two make their separation feasible. Because this distinction is not universally accepted, this chapter considers MPGN types I and III together, whereas type II is discussed separately.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS TYPES I AND III

Epidemiology and Genetics

The incidence of MPGN is difficult to ascertain; however, it is roughly estimated that there are one to two cases per

10⁶ pediatric patients (8). In most series, MPGN type I has been found to be the most common form (Table 32.2). In those studies that distinguished MPGN type I and type III, the relative frequency of type III ranges from 14 to 37% (9–12) (Table 32.2). In our experience, type III is at least as common as type I (11). MPGN types I and III usually present in older children or adolescents. Occasionally, they have been observed in patients older than 30 years or younger than 5 years. The prevalence of MPGN type I has decreased in most series from 15 to 20% of primary glomerulonephritides in the 1970s to less than 5%.

Support for a genetic susceptibility for both MPGN types I and III was provided by the observation that an extended haplotype, B8,DR3,SC01,GLO2 is significantly more frequent in patients with these two types than in the general white population (13). Also, patients with MPGN types I and III have a similarly high frequency of inherited complement deficiencies (14). Finally, there are a number of reports of familial clustering of MPGN type I (15–19). Reports of familial type III are rare (20). Recently, however, an Irish family with eight affected members in four generations was reported. Significant evidence for linkage was observed on chromosome 1q31-32 (21).

Presentation and Clinical Manifestations

The presentation of MPGN generally falls into three categories: nephrotic syndrome, acute nephritic syndrome, or asymptomatic hematuria and proteinuria discovered by chance (Table 32.3). The specific MPGN type cannot be distinguished by the presenting clinical features because of extensive overlap (22).

Nephrotic Syndrome

Edema as the presenting symptom is present in approximately one-third of patients with either MPGN type I or

TABLE 32.1. CLASSIFICATION OF MEMBRANO-PROLIFERATIVE GLOMERULONEPHRITIS (MPGN)

MPGN type I
Primary or idiopathic
Secondary/chronic infections
Bacterial: endocarditis, visceral abscesses, infected ventricular shunts, osteomyelitis
Viral: hepatitis B and C, human immunodeficiency virus
Protozoal: malaria, schistosomiasis
Other: mycoplasma, fungal
Immunologic (autoimmune) diseases
Systemic lupus erythematosus glomerulonephritis
Chronic active hepatitis
Paraprotein deposition diseases
Cryoglobulinemia
Light chain disease
Neoplastic
Leukemia or lymphoma
Neuroblastoma
MPGN type II
Idiopathic
Associated with partial lipodystrophy
MPGN type III
Idiopathic

III (Table 32.3). These patients have significant proteinuria and usually microscopic hematuria with red cell and granular casts. Serum concentrations of albumin and immunoglobulin (Ig) G are typically low, and approximately 70 to 80% have a low serum C3 level. In the absence of effective treatment, a nephrotic syndrome is strongly associated with a poor prognosis.

Acute Nephritic Syndrome

Gross hematuria with an acute nephritic syndrome is the presenting feature in approximately 25% of patients with MPGN. Mild hypoalbuminemia is common. Although renal function is usually normal, a rare patient may have a rapidly progressive course. Such patients usually have a low serum level of C3, making distinction from acute poststreptococcal glomerulonephritis difficult. A biopsy is often not performed until it is apparent that the return of C3 concen-

Acute infection before presentation	33	26

^aPatients may present with more than one clinical feature.

tration to a normal level is not occurring, as is typical for resolving acute poststreptococcal glomerulonephritis.

Asymptomatic Microhematuria and Proteinuria

The diagnosis of MPGN is made in approximately 50% of patients because of the chance discovery of hematuria and proteinuria in the otherwise healthy child. This presentation is most common in MPGN type III patients (22). Renal function and serum albumin levels are usually normal.

Associated Clinical Features

Braun et al. (11) observed that glomerular filtration rate estimated from serum creatinine is lower at presentation in patients with MPGN type I when compared to those with MPGN type III. They speculated that the relatively greater glomerular proliferation in MPGN type I is likely related to the lower glomerular filtration rate. The higher frequency of hypertension at presentation in patients with MPGN type I may also relate to the greater degree of glomerular proliferation. Encephalopathy due to hypertension is rare at presentation but has been reported during follow-up in both treated and untreated patients (10). Antecedent constitutional complaints, including fatigue, lassitude, and weight loss, characterize the onset in approximately 25% of patients with MPGN type I but are not observed in those with MPGN type III (22). Table 32.3 lists these clinical features.

Laboratory Abnormalities

An occasional patient, especially with MPGN type I, has a normochromic, normocytic anemia out of proportion to the degree of renal insufficiency. However, the distinctive feature of the three MPGN types is hypocomplementemia (Fig. 32.1), caused in many by the presence of autoantibodies, called *nephritic factors* (NFs), directed at epitopes on comple-

FIGURE 32.1. Activation of either the classical or alternative complement pathways produces activated C3, C3b, which can form fluid-phase or solid-phase C3b,Bb (convertase). Normally, both fluid-phase and solid-phase C3b,Bb are rapidly inactivated by complement control proteins. Both can be stabilized by the nephritic factor (see Fig. 32.2). C3b,Bb stabilized on a solid phase can activate C5 and form the membrane attack complex, C5b-9. (Courtesy of John Bissler, M.D.)

ment proteins (Fig. 32.2). The serum C3 concentration is low in nearly 80% at their initial evaluation. In all, three mechanisms are believed to be responsible for the hypocomplementemia: circulating immune complexes activating the classical complement pathway, NFs that interfere with the

FIGURE 32.2. Fluid-phase activation of C3 in membranoproliferative glomerulonephritis (MPGN). In MPGN type II, the convertase stabilized by nephritic factor-a (NF_a) activates only C3. The convertase produced in type I by immune complexes and the nephritic factor complex produced in type III can form a C3,C5 convertase that activates both C3 and terminal components. This results in low C3 levels in type II, low C3 and C5 levels in type I, and low C3,C5, and terminal component levels in type III. On a solid phase such as the renal glomerulus, it is possible that in type I, a C3,C5 convertase is deposited and nephritogenesis is the result. Solid-phase events that are nephritogenic in types II and III are not clear. NF_t, nephritic factor of the terminal pathway; P, properdin. (Courtesy of John Bissler, M.D.)

normal control of the complement cascade, and inhibition of C3 synthesis mediated by circulating C3 breakdown products. A rare patient with hypocomplementemia as a result of a defect in the regulatory proteins of the complement system has an MPGN-like glomerulonephritis (23).

Of patients with MPGN type I, approximately 40% of those with a low serum C3 level have in addition a low serum level of C4, suggesting classical complement pathway activation (Fig. 32.2) (22). A few also have low serum levels of C1q and C2, but these complement components may be low as a result of heavy proteinuria (24).

The complement perturbation in MPGN type III is distinct from that in both types I and II; C4 levels are typically normal, and severely hypocomplementemic patients (C3 less than or equal to 30 mg/dL) commonly have depressed levels of C5 and properdin and of one or more of the other terminal components, C6, C7, and C9 (25–27). Depression of the latter components is seen in only 10% of those with type I and is not seen in type II. The NF in MPGN type III is presumably responsible for the low levels of terminal components (Fig. 32.2). Known as the *NF of the terminal pathway* (NF_t), it differs from that found in type II in that *in vitro* it converts C3 slowly with maximum conversion in 4 hours rather than 30 minutes. The conversion is properdin dependent and activates terminal components (28). It is believed to stabilize a convertase with the composition (C3b,Bb)_n,P,NF_t. It is composed of properdin (P) and several convertase (C3b,Bb) complexes, which serve to activate C5.

Pathology

Glomeruli in MPGN type I by light microscopy (Fig. 32.3) usually have a uniform increase in cellularity due to an influx of leukocytes and mesangial proliferation. The mesangial proliferation causes glomerular enlargement and marked reduction in the number of open capillary lumens. With silver stain, capillary walls may show a double contour called *tram-tracking*. This is the result of new basement membrane formation at the site of mesangial interposition. With progression, the mesangial proliferation may become replaced by centrolobular hyalinization, giving the glomeruli a progressively more lobular appearance. In MPGN type III, the degree of mesangial proliferation is typically less in comparison to type I and often focal in distribution (Fig. 32.3). Glomerular size is usually normal. Double contoured capillary walls are rare, due to less mesangial interposition. These differences, however, cannot reliably distinguish MPGN type I from type III by light microscopy.

Immunofluorescent microscopy (29) usually can distinguish type I from types II or III (Table 32.4) in that C4 is usually present in type I; C3, C4, and IgG colocalize on the periphery of the glomerular lobules, the so-called fringe pattern (Fig. 32.4). In MPGN type III, C3 deposition is typically in a mesangial and capillary loop pattern, C4 is

FIGURE 32.3. Light microscopic appearance of membranoproliferative glomerulonephritis (MPGN) types I and II. **A:** The glomerulus is enlarged, very cellular, and has a lobulated appearance. The mesangium is markedly expanded. The capillary walls are thickened in appearance, and, frequently, the capillary lumens are obscured by the mesangial expansion. In addition to the increase in mesangial cells, scattered neutrophils are also identified in many of the segments. **B:** The type III glomerulus is less cellular in appearance, and there is less expansion of the mesangium. Most of the capillary loops are patent; however, thickened capillary walls are evident. (Courtesy of Dr. David Witte.) (See Color Plate 32.3.)

rarely present, and IgG is present in small amounts in approximately 50% of cases (22).

Ultrastructural studies are essential to distinguish MPGN type I from type III (Table 32.5). In MPGN type I, uranyl-lead–stained micrographs typically demonstrate a completely intact GBM without breaks or laminations (Fig. 32.5). There is prominent mesangial proliferation with extension of the mesangium at least partially around the glomerular capillaries (interposition), which, with the subendothelial deposits, causes narrowing of the capillary lumen.

In MPGN type III, uranyl-lead stains typically demonstrate a complex thickening and irregularity of the GBM. However, the type III lesion—characterized by a discontinuous fragmented, laminated appearance of the GBM (Table 32.5)—is best seen with methenamine silver stains (Fig. 32.5). The distribution of deposits in this lesion has been shown to vary according to the C3 level at the time of the biopsy (Table 32.5).

Pathogenesis

Idiopathic MPGN type I is presumed to be secondary to circulating immune complexes composed of IgG (antibody)–unknown antigen–C3, which deposit in the subendothelial glomerular space, giving rise to a response that

includes marked mesangial proliferation. Evidence for this hypothesis is based on the observation that indistinguishable renal pathology is present in glomerulonephritis secondary to identified infectious, oncogenic, and other antigens (Table 32.1). In addition, the pattern of complement activation is via the classical complement pathway in at least 40% of patients, favoring the presence of circulating immune complexes.

Little is known regarding the pathogenesis of MPGN type III. Normal serum C4 levels and the absence C4 in glomeruli suggest that immune complex formation does not play a major pathogenic role. West and associates have

reported a strong association between hypocomplementemia and the presence of paramesangial and subendothelial deposits (30,31). Subendothelial deposits, in particular, were never found in patients normocomplementemic at biopsy (Table 32.5). They suggest that NF_c may play a significant role in the development and perpetuation of the ultrastructural changes that define MPGN type III. Although this is a provocative and intriguing hypothesis, these findings must clearly be reconciled with other reports that have failed to demonstrate any relationship between the presence of NF, the duration or severity of hypocomplementemia, and either renal survival or disease progression in MPGN type III (11,32).

Natural History

The natural history of MPGN was described in detail by Cameron et al. (33) in a report comparing the long-term outcome of 69 children and adults with MPGN type I (type III, presumably, was included in this group) to 35 with type II (Fig. 32.6). The outcome was poor irrespective of type, with 50% losing renal function by 10 years and 90% by 20 years. Similar results have been observed by Habib et al. (4). Cameron et al. (33) noted that MPGN type I progressed more slowly in children than in adults during the first 10 years of follow-up. There are no reports that compare the courses of MPGN types I and III in the absence of effective treatment. Outcome has been shown to be adversely affected by the presence of nephrotic syndrome or renal insufficiency at onset and by the presence of crescents in the initial biopsy.

Treatment

The effectiveness of treatment regimens for MPGN has to be judged by the outcome of usually uncontrolled, retrospective observations on small numbers of patients. In several series, the basic regimen has been supplemented in some patients by other treatment modalities. Despite these shortcomings, some consensus has emerged.

Steroids

The treatment regimens that appear to improve outcome in patients with MPGN types I and III have used steroids. The Cincinnati group (11,34–36) has used high-dose (2 mg/kg to a maximum of 80 mg) alternate-day prednisone

TABLE 32.5. DIFFERENCES IN GLOMERULAR ULTRASTRUCTURE IN TYPE I AND TYPE III MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS AS VIEWED IN URANYL-LEAD- AND METHENAMINE-SILVER-STAINED PREPARATIONS

	Type I	Type III
Uranyl-lead staining		
Basement membrane	<i>Intact</i>	Thickened areas with patchy dense deposits
Methenamine-silver staining		
Basement membrane	<i>Intact</i>	<i>Type III lesion^a present with both ↓ [C3] and nl [C3]</i>
Uranyl-lead and methenamine-silver staining		
Subendothelial deposits	<i>Always present with ↓ [C3] Present in 50% with nl [C3]</i>	<i>Present in 50% with ↓ [C3] Never present with nl [C3]</i>
Subepithelial paramesangial deposits	<i>Very rare; never with nl [C3]; in ~12% with ↓ [C3]</i>	<i>Present with ↓ [C3] and in those with nl [C3] if level has been low in past year</i>
Subepithelial loop deposits	Frequent, accompany subendothelial deposits	May be present; not clearly related to [C3]

↓ [C3], serum C3 level low at time of biopsy; nl [C3], serum C3 level normal at the time of biopsy.

Note: Correlations of deposits with serum C3 levels are taken from references (3) and (31). Italics indicate key features differentiating types I and III. ^aType III lesion is a complex lesion of the GBM that appears to originate from several generations of subepithelial and subendothelial deposits forming in conjunction with multiple interruptions of the lamina densa such that the deposits are partially confluent. Lesions develop a complex laminated appearance because each generation of deposit is covered by new lamina densa-like material.

From Braun MC, West CD, Strife CF. Differences between membranoproliferative glomerulonephritis types I and III in long-term response to an alternate-day prednisone regimen. *Am J Kidney Dis* 1999;34:1022–1032, with permission.

FIGURE 32.5. Ultrastructural features of membranoproliferative glomerulonephritis types I and II. **A:** An electron photomicrograph of a glomerulus with membranoproliferative glomerulonephritis type I. Note the prominent mesangial proliferation and deposits in the mesangium. The capillary walls are thickened due to extensive interposition (*arrow*) in addition to prominent sub-endothelial deposits (*asterisk*). In this silver-stained preparation, the lamina densa can be clearly identified and is generally intact. **B:** The glomerulus with the type III lesion also shows by silver stain extensive mesangial proliferation and deposits. The capillary walls show extensive disruptions of the lamina densa, with deposits that are subepithelial and subendothelial and, at times, completely obscure the lamina densa. (Courtesy of Dr. David Witte.)

for a minimum of 2 years. Dose reduction thereafter is based on improvement of clinical parameters (e.g., urinalysis, serum albumin, serum C3 level) and glomerular morphology (e.g., degree of mesangial proliferation, number of open capillary lumens). In the long term, prednisone dose is slowly reduced if there is no evidence of disease reactivation (e.g., increase in proteinuria or hematuria or decrease in serum C3 level). Because many, if not most, patients continue with at least some degree of proteinuria as a result of chronic glomerular damage, loss of microhematuria appears to be the best clinical indicator of disease remission (35). Most patients have continued on alternate-day steroids for at least 5 years and many for much longer periods.

Reports of outcome with this regimen have been encouraging but continue to be difficult to interpret because of small patient numbers, retrospective analysis of data, lack of a control group, and use in some patients of adjunctive therapies. Kidney survival at 10 years was 84% and, at 20 years, was 54%. In the most recent report (11) using the same alternate-day prednisone regimen, renal survival was 80% at 10 years in those with type I and 70% in those with type III. In addition to a lower renal survival, those with type III had, at 10 years, a significantly greater fre-

quency of proteinuria and hematuria and a lower glomerular filtration rate.

Based on early reports of improved outcome with alternate-day prednisone, the International Study of Kidney Disease in Children sponsored a randomized, double-blind, placebo-controlled 5-year trial of alternate-day prednisone, 40 mg/m² versus placebo in 80 children with MPGN and heavy proteinuria (10). The study included 42 patients with MPGN type I and 17 with type III. Treatment failure was defined as an increase in serum creatinine of either greater than or equal to 30% over baseline or greater than 0.4 mg/dL. Outcome analysis evaluating patients with MPGN types I and III as a group showed that at last follow-up (mean 5.25 years), 33% of patients treated with prednisone and 58% in the placebo group were treatment failures ($p = .07$). The results favored treatment with prednisone.

Similar results were obtained by Mota-Hernandez et al. (37), who treated eight MPGN type I patients with alternate-day prednisone and ten with placebo. After an average follow-up of 6 years, treated patients had stable or improved renal function, whereas four of ten placebo-treated patients had progressed to end-stage renal disease.

FIGURE 32.6. Comparison of renal survival between adults and children. (From Cameron JS, Turner DR, Heaton J, et al. Idiopathic mesangiocapillary glomerulonephritis. Comparison of types I and II in children and adults and long-term prognosis. *Am J Med* 1983;74:175–192, with permission.)

Additional uncontrolled reports have favored the use of alternate-day prednisone (9,38–40). The observation that, in the absence of treatment, the disease in patients not nephrotic at presentation progresses more slowly (4,33) has led to the recommendation that steroids be withheld in these patients (41) or used in a low dose (39,40). However, others have shown significantly better outcomes in patients treated with prednisone early in the course of the disease regardless of severity (9,35).

Long-term follow-up data on patients with MPGN type III have recently been published by a number of centers (11,12,42). The data should be viewed with caution, as less than 50% of the patients initially studied were available for long-term follow-up, and the numbers of patients studied were small. The report by Iitaka et al. (42) is by far the most promising, with 100% renal survival after 16 years of follow-up. However, it is uncertain if the universally good outcome was due to early identification and aggressive therapy or to an unknown factor that moderates the course of the disease in the Japanese population. Finally, the outcome reported by Braun et al. (11) and by Schwartz et al. (12) is less encouraging, with 70% renal survival at 10 years and 50% renal survival at 15 years, respectively.

Other Therapies

Other controlled prospective therapy trials have shown no long-term benefits with the antiplatelet agent dipyridamole (43) or with cyclophosphamide, warfarin, and dipy-

ridamole (44). Uncontrolled reports have suggested no or limited benefit from treatment with other cytotoxic agents, antimalarials, or anticoagulants.

Disease Recurrence in Renal Transplant Recipients

The rate of recurrence in type I MPGN ranges between 20 and 30% (48). Patients with recurrence may remain asymptomatic or develop proteinuria or hematuria. Hypocomplementemia is inconstant. According to Briganti et al., the incidence of graft loss at 10 years due to recurrence is 15% (49). No therapy has been proven to be effective. The role of cyclosporine is uncertain, as some authors have found that the rate of recurrence had decreased from 30 to 10% after the introduction of cyclosporine, whereas other authors did not find any changes. Case reports have suggested that graft survival may be improved by the addition of cyclophosphamide to immunosuppressive drugs (45,50). There are two case reports of recurrent MPGN type III in adult cadaveric renal transplant patients (46,47).

MPGN TYPE II (DENSE DEPOSIT DISEASE)

Epidemiology and Genetics

MPGN type II is the least frequent of the three types (Table 32.2). It constitutes 19 to 34% of the cases in whites and 5% in Japanese. There is no evidence for a genetic basis for the disease. We have two families in which one of a pair of identical twins has the disease, and a similar family has been reported (51). Onset is most often in childhood.

Presentation and Clinical Manifestations

Symptoms and signs at presentation can include hematuria, proteinuria, hypertension, and edema. Hematuria is always present; in those with gross hematuria, the onset is that of an acute nephritic syndrome. Presentation with a nephrotic syndrome is common and has been associated with a poor prognosis (52,53). Even before onset of renal failure, hypertension can develop, but hypertensive encephalopathy is rarely a presenting event.

The clinical course is characterized by a nephrotic syndrome that persists or develops and increasingly severe hypertension (52,54,55). Occasionally, patients present with renal failure and have a rapidly progressive course (54,56). Conversely, a few may have periods after onset when their nephritis is silent (54); their urinary abnormalities completely disappear and only hypocomplementemia remains. Signs of nephritis may return, often associated with intercurrent infection, and persist.

There is increasing evidence that MPGN type II is a systemic disease. First, partial lipodystrophy and hypocomplementemia may be present for a considerable period before

signs of glomerulonephritis appear (57). Second, renal transplants in almost every case quickly develop dense deposits in the GBM, often in the absence of manifestations of glomerulonephritis (58). Third, dense deposits similar to those in the GBM develop in the basement membranes of the sinusoids of the spleen (59) and in Bruch's membrane in the choriocapillaris of the eye (60). The eye lesion is associated with drusen, which resemble those seen in adults with macular degeneration. It is of interest that these spleen and eye membranes, like the GBM, are unique in that they are bathed in plasma.

Laboratory Abnormalities

Distinctive features of the disease are the complement profile and the frequent presence of NF (Fig. 32.2). The profile is characterized by levels of C3, which may be markedly depressed with normal or near normal levels of other components (25). Thus, the depressed properdin and C5 levels seen in the other types of MPGN, in acute glomerulonephritis, and in the nephritis of systemic lupus are not present. The depressed C3 is produced by activation of native C3 by the alternative pathway convertase, C3b,Bb, which has been stabilized by the NF of the amplification loop, NF_a (Fig. 32.2). The stabilized convertase, C3b,Bb, NF_a, has a half-life more than 15 times that of the native convertase (61). The inactivated C3 it forms is quickly inactivated by factors H and I and is subsequently degraded to the ultimate C3 breakdown products, C3c and C3dg. All three of these derivatives may be found in the circulation (62–64). Contributing heavily to the hypocomplementemia is an inhibition of C3 synthesis attributed to a negative feedback produced by the circulating C3 breakdown products (65,66).

Pathology

In most cases, by light microscopy, the glomeruli are uniformly hypercellular with increased mesangial matrix, and the number of open capillary lumens is commensurately reduced. In contrast to MPGN type I, the proliferation is rarely great enough to increase glomerular size. The diagnosis of type II can occasionally be made by light microscopy of silver-stained preparations; the basement membrane is thickened, and at sites of the intramembranous deposits, argyrophilia is lost. The dense deposits may also be visualized by light microscopy by their ability to stain with thioflavin T (67). Deposits are located along the GBM, the Bowman's capsule, and the tubular basement membrane. By immunofluorescence, IgG, IgA, IgM, and C4 are rarely found in glomerular deposits, indicating that the classical pathway of complement is not activated.

C3 deposits are abundant. Kim et al. (68) found C3 to be present along the margin but not within the central portion of the dense deposits in the GBM, giving a double lin-

FIGURE 32.7. Ultrastructural features of membranoproliferative glomerulonephritis type II. In this electron photomicrograph of a uranyl-lead acetate-stained preparation, the lamina densa can be seen to be expanded by accumulation of electron-dense material (*arrow*), which has a fusiform configuration. In addition to the dense deposit material, there are also large, discrete subepithelial deposits (*asterisk*) located in the paramesangial region. (Courtesy of Dr. David Witte.)

ear appearance (railroad tracks). They also observed C3 deposits within the mesangium outlining circular structures that represent shed fragments of the basement membrane (mesangial rings). The railroad tracks are visualized with labeled anti-C3c and -C3d, indicating that they are composed of C3b, iC3b, and C3dg, whereas the paramesangial deposits stain only with anti-C3c, indicating that they are formed from C3c deposited from the circulation (69).

The diagnostic intramembranous deposits are best seen by electron microscopy of uranyl-lead-stained specimens (Fig. 32.7). They usually occupy only the lamina densa but occasionally may be present only in the lamina interna (70). The deposits may be discontinuous. Similar deposits may also be found in Bowman's capsule and in the basement membranes of isolated groups of tubules. If searched for, subepithelial deposits can be found on the parts of the basement membrane that overlay the mesangium (paramesangial) if the patient was biopsied when hypocomplementemic (71). Occasionally, hump-like subepithelial deposits are present on the capillary loops.

Pathogenesis

The pathogenesis of the disease is not known. Many investigators find that the actual measurement of NF or of its surrogate, hypocomplementemia, does not show a straightforward correlation with activity of the disease. A few, however, have found a correlation between absence of hypocomplementemia or of NF and a benign course (72,73). Evidence that NF is more than an epiphenomenon is the observation that patients with several uncommon conditions—one of which is homozygous deficiency of factor H—are like those with MPGN type II in that they have convertase circulating in

abnormally high concentration and have an unusual frequency of glomerulonephritis. How circulating convertase produces the nephritis is not clear (74).

It has been proposed that in consonance with the frequent association of deficiency of complement components with nephritis, the deficiency of C3 produced by NF is *per se* in some way nephritogenic. Another proposal is that it is an immune complex disease with the complexes generated by a subclinical infection, which in turn is a consequence of the hypocomplementemia. The absence of signs of classical pathway activation makes this concept unlikely.

Support for a role of complement in the pathogenesis of MPGN is provided by the observation that not only humans homozygous for deficiency in factor H can develop nephritis (23), but also that this deficiency in pigs (75) and mice (76) produces a lethal nephritis resembling MPGN type II. In mice, deposition of C3 and C9 antedating the deposition of IgG indicated that immune complexes do not initiate the glomerular injury. The disease was shown to be complement dependent in that glomerular damage can be prevented by the back-crossing of factor H-deficient mice with mice deficient in factor B, thus preventing convertase formation.

A possible link between NF and partial lipodystrophy is based on the fact that adipocytes are the only source of factor D, the enzyme that activates the convertase precursor, C3b,B, to form the alternative pathway convertase, C3b,Bb. NF has been shown to lyse adipocytes *in vitro*, and it is postulated that in certain individuals, the combination of NF and factor D in high concentrations fosters adipocyte destruction leading to partial lipodystrophy (77). This explanation requires that generation of NF antedate the onset of lipodystrophy.

Natural Course

In the absence of effective treatment, 50% renal survival after diagnosis is, in most series, 9 years. Survival is definitely shortened in patients presenting with a nephrotic syndrome. In one series, 10% of the patients went into remission.

Treatment

Because of the infrequency of the disease, a large experience with a single therapy has not been reported. Antiplatelet, anticoagulant, and immunosuppressive drugs have been used usually in combination with corticosteroids, but there is no evidence that such regimens are effective. Although not used in a clinical trial or in a large series, high-dose alternate-day prednisone is currently the most widely used treatment. We find that this regimen is not consistently effective and its effectiveness unpredictable. Of 14 patients who have received this regimen in this clinic, the disease in 5 is in remission. Serial renal biopsies have shown improvement in these patients to the extent that the dense deposit in the GBM is partially or completely lost (78).

Disease Recurrence in Renal Transplant Recipients

The rate of recurrence of dense deposits after renal transplantation is high, ranging from 50 to 100% in various series (83). Only a fraction of patients with recurrence develop proteinuria and, sometimes, nephrotic syndrome. A number of investigators have correlated disease recurrence with persistent or recurrent hypocomplementemia (58,80,84), whereas others could find no correlation with either low C3 levels or the presence of NF (81,85). The North American Pediatric Renal Transplant Cooperative Study group analyzed the 2-year kidney transplant survival and found an increased rate of graft loss for patients with MPGN type II; 45% were lost to disease recurrence. In published reports, graft loss due to recurrent MPGN type II varies widely from 0 to 100% (52,79,80–82).

MEMBRANOUS NEPHROPATHY

SUDESH PAUL MAKKER

Membranous nephropathy (MN) is a chronic glomerular disease with distinct histopathologic features. The term *membranous glomerulitis* was first used by Bell in 1938, reporting a light microscopy study of autopsied kidneys from patients with nephrotic syndrome (NS) (1). In a subgroup whose glomeruli had no proliferation, he noted that some had essentially normal glomeruli, whereas others had diffuse thickening of the glomerular basement membrane (GBM). The latter cases were termed *membranous glomerulitis*. It is interesting to note that two of them were children. Later, Bell noted that the GBM had a vacuolated appearance (2).

In 1957, Jones introduced the periodic acid–silver methenamine stain to study kidney tissue of patients with NS and observed that the GBM in membranous glomerulitis had a peculiar appearance, with the thickened GBM resolving into a thinner membrane from which protruded many silver-positive projections (3). Between the projections, a silver-negative hyaline material was present in the form of droplets. Jones' description is now widely accepted as the pathognomic feature of MN, and his stain is routinely used in the processing of renal biopsy specimens. At approximately the same time, Movat and McGregor first used electron microscopy, and Mellors et al. used immunofluorescence microscopy in the study of this disease and further elucidated the ultrastructural and immunohistologic features of MN (4,5).

The characteristic histopathologic features of MN are (a) lack of proliferation in the glomerulus and a diffusely thickened glomerular capillary wall exhibiting silver-positive projections, or so-called spikes, with silver methenamine stain under light microscopy; (b) fine granular staining for immunoglobulin (Ig) G and complement along the periphery of the glomerular capillary wall on immunofluorescence microscopy; and (c) electron-dense deposits located exclusively in the subepithelial position along the GBM on electron microscopy.

Although the term *membranous glomerulitis* was used commonly in earlier medical literature, *membranous nephropathy* is now the preferred term. *MN* is a histopathologic term used to describe a unique glomerular lesion and is not itself a clinical entity.

PATHOLOGY

Light Microscopy

Under light microscopy, the glomeruli are normal in size or slightly enlarged. Their cellularity appears normal, and there is no infiltration with inflammatory cells or proliferation of mesangial or endothelial cells. The epithelial cells may be normal or enlarged and prominent (Fig. 33.1). In most patients, no epithelial cell crescents are present, but occasionally such crescents are seen in association with a clinical picture of rapidly progressive glomerulonephritis. The mesangial matrix is not increased, and the glomerular tufts do not show excessive lobulation. The capillary loops are usually patent but may be occluded in advanced cases. The predominant change in MN is in the glomerular capillary walls, which show varying grades of diffuse thickening involving all capillary loops and all glomeruli. The thickened capillary wall is best visualized in the periodic acid–methenamine silver stained sections in which the GBM itself is stained black, and the subepithelial deposits in the GBM are not stained. Because of their location in the subepithelial space, these unstained deposits are surrounded by black-staining newly synthesized GBM that appears as small black spikes projecting from the GBM toward the urinary space (Fig. 33.2). In tangentially cut sections, it may give a vacuolated appearance. In the advanced stages, the subepithelial deposits are incorporated into the GBM, giving it a chain-like appearance. As the lesion progresses, the capillary walls increase in thickness, their lumen is occluded, and eventually the glomeruli become sclerosed.

In the early stages, the tubules, vessels, and interstitium are normal. As the disease advances, there is progressive tubular atrophy, accumulation of mononuclear cell infiltrate, and increasing interstitial fibrosis, and the kidney eventually develops the appearance of end-stage kidney disease (6,7).

Immunofluorescence Microscopy

With immunofluorescence microscopy, all cases of MN show bright, fine to coarse granular staining for IgG along the glomerular capillary wall (Fig. 33.3). Using monoclonal

FIGURE 33.1. Early membranous nephropathy with mild diffuse thickening of capillary loop membranes (*arrowhead*) (hematoxylin and eosin stain, $\times 100$). (Courtesy of Dr. John A. Wolfe, Sutter Hospitals, Sacramento, CA.)

antibodies against human IgG subclasses, it appears that the predominant IgG staining in the granules is for IgG4 (13). No staining for IgG is seen in the mesangium in idiopathic MN; if present, it should arouse the suspicion of systemic lupus erythematosus (SLE) as the underlying cause. The staining for IgA and IgM is variable and not intense and is in the same location as IgG. Staining for complement C3 is similar in character and distribution to that for IgG and is usually, but not always, of similar intensity. Staining for C1q and C4 is seen, but the intensity is much less than that for C3, and intense staining for C1q should arouse suspicion of SLE. Recently, staining for membrane attack component of complement C5b-9 has been noted in a similar location to that of IgG (14,15). Staining for fibrin is also commonly present.

FIGURE 33.2. Membranous nephropathy, silver stain showing formation of spikes (*single arrowheads*) and a moth-eaten appearance with multiple small holes in the basement membranes when cut *en face* (*double arrowhead*) (Jones silver stain, approximately $\times 160$). (Courtesy of Dr. John A. Wolfe, Sutter Hospitals, Sacramento, CA.)

FIGURE 33.3. Membranous nephropathy, immunofluorescent study showing the typical brightly stained granular immune-complex deposits along the entire glomerular basement membrane (anti-immunoglobulin G, approximately $\times 100$). (Courtesy of Dr. John A. Wolfe, Sutter Hospitals, Sacramento, CA.)

Electron Microscopy

The electron microscopy findings in MN are characteristic. The hallmark is the presence of electron-dense deposits, located exclusively in the subepithelial space along the capillary wall and corresponding to the granular IgG deposits seen on immunofluorescence microscopy (Fig. 33.4). No electron-dense deposits are seen in the subendothelial space or in the mesangium, and the mesangial cellularity is normal. An occasional mesangial deposit should arouse suspicion of MN associated with SLE. Four morphologic stages of MN are recognized:

FIGURE 33.4. Electron micrograph showing the portion of glomerular peripheral capillary membrane with multiple, fairly evenly spaced, electron-dense immune-complex deposits located on the subepithelial side of the basement membrane (*arrowheads*). There is very early deposition of basement membrane between these deposits. Notice the loss of normal epithelial cell foot process architecture (*double arrowheads*) ($\times 9700$). (Courtesy of Dr. Richard R. Wilber, and Dr. John A. Wolfe, Sutter Hospitals, Sacramento, CA.)

1. In stage I, the GBM is normal in thickness and appearance. The electron-dense deposits are small to moderate in size but discrete. The smaller deposits are generally located at the site of the slit diaphragm. Moderate-size deposits cover a greater area of the subepithelial space, adjacent to where the foot processes of the visceral glomerular epithelial cells are usually fused.
2. In stage II, the deposits are numerous, larger, and confluent. Projections of GBM, corresponding to the spikes seen on light microscopy staining black with silver stains, are seen between the deposits. The GBM itself is generally not thickened.
3. In stage III, the deposits are larger and surrounded by the projections of GBM. The density of the deposits is decreased, and the GBM appears irregularly thickened.
4. In stage IV, the deposits have been incorporated into GBM and have become electron lucent and, thus, are sometimes difficult to differentiate from the surrounding GBM. The GBM is now severely altered and irregularly thickened.

Stage II is the most common type of lesion (10,11,16,17), whereas stages III and IV are considered as showing resolution. Because MN is a chronic disease, probably involving continuous or multiple generations of deposit formation, different stages of the lesion in a patient may be seen at any given time, as reported by Habib et al. in the largest series of children with MN (10). There is insufficient information in children to determine the correlation between the different histologic stages and the clinical manifestation or course of the disease (9,12,16).

CLASSIFICATION

MN in children may be divided into two categories based on cause: (a) idiopathic or primary; and (b) secondary, in which MN develops in association with another condition, such as SLE, or the patient has been exposed to certain infectious agents or drugs (Table 33.1) (8,18–39).

Compared with adults, a greater percentage of cases of MN in children are secondary (19). In the largest series, 43% had an associated condition (8,19). In several parts of the world—particularly Southeast Asia (20,21), Japan (40), Africa (41–43), and certain parts of Europe (44–46)—hepatitis B is a significant factor in the etiology of MN. Other infections, such as congenital syphilis (22,23), malaria (24), and filariasis (25), are also of etiologic significance in those areas where they are prevalent. Whether certain host factors predispose people to the development of MN in such infected children is unclear. Medications and neoplasms are rare causes of MN in children compared with adults (8,19).

The cause of the idiopathic type of MN is unknown, but several observations suggest immune dysregulation:

TABLE 33.1. CLASSIFICATION OF MEMBRANOUS GLOMERULONEPHROPATHY IN CHILDREN

Idiopathic or primary
Associated with other conditions—secondary
Infections
Hepatitis B (8,18–21) ^a
Congenital syphilis (22,23) ^a
Malaria? (24)
Filariasis (25)
Immunologic or autoimmune diseases
Systemic lupus erythematosus (8,12,18,19) ^a
Enteropathy (27)
Crohn's disease (28, 29)
Pemphigus (30)
Drugs
o-Penicillamine (8,17) ^a
Neoplastic
Ovarian tumor (33)
Neuroblastoma (34)
Gonadoblastoma (35)
Wilms' tumor? (36)
Miscellaneous
<i>De novo</i> occurrence in renal transplant (37) ^a
Fanconi's syndrome (8,26)
Sickle cell disease (8)
Diabetes mellitus? (38)
Associated with antitubular basement membrane (8,26) and antialveolar basement membrane antibodies (38)
Thrombocytopenia (8) and microangiopathic anemia (39)
Juvenile cirrhosis or alpha-1 antitrypsin deficiency (40)

^aAccounts for majority of the cases.

1. The development of MN in certain patients (both children and adults) with SLE.
2. The development of MN in other autoimmune disorders [e.g., insulin-dependent diabetes mellitus in children (38) (S. P. Makker, *unpublished observation*, 1980) and adults (47), children with autoimmune enteropathy (27), Crohn's disease (28,29), multiple sclerosis (31) or pemphigus (29), adults with Graves' disease (6,48), primary biliary cirrhosis (6,49), Sjögren's syndrome (6), rheumatoid arthritis (6), Hashimoto's thyroiditis (6), dermatitis herpetiformis (6), and ankylosing spondylitis (6)].
3. MN can occur in association with the development of autoantibodies to other renal antigens [i.e., tubular basement membrane in children (26) and GBM in adults (50)].
4. An autoimmune MN indistinguishable from idiopathic MN in humans can be produced in rats by immunization with rat tubular antigens (Heymann nephritis).
5. Mercury is known to produce immune dysregulation and autoimmunity including MN in certain strains of rats (51), and mercury exposure in adult patients can also produce MN (6).

Genetic factors are also important in idiopathic MN. Strong associations of HLA-DR3 (52,53) and DQA1 allele

(54) have been reported with idiopathic MN in adults. MN has been reported in two HLA identical brothers (both children) (55) and, in another instance, in a father and son with HLA-DR3 (56). Based on the aforementioned observations, it may be hypothesized that idiopathic MN in humans is an autoimmune disease occurring in certain genetically predisposed individuals and precipitated by unknown exogenous or endogenous events.

IDIOPATHIC MEMBRANOUS NEPHROPATHY

Prevalence

Idiopathic MN may be discovered during evaluation of asymptomatic proteinuria or NS (8,19,57). Because all children with asymptomatic proteinuria do not come to the attention of physicians, and because renal biopsies are not performed on all patients with asymptomatic proteinuria or even those with NS, the exact prevalence of MN in children is unknown. In the International Study of Kidney Disease in Children, idiopathic MN was found in only 4 of 400 children with NS (58). The rarity of idiopathic MN as a cause of NS in children is supported by our experience and by others who have found that only 2 to 6% of those children with NS who are studied by renal biopsy have idiopathic MN (8,10,16,17,59). In contrast, idiopathic MN is a common glomerular disease in adults; it is responsible for 25 to 40% of cases of idiopathic NS (60,61).

Pathogenesis

The pathogenesis of idiopathic MN is unknown. Based on immunofluorescence and ultrastructural findings, it is clearly an immunologically mediated disease. The granular deposits containing IgG, which correspond to the subepithelial ultrastructural electron-dense deposits, are believed to represent antigen-antibody complexes. The antigen(s) in the deposits and the process by which they form, enlarge, and partially resolve are not known. Whether the antigen is exogenous or endogenous, renal or nonrenal, or the same or different in various cases of MN is also unclear. Based on studies of Heymann nephritis in the rat, both the active (62) and passive (63,64) types, it is possible that the deposits in idiopathic human MN, like the deposits of Heymann nephritis, are formed *in situ* after binding of an autoantibody to a glomerular antigen; a large (600-kDa) glycoprotein variously named as gp600/gp330/megalin (65,66) presents on the surface of the glomerular epithelial cell (67) (see Chapter 39). Recently, the pathogenic region on gp600/gp330/megalin has been localized to a small area in the N-terminal of this protein (68). Two case reports, one in a child (69) and another in an adult (70), and recent data (71,72) in a small number of patients support this concept of pathogenesis. An interesting case supporting the concept that MN can develop in a human by the binding of anti-

bodies against at least one expressed podocyte protein, neutral endopeptidase, was reported recently (73). In this case, antibodies against neutral endopeptidase produced by a mother who herself had a deficiency of this protein were transferred to her fetus, producing a MN in the newborn. The mother apparently had been immunized against this protein during an earlier pregnancy.

Also, based on the studies in Heymann nephritis, it appears that (a) the subepithelial immune deposits come to lie in this unique position after capping and shedding of the antigen-antibody complexes formed *in situ* on the surface of the glomerular epithelial cell (74); and (b) after immune-deposit formation complement activation ensues, resulting in the generation of the terminal membrane attack component (C5b-9), which may be an important mediator of the resulting proteinuria (75,76). A critical threshold of the amount of the antigen-antibody complexes and the ensuing complement activation is required for the development of proteinuria (77). The generated C5b-9 is inserted into the cell membrane of the glomerular epithelial cell and then endocytosed, transported intracellularly, and finally excreted into the urinary space and urine (78). How the activation of complement and the formation of C5b-9 produce proteinuria in Heymann nephritis is not established, but reactive oxygen species (79), metalloproteinases (80), phospholipases, and protein kinases (81) appear to play a role. Whether a similar mechanism operates in human MN is unclear. However, C5b-9 can be demonstrated in the human idiopathic MN lesion (14,15) and is also excreted in the urine (82). *In situ* subepithelial antigen-antibody deposits in experimental animals can also result from the binding of antibodies to nonglomerular, cationic, exogenous antigens implanted experimentally in the lamina rara externa of the GBM (83).

Circulating immune complexes of appropriate size and charge, made *in vitro* by artificially covalently linking an exogenous antigen and antibody followed by intravenous infusion into an experimental animal, also localize in the subepithelial region (84) and produce the subepithelial deposits of MN. Whether such a mechanism operates in humans is unknown, but it appears to be unlikely.

In summary, human MN is an antibody-mediated disease of uncertain and imprecise pathogenesis. However, the hypotheses that it is an autoimmune disease of the kidney and that the subepithelial immune deposits are formed *in situ* with an endogenous glomerular antigen are attractive.

Clinical and Laboratory Findings

Clinical features of idiopathic MN at onset are summarized in Table 33.2. MN can occur at any age, including infancy. Habib et al. (10) reported two patients of 8 and 10 months of age, and the author has seen two infants present at 5 and 11 months. Sixty percent of the children are male; 40% are female (Table 33.2). The children may have overt features of

+, present; —, not present.

NS (e.g., anasarca) or asymptomatic proteinuria (57); presentation with NS is more common (69%). Although presentation with macroscopic hematuria is rare, it has been reported (10); however, microscopic hematuria at presentation is common (69%). Presentation with isolated microscopic hematuria without proteinuria or NS is extremely rare (16). Hypertension at onset is uncommon (21%). Renal failure at onset is rare (2.3%), but the author has seen a child present with rapidly progressive acute renal failure, whose glomerular histology showed MN with glomerular crescents. In patients with edema, laboratory findings of NS (i.e., hypoproteinemia, low serum albumin concentration, hyperlipidemia, and heavy proteinuria) are present. Serum complement levels CH50, C3, and C4 are normal in most patients (Table 33.2).

Diagnosis

No specific clinical finding or simple, routinely performed laboratory test is diagnostic for MN. The condition should be suspected when (a) features of a chronic glomerulonephropathy (i.e., proteinuria, hematuria, abnormal urine sediment, with or without hypertension, or renal failure) are present; and (b) the laboratory tests for more common glomerulonephritides are negative [i.e., normal serum complement, negative

serology for syphilis, negative serologic test for hepatitis B surface antigen (HB_sAg), a negative antinuclear antibody test, and negative tests for poststreptococcal infection]. Lack of prompt response to corticosteroids in a nephrotic patient may also suggest MN. However, a definitive diagnosis can only be made by a histologic diagnosis on a renal biopsy specimen.

Treatment

Treatment consists of immunosuppressive drugs and renoprotective agents (e.g., angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists) and lipid-lowering drugs [e.g., hydroxymethylglutaryl coenzyme A reductase inhibitors (statins)]. Although there have been no reported studies employing renoprotective agents in children with MN, there are sufficient data in adults with MN (85) and other proteinuric renal diseases that it seems reasonable to use angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists in all patients with MN, except those with renal failure (86). Lipid-lowering drugs may be used in nephrotic patients (87).

There are no controlled clinical trials in children of treatment with corticosteroids or other immunosuppressive drugs. Therefore, no definitive approach to therapy is avail-

able at this time. However, based on uncontrolled studies (8,12,16,17,19,59,88), the following approach appears rational: Children with asymptomatic proteinuria and without hypertension, renal failure, or NS should be given angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists and not treated with corticosteroids or other immunosuppressive therapy because most are likely to go into remission and do well.

How to treat all other children with idiopathic MN remains a difficult decision at present. It is unlikely that sufficient numbers can be collected to conduct a prospective, randomized, double-blind controlled study because of the low prevalence of the disease in children. In the absence of such information, decisions have to be based on information available from controlled studies using immunosuppressive drugs performed in adults with idiopathic MN (Table 33.3).

Alternate-day corticosteroids alone have been used in three controlled trials (89–91). Two trials compared a 100- to 150-mg alternate-day dose of prednisone for 8 weeks with placebo. In the study from the United States (89), the treatment was associated with more complete and partial remissions of the NS. However, the follow-up period was short, and the rate of deterioration of renal function was unexpectedly high in the control group. The other study, from the United Kingdom (90), found no significant difference ($p < .05$) between the untreated and treated groups in plasma creatinine concentration, creatinine clearance, or 24-hour protein excretion. The third study, from Canada (91), using 45 mg/m² prednisone for 6 months, concluded that the therapy was of no benefit ($p < .2$).

In trials with corticosteroids and other immunosuppressive agents, a controlled study from Italy (92) used a 6-month course of daily corticosteroids alternating with chlorambucil (0.2 mg/kg/day) as follows: Methylprednisolone was first given intravenously, 1 g/day for 3 days,

followed by daily oral prednisone, 0.4 mg/kg for 27 days. Prednisone was then discontinued and chlorambucil given at a dosage of 0.2 mg/kg/day for 1 month. These alternating courses of prednisone and chlorambucil were continued for 6 months. At 5 years of follow-up, there were significantly more remissions in treated than in untreated patients ($p = .026$). There was significant deterioration of renal function in the untreated group ($p = .0002$) but not in the treated group (p value was not significant). At 10 years of follow-up, these benefits were maintained (93). The same group from Italy performed another controlled trial comparing the same regimen of chlorambucil with steroids or with steroids alone (94). The authors found that the addition of chlorambucil was associated with more remissions of the NS and preservation of renal function. In another controlled trial of selected patients with progressive MN, cyclosporine (3.5 mg/kg/day for 12 months) was found to be beneficial (95). Significant reductions of proteinuria ($p < .02$) and a slower rate of decline of renal function ($p < .02$) were observed during therapy (95). Recently, in a controlled trial of adult steroid-resistant nephrotic patients treated for 26 weeks with prednisone (0.15 mg/kg/day) plus cyclosporine (3.5 mg/kg/day) or prednisone alone, 75% of the former and 22% of the latter groups achieved partial or complete remission of proteinuria (96).

The most promising results in the aforementioned studies were obtained in the Italian study using alternating courses of daily prednisone and chlorambucil. This treatment, or treatment with cyclosporine (95,96), may be tried in children who have persistent NS with or without other features of severe disease (i.e., renal failure or hypertension). Children generally tolerate corticosteroids well and are unlikely to develop severe side effects on dosages used in the Italian protocol, but there is a possibility of gonadal toxicity and oncogenic potential with chlorambucil and renal toxicity with cyclosporine. Newer therapies are emerging. In a preliminary

TABLE 33.3. RESULTS OF CONTROLLED TRIALS OF TREATMENT OF IDIOPATHIC MEMBRANOUS GLOMERULONEPHRITIS IN ADULTS

Study (reference)	No. of patients	Follow-up (mo)	Treatment	Conclusion
Collaborative Study Group (USA) (89)	Untreated—38 Treated—34	26–52	Prednisone, 125 mg (100–150 mg) every other d × 8 wk	“Less deterioration of renal function in treated patients.”
Cattran et al. (Canada) (90)	Untreated—77 Treated—81	48 ± 3	Prednisone, 45 mg/m ² every other d × 6 mo	“No benefit.”
Cameron et al. (UK) (91)	Untreated—51 Treated—52	52 ± 6	Prednisone, 125–150 mg every other d × 8 wk	“No significant difference between treated and untreated groups in plasma creatinine, creatinine clearance or 24-h proteinuria.”
Pontelli et al. (Italy) (92)	Untreated—39 Treated—42	60 median	Methylprednisolone, 1 mg IV × 3 d Prednisone, 0.4 mg/kg × 27 d Chlorambucil, 0.2 mg/kg × 30 d Three cycles; total: 6 mo	“Produces sustained remission of nephrotic syndrome and helps preserve renal function.”

study, pentoxifylline (1200 mg/day for 6 months), which suppresses the tumor necrosis factor- α cytokine, reduced proteinuria in ten adult patients from 4.6 to 27.0 g/day to 0.0 to 10.9 g/day without causing side effects (97).

Patients with NS may develop deep vein thrombosis, particularly renal vein thrombosis. Whether prophylactic anticoagulants should be used in these patients remains unsettled.

Clinical Course

The clinical course of idiopathic MN is variable. Some patients (particularly those with asymptomatic proteinuria) achieve spontaneous remission, others continue with NS, and some develop end-stage renal failure. A review of the literature (10,12,16,59,88) (Table 33.2) shows that after a variable follow-up ranging from 1.0 to 15.8 years, irrespective of treatment, 18% of the children develop chronic renal failure, 41% achieve remission, and 37% continue to have active disease but without renal failure. These results, however, need to be interpreted in light of the uncontrolled and retrospective nature of the studies and the variable follow-up time, ranging from 2.0 months to 15.8 years. It is important to note that all 29 patients who went to chronic renal failure had NS at onset or subsequently during the course. Hypertension at onset or subsequently during the course. Hypertension at onset is associated with a less favorable outcome (Makker SP, *unpublished observation*, 2003) (10,12,16,46,59,88). There is insufficient information to determine the frequency of spontaneous remission in a child presenting with NS who is not treated or to determine the relationship between sex, age at onset, and renal failure at onset and the final outcome.

Resolution

Idiopathic MN is a chronic disease and, therefore, most likely involves continuous or multiple generations of deposits. Do children achieving complete remission (normal urine) stop forming new deposits, completely resolve their previous deposits, and normalize their GBMs? If these changes do occur, how long does it take? It is difficult to answer these questions because sequential renal biopsies after complete remissions are not often performed. We have studied the problem in active Heymann nephritis of the rat (98). Proteinuric MN kidneys were transplanted into normal, unilaterally nephrectomized syngeneic Lewis rats to follow the course of the resolution of established MN in a normal host, thus preventing any new generation of deposits. Sequential renal biopsies were performed over time (Fig. 33.5). We found that the resolution of the process was very slow. At 38 weeks, the deposits were still positively stained for rat IgG by immunofluorescence, and electron microscopy showed thickened lamina densa, irregular subepithelial contour, and lucent deposits in the lamina densa of GBM. This suggests that if a comparable pace of resolution occurs in humans, complete resolution in children will take several years, even after the cessation of new deposits.

FIGURE 33.5. Ultrastructural findings in the transplanted Heymann nephritis rat kidney at weeks 0, 28, and 38 transplanted into a normal syngeneic Lewis rat. At 0 time, the subepithelial deposits are evident. After 28 weeks, the glomerular basement membrane is thickened, the subepithelial deposits have become lucent, and the subepithelial contour is irregular. At 38 weeks, the latter changes persist ($\times 43,000$). (Electron microscopy performed by Seymour Rosen, M.D., Harvard Medical School, Boston.)

MEMBRANOUS GLOMERULONEPHROPATHY ASSOCIATED WITH HEPATITIS B

Epidemiology

Many cases of MN associated with hepatitis B in children have been reported from several parts of the world, including the United States (99), Europe (8,44,46), Africa (41,43), and the Orient (20,21,39,100). The largest series of patients have come from Southeast Asia (20,21), consistent with the higher prevalence of HB δ Ag-carrier state. The prevalence of HB δ Ag carriers is approximately 0.3 to 1.0% in North America, 1.0% in western Europe, 7.0% in Africa, and 10.0% in Southeast Asia, where it is endemic (101). For instance, in Taiwan, 95% of all MN, excluding SLE, is due to hepatitis B (21). In these areas, vertical transmission from infected mothers to their children and horizontal transmission between siblings is likely because 33 to 36% of siblings of patients show a positive blood test for HB δ Ag (21). Transmission in adolescents through drug abuse or sex is also possible (102).

Clinical Features

Children with MN associated with hepatitis B, like the children with idiopathic MN, usually have NS or are detected during evaluation of persistent proteinuria (8,20,21,40–46,99,100).

Microscopic hematuria is common, and even macroscopic hematuria has occasionally been reported. Rarely, a patient may have only microscopic hematuria without proteinuria (20). In almost all large series, boys predominate overwhelmingly (75 to 80%) (8,20,21), as opposed to idiopathic MN, in which boys and girls are affected in approximately equal numbers (Table 33.2). Age at onset in large series has varied from 2 to 16 years. Retrospective analysis of symptomatology at onset reveals that patients start with flu-like illness consisting of low-grade fever, poor appetite, nausea, vomiting, and malaise, but usually no jaundice. After these symptoms subside, hematuria and proteinuria are noted (20). However, most come to attention because of the onset of edema as the result of MN, and evidence for hepatitis is discovered only during evaluation. The liver may be enlarged in some patients at onset.

Laboratory tests on serum for a profile of hepatitis B antigen and antibodies show a positive result for HB_sAg in all patients, usually a negative result for hepatitis B antibody, and a positive result for hepatitis B early antigen (HB_eAg) in more than 90% of patients (20,21). Serum levels of complement components C3 and C4 are usually low (21) at onset, but they may return to normal at some time during the course of the disease. Serum levels of liver transaminase enzymes may be elevated on presentation and, in some cases, persist chronically (8,20,40,44). Liver biopsies usually show chronic hepatitis (8,20). However, the long-term course of the liver disease remains to be studied. Hepatitis B-associated MN is suspected in a child with features of a glomerular disease (i.e., proteinuria, hematuria, or NS), who during laboratory evaluation is found to have a positive test result for HB_sAg in serum, and the diagnosis is established by renal biopsy. If serum complement C3 levels are low, it is an additional piece of evidence in favor of hepatitis B-associated MN versus idiopathic MN. On the basis of clinical manifestations alone at the time of presentation, the two conditions may be difficult to differentiate, and a high index of suspicion is necessary.

Pathology

The pathology of MN associated with hepatitis B is similar to that of idiopathic MN and is indistinguishable in most cases. The two conditions may be differentiated on the basis of demonstration of HB_eAg in the glomerular immune deposits by immunofluorescence microscopy. When Fab₂ portions of monoclonal antibodies to HB_sAg, hepatitis B core antigen (HB_cAg), and HB_eAg are used for detection, HB_eAg is present in most (90% or greater) patients with hepatitis-associated MN, but it is not seen in idiopathic MN (20,21,103). HB_sAg and HB_cAg were not detected in hepatitis-associated MN in these studies.

Pathogenesis

The exact pathogenesis of hepatitis B-associated MN is unknown, but a high frequency of HLA allele DQB1*0603

noted in South African children suggests a role for genetic factors (104). The presence of IgG in the subepithelial deposits shows that these deposits contain immune complexes. How the deposits are formed is unclear. Two hypotheses have been considered. According to the first, circulating immune complexes consisting of antigen(s) of hepatitis virus and their corresponding antibodies (elicited as the result of chronic infection) are trapped in the glomerulus and come to lie in the subepithelial space during the formation of glomerular ultrafiltrate. According to the second hypothesis, certain freely circulating hepatitis B virus antigens pass through the GBM during the process of ultrafiltration and are implanted in the subepithelial space. Theoretically, cationic antigens are more likely to pass through the GBM than anionic ones because of the anionic nature of the GBM. Once implanted, the deposits form by the binding of antibodies crossing the GBM from the circulation.

To prove either hypothesis, hepatitis antigen(s) must be demonstrated in the glomerular immune deposits. Indeed, hepatitis B antigens have been demonstrated in these deposits by immunofluorescence microscopy. Since the first study by Combes et al. (105), HB_sAg, HB_cAg, and HB_eAg have been detected by many investigators, but the findings have been inconsistent (41). Part of the explanation for the inconsistent results is the questionable specificity of the older reagents used in the earlier studies. Recent studies, as alluded to earlier, have used Fab₂ portions of the highly specific monoclonal antibodies (20,21,103) and have found that only HB_eAg (and not the other antigens) is present in the glomerular immune deposits, suggesting the importance of HB_eAg in pathogenesis. The molecular weight of free HB_eAg in circulation is approximately 100,000 daltons, and its isoelectric point is 4.8 (anionic). These physicochemical characteristics of HB_eAg probably do not favor the *in situ* hypothesis.

To substantiate the hypothetical circulating immune complex, complexes of the same antigen antibody specificity as those detected in the glomerular immune deposits and of a size and charge that would localize in subepithelial space must be demonstrated in circulation. The available information in this regard is limited and discordant (45). Takekoshi et al. (106) have demonstrated circulating immune complexes of HB_eAg and antibody of an approximate size greater than IgG in the serum of two children they studied. However, the problem is complicated by the fact that circulating immune complexes of hepatitis B antigens and antibody are present in patients with chronic hepatitis B infection without MN.

Treatment and Course

The course of hepatitis B-associated MN is variable, ranging from spontaneous recovery in some (106) to end-stage renal failure in others (42,107). Retrospective analysis of six studies (20,21,42,107–109) comprising a total of 82 children, most of

whom had been treated with corticosteroids, showed that within 12 months after diagnosis, nearly 60% were in remission. The remainder had persistent disease, with 7.3% having chronic renal failure and 2.4% end-stage renal failure (103). In one large study of 52 patients from Taiwan (20), 38 of whom were treated with corticosteroids, 64% of the children were in remission at 1 year and 92% at 7 years after follow-up, and only one patient was in renal failure. Four children who received no treatment were in remission at 2 years. In another series of 70 patients from South Africa (110), 60 of whom were untreated, it was reported that the cumulative probability of remission was 64% at 4 years and 84% at 10 years; after 90 months of follow-up, three patients were still nephrotic, and two had developed end-stage renal failure. The average duration of proteinuria in these patients was 30 months, with remission of proteinuria usually occurring 6 months after clearance of HB_eAg from the serum. Overall, these two studies suggest that although there can be a prolonged period of morbidity, the eventual outcome in most of the children is favorable. On the other hand, in another study from Taiwan (20) of 32 patients treated with corticosteroids, 70.6% had persistent disease and 12.3% progressive disease after 2 years of follow-up, and HB_eAg in serum remained positive in most cases throughout the course of the disease, even among some who were in clinical remission (20,21). However, children whose serum became negative for HB_eAg were more likely to have remission than those whose serum remained positive for HB_eAg (20). The treatment for hepatitis-associated MN is evolving, but at present, there is no optimal and accepted treatment for hepatitis-associated MN in children. Corticosteroids do not appear to be beneficial and probably should not be used because they may enhance viral replication in mononuclear cells (111). Recently, recombinant human interferon- α (subcutaneous injections three times a week) has been reported to be beneficial (112). In this study, two groups of 20 patients each with persistent proteinuria and NS who had previously not shown a response to corticosteroids were either treated with recombinant human interferon- α for 1 year or given only supportive treatment. At the end of the study, all (20 of 20) treated patients were free of proteinuria; however, in the untreated patients, two were also free of proteinuria, 12 had mild proteinuria, and only six had persistent heavy proteinuria. Thus, without treatment, 70% of the patients showed improvement in proteinuria. All treated patients had flu-like symptoms in the first 2 weeks of therapy; later, 30% of the patients developed psychiatric problems. Longer follow-up of treated and untreated patients is needed to draw conclusions regarding the recommendation of this therapy.

MEMBRANOUS NEPHROPATHY ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS

The histopathology of the renal lesion in some patients with SLE can have an appearance that is indistinguishable

from the histology observed in idiopathic MN. In a large series of children from the United States who had renal involvement secondary to SLE, MN was present in nearly 10% (113). In another study from the United States, 10 of 64 patients evaluated for MN had SLE as the underlying cause (12). However, in a study from France (18), only 2 of 65 children with MN had SLE.

Children with MN associated with SLE commonly have features of a glomerular disease associated with other extrarenal manifestations of SLE. These usually include hematuria and proteinuria, with or without NS and with or without hypertension or renal failure. However, patients may have only a glomerular disease and no other manifestations of SLE. Laboratory tests on serum for SLE are usually positive (i.e., antinuclear antibodies, anti-double-stranded DNA antibodies, and low serum complement C3 and C4). However, occasionally all clinical manifestations may be absent, and the laboratory tests for SLE may be negative at presentation and become positive only later; in some cases, this may be years. Patients with inherited deficiency of the second component of complement are prone to develop SLE, and these patients may present initially with MN and later develop SLE. Renal biopsy findings of SLE-associated MN and idiopathic MN may be identical. However, presence of mesangial deposits and strong positive staining of the deposits for C1q and C4, as strong as the staining for C3, are suspicious of SLE. The treatment of MN associated with SLE is similar to the treatment of other SLE patients with renal involvement, including the use of corticosteroids and cytotoxic drugs.

MEMBRANOUS NEPHROPATHY IN RENAL ALLOGRAFTS

MN in a renal allograft may develop *de novo* or as a result of the recurrence of the original idiopathic MN. The recurrence rate in adults has been reported to vary from 26.3 (114) to 50.0% (115). Because of the paucity of cases, the recurrence rate in children is unknown. Several cases of *de novo* MN in the transplanted kidney have been reported (37). In children, the incidence of *de novo* occurrence of MN in transplanted kidneys is estimated to be approximately 1 to 2% (36,116), but in one large series from France, 9.3% of the renal transplants in children developed *de novo* MN (36). Part of the reason for the higher incidence in this report may be the greater frequency of routine renal transplant biopsies. MN was discovered in nine patients by the latter approach, with none of them having proteinuria, suggesting that the actual incidence of the condition is higher. In other patients, it is discovered during evaluation of proteinuria, NS, or a suspected rejection. The pathogenesis of *de novo* MN is not understood. However, there is a high rate of recurrence of the *de novo* MN in the second allograft, suggesting that host factors play a role

(36). No correlation between the development of *de novo* MN and age or sex of the patient, the original disease producing end-stage renal failure, and the time between the transplant and the onset of MN has been observed. However, ureteral obstruction (116,117) and a good histocompatibility match (118,119) could be possible predisposing factors. The course of *de novo* MN is variable. Some patients never even develop proteinuria, whereas others develop NS; in some, it may contribute to the deterioration of renal function in association with chronic rejection. In general, the demise of the graft is more often caused by the rejection process than the *de novo* MN.

MEMBRANOUS NEPHROPATHY ASSOCIATED WITH OTHER INFECTIONS

MN may be associated with a number of other infections (Table 33.1). Congenital syphilis should be considered in the differential diagnosis in any infant presenting with NS. Infants with congenital syphilis also often have other clinical features of congenital syphilis, and most have microscopic hematuria. The diagnosis can be confirmed by a positive serologic test result for syphilis. Complement levels of CH50, C3, and C4 are low at onset and return to normal after treatment with penicillin (21). Renal biopsy findings are similar to those of idiopathic MN, except that staining to C1q is commonly present (22). *Treponema* antigen has been demonstrated in the glomerular immune deposits (120). Early treatment with penicillin leads to complete recovery. This emphasizes that the physician needs to be aware that (a) a potentially curable condition can be the cause of NS in infants, and (b) once the offending agent has been eradicated, MN can resolve.

Other parasitic infections, such as malaria, filaria, and hydatid disease, can produce MN and should be considered in the differential diagnosis when exposure to these parasites is suspected. Leprosy and schistosomiasis have been associated with MN in adults (6).

MEMBRANOUS NEPHROPATHY ASSOCIATED WITH DRUGS AND TOXINS

MN has been reported in association with a number of drugs and toxins in adults, including gold, mercury, captopril, fenopropfen, penicillamine (6,18), and, more recently, mercaptopropionylglycine (121). A few cases in children associated with penicillamine used to treat cystinuria, Wilson's disease, and rheumatoid arthritis have also been reported (8,17). Generally, there is no relationship to the dose or duration of treatment, and proteinuria disappears once the drugs are withdrawn. Recently, in two children, MN was reported to be associated with exposure to formaldehyde (32).

MEMBRANOUS NEPHROPATHY ASSOCIATED WITH TUMORS

MN has been associated with a number of malignancies in adults (6,122)—the most common being bronchogenic carcinoma, gastric carcinoma, and adenocarcinoma of the colon. A few cases have also been reported in children (Table 33.1). In two cases reported in children (33,34), resolution of MN was observed after excision of the tumor.

MEMBRANOUS NEPHROPATHY ASSOCIATED WITH OTHER DISORDERS

In addition to SLE, MN has been reported with a number of other autoimmune and immunologic diseases. Cases in children have been reported with enteropathy (27), Crohn's disease (28,29), pemphigus (30), multiple sclerosis (31), immune thrombocytopenic purpura (123), and sarcoidosis (124). In a recent report of MN associated with enteropathy (27), autoantibodies to a 55-kDa epithelial cell protein common to intestine and kidney were detected in the serum of the child and were temporally related to the development of enteropathy and MN.

A distinct entity consisting of antitubular basement membrane-associated tubulointerstitial nephritis, Fanconi's syndrome, and MN has been recognized (26). All of the reported children except for one with this disease have been boys. The tubular autoantigen is a 58-kDa protein that is located in the basement membrane of the proximal tubule (125). The glomerular autoantigen is a 600-kDa protein (gp600/gp330/megalin/LRP II) (26). Isolated cases of MN are associated with a number of other conditions in children (Table 33.1).

CRESCENTIC GLOMERULONEPHRITIS

MICHAEL J. DILLON

Crescentic glomerulonephritis is the histopathologic correlate of the clinically defined condition of rapidly progressive glomerulonephritis (RPGN) (1). It is relatively rare in childhood (2–9) and is characterized by the presence of extensive crescents demonstrable on renal biopsy and by sudden and progressive decline in renal function. It can accompany most forms of primary glomerulonephritis in childhood and can be associated with various systemic disorders [e.g., systemic lupus erythematosus (SLE)] and several forms of systemic vasculitis (2,3,7,8). The severity of the condition, the multiple etiologies, and the well-recognized poor prognosis have resulted in the use of multiple treatment regimens, the efficacy of which have been difficult to assess (10), and there has been a lack of clarity in identifying variables with therapeutic and prognostic implications.

DEFINITION

There are a number of definitions of *crescentic glomerulonephritis*, and this varied nomenclature has created problems in data interpretation and comparing outcomes of treated patients. There is general agreement that crescentic glomerulonephritis is defined by the presence of large epithelial crescents within Bowman's space, but the appearance of the crescents and the number required for the diagnosis are arguable. In childhood, more than 75% (3), 50% or more (2,7), and occasionally as few as 20% of glomeruli affected have been considered to represent crescentic glomerulonephritis (5). In a series described by Neild et al. (11) of 39 patients with RPGN and extensive crescent formation, ten patients younger than 14 years of age had greater than 60% of glomeruli affected. However, in another series of 13 children with RPGN, Cunningham et al. (4) reported the number of glomeruli affected as varying from 10 to 100%. In other series with undoubtedly crescentic glomerulonephritis, the clinical factors have been emphasized irrespective of the number of crescents (12).

Jardim et al. (7) considered that crescentic glomerulonephritis was present when large epithelial crescents, filling Bowman's space, occurred in 50% or more of glomeruli present in a renal biopsy specimen, irrespective of any

changes in the underlying glomerular tuft. In addition, crescents were divided into *cellular*, *fibrocellular*, or *fibrous* categories according to their histopathologic appearances and were further subcategorized according to other criteria, including changes in the glomerular tuft, immunochemical staining, and clinicopathologic correlations.

INCIDENCE

The real incidence of crescentic glomerulonephritis in children is unknown. It comprises 2 to 5% of all cases of glomerulonephritis in adults (13); Andrassy et al. (14) calculated the annual incidence in Germany to be 0.7 per 100,000 adults. Miller et al. (15) reported crescentic lesions in 56 of 372 children with glomerular pathology on renal biopsy; in 26, there was a clinical course compatible with RPGN. These data are not dissimilar to those quoted for adults, emphasizing the relative rarity of the condition in children.

CAUSES

There are a number of ways of considering the causes of crescentic glomerulonephritis. There are classifications that consider the immunofluorescence staining patterns on renal biopsy and subdivide disorders according to the appearances into (a) anti-glomerular basement membrane (GBM) antibody disease; (b) no staining or pauci-immune disease; and (c) immune complex disease (13,16). Using these criteria, the most frequently observed pattern in childhood (in contrast to adults) is immune complex disease, constituting 80% of cases, with pauci-immune and anti-GBM disease making up the remainder in a ratio of 2:1 (2,7,13).

Other classifications consider RPGN or crescentic glomerulonephritis under headings of disease category (e.g., anti-GBM disease), primary systemic vasculitis, other disorders (e.g., SLE), primary glomerulonephritis, infection-associated glomerulonephritis, and miscellaneous causes (Table 34.1).

In four large series of childhood patients with crescentic glomerulonephritis reported from the United States, France,

TABLE 34.1. CAUSES OF CRESCENTIC GLOMERULONEPHRITIS IN CHILDHOOD

Anti-GBM antibody disease
Anti-GBM nephritis, Goodpasture's syndrome, with perinuclear antineutrophil cytoplasmic antibody-associated microscopic polyangiopathy, posttransplantation in Alport's syndrome
Primary systemic vasculitis
Henoch-Schönlein purpura, microscopic polyarteritis or polyangiopathy, idiopathic crescentic nephritis, Wegener's granulomatosis, Churg-Strauss syndrome
Systemic disorders
SLE, Behçet's syndrome, Weber-Christian disease, relapsing polychondritis, essential mixed cryoglobulinemia, mixed connective tissue disease, dermatomyositis, juvenile rheumatoid arthritis, Sjögren's syndrome, sarcoidosis
Primary glomerulonephritis
Mesangiocapillary glomerulonephritis, IgA nephropathy, membranous nephropathy
Infection-related glomerulonephritis
Poststreptococcal glomerulonephritis, legionella, mycoplasma, syphilis, hepatitis B and C, tuberculosis, human immunodeficiency virus, bacterial endocarditis, shunt nephritis, leprosy, visceral abscess
After medication
Penicillamine, rifampicin and hydralazine, enalapril, interleukin-2, interferon- α , phenylbutazone, propylthiouracil, isoniazid
Miscellaneous causes
Malignant tumors, leukemia and lymphomas, silicosis, alpha-1-antitrypsin deficiency, hyper-IgD syndrome
After transplantation
Anti-GBM disease in Alport's syndrome (mentioned above), recurrence of IgA nephropathy and mesangiocapillary glomerulonephritis, anti-GBM, Henoch-Schönlein purpura, SLE

GBM, glomerular basement membrane; Ig, immunoglobulin; SLE, systemic lupus erythematosus.

the United Kingdom, and India, the pattern of disease was similar but there was variation, as might be expected, between centers (2,3,7,8).

The Southwest Pediatric Nephrology Study Group (2) reported on 50 children with histologically 50% or more glomeruli affected by crescents. Thirteen had nonspecified immune complex disease, nine had SLE, seven had idiopathic (nonimmune complex) crescentic glomerulonephritis, six had poststreptococcal glomerulonephritis, four had immunoglobulin (Ig) A nephropathy, three had Henoch-Schönlein purpura, three had vasculitis, three had possible anti-GBM disease, and two had dense deposit disease (Table 34.2).

Niaudet and Levy (3) reported the findings in 41 children with more than 75% crescents on biopsy. Eleven had Henoch-Schönlein purpura, nine had membranoproliferative glomerulonephritis, five had acute glomerulonephritis, three had anti-GBM disease, three had IgA nephropathy, three had polyarteritis, three had glomerulonephritis without evidence of deposits, two had immune complex glomerulonephritis, one had SLE, and one had shunt nephritis (Table 34.2).

Jardim et al. (7) described 30 children with 50% or more crescents on biopsy. Of these, nine had Henoch-Schönlein purpura, seven had mesangiocapillary glomerulonephritis (type I in six and type III in one), five had vasculitis (three had microscopic polyarteritis, one had polyarteritis nodosa, and one had Wegener's granulomatosis), four had idiopathic crescentic nephritis, two had poststreptococcal glomerulonephritis, two had anti-GBM disease, and one had SLE (Table 34.2).

Srivastava et al. (8) reported 43 children with crescents in more than 50% of glomeruli. Of these, 11 had poststreptococcal glomerulonephritis; six had an underlying

systemic disorder consisting of Henoch-Schönlein purpura in three, SLE in one, anti-GBM disease in one, and chronic rheumatoid arthritis in one; and in 26, the condition was classified as idiopathic (Table 34.2).

CLINICAL PRESENTATION

Most children with crescentic glomerulonephritis have an acute nephritis presentation with proteinuria, hematuria, volume overload, hypertension, and renal impairment. This may evolve quickly and initially give the impression of a postinfectious glomerulonephritis but can be associated with a more protracted clinical course that can be deceptive and may be the cause of a delay in diagnosis and introduction of appropriate treatment. In patients in whom the crescentic glomerulonephritis is secondary to or associated with a systemic disorder (e.g., lupus or vasculitis), clinical features of this may be present and helpful diagnostically. Pulmonary hemorrhage might suggest anti-GBM disease or vasculitis. However, in childhood, anti-GBM glomerulonephritis often occurs without lung involvement, and pulmonary hemorrhage is the exception rather than the rule.

In the series of 30 patients reviewed by Jardim et al. (7), all had hematuria (macroscopic in 15); all had proteinuria (nephrotic syndrome in 14); edema was present at the onset in 24; hypertension was present in 9; oliguria requiring dialysis for fluid control occurred in 15; and the glomerular filtration rate (GFR) was less than 30 mL/min/1.73 m² at presentation in 22 patients and between 30 and 60 mL/min per 1.73 m² in the remaining 8. These data are very similar to those recorded in other reports in the literature (2–4). However, it is important to emphasize that there is a fairly wide spectrum of presenting clinical features (Table 34.3).

LABORATORY FINDINGS

Laboratory investigations substantiate the clinical impression of renal impairment as well as confirming the presence of hematuria and proteinuria. The degree of renal failure can be deceptive with GFR findings, often substantially

FIGURE 34.1. Cytoplasmic staining antineutrophil cytoplasmic antibody pattern in a standard indirect immunofluorescence assay.

more impaired than might have been deduced from random plasma creatinine values. Anemia, which is frequently present, is more marked than anticipated (13) and is usually normochromic and normocytic.

Serologic abnormalities vary according to the underlying disease state. Hypocomplementemia is not uncommon in immune complex disease and SLE. Circulating anti-GBM antibodies would be expected in anti-GBM disease (17); if this condition is suspected, it is essential to have a rapid result from the laboratory, as initiation of early treatment is critically important. Circulating anti-GBM IgG antibodies can be demonstrated by indirect immunofluorescence or enzyme immunoassay. Enzyme immunoassay is more sensitive and specific as compared to indirect immunofluorescence.

Raised anti-streptolysin O levels with or without raised anti-deoxyribonuclease B are features of poststreptococcal glomerulonephritis, but they can be increased coincidentally in other forms of crescentic glomerulonephritis and may, therefore, not be diagnostically helpful. Antinuclear

FIGURE 34.2. Perinuclear staining antineutrophil cytoplasmic antibody pattern in a standard indirect immunofluorescence assay.

FIGURE 34.3. Cellular crescent.

and anti-double-stranded DNA antibodies point to a diagnosis of SLE nephritis.

Elevated levels of antineutrophil cytoplasmic antibodies (ANCA) may reflect an underlying vasculitic cause, such as Wegener's granulomatosis or microscopic polyarteritis (or polyangiopathy) (18,19). Two neutrophil primary-granule enzymes are the targets of the majority of ANCAs in systemic vasculitis. ANCAs directed against proteinase-3 are strongly associated with Wegener's granulomatosis and produce a cytoplasmic staining pattern in a standard indirect immunofluorescence assay (19,20) (Fig. 34.1). ANCA directed against myeloperoxidase, producing a perinuclear staining pattern, is often seen in microscopic polyangiopathy, but perinuclear ANCA may also be directed against other epitopes and is seen in other nonvasculitic conditions (19,21) (Fig. 34.2). The presence of circulating ANCA in a child with crescentic glomerulonephritis might be helpful diagnostically with a cytoplasmic pattern suggestive of Wegener's granulomatosis and a perinuclear pattern suggestive of microscopic polyangiopathy (22). In children with idiopathic disease, which is considered probably to be a form of microscopic polyarteritis, such a positive finding can be helpful, but negative results do not exclude Wegener's granulomatosis, nor do they exclude microscopic polyangi-

FIGURE 34.4. Fibrocellular crescent.

FIGURE 34.5. Fibrous crescent.

itis. ANCA-positive crescentic glomerulonephritis is also associated with propyl thiouracil treatment in children (23).

HISTOPATHOLOGY

Controversy exists as to how many glomeruli have to be associated with crescents to designate the disease as *crescentic glomerulonephritis*. As mentioned previously, authors vary in their views, and more than 75% (3), 50% or more (2,7,8), and occasionally even 20% of glomeruli affected have been considered to represent crescentic glomerulonephritis (5). There is, in addition, a need to characterize the nature of the crescents, and three categories are recognized. *Cellular crescents* are those in which there is prominent proliferation of epithelial cells, with some admixture of macrophages and occasionally neutrophils filling the urinary space and compressing the tuft (Fig. 34.3). *Fibrocellular crescents* are those in which strands of membrane-like material and collagen fibers are present among the cells forming the crescent (Fig. 34.4). *Fibrous crescents* are those in which the cells of the crescent have virtually all disappeared to be replaced by collagen (7) (Fig. 34.5).

The nature of the underlying disease causing the crescentic glomerulonephritis is based on various criteria: (a) the

FIGURE 34.6. Mesangiocapillary glomerulonephritis.

FIGURE 34.7. Anti-glomerular basement membrane glomerulonephritis with linear immunoglobulin G demonstrable by immunochemical staining.

associated changes in the glomerular tuft, such as those of mesangiocapillary glomerulonephritis (Fig. 34.6); (b) the immunochemical staining, such as the presence of linear IgG staining along the glomerular capillary walls in anti-GBM glomerulonephritis (Fig. 34.7); and (c) clinicopathologic factors, such as in polyarteritis nodosa, Wegener's granulomatosis, and microscopic polyarteritis (7). However, the identification of the underlying glomerulonephritis is often difficult, but immuno-fluorescence studies can prove helpful in, for example, mesangiocapillary glomerulonephritis, anti-GBM disease, IgA nephropathy, and Henoch-Schönlein purpura (Fig. 34.8).

It is clear that the number of crescents is not necessarily the most important factor in terms of subsequent outcome. This is much more closely related to the nature of the crescents, with fibrous crescents having a worse prognosis than cellular or fibrocellular crescents (7). It is also clear that the histopathologic appearances of the crescents can change quite rapidly from cellular to fibrous, especially if therapeutic intervention is delayed. The implication from this evolution is that the underlying glomeruli became seriously compromised with progression to glomerulosclerosis and

FIGURE 34.8. Henoch-Schönlein purpura mesangial deposition of immunoglobulin A demonstrable by immunochemical staining.

irrecoverable renal impairment. This process leading to glomerulosclerosis is similar in most causes of crescentic glomerulonephritis, and at a late stage, it is usually not possible to distinguish the etiology from histopathologic examination.

IMMUNOPATHOGENETIC MECHANISMS

In severe inflammatory glomerular injury, whatever the initial insult or injury, crescent formation may be the final pathway. A crescent is a proliferation of extracapillary cells within Bowman's space. There is evidence that crescent formation is initiated by cytokine-driven proliferation of the parietal glomerular epithelial cells (24–26). Associated with this, localized breaks in the GBM of Bowman's capsule (27–29), mediated by activated leukocytes, are followed by macrophage infiltration into Bowman's space with local fibrin formation (30). Current evidence suggests that crescent formation is a feature of cell-mediated rather than humoral immune mechanisms (31).

TREATMENT AND OUTCOME

The heterogeneity and poor outcome of childhood crescentic glomerulonephritis has led to multiple treatment regimens. Steroids (oral or high-dose intravenous), cytotoxic agents, anticoagulants, antiplatelet agents, and plasma exchange, alone or in different combinations, have all been described (2,3,7,8,10,11,32) (Table 34.4).

High-dose intravenous methylprednisolone, often recommended in adults (33), has been used in children with crescentic glomerulonephritis by Ferraris et al. (32), coupled with cyclophosphamide, with long-term renal recovery in five children after a mean follow-up of 35 months. Methylprednisolone has also been used alone in 29 children with severe proliferative glomerulonephritis (12), with a favorable outcome (GFR greater than 80 mL/min/1.73 m²) observed in 18 (62%) after a mean follow-up of 35 months.

Combined immunosuppressive and anticoagulant therapy as reported by the Southwest Pediatric Nephrology Study Group (2) resulted in 24 of 47 (52%) patients recovering renal function. The importance of anticoagulants in this regimen has been emphasized by Cunningham et al. (4) who reported recovery of renal function in 7 of 13 (54%) patients with crescentic glomerulonephritis. A similar regime used by Niaudet and Levy (3) was associated with renal recovery of varying degree in 19 of 41 (46.3%) patients (Table 34.5).

Treatment regimens used in the study of Jardim et al. (7) included corticosteroids, cyclophosphamide, azathioprine, anticoagulant and antiplatelet agents, and plasma exchange in varying combinations. Despite these intensive therapeutic approaches, approximately 50% of patients eventually pro-

TABLE 34.4. TREATMENT OPTIONS FOR CRESCENTIC GLOMERULONEPHRITIS IN CHILDHOOD

Induction	
Prednisolone 2 mg/kg/d PO	
If fulminant disease, methyl prednisolone, 600 mg/m ² /d × 3 IV, followed by PO prednisolone in above dose	
Cyclophosphamide, 2 mg/kg/d PO (for 2–3 mos), or pulsed cyclophosphamide, 500–750 mg/m ² /dose IV every 3–4 wks × 6	
If fulminant or unresponsive disease or if anti-GBM disease, plasma exchange, two volume exchanges daily × 5–10 d	
Antiplatelet therapy ± anticoagulation	
Treatment for underlying disease (often covered by above) with antimicrobial therapy, removal of offending drugs, and treatment of malignant disease	
Maintenance	
Alternate-day low-dose prednisolone (tapering from high induction dose)	
Azathioprine, 2 mg/kg/d, at least until remission maintained for >1 yr and in practice for approximately 18 mo	
Cyclosporin, methotrexate, and mycophenolate mofetil as alternative maintenance drugs if azathioprine incapable of controlling the disease	
Refractory disease	
Humanized monoclonal antibodies [e.g., anti-CD4 and anti-CD52 or anti-tumor necrosis factor agents (e.g., infliximab)]	
Supportive therapy	
Dialysis, diuretics, antihypertensives, and so forth	

gressed to end-stage renal failure. Four children on long-term follow-up had GFRs greater than 80 mL/min per 1.73 m², six had GFRs of 30 to 80 mL/min per 1.73 m², and three had GFRs of less than 30 mL/min per 1.73 m². Patients with fibrous crescents did less well, and there was evidence to support the view that the longer the interval between disease onset and commencement of treatment, the worse the prognosis. All patients whose treatment was delayed to beyond 3 months after disease onset went into end-stage renal failure; those treated 1 to 3 months after onset had variable results (two out of five patients recovered renal function); and the 12 patients treated in the first month after onset responded well (7) (Table 34.5).

The benefits of plasma exchange in anti-GBM nephritis have been demonstrated in adult patients (34) and have

led to its use in other disorders (e.g., immune complex-mediated RPGN) (34). The literature remains confusing in terms of the benefits of plasma exchange in RPGN from other causes, with some showing benefit (35) and others no effect (36). Pusey et al. (37) demonstrated that dialysis-dependent patients were more likely to recover renal function if treated with plasma exchange. Jardim et al. (7) treated 24 children by plasma exchange; although statistically there was no significant difference between patients who were and who were not exchanged, nine of the ten patients with a GFR of greater than 30 mL/min per 1.73 m² at latest follow-up received this treatment. However, the majority of the patients who progressed to renal failure despite plasma exchange had fibrous crescents on presentation. In the Niaudet and Levy report (3), plasma exchange was used in seven of 41 patients, and only the two patients not requiring dialysis on presentation recovered renal function. This emphasizes that the need for dialysis at onset is a predictor of worse outcome as has been shown in several series (3,7,11). Gianviti et al. (38) also showed that the addition of plasma exchange to other intensive therapy in patients with RPGN had beneficial effects.

Evidence-based data on treatment are very limited and unavailable in children. However, for adults, an analysis of evidence-based recommendations was published by Jindal in 1999 (39). In this report, early aggressive therapy was recommended despite weak supporting evidence because of the high risk of end-stage renal disease. Treatment for anti-GBM antibody-induced crescentic glomerulonephritis should be initiated early and should include pulsed methylprednisolone, a 2-week course of plasmapheresis, and 2 months' treatment with corticosteroids and cyclophosphamide. Treatment for pauci-immune crescentic glomerulonephritis should be pulsed methylprednisolone, followed by oral corticosteroids and cyclophosphamide for 6 to 12 months. Recurrences can be managed similarly along with appropriate supportive therapy.

In terms of prognosis, it is accepted that poststreptococcal crescentic glomerulonephritis has a better prognosis, with spontaneous improvement after supportive management (3,40). Roy et al. (41) found no advantage from immuno-

TABLE 34.5. OUTCOME IN CHILDREN WITH CRESCENTIC GLOMERULONEPHRITIS

suppression and anticoagulants over conservative management in children with poststreptococcal disease. However, progression to renal failure has been reported in children (3–5,7,8); hence, the outlook is not uniformly good.

Of other causes of crescentic glomerulonephritis, mesangiocapillary glomerulonephritis, microscopic polyangiitis, anti-GBM disease, and the idiopathic form seem to have a worse prognosis than, for example, Henoch-Schönlein purpura or SLE, which are among the more common causes of the condition (3,7). However, the outlook for any patient is very dependent on the need for dialysis at onset and the presence of fibrous crescents on biopsy (3,7,11).

In conclusion, it is clear that crescentic glomerulonephritis in childhood, as in adult practice, is caused by many different conditions with diverse pathogenetic mechanisms. These determine the natural history and the most appropriate treatment. Precise rapid diagnostic categorization and aggressive appropriate therapy are, in the majority of cases, indicated in light of the well-recognized poor prognosis in a substantial proportion of those affected.

TUBULAR DISEASE

NEPHRONOPHTHISIS-MEDULLARY CYSTIC KIDNEY DISEASE

FRIEDHELM HILDEBRANDT

DEFINITION OF THE NEPHRONOPHTHISIS-MEDULLARY CYSTIC DISEASE COMPLEX

The nephronophthisis-medullary cystic disease (NPH-MCKD) complex describes a distinct clinicopathologic entity of inherited diseases that lead to chronic renal failure on the pathologic basis of a chronic sclerosing tubulointerstitial nephropathy (1). Whereas NPH is an autosomal recessive disease with onset of end-stage renal disease in adolescence, the term *medullary cystic kidney disease* is used for autosomal dominant variants with onset in adulthood. NPH represents the most frequent genetic cause of chronic renal failure in the first two decades of life (6–8). Diseases of the NPH-MCKD complex are characterized clinically by a defect in urinary concentrating capacity, anemia, and progression into terminal renal failure in adolescence or young adulthood (2,3). On renal histology, NPH-MCKD exhibits a characteristic triad of disruption of renal tubular basement membranes (TBMs) with tubular cell atrophy, tubulo-interstitial fibrosis, and cyst formation (4,5). Extrarenal manifestations have been described in association with recessive NPH, but are absent from MCKD. After the first descriptions of NPH by Smith and Graham (2) and Fanconi et al. (3), more than 300 cases have been reported (4,5), and the disease complex has been extensively reviewed (1,6–8). The term *nephronophthisis* is used for the recessively inherited variants of the complex, and the term *medullary cystic kidney disease* denotes the autosomal dominant variants.

ETIOLOGY AND MOLECULAR GENETICS

To date, no aberrations of chromosome number have been reported in any disease of the NPH-MCKD complex, with the single exception of a partial monosomy of chromosome 3 described by Sarles et al. (9). Because little insight had been available into the pathogenesis of NPH-MCKD, a positional cloning approach was used toward the identification of genes for the complex. After chromosomal localiza-

tion and gene identification by positional cloning, different disease variants can be distinguished on the basis of distinct gene loci (Table 35.1).

In juvenile NPH (NPH1), a gene locus has been mapped to chromosome 2q12.3 (10). This locus was further refined (11–16), and the gene (*NPHP1*) responsible for NPH1 was identified by positional cloning (17,18). Approximately 85% of patients with NPH1 carry large homozygous deletions of the *NPHP1* gene (19,20). Spontaneously occurring deletions of the *NPHP1* locus (20) as well as specific loss-of-function point mutations of *NPHP1* have been characterized (18,21,22). In a subset of patients with large deletions in *NPHP1*, there is an association with oculomotor apraxia type Cogan (23). Another subset shows an association with retinitis pigmentosa (22). No specific molecular characteristics have been detected that clearly identify the subgroup of NPH1 patients with extrarenal associations. The protein encoded by *NPHP1*, “nephrocystin,” contains an *src*-homology 3 (SH3) domain with high sequence similarity to the *c-crk* proto-oncogene. This suggests that nephrocystin may play a role as a docking protein in cell-cell or cell-matrix signaling processes, or both. Nephrocystin is highly conserved in evolution, including the nematode *Caenorhabditis elegans*.

Infantile NPH (NPH2) is a distinct disease entity, in which end-stage renal failure occurs within the first 3 years of life (24,25). NPH2 differs from other forms of NPH by the presence of enlarged kidneys and cortical microcysts and the absence of medullary cysts. Histologically, there is no disruption of TBMs. A gene locus (*NPHP2*) for NPH2 was localized to 9q22-q31 in one Bedouin kindred (26). Morphologically, the disease phenotype encompasses features of both NPH and autosomal recessive polycystic kidney disease (ARPKD). Recently, recessive mutations in the *inversin* gene have been identified as the cause of *NPHP2* (26a).

In NPH type 3 (NPH3), a third NPH gene locus (*NPHP3*) for “adolescent NPH” has been localized to chromosome 3q21-q22 (27), and several candidate genes

TABLE 35.1. DISEASE VARIANTS, GENE LOCI, AND EXTRARENAL MANIFESTATIONS OF THE NEPHRONOPHTHISIS-MEDULLARY CYSTIC KIDNEY DISEASE (NPH-MCKD) COMPLEX

Disease	Inheritance	ESRD (median in yr)	Chromosome	Gene (product)	Extrarenal association

MCKD2	AD	32	16p12	<i>UMOD</i> (Thamm-Horsfall protein)	Hyperuricemia

AR, autosomal recessive; AD, autosomal dominant; ESRD, end-stage renal disease; OMA, oculomotor apraxia type Cogan; SLS, Senior-Loken syndrome.

have been excluded (28,29). In addition, linkage to *NPHP3* was identified in families with Senior-Loken syndrome (SLS) (30).

The disease gene for NPH type 4 (NPH4) has been identified on chromosome 1p36 (31–33). The gene and its gene product nephroretinin are novel and highly conserved in evolution. Subsets of patients with mutations in the *NPHP4* gene exhibited SLS as well as Cogan syndrome (31,32).

The locus for MCKD type 1 (MCKD1) has been mapped to 1q21 (34–36). Microscopic and macroscopic pathology of dominant MCKD is indistinguishable from recessive NPH. The *MCKD1* locus has been refined to 4 centi-Morgan (cM) (37), and the gene (*NPR1*) for natriuretic peptide receptor-1 has been excluded as a candidate gene (38).

A second locus, MCKD type 2 (MCKD2), has been mapped to chromosome 16q12 (39–44). The *MCKD2* locus was refined to a 1.3-megabase (Mb) interval, demonstrating that it co-localizes with the locus for familial juvenile hyperuricemic nephropathy (45). The *UMOD* gene has very recently been identified as causative for MCKD2. There is evidence for existence of a third MCKD locus (46,47).

HISTOPATHOLOGY

Renal histopathology is similar in all variants of the NPH-MCKD complex, and has been described in 27 patients with NPH by Waldherr et al. (4). Kidney size is normal or moderately reduced. There is always bilateral renal involvement. Macroscopically, the kidney surface has a finely granular appearance, most likely due to the protrusion of dilated cortical collecting ducts. There are between 5 and approximately 50 cysts of 1 to 15 mm in diameter located preferentially at the corticomedullary border. The cysts arise primarily from the distal convoluted and medullary collecting tubules, as shown by microdissection (48), but may also appear in the papilla. Cysts are observed only in approximately 70% of autopsy cases and seem to arise late in the course of the disease (49). Therefore, the presence of cysts is not a prerequisite for diagnosis. No cysts are present in organs other than the kidney.

The histologic changes of NPH are characteristic but not specific for the disease and develop postnatally. Typically, there is pronounced thickening and multilayering of the TBM, which represents the most characteristic histologic feature of the NPH-MCKD complex (Fig. 35.1). By light microscopy, there appears to be a sequence of events. TBM disruption is followed by lymphocytic and histiocytic peritubular infiltration. Subsequently, atrophic or dilated and tortuous tubules develop predominantly at the corticomedullary junction. In advanced stages, the picture

FIGURE 35.1. Renal histology of nephronophthisis-medullary cystic kidney disease. Note the characteristic triad of tubular basement membrane disruption, tubular cell atrophy with cysts, and interstitial infiltration and fibrosis. Hematoxylin-eosin stain. (Courtesy of Prof. R. Waldherr, Heidelberg, Germany.)

merges into a diffuse, sclerosing, tubulo-interstitial nephropathy. TBM changes and cyst formation are most prominent in distal tubules, where cysts are lined with a single layer of cuboidal or flattened epithelium (50–53). Glomeruli demonstrate periglomerular fibrosis with splitting and thickening of Bowman's capsule. Glomerular obsolescence is only present in nephrons that have been destroyed by tubular alterations. Leakage of Tamm-Horsfall protein from damaged collecting tubules into the interstitium has been demonstrated (54). On transmission electron microscopy, there is thickening, splitting, attenuation, and granular disintegration of the TBM without clear stages of transition (55). A marked increase of microfilaments is seen at the base of the tubular epithelial cells.

PATHOGENESIS

Changes in tubular function characterize NPH-MCKD and include decreased urinary concentration ability and aminoaciduria. Proteinuria is a rare finding. Histologic changes (see Histopathology) also emphasize the central role of altered tubular structure in the pathogenesis. Cysts do not seem to be important for disease progression (56). Cohen and Hoyer (57) have hypothesized that NPH results from a primary defect of TBM matrix components. Such abnormalities lead to reduced mechanical compliance of the distal tubule with consecutive cyst development. In SLS, both renal and retinal changes are thought to be degenerative rather than dysplastic (58).

Recent data suggest that NPH results from a primary defect in tubular cell-cell contacts (adherens junctions) or tubular cell-matrix interactions, or both (59). The *NPHP1* gene product, nephrocystin, is a docking protein that binds through multiple domains of protein-protein interaction to proteins of cell-cell signaling and cell-matrix signaling at adherens junctions and focal adhesions, respectively. The src-homology-3 domain of nephrocystin binds to proline-rich peptides on the protein p130cas (c-crk-associated substrate), which is known to be a major mediator of adherens junction and focal adhesion signaling (60–62). Nephrocystin, in MDCK cells, co-localizes to adherens junctions with p130Cas and with the integral adherens junction protein E-cadherin (61). Expression of an exogenous nephrocystin construct with a defective SH3 domain in MDCK cells decreased electrical resistance (63). In addition, it has been shown that targeting of nephrocystin to adherens junctions of MDCK cells was dependent on the nephrocystin homology domain (NHD). The NHD represents the C-terminal half of nephrocystin, which by secondary structure prediction is featureless and exhibits no homology with any known proteins. Binding of nephrocystin to the actin-organizing proteins filamin A and B occurs via the NHD domain (63).

Nephrocystin binds to the signaling proteins p130Cas (64), focal adhesion kinase 2 (Fak2, *alias* Pyk2), and tensin, which are integral components of focal adhesion signaling

(62). Nephrocystin expression leads to phosphorylation of Pyk2 on tyrosine residue 402, which in turn activates the transcription factors ERK1 and ERK2 (extracellular signal-related kinases 1 and 2). Thus, nephrocystin helps recruit Pyk2 to cell-matrix adhesions, thereby initiating Pyk2-dependent signaling (62). Nephroretinin, the product of the *NPHP4* gene mutations that cause NPH4 and SLS type 4 (32), has been shown by co-immunoprecipitation to interact with nephrocystin (33). In patients with NPH, abnormal expression of the α_5 integrin fibronectin receptor has been demonstrated in renal TBMs (65). This leads to the hypothesis that renal tubular cells in NPH express α_5 integrin fibronectin receptor within focal adhesions as a compensatory mechanism for defective function of the α_6 integrin molecule. This, in turn, would lead to destruction of the TBM, which is a typical histologic finding early in the course of NPH. In addition, alterations in hepatocyte growth factor (66) and Pax2 (67) have been described in NPH.

ANIMAL MODELS

Further support for the hypothesis that a defect in tubular cell-cell or cell-matrix interaction is an important pathogenetic mechanism in NPH comes from the finding that targeted disruption of the mouse tensin gene leads to a renal phenotype closely resembling human NPH (68). Because tensin is a major component of focal adhesions, defects in these matricellular contact points might play a central role in the pathogenesis of NPH. Additional mouse models with features of NPH include kd/kd mice (69,70), angiotensin-converting enzyme knock-out mice (71), and Bcl-2 knock-out mice (72). Recently, strong synteny of the human *NPHP3* locus has been demonstrated to the locus *pcy* mouse whose renal histopathology closely resembles human NPH (73). Also, the RhoGDI- α -“knock-out”-mouse model exhibits a renal cystic phenotype, which shares certain histologic features with human NPH (74).

Recently, nephrocystin was shown to interact with inversin, the gene product defective in NPH2, and both nephrocystin and inversin have been demonstrated to co-localize to single cilia on MDCK cells (26a). This expression pattern provides a possible link between the pathogenesis of NPH and the pathogenesis of polycystic kidney disease because polycystin-1 and polycystin-2 have been shown to be expressed in cilia of renal epithelial cells, where they might exert a function as a mechanosensory renal tubular flow sensor (75).

CLINICAL PRESENTATION

Nephronophthisis

Diseases of the NPH-MCKD complex are characterized by the insidious onset of renal failure. In recessive NPH, the

FIGURE 35.2. Progression chart representing the average course of deterioration of renal function in 19 patients of eight families with juvenile nephronophthisis as proven by deletion detection. Median (solid line) and quartile (dashed lines) curves were calculated from 308 serial serum creatinine values. (From Hildebrandt F, Strahm B, Nothwang HG, et al. Molecular genetic identification of families with juvenile nephronophthisis type 1: rate of progression to renal failure. *Kidney Int* 1997;51:261–269, with permission.)

symptoms of polyuria, polydipsia, decreased urinary concentrating ability, and secondary enuresis are the earliest presenting symptoms in more than 80% of cases (5) and occur at 4 to 6 years of age. The symptom of starting to regularly drink at night, once children are 6 to 10 years old, is rather characteristic of NPH. Pallor, weakness, and generalized pruritus are also common. Anemia and growth retardation occur later and are usually pronounced. All affected individuals progress to end-stage renal disease and therefore require renal replacement therapy. In a study conducted in 19 patients of eight families with deletion-positive NPH1, a serum creatinine of 5.5 mg/dL was reached at an average age of 13.1 years of age (range, 7 to 25 years) (76). From this study, charts for prediction of progression toward renal failure were derived (Fig. 35.2). A difference in age of progression to renal failure was shown between patients with deletion-positive NPH1 and patients from a Venezuelan kindred of adolescent NPH (NPH3), in which median age of onset of end-stage renal disease was 19 years (27). If renal failure has not developed by the age of 25 years, the diagnosis of recessive NPH should be questioned. A high concordance rate (77) of the development of renal failure has been noted in monozygotic twins (78). A characteristic early finding in NPH is the decreased ability to concentrate the urine above 800 mOsm/kg of water after an 8-hour water deprivation test or vasopressin administration (1). Published reports do not adequately answer the question of whether renal sodium loss is a typical finding in the disease complex. Typically, edema, hematuria, and urinary tract infections are absent in NPH. Hypertension is rare, particu-

larly given the degree of chronic renal insufficiency. Due to the lack of specificity of the initial symptoms with absence of edema and hypertension, most children have already developed chronic renal failure when they first come to clinical attention. This presents a small but definite risk of sudden death from fluid and electrolyte imbalance. Disease recurrence has never been reported after renal transplantation for NPH (79,80).

Extrarenal manifestations occur only in recessive NPH, but are absent from MCKD. The most frequent extrarenal association is retinitis pigmentosa seen in SLS (81,82). SLS occurs in approximately 12% of all patients with the NPH-MCKD complex (83), which would be equivalent to 18% of all autosomal recessive cases. An early-onset and a late-onset type of SLS have been described. Intrafamilial dissociation of renal and eye involvement has never been demonstrated convincingly in any published pedigree. In the early-onset type, children present with coarse nystagmus and/or blindness at birth or within the first 2 years of life. Funduscopic alterations are present in all SLS patients by the age of 10 years. The late-onset form is characterized by development of blindness during school age after a variable period of night blindness. Other eye symptoms besides tapeto-retinal degeneration comprise nystagmus, myopia, coloboma of the chorioidea, strabismus, hyperopia, optical nerve atrophy, and amblyopia (5). Age of onset, symptoms, and histology of renal disease is identical to what is known from NPH patients without ocular involvement. In patients with recessive mutations in the *NPHP1* gene, no molecular difference in defects of the *NPHP1* gene have been identified that would distinguish patients with the purely renal form of NPH from patients with the association of NPH and retinitis pigmentosa. As in SLS, no specific molecular differences of the *NPHP1* gene distinguish patients with the purely renal form of NPH from patients with the association of NPH and Cogan syndrome (23). With ocular motor apraxia, infants with Cogan syndrome cannot move their eyes sideways, which leads to a pattern of compensatory head thrusts. This symptom resolves within the first few years of life. Additional forms of extrarenal involvement are congenital hepatic fibrosis (84,85) and developmental defects of bone, predominantly in the form of cone-shaped epiphyses (type 28 and 28A) (86). These can also occur in combination with retinal degeneration and cerebellar ataxia (87,88). In Joubert syndrome type B, a developmental disorder with multiple organ involvement, NPH occurs in association with coloboma of the eye or retinal degeneration; aplasia of the cerebellar vermis with ataxia; and the facultative symptoms of psychomotor retardation, polydactyly, and neonatal tachypnea/dyspnea (89,90). An NPH-like phenotype has also been observed in Sensenbrenner syndrome (91).

Medullary Cystic Kidney Disease

Goldman and associates were the first to report a large kindred with autosomal dominant, adult-onset MCKD (92).

This was followed by the publication of two large pedigrees from the United States by Gardner and Burke et al. (93,94). The dominant form of the disease complex differs from the recessive forms in that the onset of end-stage renal disease is in the third decade of life or even later (95), with an average at age 28.5 years (96). In MCKD, penetrance appears to be very high by the age of 45 years. The second feature distinguishing MCKD from NPH is the lack of extrarenal involvement in dominant disease, with the exception of hyperuricemia and gout. For MCKD1, an association of the renal symptoms with hyperuricemia and gout has been described (34,39), and MCKD2 has been found to localize to the same chromosomal region as familial juvenile hyperuricemic nephropathy (45).

EPIDEMIOLOGY

NPH and dominant MCKD seem to be distributed evenly among males and females. NPH has been reported from virtually all regions of the world (5). The incidence of the disease has been estimated to be 9 per 8.3 million patients in the United States (97) or 1 in 50,000 live births in Canada (98). The condition constitutes the most frequent genetic cause for end-stage renal disease in the first two decades of life and is a major cause of end-stage renal disease in children, accounting for 10 to 25% of these patients (5,99,100). In the North American pediatric end-stage renal disease population, pooled data indicate a prevalence of less than 5% (101,102). MCKD appears to be somewhat less infrequent.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Laboratory Studies

Patients with NPH are usually diagnosed when an increased serum creatinine value is detected during evaluation for nonspecific complaints. History generally reveals prolonged nocturia since school age. Specific gravity of a morning urine specimen will be low. Renal ultrasound will then corroborate the diagnosis (see Imaging) (Fig. 35.3), which can be subsequently confirmed by molecular genetic diagnostics if NPH1, NPH2, or NPH4 is present (<http://www.renalgenes.org>). A diagnostic algorithm for NPH has been suggested (76). Hematuria, proteinuria, and bacteriuria are uncommon in NPH. In rare cases when proteinuria is present, it is usually mild and of the tubular type. Laboratory studies are needed to assess the severity of renal failure and generally demonstrate elevated serum creatinine, blood urea nitrogen, phosphorus, metabolic acidosis, hypocalcemia, and anemia. In SLS, retinitis pigmentosa is diagnosed by its specific findings on ophthalmoscopy, including increased pigment, attenuation of retinal vessels, and pallor of the optic disk. If retinitis pigmentosa is

FIGURE 35.3. Renal ultrasound in nephronophthisis. Note loss of cortico-medullary differentiation, cysts at the cortico-medullary border of the kidney, and increased echogenicity, which renders the ultrasound pattern similar to the pattern of liver (arrow). In nephronophthisis, kidneys are typically normal in size. (Courtesy of Dr. U. Vester, Essen, Germany.)

present, electroretinography and electro-oculography can be used to evaluate severity. Retinal degeneration is characterized by a constant and complete extinction of the electroretinogram, preceding the development of visual and fundoscopic signs of retinitis pigmentosa (103). Ophthalmoscopy should be performed in any patient to evaluate for signs of SLS, as it may occur in patients with NPH1, NPH2, or NPH3. Liver function tests and hepatic ultrasonography are important to facilitate detection of patients with hepatic fibrosis.

Imaging

The most useful imaging technique in the NPH-MCKD complex is ultrasonography. Kidneys are of normal or moderately reduced size and show increased echogenicity (which renders the renal echo texture more echogenic than that of the liver), loss of cortico-medullary differentiation, and, in later stages, cyst formation at the cortico-medullary border of the kidneys (104) (Fig. 35.3). Garel et al. have seen medullary cysts in 13 of 15 children studied at the time of renal failure (mean age, 9.7 years) (105). Roentgenography contributes little to the diagnosis of the disease. Medullary cysts can sometimes also be demonstrated on magnetic resonance imaging or computed tomography (106,107). Histology is characteristic but not pathognomonic in NPH-MCKD because cysts may be absent, and tubulointerstitial disease can be relatively nonspecific. Renal biopsy can be circumvented as an initial procedure due to the availability of molecular genetic diagnostics in NPH1, NPH2, and NPH4. If molecular genetic diagnostics do not detect a molecular defect, the diagnosis can be based on the combined results of typical history, with polyuria, polydipsia, and anemia; the classical appearance of the kidney on

ultrasound; and renal histology. A thorough pedigree analysis should be documented for each of three successive generations to rule out autosomal dominant MCKD.

Molecular Genetic Diagnosis

Recently, molecular genetic diagnosis has become available for NPH1, NPH2, and NPH4 through identification of the respective genes (see Laboratory Studies) (<http://www.renalgenes.org>). A diagnostic algorithm should be followed to avoid unnecessary renal biopsy (76). Molecular genetic analysis is the only diagnostic procedure by which the diagnosis of NPH1, NPH2, and NPH3 can be made with certainty. However, due to the presence of additional loci for NPH, the lack of detection of mutations in the *NPHP1* gene does not exclude the diagnosis of NPH. If renal disease with features of the NPH-MCKD complex occurs in a person older than 25 years, its presence should be thoroughly sought in preceding generations. This may frequently result in detection of a pattern of autosomal dominant inheritance. In MCKD1, only indirect molecular genetic diagnosis by haplotype analysis is possible so far, as the respective genes have not yet been identified. For this purpose, a pedigree and blood samples from at least seven affected members and their first-degree relative will have to be obtained. In MCKD2, mutational analysis of the *UMOD* gene can be performed.

Molecular genetic testing should be performed only after consent within the guidelines of the National and International Societies for Human Genetics. Before genetic counseling, a thorough pedigree analysis to distinguish recessive (early-onset) from dominant (late-onset) disease is mandatory, and extrarenal organ involvement should be sought. Because nonsymptomatic potential carriers of recessive defects should not be examined by molecular genetic diagnostics, unaffected siblings younger than 13 years of age should be re-evaluated yearly for maximal urinary concentrating ability and renal ultrasound. If symptoms evolve and serum creatinine changes, molecular genetic diagnostics after informed consent is warranted to allow early prevention of complications from electrolyte disturbances, dehydration, anemia, and growth retardation. If a transplant recipient's renal histology suggests NPH and a living related donor is considered, molecular genetic diagnostics may help to exclude or detect renal disease within the family. Because there is genetic locus heterogeneity in diseases of the NPH-MCKD complex, prenatal diagnosis can only be performed by direct genetic testing. This requires a setting in which a specific mutation or deletion of the *NPHP1* gene has already been characterized in an affected sibling.

Differential Diagnosis

On histopathology, the NPH-MCKD complex has to be differentiated from other forms of interstitial nephropathies

such as chronic pyelonephritis or drug injury. In oligomeganephronic dysplasia, kidney size is reduced, and histology is distinct from NPH. The paucity of urinary abnormalities, the frequent lack of hypertension, normal kidney size, and the localization of renal cysts (if present) readily differentiate variants of the NPH-MCKD complex from recessive or dominant polycystic kidney disease. Finally, medullary sponge kidney (108) can easily be distinguished from the complex, as it does not usually lead to chronic renal failure and shows calcifications and calculi on renal ultrasound.

PROGNOSIS AND THERAPY

There is no specific therapy for NPH or MCKD. Therapy is symptomatic and is directed toward the treatment of hypertension, if present, as well as the correction of disturbances of electrolyte, acid-base, and water balance. Hypokalemia may contribute to polyuria, and oral potassium supplementation may alleviate this symptom. Metabolic acidosis should be corrected and osteodystrophy and secondary hyperparathyroidism treated with adequate calcium supplementation, phosphorus restriction, non-magnesium-containing phosphate binders, and vitamin D therapy. Anemia should be treated with iron supplementation and erythropoietin, and growth retardation may require administration of growth hormone if the diagnosis is made early enough for an intervention. Adequate nutrition should be maintained with the help of a dietitian. Psychological counseling of the patients is an integral part of therapy because of the poor self-image associated with growth retardation and to alleviate pressures resulting from the need to comply with complicated medications and dietary prescriptions. All patients require renal replacement therapy by dialysis and renal transplantation during childhood, adolescence, or, in dominant disease, in early adult life.

POLYCYSTIC KIDNEY DISEASE

**KATHERINE MacRAE DELL
RUTH A. McDONALD
SANDRA L. WATKINS
ELLIS D. AVNER**

Polycystic kidney disease (PKD) is a heritable disorder with diffuse cystic involvement of both kidneys without dysplasia (1). All forms of PKD can have clinical manifestations in infants and children. The major clinical entities of autosomal recessive PKD (ARPKD) and autosomal dominant PKD (ADPKD) have considerable overlap in clinical presentation and radiographic features. Glomerulocystic kidney disease (GCKD) can be a feature of several inherited, sporadic, and syndromal conditions, as well as an expression of ADPKD.

PATHOPHYSIOLOGY OF CYST FORMATION IN POLYCYSTIC KIDNEY DISEASE

In the 1990s, major advances were made in understanding the molecular genetics of PKD. Through a combination of positional cloning, direct sequencing, and use of the rapidly expanding genome databases, the major causative genes for both ADPKD (*PKD1* and *PKD2*) as well as ARPKD (*PKHD1*) have been identified (2–5) (Table 36.1). Details specific to the molecular genetics of ARPKD and ADPKD are addressed in the respective sections that follow. Despite the advances in the identification of the PKD genes and proteins, the precise mechanisms by which these gene defects result in cyst formation have not yet been fully elucidated. Considerable insights into the understanding of cyst formation pathogenesis have been provided by many studies of the cellular pathophysiology of PKD. These studies complement the advances made in the genetics of the diseases and may form the basis for future therapeutic interventions.

On the basis of extensive *in vivo* and *in vitro* studies using human tissue and animal models of PKD, at least three basic processes are operative in renal cyst formation and progressive enlargement: (a) tubular cell hyperplasia; (b) tubular fluid secretion; and (c) abnormalities in tubular extracellular matrix (ECM), structure, and/or function (6–

12) (Fig. 36.1). Delineating the extent to which these factors, singly or in combination, contribute to cyst development and enlargement in ADPKD and ARPKD remains an area of active investigation.

TUBULAR HYPERPLASIA

Tubular hyperplasia is a central morphologic feature of all described human renal cystic diseases (7,10). On the basis of mathematic modeling of cyst growth, it has been shown that tubular cell hyperplasia, with expansion of tubular wall segments to accommodate an increased cellular mass, is an essential factor in cyst formation and enlargement (12). Furthermore, cyst-derived epithelial cells from ADPKD and ARPKD demonstrate increased cell growth potential compared with controls (9,13). Unlike normal renal epithelia, ADPKD cystic epithelia respond to increased intracellular cyclic adenosine monophosphate (cAMP) with proliferation (14,15). Recent data demonstrate differences in cAMP-dependent protein kinase and proliferation in normal and polycystic kidney epithelia in a murine model of ARPKD (16). Additional *in vivo* data demonstrate increased renal tubular epithelial cell proliferation in both cystic and noncystic tubular epithelium from ADPKD and ARPKD kidneys (17).

A growing body of evidence implicates the epidermal growth factor receptor (EGFR) and its respective ligands, including epidermal growth factor (EGF) and transforming growth factor- α (TGF α), in proliferation of cystic epithelium. In both human ADPKD and ARPKD and in several murine models of PKD, cystic kidneys display characteristic alterations in EGFR expression. Quantitative abnormalities, including increased messenger RNA (mRNA) and protein, and qualitative differences, in particular, the appearance of “mislocalized” EGFR expressed on the apical surface of tubular epithelium, are seen (18–20). Apical EGFR is functional and capable of transmitting mitogenic signals *in vitro* (21).

TABLE 36.1. HUMAN POLYCYSTIC KIDNEY DISEASE GENES AND PROTEINS

Disease	Gene	Mode of inheritance	Chromosome location	Protein	Function/role
ADPKD	<i>PKD1</i>	AD	16p13.3–p13.12	Polycystin 1	?Receptor
ADPKD	<i>PKD2</i>	AD	4q21–q23	Polycystin 2	Cation channel
ARPKD	<i>PKHD1</i>	AR	6p21	Fibrocystin (polyductin)	?Receptor
GCKD (hypoplastic variant)	<i>HNF-1β</i>	AD	17cen–q21.3	Hepatocyte nuclear factor-1 β	Transcription factor

ADPKD, autosomal dominant polycystic kidney disease; ARPKD, autosomal recessive polycystic kidney disease; GCKD, glomerulocystic kidney disease.

Inhibition of EGFR function *in vitro* by treatment with either an inhibitor of tyrosine kinase function or a blocking antibody inhibits formation of proximal tubule cysts and significantly decreases explant growth and distal nephron differentiation (22,23). Additional support for a central role for EGFR in the pathogenesis of cyst formation is provided by *in vivo* data. Inhibition or reduction of EGFR function, either by treatment with a novel tyrosine kinase inhibitor (24) or genetic manipulation (25), leads to a marked reduction in cyst formation and enlargement in animal models. Of note, EGFR is part of a larger family of receptors (the c-ErbB/HER receptors), and there are limited data on the expression and function of these related receptors in PKD. C-ErbB2 (HER2) overexpression is seen in some cysts of ADPKD kidneys but not in late-stage ARPKD kidneys (26). However, late-gestation/early postnatal human ARPKD samples showed increased ErbB-2 expression compared with normal human fetal and postnatal kidneys (27). The functional significance of altered ErbB2 expression in PKD remains to be determined. Studies in a murine models of ARPKD demonstrate that ErbB4 expression increases with progressive cystic disease, whereas a decrease is seen in normal (noncystic) age-matched controls (28).

Abnormalities in EGFR ligand expression have also been reported in both ARPKD and ADPKD. Renal cyst fluid

contains EGF or EGF-like peptides in mitogenic concentrations, despite apparent reductions in EGF tissue expression (9,29–31). Treatment with EGF transiently improves renal function in murine models (32) but has no effect on histopathologic abnormalities, and continued EGF treatment worsens disease and shortens survival (33). TGF α and EGF are cystogenic in both murine embryonic organ cultures (34) and normal human kidney cells grown in a unique collagen gel system *in vitro* (35). ADPKD kidneys and cells derived from ADPKD have increased mRNA or protein levels of TGF α (18,36). Transgenic mice that overexpress TGF α develop cystic kidneys (37). Additional data suggest that inhibiting EGFR ligand function may also partially ameliorate disease. Treatment with an inhibitor of TGF α processing decreases cystic kidney disease in a murine model, although less effectively than EGFR inhibition. (38). Recent data demonstrate that combining inhibition of EGFR ligand function with EGFR inhibition may maximize therapeutic effectiveness while minimizing toxicity (39). Additional EGFR ligands, including amphiregulin and heparin-binding EGF, are abnormally expressed in PKD and may prove to also have a role in proliferation of cystic epithelium (40).

Epithelial cell hyperplasia may be mediated not only by factors that control cell proliferation (such as activation of the EGFR/EGFR ligand axis) but also by alterations of

FIGURE 36.1. Pathophysiology of renal cyst formation. Studies in a variety of experimental models and human diseases implicate three major factors in renal cyst formation and progressive enlargement. Normal renal tubular absorptive epithelium can become cystic if (a) hyperplasia, localized to a distinct nephron segment, requires accommodation of an increased cell mass; (b) secretion, as opposed to absorption, leads to the net accumulation of intratubular fluid with low (or no) afferent tubular flow or efferent tubular obstruction; or (c) extracellular matrix (ECM) abnormalities alter the epithelial microenvironment such that abnormal cell-matrix interactions result in abnormal epithelial hyperplastic and secretory activity. These processes are not mutually exclusive, may reflect some characteristics of undifferentiated epithelium, and probably operate in concert during renal tubular cyst formation and progressive enlargement.

normal apoptotic mechanisms. Emerging evidence suggests that dysregulation of apoptosis, or the balance between apoptosis and proliferation, may contribute to the progression of ARPKD and ADPKD (41–43). Evidence in support of a role for apoptosis in the pathogenesis of PKD is provided by studies of various components of the apoptosis pathway, including several caspases and the bcl-2/bax family of proteins. Ali et al. (44) demonstrated a six- to sevenfold increase in caspase 3 and 4 activity in kidneys of *cpk* mice, a murine model of ARPKD. Unlike previous studies in which increased apoptosis was found in renal tubules, this study localized apoptosis primarily to the interstitium with little evidence of cell death in either cystic or noncystic tubules. Increased rates of apoptosis in a murine model of ARPKD were demonstrated in the interstitial cells surrounding cystic collecting tubules (CT) when compared to interstitial cells surrounding normal CT (45). Ecker et al. (46) have reported upregulation of caspase 3 in the Han/SPRD rat, a model of ADPKD.

Data regarding the antiapoptotic molecule, bcl-2, and its related proteins are somewhat conflicting. Mice deficient in bcl-2 develop severe multicystic hypoplasia characterized by proximal and distal tubular cysts and hyperproliferation of epithelium and interstitium (47). In contrast, increased bcl-2 expression has been demonstrated in animal models of both ARPKD and ADPKD (42,44,46). Of note, in one study, decreased expression of another antiapoptotic molecule, Bcl-X(L), suggests that the balance (rather than the absolute expression levels) of different components of the pro- and antiapoptotic pathways may be the critical factor in the development of cystic kidney disease (46). Abnormalities in the apoptotic pathway may also directly or indirectly impact on the normal cell-cell interactions (48–51). Alterations in apoptosis may also be mediated, in part, by abnormal expression of proto-oncogenes, in particular, *c-myc*. In both murine ARPKD and human ADPKD kidneys, *c-myc* is overexpressed in cystic tissue (42,52–54) and associated with a marked increase in both tubular cellular proliferation and apoptosis (55–57). Other genes, such as *pax2*, may also have a role in apoptosis in PKD (58).

FLUID SECRETION

In addition to epithelial hyperplasia, some data demonstrate a significant role for tubular fluid secretion in cyst formation and progressive enlargement (7,9,10). On a theoretical basis, tubular fluid secretion, in addition to hyperplasia, fulfills the requirements for cyst growth predicted by mathematic modeling (12). Cellular proliferation without tubular secretion would produce solid tumor nests of tubular cells rather than cysts. In ADPKD, more than 70% of cysts have no afferent or efferent tubular connections, and thus must fill by transepithelial secretion of solute and fluid (59,60).

Studies in a variety of model systems have evaluated possible mechanisms involved in PKD tubular fluid secretion. Work to date has identified a major role for cAMP-mediated chloride secretion during *in vitro* cyst formation (14,61–63). A putative lipid “secretagogue” isolated from cyst fluid of human ADPKD kidneys was found to stimulate intracellular cAMP and stimulate fluid secretion (64).

Additional *in vivo* and *in vitro* studies demonstrate a potential role for quantitative and qualitative alterations in Na⁺-K⁺-adenosine triphosphatase (ATPase) activity in mediating tubular fluid secretion in cystogenesis (65–70). In proximal tubules, it has been postulated that increases in Na⁺-K⁺-ATPase activity modulate tubular secretion and cyst formation through activation of a secondary active transport process (e.g., tubular organic anion secretion), which osmotically obligates intratubular fluid accumulation and cystogenesis (65–67). In collecting tubules, apical, as opposed to normal, basolateral cell surface Na⁺-K⁺-ATPase expression may mediate basal to apical vectorial sodium transport and thus directly drive fluid secretion in affected nephron segments in ADPKD and ARPKD (68–70). Apical Na⁺-K⁺-ATPase expression in murine ARPKD may reflect an exaggeration of the normal developmental profile of collecting tubule sodium pump expression (70). This, in association with the relatively undifferentiated ultrastructural and genetic profile of cystic tubular epithelium (11), suggests that abnormalities in the differentiation program of cystic tubular cells may be basic to the process of cystogenesis. Of note, however, apical Na⁺-K⁺-ATPase expression has not been a consistent finding in all PKD models (71).

It has been hypothesized that cAMP-stimulated chloride and fluid secretion occurs through activity of the cystic fibrosis transmembrane receptor (CFTR), the chloride channel mutated in cystic fibrosis (72). CFTR Cl⁻ channels exist in apical membranes of ADPKD and are major mediators of forskolin-stimulated chloride and fluid secretion by epithelial cells of human polycystic kidneys *in vitro* (72,73). CFTR is required for cAMP-dependent *in vitro* renal cyst formation (74). *In vivo* support for a role of CFTR in the pathogenesis of PKD was provided in a report of an ADPKD kindred in which cystic fibrosis was also present. Patients with ADPKD and CF (which results in a loss of functioning CFTR) were found to have less severe disease than those with ADPKD who did not have CF (75). However, a subsequent report failed to demonstrate such a protective effect (76). Because of the phenotypic variation within ADPKD families, it was difficult to determine if CFTR was, in fact, functioning as a significant modifying disease gene, or if the phenotypic differences were due to other modifying factors. This question was recently directly addressed in a murine model of ARPKD. Mice homozygous for the CFTR mutation (CFTR “knock-out” mice) were bred with the *bpk* mouse, a murine model of ARPKD. No improvement in cystic disease in resultant double mutants was found (77). These data suggest that CFTR activity does not play a central role in the pathogenesis of ARPKD, and that it is not necessary for cyst growth or

enlargement. Chloride channels (other than CFTR) or abnormalities in amiloride-sensitive sodium transport may have roles in fluid secretion in cystic ARPKD epithelium (77). The role of CFTR in ADPKD remains to be determined.

EXTRACELLULAR MATRIX

The third major mediator of tubular cyst formation and progressive enlargement is abnormalities involving the ECM (7,9–11,68). Diffuse ultrastructural and biochemical abnormalities of tubular basement membranes have been demonstrated in human and animal models of PKD. Specific defects in the biosynthesis and transport of sulfated proteoglycans have also been identified (9,11,78–80). Renal tubular cells from patients with ADPKD grown *in vitro* produce increased amounts of ECM when compared with normal tubular epithelia (81).

It does not appear that matrix abnormalities mediate simple changes in the compliance or viscoelastic properties of tubular basement membranes, leading to distention under normal intratubular pressures (82). Rather, it would appear that altered matrix composition modulates cyst formation through altered tubular epithelial cell matrix interactions. These interactions regulate various aspects of cell growth, cell surface protein expression, cytodifferentiation, and gene expression (8,11). Conceivably, altered epithelial cell matrix interaction could modulate or amplify the processes of hyperplasia and fluid secretion discussed above.

Experimental evidence suggests that matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases may play a role in progression of disease in PKD (83–85). Elevated serum levels of MMPs, including MMP-1, tissue inhibitor of metalloproteinase-1, and MMP-9, have been demonstrated in a cohort of ADPKD patients when compared to normal controls (86). Although it is difficult to determine whether abnormal MMP expression is a reflection of a primary abnormality or a secondary effect, recent data suggest that inhibition of MMPs may have an impact on the severity of disease in animal models of ADPKD and ARPKD (38,87). Overexpression of other basement membrane, ECM, and cell adhesion components have also been demonstrated in PKD. Tenascin, an ECM glycoprotein, is abnormally expressed in human ARPKD and ADPKD fetal kidneys and in a murine model of ARPKD (88,89). Irregular expression of α -integrin subunits has also been demonstrated in fetal PKD kidneys (90).

Abnormal processes within the interstitium leading to interstitial inflammation and fibrosis contribute to progression in all cystic kidney diseases. For instance, monocyte chemoattractant protein-1, a chemoattractant and mediator of interstitial inflammation, is upregulated in ADPKD rats (91). In addition, oxidant stress is increased and protective effects of antioxidants decreased in the kidneys of animal models of both ARPKD and ADPKD models (92). Abnormalities in steroid and lipid metabolism have also been demonstrated in murine ARPKD (93–95). Angiogenesis may have a role in the pathogenesis of

cyst expansion in ADPKD as well. When cysts enlarge, their nutrient requirements may outstrip their blood supply in a manner analogous to tumor progression in cancer. Recent studies demonstrate increased vascularity around cysts and evidence of ongoing angiogenesis (96). Whether angiogenesis has a role in cyst expansion in ARPKD remains to be determined.

Theories of renal cyst formation generated in experimental models are not mutually exclusive and are largely complementary. A mutant gene or environmental factors can directly lead to alterations in tubular epithelial metabolism. Some environmental factors can modulate the expression of a mutant gene or directly lead to tubular cell death. An induced alteration of tubular cell metabolism may subsequently lead directly to the abnormal sorting of transport proteins, growth factor receptors, or cell adhesion molecules, with resultant abnormal ECM production or production of growth factors mediating tubular hyperplasia. Induced changes in transtubular transport energetics may lead to hyperplasia secondary to increased transmembrane sodium flux, whereas programmed cell death may lead to further hyperplasia secondary to tubular regeneration. Alterations in sodium- or chloride-mediated transtubular transport could lead to net intratubular fluid accumulation. Subsequent increases in tubular wall tension may further increase stimulation of epithelial proliferation, leading to tubular hyperplasia. The presence of a particular pattern of tubular hyperplasia, along with necrotic debris from cell death, may lead to partial tubular obstruction and further increases in tubular wall tension. Finally, abnormal ECM production could alter the epithelial microenvironment, further increasing hyperplasia and transtubular transport, thereby contributing to cyst formation and progressive cyst enlargement. Such an overall hypothetical schema of renal cyst formation appropriately focuses future investigations on the molecular mechanisms by which tubular epithelial hyperplasia is controlled and tubular metabolism is altered in both experimental and human cystic diseases.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

ARPKD is an inherited disorder characterized by cystic dilations of renal collecting ducts and varying degrees of hepatic abnormalities consisting of biliary dysgenesis and periportal fibrosis (97). ARPKD has alternatively been referred to as *infantile PKD*. This term, however, is generally no longer used because of recognition that the disease can present any time from the prenatal period through adolescence. Furthermore, other forms of PKD, including ADPKD, can present in the neonatal period (98).

Epidemiology, Genetics, and Prenatal Diagnosis

Based on published reports, ARPKD occurs at an incidence of 1 in 10,000 to 1 in 40,000 pregnancies (99,100). The fre-

quency of the gene in the population is estimated to be approximately 1 in 70 (101). However, the exact incidence is unknown, because published reports vary in the populations studied (e.g., autopsied patients vs. survivors), and affected children may die in the perinatal period without a definitive diagnosis. With improvements in neonatal management leading to improved survival rates, as well as formal reporting mechanisms (such as a newly developed ARPKD registry), more accurate incidence rates may become established. Consistent with autosomal recessive disease, heterozygotes (carriers) are unaffected. The recurrence risk for subsequent pregnancies is 25%, and unaffected siblings have a 66% risk of being a carrier for ARPKD (97). Males and females are affected equally, and ARPKD affects all racial and ethnic groups.

In 1994, Zerres et al. (102) localized *PKHD1* to a region on chromosome 6p21. To date, all kindreds with features typical of ARPKD have demonstrated linkage to the 6p21 locus (101). Thus, there is no evidence for genetic heterogeneity in patients with the typical features of ARPKD. However, a kindred with features of ARPKD as well as additional extrarenal abnormalities, including skeletal and facial anomalies, has recently been described, and linkage to the 6q21 locus excluded (103).

In 2002, the gene for ARPKD was cloned by two independent research groups (4,5). *PKHD1* spans a region of more than 400 kilobases (kb) of genomic DNA and contains at least 66 and possibly over 86 exons. The mRNA for the gene is produced as multiple alternative transcripts. The primary transcript of approximately 14 to 16 kb in length encodes a novel protein termed *fibrocystin* (alternatively named *polyductin*). Fibrocystin is a large protein with a predicted molecular weight of 447 kDa, similar in size to polycystin 1. The precise function of fibrocystin is unknown at present. However, protein modeling suggests that it is a membrane-bound protein with immunoglobulin-like properties, including the presence of several TIG/IPT domains (immunoglobulin-like folds shared by plexins and transcription factors). These motifs suggest that fibrocystin may function as a receptor. Several alternative transcripts described lack the transmembrane domain, suggesting that (if translated) they may result in production of secreted forms of fibrocystin as well (5). Northern analyses and reverse transcriptase-polymerase chain reaction demonstrate that *PKHD1* is expressed in both fetal and adult kidney, and to a much lesser extent in liver, pancreas, and lung. Expression in other organs was not seen (4,5).

Prenatal diagnosis may be made in a family with at least one known affected child through the technique of linkage analysis (see Chapter 18). Linkage analysis uses analysis of polymorphic markers that flank the location of a known disease gene to "track" the disease. This technique can also be used to identify whether the unaffected sibling is a carrier of the disease. In informative families, the accuracy of prenatal diagnosis using linkage analysis was greater than 95% (104). An accurate genetic diagnosis, however, is criti-

cally dependent on confirming the diagnosis of ARPKD in the affected sibling (104). Diagnostic criteria as modified from Dell and Avner and Zerres et al. (97,105) include

1. Ultrasonographic features typical of ARPKD, including enlarged, echogenic kidneys with poor corticomedullary differentiation
2. One or more of the following:
 - a. Absence of renal cysts in both parents when ages older than 30 years
 - b. Clinical, laboratory, or radiographic evidence of hepatic fibrosis
 - c. Hepatic pathology demonstrating characteristic ductal plate abnormality
 - d. Previous affected sibling with pathologically confirmed disease
 - e. Parental consanguinity suggestive of autosomal recessive inheritance

Although *PKHD1* has been cloned and identified, direct mutation analysis is currently not available for clinical purposes due to its large size and the presence of multiple exons.

Pathogenesis

Despite recent advances in the understanding of the molecular genetics of ARPKD, the pathogenesis remains undefined. Analysis of *PKHD1* mutations in 14 probands demonstrated six truncating and 12 missense mutations throughout the gene (4). Eight affected patients were actually compound heterozygotes. However, because the actual function of fibrocystin has not been determined, the mechanism by which abnormalities in this protein produce renal cysts and hepatic fibrosis is unknown. It is anticipated that with greater understanding of the function of fibrocystin, genotype-phenotype studies in the future may be informative.

Insights provided by several murine models of ARPKD (Table 36.2), especially those for which the causative gene has been identified, may shed light on the pathogenesis of this disease.

The *pck* rat developed spontaneously in a colony of Sprague-Dawley rats and was initially reported to be a model of ADPKD in 2001 (106). Affected animals develop progressive cystic enlargement of the kidneys after the first week of life. Renal cysts develop from several nephron segments, including loop of Henle, distal tubules, and collecting ducts. Liver cysts are evident at birth. In addition, *pck* rats develop a liver lesion consistent with Caroli's disease (congenital hepatic fibrosis) (107). Segmental and saccular dilatation of the intrahepatic bile ducts is first seen *in utero* and progresses with age. A ductal plate abnormality with overgrowth of portal connective tissue is seen. Proliferative activity of biliary epithelium is increased compared to controls. Rates of apoptosis in biliary epithelium are lower than controls in the first week of life, then increase to greater than controls after 3 weeks (107). The severity of the kidney disease was found to be greater in males,

TABLE 36.2. MURINE MODELS OF POLYCYSTIC KIDNEY DISEASE (PKD)^a

Species	Gene/mutant	Mode of inheritance	Chromosome location	Protein product	Function/role/comments
Mouse	Bpk	AR	10	Bicaudal	RNA-binding protein
	Cpk	AR	12	Cystin	Cilia-associated protein
	Inv	AR	4	Inversin	Role in left-right axis development
	Jck	AR	11	Nek8	Function unknown
	Kat	AR	8	Nek1	Function unknown
	Jcpk	AR	10	?	Allelic with <i>bpk</i>
	orpk (TgN737)	AR	14	Polaris	Role in left-right axis development; cilia-associated protein
Rat	Pcy	AR	9	?	Phenotype consistent with ADPKD
	Han-SPRD(Cy)	AD	5	?	Function unknown
	Pck	AR	9	Fibrocystin (polyductin)	Some clinical features of ADPKD
	Wpk	AR	5	?	Function unknown

AD, autosomal dominant; AR, autosomal recessive.

^aKnock-out models for PKD are not included in this listing.

although the liver disease did not show a similar pattern. Although phenotypically similar to both ADPKD and ARPKD, the *pck* trait, which is inherited in an autosomal recessive fashion, was found to map to an area syntenic with the region for human ARPKD. Subsequent genetic studies led to the cloning of human *PKHD1* (see Epidemiology, Genetics, and Prenatal Diagnosis) and confirmed that the mutation in *pck* mice lies within the region of *PKHD1*, and, thus, *pck* is a genetic model for human ARPKD (4). The question of why this model displays features of both ARPKD and ADPKD remains unanswered at this time.

Recent studies of two murine ARPKD models, *cpk* and *orpk*, suggest that ARPKD may result, in part, from disruptions in some function or functions of cilia present on the apical surface of the renal tubule cells. The *cpk* (congenital PKD) mouse model arose from a spontaneous mutation in C57BL/6J mice (108) and is the most well-studied ARPKD murine model. *Cpk* mice appear normal at birth, but starting at postnatal day 5, progressive proximal tubule and collecting duct cystic enlargement occurs with prominent tubular cell hyperplasia (109,110). Animals die in renal failure at 3 to 4 weeks of age with massively enlarged kidneys (109,111,112). Although the renal abnormalities are consistently present on a number of genetic backgrounds, the liver phenotype and other extrarenal manifestations are highly influenced by genetic background effects (95,112,113).

By positional cloning, the *cpk* gene was localized to mouse chromosome 12, and the gene was recently cloned and identified (114). The *cpk* gene has five exons spanning approximately 14.4 kb of genomic DNA. The complementary DNA is 1,856 base pairs (bp) in length, and at least two splice variants are recognized. The mutation in *cpk/cpk* mice is a 12-bp and 19-bp deletion, resulting in a frame shift. The gene encodes a novel protein, cystin. Expression

analysis demonstrates that cystin is a novel cilia-associated protein that localizes to the apical cilia of renal tubule epithelia (114). However, the mechanism by which the mutation results in polycystic kidneys remains unknown.

The *orpk* model (Oak Ridge PKD) arose as the result of large-scale mutagenesis project (6). The mutated gene, Tg737, has been localized to chromosome 13 (115). Mice homozygous for the *orpk* mutation develop polycystic kidneys and hepatic fibrosis. Functional correction ("rescue") of the renal but not the liver disease was accomplished by expression of cloned wild-type Tg737 in affected *orpk* animals (116,117). The Tg737 protein product, polaris, appears to have a key role in development, in particular left/right axis determination (118). Of note, however, polaris has also been found to localize to the cilia of Madin-Darby canine kidney cells, and cells derived from collecting tubules of *orpk* mice demonstrate abnormal cilia development (119). Whether the emerging "cilia hypothesis" of PKD pathogenesis will have relevance to human ARPKD (or to ADPKD) remains to be determined.

The pathogenesis of congenital hepatic fibrosis in ARPKD remains obscure. Increased expression of both the profibrotic molecules TGF β and thrombospondin-1 have been demonstrated in human ARPKD livers (120). The study of the hepatic abnormality in the *pck* rat (discussed above) or the *bpk* mouse model of ARPKD may provide additional insights. The latter arose from a spontaneous mutation in an inbred colony of Balb/c mice and results, apparently, from a mutation in a gene encoding the mRNA and targeting protein, bicaudal C (121,122). These animals develop massively enlarged kidneys and die of renal failure in the first month of postnatal life. In addition to cystic kidneys, *bpk* animals develop hepatic abnormalities consisting of proliferative intrahepatic biliary tract ectasia and nonobstructive dilation of the common bile duct (121). Biliary epithelial hyperplasia, like renal tubule hyperplasia

sia in this model, appears to be mediated by a mitogenic cycle driven by the TGF α /EGF/EGFR axis (123). In addition, both the renal and hepatic diseases of these mice are ameliorated by treatment with EGFR tyrosine kinase inhibitor (24).

Pathology

In the infant and young child, the kidneys are reniform but grossly enlarged. Pinpoint opalescent dots are visible on the capsular surface and correspond to cystic cortical collecting ducts (124). Microscopically (Fig. 36.2A), the cysts are usually smaller than 2 mm in size ("microcysts") and have been shown by microdissection (125), histochemical, and immunologic studies (126–128) to be dilated collecting ducts lined

by low columnar or cuboidal epithelium. The glomeruli and other tubular structures appear to be decreased in number because of marked collecting duct ectasia and interstitial edema. In fetal kidneys, proximal tubular cystic lesions have also been identified (129), but are largely absent by birth. The pelvicaliceal system and renal vessels appear normal. Unlike ADPKD, in which the cysts become discontinuous with the tubule, the cystic tubules in ARPKD are fusiform in shape and remain in contact with the urinary stream. Microdissection studies and scanning electron microscopy demonstrate that obstruction of urinary flow is not a component of ARPKD (124,125). With increased patient survival, the development of larger renal cysts, interstitial fibrosis, and hyperplasia produces a pattern more like ADPKD (see later) (130). Gang and Herrin (131) described increasing fibrosis and inflammation in later specimens from patients who had typical collecting duct microcysts during infancy. It is unclear whether the fibrotic change is part of natural course of disease or caused by environmental factors such as toxins, hypertension, end-stage renal failure, or hemodialysis.

Some degree of biliary dysgenesis and hepatic fibrosis is always present in ARPKD. Even in the newborn, the liver demonstrates microscopic abnormalities. The classic liver lesion shows a typical ductal plate abnormality consisting of portal fibrosis surrounding increased numbers of hyperplastic, ectatic biliary ducts with normal hepatocellular histology (130,132). With time, hepatomegaly and portal hypertension become evident in many patients. Intrahepatic biliary ectasia may result in macrocysts and dilation of extrahepatic bile ducts sometimes resulting in an enlarged gallbladder (133) or choledochal cysts (134). Although the combination of collecting tubule and biliary ectasia with periportal fibrosis is unique to ARPKD, portal fibrosis and bile duct proliferation may be associated with other types of renal diseases, including ADPKD (135,136) and cystic dysplasia.

Clinical and Radiographic Features

Historically, ARPKD was originally separated into four distinct clinical entities based on age at presentation and relative degrees of renal and hepatic involvement (137). Although such distinctions present a useful clinicopathologic classification, there is often much overlap between the degrees of renal and hepatic involvement present. ARPKD and congenital hepatic fibrosis with renal tubular ectasia are likely different phenotypic manifestations of the same genetic abnormality (138). In contrast to ADPKD (see later), intrafamilial variability in ARPKD disease phenotype is reportedly small (139).

The majority of patients with ARPKD present in infancy (105,140). In a series of 33 patients with ARPKD who survived the neonatal period, 11 were diagnosed in the first days of life, 18 between 1 and 18 months, and four between 6 and 11 years of age (141). Rare presentations late in adolescence and even into adulthood have been described (142). With the widespread use of prenatal ultrasound, many patients

FIGURE 36.2. Kidney histology and ultrasonography of autosomal recessive polycystic kidney disease (ARPKD). **A:** Microscopic appearance of a kidney biopsy from a 7-month-old with ARPKD demonstrating multiple radially oriented collecting tubule cysts extending from the medulla to the peripheral cortex. A small amount of residual parenchyma contains glomeruli and noncystic tubules situated between the cysts. No glomerular cysts or signs of renal dysplasia are present. (Hematoxylin and eosin stain; original magnification $\times 1$.) (Specimen kindly provided by Dr. Steven Emancipator, Case Western Reserve University.) **B:** Renal ultrasound (right kidney) of a newborn with ARPKD demonstrates the typical appearance of echogenic, enlarged kidneys (length = 6.5 cm; normal for age = 4.48 ± 0.62 cm) with poor corticomedullary differentiation.

with ARPKD are detected *in utero*. Prenatal ultrasound may demonstrate the findings of oligohydramnios, large renal masses, or absence of fetal bladder filling (143).

At birth, patients usually present with large, palpable flank masses that may be large enough to complicate delivery. Urine output is usually normal; however, oliguric acute renal failure may occur (99). In that subset of patients, increased urine output and a corresponding improvement in renal function may be seen after improvement in respiratory status (144). Most patients (70 to 80%), even without overt renal failure, have evidence of impaired renal function in the newborn period (105,145). However, death from renal insufficiency is uncommon in that age group (137). Hyponatremia related to a urine dilution defect is often present, but usually resolves over time (105,140). Metabolic acidosis has also been reported (140,145). As might be predicted from a pathologic process that affects the collecting tubule, most patients have a urinary concentrating defect and symptoms of polyuria and polydipsia (130,140,141,145).

Hypertension, which may be severe, is common in both infants and children and can be a presenting feature (99,130). It can be present in patients with normal renal function and eventually affects almost all children with the disease (145). Although the pathophysiology of hypertension in ARPKD is not clearly understood, peripheral vein renin levels are not usually elevated (140,141). If not aggressively managed, hypertension can result in cardiac hypertrophy and congestive heart failure (CHF), which may be a factor in progression of underlying renal insufficiency.

Pulmonary insufficiency, as manifest by respiratory distress, is a major cause of morbidity and mortality in neonates with ARPKD. Pulmonary hypoplasia, resulting from oligohydramnios, may be complicated by respiratory embarrassment due to massively enlarged kidneys. Additional causes of respiratory distress in these patients include pneumothorax and atelectasis, or a variety of common neonatal pulmonary disorders such as surfactant deficiency, bacterial pneumonia, meconium aspiration, or persistent fetal circulation. Severely affected infants may demonstrate the full components of the oligohydramnios sequence, including pulmonary hypoplasia, abnormal extremities, and characteristic Potter's facies (146). Infants with true pulmonary hypoplasia often die soon after birth secondary to pulmonary insufficiency.

A subset of patients with ARPKD may present as older infants with abdominal enlargement secondary to enlarged kidneys or hepatosplenomegaly without the full spectrum of clinical symptoms outlined above. Although hepatic involvement is invariably present microscopically, it may be clinically absent in at least 50 to 60% of neonates (105). In contrast, the small percentage of patients who are diagnosed with ARPKD as older children often present primarily with signs and symptoms of hepatic fibrosis and portal hypertension, including hepatosplenomegaly (101,147). In fact, cystic renal disease in these patients may be detected as

an incidental finding during abdominal imaging. Liver synthetic function is usually intact.

By ultrasonography, infants have characteristic large echogenic kidneys with poor corticomedullary differentiation (Fig. 36.2B). Macrocysts are usually not present, although they may be seen with worsening disease. Renal macrocysts smaller than 2 cm and increased medullary echogenicity have been reported in older children (130). In a study of sonographic features of adult patients with ARPKD, Nicolau et al. (148) noted the presence of multiple small cysts in a normal-sized kidney, increased cortical echogenicity, and loss of corticomedullary differentiation as common features.

Ultrasonographic findings in the liver include hepatomegaly, increased echogenicity, and poor visualization of the peripheral portal veins. Reversal of normal venous flow by Doppler study, suggestive of portal hypertension, may be seen. Macroscopic liver cysts are uncommon (149), although choledochal cysts have been reported (134). A smaller percentage of patients have overt evidence of biliary duct dilatation (Caroli's disease).

Diagnosis

Prenatal diagnosis may be suggested by antenatal ultrasound findings of enlarged kidneys, oligohydramnios, and absence of urine in the bladder (150). Sonographic features of ARPKD may present in the second trimester but usually are not apparent until after 30 weeks' gestation (151). Both false-positive and false-negative results have been reported (152). However, with newer high-resolution obstetric ultrasonography, it is probable that diagnostic sensitivity and detection rates will improve. Wisser et al. (153) reported a case of a fetus with pathologically confirmed ARPKD who demonstrated echogenic, normal-sized kidneys at 15 ± 4 weeks' gestation. Although less common, ADPKD in infants may have an antenatal sonographic appearance that is difficult to distinguish from ARPKD (98). Increased maternal alpha fetoprotein and amniotic fluid trehalase activity have been identified as potential markers for ARPKD, but neither has been confirmed as specific or sensitive for disease detection *in utero* (154,155).

Although specific clinical diagnostic criteria for ARPKD have not been established, the clinical constellation of bilateral palpable flank masses, respiratory distress, and history of oligohydramnios and hypertension in an infant is suggestive of ARPKD. Diagnostic criteria modified from Zerres et al. (105) are outlined in Epidemiology, Genetics, and Prenatal Diagnosis. For the minority of children who present later in childhood, renal ultrasonographic features may be less reliable. Kidneys are echogenic and large, but massive enlargement is generally not seen. The echogenicity of the kidneys in older children may be similar to that of ADPKD, and macrocysts more typical of ADPKD may be present (156). As noted, in the subset of patients who

present as older children and adolescents, hepatic abnormalities are often the prominent presenting feature.

Magnetic resonance imaging (MRI) shows enlarged kidneys with hyperintense T2-weighted signals. A characteristic hyperintense, linear radial pattern in the cortex and medulla representing microcystic dilatation has been described on RARE-MR urography (17). Radionuclide studies, such as renal technetium-99m DMSA and liver HIDA imaging, may also aid in establishing the diagnosis of ARPKD (158). As noted previously, genetic testing is available at present only for families that already have an affected child. With the recent cloning and ongoing characterization of *PKHD1*, however, it is possible that direct mutation analysis may become available in the future.

Treatment and Complications

Survival of neonates with ARPKD has improved in concert with overall advances in neonatal artificial ventilation and intensive care. It is currently impossible to predict which neonates with ARPKD requiring immediate artificial ventilation have critical degrees of pulmonary hypoplasia incompatible with survival (1,145). In some instances, severe pulmonary distress may be secondary to potentially reversible fluid overload, neonatal lung disease, or restricted diaphragmatic motion secondary to massively enlarged kidneys. In selected cases, some authors have advocated continuous venovenous hemofiltration, unilateral nephrectomy, or bilateral nephrectomy coupled with peritoneal dialysis to allow optimal ventilation and thereby assess the long-term pulmonary prognosis of the patient (159–161).

Infants and young children without significant renal insufficiency must be followed closely. Because most children with ARPKD have a concentrating defect, significant dehydration is a particular risk during intercurrent illnesses that may increase insensible water loss (e.g., through fever), limit free water intake (e.g., through nausea), or increase extrarenal water loss (e.g., through vomiting or diarrhea). In patients with severe polyuria, thiazide diuretics may be of benefit to decrease distal nephron solute and water delivery. Supplemental bicarbonate therapy is required for those with metabolic acidosis.

Hypertension can be difficult to manage and may require multiple medications (99). Despite the fact that peripheral vein renin values are not usually elevated in hypertensive ARPKD patients, most patients respond well to angiotensin-converting enzyme (ACE) inhibitors, which are the treatment of choice. If additional medications are required, calcium channel blockers, β -blockers (in those without chronic lung disease or signs of CHF), and diuretics are appropriate choices.

Urinary abnormalities may be present or develop over the course of disease. Pyuria is a relatively common finding and can be seen in the absence of demonstrable bacteriuria or documented infection (130). Urinary tract infection (UTI)

has been reported as a common complication in at least one uncontrolled series (145), but it is unclear whether children with ARPKD truly have an increased incidence of upper or lower UTIs when compared with appropriately age-matched controls. Thus, as in any child with an abnormal urinalysis, clinical features and appropriately obtained urine cultures must guide antibiotic therapy. If a UTI is documented, a voiding cystourethrogram and renal ultrasound should be performed to determine the possible presence of vesicoureteral reflux and rule out obstruction or superimposed upper tract structural abnormalities (131). Microscopic or gross hematuria and proteinuria may also be seen on occasion (99,145). In infants and children who develop renal insufficiency, the consequences of chronic renal failure (e.g., growth failure, anemia, and osteodystrophy) become apparent as renal function decreases.

Difficulties in feeding, even in patients without renal insufficiency, are often noted. This is presumably due to the presence of enlarged kidneys or liver, or both, interfering with normal gastrointestinal function. Supplemental feeding via nasogastric or gastrostomy tubes may be required to optimize weight gain and growth.

Dialysis or transplantation, or both, are indicated when children with ARPKD reach end-stage renal failure. Peritoneal dialysis in ARPKD is often successful even in the face of large kidneys and hepatosplenomegaly. Kidney transplantation offers definitive renal replacement therapy in children with ARPKD. Successful kidney transplantation prolongs survival and often accelerates growth and development in young uremic children. Nephrectomies may be indicated before, or at the time of, transplantation to control hypertension and/or to permit room for transplant placement in patients with massively enlarged kidneys.

With improved patient survival and advances in renal replacement therapy, hepatic complications progressively dominate the clinical picture of many patients with ARPKD (105,147,162). The older child may have complications of hepatic fibrosis and portal hypertension (130,137). These include hepatosplenomegaly, bleeding esophageal varices, portal thrombosis, and hypersplenism causing thrombocytopenia, anemia, and leukopenia.

A serious and potentially lethal complication in ARPKD patients with significant hepatic involvement is bacterial cholangitis, which has been reported as early as a few weeks of age (145). Fever or elevation of liver function tests at any time should lead to the suspicion of cholangitis and result in complete evaluation and appropriate antimicrobial therapy. However, patients may not present with the classic clinical findings of cholangitis, and the diagnosis should be strongly considered in ARPKD patients with unexplained recurrent sepsis with gram-negative organisms (163).

In infants and children with hepatic involvement, close monitoring for complications of portal hypertension is mandated, particularly as typical liver function tests (e.g., serum albumin and transaminases) are normal. Yearly ultrasonogra-

phy to determine changes in liver or spleen size or identify portal hypertension by reversal of venous flow is noninvasive and may be of value. Endoscopy is necessary to evaluate suspected esophageal varices that can be treated by sclerotherapy or banding before life-threatening hemorrhage. Periodic monitoring should reveal the hematologic profile of hypersplenism. Sudden worsening of anemia should raise the possibility of occult gastrointestinal blood loss secondary to splenic sequestration or variceal bleeding. Portosystemic shunting may be indicated in some cases (140,164). However, Tsimaratos et al. (165) recently reported recurrent hepatic encephalopathy leading to death in two children with portocaval shunts who progressed to ESRD. It has been hypothesized that loss of kidney function results in impaired clearance of toxins that are shunted from the liver. This finding has raised concerns about whether liver transplantation should be considered as an alternative therapy for ARPKD patients with portal hypertension being evaluated for possible shunts. With the increased use and successful outcome of living-related partial liver transplants, this option may be more viable than previously considered. In fact, sequential liver and kidney living-related transplants have recently been reported (166).

In addition to the significant medical problems noted, the psychosocial stresses of ARPKD on the patient and family can be overwhelming. Social support measures and periods of respite care are often necessary. A team approach using the skills of pediatric nephrologists in concert with other pediatric medical subspecialists, specialized nurses, dietitians, social workers, psychiatrists, and other support staff is required to provide optimal comprehensive care for children with ARPKD.

Prognosis

Prognosis is difficult to assess, although it is now clear that survival of all but the most severely affected neonates who demonstrate pulmonary hypoplasia is possible (1,130). Published reports vary with respect to neonatal survival rates, but suggest that approximately 70% of patients survive the newborn period with aggressive neonatal intensive care (140,145,147). Actuarial survival rates calculated from birth for 55 patients with ARPKD referred to a pediatric tertiary care center revealed that 86% were alive at 3 months, 79% at 1 year, 51% at 10 years, and 46% at 15 years (140). Calculations based on patients who survived to 1 year of age showed that 82% were alive at 10 years and 79% at 15 years (140). Patients who survive the neonatal period usually have a decreased glomerular filtration rate (GFR), but studies have demonstrated subsequent improvement in renal function consistent with some degree of continued renal maturation (99). Indeed, GFR may be normal by 12 months of age, and those patients with neonatal presentations who survive past 1 month of age generally do not develop renal insufficiency until late childhood

or early adolescence. Life-table analysis of a cohort of patients surviving the first month of life revealed a renal survival of 86% at 1 year and 67% at 15 years (147).

As noted, with the success of renal transplantation and improved survival of patients with ARPKD, morbidity and mortality of complications related to congenital hepatic fibrosis are more common and clinically relevant. Khan et al. recently reported the outcome of 14 patients with ARPKD after renal transplantation (167). With a mean follow-up of 14 years, the study showed 1- and 5-year patient survival rates of 93% and 86%, respectively. Overall, 36% of patients died, and in four of five of those patients, death was directly related to complications of hepatic disease. In those who survived, 63% had portal hypertension. Thus, complications of CHF developed in almost 80% of patients after renal transplantation for ARPKD.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD is a systemic inherited disease characterized by progressive cystic enlargement of the kidneys coupled with variable extrarenal manifestations involving the gastrointestinal tract, cardiovascular system, reproductive organs, and the brain (168). ADPKD has alternatively been called *adult PKD*. However, this term is a misnomer because ADPKD has been diagnosed in the fetus, newborn, and older child and adolescent (99,141,169,170).

Epidemiology, Genetics, and Prenatal Diagnosis

ADPKD is the most common inherited human kidney disease and occurs at an incidence of approximately 1 in 1000. It affects all races, and males and females are both affected; however, the phenotype may be more severe in males (171). ADPKD is a rare cause of ESRD in the pediatric population, but accounts for approximately 5 to 10% of ESRD in adults. The two major disease-causing genes are *PKD1* and *PKD2*. In the general population, *PKD1* accounts for approximately 85% of ADPKD, with *PKD2* accounting for the remaining 15%. A third ADPKD locus (*PKD3*, or non-*PKD1* or *PKD2*) has been suggested by a few case reports (172–174). Mutations in *PKD1* and *PKD2* produce similar phenotypes; however, the age of onset of cystic disease, hypertension, and renal insufficiency is delayed in the latter (175–177).

PKD1 has been mapped to chromosome 16p13.3 (178). Its exact location was pinpointed because it was bisected by a chromosome translocation; members with the balanced exchange had PKD (2). Like *PKHD1*, *PKD1* is a very large gene, spanning 53 kb of genomic DNA, with 46 exons encoding a 14.5-kb transcript (179). A portion of the gene is duplicated in the proximal portion of chromosome 16.

The gene encodes a large 4304–amino acid protein product, polycystin-1, a novel 460-kDa protein that is predicted to be involved in cell-cell or cell-matrix interactions (180).

PKD2 has been linked to chromosome 4q13-q23 and was cloned and identified in 1996 (3,181). The *PKD2* gene expresses a 5.4-kb mRNA, which encodes a 968–amino acid polypeptide, polycystin-2 (3). Polycystin-2 has been recently shown to be a nonselective voltage-gated ion channel (182).

Prenatal genetic diagnosis is available for “informative” families with suitable pedigree structures using the technique of linkage analysis (141). In addition, techniques for accurate mutation screening by DHPLC for both *PKD1* and 2 are currently being refined, but the mutation detection rate has not been fully determined (168,183). As with any prenatal genetic testing, the question arises as to whether termination of an affected pregnancy is an acceptable option for couples, especially given the wide clinical spectrum and the treatable nature of the disease (i.e., treatment of chronic renal failure and dialysis or transplantation) (184). In the majority of kindreds, fetuses harboring an ADPKD mutation will not show any obvious renal or other abnormalities, and patients may be asymptomatic for two to three decades. Potential benefits of prenatal diagnosis, either by genetic testing or ultrasonography, include early genetic counseling, careful preparation for management of an affected fetus at and after delivery (in the case of a fetus with clinical evidence of disease), and close follow-up of an affected child. However, diagnosing ADPKD years before the onset of symptoms has potential major adverse outcomes that must be considered, including psychological stress on the child and family and potential discrimination in employment, financial, and insurance matters (185,186). Surveys of ADPKD families indicate that only 4% would consider pregnancy termination if the fetus were affected (187). Genetic linkage analysis for *PKD1* or *PKD2* is not routinely performed for prenatal diagnosis in the United States or Europe (188).

Pathogenesis

Despite the extraordinary advances in the 1990s in defining the genetics of ADPKD, the precise mechanisms by which mutations in the *PKD1* and *PKD2* genes result in the formation of renal and extrarenal cysts is unknown (189).

PKD1

Polycystin-1 possesses a large extracellular domain, transmembrane spanning regions, and an intracellular carboxy-terminus (190,191). The extracellular domain is dominated by the presence of 16 copies of an 80–amino acid immunoglobulin-like repeat, the PKD domain. Although the function of this domain is unknown, PKD domains in several other proteins are located on their extracellular surface and are highly glycosylated. The amino-terminal domain of polycystin 1 also contains a leucine-rich repeat, an LDL-A domain, an REJ domain,

and a calcium-dependent lectin domain. The presence of the REJ domain is particularly intriguing because it may be a potential regulatory site for the molecule (192). These structural components, taken as a whole, suggest that the extracellular portion of polycystin-1 may be capable of binding an as yet undefined ligand (191). Polycystin-1 is anchored to the cell membrane by 7 to 11 putative transmembrane domains. The carboxy-terminus (intracellular portion) of polycystin 1 contains several phosphorylation sites and a putative coiled-coil domain, which has been demonstrated to interact *in vitro* with the carboxy-terminus of the protein product of the *PKD2* gene (193,194). These numerous features suggest that polycystin-1 is a large, multifunctional molecule that is involved in carbohydrate motif recognition, ligand binding, and Ca^{2+} regulation. It may engage in cell-cell and/or cell-matrix interactions, which regulate signal transduction pathways mediated by cell-surface protein-protein interactions.

Defining the expression pattern of polycystin-1 has been hampered, in part, by discrepancies in the reported tissue and cellular localization of the protein. This is likely due to issues related to antibody specificities (191). However, it appears that polycystin-1 is expressed in multiple tissues, including kidney, liver, pancreas, intestine, and cerebral blood vessels (all sites of cystic changes in ADPKD), as well as in the lung, testis, and other tissues (195–198). The protein is overexpressed in the cystic epithelium of ADPKD kidneys (195), and these cells remain phenotypically immature. Immunohistochemistry studies located the protein in renal tubular epithelial cells of human fetuses, diminishing in abundance with age but with persistent expression into adulthood (195,199), suggesting a role in renal development. Further evidence of the importance of polycystin-1 in development was provided by knock-out mouse models in which a variety of mutations have been introduced that result in the loss of functional polycystin. Animals lacking polycystin-1 die *in utero* or soon after birth and demonstrate abnormalities in multiple organs, including the heart, blood vessels, kidneys, and pancreas (200–202). The subcellular localization of polycystin-1 in renal tubular epithelium appears to shift during development from a predominantly basal staining in fetuses to apical/lateral staining in adult kidneys (203).

Although the precise function of polycystin-1 is unknown, emerging data regarding its binding partners may shed light on its role in normal and cystic kidney epithelium. As noted, polycystin-1 has recently been shown to bind polycystin-2 at the coiled-coil domain. Polycystin-2 is a cation channel, and it has been suggested that polycystin-1 plays a role in regulation of that channel. Results of immunohistochemistry and functional studies suggest that polycystin co-localizes with and forms large complexes with a wide variety of proteins, including those involved with cell-matrix interactions (such as $\alpha_2\beta_1$ integrins and focal adhesion complexes) as well as cell-cell interactions (including E-cadherin- β -catenin complexes) (191,203,204). Additional data demonstrate that polycystin-1 induces resistance to apoptosis and spontaneous tubulogenesis

in Madin-Darby canine kidney cells (205). Nickel et al. (206) reported that the C terminal of polycystin-1 triggers branching morphogenesis and migration of inner medullary collecting duct cells and supports *in vitro* tubule formation. These studies suggest a potential connection between altered polycystin-1 function and cystogenesis (204).

ADPKD is characterized by considerable intrafamilial phenotypic variation. By analyzing two closely linked polymorphic markers within the *PKD1* gene, Qian et al. revealed that the renal epithelia from single cysts are monoclonal, containing only the mutant haplotype (207). A subsequent study by Brasier et al. (208) confirmed these findings. These two studies suggest that patients harboring a germline mutation in the one allele of a PKD gene undergo a somatic "second hit," which results in the loss of the remaining normal allele and genetic homozygosity in the affected cell or cells. These studies provide a possible molecular explanation for both the focal nature of cysts (only 1 to 2% of tubules may be cystic in ADPKD) as well as the phenotypic variability within families harboring the same germline mutation.

To date, multiple different mutations throughout the *PKD1* gene have been identified in patients with ADPKD, with no particular "hot spots" for mutations identified (209). The majority of mutations are predicted to result in truncation of the polycystin-1 protein. Of note, several kindreds were identified that had tuberous sclerosis coexistent with severe childhood-onset ADPKD. These kindreds were subsequently found to have large deletions in an area containing both *PKD1* and adjacent tuberous sclerosis 2 (*TSC2*) genes, resulting in a contiguous gene syndrome (210). Another kindred has been identified exhibiting cosegregation of an overlapping connective tissue disorder and ADPKD 1 (211). Although consistent genotype/phenotype correlations have not been demonstrated to date, Rosetti et al. (212) recently found that even in light of significant inter- and intrafamilial phenotypic heterogeneity, patients with mutations in the 5' region of *PKD1* had significantly more severe disease than those with mutations in the 3' portion of the gene. The location, rather than the type of mutation, was found to be the factor that correlated with the onset of ESRD.

PKD2

Polycystin-2 contains six transmembrane regions and has intracellular domains at both its amino- and carboxy-termini. The transmembrane regions share significant homology with voltage-activated $\text{Ca}^{2+}/\text{Na}^{+}$ channels, which suggests that polycystin-2 could be a channel protein. The carboxy-terminus contains an EF-hand domain that binds Ca^{2+} . The carboxy-terminus also contains several potential phosphorylation sites. By immunostaining of human and murine renal tissues, polycystin-2 was found to be widely expressed and was present in the kidney. The highest levels of expression within the kidney were the thick ascending

loop of Henle and the distal convoluted tubule, where it localized to the basolateral plasma membrane of kidney tubular epithelium (213). Polycystin-2, like polycystin-1, is expressed in the vasculature, including porcine aorta and normal human elastic and intracranial arteries (214).

Recently, Koulen et al. (182) confirmed by single channel studies that polycystin-2 (a member of a subfamily of the transient receptor potential channel superfamily) functions as a calcium-activated intracellular ion release channel *in vivo* and hypothesized that PKD results from the loss of regulation of an intracellular calcium release signaling pathway.

Multiple mutations in *PKD2* have been identified in affected families, and as with *PKD1*, most families have unique mutations (215). These mutations truncate polycystin-2 and appear to be loss-of-function mutations. Similar to *PKD1*, mice homozygous for targeted mutations in *PKD2* die *in utero* or soon after birth and demonstrate cardiac defects in septum formation as well as kidney and pancreatic cysts (216). Although there is significant genetic and phenotypic variability in patients with PKD2 mutations, it has recently been suggested that certain clusters or groups of mutations may be associated with more severe clinical disease (217).

Pathology

In ADPKD (Fig. 36.3A), kidney cysts form in glomeruli and all tubular segments, although the proximal tubule is a common site of involvement. Glomerular cysts may be seen as a component of ADPKD or as a separate disease entity. Unlike ARPKD, in which the cystic dilatations are fusiform in nature and remain in connection with the tubular lumen, in ADPKD the enlarging cysts eventually "pinch off" and become disconnected from the tubular lumen and urinary space.

Clinical and Radiographic Features

Patients with ADPKD are usually diagnosed and become symptomatic in adulthood. However, children affected with ADPKD may become symptomatic or be diagnosed as an incidental finding. The clinical spectrum of pediatric ADPKD ranges from severe neonatal manifestations indistinguishable from ARPKD to renal cysts noted on ultrasound in asymptomatic children (1,98,99,141,169). The diagnosis of ADPKD has been made *in utero* by ultrasound, and affected newborns can present with Potter's phenotype and die from pulmonary hypoplasia. Affected infants can be born with large hyperechoic kidneys with or without macrocysts and variable degrees of renal insufficiency. As with ARPKD, hypertension can present during the newborn or infant periods and is common even in pediatric patients with normal renal function (141,169,218). Hypertension appears to be mediated by reduced renal blood flow, activation of the renin-angiotensin system, and increased sodium retention (219,220).

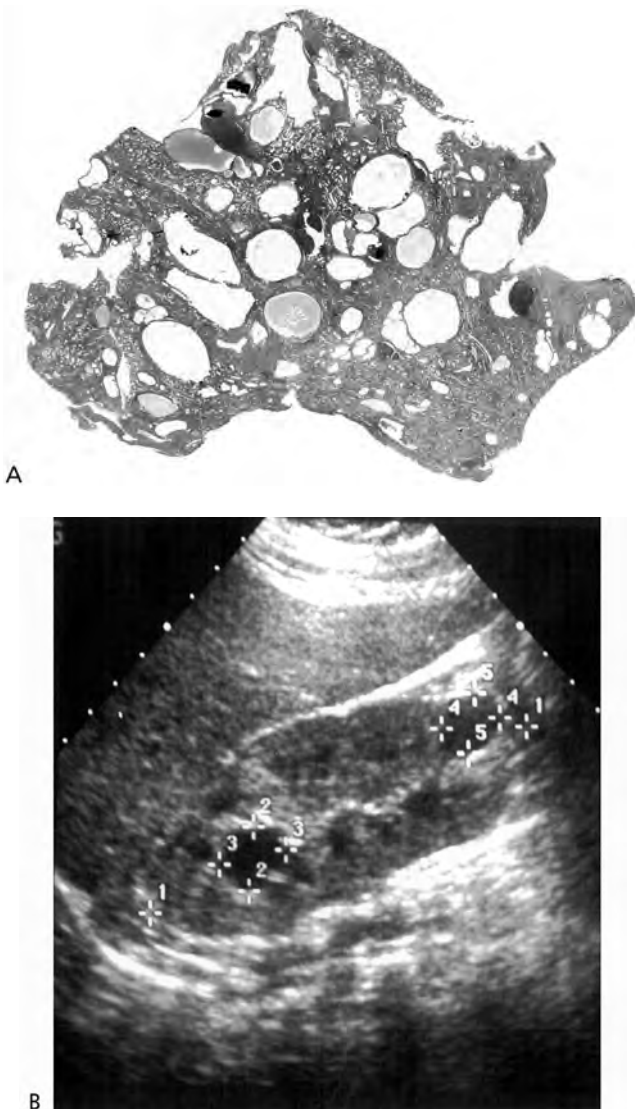

FIGURE 36.3. Kidney histology and ultrasonography of autosomal dominant polycystic kidney disease (ADPKD). **A:** Microscopic appearance of a kidney biopsy from an adult with ADPKD demonstrating multiple thin-walled cysts of varying sizes involving different nephron segments. Focal hemorrhage is noted within some cysts. (Hematoxylin and eosin stain; original magnification $\times 1$.) (Specimen kindly provided by Dr. Steven Emancipator, Case Western Reserve University.) **B:** Renal ultrasound (right kidney) of a 13-year-old with ADPKD demonstrates several cysts (the largest measuring 1.5 cm \times 1.6 cm). The left kidney also had several cysts not present on an ultrasound 2 years before this study. Kidneys are 11.4 cm (right) and 11.7 cm (left) (normal for age = 9.79 cm \pm 1.5 cm).

In older children, presenting symptoms include abdominal pain, palpable abdominal masses, gross or microscopic hematuria, UTIs, abdominal or inguinal hernias, and hypertension. The occurrence of gross hematuria after seemingly minor trauma to the flank region should raise the possibility of ADPKD (or obstructive uropathy). Renal insufficiency is rare but can occur in childhood (169,221). A concentrating defect may be present, leading to polyuria and polydipsia, but this is more consistently a clinical feature of ARPKD

than ADPKD (145,222). Renal infections are common in adult patients with ADPKD and can be a presenting feature in the affected infant and child (141). Potential complications of pediatric renal infection include pain, perinephric abscess, hemorrhage, chronic pyelonephritis, sepsis, and death. It has been reported that the risk of pyuria and bacteriuria in ADPKD increases progressively from 2% in the second decade to 32% in the seventh decade.

In families with known ADPKD, asymptomatic children may be identified by ultrasonographic examination (Fig. 36.3B) (169). In children at risk, the presence of even single cysts in normal-sized kidneys is highly predictive of future development of symptomatic ADPKD (169). In children with ADPKD, renal involvement is commonly asymmetric (including asymmetric kidney enlargement) and is unilateral in a small minority (223). The extrarenal features of ADPKD seen commonly in adults (224,225) are only rarely seen in pediatric patients. When present, they can sometimes help to clinically differentiate ADPKD from ARPKD. Although hepatic, pancreatic, or ovarian cysts are rarely detected before puberty, they have been reported in affected children in the first year of life (226,227). Liver cysts in children are not generally associated with pain, infection, and hepatomegaly as noted in adult patients. Congenital hepatic fibrosis with severe portal hypertension in children and adults with ADPKD has been reported (135,136). The presence of pancreatic cysts has been found exclusively in *PKD1* patients, and they do not appear to contribute to morbidity or mortality (228). Similarly, although rarely detected before the age of 20 years, there are reports of clinically significant cerebral vessel aneurysms in pediatric ADPKD patients (229). The increased incidence of cardiac valvular abnormalities, such as mitral valve prolapse, commonly seen in the adult ADPKD population (224,230), has also been reported in children with ADPKD (231). There have also been several reports of endocardial fibroelastosis in children with ADPKD (232,233). Increased left ventricular mass and Doppler abnormalities consistent with early diastolic dysfunction has been reported to occur in normotensive children and young adults with ADPKD (234). An increased risk of coronary aneurysms has been reported in adults, but no pediatric cases have been reported to date (235).

Diagnosis

There are no specific clinical diagnostic criteria for children with suspected ADPKD. Prenatal diagnosis is suggested by antenatal ultrasound findings of enlarged kidneys with or without cysts and absent urine in the bladder. However, these findings may not be evident until the third trimester. (236,237). In families not known to have ADPKD, diagnosis of ADPKD in the fetus or young child can lead to the diagnosis of ADPKD in asymptomatic adults after parental radiographic studies. Because simple cysts are extremely rare in childhood (238), the finding of even one renal cyst should alert the clinician to the possibility of ADPKD. In

pediatric patients with a 50% risk of ADPKD, the finding of one cyst is considered diagnostic. Ultrasonographic screening of asymptomatic pediatric patients at risk is an issue of some debate. Because cysts may not be evident until adulthood, the finding of a negative ultrasound may be falsely reassuring (239). Conversely, there may be significant psychosocial and financial implications of a diagnosis of ADPKD in an asymptomatic patient who may not develop clinical signs of disease for several decades. If ADPKD is clinically suspected, family members (including the grandparents if the parents are younger than 30 years) should be considered for radiographic evaluation (240). As noted previously, genetic testing in the form of linkage analysis is available. Direct mutation screening is available, but accuracy has not been fully determined, particularly for *PKD1* mutations. An up-to-date listing of laboratories currently performing genetic testing for PKD for clinical or research purposes is available at www.geneclinics.org.

Treatment and Complications

At present, there are no disease-specific therapies for ADPKD. However, a number of interventions have been shown to slow progression of disease in animal models, including dietary flaxseed, soy protein or protein restriction, sodium citrate, caffeine restriction, and EGFR tyrosine kinase inhibition (241–247). To date, none has proven to significantly alter the clinical course of disease in humans (248).

Asymptomatic children at risk for ADPKD should be followed annually for the development of hematuria, hypertension, or palpable abdominal masses. Any of these findings is an indication for ultrasound examination and close clinical follow-up. Renal insufficiency and ESRD in the child with ADPKD is treated with standard medical management of chronic renal failure and renal replacement therapy as indicated (see Chapters 70 through 74). As with other forms of chronic kidney disease, hypertension management is essential in slowing progression to ESRD in PKD. It has been suggested that ACE inhibitors, angiotensin II receptor antagonists, and chymase inhibitors may offer benefits in addition to antihypertensive effects (249–251); however, this has not been confirmed. A longitudinal study of children with ADPKD treated with ACE inhibitors is currently under way, and a larger scale, multicenter National Institutes of Health trial is being planned to address the question in adults. Of note, reversible acute renal failure may be precipitated by ACE inhibitors in ADPKD patients with diminished kidney function and massive cystic involvement (252).

A number of renal and extrarenal complications may occur in patients with ADPKD. In pediatric patients, gross hematuria and UTI, in particular, cyst infection, are the more common. Flank pain may also be seen. Renal calculi, a common finding in adult patients with ADPKD (253), are rare in childhood. Although no data are available regarding specific

features of UTIs or renal cyst infections in pediatric ADPKD patients, it is reasonable to assume that their clinical course is similar to that described for adult ADPKD patients (254). Sterile pyuria is common, and appropriate cultures are needed to determine whether an infection is present. Most renal infections are caused by gram-negative enteric organisms and can be complicated by cyst infection. Eradication of cyst infections is often difficult, despite *in vitro* sensitivity of responsible organisms; thus, the use of antibiotics that penetrate cyst walls is mandated (255). Antibiotics that generally penetrate cyst walls include ciprofloxacin (256) and sulfonamides. Penicillins and aminoglycosides (standard treatments for UTI) are generally ineffective in treating cyst infection (255,257). Aggressive antibiotic treatment is critical because recurrent or ineffectively treated UTIs appear to be a definite risk factor in progression of renal disease (258). Occasionally, cyst drainage may be required to control infection, and MRI may be a useful modality for identifying which cyst is infected (259). In extreme cases, nephrectomy may be indicated (255). Prophylactic antibiotics should be considered before the introduction of any urinary tract instrumentation in children with ADPKD.

Episodes of flank pain are unusual in pediatric patients with few cysts. With progressive disease, however, particularly in certain adolescents, flank pain may become a more prominent feature. In the majority of instances, the painful episodes resolve within a few days. Pain relief is accomplished with acetaminophen or brief courses of oral narcotics. Nonsteroidal antiinflammatory agents should be avoided. Long-term narcotic use is discouraged due to abuse potential. Nonpharmacologic interventions and referral to a chronic pain management center should be considered (260). In cases of severe pain, laparoscopic cyst decortications may be performed (261).

As noted, hepatic cysts are rare in the pediatric population. Patients with hepatic cysts may develop cyst infections. Typically, these infections present as right upper quadrant pain, fever, leukocytosis, and a rise in liver enzymes (262). Antibiotics alone may be ineffective, and the addition of surgical drainage is generally recommended (263). Intestinal diverticular disease (224) has not been reported in pediatric ADPKD patients.

Routine cerebral arteriography is not recommended for screening of possible intracranial aneurysms in pediatric ADPKD patients. The optimal age for screening and the natural history of aneurysm development are unknown in pediatric patients. Although aneurysms are found in patients with negative family histories, intrafamilial clustering of aneurysms has been reported in ADPKD populations (264,265). Thus, it may be reasonable to consider investigation of children with positive family histories of cerebral aneurysms or those with symptoms such as headache. Use of magnetic resonance angiography may permit effective, noninvasive detection of significant aneurysms (266). Even in adults, however, routine screening by magnetic resonance

angiography is generally reserved for those patients with symptoms or a positive family history.

Prognosis

The prognosis of ADPKD presenting in the fetus or neonate is uncertain, given the small number of cases and short follow-up periods reported. Although neonatal ADPKD was once thought to have an ominous prognosis, small series suggest that it may be compatible with favorable long-term patient and renal survival (141,145,169,236). Prognosis in the older child generally better. Progression to ESRD in childhood is rare in this latter group, and the majority maintain normal renal function through adolescence (267). However, progression of disease does occur during childhood, especially in children with evidence of severe renal enlargement at a young age (267). Proteinuria has been identified as a potential early marker of severe cystic disease in children (268). Approximately 50% of adult patients with ADPKD progress to ESRD. On average, patients with PKD1 typically progress at an earlier age, with a mean age at ESRD of 53.0 years, whereas those with PKD2 progress to ESRD at a mean age of 69.1 years (176). In light of the significant inter- and intrafamilial phenotypic heterogeneity, it is difficult to predict at what age a given patient with ADPKD will develop renal failure.

Once renal insufficiency occurs, GFR typically decreases at a rate of approximately 2 to 3 mL/min/1.73 m² per year, with GFR declining at a faster rate in men than women (171). Decline in GFR correlates with an increase in renal cyst volume and a decrease in parenchymal volume as determined by CT (269,270). Moreover, increased renal volume growth rate positively correlates with decline in renal function in patients with early disease and preserved GFR (171). Thus, renal volumes and rate of renal growth may be markers for disease progression in ADPKD.

GLOMERULOCYSTIC KIDNEY DISEASE

The term *glomerulocystic kidney disease* (GCKD), coined by Taxy and Filmer in 1976, is used to describe the morphologic appearance of glomerular cysts, which occur in a variety of conditions (271). GCKD was first described clinically by Ross in 1941 (272). GCKD can be categorized into three major groups: (a) nonsyndromal heritable and sporadic forms of GCKD, (b) GCKD as the major component of heritable malformation syndromes, and (c) glomerular cysts as a minor component of abnormal or dysplastic kidney disease, some of which are syndromal.

Epidemiology, Genetics, and Prenatal Diagnosis

Primary GCKD with isolated renal involvement can be an autosomal dominant disease, a familial hypoplastic disease,

or a sporadic occurrence. Reports exist of infants with GCKD who have family members affected with ADPKD, which raises the question of whether these two entities are different expressions of the same genetic defect. Sporadic GCKD and GCKD occurring in the context of familial ADPKD are clinically, sonographically, and histopathologically indistinguishable. The sporadic cases are conceivably new mutations of the same disease.

Reports of kindreds with GCKD suggest autosomal dominant inheritance in some cases (273). Carson et al. described a family of 18 first-degree relatives with six affected individuals (274). Their review of the literature for reported cases revealed several other such families, although sporadic cases constitute the bulk of patients with this diagnosis. An apparently distinct entity is hypoplastic GCKD, a dominantly inherited disease reported in only a few families (275,276). These kidneys, apart from being glomerulocystic, are small, and imaging studies show abnormal pyelocaliceal anatomy. Recently, mutations in the hepatocyte nuclear factor-1 β gene were identified in four kindreds with this hypoplastic GCKD variant (277).

GCKD can be associated with such syndromes as orofaciocigital syndrome type I (278), brachymesomelia-renal syndrome (279), trisomy 13 (280), Majewski-type short rib polydactyly syndrome (280), and Jeune syndrome (281) and can be seen as a component of the renal abnormalities in nephronophthisis (282). Although tubular sclerosis generally includes tubular cysts, glomerular cysts can be present (282). Glomerular cysts also occur as a minor component in several other syndromes, including Zellweger cerebrohepato-renal syndrome (280,281) in which the cysts are typically present but rarely serious enough to affect renal function.

Other syndromes that may be associated with glomerular cysts as a component of renal dysplasia include Meckel syndrome, glutaric aciduria type II, and renal-hepatic-pancreatic dysplasia (282). The glomerular cysts are minor in comparison with the dysplastic components of the renal disease, although they may be present in sufficient numbers to create confusion with other glomerulocystic conditions.

Pathogenesis and Pathology

The pathogenesis of GCKD remains unknown. Clinically, GCKD can be difficult to distinguish from other cystic kidney diseases. The diagnosis can only be established by histologic examination of renal tissue. Sporadic GCKD in young infants is histopathologically indistinguishable from ADPKD-related GCKD. The kidneys in both the familial and sporadic forms are variably enlarged, with the degree of renal enlargement related to the degree of cyst formation (282). The cysts in both groups may be diffuse but can also be clustered, which may be responsible for asymmetric and asynchronous clinical presentations. Diffuse involvement is associated with interstitial edema, whereas patchy involvement is associated with better preservation of overall renal structure and function.

Characteristically, the cysts are dilated Bowman's spaces, comprising a sphere lined with cuboidal or columnar cells and containing abortive or primitive-appearing glomeruli (271), which occur as small scattered cysts separated by normal parenchyma. The cysts are located in the cortex, with preservation of the medulla. This lack of tubular involvement differentiates GCKD from other cystic diseases in which cysts generally arise from tubular dilation. In rare cases, they are more diffuse, surrounded by atrophic and fibrotic parenchyma. They may be found in association with tubular cysts and dysplasia (282).

The kidneys in sporadic GCKD and the GCKD form of ADPKD often contain abnormally differentiated pyramids, a type of medullary dysplasia. Both forms of GCKD are associated with biliary dysgenesis in approximately 10% of cases (282).

Clinical and Radiographic Features

Most GCKD patients described in the literature have some degree of renal failure, and many have hypertension at presentation. The typical presentation is that of an infant with abdominal masses, renal insufficiency, and enlarged cystic kidneys on sonography. GCKD may manifest in adulthood with hypertension, flank pain, and hematuria. Variable degrees of renal dysfunction are seen. Later detection may be consistent with a milder course (169,274). Clinically, hepatic cysts have also been described (282).

Patients with the familial hypoplastic GCKD variant have small kidneys with abnormal collecting systems and abnormal or absent papillae (275,276). Family studies show a pattern compatible with autosomal dominant inheritance. Most patients appear to have chronic renal failure early in life but subsequently have stable courses without progression to ESRD.

Several reports of GCKD describe patients with no clear familial or syndromic association (280,283,284). Histologically and clinically, these patients resemble familial cases with large, hyperechoic kidneys. It remains unclear whether these sporadic cases are a distinct entity or are associated with unrecognized syndromal or familial cases. Reports on an infant with GCKD and multiple cardiac rhabdomyomas and an infant with severe GCKD who later developed skin findings consistent with tuberous sclerosis strongly suggest an association of GCKD with tuberous sclerosis (285,286). This, together with the new information regarding the molecular basis of ADPKD and tuberous sclerosis and the reported familial association of GCKD and ADPKD, raises the possibility that autosomal dominant GCKD, ADPKD, and tuberous sclerosis are genetically linked in some kindreds. Single case studies have also reported GCKD in association with Henoch-Schönlein purpura (287), hepatoblastoma (288), and as a sequela of hemolytic-uremic syndrome (289,290).

Ultrasonography demonstrates bilateral renal enlargement without distortion of the renal contour, increased

echogenicity of the cortex and medulla, loss of corticomedullary junction differentiation, and small cortical cysts (283,291). Radiographically, a feature that can help distinguish GCKD from ARPKD is abnormal medullary pyramids in the latter. In the future, CT and nuclear MRI may be of some value in differentiating between these two diseases (292). Reduced intensity of cortex on T1-weighted images and abnormalities of corticomedullary differentiation may help confirm the diagnosis.

In summary, GCKD represents a heterogeneous collection of heritable and nonheritable clinical entities. The clinical course and prognosis are quite variable and often dependent on the presence of associated disorders.

POLYCYSTIC KIDNEY DISEASE ASSOCIATED WITH CONGENITAL SYNDROMES

Many diseases can present with enlarged kidneys or cysts in the infant and young child and can initially be confused with PKD (Table 36.3). Abdominal ultrasound examination and nuclear isotope scanning help rule out multicystic renal dysplasia and obstructive uropathy. Multicystic dysplastic kidney is generally unilateral with macrocysts of varying sizes, differ-

TABLE 36.3. DIFFERENTIAL DIAGNOSIS OF POLYCYSTIC KIDNEY DISEASE IN THE PEDIATRIC PATIENT

Cystic diseases
Autosomal recessive polycystic kidney disease
Autosomal dominant polycystic kidney disease
Glomerulocystic kidney disease
Congenital and hereditary diseases
Tuberous sclerosis
Multicystic dysplastic kidney
Nephronophthisis complex
Glycogen storage disease
Congenital nephrosis
Syndromes
Meckel-Gruber syndrome
Jeune syndrome and other chondrodysplasia syndromes
Ivemark syndrome
Bardet-Biedl syndrome
Zellweger cerebrohepatorenal syndrome
Beckwith-Wiedemann syndrome
Trisomy 9 and 13
Neoplasia
Nephroblastomatosis
Bilateral Wilms' tumor
Leukemia or lymphoma
Miscellaneous
Pyelonephritis
Glomerulonephritis
Radiocontrast nephropathy
Bilateral renal vein thrombosis
Transient nephromegaly

entiating it from ARPKD (see Chapter 5). On radionuclide scanning, it demonstrates no function, permitting differentiation from ADPKD. Most syndromic and other inherited disorders can usually be differentiated from ARPKD and ADPKD by associated clinical features, with the exception of GCKD, occasionally tuberous sclerosis, and von Hippel-Lindau disease (1,97,293). GCKD can be a feature of several inherited, sporadic, or syndromic conditions as discussed above. In addition, GCKD may be an early histopathologic expression of the ADPKD gene in young patients. Tuberous sclerosis is an autosomal dominant neurocutaneous disorder, in which hyperplastic cystic lesions may affect any portion of the nephron (285). Genetic linkage of the chromosome 16 loci for tuberous sclerosis and ADPKD1 has been demonstrated (294). The *TSC2* gene has been identified and encodes a novel protein, tuberin. Uncommonly, patients show polycystic renal involvement without clinical neurocutaneous involvement or positive family history. Several kindreds have been identified with tuberous sclerosis and severe childhood-onset ADPKD; they have large deletions in the area containing *PKD1* and adjacent *TSC2* gene (210). Analysis of the deletions indicates that they inactivate *PKD1*, in contrast to mutations reported in ADPKD patients in which abnormal transcripts have been detected. von Hippel-Lindau disease is a dominantly inherited cancer syndrome characterized by renal cell carcinoma, pheochromocytoma, and hemangioblastomas of the eye, spine, and cerebellum. Cystic kidneys and pancreas may be seen and, rarely, patients may present with “typical” features of ADPKD (295). To differentiate GCKD, tuberous sclerosis, and von Hippel-Lindau from ARPKD and ADPKD, detailed family history, physical examination, and close clinical follow-up are necessary.

DIFFERENTIAL DIAGNOSIS OF POLYCYSTIC KIDNEYS IN CHILDHOOD

In most clinical settings, the major problem in differential diagnosis of PKD in the pediatric patient is clearly delineating ARPKD from ADPKD. In fact, ADPKD presenting in the neonatal period may be indistinguishable clinically from ARPKD (98,145). In such instances, a staged evaluation, including careful history, physical examination, imaging, and histologic examination, is recommended. As noted in Table 36.4, certain clinical features can help differentiate between ARPKD and ADPKD, although no single finding is diagnostic. A complete family history is often the most important element in difficult cases. Parents should have renal and liver ultrasonography. If the parents of a child with undiagnosed PKD are younger than 30 years, the grandparents should also be evaluated because 4 to 5% of patients with ADPKD may not have visible renal cysts before age 30. Absence of any cystic disease in family members makes the diagnosis of ARPKD more likely because less than 5 to 8% of all ADPKD cases appear to result from new gene muta-

TABLE 36.4. DIFFERENTIAL CLINICAL FEATURES OF CHILDHOOD POLYCYSTIC KIDNEY DISEASE

Major clinical features of both ARPKD and ADPKD	
	Enlarged kidneys
	Hypertension
	Concentrating defect
	Sterile pyuria
Clinical features suggesting ARPKD rather than ADPKD	
	Neonatal presentation
	Progression to end-stage renal disease as a child
	Hepatosplenomegaly
	Portal hypertension and esophageal varices
	Bacterial cholangitis
	Negative family history
Clinical features suggesting ADPKD rather than ARPKD	
	Positive family history
	Extrarenal cysts
	Cerebral aneurysms
	Asymptomatic presentation
	Unilateral renal presentation
	Hematuria
	Urinary tract infection

tions (168). Radiographic studies may clearly distinguish ARPKD and ADPKD in some cases (Table 36.4). However, in clinical practice, 20 to 30% of all cases show certain features of both diseases on radiographic studies, making definitive diagnosis difficult if not impossible. If the constellation of physical and radiologic findings is equivocal, a tissue diagnosis may be required (Figs. 36.2 and 36.3). Renal biopsies, particularly when stained with segment-specific lectins (127,296), clearly differentiate the isolated fusiform cortical collecting tubular cysts of ARPKD (Fig. 36.2) from the heterogeneous cystic nephron involvement of ADPKD (Fig. 36.3). In certain instances, liver biopsy may provide additional information and reveal the characteristic biliary dysgenesis of ARPKD. However, hepatic portal fibrosis and bile duct ectasia have been associated with other types of renal cystic diseases, including ADPKD. In the future, further molecular analysis of ARPKD and ADPKD mutations will permit definitive genetic diagnosis and guide genetic counseling in childhood PKD.

AMINOACIDURIA AND GLYCOSURIA

ISRAEL ZELIKOVIC

Only negligible amounts of amino acids and glucose are normally present in the final urine, reflecting very efficient reabsorption mechanisms for these organic solutes in the proximal tubule. Renal tubular transport defects or specific metabolic abnormalities result in excretion of significant quantities of amino acids or glucose in the urine. Although hereditary defects in renal tubular transport of most of these substances are uncommon, they are of major biologic importance. First, some of these membrane transport disorders [e.g., cystinuria, lysinuric protein intolerance (LPI), Hartnup disease] are associated with significant morbidity. Second, the study of these disorders has provided much insight into the physiology of renal tubular reclamation of amino acids and glucose and into the specific metabolic pathways that control their reabsorption and has been crucial in understanding the genetics of tubular transport systems.

This chapter summarizes the general characteristics of renal tubular transport of amino acids and glucose, reviews recent studies on the molecular biology of the transporters, describes the ontogeny of these transport processes, and discusses the specific hereditary membrane transport disorders that result in abnormal aminoaciduria and glycosuria. Special emphasis is given to classic cystinuria, including molecular genetic aspects of this disease. Not discussed in this chapter are overflow aminoaciduria and glucosuria, which occur when the filtered load of these solutes exceeds the transport capacity of the renal tubule. This tubular overload is characteristic of various inborn errors of amino acid metabolism and diabetes mellitus, which result in elevated plasma levels of amino acids and glucose, respectively. *Fanconi syndrome*, a proximal tubular disorder characterized by generalized aminoaciduria and urinary hyperexcretion of glucose, bicarbonate, phosphate, and other solutes, is discussed in Chapter 41.

AMINOACIDURIA

General Characteristics of Tubular Amino Acid Transport

Circulating free amino acids are derived from dietary protein that is hydrolyzed and absorbed in the intestine, from

intracellular catabolism of peptides, and from *de novo* synthesis within cells. More than 99% of the load of free amino acid filtered by the kidneys of humans and other mammals is reabsorbed in the renal tubule and returned to plasma (1,2). Amino acid reabsorption occurs predominantly in the pars convoluta of the proximal tubule and, to a small extent, in the pars recta (1,2). Amino acids are reabsorbed primarily from tubular lumen by an active uphill transport across the luminal membrane (1). In studies using renal brush-border membrane vesicles (BBMV) from various animals to explore amino acid transport across this membrane, the rate of accumulation by vesicles and the magnitude of the overshoot, which indicates active concentrative transport, were greatly augmented by an external Na^+ gradient across the vesicle membrane (1). Hence, it is widely accepted that uptake of most amino acids at the brush-border surface occurs by Na^+ -amino acid cotransport driven by the electrochemical Na^+ gradient from tubular lumen to cell (1,2) (Fig. 37.1). The energy maintaining the Na^+ gradient is established by the Na^+ - K^+ -adenosine triphosphatase (ATPase), which is located at the basolateral membrane and translocates Na^+ out and K^+ into the cell.

Active amino acid transport across the brush-border membrane is followed by efflux, mainly via carrier-mediated, Na^+ -independent, facilitated diffusion or exchange from the cell into the peritubular space across the basolateral membrane (2–4) (Fig. 37.1). Thus, under normal conditions, net transepithelial movement of amino acids occurs from the tubular lumen to the peritubular space. However, net transepithelial flux of amino acids is composed of amino acid transport in both directions, namely lumen \rightarrow interstitium and interstitium \rightarrow lumen (3,4). Indeed, the basolateral membrane harbors active Na^+ -dependent and Na^+ -independent transport and exchange systems mediating amino acid uptake in the tubular cell (Fig. 37.1), and diffusional backflux of amino acids from cell into the tubular lumen is a well-documented phenomenon (3). Interstitium \rightarrow lumen-oriented backflux through paracellular pathways also occurs. The sum of these vectorial fluxes determines the direction and the rate of transepithelial amino acid transport. This notion may be of major impor-

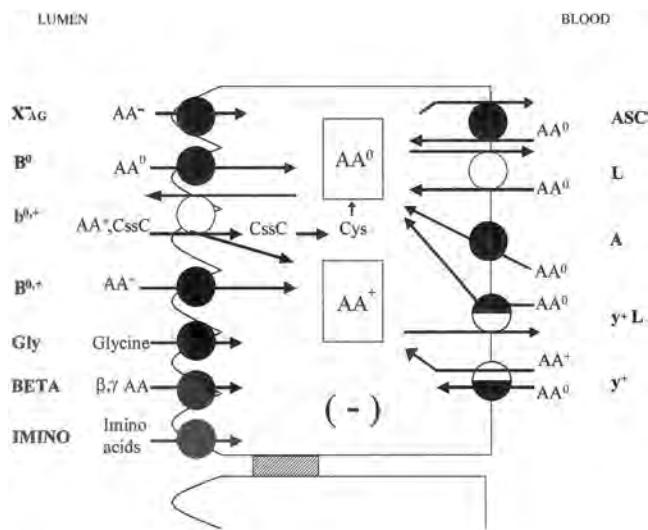

FIGURE 37.1. Summary of amino acid transport mechanisms in the proximal tubule. Filled circles indicate Na^+ -dependent, active, carrier-mediated cotransport or antiport. Empty circles indicate Na^+ -independent antiport or uniport (facilitated diffusion). Half-filled, half-empty circles indicate various combinations of the previously described circles. AA^0 , neutral amino acids; AA^+ , basic amino acids; AA^- , acidic amino acids; CysC, cystine; Cys, cysteine. See text for details.

tance in understanding renal tubular amino acid transport, particularly in disease states and during maturation (4,5).

Na^+ -amino acid symport across the luminal membrane is a carrier-mediated saturable process obeying Michaelis-Menten kinetics (1,2). The effectiveness of the active reabsorption process for a specific amino acid depends on the ratio $V_{\max}:K_m$ (1). A low V_{\max} (decreased transport capacity) or a high K_m (diminished transporter-substrate affinity) for a given amino acid results in decreased reabsorption rate of this amino acid. Changes in efficiency or capacity of amino acid transport also play an important role in both neonatal aminoaciduria and hereditary aminoacidurias.

In analyzing the data obtained from microperfusion and micropuncture experiments and studies using BBMVs for various amino acids (1), two or more Na^+ -linked transport systems with different kinetic characteristics have been described. The demonstration of multiple transport systems for the same amino acid becomes meaningful if the reduced concentrations of filtered amino acid presented to the proximal straight tubule are considered. Thus, in the case of glycine, for example, two Na^+ -dependent, active transport systems have been demonstrated along the luminal membrane of the isolated perfused proximal tubule (6): a low-affinity, high-capacity system in the convoluted segment and a high-affinity, low-capacity system in the straight segment. The latter system, which also operates in parallel to lower apical membrane backflux permeability in the proximal straight tubule (3), absorbs less glycine against a greater concentration gradient and probably permits the reduction of the luminal glycine concentration to lower levels than could

be achieved in the proximal convoluted tubule (3,6). This axial heterogeneity of Na^+ -linked amino acid uptake systems with respect to kinetic characteristics has been demonstrated for several amino acids (1) in BBMVs derived from pars convoluta and pars recta of the proximal tubule. The recognition of several transport systems for the same amino acid as well as their axial heterogeneity is of major importance in understanding the pathophysiology of hereditary aminoaciduria.

One or more Na^+ ions are transported for each amino acid molecule translocated, and with most amino acids this process is electrogenic-positive favored by a negative cell interior (1,7). Na^+ -amino acid stoichiometry determines the electrogenicity and efficiency of the transport system (3). Additional ions besides Na^+ are involved in the translocation of the amino acid carrier complex across the brush-border membrane (1). Taurine (8), glycine (9), and proline (10) transports, for example, operate by means of 2 or 3 $\text{Na}^+:1 \text{Cl}^-:1$ amino acid carrier complex.

Specificity of Transport

At least seven distinct group-specific Na^+ -dependent transport systems exist in the tubular luminal membrane (1,2). Evidence for these systems is derived from a variety of microperfusion experiments and vesicle studies and, in humans, from the existence of inborn errors of renal tubular transport that can be explained only by defects in specific transport pathways (1,11). These include systems for dibasic amino acids, acidic amino acids, neutral α -amino acids, imino acids, glycine, β - and γ -amino acids, and cystine/cysteine.

There is good evidence to suggest that in addition to separate systems for L-cystine and the dibasic amino acids (L-lysine, L-arginine, and L-ornithine), these amino acids share a common transport pathway (12–14), as also suggested by the urinary hyperexcretion of all four amino acids in classic cystinuria (see Classic Cystinuria). Transport of L-cystine but not L-cysteine can also proceed via Na^+ -dependent transport pathways for neutral amino acids (1,2). L-Cysteine is probably reabsorbed by an additional, separate, and specific transport system (2).

The broad-specificity transport pathway for neutral α -amino acids, which is a low-affinity, high-capacity system, is located in the proximal convoluted tubule (11). However, there are several alternative specific renal transport systems for neutral amino acids, including high-affinity systems located in the proximal straight tubule. The presence of such pathways is also suggested by the finding of isolated transport defects for neutral amino acids (see Neutral Aminoaciduria). The imino acids proline and hydroxyproline are reabsorbed by at least two systems, a low-affinity/high-capacity system in the proximal convoluted tubule shared with glycine and an imino acid-specific, high-affinity/low-capacity system in the proximal straight tubule (6,15). There also is a separate high-affinity/low-capacity system for glycine in the late proximal tubule (6).

TABLE 37.1. AMINO ACID TRANSPORT SYSTEMS OPERATING IN THE RENAL TUBULE

Amino acid transport system	Cloned cDNA	Amino acids transported	Mechanism of action	Localization
Neutral				
A	—	Short chain neutral	Na ⁺ -AA cotransport	BLM
ASC	ASCT 1–2	Short chain neutral	Na ⁺ -dependent AA antiport	BLM
B ⁰	ATB ⁰	Most neutral	Na ⁺ -AA cotransport	BBM
Gly	GLYT 1–2	Glycine, sarcosine	2–3 Na ⁺ /1Cl ⁻ /1AA cotransport	BBM
IMINO	—	Proline, hydroxyproline	2–3 Na ⁺ /1Cl ⁻ /1AA cotransport	BBM
BETA	TAUT, GAT 1–3, BGT-1	Taurine, β-alanine, GABA, betaine	2–3 Na ⁺ /1Cl ⁻ /1AA cotransport	BBM
L	4F2hc/LAT-1, 4F2hc/LAT-2	Large, branched chain neutral	AA antiport	BLM
Cationic				
B ^{0,+}	ATB ^{0,+} (?)	Cationic and neutral	Na ⁺ /Cl ⁻ /AA cotransport	BBM
b ^{0,+}	rBAT/b ^{0,+} AT	Cationic and neutral (including cystine)	AA antiport	BBM
y ⁺	CAT 1–4	Cationic and neutral (excluding cystine)	AA uniporter (facilitative transporter)	BLM
y ⁺ L	4F2hc/y ⁺ LAT-1 4F2hc/y ⁺ LAT-2	Cationic and neutral (excluding cystine)	Na ⁺ -dependent AA antiport	BLM
Anionic				
X ⁻ _{AG}	EAAT 1-5	Anionic	3Na ⁺ /AA cotransport, 1K ⁺ -antiport	BBM

AA, amino acid; BBM, brush-border membrane; BLM, basolateral membrane; GABA, γ-aminobutyric acid.

The investigation of amino acid transport pathways in the plasma membrane of mammalian cells has delineated several transport systems (16–20) (Table 37.1; Fig. 37.1). Most of these transport systems also have been identified in the kidney (16,17,19,21). These systems include the Na⁺-dependent concentrative A and ASC systems (for small neutral amino acids), B⁰ (for most neutral amino acids), B^{0,+} system (for dibasic and some neutral amino acids), X⁻_{AG} system (for acidic amino acids), Gly system (for glycine and sarcosine), IMINO system (for proline and hydroxyproline), and β system (for taurine, β-alanine, and γ-aminobutyric acid), as well as the Na⁺-independent nonconcentrative L system (for bulky neutral, branched-chain amino acids and cysteine), y⁺ system (for the dibasic amino acids lysine, arginine, and ornithine), y⁺L system (for dibasic and neutral amino acids excluding cystine), and b^{0,+} system (for dibasic and neutral amino acids including cystine). Systems A, ASC, L, y⁺, and y⁺L operate in the basolateral membrane (18,19,21) (Fig. 37.1). All these basolateral transporters (except for system A), as well as the luminal membrane-bound b^{0,+} system, function as antiport (exchange) systems (19,20) (Fig. 37.1). Recent progress in molecular cloning of amino acid transporters has helped to characterize and define the nature and the role of most of these tubular amino acid transport mechanisms (see Molecular Structure of Amino Acid Transporters).

Adaptation and Regulation of Amino Acid Transport

Although the exact mechanisms regulating renal tubular amino acid reclamation have not been established, several

factors are known to modulate transmembrane amino acid transport (1,22). These include ionic and voltage conditions (discussed earlier), as well as availability of amino acid substrate, osmotic changes, and protein phosphorylation.

Reabsorption of amino acids in the proximal tubule increases during periods of reduced amino acid intake and decreases with dietary excess (1). This renal adaptive response to diet is expressed at the tubular luminal membrane surface. It has been suggested (22,23) that both new synthesis of transporter protein and shuttling of preformed transporters are required for expression of the adaptive response. A recent expression study in *Xenopus* oocytes (24) has demonstrated that the rat renal taurine transporter is regulated by dietary taurine at the level of both messenger RNA (mRNA) accumulation and protein synthesis.

Amino acids are known to serve as regulatory osmolytes in mammalian cells, including kidney cells (25–27). The main amino acids involved in this function are taurine, proline, and glutamic acid (25,26,28). Studies using MDCK cells, a cell line of distal tubular origin, demonstrate changes in taurine transport in response to changes in osmolarity of the medium (29). It has been shown that osmotic regulation of taurine transport depends on changes in taurine transporter gene expression (30).

Serine/threonine protein kinases play a central role in signal transduction by phosphorylating and thereby activating effector proteins (31,32). Recent studies suggest that the three main groups of serine/threonine protein kinases, namely cyclic adenosine monophosphate-dependent protein kinase [protein kinase A (PKA)], Ca²⁺- and phospholipid-dependent protein kinase [protein kinase C (PKC)], and

multifunctional Ca^{2+} /calmodulin-dependent protein kinase II (CaMK II) alter amino acid transport across the tubular brush-border membrane (33–35). However, the exact role of protein kinase-induced phosphorylation in renal tubular amino acid transport remains to be established.

Molecular Structure of Amino Acid Transporters

Extensive efforts to isolate and identify the amino acid transport proteins in various tissues, including the kidney, have been largely unsuccessful. The isolation and molecular characterization of amino acid carrier proteins has been hindered by their very low abundance in the membrane, their poor stability *in vitro*, and the lack of specific tight-binding labels or inhibitors. Indirect approaches such as solubilization of proteins by organic solvents and incorporation into proteoliposomes, lectin-affinity chromatography, immunoprecipitation using monoclonal antibodies, and radiation inactivation analysis (36,37) have yielded little structural data. Since 1990, however, by using molecular biology techniques, much progress has been made in elucidating the molecular structure of various membrane-bound transport proteins, including amino acid transporters. This new area in the study of brush-border membrane transporters was pioneered by Hediger et al. (38), who cloned the small intestinal Na^+ -glucose cotransporter using the powerful method of expression cloning in *Xenopus* oocytes. This strategy involves isolation of mRNA from the tissue of interest, microinjection into *Xenopus* oocytes, and analysis of expressed transport activity by measuring uptake of radiolabeled substrate. After size fractionation of mRNA, complementary (cDNA) synthesis, and DNA library screening by functional expression in oocytes, a single clone encoding the transporter activity is isolated. A similar approach has been used to clone, functionally express, and sequence various amino acid transporters.

The structural information and functional characteristics of amino acid transporters have led to their classification into four different gene families (19,20,39,40): Na^+ - and Cl^- -dependent transporters (the GAT family), the anionic/neutral amino acid transporters (the EAAT/ASCT family), cationic amino acid transporters (the CAT family), and cationic/neutral amino acid transporters [the rBAT/4F2 heavy chain (4F2hc) family]. Investigation of the primary structure of amino acid transporters has elucidated two main types of membrane proteins involved in amino acid transport (19): (a) members of the GAT, EAAT/ASCT, and CAT families, which present multiple transmembrane domains (Fig. 37.2) and are therefore considered putative carriers; and (b) members of the rBAT/4F2hc family, which do not fit this model (Figs. 37.3 and 37.4) and are known to function as components or subunits of heteromultimeric carriers.

GAT Family

The GAT family includes Na^+ - Cl^- - γ -aminobutyric acid (GABA) (41), Na^+ - Cl^- -taurine (42), Na^+ - Cl^- -glycine (43),

and Na^+ -proline (44) cotransporters of the brain, which serve as neurotransmitters, as well as the Na^+ - Cl^- -taurine (45) cotransporter of the kidney. In addition to the taurine transporter of the kidney, Northern hybridization and polymerase chain reaction analysis have identified two GABA transporter isoforms, called *GAT 2* and *GAT 3* (46,47), as well as glycine transporter isoforms called *GLYT 1* and *GLYT 2* (48–50) in the kidney. The GAT family also includes the renal Na^+ - Cl^- -betaine transporter. All these transporters show high homology in sequence and structure, and most of them have an absolute requirement for Cl^- .

The proposed model of the GABA transporter (*GAT 1*) is shown in Figure 37.2. It is a 655-residue protein with a relative molecular mass of 73,925 d. The predicted secondary structure shows 12 hydrophobic, membrane-spanning domains with a large extracellular hydrophilic loop between spans 3 and 4. The molecular structure contains putative *N*-glycosylation and phosphorylation sites. The similarities between the family members may point toward domains important in Na^+ , Cl^- , and substrate coupling (51). The Na^+ - Cl^- -betaine and Na^+ - Cl^- -taurine transporters are thought to play a major role in cell volume regulation in the renal medulla (26) (see Adaptation and Regulation of Amino Acid Transport).

EAAT/ASCT Family

The EAAT/ASCT family of transporters is made up of five Na^+ - and K^+ -dependent, Cl^- -independent anionic amino acid transporters, and three neutral amino acid transporters (19,20). The anionic amino acid transporters include the GLAST (or EAAT1) (52), GLT (or EAAT2) (53), and EAAC1 (or EAAT3) (54), as well as EAAT4 (55) and EAAT5 (56), which serve as neurotransmitters and show marked similarity in sequence and structure. EAAC1, a neuronal and epithelial high-affinity glutamate transporter first cloned from rabbit small intestine (54), was also identified in the kidney by Northern hybridization analysis (54). *In situ* hybridization and immunofluorescence studies revealed that EAAC1 is expressed predominantly in the S2 and S3 segments of the proximal tubule (57).

The proposed model of EAAC1 (Fig. 37.2) shows a protein of 524 amino acids with a predicted molecular mass of 57,000 d and ten hydrophobic, membrane-spanning domains. The kinetics and specificity of this protein when expressed in *Xenopus* oocytes were similar to those of the X_{AG}^- transport system (see Specificity of Transport; Fig. 37.1). The gene for human EAAC1 (termed *SLC1A1*) has been localized to chromosome 9p24 (58). A defect in the EAAC1 gene is a likely cause of dicarboxylic aminoaciduria (see Dicarboxylic Aminoaciduria).

The neutral amino acid transports include the ASCT1 (or SATT) (59), ASCT2 (or AAAT) (60), and ATB⁰ (61). ASCT1 and ASCT2, which were cloned from human brain (59) and mouse testis (60), respectively, have structural similarity to the anionic amino acid transporter gene family and appear to encode Na^+ -dependent neutral amino acid trans-

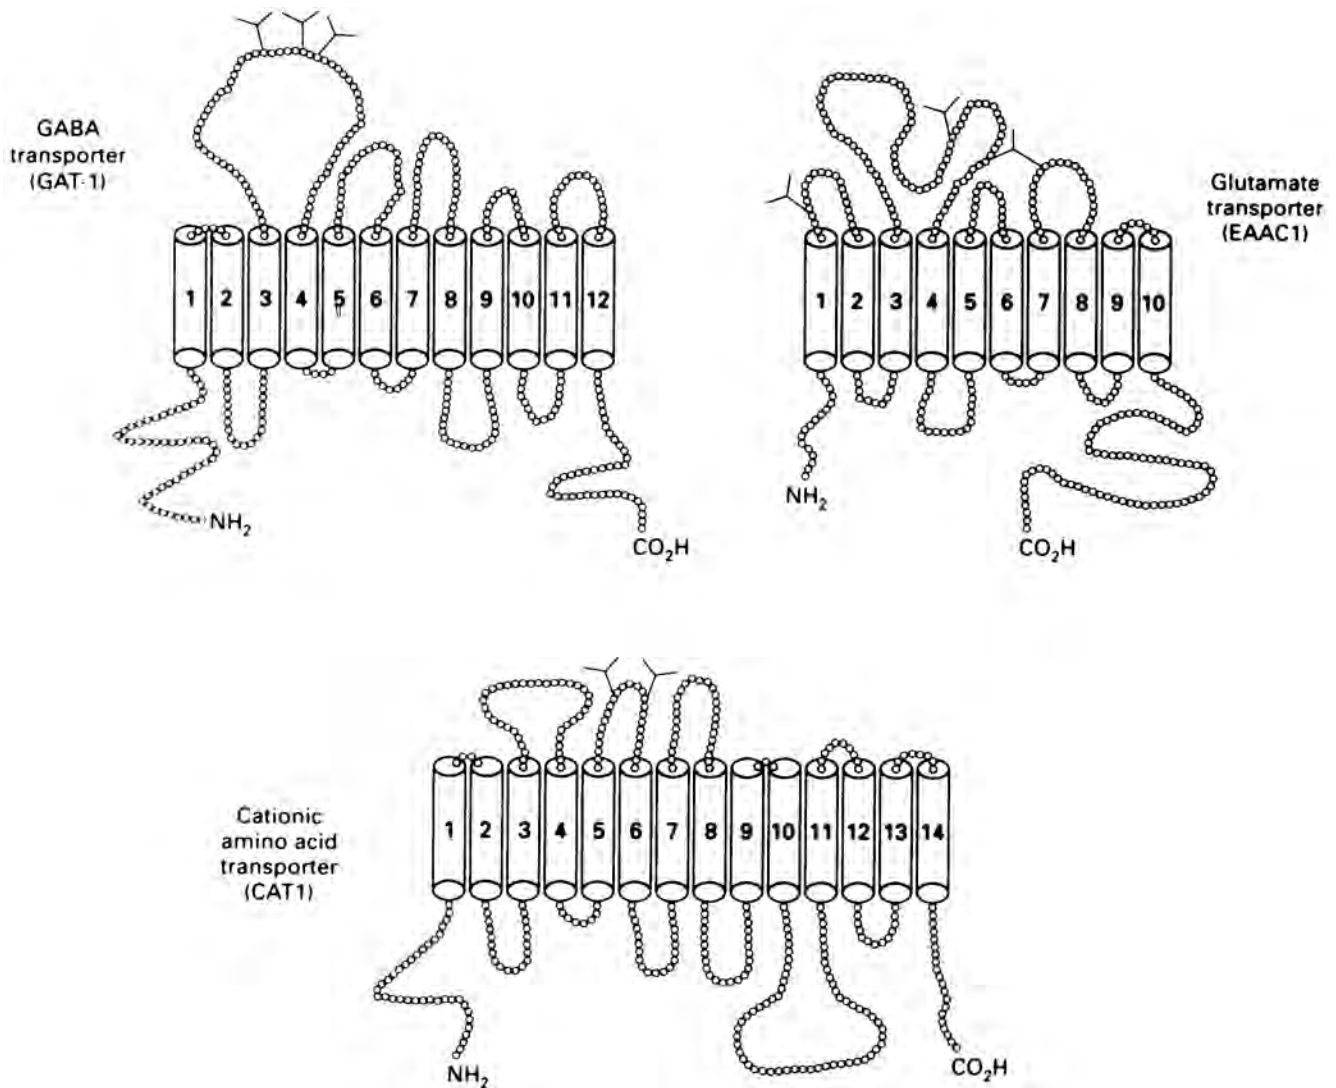

FIGURE 37.2. The putative transmembrane orientations of the γ -aminobutyric acid (GABA) transporter (GAT-1), the glutamate transporter (EAAC1), and the cationic amino acid transporter (CAT1) are shown as representative of three families of amino acid transporters. (Adapted from McGivan JD, Pastor-Anglada M. Regulatory and molecular aspects of mammalian amino acid transport. *Biochem J* 1994;299:321–334.)

porters with specificity characteristics of system ASC (see Specificity of Transport; Fig. 37.1). Northern blot analysis (59,60) revealed ubiquitous expression of these genes in several tissues, including expression in the kidney, consistent with the general metabolic role ascribed to system ASC. ATB⁰ was cloned from human choriocarcinoma cells (61), and its transcripts were detected in the kidney among other tissues. Expression studies in the HeLa cells and oocytes showed a Na⁺-dependent uptake of neutral amino acids with characteristics of the brush-border membrane system B⁰ (see Specificity of Transport; Fig. 37.1). It is noteworthy that the transport systems EAAT1-5 (19,62), ASCT1 (63), and possibly ATB⁰ (64) have a Cl⁻ channel mode of action in addition to their amino acid transport mode of activity.

CAT Family

The CAT genes were the first mammalian amino acid transporters cloned (40). Expression studies in *Xenopus* oocytes identified the ecotropic murine leukemia virus as the ubiquitous y⁺ system (now called CAT1), an Na⁺-independent transport system that accepts dibasic amino acids and excludes cystine (65,66). In addition, it catalyzes transport of neutral amino acids only in the presence of Na⁺ (19) (Fig. 37.1). Northern hybridization analysis revealed the CAT1 gene in various mouse tissues, including the kidney (65). Since then, three other homologous murine cDNAs have been found to express a similar amino acid transport activity, CAT2, CAT3, and CAT4, all of which (except CAT3) are expressed in the kidney (19,67,68). The CAT

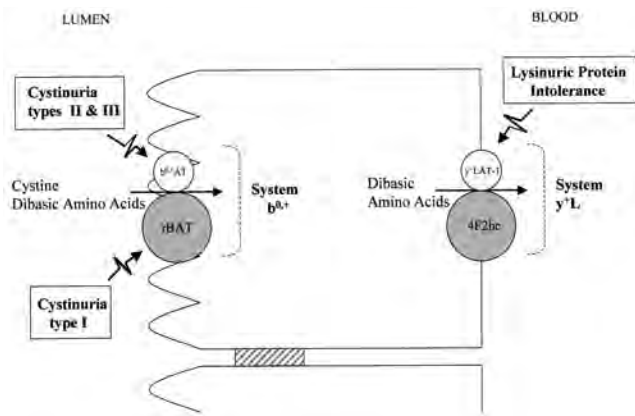

FIGURE 37.3. Transport pathways for cystine and dibasic amino acids at the luminal and basolateral membranes of a proximal tubular cell. Large circles represent the heavy subunits and small circles the light subunits of the heteromeric amino acid transporters $b^{0,+}$ and y^+L . Depicted are hereditary aminoacidurias caused by defects in these transporters. (Modified from Zelikovic I. Molecular pathophysiology of tubular transport disorders. *Pediatr Nephrol* 2001;16:919–935.)

transporters allow accumulation of cationic amino acids within the cell for general metabolic purposes. Also, it has been postulated that CAT-mediated arginine flux into cells could play a role in modulating nitric oxide synthesis in various cell types (67,69). This notion has been supported

FIGURE 37.4. Schematic representation of the heteromeric amino acid transporters (HAT). The heavy subunit of HAT (HSHAT; dark gray) is linked by a disulfide bridge to the corresponding light subunit of HAT (LSHAT; light gray). The cysteine residues involved in this bond (S-S) are located extracellularly, just after the transmembrane (TM) domain of HSHAT and in the proposed extracellular loop 2 (EL2) of LSHAT. Loops and TM domains are not drawn to scale. See text for details. (Adapted from Chillaron J, Roca R, Valencia A, et al. Heteromeric amino acid transporters: biochemistry, genetics, and physiology. *Am J Physiol* 2001;281:F995–F1018.)

by studies demonstrating that CAT2 and nitric oxide synthase 2 transcripts are co-induced in concert with system y^+ activity (70). The CAT1 cDNA predicts a 629–amino acid protein with 14 membrane-spanning domains and a molecular mass of 68,000 d (Fig. 37.2).

rBAT/4F2 Heavy Chain Family

To gain insight into the transport defect in cystinuria, recent research has focused on the molecular structure of the family of carrier proteins responsible for transport of cystine and other dibasic amino acids. Several groups have demonstrated the expression of cystine (71) and dibasic and neutral amino acids (72–74) in *Xenopus* oocytes injected with mRNA of small intestine and kidney. In 1992 (75,76), kidney cortex cDNAs from rabbit and rat [named *rBAT* (75) and *D2* (76), respectively] have been cloned. On *in vitro* transcription to chromosomal RNA and injection into oocytes, they induce system $b^{0,+}$, the Na^+ -independent transporter for neutral amino acids, dibasic amino acids, and cystine (see Specificity of Transport; Figs. 37.1 and 37.3). The predicted proteins for *rBAT* and *D2* demonstrate significant homology with a family of the carbohydrate-metabolizing enzymes α -glucosidases. Similarly, chromosomal RNA from the human 4F2hc surface antigen, a glycoprotein highly regulated at the onset of cell proliferation, stimulated system y^+L amino acid transport (see Specificity of Transport; Figs. 37.1 and 37.3) in *Xenopus* oocytes (77).

The *rBAT* cDNA contains an open reading frame of 2049 nucleotides coding for a protein of 685 amino acids with a molecular mass of approximately 90,000 d (40). The predicted proteins for *rBAT* and *D2*, as well as the 4F2hc antigen (all of which show high structural similarity), were found to contain only one (19) or four (78) putative membrane-spanning domains, depending on different typologic models. This structure, which is atypical of the known membrane transport proteins, raised the possibility that these proteins function as activators of transport systems y^+L and $b^{0,+}$ or as regulatory subunits of these transporters. The functional promoter of the rat *rBAT* gene has been identified (79), and the gene for the human *rBAT*, named *D2H*, was localized to chromosome 2p21 (79,80). The human *rBAT* (*D2H*) gene has been called *SLC3A1* (see Classic Cystinuria).

In situ hybridization and immunolocalization studies have localized *rBAT* mRNA expression in the brush-border membrane of the proximal straight tubule (S3 segment) and the small intestinal mucosa (81,82). In contrast to *rBAT*, 4F2hc mRNA is almost ubiquitous with marked expression in kidney, where it localizes to the basolateral membrane of proximal tubular cells (19). Studies from several laboratories have demonstrated that both *rBAT* and 4F2hc are type II membrane glycoproteins, which constitute heavy subunits of heteromeric amino acid transporters (83–86). These studies showed that *rBAT* (90 kDa) and 4F2hc (85 kDa) associated by disulfide bridges with a light subunit (40 kDa) forming a heterodimeric complex of 125 kDa (85,86) (Fig. 37.4).

The light subunit of rBAT, termed $b^{0,+}AT$, and the light subunit of 4F2hc, termed y^+LAT-1 , which were identified in 1998–1999 (87–89), are members of the family of light subunits of the heteromeric amino acid transporters (LSHAT) (85,86). As of 2000, seven members of the LSHAT family have been identified (85,86), to which the light subunits LAT-1 and LAT-2 that combine with 4F2hc to form the L system (see Specificity of Transport; Table 37.1; Fig. 37.1) also belong. Recent research on the characteristics of LSHATs (83,85) has revealed that they are unglycosylated proteins that contain 12 putative transmembrane domains (Fig. 37.4), they need coexpression with the corresponding heavy subunit to reach the plasma membrane, they confer the specific amino acid transport activity to the heteromeric complex, and, finally, all the amino acid transport activities associated with the LSHATs behave as amino acid exchangers (85,86). In the kidney, system $b^{0,+}$ (induced by rBAT and $b^{0,+}AT$; Figs. 37.1 and 37.3) acts as tertiary active exchange mechanism of tubular reabsorption of dibasic amino acids and cystine. This tertiary transport mechanism is linked to a high intracellular concentration of neutral amino acids (Fig. 37.1). System $b^{0,+}$ -mediated efflux of neutral amino acids from renal epithelial cells is the driving force for cystine and cationic amino acid reabsorption from lumen to cell (84,90,91) (Fig. 37.1). Reabsorption of cystine and cationic amino acids is also favored by the intracellular-negative membrane potential and by the reduction of cystine to cysteine (Fig. 37.1) (84,91). System y^+L (induced by 4F2hc and y^+LAT-1 ; Figs. 37.1 and 37.3) mediates an electroneutral exchange mechanism in which efflux of cationic amino acids (against the intracellular-negative voltage) is enhanced by the influx of neutral amino acids in the presence of Na^+ (Fig. 37.1) (84,91). The tissue distribution of rBAT/ $b^{0,+}AT$ and 4F2hc/ y^+LAT-1 and their role in renal uptake of cystine and dibasic amino acids have made them candidates for the defective genes in cystinuria and LPI, respectively (see Hereditary Aminoacidurias).

Future investigations into the molecular and biochemical characteristics of this expanding group of cloned amino acid transporters may yield important insight into the inherited human diseases that result from a defective transport of amino acids (see Hereditary Aminoacidurias).

Maturation of Tubular Amino Acid Transport

Urinary fractional excretion of almost all amino acids in humans (92) (Fig. 37.5) and animals (4) is higher in the newborn than later in life. A very high rate of urinary amino acid excretion is found in immature, very-low-birth-weight infants (93). Some amino acids, including glycine, alanine, proline, dibasic amino acids, and taurine (4,93), have been shown to contribute more to neonatal aminoaciduria than other amino acids. Theoretically, a structural, quantitative, or regulatory change in any one of the membrane-related events depicted in Figure 37.1 may underlie the diminished reabsorptive capacity of the renal tubule during early life (4,5).

As indicated earlier, proline and glycine reabsorption in the proximal tubule occurs predominantly by a shared low-affinity/high-capacity transport system in the proximal convoluted tubule as well as by two specific, high-affinity/low-capacity systems located in the proximal straight tubule—one for proline and one for glycine (1,6). Lasley and Scriver studied infants affected with familial renal iminoglycinuria to explore the ontogeny of proline and glycine reabsorption in the renal tubule (94). In iminoglycinuria, the shared transport system for proline and glycine is affected by mutation (see Iminoglycinuria). Using the occurrence of ontogeny and maturation together, Scriver's group provided evidence for the appearance of the two specific high-affinity transport systems in succession—the proline transporter by 3 months of age and the glycine transporter by 6 months of age (94). Similarly, earlier studies on glycine and proline transport in rat renal cortical slices (4) showed that the specific high-affinity transporters were not present at birth, yet appeared when

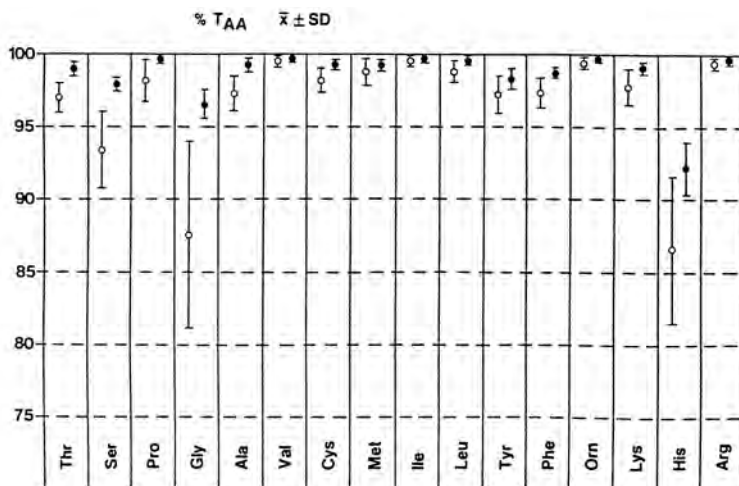

FIGURE 37.5. Tubular reabsorption of free amino acids (% T_{AA}) compared between infants (open circles) and children (black dots). amino acid reabsorption reached adult levels. In contrast, subsequent animal studies demonstrated the existence of both low-affinity/high-capacity and high-affinity/low-capacity systems for several amino acids (4) in neonatal and adult kidneys; no new systems were acquired with maturation.

Studies using cortical slices and isolated tubules from several species have provided evidence for an impaired basolateral membrane exit step of amino acids from immature tubular cells (4). Decreased Na⁺-dependent taurine transport has been demonstrated in basolateral membrane vesicles from hypertaurinuric mice (95). It remains to be established whether a similar alteration in basolateral membrane amino acid transport during early life contributes to neonatal hyperaminoaciduria.

Several studies explored the maturation of the first step of amino acid reabsorption, namely transport across the brush-border membrane. A gradual age-related increase in Na⁺-coupled uptake of taurine (96) and proline (97) by rat renal BBMVs and of cystine by isolated dog renal cortical tubules (98) has been demonstrated. Whereas the maturation of proline transport involved an increase in affinity (decrease in K_m) of transport (97), the maturation of cystine transport was associated with an increase in capacity (increased V_{max}) of transport (98).

Alterations in phospholipid composition have been documented during rat tubular brush-border membrane maturation (4), suggesting that changes in membrane fluidity may account for the observed maturational changes in Na⁺-linked tubular amino acid transport. In addition, an increased permeability to Na⁺ (97) and an enhanced amiloride-sensitive Na⁺-H⁺ exchange activity (99) have been demonstrated in neonatal rat renal BBMVs. This alteration in ionic permeability and the increased luminal membrane Na⁺-H⁺ antiport [coupled with a diminished Na⁺-K⁺-ATPase activity known to exist in the basolateral membrane of the neonatal proximal tubular epithelium (100)] may result in a rapid dissipation of the electrochemical Na⁺ gradient necessary for Na⁺-amino acid cotransport, thereby contributing to the aminoaciduria of early life (97,99).

Protein kinases modulate renal tubular amino acid transport (see Adaptation and Regulation of Amino Acid Transport). Recent studies (32,101) demonstrate higher activity of PKC and CaMK II in the cytosol and the brush-border membrane derived from immature kidneys than in adult kidneys. Furthermore, the studies provide evidence for differential regulation of PKC (101) and CaMK II (32) isoenzymes during kidney development. Age-related changes in the activity and expression of protein kinases may underlie the developmental changes in tubular reclamation of amino acids and other solutes.

In summary, hyperaminoaciduria is a characteristic of the immature mammalian tubule. Although the mechanisms governing the developmental changes in tubular amino acid transport have not been fully established, evidence has accumulated that both luminal and antiluminal membrane-

related events play a role in the maturation of amino acid transport. Most studies indicate that transport maturation does not represent the acquisition of new transport systems but rather a change in affinity or capacity of transporters. The role of protein kinase-induced phosphorylation in the maturation of renal tubular amino acid transport remains to be established. The exact cellular mechanisms and the biologic signals responsible for the observed developmental changes await future studies. Studies into the molecular structure of amino acid transporters will undoubtedly shed light on the mechanisms underlying the development of tubular amino acid reclamation.

Hereditary Aminoacidurias

Aminoacidurias are a group of disorders in which a single amino acid or a group of amino acids are excreted in excess amounts in the urine. The defective tubular reabsorption is assumed to result from a genetic defect in a specific transport system that directs the reabsorption of these amino acids under normal conditions. Some of these disorders also involve a similar transport abnormality in the intestine. As opposed to inborn errors of amino acid metabolism, in which plasma levels of amino acids are elevated, resulting in overflow aminoaciduria, plasma levels of amino acids in hereditary aminoacidurias are largely normal.

The aminoacidurias are generally categorized into five major groups according to the group-specific transport pathway presumed to be affected (Table 37.2). The groups are further subdivided into several disorders based on the profile of the affected amino acids within that group.

Cationic Aminoaciduria

Five distinct inborn errors of cationic amino acid transport have been identified: (a) classic cystinuria, (b) isolated cystinuria, (c) hyperdibasic aminoaciduria, (d) LPI, and (e) isolated lysinuria. These diseases differ in defined or putative transport systems affected, pathophysiology, organs involved, and clinical features. Classic cystinuria is the prototype for this group of hereditary aminoacidurias.

Classic Cystinuria

Cystinuria is a disorder of amino acid transport characterized by excessive urinary excretion of cystine and the dibasic amino acids lysine, arginine, and ornithine. The pathogenic mechanism of cystinuria is defective transepithelial transport of these amino acids in the proximal tubule and the small intestine (102). The very low solubility of cystine in the urine results in cystine stone formation in homozygous patients. Lysine, arginine, and ornithine do not form urinary stones. Urinary cystine calculi may produce considerable morbidity, including urinary obstruction, colic, infection, and in severe cases, loss of kidney function. Cystinuria accounts for 1 to 2% of all urolithiasis and 6 to 8% of urolithiasis in children

TABLE 37.2. HEREDITARY AMINOACIDURIAS

Disorder	Defective gene	Locus	Amino acid transport system defective		Individual amino acids affected	Localization of defect	Mode of inheritance	Prevalence	Clinical manifestations	Organs involved	OMIM no. ^a
			system	defective							
Cationic aminoaciduria											
Classic cystinuria Type I	SLC3A1	2p16.3-21	rBAT (heavy subunit of b ⁰⁺)		Cystine, lysine, arginine, ornithine	BBM	Autosomal recessive	1:7000–1:15,000	Urolithiasis	Kidney, intestine	220100
Type II and III	SLC7A9	19q13.1	b ⁰⁺ -AT (light subunit of b ⁰⁺)		Cystine, lysine, arginine, ornithine	BBM	Incompletely autosomal recessive	1:7000–1:15,000	Urolithiasis	Kidney, intestine	600918
Isolated cystinuria	—	—	Cystine		Cystine	BBM	Autosomal recessive	Two siblings reported	Benign	Kidney	238200
Hyperdibasic aminoaciduria type I	—	—	Dibasic amino acids		Lysine, arginine, ornithine	BBM	Autosomal dominant	Two families reported	Mental retardation	Kidney, intestine	222690
Lysinuric protein intolerance (hyperdibasic aminoaciduria type II)	SLC7A7	14q11-13	y ⁺ LAT-1 (light subunit of y ⁺ L)		Lysine, arginine, ornithine	BLM	Autosomal recessive	1:60,000 (Finland)	Protein malnutrition, failure to thrive, hyperammonemia, seizures, coma	Kidney, intestine, liver	222700
Isolated lysinuria	—	—	Lysine (?)		Lysine	BBM (?)	Autosomal recessive	One patient reported	Failure to thrive, seizures, mental retardation	Kidney, intestine	—
Neutral aminoaciduria											
Hartnup disease	ATB ⁰ (?)	19q13.3	B ⁰ (neutral, monoamino monocarboxylic α-amino acids)		Alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine, glutamine, asparagine	BBM	Autosomal recessive	1:20,000	Skin rash, cerebellar ataxia, psychiatric illnesses	Kidney, intestine	234500
Methioninuria	—	—	Methionine		Methionine	BBM	Autosomal recessive	Two cases reported	Edema, seizures, mental retardation	Kidney, intestine	250900
Histidinuria	—	—	Histidine		Histidine	BBM	Autosomal recessive	Four cases reported	Mental retardation	Kidney, intestine	235830
Imminoaciduria and glycinuria											
Imminoglycinuria	—	—	Immino acids and glycine		Proline, hydroxyproline, glycine	BBM	Autosomal recessive	1:15,000	Benign	Kidney, intestine	242600

(103,104). The defective gastrointestinal transport of cystine and dibasic amino acids in cystinuria does not result in intestinal disease.

The disease was first recognized in 1810 by Wollaston (105) and later by Berzelius (106), who called the stones "cystic oxide" and "cystine," respectively, assuming that the stones they analyzed originated in the bladder. In 1908, Garrod (107) postulated that cystinuria was an inborn error of cystine metabolism. In the 1950s, Dent and Rose (108) first recognized the true nature of the disease, suggesting that cystine and the dibasic amino acids lysine, arginine, and ornithine that have structural similarity (two amino groups separated by four to six chemical bonds) share a carrier protein in the brush-border membrane of the renal tubule and the small intestine. They postulated that this transport mechanism was defective in cystinuria.

Transport Defect. Normally, 1% of the filtered cystine and dibasic amino acids is excreted. In classic cystinuria, cystine clearance may be near or equal to the glomerular filtration rate (GFR), and in some patients even twice as high as the GFR, suggesting active cystine secretion (109). Lysine and ornithine clearance is 30 to 80% of the GFR, and arginine excretion is less abnormal.

Dent's postulate about a defective shared transport system for cystine and dibasic acids in cystinuria has been supported by the *in vivo* experiments of Kato (110) and Robson and Rose (111), demonstrating that in healthy subjects and cystinuric patients, increasing the filtered load of one of these amino acids decreased reabsorption of the others. However, this hypothesis was challenged by studies showing that cystine uptake was not impaired in kidney slices from cystinuric patients (112) and that cystine and dibasic amino acids did not share a common transport system in kidney slices of healthy and cystinuric patients (112). The reports of isolated cystinuria (113), isolated dibasic aminoaciduria (114), and isolated lysinuria (115) cast further doubts on Dent's hypothesis and suggested the existence of specific transport systems for these amino acids. Furthermore, the occurrence of several transport systems for cystine and dibasic amino acids was supported by the observations of Brodehl and Gellissen (92) and Scriver et al. (116) that tubular reabsorption capacity matures at different rates for different amino acids.

Subsequent studies using isolated cortical tubules and BBMVs (12,13,117) have clarified the picture of tubular amino acid transport. These studies, coupled with the recognition that kidney slices preferentially expose the basolateral membrane, provided evidence for three brush-border membrane-bound and two basolateral membrane-bound carrier systems for cationic amino acids in the kidney. Transport at the brush-border membrane occurs by a system shared by cystine and the dibasic amino acids, a system specific for cystine, and a system specific for dibasic amino acids. It is the shared high-affinity, low- K_m system located in the S3 seg-

ment of the proximal tubule and identified as system $b^{0,+}$ (see Specificity of Transport; Figs. 37.1, and 37.3) that is defective in classic cystinuria. The low-affinity, high- K_m , unshared cystine system and the low-affinity, unshared dibasic amino acid system, both located in the S1-S2 segments of the proximal tubule, may be abnormal in isolated cystinuria and dibasic aminoaciduria, respectively. The antiluminal membrane harbors two specific systems, one for dibasic amino acids identified as *system y^+L* (see Specificity of Transport; Figs. 37.1 and 37.3) and one for cystine, but no shared system. These transport mechanisms mediate uptake and efflux of these amino acids across the basolateral membrane. The brush-border membrane of the intestinal cell has a single high-affinity, low- K_m , shared $b^{0,+}$ transport system for cystine and dibasic amino acids that is defective in classic cystinuria. Like kidney cells, intestinal cells have two basolateral membrane-bound, unshared specific transport systems; one (system y^+L) for dibasic amino acids; and one for cystine (5). The basolateral membrane-bound y^+L transporter for dibasic amino acids in the kidney and the intestine is defective in LPI (see Lysinuric Protein Intolerance). Amino acid transport in parenchymal cells and leukocytes from cystinuric patients is not impaired (5) because the defect is not expressed in the plasma membrane of these cells.

Genetics. Classic cystinuria is inherited in an autosomal recessive fashion. It is a common disorder with an overall prevalence of 1:7000 to 1:15,000 and estimated gene frequency of 0.01 (102). A very high prevalence, 1:2500, is observed in Israeli Jews of Libyan origin (118).

Although it is a recessive disease, phenotypic heterogeneity in homozygotes and heterozygotes is evident. The excretion patterns of cystine and dibasic amino acids in heterozygotes and analysis of amino acid transport in jejunal mucosa have delineated three cystinuric subtypes (119). In type I, the most common phenotype, heterozygotes have normal urinary amino acid excretion, and homozygotes have impaired intestinal transport of cystine and dibasic amino acids. In type II, heterozygotes have high excretion of cystine and dibasic amino acids, and homozygotes show impaired intestinal transport of dibasic amino acids but not of cystine. Type III heterozygotes have excretion rates intermediate between the other two, and homozygotes have normal intestinal transport of the four amino acids involved. The three subtypes were considered to be allelic, namely mild; moderate; and severe mutations at a single cystinuria gene locus (11). However, Goodyer et al. (120) provided evidence that type I and type III cystinuria mutations might involve two distinct genetic loci. This was demonstrated by the finding that type I/III compounds excreted less cystine than type I/I probands, although type III/N heterozygotes excrete higher levels of cystine than their type I/N counterparts. These findings could be explained by genetic complementation between nonallelic cystinuria genes. Subsequent genetic studies have supported this hypothesis (see Molecu-

lar Genetics). Whereas type I cystinuria is inherited as a fully recessive trait, type II and III (collectively termed *non-type I*) subtypes are inherited as incompletely recessive traits.

Renal ontogeny has important implications for genetic counseling in cystinuria. This was demonstrated by Scriver and colleagues' finding that heterozygous infants under 6 months of age who have immature tubular function can excrete cystine and dibasic amino acids at levels equivalent to those found in homozygous adults (116). Urinary excretion of these amino acids decreased steadily with age to reach the variant parental value in heterozygous infants but not in homozygotes. Hence, final classification of a cystinuric phenotype should not be done before the age of 6 months.

Molecular Genetics. The identification and characterization of the rBAT/D2H gene have led to the speculation that a defect in the human form of rBAT (SLC3A1) causes cystinuria. Pras et al. (121), using linkage analysis in 17 cystinuric families, demonstrated linkage between cystinuria and three genetic markers on chromosome 2p, providing strong evidence that SLC3A1 was indeed the gene causing the disease. Calonge et al. (122) identified six specific mutations in the SLC3A1 gene that segregated with a cystinuria phenotype, thereby establishing the rBAT gene as the cystinuria gene (Fig. 37.3). Subsequent studies have revealed additional mutations in SLC3A1 (123–125). As of 2000, more than 60 different rBAT mutations have been reported in patients with type I cystinuria (126). These mutations include nonsense, missense, splice site, frameshift mutations, and large deletions (102,126). Defective transport of cystine and dibasic amino acids has been demonstrated for many of these mutations when expressed in *Xenopus* oocytes (84). The most commonly occurring mutation is methionine 467 to threonine (M467T), which causes a defect in trafficking to the plasma membrane (127,128). This trafficking defect, which has also been demonstrated for other rBAT mutations (126,129), is consistent with the proposed role of rBAT as a “helper” of the corresponding light subunit in the heteromeric amino acid transporter. No SLC3A1 mutations have been found in type II or III patients (125,130).

In 1997, Wartenfeld et al. (131) and Bisceglia et al. (132) demonstrated that cystinuria type III (and possibly cystinuria type II) is linked to a locus on chromosome 19q13.1. In 1999, the International Cystinuria Consortium (133) identified the gene SLC7A9, which encodes the 487–amino acid protein B⁰+AT that belongs to the family of light subunits of amino acid transporters (see Molecular Structure of Amino Acid Transporters; Fig. 37.3). The gene localized to the non-type I cystinuria 19q locus. Cotransfection of B⁰+AT and rBAT in COS cells resulted in trafficking of rBAT to the plasma membrane and induced L-arginine uptake by cells. SLC7A9 mutations were found in Spanish, Italian, North American, and Libyan-Jewish cystinuria patients (133). The mutations in Jews of Libyan origin is valine 170 to methionine, which leads to complete loss of B⁰+AT amino acid

FIGURE 37.6. Representation of the cystinuria-specific missense or single amino acid point mutations identified in the B⁰+AT amino-acid transporter. Twenty-three missense or single amino acid point mutations in SLC7A9 (B⁰+AT) are depicted. Amino acid residues conserved in all the human members of the light subunit of heteromeric amino acid transporter family are indicated in black. Mutations that are associated mainly with a severe urinary phenotype in heterozygotes (urine cystine levels similar to or below 200 $\mu\text{mol/g}$ of creatinine and the sum of urine levels of cystine and the three dibasic amino acids similar to or below 1000 $\mu\text{mol/g}$ of creatinine) are boxed. Mutations that are associated mainly with a mild urinary phenotype in heterozygotes (urinary levels of amino acids below the above indicated limits) are indicated in italics. The rest of mutations (with undefined or ambiguous phenotype) are indicated in smaller font. See text for details. (Adapted from Palacin M, Borsani G, Sebastio G. The molecular bases of cystinuria and lysinuric protein intolerance. *Curr Opin Gen Dev* 2001;11:328–335.)

uptake activity when cotransfected with rBAT in COS cells. As of 2000, more than 35 different B⁰+AT mutations have been identified in non-type I cystinuria patients (126,134) (Fig. 37.6). These mutations explain 79% of the alleles in 61 non-type I cystinuria patients included in the recent study by the International Cystinuria Consortium (134). The unexplained alleles might be due to mutations outside the open reading frame of the SLC3A1 gene, although mutations in other genes might cause non-type I cystinuria (85,126). One patient with I/III phenotype had a dual mutation in both SLC3A1 and SLC7A9, suggesting the existence of a digenic form of the disease (133).

Interestingly, although heterozygous for SLC7A9 mutation show type II or III trait, a minority have type I phenotype (84,135). These data have prompted the International Cystinuria Consortium to consider reclassification of cystinuria subtypes based on genotype rather than phenotype. This new classification includes the following:

Type A—due to two mutations on SLC3A1 on chromosome 2

Type B—due to two mutations on SLC7A9 on chromosome 19

Possible AB type—one mutation on each SLC3A1 and SLC7A9 (135)

Diagnosis and Clinical Features. The simplest diagnostic test is the microscopic examination of the urinary sediment of a freshly voided morning urine (102). The presence of typical flat hexagonal cystine crystals is diagnostic. Acidification of the urine precipitates cystine crystals and may improve the yield of the test. The best screening procedure is the cyanide-nitroprusside test (102). A positive reaction occurs with as little as 75 to 125 mg cystine per gram of creatinine, which is well below that of homozygotes, which excrete at least 250 mg/g creatinine. Some heterozygotes may also be detected by this procedure (105). The test is not specific and may detect acetone or homocystine as well. The definite test is a measurement of urine cystine and dibasic amino acid concentration by ion exchange chromatography. The upper limits of normal are 18, 130, 16, and 22 mg/g creatinine for cystine, lysine, arginine, and ornithine, respectively (104). In establishing the diagnosis of classic cystinuria, it is important to exclude other conditions associated with increased urinary cystine excretion, including isolated cystinuria, tubular immaturity in young infants, generalized aminoaciduria (Fanconi syndrome), and organic acidemias (102,104).

Cystine stones are radiopaque because of the density of the sulfur molecule, and on a roentgenogram, they appear smooth. Occasionally, they form staghorn calculi. Cystine also may act as a nidus for calcium oxalate so that mixed stones may be found (136). Factors contributing to mixed stone formation in cystinuria include alkalinization of urine and urinary tract infections.

The disease usually presents with renal colic. Occasionally, infection, hypertension, or renal failure may be the first manifestation (102). Cystinuria occurs with equal frequency in males and females, but males are more severely affected because of a greater likelihood of urethral obstruction in the male. Clinical manifestations usually occur in the second and third decades of life, with a 62% probability of stones by age 25 years (137). Most patients have recurrent stone formation. Cystinuric patients who receive a kidney transplant have normal urinary cystine and dibasic amino acid excretion after transplantation (138,139).

Treatment. Cystine crystalluria occurs when the cystine content of the urine exceeds 300 mg/L at pH 4.5 to 7.0. Cystine solubility increases sharply at a urine pH above 7 (104). The major therapeutic approaches to cystinuria are designed to increase the solubility of cystine, reduce excretion of cystine, and convert cystine to more soluble compounds (102). Therapies used in the management of cystinuria include the following:

- Increased oral fluid intake to increase urine volume and cystine solubility. Because cystinuric patients excrete 0.5 to 1.0 g cystine/day, intake of 3 to 4 L could be required to keep the urinary cystine concentration below 300 mg/L. Patients should develop a 24-hour schedule for drink-

ing and voiding, with particular attention to nighttime hours, when urine may become supersaturated with cystine. Water should be taken at bedtime and whenever the patient awakens at night. Rigid adherence to fluid therapy is effective in approximately 70% of patients (102).

- Oral alkali in addition to high fluid intake to further increase cystine solubility in the urine (104). A urine pH of 7.5 to 8.0 can be maintained by the provision of 1 to 2 mEq/kg/day of bicarbonate or citrate in divided doses. Because high sodium intake increases cystine excretion (see Dietary Therapy), potassium citrate is preferred (104). Because urine alkalinization may result in formation of mixed calcium-containing stones, adherence to high fluid intake is crucial.
- Dietary therapy to reduce cystine production and excretion. Studies examining the effect of dietary restriction of methionine (a metabolic precursor to cystine) on urine cystine excretion have yielded variable results (104). Also, diets low in methionine are very difficult to follow and may be harmful to growing children. Therefore, dietary methionine restriction is not recommended (104). Urinary excretion of cystine and dibasic amino acids in cystinuric patients has been shown to correlate with urinary sodium excretion (140,141). Hence, dietary sodium restriction is recommended by some authors as a safe approach to the treatment of cystinuria (102). L-glutamine administered orally or intravenously in conjunction with low salt intake reduces cystine excretion (140,142), but this effect was not observed in patients receiving a normal salt diet (143). The mechanism of the anticystinuric effect of glutamine is unclear.
- Pharmacologic therapy to increase cystine solubility and decrease cystine excretion. The sulfhydryl-binding compound D-penicillamine (β -dimethylcysteine) leads to the formation of the mixed disulfide penicillamine-cysteine after a disulfide exchange reaction. This mixed disulfide is far more water-soluble than cystine. Hence, penicillamine acts by reducing cystine excretion as well as by permitting the excretion of a more soluble compound. Penicillamine, given at a dosage of 1 to 2 g/24 hours (30 mg/kg in children), is highly effective and reduces urinary cystine excretion to under 200 mg/g creatinine (144). Unfortunately, penicillamine produces serious side effects in 50% of patients (145). These reactions include rashes (including pemphigus), fever, arthralgia, nephrotoxicity (including nephrotic syndrome in up to 30% of patients and rapidly progressive glomerulonephritis), pancytopenia, and loss of taste. Penicillamine also increases copper and zinc excretion in the urine. The loss of taste may be reversed by copper administration (104). Pyridoxine metabolism may be impaired, and pyridoxine supplementation should be provided for patients receiving D-penicillamine. Most of these side effects revert to normal on discontinuation of the drug. Because of the serious side effects, D-penicillamine therapy should be reserved for patients unresponsive to conservative management, and

stepwise dosing is recommended (102). D-acetyl penicillamine, another anticystinuric sulfhydryl agent, has fewer side effects than D-penicillamine. Mercaptopropionyl glycine (MPG), another agent undergoing a disulfide exchange reaction, is as effective as D-penicillamine in the treatment of cystinuria (146). MPG has the same toxicity as D-penicillamine, but serious renal and hematologic reactions requiring cessation of therapy are much less common with MPG (146). Because of the lower incidence of side effects and because this compound can be used in patients who develop allergic reactions to D-penicillamine, MPG is the pharmacologic agent of choice in the therapy of cystinuria (146,147).

Several studies have examined the effect of captopril, an angiotensin-converting enzyme inhibitor, on urinary cystine excretion in cystinuric patients (148–150). This nontoxic sulfhydryl compound builds highly soluble captopril-cysteine disulfides. Although a reduction in cystine excretion has been demonstrated in some studies (148,149), others (150) have failed to show an effect. Further studies are needed to evaluate the efficacy of captopril therapy in cystinuria. It has been proposed that meso-1,3 dimercaptosuccinic acid (DMSA), an additional compound forming disulfide linkage with cysteine, might be a useful therapeutic agent in cystinuria (151). The efficacy of this agent in cystinuria remains to be established.

Ascorbic acid, which acts as a reducing agent to convert cystine to the more soluble cysteine, has been suggested as a therapeutic modality in patients with cystinuria (147). To date, the results of the use of this compound on a limited number of patients have been variable (104,147). Also, concerns have been raised that ascorbic acid therapy in cystinuria is potentially lithogenic because of the hyperoxaluric and hypocitraturic effect of this agent.

Several urologic procedures have been used to treat cystine stones:

- Chemolysis of stones by irrigation through a percutaneous nephrostomy. Successful dissolution of stones has been achieved using *N*-acetylcysteine, D-penicillamine, α -MPG, and a very alkaline agent, tromethamine (103,104).
- Extracorporeal shock wave lithotripsy. This therapeutic modality has been only partially successful because of the organic nature and the uniform crystal structure of cystine stones (103,152). Percutaneous ultrasonic lithotripsy has been somewhat more effective (153).
- Lithotomy. Surgical removal of stones is necessary only in rare patients with obstructing or infected stones unresponsive to a more conservative approach.

In summary, the mainstays of therapy in cystinuria include hydration, alkalization of the urine, and dietary sodium restriction. Full compliance with this regimen results in significantly reduced urinary cystine excretion and good long-term prognosis in most patients. Pharmacologic treatment with sulfhydryl agents should be reserved

for patients in whom conservative therapy fails. Urologic intervention may be indicated in selected patients.

Isolated Cystinuria

Brodehl et al. (113) report two siblings who showed high urinary excretion rates of cystine but normal dibasic amino acid excretion. The children did not develop renal stones. This report, along with the detection of a similar abnormality in dogs (154), provides evidence of a separate cystine transporter not shared with dibasic amino acids in the tubular brush-border membrane, which appears to be defective in isolated cystinuria. The molecular nature of this proposed transporter is unknown.

Lysinuric Protein Intolerance (Hyperdibasic Aminoaciduria Type II)

LPI is a rare autosomal recessive disorder characterized by excessive urinary excretion of dibasic amino acids (especially lysine), normal cystine excretion, and poor intestinal absorption of dibasic amino acids (155–157). Plasma values of dibasic amino acids are subnormal. The disease is relatively common in Finland, where the prevalence of the disease is 1:60,000 (157). Approximately 100 patients, one-half of them Finns, have been described (157). Homozygous patients show massive dibasic aminoaciduria as well as hyperammonemia after a protein overload; heterozygotes have normal urinary amino acid excretion but impaired renal and intestinal transport of dibasic amino acids at increased loads. The clinical manifestations in homozygotes for LPI are those of protein malnutrition and postprandial hyperammonemia. They include failure to thrive, marked protein intolerance, anorexia, vomiting, diarrhea, hepatosplenomegaly, muscle hypotonia, interstitial lung disease, osteoporosis, seizures, and coma (157).

The pathogenic mechanism of LPI appears to be a defective transport of dibasic amino acids in the basolateral membrane of renal and intestinal epithelial cells, resulting in impaired efflux from cell to interstitium (158,159). This has been confirmed by a measurement of fluxes in jejunal biopsy specimens from LPI patients (158), as well as by the observation that infusion of citrulline to these patients results in massive argininuria and ornithinuria (159). Citrulline is reabsorbed from the tubular lumen by a neutral amino acid transport mechanism and is converted to arginine and ornithine in the renal cell. Impaired exit at the antiluminal membrane results in backflux of accumulated arginine and ornithine at the brush-border membrane surface. It is the high-affinity, specific dibasic amino acid transporter γ^+L that is affected in this disease (84,128). Because basolateral membrane transporters of epithelial cells and plasma membrane transporters of parenchymal cells are homologous carriers, it is not surprising that hepatocytes (160), granulocytes (160), and cultured skin fibroblasts (161) from patients with LPI show impaired transport of dibasic amino acids. Erythrocytes from LPI patients, which

do not have the y^+L system, show normal cationic amino acid transport (162).

It is presumed that the defective hepatic transport of dibasic amino acids deprives hepatic cells of ornithine and arginine, which are necessary for urea production (157). This results in protein intolerance, hyperammonemia, and low urea formation. This notion is supported by the observation that L-citrulline supplements improve protein tolerance in LPI patients (159). This amino acid, a metabolic precursor of ornithine and arginine, is absorbed in the intestine, enters the hepatic cell via neutral amino acid transport mechanisms, is metabolized in the liver to ornithine and arginine, and restores the pathway for ammonia disposal (157).

In 1992, the rBAT homologous protein, the human cell surface glycoprotein 4F2hc (encoded by the gene CD98), was shown to induce y^+L cationic amino acid transport in *Xenopus* oocytes (77). Like rBAT, 4F2hc represents the heavy subunit of a disulfide-linked heteromeric amino acid transporter (163) (see Molecular Structure of Amino Acid Transporters; Figs. 37.3 and 37.4). Molecular analysis excluded CD98, which has been localized to chromosome 11, as a candidate gene for LPI (164). Linkage studies in Finnish and non-Finnish LPI families placed the gene of the disease to 14q11-13 (165,166).

In 1998, Torrents et al. (87) identified a human cDNA, SLC7A7, as encoding y^+LAT-1 —a member of the family of light subunits that combine with 4F2hc to form heteromeric amino acid transporters (see Molecular Structure of Amino Acid Transporters; Fig. 37.3). The 4F2hc/ y^+LAT-1 transporter has been shown to have the activity of amino acid transport system y^+L that is responsible for the efflux of basic amino acids at the basolateral plasma membrane of epithelial cells (128) (see Specificity of Transport; Figs. 37.1 and 37.3). The SLC7A7 gene localized to the LP1 locus (87). In 1999, the two groups (164,167) demonstrated that mutations in SLC7A7 cause LPI in Finnish, Italian, and Spanish patients. As of 2000, more than 25 SLC7A7 mutations, spread along the entire SLC7A7 gene, have been found in LPI patients from different ethnic groups (126). Expression studies in *Xenopus* oocytes showed that various LPI mutations result in proteins that fail to co-induce amino acid transport activity when expressed with 4F2hc (168). Two of the mutants reached the oocyte plasma membrane when coexpressed with 4F2hc, demonstrating that they are transport-inactivating mutations (168).

LPI is characterized by poor genotype/phenotype correlation. Even Finnish patients, who share the same founder mutation, show variation in the clinical picture (168). Similarly, both interfamilial and intrafamilial phenotypic variability were observed in Italian LPI patient heterozygotes for the same mutation (169). This suggests that, in addition to SLC7A7 mutations, hitherto unknown factors play a role in the pathogenesis of LPI (126,128).

Therapy of LPI consists of protein restriction to prevent hyperammonemia, as well as oral supplements of arginine,

ornithine, and, most important, citrulline (170). Administration of the latter amino acid, which corrects the hepatic deficiency in ornithine and arginine, results in clinical improvement and catch-up growth.

Hyperdibasic Aminoaciduria Type I

An autosomal dominant cationic aminoaciduria has been described in two families containing several heterozygotes and a single homozygote (114,171). This disease, called *hyperdibasic aminoaciduria type I*, is characterized by impaired renal reabsorption and intestinal absorption of the dibasic amino acids lysine, arginine, and ornithine but not of cystine. Plasma values of dibasic amino acids are normal, and there is no protein intolerance or hyperammonemia. The reported homozygous patient had mental retardation (171). Hyperdibasic aminoaciduria type I heterozygotes have modest cationic aminoaciduria, whereas LPI heterozygotes have no hyperaminoaciduria. It has been speculated that the brush-border membrane-bound, high-capacity transporter for dibasic amino acids, which excludes cystine, is defective in this disease. The molecular nature of this transporter is unknown.

Isolated Lysinuria

Omura et al. (115) reported a single child with increased urinary excretion of lysine; impaired intestinal absorption of this amino acid; low plasma lysine levels; and normal renal and intestinal transport of ornithine, arginine, and cystine. The patient did not have hyperammonemia but had failure to thrive and mental retardation, probably secondary to the deficiency of the essential amino acid, lysine. This case implies a defect in a selective transport system for lysine in the kidney and the intestine. Such a system has not been identified in physiologic or molecular studies.

Neutral Aminoaciduria

Three distinct disorders of neutral amino acid transport have been identified: Hartnup disorder, methioninuria, and histidinuria.

Hartnup Disease

Hartnup disease, which may have afflicted Julius Caesar and his family (172), was first recognized in two siblings in England in 1956 (173). This disease is characterized by intestinal malabsorption and massive aminoaciduria of the neutral monoamino monocarboxylic amino acids alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine, glutamine, and asparagine (174). Most patients also have increased excretion of indolic compounds that originate in the gut from bacterial degradation of tryptophan (175). Transport of other neutral amino acids, including cystine, imino acids, glycine, and β -amino acids, is unaffected. The disease is inherited as an autosomal recessive trait and has an estimated incidence

of 1:20,000 live births. Heterozygotes have normal urinary acid excretion under physiologic conditions. Clinical features in homozygotes may include photosensitive rash, cerebellar ataxia, and a variety of psychiatric manifestations, as in the features of pellagra (171). The pellagra-like manifestations are primarily caused by intestinal malabsorption and urinary loss of tryptophan, an amino acid that is required for niacin synthesis. The diagnosis should be suspected in any patient with pellagra who has no history of niacin or nicotinamide deficiency and should be made by chromatographic analysis of the urine (174).

A defect in the broad-specificity neutral α -amino acid transport mechanism in the renal and intestinal brush-border membrane is presumed to be the pathogenic mechanism underlying this disorder (11,176). Two lines of evidence support the hypothesis that the lesion is localized in the brush-border membrane (11). First, plasma amino acid response in patients with Hartnup disease was attenuated after oral feeding of free α -amino acids but not when appropriate dipeptides were given orally (177). The dipeptides are presumed to be reabsorbed by a dipeptide-specific brush-border membrane transporter and hydrolyzed in the enterocyte; the free amino acids exit the cell via a nondefective basolateral membrane-bound carrier. Second, tryptophan transport is normal in various parenchymal cells from patients with Hartnup disease, including leukocytes, placenta, and cultured skin fibroblasts (174,178). As indicated earlier, carriers in plasma membranes of parenchymal cells are homologous to basolateral membrane carriers in epithelial cells, which are supposed to be normal in Hartnup disease.

The transport characteristics and the epithelial distribution of the Na^+ -dependent neutral amino acid transport B^0 (see Specificity of Transport; Fig. 37.1), which is encoded by the recently identified ATB^0 gene (61) (see Molecular Structure of Amino Acid Transporters), raise the possibility that this transporter is defective in Hartnup disorder. The role of this gene, which localizes to chromosome 19q13.3 (61), in the pathogenesis of Hartnup disorder has not been investigated.

The presence of alternative transport pathways for neutral amino acids in the renal tubule explains why the defect in the broad-specificity neutral amino acid transport in Hartnup disease results in only partial loss of some amino acids (e.g., phenylalanine) (11). These alternative systems, as well as the oligopeptide-preferring carriers in the kidney and intestine, are responsible for normal plasma amino acid values and lack of symptoms in most patients (179). As suggested by Scriver et al. (179), Hartnup disease is multifactorial in its pathogenesis, and only patients genetically predisposed to low plasma amino acid levels and impaired tryptophan metabolism develop symptoms.

Patients with Hartnup disease respond well to oral therapy with nicotinamide, 40 to 100 mg/day (180). More recently, oral administration of *tryptophan ethylester*, a lipid-

soluble form of tryptophan, has been shown to increase serum tryptophan and reverse clinical symptoms in patients with Hartnup disease (181).

Methioninuria

There are two case reports of patients with isolated increased urinary excretion of methionine and its metabolic breakdown products (182,183). The patients had malodorous urine, edema, episodic hyperventilation, seizures, and mental retardation. The underlying defect appeared to be abnormal transport of methionine in the kidney and in the intestine. α -Hydroxybutyric acid, a bacterial degradation product of unabsorbed intestinal methionine, appeared in the urine of these patients. This organic acid may have been responsible for the neurologic manifestations in these patients. A low-methionine diet resulted in significant clinical improvement. These cases of isolated methioninuria, as well as the observation that methionine, which shares the broad-spectrum amino acid transport system with other neutral amino acids, are not hyperexcreted in Hartnup disease, provided evidence for the existence of a specific transport pathway for methionine in renal and intestinal epithelium.

Histidinuria

Two siblings (184) and two other patients (185,186) have been reported with isolated histidinuria. All showed significant mental retardation. Investigation revealed impaired transport of histidine in the kidney and intestine. Parents of the two affected siblings showed normal urinary histidine excretion under normal conditions but hyperhistidinuria after an oral histidine load. The mode of inheritance of this disease is uncertain, but autosomal recessive inheritance has been suggested (11). Although the broad-specificity transporter of neutral amino acids is the major carrier for histidine, as suggested by *in vitro* studies as well as by fractional excretion rates above 50% for this amino acid in Hartnup disease (11), the case reports of histidinuria suggest that an isolated histidine carrier is operating in the renal tubule and the intestine.

Iminoaciduria and Glycinuria

Two distinct disorders belong to this group of aminoacidurias: iminoglycinuria and isolated glycinuria.

Iminoglycinuria

Iminoglycinuria is an autosomal recessive membrane transport defect characterized by excretion of excessive amounts of proline, hydroxyproline, and glycine in the urine (187). Iminoglycinuria is a benign condition with an estimated incidence of 1:15,000 live births (187,188). It is the shared, brush-border membrane-bound, group-specific transport pathway for imino acids and glycine (see Specificity of Transport) that is defective in this condition (94,187). The selective glycine-specific and imino acid-specific transport systems are not affected. The activity of these selective transporters

accounts for the normal plasma levels of glycine and imino acids observed in iminoglycinuria. As discussed earlier, the late maturation of these selective transporters in normal infants is responsible for neonatal physiologic iminoglycinuria (92,94). The absence of the selective transporters during early life also explains why infants with iminoglycinuria who lack the shared transporter have fractional excretion values for glycine and proline approaching 100%, which decline after the first months of life (11). Defective intestinal transport of proline has been found in some patients with iminoglycinuria (187). As expected, proline transport is not defective in leukocytes or skin fibroblasts because these cells do not possess carriers corresponding to a brush-border membrane carrier (11).

Iminoglycinuria is a genetically heterogeneous condition with several mutant alleles (11,187). This view is supported by several observations. First, obligate heterozygotes may have hyperglycinuria (but not iminoaciduria) or may have normal urinary amino acid excretion (189). Second, some homozygous patients have an intestinal transport defect. Third, a variant exists with normal transport maximum (T_m) for proline and a defect affecting glycine transport more than proline transport, indicating a K_m defect (190).

The genetic defect responsible for iminoglycinuria is unknown. The transport characteristics of the amino acid transport system expected to be defective in this disorder fit those of the IMINO and/or the Na^+ - and Cl^- -dependent transporters of the GAT transporter family (see Specificity of Transport). The latter group includes GLYT1, GLYT2, and PROT, which transport glycine and/or proline. The GLYT transporters are expressed in the kidney and may be good candidates for the iminoglycinuria phenotype.

Differential diagnosis of iminoglycinuria includes neonatal iminoglycinuria; Fanconi syndrome, in which generalized aminoaciduria occurs; and hyperprolinemia, an inborn error of proline metabolism that exhibits overflow prolinuria as well as hydroxyprolinuria and glycinuria secondary to a proline-induced inhibition or hydroxyproline and glycine transport. This inhibition occurs at the shared luminal carrier for these amino acids.

Isolated Glycinuria

Isolated glycinuria without iminoaciduria has been reported in two families (190,191). It has been suggested that this condition is a manifestation of a mutation affecting the specific high-affinity carrier for glycine, the molecular identity of which remains to be established (11). It is possible, however, that hyperglycinuria represents a defect in the shared, imino acid-glycine transport system affecting affinity rather than capacity of the system (K_m variant). Because the condition appears to be inherited as an autosomal dominant trait, it also is possible that these cases represent hyperglycinuric heterozygotes for the iminoglycinuria allele. Glycinuria has also been reported in association with glycosuria, called *glycoglycinuria* (192). The defect underlying this autosomal dominant condition is unknown.

Dicarboxylic Aminoaciduria

Selective urinary hyperexcretion of the acidic amino acids glutamate and aspartate was first reported in two children (193,194). One of the children also had impaired intestinal absorption of these amino acids. The condition is inherited as an autosomal recessive trait and appears to be benign; screening in a French-Canadian population revealed a large number of healthy probands with hyperdicarboxylic aminoaciduria and an incidence of 1:29,000 live births (195).

The pathogenic mechanism appears to be a defect in the dicarboxylic amino acid transport system in the brush-border membrane. The excretion of dicarboxylic amino acids in homozygous patients may greatly exceed the GFR, suggesting tubular secretion or backflux of dicarboxylic amino acids from cell to lumen (11). Treatment with glutamate and aspartate corrected the hypoglycemia observed in one patient (193). This hypoglycemia probably resulted from the absence of these gluconeogenic amino acids.

The neuronal and peripheral anionic amino acid transporter EAAC1 (EAAT3) (see Molecular Structure of Amino Acid Transporters) is an obvious candidate for the transporters defective in dicarboxylic aminoaciduria. The transporter is highly expressed in the kidney and intestine (54). Peghini et al. (196) have shown that EAAC1-deficient mice develop dicarboxylic aminoaciduria, a finding that strongly suggests that the EAAC1 gene is a candidate gene for dicarboxylic aminoaciduria. In 2001, Nozaki et al. (197), by using homozygosity mapping, assigned the Hartnup disease locus to chromosome 5p15. Nevertheless, there are no functionally characterized genes mapped to this locus that seem to be obvious candidates for the Hartnup disorder.

An interesting feature of dicarboxylic aminoaciduria is the decreased uptake of anionic amino acids by cultured skin fibroblasts from patients with this condition (198). It has been shown that anionic amino acid-preferring carriers in epithelial brush-border and parenchymal cells have similar characteristics (11,198). As pointed out by Scriver and Tenenhouse (11), the apparent expression of the mutant gene in both the brush-border membrane of the epithelium and the plasma membrane of parenchymal cells is unique and contrary to the expected pattern of analogy between basolateral membrane-bound and plasma membrane-bound carriers (see Classic Cystinuria, Hartnup Disease, and Lysinuric Protein Intolerance). The possibility that the EAAC1 transporter, likely defective in dicarboxylic aminoaciduria, is expressed at both the luminal and basolateral membranes of the proximal tubule awaits future investigation.

β -Aminoaciduria

No inborn error of the β/γ -amino acid transport system that carries taurine, β -alanine, β -aminobutyric acid, and GABA has been reported in humans. An impaired taurine transport, however, has been found in an inbred mouse

strain (C57BL/6J) (199). Studies using kidney slices (199) and isolated basolateral membrane vesicles (95) have localized the transport defect to the antiluminal membrane of the proximal tubular epithelium. In analogy with the defect in LPI, an impaired taurine exit across the basolateral membrane and backflux from cell to lumen may underlie the hypertaurinuria observed in the C57BL/6J mouse (95,199).

GLYCOSURIA

General Characteristics of Renal Glucose Transport

Under normal conditions, the reabsorption of filtered glucose by the renal tubule is almost complete. Less than 0.05% of the renal glucose load is excreted in the human urine (200); 90% of the filtered glucose is reabsorbed in the proximal convoluted tubule; and the rest is reclaimed in the proximal straight tubule, the loop of Henle, and, to some extent, the collecting duct (201).

Reabsorption of glucose across the proximal tubular brush-border membrane occurs by an active, carrier-mediated, concentrative, Na^+ -dependent transport process (200,201). The Na^+ electrochemical gradient driving glucose transport across the brush-border membrane is maintained by the activity of the basolateral membrane-bound Na^+ - K^+ -ATPase that pumps Na^+ out and K^+ into the cell. Na^+ -glucose cotransport across the luminal membrane is electrogenic positive and phlorizin inhibitable. Glucose exit from the cell occurs by an Na^+ -independent-facilitated diffusion down the glucose concentration gradient (201). This diffusional exit of glucose is mediated by a carrier that is distinct from that found at the luminal membrane surface (see Facilitative Glucose Transporters).

The mammalian kidney is characterized by a limited capacity to reabsorb D-glucose (200). As plasma glucose

concentration is progressively elevated, the amount of glucose reabsorbed increases linearly until a maximum value is reached (Fig. 37.7). Beyond this maximum rate of glucose reabsorption, further increases of filtered D-glucose are excreted in the urine. As shown in Figure 37.7, the glucose titration curve provides parameters of glucose transport such as minimum threshold (F_{minG}), defined as the filtered glucose load at which 1 mg of glucose per minute appears in the urine, and the tubular maximum for glucose reabsorption (T_{mG}). Reported T_{mG} values for glucose in human adults and children have ranged between 260 and 350 mg/min/1.73 m^2 (202–204), with lower values in infants (204,205). When corrected for the GFR (T_{m}/GFR), T_{m} value for glucose in infants, children, and adults is approximately 2.5 mg/mL (204).

The glucose titration curve (Fig. 37.7) is characterized by a splay—a rounding of the curve during the transition from virtually complete reabsorption of filtered D-glucose to complete excretion of excess glucose load. This deviation from the theoretical curve is explained by the nephron functional heterogeneity (the gradual progression from the first to the last nephron to saturate), as well as by the variation in affinity for glucose or K_{m} values between carriers (the magnitude of the splay is inversely proportional to the affinity of the transporter for the D-glucose) (200).

Studies in isolated perfused tubules (206) and later experiments using isolated BBMVs from pars convoluta (S1 and S2 segments) and pars recta (S3 segment) of the proximal tubule (207–209) demonstrate that the kinetic properties and stoichiometric relationships of D-glucose reabsorption change along the length of the nephron. These studies provide evidence for two Na^+ -dependent transport mechanisms, a low-affinity/high-capacity cotransport system in the early proximal tubule and a high-affinity/low-capacity system in the late proximal tubule. The Na^+ -glucose coupling ratio was found to be 1:1 in the convoluted proximal tubule and 2:1 in the straight proximal tubule (208,209).

FIGURE 37.7. Renal glucose titration curves. Theoretical and observed normal curves are compared to abnormal curves observed in type A and type B renal glycosuria. T_{mG} , maximum rate for glucose reabsorption; F_{minG} , minimum threshold. (From Elsas LJ, Longo N. Glucose transporters. *Annu Rev Med* 1992;43:377–393, with permission.)

FIGURE 37.8. Schematic structure of the Na⁺/glucose cotransporter (SGLT) and the facilitative glucose transporter (GLUT). The two mutations shown in SGLT were identified in one of the original families with glucose-galactose malabsorption. (Adapted from Longo N. Human glucose transporters. *Adv Pediatr* 1998;45:293–313.)

The efficiency of a coupled carrier system increases as the power of the stoichiometry increases (201,209). Whereas the early proximal tubule glucose transporter is responsible for the reabsorption of the bulk of filtered D-glucose from the tubular lumen, the late proximal tubule glucose transporter is responsible for the removal of the last traces of glucose from the urine (209). The arrangement of transporters in series along the proximal tubule enables the kidney to reabsorb glucose from the urine in a more energy-efficient mechanism than can be achieved by either of the cotransporters acting alone.

Molecular Biology of Na⁺-Glucose Cotransporters

Various approaches have been used to identify and isolate the Na⁺-glucose cotransporters. Earlier methods, including solubilization and reconstitution techniques, semiselective and photoaffinity labeling, phlorizin affinity chromatography, radiation inactivation, and immunoaffinity absorption (201), have been inconclusive and yielded very limited biochemical data. However, considerable progress has been made in the past decade in elucidating the molecular structure of membrane proteins that catalyze sugar transport processes, including the Na⁺-glucose cotransporter (51,210,211). Hediger et al., using expression cloning in *Xenopus* oocytes (see Molecular Structure of Amino Acid Transporters), cloned and sequenced the Na⁺-dependent D-glucose transporter from rabbit (38) and human (212) intestine. Subsequently, molecular analysis revealed that rabbit intestinal and renal Na⁺-glucose cotransporters are essentially identical (213). The Na⁺-glucose cotransport proteins belong to the SGLT1 family

of sodium cotransport proteins, which includes the renal Na⁺-nucleoside, renal Na⁺-myoinositol, and the *Escherichia coli* Na⁺-proline cotransporters (51,211).

The SGLT1 transporter (Fig. 37.8) consists of 662 to 664 amino acids and has 14 membrane-spanning sequences that are presumed to be α -helical, with the NH₂ and COOH termini located on the cytoplasmic side of the membrane. A simple glycosylation site is found in the hydrophilic domain between transmembrane segments 5 and 6 (214). SGLT1 from rabbit (38), rat (216), pig (216), and human (212) show high homology in sequence and structure. The gene encoding the human intestinal SGLT1 has been recently localized to the q11.2lqter region of chromosome 22 (217). Recent studies using *Xenopus* oocytes (218) demonstrate that protein kinases (PKA and PKC) regulate SGLT1 activity by controlling the distribution of transporters between intracellular compartments and the plasma membrane and that this occurs by exocytosis and endocytosis.

Studies by Pajor et al. (219) and Lee et al. (215) using expression studies in *Xenopus* oocytes, Western and Northern analysis, and *in situ* hybridization and immunocytochemistry have provided evidence that the renal Na⁺-glucose cotransporter SGLT1 is the high-affinity/low-capacity transporter found predominantly in the straight proximal tubule (S3 segment). Evaluation of the stoichiometry of SGLT1-mediated transport in *Xenopus* oocytes revealed an Na⁺ to glucose coupling ratio of 2:1 (215).

A second low-affinity Na⁺-glucose cotransporter named SGLT2 was isolated from rat (220) and human (221,222) kidney. The amino acid sequence of SGLT2 is 59% identical to that of SGLT1 (221). SGLT2 has an Na⁺ glucose coupling ratio of 1:1, does not recognize galactose (which is a substrate

for SGLT1), and is strongly expressed in proximal tubule S1 segments (222). Human SGLT2 gene was mapped to chromosome 16p11.2 close to the centromere (223).

A third Na⁺-dependent glucose transporter, termed *SGLT3*, was isolated from an LLC-PK₁ pig renal cell line (224). It is a low-affinity, Na⁺-glucose (not galactose) cotransporter (225). Human *SGLT3* gene is located on chromosome 22 (211).

Facilitative Glucose Transporters

Glucose concentrated inside tubular epithelial cells flows to the interstitium down its concentration gradient through facilitative glucose transporters located in the basolateral membrane (200,226). The basolateral Na⁺-independent and the luminal Na⁺-dependent glucose transport systems also differ with respect to inhibition and specificity (201). The basolateral glucose transporter is inhibited by the mold metabolite cytochalasin-B but not by phlorizin. It also accepts D-glucose.

The basolateral membrane glucose transporters belong to a family of Na⁺-independent facilitative glucose transporters, of which five different isoforms called *GLUT1*, *GLUT2*, *GLUT3*, *GLUT4*, and *GLUT5* have been identified (226–228). These subspecies have extensive structural homologies but differ in their tissue distribution, specific function, insulin sensitivity, sugar specificity, and kinetic characteristics. The human erythrocyte glucose transporter GLUT1 was the first glucose transporter to be cloned and sequenced (229). It is the most ubiquitously distributed of the transporter isoforms (227). Isoforms GLUT2 to GLUT5 have been cloned by screening cDNA libraries from various tissues and species with a GLUT1 DNA probe (226). The facilitative glucose transporters (Fig. 37.8) have 12 membrane-spanning domains, with both the NH₂ and the COOH termini of the protein facing the cytoplasm. A single glycosylation site is located between transmembrane domains 1 and 2.

GLUT2, a low-affinity transporter, is the predominant facilitative glucose transporter in hepatocytes and in the basolateral membrane of intestinal and renal tubular cells (230,231). In the kidney, GLUT2 is present only in the basolateral membrane of cells in the proximal convoluted tubule (S1 and S2 segments) (230,231). Studies using anti-peptide antibodies specific for GLUT1 have detected this high-affinity transporter in the kidney (231,232). It was found in the basolateral membrane of cells forming the proximal straight tubule (S3 segment). GLUT5 has also been identified in the kidney (233).

Thus, it appears that transepithelial glucose transport in the proximal tubule occurs by two different pairs of apical Na⁺-dependent and basolateral Na⁺-independent glucose transporters (200,226) (Fig. 37.9). A luminal Na⁺-dependent, low-affinity/high-capacity glucose transporter (designated SGLT2) and a basolateral Na⁺-independent, low-affinity GLUT2 are responsible for the bulk of glucose reabsorption in the early part of the proximal tubule. A

FIGURE 37.9. Schematic model for the distribution (luminal or basolateral) of cloned glucose transporters in renal tubular epithelium. Orientation permits net reabsorption from lumen to interstitium. (Adapted from Silverman M. Structure and function of hexose transporters. *Annu Rev Biochem* 1991;60:757–794.)

luminal Na⁺-dependent, high-affinity/low-capacity SGLT1 coupled with the basolateral Na⁺-independent, high-affinity GLUT1 reabsorb the remaining low concentration of glucose in the late part of the proximal tubule.

Maturation of Glucose Transport

The immature renal tubule in animals (234,235) and humans (204,236,237) is characterized by decreased ability to reabsorb glucose. Tubular reabsorption of glucose relates directly to postnatal age, and glycosuria occurs commonly in infants less than 30 weeks' gestational age (236–238). There are few data on the development of renal glucose transport mechanisms. The fetal kidneys of various animal species (234,239,240) have been shown to reabsorb glucose. In the fetal rat kidney (239), glucose reabsorption appeared to be Na⁺ dependent and phlorizin inhibitable. A decreased initial rate uptake of α -methyl-D-glucoside was found in isolated renal tubules from neonatal rat (241) and dog (235). BBMV studies (242) demonstrated a concentrative, Na⁺-dependent, electrogenic and phlorizin-sensitive glucose transport in the fetal rabbit kidney. The fetal glucose transport mechanism, however, had a significantly lower capacity than the adult glucose transport system. Recent experiments exploring the expression of SGLT1 and SGLT2 mRNAs in embryonic rat kidneys (220) revealed that the two Na⁺-glucose cotransporters appeared early in gestation and that they were developmentally regulated. Recent evidence suggests that the increase in SGLT1 mRNA-accompanying cell differentiation in the pig kidney cell line LLC-PK₁ is regulated by PKA (243) and PKC (244).

Little is known about the maturation of the facilitative glucose transporters in the kidney. A study (245) examining the developmental pattern of these transporters in the rat kidney showed that renal GLUT1 and GLUT5 gene expression was unchanged throughout development, whereas

GLUT2 was most abundant before weaning. The latter finding may be related to the fact that the kidney alone seems to be responsible for gluconeogenesis before expression of gluconeogenic enzymes by the liver.

Further studies are needed to explore the activity, expression, and distribution of various glucose transporters during kidney development and to elucidate the molecular mechanisms underlying the maturation of renal tubular glucose transport.

Glycosuria

Hereditary renal glycosuria is an abnormality in which variable amounts of glucose are excreted in the urine at normal concentrations of blood glucose (246). The renal defect is specific for glucose, and there is no increase in the urinary excretion of other sugars. Renal glycosuria is a benign condition without symptoms or physical consequences except during pregnancy or prolonged starvation—when dehydration and ketosis may develop (246). The metabolism, storage, and use of carbohydrates as well as insulin secretion are normal. The condition exists from infancy throughout adult life, and diagnosis usually is done on routine urine analysis. The distinction between renal glycosuria and diabetes mellitus is made with a fasting blood glucose level and a glucose tolerance test. The genetic pattern in renal glycosuria is autosomal recessive, although glycosuria in some heterozygotes has led some investigators to postulate a dominant inheritance (246,247).

The underlying pathogenic mechanism appears to be an isolated, selective defect in proximal tubular glucose transport. Renal glycosuria is not associated with impaired D-glucose transport in the intestinal epithelium (248).

Renal glycosuria is a heterogeneous condition resulting from several mutations. Analysis of renal titration curves for glucose reabsorption reveals two types of renal glycosuria (246,249) (Fig. 37.7). In type A, or classic renal glycosuria, $F_{\min G}$ and Tm_G are reduced. In type B, $F_{\min G}$ is reduced, whereas Tm_G is normal but has an increased splay. It has been suggested that the type A mutation reflects reduction in the capacity of the glucose transport system, which might arise from a uniform defect in all nephrons, and type B reflects a decrease in the affinity of the transport system, which might also be a consequence of nephron heterogeneity (248,250). A third type of glycosuria, termed *type O*, was described by Oemar et al. (251). In this rare condition, tubular reabsorption of glucose is virtually absent, and all glucose filtered is excreted in the urine.

It is important to consider the relationships between renal glycosuria, a benign condition, and intestinal glucose-galactose malabsorption, a potentially lethal disease. Glucose-galactose malabsorption, an autosomal recessive disease, is characterized in homozygotes by a neonatal onset of severe watery diarrhea that results in death unless glucose and galactose are removed from the diet (246). Studies using jejunal biopsy specimens from affected patients have demon-

strated a defect in intestinal Na⁺-dependent glucose transport (252). In 1991, molecular genetic studies in two sisters afflicted with glucose-galactose malabsorption revealed a missense mutation that causes a change in residue 28 from aspartate to asparagine in the intestinal brush-border SGLT1 Na⁺-glucose cotransporter (253). This made glucose-galactose malabsorption the first reported disease that is caused by a mutation in a membrane transport protein. As of 2000, more than 40 mutations have been identified in patients with glucose-galactose malabsorption (246). The mutant proteins, when expressed in *Xenopus* oocytes, cause a marked reduction in Na⁺-glucose transport activity (246).

Patients with glucose-galactose malabsorption who have been studied show a mild defect in renal tubular reabsorption of glucose, with normal Tm for glucose but decreased minimal threshold ($F_{\min G}$) (246,252). In contrast, patients with renal glycosuria show no defect in intestinal D-glucose absorption. This indicates that the SGLT1 Na⁺-glucose cotransporter affected in glucose-galactose malabsorption is shared between the intestine and the kidney, as also suggested by the molecular studies of Pajor et al. (219) and Lee et al. (215) (see Molecular Biology of Na⁺-Glucose Cotransporters). The glucose transporter impaired in glycosuria is not shared.

The accumulating clinical, physiologic, and molecular data on renal glucose transport have led to the following hypothesis of the pathogenesis of hereditary renal glycosuria (200,249). A defect in the low-affinity/high-capacity 1 Na⁺:1 glucose cotransporter (SGLT2) of the early proximal tubule, which reabsorbs most renal tubular glucose, would produce type A classic renal glycosuria but has no effect on glucose absorption in the intestine. By contrast, SGLT1, the high-affinity/low-capacity 2 Na⁺:1 glucose cotransporter of the late proximal tubule (which also carries galactose), mediates residual glucose reabsorption in the renal tubule, and when defective, as in glucose-galactose malabsorption, causes only mild type B renal glycosuria.

It is noteworthy that mutations in the gene for GLUT2, the facilitative glucose transporter, are also associated with glycosuria in the Fanconi-Bickel syndrome (254,255). This autosomal recessive disorder is characterized by hepatorenal glycogen accumulation, Fanconi syndrome, and impaired use of glucose and galactose. The renal loss of glucose is due to the transport defect for monosaccharides across the renal basolateral membrane. A recent study (256) has demonstrated that knock-out mice lacking the GLUT2 gene exhibit extreme glycosuria.

TUBULAR DISORDERS OF ELECTROLYTE REGULATION

JUAN RODRÍGUEZ-SORIANO

HYPOKALEMIC STATES

Hypokalemia may be due to a great number of causes, including inadequate dietary intake; increased losses by the gastrointestinal tract, skin, or kidney; and abnormal distribution of K in the body (see Chapter 8). In this section we discuss only the renal tubular disorders in which hypokalemia constitutes a prominent biochemical feature, as occurs in Bartter's and Gitelman's syndromes and in states of pseudohyperaldosteronism. For description of other hypokalemic tubulopathies, such as renal tubular acidosis or Fanconi's syndrome, the reader is referred to Chapters 39 and 42, respectively.

Bartter's-Like Syndromes

In 1962, Bartter and coworkers (1) reported two patients presenting with a new syndrome characterized by hypokalemia, metabolic alkalosis, hyperaldosteronism with normal blood pressure, decreased pressor responsiveness to infused angiotensin II, and hyperplasia of the juxtaglomerular complex. Since then, many reports, both in children and in adults, have appeared in the literature under the heading of Bartter's syndrome. It is now evident that this term encompasses a variety of inherited disorders of renal tubular transport that are characterized by a biochemical picture of hypokalemia, hypochloremia, metabolic alkalosis, hyperreninemia, normal blood pressure, and increased urinary excretion of Na, Cl, and K. Thus, the term *Bartter's-like syndromes* better defines this ensemble of closely related tubular disorders.

At the present time, patients with Bartter's-like syndromes can be divided into three different genetic and clinical entities (2–6): (a) neonatal Bartter's syndrome, (b) classic Bartter's syndrome, and (c) Gitelman's syndrome. Obviously, this classification may require modification in the future as new mutations are described and genotypic-phenotypic correlations are better known.

Neonatal Bartter's Syndrome

Genetics

The known appearance in the same sibship, with apparent normality of the parents and equal incidence in both sexes, points to an autosomal recessive inheritance. Recent findings have established the genetic heterogeneity of neonatal Bartter's syndrome (Table 38.1). In so-called type 1, frame shift, nonsense, and missense mutations in the gene locus SLC12A1 have been found (7–9). Probably these mutations are quite rare in the population because almost all patients studied to date are homozygous for an identical disease mutation in both chromosomes, as a consequence of parental consanguinity (7). The gene, located on 15q15-q21 and containing 26 exons, encodes the renal bumetanide-sensitive Na-K-2Cl cotransporter (also termed NKCC2) of the thick ascending limb of the loop of Henle.

Frame shift, nonsense, and missense mutations in the ROMK gene (locus symbol KCNJ1) have been demonstrated in patients affected with type 2 of the neonatal form (10–14). This gene, located on chromosome 11q24, encodes an adenosine triphosphate (ATP)-sensitive, inwardly rectifying K channel (ROMK) that recycles reabsorbed K back to the tubular lumen. There are 5 exons that are used in varying combinations to produce three isoforms of ROMK proteins that share a core of 372 amino acids encoded by exon 5. Most of the mutations causing neonatal Bartter's syndrome are located in this common exon 5 and disrupt an arginine-lysine-arginine triad necessary for the normal pH gating of the K_{ir} channels (15). However, there are reports showing that homozygous deletions removing exons 1 and 2 also result in neonatal Bartter's syndrome (13,16).

In some families, mutations in genes coding for NKCC2 or ROMK have not been found, reflecting further genetic heterogeneity. In fact, mutations in a third gene have been recently identified as a cause of a peculiar type of neonatal Bartter's syndrome that is associated with neurosensorial deafness and early chronic renal insufficiency (17). This gene, called BSND, is localized on 1p32.3 and is formed by

TABLE 38.1. GENETICS OF INHERITED DISORDERS OF ELECTROLYTE TRANSPORT

Inherited disorder	Type of inheritance	Gene localization	Gene symbol	Gene product
Neonatal Bartter's syndrome (type 1)	AR	15q15-21	SLC12A1	NKCC2
Neonatal Bartter's syndrome (type 2)	AR	11q24	KCNJ1	ROMK
Neonatal Bartter's syndrome with neurosensory deafness (type 4)	AR	1p32.3	BSND	Barttin
Classic Bartter's syndrome (type 3)	AR	1p36	CLCNKB	ClC-Kb
Gitelman's syndrome	AR	16q13	SLC12A3	NCCT
Glucocorticoid-remediable aldosteronism	AD	8q22	CYP11B1/CYP11B2	11 β -hydroxylase/aldosterone synthase
Liddle's syndrome	AD	16p12	SNCC1B, SCNN1G	β , γ ENaC
Apparent mineralocorticoid excess	AR	16q12	HSD11B2	11 β -HSD2
Pseudohypoaldosteronism type 1				
AD renal form	AD	4q31.1	MLR	Mineralocorticoid receptor
AR multiple-organ form	AR	16p12	SNCC1B, SCNN1G	β , γ ENaC
	AR	12p13	SNCC1A	α ENaC
Pseudohypoaldosteronism type 2	AD	1q31-42, 12p13.3, 17p11-21	WKN1, WKN4	WKN1, WKN4 kinases
Hypomagnesemia with secondary hypocalcemia	AR	9q22	TRPM6	TRPM6
Isolated familial hypomagnesemia				
AD form	AD	11q23	FXD2,	Na ⁺ ,K ⁺ -adenosine triphosphatase γ subunit
AR form	AR	?	?	?
Familial hypomagnesemia and hypercalciuria	AR	3q	PCN1	Paracellin-1 (claudin-16)

AD, autosomal dominant; AR, autosomal recessive.

four exons and encodes a novel protein that has been termed *barttin* (18). This protein has two transmembrane α helices and is preferentially expressed in the ascending loop of Henle and inner ear. It acts as an essential β subunit for ClC-Ka and ClC-Kb chloride channels. It seems that heteromers formed by ClC-K channel and barttin are crucial for renal NaCl reabsorption and K recycling in the inner ear (19).

The correspondence between genotype and phenotype may not be as consistent as presented here, because there are patients with the hypercalciuric variant and abnormalities in the NKCC2 gene who have clinical onset beyond the neonatal period (9), and there are also occasional patients with classic Bartter's syndrome type 3, due to mutations or deletions in the CLCNKB gene, who may present with polyhydramnios and symptoms during the neonatal period (20).

Clinical and Biochemical Features

This subject has been reviewed by Proesmans (21). Clinical signs may be observed antenatally or immediately after birth and include marked polyhydramnios (appearing between 24 and 30 weeks' gestation and caused by intrauterine polyuria), premature delivery, massive polyuria, life-threatening episodes of dehydration, hypercalciuria, and early-onset nephrocalcinosis (Table 38.2). Urine output may be as great as 12 to 50 mL/kg/hr and continue to be greatly increased for at least 4 to 6 weeks after birth. Some patients have a distinctive appearance: they are thin, with small muscles and a triangular face characterized by promi-

nent forehead, large eyes, protruding ears, and drooping mouth. Strabismus and sensorineural deafness have been reported (22,23). Failure to thrive and growth retardation are the rule, but appropriate therapy is followed by satisfactory growth (24). The presence of systemic manifestations such as osteopenia, fever, secretory diarrhea, convulsions, and increased susceptibility to infection has been noted (4).

Prenatal diagnosis can be made by the high Cl content of the amniotic fluid. Of interest, concentrations of amniotic fluid Na, K, Ca, and prostaglandin E₂ are normal (25). The biochemical examination of the mother's urine may also be useful for prenatal diagnosis because it may show very low concentrations of Na, Cl, and Ca (26). The definitive way to establish a prenatal diagnosis is through the mutational analysis of genomic DNA extracted from cultured amniocytes obtained by amniocentesis (27).

Patients with type 2 often present at birth with mild NaCl wasting and a biochemical picture that mimics primary pseudohypoaldosteronism type 1 (i.e., hyponatremia, hyperkalemia, and metabolic acidosis). Renal potassium wasting leading to hypokalemia and metabolic alkalosis may not be apparent until 3 to 6 weeks postnatally outside of the neonatal period, the biochemical features (hypokalemia, metabolic alkalosis, impaired concentrating ability, hyperreninism, and hyperaldosteronism) are identical to those later described with more detail in the section Classic Bartter's Syndrome.

Urinary Ca excretion always remains very elevated in spite of therapy. The presence of marked hypercalciuria and

TABLE 38.2. CLINICAL AND BIOCHEMICAL FEATURES OF BARTTER'S-LIKE SYNDROMES

Features	Neonatal Bartter's syndrome	Classic Bartter's syndrome	Gitelman's syndrome
Clinical onset	Neonatal	Infancy or childhood	Childhood or adulthood
Polyhydramnios/prematurity	Present	Often present	Absent
Polydipsia/polyuria	Present	Present	Absent
Salt craving	Present	Present	Absent
Growth retardation	Present	Present	Absent or occasional
Dehydration	Present	Often present	Absent
Muscle weakness/tetany	Absent	Occasionally present	Present
Nephrocalcinosis	Present	Absent	Absent
Sensorineural deafness	Occasionally present	Absent	Absent
Metabolic alkalosis	Present (it may be delayed)	Present	Present
Hypokalemia	Present (it may be delayed)	Present	Present
Hypomagnesemia	Absent or exceptional	Occasionally present?	Present
Urinary NaCl excretion	Very high	High	Normal or high
Urinary Ca excretion	Very high	Normal or high	Low
Urinary concentrating ability	Impaired	Impaired	Normal
Hyperrenin/hyperaldosteronism	Present	Present	Present
Hyperprostaglandinism	Present (it may be delayed)	Present	Absent
Hypertrophy of juxtaglomerular apparatus	Present	Present	Occasionally present

nephrocalcinosis in an infant or child with apparent Bartter's syndrome is consistent with the neonatal form beyond the neonatal period. Increased urinary excretion of prostaglandin E_2 has been considered a characteristic feature of neonatal Bartter's syndrome, but this is secondary to the basic defect of renal NaCl reabsorption and, therefore, may not be present in all patients, especially during the early neonatal period (28). Renal function is generally well preserved, but an occasional child may develop end-stage chronic renal disease.

Pathology

Placental pathology in two cases showed large placentas with extensive subtrophoblastic basal membrane mineralization (29). The cardinal renal biopsy finding is hyperplasia of the juxtaglomerular apparatus. Occasional absence of Tamm-Horsfall protein in the kidney probably represents a secondary phenomenon (30).

Pathophysiology

Seyberth et al. (4) suggested that the neonatal cases represented a different pathogenic entity, related to systemic overproduction of prostaglandins, so the term *hyperprostaglandin E_2 syndrome* was proposed. The increased renal and systemic prostaglandin E activity was indicated by symptoms such as fever, diarrhea, vomiting, osteopenia, and generalized convulsions, and by elevation of the urinary excretion of prostaglandin E-M metabolite (the major urinary metabolite of the E prostaglandins). However, molecular biology findings demonstrate abnormalities in the genes coding for either NKCC2 (genetic type 1) or ROMK (genetic type 2), and the prostaglandin abnormalities appear to be secondary phenomena.

The channels and transporters implied in NaCl reabsorption in the distal nephron are depicted in Figure 38.1.

The absorptive Na-K-2Cl cotransporter or NKCC2 is a member of a family of four proteins also including secretory Na-K-2Cl, NaCl, and KCl cotransporters. All are structurally similar and are formed by 12 membrane-spanning helices and long cytosolic amino- and carboxy-terminal segments (31). Structural abnormalities of this protein due to mutations of the encoding gene obviously lead to altered NaCl transport. The importance of NKCC2 in renal NaCl transport is underlined by findings in a knock-out mouse model of Bartter's syndrome. These mice with an abated SLC12A1 gene manifest severe salt-wasting, which results in rapid neonatal death unless they are rescued by indomethacin treatment (32).

ROMK is a protein with two intramembranous domains containing the channel pore and two cytosolic amino- and carboxy-terminal segments. It is found along the distal nephron and is believed to be responsible for K secretion in the cortical collecting duct and K recycling in the thick ascending limb of the loop of Henle (33). Loss of ROMK function impairs the ability to recycle K from cells back into lumen, resulting in luminal K concentrations too low to permit continued Na-K-2Cl activity (34).

Normal function of the Na-K-2Cl cotransporter is responsible for the reabsorption of approximately 30% of filtered sodium. Therefore, it is not surprising that altered function of this cotransporter results in renal sodium wasting, volume contraction, hyperreninism, hyperaldosteronism, hyperkalemia, hypokalemia, metabolic alkalosis, and hyperprostaglandinism, thus closing the pathogenic circle (Fig. 38.2). As expected, patients with neonatal Bartter's syndrome exhibit a blunted natriuretic and hormonal response to furosemide when compared to controls (35). Elevated prostaglandin E_2 secretion aggravates the picture further by independent stimulation of the renin-aldosterone axis and inhibition of both ROMK channel activity and

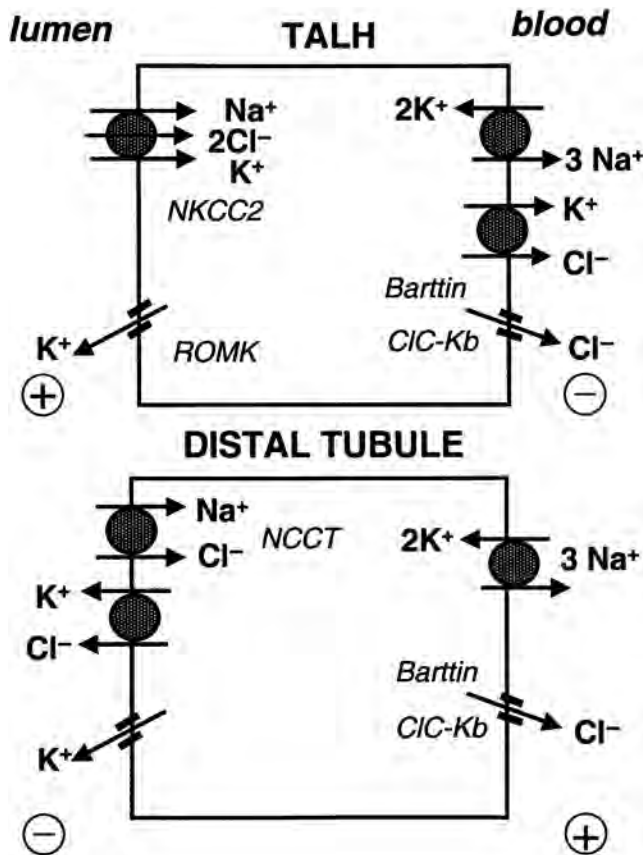

FIGURE 38.1. Schematic models of NaCl reabsorption in thick ascending limb of Henle (TALH) and convoluted distal tubule. In TALH, NaCl enters the cell from the lumen via an Na-2Cl-K cotransporter (NKCC2). K is recycled into the lumen via the K channel ROMK to permit the continuous functioning of this cotransporter. Cl leaves the cell across the basolateral membrane via a Cl channel (CIC-Kb) or in cotransport with K, while Na exits the cell through the Na,K-ATPase system. Barttin acts as an essential subunit of CIC-Kb. In the distal convoluted tubule, NaCl reabsorption in the luminal membrane is mediated by the NaCl cotransporter (NCCT) and leaves the cell through Cl channels and the Na,K-ATPase. A K-Cl cotransporter is also present at the luminal membrane.

NaCl transport in the thick ascending limb of Henle (36). However, although administration of prostaglandin synthetase inhibitors results in the impressive clinical and biochemical improvement, especially in type 2, it is not followed by complete correction of the tubular defect. Recent findings indicate that cyclooxygenase-2 is highly expressed in the macula densa of patients with salt-losing Bartter's syndrome and hyperreninemia (37) and that preferential inhibition of this enzyme by nimesulide in patients with neonatal Bartter's syndrome results in impressive improvement of hyperprostaglandinuria, secondary hyperaldosteronism, and hypercalciuria (38). These data would indicate that cyclooxygenase-2-derived prostaglandin E₂ is an important mediator for stimulation of the renin-angiotensin-aldosterone system in the kidney and that its preferential inhibition may offer a potential therapeutic benefit.

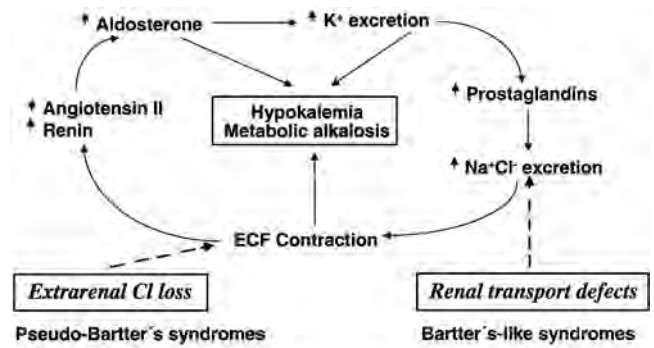

FIGURE 38.2. Schematic representation of pathophysiologic events leading to hypokalemia and metabolic alkalosis. Each of the biochemical and hormonal abnormalities observed in Bartter's syndrome could represent a proximate defect turning on the vicious circle. However, only extrarenal Cl loss (causing pseudo-Bartter's syndrome) and renal transport defects (causing Bartter's-like syndromes) appear as clinically relevant. ECF, extracellular fluid.

The presence of a primary NaCl transport defect in the loop of Henle was denied in the past by Seyberth et al. (4) on the basis that no abnormality in distal NaCl reabsorption could be demonstrated when children with this syndrome were studied beyond the neonatal period by oral hypotonic fluid administration. However, in our experience, when patients are studied after hypotonic saline infusion, a profound defect in distal NaCl reabsorption can be identified. The percent of distal NaCl reabsorption is dramatically low during infancy due to the increased distal NaCl delivery characteristic during this age.

The characteristic presence of hypercalciuria is not surprising because approximately 25% of filtered Ca is reabsorbed in the thick ascending limb of Henle coupled to Na-K-2Cl activity. Impaired electrogenic Cl transport impairs voltage-driven, paracellular Ca and Mg reabsorption. Hypercalciuria has also been related to an excessive synthesis of 1,25-dihydroxy-vitamin D (39) leading to augmented bone resorption and renal leak (40,41). Recent studies have shown that serum and urine of children with neonatal Bartter's syndrome contain excessive amounts of a heparin-like calciotropic factor closely related to basic fibroblastic growth factor, providing additional evidence that hypercalciuria is not solely due to an intrinsic renal leak (42,43).

Reabsorption of approximately 60% of filtered Mg also occurs in the loop of Henle and is dependent on the positive luminal voltage generated by the activity of the cotransporter. Absence of hypermagnesiuria in neonatal Bartter's syndrome may be explained by the compensatory Mg reabsorption taking place in distal convoluted tubules.

Differential Diagnosis

The clinical picture of neonatal Bartter's syndrome is so characteristic that diagnostic doubts rarely arise. A similar

but apparently different syndrome has been described in a female infant, aged 5 weeks, who, in addition to the usual clinical features of neonatal Bartter's syndrome, had massive urinary excretion of prostaglandins E₂ and E-M metabolite, normal calcium metabolism, hyperphosphaturia, and severe hyperchloriduria and hyperkalemia with limited response to indomethacin. Molecular analysis determines if these findings really represent a new congenital renal tubular abnormality as proposed by the authors (44).

Type 2 neonatal Bartter's syndrome, due to mutations in the ROMK gene, may exhibit hyponatremia and hyperkalemia in the early neonatal period, thus mimicking the picture of primary pseudohypoaldosteronism type 1. The possible existence of prematurity, polyhydramnios, hypercalciuria, and nephrocalcinosis in the latter syndrome may contribute to the clinical confusion (45–48). The syndrome of familial hypomagnesemia-hypercalciuria with nephrocalcinosis may also be confused with neonatal Bartter's syndrome because hypercalciuria and nephrocalcinosis are already present, but significant hypomagnesemia may be absent in the early neonatal period.

Pseudo-neonatal Bartter's syndrome is rare, but biological abnormalities simulating Bartter's syndrome were observed in a preterm neonate with complex cyanotic heart disease, in whom the ductus arteriosus was maintained open by high doses of prostaglandin E₁ (49).

Treatment and Prognosis

In the immediate neonatal period, all therapeutic efforts should be directed to correct dehydration and electrolytic imbalance. Continuous saline infusion may be needed to attain this goal. Administration of indomethacin in the early postnatal period may not only be unnecessary but dangerous, given the risk of necrotizing enterocolitis. Prenatal treatment with indomethacin has been advocated when diagnosis is made prenatally (27). The apparent beneficial effects of indomethacin should be taken with extreme caution, however, and should be weighed against the potential therapeutic risks (50). Administering indomethacin to a mother whose fetus is known to have mutations characteristic of neonatal Bartter's syndrome may prevent progression of polyhydramnios, but may also be dangerous for the fetus.

At 4 to 6 weeks of life, patients greatly benefit from the administration of indomethacin and, eventually, of potassium chloride supplements. Although indomethacin has no direct effect on the inherited renal tubular abnormality, it is beneficial because it neutralizes the amplifying effect of prostaglandins on the features of Bartter's syndrome. In my experience, patients with the type 2 genetic defect are especially sensitive to indomethacin, and doses below 1 mg/kg/day may be sufficient to maintain plasma K levels within the normal range. In fact, a high dosage may lead to hyperkalemia, and K supplements may not be necessary with appropriate therapy.

In general, therapy permits clinical stabilization and catch-up growth. Bone age has been appropriate for chronological age, and pubertal and intellectual development have been normal. An occasional patient may even have a spontaneous resolution of all signs and symptoms at approximately 6 years of age (51). Although indomethacin may reduce the degree of hypercalciuria, renal calcium excretion remains greatly elevated, thus creating a real concern for the progression of the nephrocalcinosis. The use of preferential cyclooxygenase-2 inhibitors remains experimental. All coadjuvant therapies (e.g., amiloride, hydrochlorothiazide, potassium phosphate) have been ineffective, so one should expect a low decrease of glomerular filtration rate (GFR) over the years as a result of chronic tubulointerstitial nephropathy.

The neonatal form associated with neurosensorial deafness due to mutations in the BSND gene is resistant to therapy with indomethacin and always carries a bad long-term prognosis due to the progressive development of chronic renal insufficiency (52).

Classic Bartter's Syndrome

Genetics

The so-called classic form, or Bartter's syndrome type 3, is an autosomal recessive disease caused by large deletions or nonsense, missense, and splice mutations in a renal chloride channel gene (ClC-Kb) (20,53) (Table 38.1). In humans, there are two closely related voltage-gated chloride channels (ClC-Ka and ClC-Kb), proteins of 687 amino acids specifically expressed in mammalian kidney and encoded by two genes (locus symbols CLCNKA and CLCNKB), closely located on 1p36 where they are separated by only 11 kb (54). The fact that a certain number of patients with classic Bartter's syndrome do not demonstrate abnormalities in the CLCNKB gene indicates that other genes implicated in NaCl transport in the ascending loop of Henle may also be involved as a cause of this syndrome. A possible candidate gene could be the one encoding the synthesis of the basolateral KCl cotransporter.

Clinical Features

Frequently, there is a history of maternal hydramnios and premature delivery. Symptoms start during the first 2 years of life and include polyuria, polydipsia, vomiting, constipation, salt craving, tendency to dehydration, and failure to thrive (Table 38.2). Occasional cases may have a clinical onset during the neonatal period (20). Growth retardation occurs if early therapy is not instituted. However, normal adult height may be achieved with a delayed adolescent growth spurt. Associated growth hormone deficiency has been found in occasional patients (55). The clinical findings of fatigue, muscle weakness, cramps, and recurrent episodes of carpopedal spasm may be observed late in childhood but are more characteristically observed

in Gitelman's syndrome. Some patients have a distinctive appearance: they are thin, with small muscles and a triangular face characterized by prominent forehead, large eyes, and drooping mouth. Other possible signs are developmental delay, minimal brain dysfunction with nonspecific electroencephalographic abnormalities, nephrocalcinosis, and polyuria-related ureterohydronephrosis. If hypokalemia is profound and prolonged, it may give rise to the formation of medullary cysts (56). Nephrocalcinosis is very rarely observed. Patients are always normotensive. On occasion, the diagnosis is suspected in an asymptomatic child because hypokalemia is found in a routine investigation.

Biochemical Features

The outstanding laboratory finding is hypokalemia, with K concentrations in blood ranging between 1.5 and 2.5 mEq/L. Hypokalemia is almost always accompanied by hypochloremia and metabolic alkalosis, although (exceptionally) the patient may present with metabolic acidosis (57). Hyperuricemia, induced by contraction of extracellular fluid volume, may be observed in approximately 50% of patients. Hypomagnesemia is rarely encountered, and its presence in a patient with features of Bartter's syndrome necessitates exclusion of the diagnosis of Gitelman's syndrome, in which hypomagnesemia is a cardinal finding. Other biochemical features rarely present are polycythemia, hypercalcemia, and hypophosphatemia.

The most characteristic urinary findings are the increased fractional excretion of K, Na, and Cl. The demonstration of a urinary Cl concentration above 10 mEq/L in a patient with hypochloremic metabolic alkalosis rules out extrarenal causes of Cl depletion (e.g., dietary deficiency, vomiting, cystic fibrosis) in which urinary Cl excretion is very low or even absent (58). Urinary Na wasting is also present, and it may be especially evident during dietary Na restriction. A very important urinary finding is the presence of normal or high urinary Ca excretion (59). Hypocalciuria is a characteristic finding of Gitelman's syndrome, but in exceptional cases it may also be observed in the follow-up of patients with classic Bartter's syndrome (60).

Defects in concentrating and diluting abilities are always present and are the result of both hypokalemia and impaired NaCl reabsorption in the ascending limb of the loop of Henle. The role played by prostaglandin oversecretion is probably secondary, because administration of prostaglandin synthetase inhibitors is not followed by complete correction of hyposthenuria. Another relevant finding is the inability to appropriately decrease urine pH during ammonium chloride loading. This is due to high rates of ammonium excretion, caused by both increased production and preferential diversion of ammonia into the urine. GFR is normal in early stages of the disease but may become impaired in untreated patients as a result of chronic hypokalemia. The sus-

tained high levels of angiotensin II may theoretically cause progressive tubulointerstitial damage. However, if therapy is adequate, there is no long-term deterioration of renal function.

Hyperreninemia is constantly present and is accompanied, in most cases, by an elevated plasma concentration of aldosterone. In a few patients, however, aldosterone secretion is suppressed by K depletion. The renal K loss is not exclusively related to hyperaldosteronism, because it persists after renin suppression or adrenalectomy.

Paradoxically, blood pressure is normal despite increased blood levels of renin, angiotensin II, norepinephrine, and endothelin (61). In fact, stimulation of the renin-angiotensin-aldosterone axis might be necessary to maintain normotension, as administration of saralasin (a competitive inhibitor of angiotensin II) or captopril (a blocker of angiotensin-converting enzyme) induces a significant fall in blood pressure. The blunted increase in blood pressure after infusion of angiotensin II is not a constant diagnostic feature as initially reported by Bartter (1), because it improves after expansion of extracellular fluid volume or administration of prostaglandin synthetase inhibitors. The beneficial effect of indomethacin in this regard depends on its capacity not only to correct sodium depletion and thus suppress angiotensin production but also to normalize the pressor responsiveness to the latter hormone by inhibiting the secretion of prostaglandins. Indomethacin also corrects the hyperactivity of the adrenergic system, manifested by increased plasma levels of noradrenaline and vascular, but not metabolic, unresponsiveness to this hormone. Probably, the vascular hyporeactivity of Bartter's syndrome is a complex phenomenon dependent not only on vascular underfilling and increased prostaglandin synthesis but also on nitric oxide-mediated vasodilation. Increased urinary excretions of nitrites NO_2^- and NO_3^- and cyclic guanosine monophosphate all point to increased nitric oxide synthesis in vascular endothelial cells (62). Patients with Bartter's-like syndromes evidence a blunted Gq-mediated cell signaling that results in reduction in protein kinase C production and upregulation of the nitric oxide system (63).

A very important finding is the increased urinary excretion of prostaglandins, principally prostaglandin E_2 and 6-keto-prostaglandin F_{1a} , the main metabolite of prostaglandin I_2 or prostacyclin (64). Urinary excretion of prostaglandin F_{2a} is more variable. Urinary kallikrein excretion is also increased. Prostaglandin overproduction may cause defective platelet aggregation and inhibition of phytohemagglutinin-induced lymphocyte proliferation.

Pathology

The cardinal renal biopsy finding is hyperplasia of the juxtaglomerular apparatus, although it may be absent in occasional cases. Hyperplasia of interstitial renomedullary cells is observed more rarely. Glomerular hyalinization, apical vacuolization of proximal tubular cells, tubular atrophy,

and interstitial fibrosis may be also observed as a long-term consequence of chronic K deficiency.

Pathophysiology

Different hypotheses (e.g., vascular resistance to angiotensin II, tubular defect in potassium secretion, primary hyperprostaglandinism, increased secretion of atrial natriuretic peptide) have been presented to explain the range of abnormalities seen in classic Bartter's syndrome, but it is now well established that most cases result from mutations in the renal Cl channel *ClC-Kb* or genetic defect type 3. Other patients who apparently have classic Bartter's syndrome may indeed have neonatal Bartter's syndrome with a delayed clinical onset, which may be caused by defects in *NKCC2* or *ROMK* genes. The presence of nephrocalcinosis in the latter cases is an important clinical clue.

The *ClC* chloride channels are members of a single family originally defined by the voltage-gated Cl channel *ClC-0*, isolated from Torpedo electric organ and formed by at least nine different proteins (65). The members of this family, *ClC-K1* and *ClC-K2*, were shown in the rat to be kidney-specific and expressed from the thin ascending limb of the loop of Henle onward (Fig. 38.1). The human homolog genes are called *CLCNKA* and *CLCNKB*. These genes encode the channels *ClC-Ka* and *ClC-Kb*, both formed of 687 amino acids and containing 12 transmembrane domains and cytosolic amino- and carboxy-terminal segments. Like other members of the family, these channels are gated by both voltage and chloride.

The Cl channel *ClC-Kb* is situated at the basolateral membrane of distal nephron segments and is mainly responsible for Cl exit from the cell into the bloodstream. It needs the β subunit barttin for functional expression. Therefore, it is not surprising that structural defects of the genes encoding both the channel itself and barttin are followed by defective NaCl reabsorption in the distal nephron. Alternative mechanisms of Cl transit across the basolateral membranes, such as a KCl cotransport, have also been proposed, so it must be assumed that overfunction of these other transporters cannot compensate completely for loss of function of the Cl channel. However, some compensation probably takes place because renal salt loss is not as massive as that observed in neonatal cases, and the phenotype of this genetic defect is quite variable.

The presence of a defective NaCl transport at the level of the ascending loop of Henle in classic Bartter's syndrome has long been suspected on the basis of the study of fractional clearances of Cl during hypotonic saline diuresis. The index of distal Cl reabsorption ($C_{H_2O} / C_{H_2O} + C_{Cl} \times 100$) is normally above 80% (66), whereas patients with this phenotype have values characteristically diminished, often below 60% (67). This defect is not observed in patients with hypokalemia of different etiologies (68). To reveal the tubular defect, the conditions of the study, especially NaCl intake, and route of administration must be rigorously standardized, and the diluting segment Cl reabsorption must be

judged in relation to distal Cl delivery. In fact, distal Cl reabsorption is less affected or is even normal when renal clearance studies are performed after an oral water load instead of during hypotonic saline infusion (69,70).

It has long been postulated that the membrane ion transport defect was not limited to tubular cells but represented a generalized membrane transport defect, as intracellular Na concentration in erythrocytes or muscle cells was found to be consistently increased. The reasons proposed were either an increased Na permeability or a decreased passive Na efflux related to the low number of ouabain-sensitive Na-pumping sites (71). However, on the basis of recent data, it is more probable that these transport abnormalities are simple consequences of the hypokalemic state. The response to therapy has been variable; indomethacin corrects the intracellular action abnormalities but has little effect on the membrane transport defect, whereas complete correction of hypokalemia apparently normalizes all parameters (72).

Clinical Variants

Associated with Proximal Tubular Dysfunction. A few cases of Bartter's syndrome have been associated with signs of the Fanconi's syndrome (73–75). In a personal case and in the case reported by Fricker et al. (75), the renal biopsy showed hyperplasia of the juxtaglomerular apparatus but also marked interstitial fibrosis with hyalinized glomeruli and tubular atrophy. The interstitial fibrosis may not represent a differential finding and may only be the result of chronic hypokalemia (76). This entity should probably not be classified as a different syndrome, because in our case a homozygous missense mutation in the *CLCNKB* gene could be demonstrated. This clinical variant of Bartter's syndrome should be distinguished from the opposed situation (i.e., cases of primary Fanconi's syndrome) or cystinosis mimicking Bartter's syndrome due to the presence of hypokalemia and metabolic alkalosis (77–79). Patients with mitochondrial cytopathies often have signs of proximal tubular dysfunction but, exceptionally, a 10-year-old child with the Kearns-Sayre syndrome presented with signs of Bartter's syndrome (80).

Associated with Distal Tubular Defects Rather Than Loop of Henle Defects. Some adult patients reported as cases of Bartter's syndrome show a normal or near-normal capacity to form solute-free water after oral water loading and are therefore interpreted as having a distal tubular defect rather than a loop of Henle defect (81–84). Most of these patients exhibit hypocalciuria and should be considered to have Gitelman's syndrome and not a clinical variant of Bartter's syndrome (85).

Differential Diagnosis

Familial hypokalemic alkalosis with proximal tubulopathy (Güllner's syndrome) has been uniquely observed in three

siblings of a sibship of four presenting with features very similar to Bartter's syndrome but with normal distal Cl reabsorption and characteristic focal histologic lesions consisting of dark staining of proximal tubular cells. Hypouricemia was the only biochemical abnormality that could be ascribed to impaired proximal tubular function (86,87).

Among the renal causes mimicking Bartter's syndrome, one should also consider the surreptitious use of loop diuretics such as furosemide (88,89). Although this situation is exceptional in children, the presence of diuretics in the urine may help to establish the diagnosis. There is a report of an 11-year-old boy presenting with a chronic salt-losing nephropathy manifested by volume depletion, hypodipsia, absence of salt appetite, normokalemic metabolic alkalosis, hyperreninemic hyperaldosteronism, hypertrophy of juxtaglomerular apparatus, highly conserved capacities to concentrate and dilute the urine, and paradoxically increased levels in plasma of atrial natriuretic peptide. Although this patient clinically resembles Bartter's syndrome, values of fractional NaCl reabsorption during hypotonic saline diuresis were normal, and no clinical amelioration was observed while on indomethacin therapy (90).

Bartter's syndrome should also be distinguished from states of Cl depletion from extrarenal causes: cyclical vomiting, laxative abuse, and cystic fibrosis. In these circumstances, the biochemical and histologic pictures may be identical to those present in Bartter's syndrome, but diagnosis is rapidly made if one measures urinary Cl excretion (58). States of mineralocorticoid excess should be easily excluded because all are associated with arterial hypertension.

Treatment and Prognosis

Treatment is designed primarily to correct the hypokalemia. Potassium supplementation in the form of KCl (1 to 3 mEq/kg/day or more) is always necessary. The amount needed changes according to the patient and must balance the amount of K lost by the kidney. However, in most cases, K supplementation alone is almost completely ineffective, as administered K is quickly lost into the urine. Addition of spironolactone (10 to 15 mg/kg/day) or triamterene (10 mg/kg/day) may be initially effective in the control of hypokalemia, but its effect is often transient. The administration of β -adrenergic inhibitors (e.g., propranolol) does not offer any additive advantage.

Therapy of Bartter's syndrome is today best accomplished by the use of prostaglandin synthetase inhibitors: indomethacin (2 to 5 mg/kg/day), acetylsalicylic acid (100 mg/kg/day), ibuprofen (30 mg/kg/day), or ketoprofen (20 mg/kg/day). Indomethacin is the drug most frequently used and is remarkably well tolerated. However, attention should be paid to signs of intolerance or toxicity (e.g., nausea, vomiting, abdominal pain, peptic ulcer, hematopoietic toxicity, or liver damage). The possibility of developing pseudotumor cerebri should also be considered, as it has been reported after both indomethacin and

ketoprofen administration. The early effects of prostaglandin inhibition are spectacular, with improved well-being, strength and activity, diminution of polyuria and polydipsia, and reinstatement of normal, or even catchup, growth. There is an immediate increase in plasma K, which, however, rarely exceeds a concentration of 3.5 mEq/L. Plasma renin activity and aldosterone concentration decrease to normal, and the vascular response to angiotensin II or noradrenalin also normalizes. The distal tubular defect in Cl reabsorption remains unmodified. Addition of Mg salts should always be considered when hypomagnesemia is present because Mg deficiency may aggravate K wasting.

The efficacy of long-term use of prostaglandin synthetase inhibitors has been clearly established. When patients reach adulthood, clinical improvement is generally maintained, but there is some recurrence of hypokalemia and hyperreninemia, and there is a tendency to develop hypomagnesemia and hypocalciuria, thus mimicking the biochemical profile of Gitelman's syndrome (60). Tetanic episodes, which are always absent during childhood, may be observed in adults. Long-term prognosis remains guarded, however, and lack of rigorous therapeutic control may lead to slow progression to chronic renal failure (91). If the symptoms reappear, the dose of indomethacin should be readjusted, and a combined therapy with indomethacin and spironolactone should be initiated. In adults, the use of angiotensin-converting enzyme inhibitors (e.g., captopril, enalapril) has been tried with conflicting results (92,93). There are no data concerning their use in children with Bartter's syndrome, but one should be cautious given the risk of developing symptomatic hypotension.

Anesthetic procedures should be carefully managed in patients with Bartter's syndrome and special attention should be paid to maintain cardiovascular stability, control plasma K, and prevent renal damage (94). Maintenance of indomethacin therapy is mandatory when undergoing surgical procedures such as a percutaneous renal biopsy to avoid the risk of bleeding due to defective platelet aggregation.

Gitelman's Syndrome

The syndrome of familial hypokalemia-hypomagnesemia (Gitelman's syndrome) was first described by Gitelman, Graham, and Welt in 1966 (95). It is not as infrequent as reflected in the literature, because in the past it has been confused with Bartter's syndrome (96). Adult patients with Gitelman's syndrome are much more common than those with Bartter's syndrome. During childhood the incidence is probably similar (97).

Genetics

The equal incidence in both sexes and the lack of significant abnormalities in the parents suggest an autosomal

recessive inheritance (Table 38.1). Molecular biology findings have established that almost all families studied have mutations in the gene locus *SLC12A3* (98–102). This gene, located in 16q13 and containing 26 exons, encodes the renal thiazide-sensitive NaCl cotransporter (also variously abbreviated as TSC, NCC, NCCT, or ENCC1) that is mainly located in the distal convoluted tubule.

Clinical and Biochemical Features

Patients with Gitelman's syndrome are often asymptomatic, with the exception of transient episodes of weakness and tetany that are usually accompanied by abdominal pain, vomiting, and fever (Table 38.2). The disease-free intervals may be prolonged, and in many cases, diagnosis is only made during adult life. However, almost one-half of the patients complain of salt craving, musculoskeletal symptoms (e.g., cramps, muscle weakness, and aches), and constitutional symptoms (e.g., fatigue, dizziness, nocturia, and polydipsia) (103). In children, growth retardation is usually absent, but occasional cases may present evidence of associated growth hormone deficiency that improves with recombinant human growth hormone therapy (104,105). Chondrocalcinosis has been occasionally reported in adult patients and is due to deposition of calcium pyrophosphate dehydrate crystals (106,107). Ophthalmic examination may show choroidal calcifications (108).

The outstanding biochemical features are hypomagnesemia, hypokalemia, and moderate metabolic alkalosis. A modest elevation in uric acid may be present, although, on the whole, renal function is normal. The presence of hyperreninism and hyperaldosteronism may contribute to the confusion with classic Bartter's syndrome. However, a normal urinary excretion of prostaglandin E_2 has been reported (109). Generally, no abnormal findings are present at renal biopsy, although hypertrophy of juxtaglomerular apparatus may be occasionally observed.

The most characteristic finding in the urine, besides the presence of hypermagnesuria and hyperkaluria, is the striking diminution of urinary Ca excretion, which rarely exceeds 0.5 mg/kg/day. Plasma levels of parathyroid hormone and urinary excretion of cyclic adenosine monophosphate are normal. The study of distal tubular function reveals normal or only slightly impaired concentrating and acidifying mechanisms, but modestly reduced distal fractional Cl reabsorption during hypotonic saline diuresis. Values obtained are intermediary between normal values and values present in children with classic Bartter's syndrome (110). A striking finding is the increased natriuretic and kaliuretic response to the intravenous administration of furosemide and a blunted natriuretic response to hydrochlorothiazide (111). This suggests that the defect in NaCl reabsorption is in the distal tubule rather than in the ascending loop of Henle. The calciuric response to furosemide is blunted. This readily permits

differentiation from patients with Bartter's syndrome, who exhibit an enhanced calciuric response to furosemide (112).

Pathophysiology

Gitelman's syndrome results from diminished NaCl transport in the distal convoluted tubule caused by defective function of the thiazide-sensitive NaCl cotransporter NCCT (Fig. 38.1). This was the first member of the Na-K-Cl cotransporter family to be identified and, as other members of this family, is formed by 12 membrane-spanning helices and long cytosolic amino- and carboxy-terminal segments (31). Structural abnormalities of this transporter due to mutations of the encoding gene lead to defective processing with retention of the protein in the endoplasmic reticulum and lack of activity at the plasma membrane (113). As in Bartter's syndrome, the NaCl cotransporter defect directly leads to NaCl wasting, mild hypovolemia, metabolic alkalosis, and stimulation of the renin-angiotensin axis.

The exact mechanisms underlying hypocalciuria and hypomagnesemia are not yet fully elucidated, but both abnormalities may be direct consequences of the primary defect. In fact, they are also observed after administration of thiazide diuretics, which inhibit the distal luminal NaCl cotransporter. Hypocalciuria may result from increased tubular reabsorption of filtered Ca via a basolateral NaCa exchanger. No obvious abnormalities are found in plasma levels of parathyroid hormone or 1,25-dihydroxy vitamin D_3 levels (114,115). Hypermagnesuria also results from decreased tubular reabsorption of filtered Mg due to inhibition of an apical NaMg exchanger. Metabolic alkalosis may play an important role in the pathogenesis of hypermagnesuria by making the distal tubule cells resistant to Mg uptake (116). A study of renal tubular reabsorption of Mg, performed in three children with Gitelman's syndrome (96), revealed normal rates of Mg reabsorption when the amount filtered exceeded 1.2 mg/dL glomerular filtrate. However, in contrast to normal children, Mg excretion was also evident at levels of filtered Mg below 1.2 mg/dL GF, indicating a low renal Mg threshold. These data are compatible with the known fact that the bulk of filtered Mg is reabsorbed in the thick ascending loop of Henle and that the distal convoluted tubule only reabsorbs approximately 5% of filtered Mg (117).

Differential Diagnosis

Hypomagnesemia and hypocalciuria are universal in Gitelman's syndrome, thus allowing an easy differentiation from other hypokalemic syndromes (Table 38.2). Gitelman's syndrome should be differentiated from a rare entity described in an adult man who presented with a clinical syndrome of a probable proximal tubular origin, associating moderate glomerular impairment, hypokalemia, metabolic alkalosis,

hypomagnesemia, glycosuria, hypocalciuria, and relative hypomagnesuria (118). Surreptitious diuretic ingestion may also mimic Gitelman's syndrome. Besides the urinary determination of diuretics, the molecular genetic diagnosis may also help to establish the correct diagnosis (119).

Treatment and Prognosis

Patients with Gitelman's syndrome are best treated with Mg salts alone, with no need, in most cases, to add either K salts or prostaglandin inhibitors. Many Mg salts have been used in the treatment of hypomagnesemic states (e.g., Mg oxide, Mg chloride, Mg pidolate, Mg lactate, Mg pyrrolidone carboxylate). In Gitelman's syndrome, we recommend the use of Mg chloride (MgCl_2) that also compensates for ongoing urinary Cl losses. Magnesium chloride has a high Mg content, is very soluble, and is not dependent on gastric acidity for absorption. Also, its administration is less often followed by diarrhea, although this complication may still develop with increasing dosage. We use a 5% solution that contains approximately 0.5 mEq (0.6 mg) Mg^{2+} /mL. The total dose should be individualized for each patient and given at 6- to 8-hour intervals. In our experience, regular administration of MgCl_2 not only partly corrects the hypomagnesemia and prevents the appearance of tetanic episodes, but also normalizes plasma K concentration, acid-base equilibrium, the renin-aldosterone axis, and urinary Ca excretion. However, there is some disagreement whether the K wasting may or may not be exclusively attributed to hypomagnesemia (120,121). In fact, occasional cases may require the additional administration of potassium salts or antialdosterone drugs (e.g., spironolactone or amiloride) to correct the hypokalemia (122). High-dosage indomethacin may be especially indicated in exceptional cases with growth retardation and bad tolerance to Mg supplementation (123).

The long-term prognosis of Gitelman's syndrome, in terms of preserving renal function and maintaining growth, appears to be excellent, but sustained lifelong Mg supplementation remains necessary to reduce the risk of tetanic episodes (124). There is a single report of an adult patient who developed end-stage renal disease (125).

Hyperaldosteronism

Although the common adult syndromes of primary hyperaldosteronism (e.g., renin-secreting tumor and Conn disease due to adrenal adenoma, carcinoma, or micronodular hyperplasia) (126) are outside the scope of this chapter, we will refer to one rare disorder, which may be observed during the pediatric age, the so-called glucocorticoid-remediable aldosteronism.

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism, also called *familial hyperaldosteronism type I*, represents a rare cause of low-renin hypertension in children and adults.

Genetics

Glucocorticoid-remediable aldosteronism, an autosomal dominant disease, arises due to a chimeric gene formed at meiosis after genetic recombination between two homologues, adjacent genes on chromosome 8q22, CYP11B1 and CYP11B2, encoding the enzymes 11β -hydroxylase and aldosterone synthase involved, respectively, in the final pathways of cortisol and aldosterone synthesis within the adrenal cortex (127) (Table 38.1). The final 11β -hydroxylation in the synthesis of cortisol in the zona fasciculata is regulated by 11β -hydroxylase, which depends on adrenocorticotrophic hormone (ACTH) secretion. The final stages of aldosterone synthesis are catalyzed by the P-450 enzyme aldosterone synthase, whose expression is limited to the zona glomerulosa and is regulated by angiotensin II and K.

Clinical and Biochemical Features

Glucocorticoid-remediable aldosteronism manifests clinically by the presence of familial low-renin hypertension. In affected family members, hypertension is already observed in those younger than 21 years of age and often during childhood (128). Hypertension is especially severe and may lead to cardiovascular complications (e.g., hemorrhagic stroke) in almost 20% of cases. Characteristic biochemical findings are metabolic alkalosis and very low plasma renin activity. Hypokalemia may be present but is not an obligatory finding.

Pathophysiology

Hypertension results from aldosterone excess, with aldosterone being under the control of ACTH rather than the normal secretagogue, angiotensin II. The chimeric gene possesses the 5' 11β -hydroxylase and the 3' aldosterone synthase sequences, and although it promotes the synthesis of aldosterone, it is under the regulatory control of ACTH and not of angiotensin II.

Diagnosis

The ratio between urinary concentrations of C-18 oxidation products (18-oxotetrahydrocortisol and 18-hydrocortisol) and tetrahydroaldosterone is characteristically increased, but given the technical difficulty of these analytical procedures, the diagnosis is generally established by the use of the dexamethasone suppression test, which is based on the decrease of aldosterone production after ACTH suppression. A value of plasma aldosterone below 4 ng/dL postdexamethasone correctly diagnoses glucocorticoid-remediable aldosteronism with high sensitivity and specificity (129). However, definitive diagnosis is established by the use of molecular biology techniques (130). There are a few patients who present with a positive dexamethasone

suppression test without any evidence of abnormalities in CYP11B1 and CYP11B2 genes. The pathogenesis of these rare cases of glucocorticoid-remediable aldosteronism not linked to a chimeric CYP11B1/CYP11B2 gene remains unknown (131).

Therapy

Hypertension is refractory to therapy with the usual antihypertensive drugs but quickly resolves after administration of K-retaining diuretics such as spironolactone or amiloride. Occasionally, patients may require a combined therapy with nifedipine (132). Although administration of dexamethasone may also ameliorate the hypertension, its prolonged use is not recommended in childhood given its deleterious effect on growth.

Pseudohyperaldosteronism

Under the term *pseudohyperaldosteronism*, we include a few syndromes that present clinical and biochemical findings similar to those observed in primary hyperaldosteronism but without evidence of increased secretion of mineralocorticoids. In fact, plasma aldosterone levels are often undetectable.

Liddle's Syndrome

Liddle's syndrome is a very rare disorder of tubular transport, simulating primary hyperaldosteronism but with negligible aldosterone secretion. It was described in 1963 by Liddle, Bledsoe, and Copping (133) in eight individuals of the same family.

Genetics

A pattern of autosomal dominant inheritance has been described, although some cases appear to be sporadic (134–136) (Fig. 38.1). Recent studies have demonstrated that this entity is caused by mutations of the genes encoding two of the three constitutive subunits of the amiloride-sensitive epithelial sodium channel (ENaC). Mutations of the genes encoding β subunit (β ENaC) (137,138) and γ subunit (γ ENaC) (139) have been described. Both genes SNCC1B and SNCC1G are located on 16p12. No abnormalities have been noted in the gene SNCC1A, located at 12p13, or in encoding the α subunit (α ENaC).

Clinical and Biochemical Features

Characteristic clinical and laboratory findings start in infancy and early childhood and include polyuria, polydipsia, failure to thrive, arterial hypertension, hypokalemic metabolic alkalosis, and almost absent renin and aldosterone secretion. Hypercalciuria, nephrocalcinosis, and renal

medullary cysts have been noted in a few cases. Aldosterone secretion is not stimulated by salt restriction, and improvement is observed after administration of triamterene but not after administration of spironolactone.

Pathophysiology

Liddle's syndrome results from excessive renal tubular Na absorption through activation of the renal epithelial sodium channel. As mentioned above, this channel is formed by three subunit proteins (α , β , and γ) having short cytosolic termini, two transmembrane domains, and a large extracellular loop (140). The α subunit appears to be required for the assembly or function of the whole complex. The three ENaC subunits are homologous to each other and have approximately 35% amino acid identity. A possible membrane topology of the heterotetrameric complex is formed by two α subunits, one β subunit, and one γ subunit, because this complex maintains a high amiloride sensitivity and a very Na⁺-selective pore (Fig. 38.3). The ENaC is not only present in the kidney but also in other organs (e.g., lung, colon, exocrine glands, skin and hair follicles). The C terminal of each ENaC subunit contains a xPPxY motif, which is necessary for interaction with the WW domains of the ubiquitin-protein ligase, Nedd4 (141). Nedd4 regulates ENaC function by controlling the number of channels at the cell surface. Liddle's mutations, leading to truncated C-terminus of the β or γ subunits,

FIGURE 38.3. Membrane topology of the epithelial Na⁺ channel. The proposed model is a heterotetrameric structure formed by two α subunits, one β subunit, and one γ subunit. Each subunit is formed by two membrane-spanning domains, a large extracellular loop, and cytoplasmic amino- and carboxytermini.

alter or delete the xPPxY motif, interrupt the interaction with Nedd4 protein, and lead to an increased number of Na channels in the apical membrane, increased Na reabsorption, expanded plasma volume with resulting hypertension, and inhibited renin-aldosterone axis with secondary potassium wasting (142–144). A transgenic mouse model for Liddle's syndrome reproduces, to a large extent, a human form of salt-sensitive hypertension (145). It is possible that polymorphisms of the β and γ subunits of the ENaC are related to variations of blood pressure in humans (146) and may contribute to the high incidence of salt-related hypertension in blacks (147).

Diagnosis

Diagnosis is mainly established with the syndrome of apparent mineralocorticoid excess. The presence of hypertensive individuals in successive generations is very suggestive of Liddle's syndrome. The lack of hypotensive effect of spironolactone or dexamethasone administration also suggests the diagnosis. Nowadays, genetic testing allows a sure and rapid diagnosis (148).

Therapy and Prognosis

Therapy consists of the combined administration of K supplementation (as KCl) and triamterene (10 mg/kg/day). Improvement is manifest by normalization of Na and K balances, resolution of hypertension, and reinstatement of normal growth. However, catch-up growth rarely occurs, and patients may remain significantly growth-retarded if the syndrome has been manifest early in infancy. If the diagnosis is not firmly established, a therapeutic trial with spironolactone or dexamethasone should also be considered given the clinical similarity with 11 β -hydroxysteroid dehydrogenase (11 β -HSD) deficiency.

Apparent Mineralocorticoid Excess

This entity, identified by Ulick and New (149), gives rise to a state of apparent mineralocorticoid excess (AME), which is clinically and biochemically very similar to Liddle's syndrome. Approximately 40 affected patients have been described worldwide (150).

Genetics

There are two isoenzymes of 11 β -HSD: NADP(+)-dependent isoenzyme 1 (11 β -HSD1), isolated from liver but widely expressed in many tissues; and NADP(+)-dependent isoenzyme 2 (11 β -HSD2), highly expressed in kidney, placenta, and adrenal gland (151) (Table 38.1). The genes encoding both isoenzymes have been recently cloned. The gene HSD11B1, encoding 11 β -HSD1 (liver isoenzyme), contains 6 exons and is located in chromosome 1, whereas the gene

HSD11B2, encoding 11 β -HSD2 (renal isoenzyme), contains 5 exons and is located in 16q12 (152,153).

AME is caused by autosomal recessive mutations in the HSD11B2 gene, which results in a deficiency of 11 β -HSD2 (154–158). Most patients are homozygotes for one of the different mutations, and few compound heterozygotes have been identified.

Clinical and Biochemical Features

AME usually presents early in life and is characterized by polyuria, polydipsia, failure to thrive, hypertension, hypokalemic alkalosis, suppressed plasma renin activity, and absence of adrenal secretion of any known mineralocorticoid. Renal cysts, nephrocalcinosis, rickets, and hyperparathyroidism have been sporadically reported (159). Damage of many organs (e.g., kidneys, retina, heart, central nervous system) universally follows long-standing hypertension. Intrauterine growth retardation is a common finding and is probably secondary to placental 11 β -HSD2 deficiency. The human placenta contains abundant 11 β -HSD2, which has an important regulatory role of fetal growth (160).

A mild form of AME has been described in a 12.5-year-old girl presenting with mild hypertension and suppressed renin and aldosterone secretion but lacking hypokalemia and low birth weight. Despite these mild symptoms, it was proven that this girl was homozygous for a missense mutation in the HSD11B2 gene (150).

Pathophysiology

11 β -HSD (EC 1.1.1.146) plays a critical role in determining the specificity of type I receptors. In the normal state, cortisol is converted by 11 β -HSD to cortisone, thus allowing the preferential binding of aldosterone to type I receptors. In cases of 11 β -HSD deficiency, there is a high intrarenal cortisol concentration that facilitates binding to the type I receptor, thus resulting in AME (161). Transgenic mice lacking 11 β -HSD2 present all major features of human AME (162).

Diagnosis

Biochemical diagnosis can be made by measuring the ratio of cortisol to cortisone metabolites (tetrahydrocortisol plus allotetrahydrocortisol or tetrahydrocortisone). The optimal diagnostic test is to measure the generation of titrated water in plasma samples when 11-titrated cortisol is injected. Conversion of cortisol to cortisone is only 0 to 6% in AME patients, whereas the normal conversion is 90 to 95% (150).

Therapy

Therapy consists of the administration of the mineralocorticoid receptor blocker, spironolactone. After the adminis-

tration of spironolactone, hypertension disappears, natriuresis ensues, and plasma renin activity becomes detectable. The daily dose of spironolactone ranges between 2 and 10 mg/kg. As hypercalciuria and nephrocalcinosis are consistent features of the disease, a thiazide diuretic may be added. Thiazide diuretics may not only contribute to improve hypercalciuria but also may aid to lower blood pressure and allow for the dose of spironolactone to be reduced (157). Renal transplantation, performed in exceptional cases, completely normalizes the clinical and biochemical picture (163).

Hypertension Secondary to Activated Mineralocorticoid Receptor

Geller et al. (164) have reported on a family whose propositus, a 15-year-old boy, had severe hypertension and suppressed plasma aldosterone levels. This patient and 11 of 21 at-risk relatives, all hypertensive, were heterozygous for a missense mutation substituting leucine for highly conserved serine at codon 810 of the mineralocorticoid receptor. This mutation resulted in a gain of function of the receptor and alteration of its specificity because it was also activated by progesterone. Carriers not only presented with severe early-onset hypertension but also, although normokalemic, tended to have lower plasma K values and manifested severe hypertension during episodes of pregnancy.

Secondary Pseudohyperaldosteronism

An acquired syndrome of pseudohyperaldosteronism, in all ways identical to 11 β -HSD2 deficiency, has been observed after chronic ingestion of licorice (165). Natural licorice, an extract of *Glycyrrhiza glabra* root, contains glycyrrhizic acid, which is a potent inhibitor of 11 β -HSD2. This complication is exceptionally observed in children (166). Carbenoxolone, an antiulcer drug, also competitively inhibits 11 β -HSD and causes sodium retention as a relevant side effect. The possibility that a syndrome of AME is secondary

to creams or nasal sprays containing 9 α -fluorinated corticoids should also be considered.

HYPERKALEMIC STATES

A situation of hyperkalemia may be caused by increased intake or endogenous liberation of K, decreased renal output, or abnormal distribution of K in the body (see Chapter 8). Most children with persistent hyperkalemia, in the absence of oversupplementation, demonstrate decreased renal excretion of K. In such cases, one must differentiate extrinsic causes, such as mineralocorticoid deficiency due to primary adrenal disorders, from intrinsic causes, such as renal failure or tubular renal disorders limiting K transport. The term *renal tubular hyperkalemia* has been proposed to describe a group of isolated renal tubular defects of K secretion in which hyperkalemia constitutes the outstanding biochemical feature (167).

To examine whether sustained hyperkalemia is due to a tubular defect of K secretion, it is necessary to challenge the mechanisms of tubular transport and to study the functioning of the renin-aldosterone system. Although sulfate infusion has been widely used to test the functioning of the cortical distal nephron, identical results can be obtained by acute intravenous administration of furosemide (1 mg/kg body weight). This diuretic blocks NaCl reabsorption in the ascending limb of the loop of Henle and thus increases the delivery of fluid and NaCl to the cortical collecting tubule. By enhancing Na reabsorption in excess of Cl reabsorption in this cortical segment, it creates a favorable electric gradient (lumen-negative) and facilitates the exit of K and H. Furosemide, by causing volume depletion, also enhances the secretion of renin and aldosterone. A summary of the results obtained by our group in a study of normal children is presented in Table 38.3 (167).

When assessing urinary K excretion, one must take into account that as GFR decreases, fractional K excretion increases exponentially. Because many patients with renal tubular hyper-

kalemia may exhibit some degree of renal insufficiency, it is necessary to relate values of fractional K excretion to the corresponding values for GFR. To study the action of aldosterone at the level of distal and collecting tubules, it is useful to calculate the so-called transtubular K concentration gradient (TTKG) by the formula proposed by West et al. (168):

$$\text{TTKG} = \frac{\text{K urine}/(\text{U/P osmolality})}{\text{K blood}}$$

This index provides a ratio of the estimated concentration of K in the cortical collecting tubule (or urine K concentration adjusted for medullary water abstraction) to that of K in the peritubular fluid in the renal cortex. Values in normal children follow a nongaussian distribution, with a median of 6.0 and a range of 4.1 to 10.5. Transtubular K concentration gradient is significantly higher in infants, with a median value of 7.8 and a range of 4.9 to 15.5 (169). Any value below these limits should be interpreted as indicating mineralocorticoid deficiency or mineralocorticoid unresponsiveness.

MINERALOCORTICOID DEFICIENCY

Hyperreninemic Hypoaldosteronism

Several adrenal disorders are associated with a primary defect in aldosterone secretion that is accompanied by a secondary increase in plasma renin activity. This situation is almost always accompanied by salt-wasting and hyperkalemia, and, therefore, it should be distinguished from tubular resistance to aldosterone or pseudoaldosteronism. A detailed description of adrenal disorders is beyond the scope of this chapter.

Adrenal Insufficiency (Addison's Disease)

When adrenal insufficiency occurs in infancy, it is usually due to congenital adrenal hypoplasia, a condition that may be sporadic or inherited in an autosomal recessive or a sex-linked pattern. The X-linked adrenal hypoplasia is often associated with gonadotrophin deficiency, progressive hearing loss, glycerokinase deficiency, and muscular dystrophy. In older children and adults, other causes may be observed: autoimmune adrenalitis and, more rarely today, tuberculosis, amyloidosis, and acute adrenal hemorrhage or infarction. Adrenal leukodystrophy (Addison's-Schilder's disease) is a rare sex-linked inherited condition characterized by progressive neurologic damage associated with primary adrenal insufficiency.

Hereditary enzymatic defects may also cause mineralocorticoid deficiency. Salt-wasting is present in approximately two-thirds of patients with the classic form of congenital adrenal hyperplasia resulting from 21-hydroxylase deficiency (150,170). Salt-wasting occurs usually during the first weeks of life and results from inadequate synthesis of

aldosterone. Patients become suddenly dehydrated, with signs of extracellular fluid volume depletion. Hyponatremia and hyperkalemia are present, and urinary NaCl excretion is inappropriately high. Urgent therapy is mandatory and includes NaCl supplementation and administration of hydrocortisone and 9 α -fludrocortisone. Glucocorticoid and mineralocorticoid therapy should be maintained for life.

Isolated Defects of Aldosterone Biosynthesis

Aldosterone biosynthetic defects other than 21-hydroxylase deficiency can also cause salt-wasting and hyperkalemia (171). The conversion of 11-desoxycorticosterone to aldosterone requires the successive steps of 11 β -hydroxylation, 18-hydroxylation, and 18-oxidation, all catalyzed by a single enzyme, aldosterone synthase (P450c11AS) (172). There are two inborn errors caused by different mutations in the CYP11B2 gene encoding aldosterone synthase, the so-called corticosterone methyloxidase type I and type II defects (173). Infants with both defects, but especially with type I, present with failure to thrive, recurrent episodes of dehydration and salt-wasting, and hyperkalemia (174,175). Simultaneous serum determination of aldosterone and 18-hydroxycorticosterone levels permits differentiation between type I and type II defects (176). As in salt-wasting congenital adrenal hyperplasia, mineralocorticoid replacement therapy should be maintained for life.

Hyporeninemic Hypoaldosteronism

Hyporeninemic hypoaldosteronism is a syndrome characterized by inappropriately low aldosterone secretion without an associated impairment in the synthesis of cortisol but with low plasma renin activity. In fact, hypoaldosteronism apparently results from insufficient stimulation of the adrenal gland by the renin-angiotensin system. This condition was first reported by Hudson et al. (177), and since then, a great number of cases have been documented in the literature, particularly in adults with moderate chronic renal insufficiency due to diabetic nephropathy or chronic tubulointerstitial disorders. Hyperkalemia and metabolic acidosis constitute the cardinal biochemical features. Salt-wasting is not generally present. This syndrome has been rarely reported in children, but its frequency is probably higher than is usually recognized in patients with moderate chronic renal insufficiencies of various etiologies (178). This condition appears to be especially frequent in children with lupus nephritis or with chronic nephropathy secondary to methylmalonic acidemia.

The pathogenesis of hyporeninemic hypoaldosteronism in patients with chronic renal insufficiency is not yet elucidated. The hyperkalemia may be ascribed solely to hypoaldosteronism, but pharmacologic doses of mineralocorticoids are often needed to correct it. This indicates associated tubular resistance to aldosterone's action. Metabolic acidosis may

TABLE 38.4. CHARACTERISTICS OF TWO MAJOR FORMS OF PRIMARY TYPE I PSEUDOHYPALDOSTERONISM

Characteristics	Renal	Multiple

result from selective aldosterone deficiency and from the direct inhibitory action of hyperkalemia on renal ammonia genesis and tubular transport of ammonia. Hypoaldosteronism appears to be the consequence of hyporeninemia, but the reason for this is unclear. Chronic extracellular fluid expansion, damage to the juxtaglomerular apparatus, reduced activity of the adrenergic system, impaired formation of active renin, or decreased synthesis of prostacyclin have all been advocated as possible causes (179).

Specific therapy is often not required if attention is paid to avoidance of renin-suppressing agents (i.e., beta-blockers, calcium channel blockers, and nonsteroidal antiinflammatory agents), or K-retaining drugs (i.e., amiloride, spironolactone, heparin, captopril, trimethoprim, tacrolimus, or cyclosporine) (180). However, when dangerous hyperkalemia or severe metabolic acidosis is present, therapeutic measures become necessary. Good results have been reported with the sustained administration of furosemide, either alone or combined with 9α -fludrocortisone.

The syndrome of hyporeninemic hypoaldosteronism may be occasionally observed as an isolated or familial entity, not necessarily in association with chronic renal insufficiency (181–183). An interesting feature of all these cases is the presence of salt-wasting, a condition rarely observed in cases of hyporeninemic hypoaldosteronism associated with chronic renal insufficiency.

Apparent Mineralocorticoid Unresponsiveness

The term *pseudohypoaldosteronism* has been coined to describe disorders of electrolyte homeostasis characterized by an apparent state of renal tubular unresponsiveness to the action of aldosterone and manifested by salt-wasting, hyperkalemia, and metabolic acidosis. Recent molecular biology studies have shown that these syndromes do not always result from target-organ unresponsiveness to mineralocorticoids but more often are caused by inherited abnormalities of renal Na transport.

Primary Type 1 Pseudohypoaldosteronism

Type 1 pseudohypoaldosteronism (PHA1) is a hereditary condition characterized by salt-wasting, hyperkalemia, and metabolic acidosis in the presence of markedly elevated plasma renin activity and aldosterone concentrations. Since its first description by Cheek and Perry in 1958 (184), many cases have been reported. In recent years, it has become clear that PHA1 is a heterogeneous syndrome that includes at least two clinically and genetically distinct entities with either *renal* or *multiple* target-organ defects (185) (Table 38.4). An exceptional case with apparent resistance to aldosterone limited to sweat and salivary glands without associated salt-wasting has also been reported (186).

Renal Type 1 Pseudohypoaldosteronism

Genetics

Renal PHA1 represents the most frequent form of PHA1 (Table 38.1). The mode of inheritance is autosomal dominant, with variable expression. Many cases appear as sporadic, but familial studies reveal high plasma levels of aldosterone in one of the apparently asymptomatic parents. The pathogenesis of renal PHA1 has been greatly clarified with the identification of heterozygous mutations in the mineralocorticoid receptor gene (187–189). The structure of the gene encoding the human mineralocorticoid receptor (MLR) has been elucidated. It is formed by 9 exons and is located at 4q31.1. Two different isoforms have been identified. Each isoform is expressed in approximately equivalent levels in kidney, colon, and sweat glands.

Clinical and Biochemical Features

Clinical features are extremely variable. In general, symptoms appear in early infancy with failure to thrive, weight loss, vomiting, and dehydration. Salt-wasting and polyuria may be already present in fetal life and manifested by maternal hydramnios. Occasional patients may present also

with hypercalciuria and nephrocalcinosis. If therapy is delayed, patients may become severely undernourished. During the salt-wasting episodes, which may be triggered by intercurrent infections, patients appear shocked and comatose. A partial form with mild course of the disease and almost absent salt-wasting may be observed (190). Sweat and salivary electrolytes are characteristically normal. In exceptional cases, diagnosis can be made in asymptomatic newborn babies or even in cord blood on the basis of a positive family history.

The outstanding laboratory findings are hyponatremia and hyperkalemia. Metabolic acidosis may be also present. Hyponatremia may be masked by the hemoconcentration. Hyperkalemia varies from moderately to greatly increased values for plasma K concentration. Urinary Na excretion is inappropriately high, given the presence of hyponatremia. On the contrary, urinary K excretion is very low, with decreased values of fractional K excretion and transtubular K concentration gradient. GFR is normal after sodium depletion is corrected. Renal biopsy findings are usually negative, but in a few cases, hypertrophy of the juxtaglomerular apparatus has been reported. Although plasma electrolyte findings are very similar to those seen in defects of aldosterone biosynthesis, both plasma renin activity and aldosterone concentration are markedly elevated, urinary excretion of aldosterone and tetrahydroaldosterone are elevated, and a urinary pattern of aldosterone metabolites conforms to a normal pattern (i.e., a normal 18-hydroxy-tetrahydrocompound A to tetrahydroaldosterone ratio) (191). There is also a characteristic lack of improvement despite administration of large doses of mineralocorticoids.

The observation that many adult gene carriers have elevated aldosterone levels but no history of clinical disease raises the possibility that only a fraction of such carriers develop clinically evident disease (192). The reasons for the phenotype differences are unknown, but they may be related to intercurrent volume-depleting events or to dietary habits of salt ingestion. Also, the coexistence of polymorphisms or mutations in the gene encoding ENaC could play a potential contributory role. Polymorphisms and mutations that lead to either loss of function or gain of function of the epithelial Na⁺ channel may aggravate or attenuate, respectively, the consequences of deficient mineralocorticoid receptor function.

Pathophysiology

The pathogenesis of renal pseudohypoaldosteronism type 1 is related to the loss of function of the mineralocorticoid receptor. The mineralocorticoid receptor is a protein of 984 amino acids belonging to the superfamily of steroid receptors. It contains an immunogenic domain, a zinc-finger DNA-binding domain, and a hormone-binding domain (193). At variance with glucocorticoid receptor that is almost ubiquitous, mineralocorticoid receptor expression is

restricted to specific cells of kidney distal and collecting tubules, colonic epithelium, and sweat and salivary gland ducts. In all these epithelia, aldosterone stimulates Na reabsorption. Mineralocorticoid receptor-deficient mice have been generated by gene targeting technology. These knock-out mice develop symptoms of pseudohypoaldosteronism soon after birth, which can be compensated by abundant NaCl administration. These NaCl-rescued mice display a strongly enhanced fractional renal excretion of Na, hyperkalemia, a persistently activated renin-angiotensin-aldosterone system, and very reduced ENaC activity in the kidney and colon (194).

Treatment and Prognosis

Renal PHA1 is treated with NaCl supplementation (3 to 6 g/day), which is followed by marked clinical and biochemical improvement. The expansion of extracellular fluid volume results in an increase of tubular flow and NaCl delivery to the distal nephron, thus creating a favorable gradient for K secretion despite the lack of mineralocorticoid action. The amount of NaCl required is deduced from the normalization of plasma K concentration and renin activity. Although the primary defect persists for life, improvement may occur beyond 1 or 2 years of age, due to maturation of proximal tubular transport, development of salt appetite, and improvement in the renal tubular response to mineralocorticoids (195). Older children with renal PHA1 are generally asymptomatic when eating a normal salt intake, but plasma aldosterone concentrations remain elevated. In contrast to aldosterone levels, plasma renin activity decreases into the normal range with advancing age. The discrepancy between renin and aldosterone secretion may be explained by the development of autonomous, tertiary hyperaldosteronism, as demonstrated by the increased excretion of 18-hydroxy-compound B (a characteristic marker of the functioning of the zona glomerulosa). Exceptionally, subtle symptoms leading to growth failure or even overt salt-wasting may persist to late childhood.

Multiple Type 1 Pseudohypoaldosteronism

Genetics

A few kindreds have been reported with multiple end-organ PHA1 since its original description (196,197) (Table 38.1). mineralocorticoid resistance is evident in kidney, lung, colon, and sweat and salivary glands. This variant is inherited as an autosomal recessive disorder, with uniform expression. The parents of affected children are asymptomatic and evidence normal plasma aldosterone levels. It has been demonstrated that this entity is caused by loss-of-function mutations of genes encoding one of the three constitutive subunits (i.e., α , β , and γ) of the ENaC (198–201). Critical hot spots for loss-of-function mutations seem to be the cysteine-rich domains in the large extracellular loop of the proteins (202).

Clinical and Biochemical Features

The multiple PHA1 presents with more severe salt-wasting and has a poorer outcome than the renal form. These patients manifest salt-wasting episodes early after birth, and death may ensue during the neonatal period. Sweat and salivary electrolytes are markedly elevated, and active Na transport in the rectal mucosa is impaired. Neither abnormality is corrected by the administration of exogenous mineralocorticoids. The high incidence of lower respiratory tract involvement may contribute to the confusion with cystic fibrosis (203,204). As in the renal form, hypercalciuria may be present.

Pathophysiology

Multiple target-organ PHA1 is due to defective Na transport in many organs containing the ENaC: kidney, lung, colon, and exocrine glands. Multiple PHA1 is allelic to Liddle's syndrome, but the mutations present result in loss of the channel activity with ensuing renal and rectal Na loss and increased sweat and saliva electrolyte values. The frequent lower respiratory involvement may be explained by the dysfunction of the ENaC of the respiratory epithelia (205). The impaired bacterial killing may be due to increased NaCl concentration in the airway surface fluid (206). The state of secondary hyperreninism and hyperaldosteronism is not caused by peripheral resistance to mineralocorticoids but derives from sustained extracellular fluid volume depletion.

Insights into pathogenesis have been facilitated by the development of transgenic mouse models in which expression of the α , β , or γ subunits of ENaC has been ablated. Of interest, only the α ENaC-deficient mice present marked failure to clear the fetal lung fluid that leads to early neonatal death (207). If the mice are rescued from death by the engineered expression of the α subunit gene in the lung, they develop a full-blown picture of PHA, with salt-wasting and hyperkalemia (208). The β ENaC- and γ ENaC-deficient mice do not die of neonatal respiratory failure but develop a very severe picture of neonatal salt-wasting and hyperkalemia from birth, similar to human PHA1 (209–211).

The neonatal lung findings present in α ENaC-deficient mice are only exceptionally observed in humans (212), despite impressive truncations of the α subunit in some kindreds. However, some impairment in Na transport across airway epithelia may persist throughout life. In fact, pulmonary symptoms in patients with autosomal recessive PHA1 are not always related to infection and may be secondary (especially in young patients) to failure to absorb liquid from airway surfaces (213). The defect in Na transport can be demonstrated by measurement of transepithelial voltage across the nasal epithelium (214).

Treatment and Prognosis

There is a poor response to NaCl supplementation alone, and rectal administration of exchange resins and dietary manipulation reducing the intake of K are often necessary. Administration of indomethacin or hydrochlorothiazide or both may be useful in occasional patients (215). Improvement with age is less apparent, and therapy must be maintained throughout childhood and probably throughout life (216).

Early-Childhood Hyperkalemia

McSherry (217) described 13 infants and young children who presented with failure to thrive or growth retardation and frequent vomiting. The only biochemical abnormalities were hyperkalemia and metabolic acidosis. Clinical salt-wasting or hypertension was absent. Functional evaluation revealed a normal ability to acidify the urine, low NH_4 and K excretion, and a mild defect in HCO_3 reabsorption (i.e., functional markers of type 4 renal tubular acidosis). Plasma renin activity and aldosterone excretion were consistently normal or elevated. McSherry speculated that this entity could be due to a primary or idiopathic unresponsiveness of the distal nephron to aldosterone that manifested itself by defects in K and H excretion with integrity of Na reabsorption. However, Appiani et al. (218) reported five infants with similar clinical features who demonstrated a significantly increased fractional Na excretion. As in the cases communicated by McSherry, no clinical evidence of salt-wasting was observed.

Early-childhood hyperkalemia represents a variant of the renal form of PHA1. Therapy is generally required during the first years of life in the form of sodium bicarbonate alone or associated with cation-exchange resin. With treatment, growth accelerates and normal height is achieved within 6 months. The disorder appears to be transient, and at approximately 5 years of age, therapy is no longer needed.

Secondary Type 1 Pseudohypoaldosteronism

Secondary forms of PHA1 have been rarely reported. A partial tubular insensitivity to aldosterone may account for the hyperkalemia observed in some infants after unilateral renal vein thrombosis or for the salt-wasting and hyperkalemia that follow neonatal medullary necrosis. A syndrome of apparent renal tubular resistance to aldosterone was first documented in 1983 by Rodríguez-Soriano et al. in young infants with urinary tract infection and associated urinary tract malformations (219). Since then, 62 cases have been reported (220). After medical or surgical therapy, all abnormalities generally disappear, although, in cases of severe obstructive uropathy, renal sodium loss may become transiently more severe during the early obstructive period (221,222). The picture of hyponatremia or hyperkalemia

may be also observed in infants and children with acute pyelonephritis, even in the absence of associated uropathy (223–225). All these observations indicate that renal ultrasonography and urine culture should be performed in any infant or child presenting with salt-wasting or hyperkalemia to exclude structural renal lesions or infection as the cause of the electrolyte disturbances.

Type 2 Pseudohypoaldosteronism (Gordon's Syndrome)

A familial syndrome (type 2 pseudohypoaldosteronism) of arterial hypertension, hyperkalemia, metabolic acidosis, suppressed plasma renin activity, and normal glomerular function was first described by Paver and Pauline in 1964 (226), although it was characterized as a new clinical entity by Gordon et al. in 1970 (227). Approximately 100 cases of so-called Gordon's syndrome have been reported in the literature (228). Hypertension represents a feature limited to adolescent or adult individuals. A similar condition has been reported in children with short stature, hyperkalemia, and metabolic acidosis but with normal blood pressure (Spitzer-Weinstein syndrome) (229–232). The finding in the same family of affected siblings with and without hypertension supports the conclusion that both syndromes are indeed the same genetic entity.

Genetics

Type 2 pseudohypoaldosteronism is inherited as an autosomal dominant entity. Linkage analysis has demonstrated genetic heterogeneity of the trait with involvement of at least three different loci in chromosomes 1q31-42, 12p13.3, and 17p11-q21 (233–235) (Table 38.1). Recently, mutations in two different genes belonging to the WNK family of serine-threonine kinases have been identified as a cause of type 2 pseudohypoaldosteronism (236). The WNK1 gene, formed by 28 exons and located in chromosome 12p, encodes the WNK1 kinase. Disease-causing mutations in WNK1 are large intronic deletions that increase WNK1 expression. WNK4 gene, formed by 19 exons and located in chromosome 17p, encodes the WNK4 kinase. The mutations in WNK4 are gain-of-function missense and cluster in a short, highly conserved segment of the encoded protein.

Clinical and Biochemical Features

Short stature and arterial hypertension are the cardinal signs in children and adults, respectively. Muscle weakness has also been reported. The relevant laboratory findings are hyperkalemia, hyperchloremic metabolic acidosis, hyporeninemic hypoaldosteronism, and normal GFR. Exceptionally, the metabolic manifestations may be already apparent in early infancy. Although not mentioned by most authors, hypercalciuria may be present and give rise to the formation of calcium oxalate stones.

Pathophysiology

Schambelan et al. (237) proposed the name of *chloride-shunt syndrome* (or type 2 pseudohypoaldosteronism), according to the hypothesis that the primary abnormality was a tubular hyperreabsorption of NaCl such that the mineralocorticoid-induced, charge-dependent K and H secretion would be attenuated by a voltage-shunting defect. Increased NaCl reabsorption would lead to expansion of plasma volume, suppressed secretion of renin and aldosterone, and eventual development of hypertension. In favor of this hypothesis was the complete reversal of the defect when distal NaCl delivery was increased by sodium sulfate or bicarbonate infusions or by the acute administration of furosemide.

Molecular biology studies have confirmed that increased distal tubular reabsorption of NaCl is the primary pathologic event in this syndrome. Both WNK1 and WNK4 kinases localize to the distal nephron segments known to play a key role in the homeostasis of Na reabsorption and H and K secretion. WNK1 is cytoplasmic, whereas WNK4 localizes to tight junctions. The gain-of-function mutations in these kinases may serve to increase transcellular or paracellular Cl conductance in the collecting duct, thereby increasing NaCl reabsorption and intravascular volume, while concomitantly dissipating the electrical gradient and diminishing H and K secretion (236).

Treatment and Prognosis

Diuretic therapy results in complete reversal of both clinical and biochemical abnormalities, with return of blood pressure to normal levels (when it is elevated), rise in plasma renin activity and aldosterone concentration, and correction of hyperkalemia and metabolic acidosis. Furosemide administration is very effective, but it aggravates the hypercalciuria and thus increases the risk of urolithiasis. In our opinion, the best treatment is the administration of hydrochlorothiazide (1.5 to 2.0 mg/kg/day) that is as effective as furosemide in the reversal of biochemical abnormalities and also corrects the hypercalciuria. Long-term prognosis remains uncertain because follow-up data are still limited.

HYPOMAGNESEMIC STATES

Chronic hypomagnesemia may be caused by inadequate dietary intake, defective gastrointestinal absorption, or increased urinary excretion and may be associated with hypocalcemia and hypokalemia. Mg depletion due to excessive urinary losses may occur as an acquired entity, in postobstructive diuresis; the diuretic phase of renal transplantation or acute tubular necrosis; states of hyperparathyroidism or hyperaldosteronism; or administration of diuretics (e.g., loop diuretics, thiazides), antiinfectious agents (e.g., aminoglycosides, capreomycin, amphotericin B, pentamidine), antineoplastic agents (e.g., cisplatin), or immunosuppressive

drugs (e.g., cyclosporine) (238). Cisplatin may not only cause an acute renal Mg loss but also a chronic disorder that persists after withdrawal of the drug and may be associated with hypokalemia, metabolic alkalosis, and hypocalciuria (239,240).

Hypomagnesemia may also have a hereditary renal origin. This syndrome, known as *familial* or *congenital magnesium-losing kidney*, was first described by Freeman and Pearson in 1966 (241) and includes several different conditions, including familial hypokalemia or hypomagnesemia or Gitelman's syndrome, as discussed above (242,243). To differentiate between primary renal loss from intestinal loss of Mg, a 24-hour urinary Mg excretion or the fractional excretion of Mg in a random urine specimen should be obtained. Daily excretion of more than 30 mg of Mg per 1.73 m² or a fractional excretion of Mg above 2% in an individual with normal renal function points to renal Mg wasting (243).

Hypomagnesemia with Secondary Hypocalcemia

Hypomagnesemia with secondary hypocalcemia is an autosomal recessive disorder that manifests in the newborn period by very low plasma Mg and Ca concentrations (244). Patients usually present with restlessness, tremor, tetany, and overt seizures. In older children, clouded sensorium, disturbed speech, and choreoathetoid movements have been described. The hypocalcemia is secondary to parathyroid failure and peripheral parathyroid hormone resistance as a result of Mg deficiency. Hypokalemia is occasionally present and is corrected after normalization of plasma Mg. The disease appears to be fatal unless treated with very high oral intakes of Mg or, preferably, with continuous nocturnal nasogastric infusion of Mg (245).

Mg deficiency seems to depend on a double intestinal and renal transport defect (246). Genetic linkage to chromosome 9q22 was found in inbred Beduin families (247), and, recently, two groups of investigators have found independently that the disease is due to mutations in a new gene, TRPM6, belonging to the TRPM family (248,249) (Table 38.1). The TRPM6 gene, formed by 39 exons, encodes a protein with 2022 amino acids, which acts as a putative ion channel that is highly similar to the transient receptor potential channel family. These channels are characterized by six transmembrane domains, a conserved pore-forming region, and a Pro-Pro-Pro motif after the last transmembrane segment (250). TRPM6 is highly expressed in intestinal epithelia and kidney tubules and shows great similarity with TRPM7, a bifunctional protein that combines Ca and Mg-permeable action channel properties with protein kinase activity.

Isolated Familial Hypomagnesemia

Isolated hypomagnesemia, caused by congenital impairment of renal tubular Mg reabsorption, is a rare inherited disorder for which both autosomal dominant and autosomal recessive

modes of inheritance have been described. Clinical features are variable, from asymptomatic cases to occurrence of carpedal spasm or generalized convulsions. The nosologic classification of all these patients is difficult at present, but the absence of hypokalemia or nephrocalcinosis clearly separates them from the other entities discussed.

Autosomal Recessive Form

In the autosomal recessive form, the patients also have variable symptoms, but the urinary Ca excretion is normal (251,252). It probably represents a distinct disease because no linkage to any known previously reported loci has been found (243).

Autosomal Dominant Form

The autosomal dominant form is also associated with few symptoms other than chondrocalcinosis. Patients always have hypocalciuria and variable but usually mild hypomagnesemic symptoms (253,254). The disease locus, HOMG2, has been mapped to chromosome 11q23 in two Dutch families (255), but not in an American family (256), pointing out the existence of genetic heterogeneity. In the Dutch families, the disease was due to dominant-negative mutations in the gene FXVD2, encoding the Na⁺,K⁺-ATPase γ subunit (257) (Table 38.1). This mutation leads to a routing defect of the protein to the plasma membrane, thus decreasing the activity of Na⁺,K⁺-ATPase. Depolarization, reduced intracellular K, or increased intracellular Na could then determine a reduced Mg influx and secondary Mg wasting (257).

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

The syndrome of familial hypomagnesemia with hypercalciuria and nephrocalcinosis should also be distinguished from other hereditary renal conditions leading to chronic hypomagnesemia. The first description was made by Michelis et al. in 1972 (258), but it was further characterized by Castrillo et al. in 1983 (259) (Michelis-Castrillo syndrome) and by Rodríguez-Soriano et al. in 1987 (96). Although only approximately 50 cases have been reported (260), the disease may be more common than usually appreciated.

Genetics

Hypomagnesemia with hypercalciuria and nephrocalcinosis behaves as an autosomal recessive disorder (Table 38.1). In favor of this type of inheritance is the fact that two sisters were transplanted with their parents' kidneys without reappearance of the disease (261). However, a study of 26 relatives belonging to four families is more suggestive of autosomal dominant inheritance with variable clinical expression in affected members (262). In the relatives, nei-

ther hypomagnesemia nor nephrocalcinosis or ocular abnormalities were present, but 11 of the 26 relatives (42%) exhibited isolated hypercalciuria. Praga et al. speculate that isolated hypercalciuria may represent a milder clinical expression of the disease, whereas the syndrome of hypomagnesemia with hypercalciuria and nephrocalcinosis could be the complete expression of this familial disorder.

Recent studies have demonstrated that this disease is caused by mutations in a novel gene, PCLN-1, located in chromosome 3q and encoding a novel renal tight junction protein involved in Mg and Ca transport, which was named *paracellin-1*, that belongs to the claudin family (claudin-16) (263–266).

Clinical and Biochemical Features

The cardinal clinical finding, besides episodic tetany or convulsions, is the development of nephrocalcinosis. This is constantly associated with polyuria and, more occasionally, with urinary tract infection or arterial hypertension. Nephrolithiasis has also been documented in several cases. Growth retardation is rarely present and, when observed, is more dependent on the nephrocalcinosis-related renal insufficiency than on the hypomagnesemia itself. An outstanding feature is the presence of ocular abnormalities such as myopia magna, horizontal nystagmus, chorioretinitis, and macular coloboma. Hearing impairment has also been occasionally reported. In some cases with profound hypomagnesemia, hypocalcemia, or a picture of vitamin D-resistant rickets may be observed, thus contributing to diagnostic confusion with distal renal tubular acidosis.

In contrast to Gitelman's syndrome, hypomagnesemia is not accompanied by hypokalemia, and there is a normal acid-base equilibrium or a tendency to metabolic acidosis instead of metabolic alkalosis. Hyperuricemia is manifest and may occasionally lead to gouty arthritis. The presence of variable degrees of renal insufficiency is related to the progression of the tubulointerstitial nephropathy induced by the nephrocalcinosis.

Hypermagnesuria occurs to a greater degree than with Gitelman's syndrome, despite a similar degree of hypomagnesemia. Documentation of marked hypercalciuria is the rule. Asymptomatic family members may exhibit isolated hypercalciuria, without hypomagnesemia. Defects in concentrating and acidifying mechanisms are probably secondary to nephrocalcinosis and contribute to the confusion with primary distal renal tubular acidosis (267). However, hypermagnesuria (but not hypomagnesemia) is only transiently observed in acidotic patients with distal renal tubular acidosis and rapidly corrects with alkali therapy. Thus, the association of hypomagnesemia and defective distal urinary acidification should strongly suggest the diagnosis of the syndrome of hypomagnesemia-hypercalciuria. Distal fractional Cl reabsorption, studied

during hypotonic saline diuresis, is normal or very mildly impaired.

Pathophysiology

The primary defect is related to impaired tubular reabsorption of Ca and Mg in the thick ascending limb of Henle (Fig. 38.4). The study of tubular Mg reabsorption during continuous Mg sulfate infusion revealed a marked impairment of Mg reabsorption at all levels of filtered Mg, indicating that both renal threshold and renal tubular maximal reabsorption were decreased in this condition (96). These data strongly suggested the existence of a defect in Mg reabsorption at the level of the ascending limb of the loop of Henle, where most of filtered Mg is reabsorbed via the paracellular pathways and driven by the lumen-positive transepithelial electrical gradient (268). Recent molecular biology findings have shown that paracellin-1 plays a critical role in the control of Ca and Mg reabsorption in this nephron segment.

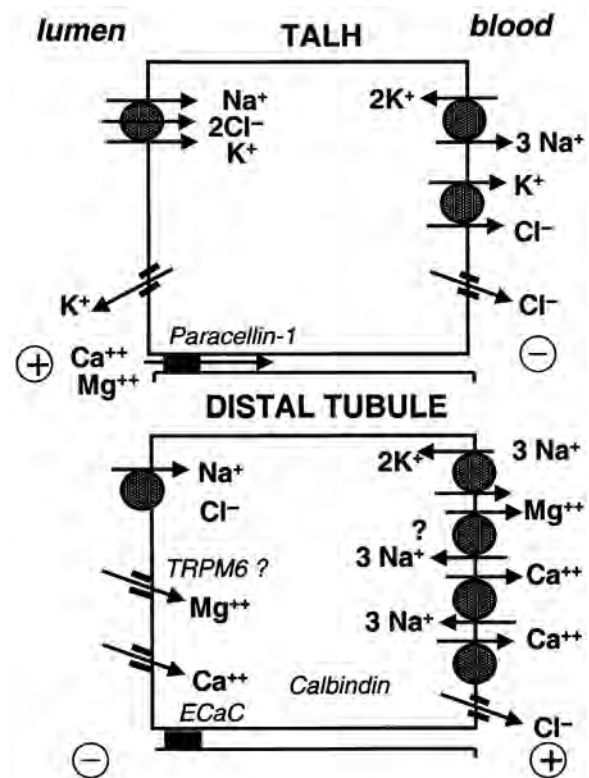

FIGURE 38.4. Schematic models of Ca and Mg reabsorption in thick ascending limb of Henle (TALH) and convoluted distal tubule. In TALH, Ca and Mg are exclusively reabsorbed via paracellular pathway through the action of paracellin-1 (claudin-16). In the distal convoluted tubule, Ca enters the cell from the lumen via an epithelial Ca channel (ECaC) and leaves the cell through a Ca ATPase and in exchange with Na. Mg absorption in the luminal membrane is mediated by an Mg channel (TRPM6?) and probably leaves the cell in exchange with Na. The functional integrity of Na^+ , K^+ -ATPase subunit appears to be essential for Mg reabsorption in the distal tubule.

Paracellin-1 belongs to the claudin family, and it has been renamed *claudin-16*. It shows sequence and structural similarity to other members of the claudin family. More than a dozen members of this family have been identified; all localize to tight junctions and appear to bridge the intercellular space by homo- or heterotypic interactions (269). Paracellin-1 is constituted by 305 amino acids with four transmembrane domains and intracellular N and C termini and is exclusively expressed in the kidney at the level of the thick ascending limb and distal tubule (263). Although almost 50% of Na reabsorption in the ascending loop of Henle also occurs via the paracellular pathways, it is likely that paracellin-1 only selectively mediates the barrier to divalent but not monovalent cations (270).

Treatment and Prognosis

The therapeutic results are poor. Combined therapy with Mg salts and hydrochlorothiazide permits some correction of the hypercalciuria, but the level of plasma Mg remains virtually the same. As the progression of the disease appears to be related to the worsening of the nephrocalcinosis, the administration of potassium citrate in the hope of arresting Ca deposition has been recommended (271,272).

Progressive renal impairment appears to be almost universal, and end-stage renal failure develops between 10 and 25 years of age. Treatment with Mg salts and thiazides for the majority of patients apparently failed to prevent the progression of the disease (264). At least 14 patients [five from our own series and nine from the literature (261,262)] have been successfully transplanted without recurrence of the disease, a fact strongly suggesting the existence of an intrinsic defect in Mg and Ca reabsorption of the native kidneys.

RENAL TUBULAR ACIDOSIS

JOHN T. HERRIN

Renal tubular acidosis (RTA) is a clinical syndrome in which either an inherited or acquired renal tubular defect leads to failure to maintain a normal plasma bicarbonate concentration in the presence of a normal rate of acid production from the diet and metabolism. Systemic metabolic acidosis (MA) results from a decrease in net acid excretion (NAE) occurring as a defect in handling bicarbonate reabsorption or defect in hydrogen ion secretion.

RTA, clinically, is characterized by a normal anion gap, MA with hyperchloremia, bicarbonaturia, reduced urinary excretion of titratable acid (TA) and ammonia, and an elevated urinary pH. Disorders of bicarbonate reclamation by the proximal tubule are classified as *proximal* or *type 2 RTA*, whereas disorders resulting from a primary defect in distal tubular net proton secretion or from reduced buffer trapping in the tubular lumen (decreased generation of new bicarbonate for reabsorption) are called *distal* or *type 1 RTA*. Distal RTA (DRTA) results in low ammonium (NH_4^+) or in low TA excretion (1–8). Hyperkalemic RTA may occur as a result of aldosterone deficiency or tubular insensitivity to its effects (RTA type 4) (9–17). Low potassium excretion in the absence of aldosterone abnormalities may also lead to a hyperkalemic DRTA in obstructive uropathy and sickle cell anemia (18,19). In children with type 1 RTA, nonspecific symptoms occur early. If the acidosis is not corrected, electrolyte abnormalities, growth retardation, rickets, and nephrocalcinosis may follow. Growth retardation is a consistent feature of RTA in infants. Experimentally, MA in rats leads to inhibition of growth hormone secretion, decreased caloric intake, and decreased levels of hepatic insulin-like growth factor I expression (20,21). Similar abnormalities have been observed during systemic acidosis in childhood. Identification and correction of acidosis are important in preventing symptoms and guide approved genetic counseling and testing.

CLASSIFICATION AND TERMINOLOGY

The somewhat confusing nomenclature in RTA reflects the history of disease identification. Type 1, classic, or

DRTA was the first recognized syndrome. Type 2, or proximal RTA (PRTA), was subsequently identified, then appreciated as the result of defective bicarbonate reabsorption. The hybrid nature of the infantile variant of DRTA, in which a distal tubular defect is coupled with an increased fractional excretion of bicarbonate, was initially believed to represent a distinct disease entity and was designated *type 3 RTA*. This term was subsequently applied to the mixed defects of proximal and distal tubular acidification, which result from a deficit in carbonic anhydrase (CA) 2 in osteopetrosis. The term *type 3 RTA* was later dropped from classification schemes, but only after aldosterone-dependent RTA type 4 was described. The present terminology in which type 1 = DRTA, type 2 = PRTA, and type 4 = aldosterone-dependent RTA is thus historically, rather than pathophysiologically, based (Table 39.1) (3,20,22).

Although DRTA is characterized by a low NH_4^+ excretion, some clinical syndromes with proximal tubular defects also demonstrate low NH_4^+ excretion. Bicarbonaturia most commonly results from proximal tubular loss but can also result from distal H^+ secretion. Because of such overlap syndromes, classification of RTA based on pathophysiology of the disorders is preferred (20,23,24).

The classification of RTA into primary defects in bicarbonate reabsorption, defects in net hydrogen ion excretion, or defects in aldosterone-sensitive acid secretion is shown in Table 39.1. Combined defects in proximal HCO_3^- reabsorption and H^+ ion secretion have been described and separate patients or families have variations of standard patterns; a subgroup of adolescents and adult patients with apparent DRTA can lower urinary pH in response to acidosis but cannot increase urinary partial pressure of carbon dioxide (PCO_2) in response to alkalinization of the urine by bicarbonate titration (25). Two patterns of combined or hybrid RTA have been described: (a) infants and young children with DRTA show high $\text{FE}_{\text{HCO}_3^-}$ of 5 to 15% that clears with treatment and growth—bicarbonate loss is rare in older children but may occur with prolonged periods of untreated RTA with concurrent hyperparathyroidism (4,26); and (b) adult patients with Sjögren's syndrome and renal amyloidosis (2,27,28) show significant

TABLE 39.1. CLASSIFICATION AND NOMENCLATURE IN RENAL TUBULAR ACIDOSIS (RTA): CLINICAL AND PATHOPHYSIOLOGIC CRITERIA

Primary defect in bicarbonate reabsorption (proximal RTA, type 2)
Mild to moderate metabolic acidosis or acid loading lowers the urine pH below 5.5. Low bicarbonate threshold FE_{HCO_3} above 10% by titration.
Primary defect in distal net H⁺ secretion
Inability to lower urine pH below 5.5 if FE_{HCO_3} exceeds 5%; suspect an associated bicarbonate leak and test the ability to increase urinary P_{CO_2} during bicarbonate loading
Inability to maximally acidify urine (DRTA, type 1)
Diminished Na ⁺ to distal tubule; functional RTA (exchange defect)
Inability to secrete H ⁺ (secretory defect)
Increased back diffusion H ⁺ (gradient defect)
Abolition of the electrical gradient for H ⁺ ion secretion (short circuit or voltage defect) with concurrent impairment to K ⁺ secretion, furosemide decreases U_{pH} to normal
Hyperkalemic DRTA: hyperkalemia with U_{pH} above 5.5
Combined defects in proximal HCO_3 reabsorption and H ⁺ ion secretion (hybrid RTA type 1 = type 3, incomplete RTA) FE_{HCO_3} above 5%
RTA secondary to deficits in aldosterone activity or chloride reabsorption: type 4 RTA
Hyperkalemia, U_{pH} below 5.5, further differentiation by assessment volume status, renin-aldosterone
Subtypes
Aldosterone deficiency
High renin hypoaldosteronism = primary adrenal abnormality with normal renal function
Low renin hypoaldosteronism = primary renal disease with secondary mineralocorticoid deficit
Attenuated renal response to aldosterone with relative aldosterone deficiency
Chloride shunting (pseudohypoaldosteronism type 2); abnormal Na ⁺ -K ⁺ -2Cl ⁻ exchange
Deficient renin
Attenuated renal response: pseudohypoaldosteronism
Pseudohypoaldosteronism (infancy)
Primary transient early RTA4

DRTA, distal renal tubular acidosis; U_{pH} , urine pH.

Note: Incomplete DRTA syndrome: low NH_4^+ , high U_{pH} , patient is not acidotic unless stressed.

reduction in tubular reabsorption of bicarbonate at normal plasma levels (i.e., a low threshold similar to type 2 RTA), combined with an inability to acidify maximally even with severe acidosis (25). A similar defect occurs in patients with Leigh's syndrome and osteopetrosis (29,30).

Incomplete RTA is a condition in which normal plasma bicarbonate is maintained despite decreased ability to acidify the urine (5). It is possible that a high rate of NH_4^+ excretion compensates for a decrease in TA excretion. Initially, the condition was described in patients with nephrocalcinosis or recurrent nephrolithiasis (5), or in families in which a propositus had complete RTA (31). It has been suggested that this latter condition represents a developmental stage of RTA (32).

RENAL CONTROL OF ACID-BASE BALANCE

The following brief review of the kidney's role in acid-base metabolism and renal acidification provides an outline to permit appropriate investigation, classification, and understanding of the pathophysiologic basis of symptomatology and treatment in RTA.

The activity of almost all body enzyme systems is dependent on hydrogen ion concentration; hence, the balance of hydrogen ion is tightly regulated. Normal body defenses against inappropriate changes in hydrogen ion concentration include (a) body buffering of generated or administered H⁺, (b) respiratory excretion of volatile acid as carbon dioxide, and (c) renal reabsorption of filtered bicarbonate and generation of new bicarbonate by excretion of hydrogen ion from nonvolatile acid, produced as a result of protein metabolism. Excretion of protons provides for reabsorption of filtered bicarbonate and regeneration of bicarbonate when secreted hydrogen ion combines with a buffer other than bicarbonate (33).

Initial defense against change in pH occurs within seconds through the combination of H⁺ with chemical buffers. These buffers do not remove the hydrogen ion from the body, but rather bind it until secondary excretion can occur as a result of respiration (within minutes) or renal excretion (within hours or days). Bicarbonate is the major extracellular fluid buffer, whereas phosphate acts as the major buffer in intracellular fluid and the urine, to increase H⁺ excretion as TA.

In normal individuals, net acid production is balanced by NAE. In an average American diet (34,35), net endogenous noncarbonic acid production averages approximately 1 mEq/kg/day in adults and 1 to 3 mEq/kg/day (1 to 3 mEq per 100 calories) in healthy infants and children (36). Children generate as much as 2 to 3 mEq H⁺/Kg, particularly during active growth, as a result of combination of OH⁻ and phosphate to form hydroxyapatite during bone formation. NAE results from excretion of ammonia and TA minus excreted bicarbonate ($NAE = U_{NH_4} V + U_{TA} V$). $U_{NH_4} V$ may be measured chemically or estimated clinically as U_{AG} , or urinary net charge. If U_{pH} is low (6.1 to 6.5), bicarbonate excretion may be omitted from calculations. $U_{TA} V$ is proportional to urinary phosphorus (31,33,37).

Each day, the kidney prevents loss of a large amount of filtered bicarbonate (i.e., 180 L/day × 25 mEq HCO_3^- /L = 4500 mEq/day in an adult). This is accomplished by secretion of H⁺ into the tubular lumen by secondary active transport in tubular segments where filtered bicarbonate ions are reabsorbed by interaction with H⁺ in the tubule to form H_2CO_3 in the presence of CA. Renal acid excretion is regulated by hormones that concurrently control sodium reabsorption and thus volume control (e.g., angiotensin II in the proximal tubule and aldosterone, antidiuretic hormone, and endothelin 1 in the distal tubule) (39). In addition, renal acid excretion is affected by factors that regulate bicarbonate reabsorption PCO_2 and by potassium balance, because

hypokalemia increases H^+ distally by decreasing potassium exchange for NH_4^+ at the $Na^+-K^+-2Cl^-$ antiporter. K^+ and NH_4^+ compete for a common site in the triporter of the thick ascending loop of Henle and for secretion in conjunction with basolateral Na^+ pumps (39,40).

Primary H^+ secretion occurs actively in the intercalated cells of the late distal tubule and collecting ducts, whereas excess H^+ combines in the tubule with phosphate and ammonia buffers (plus urate, creatinine, and citrate), generating new bicarbonate ions (37,38). In chronic acidosis, ammonia production and excretion increase (33,41–43). This pH balance is linked to sodium and water balance, with aldosterone stimulation of intercalated cells leading to excretion of hydrogen ion (44,45). Changes in plasma PCO_2 are linked to renal H^+ excretion, with increased PCO_2 leading to increased hydrogen ion secretion. Acid balance requires that dietary H^+ (which results from the metabolism of methionine, cysteine, and the chloride salts of lysine, arginine, and histidine) be removed by combination with bicarbonate to form an acid salt, water, and CO_2 (46). As CO_2 is exhaled (respiration), a deficit of bicarbonate is sustained. When reduced excretion of a metabolizable anion (e.g., ketones, hydroxy butyric acid) occurs in the presence of acid loading, there is an increased output of NH_4^+ with Cl^- (47,48). Retained anions are metabolized to neutral end products (48).

NAE results in the generation of new bicarbonate, which exits the cell by electroneutral chloride exchange. The bicarbonate generated is equal to that lost in buffering the endogenous load of noncarbonic (nonvolatile) acid generated from dietary intake and metabolism. If the diet is high in acid, increased acid excretion occurs, the urine is free of bicarbonate, and urinary pH approaches 4.5. In the presence of an alkaline load, the tubule rejects excess filtered bicarbonate, and urinary pH may approach 8 or 9. Phosphate buffer activity, and hence TA, is limited by dietary intake and reabsorption (22,38). Ammonium, on the other hand, is generated in the presence of acidosis. RTA is predominantly the result of either excess bicarbonate excretion or low NH_4^+ excretion (22).

RENAL ACIDIFICATION MECHANISM

The schema for normal acidification and sites of potential inherited or acquired defects are presented in Figure 39.1 and Table 39.2. Genetic control of H^+ excretion is mediated through control of the expression of membrane transporters in α -intercalated cells of the distal nephron, where luminal H^+ secretion occurs by an adenosine triphosphatase (ATPase)-dependent proton pump in the apical membrane that is linked to basolateral anion exchange (bicarbonate-chloride) AEI 3 (49). AEI mutations have been in DRTA (49,50). Enzyme defects in the CA2 system explain common pathophysiology of bone and ear in addition to both

proximal and distal tubules in osteoporosis, as well as ear and kidney abnormalities in ATP6B1- β 1 subunit mutations in DRTA with deafness (49,52). Mutations in the gene encoding NBC 1 (Na-HCO₃ transporter) lead to autosomal recessive PRTA (53).

Renal NH_4^+ Production and Transport

Ammonium is the source of H^+ for reabsorption of bicarbonate in the proximal tubule. Ammonia generation and excretion is the expected response to acidosis and the key to understanding RTA. At physiologic pH, NH_3 , and NH_4^+ production from glutamine is regulated through glutaminase and phosphoenol-pyruvate carboxykinase with the production of α -ketoglutarate as a byproduct, which leads to the generation of two bicarbonate molecules (37,54,55).

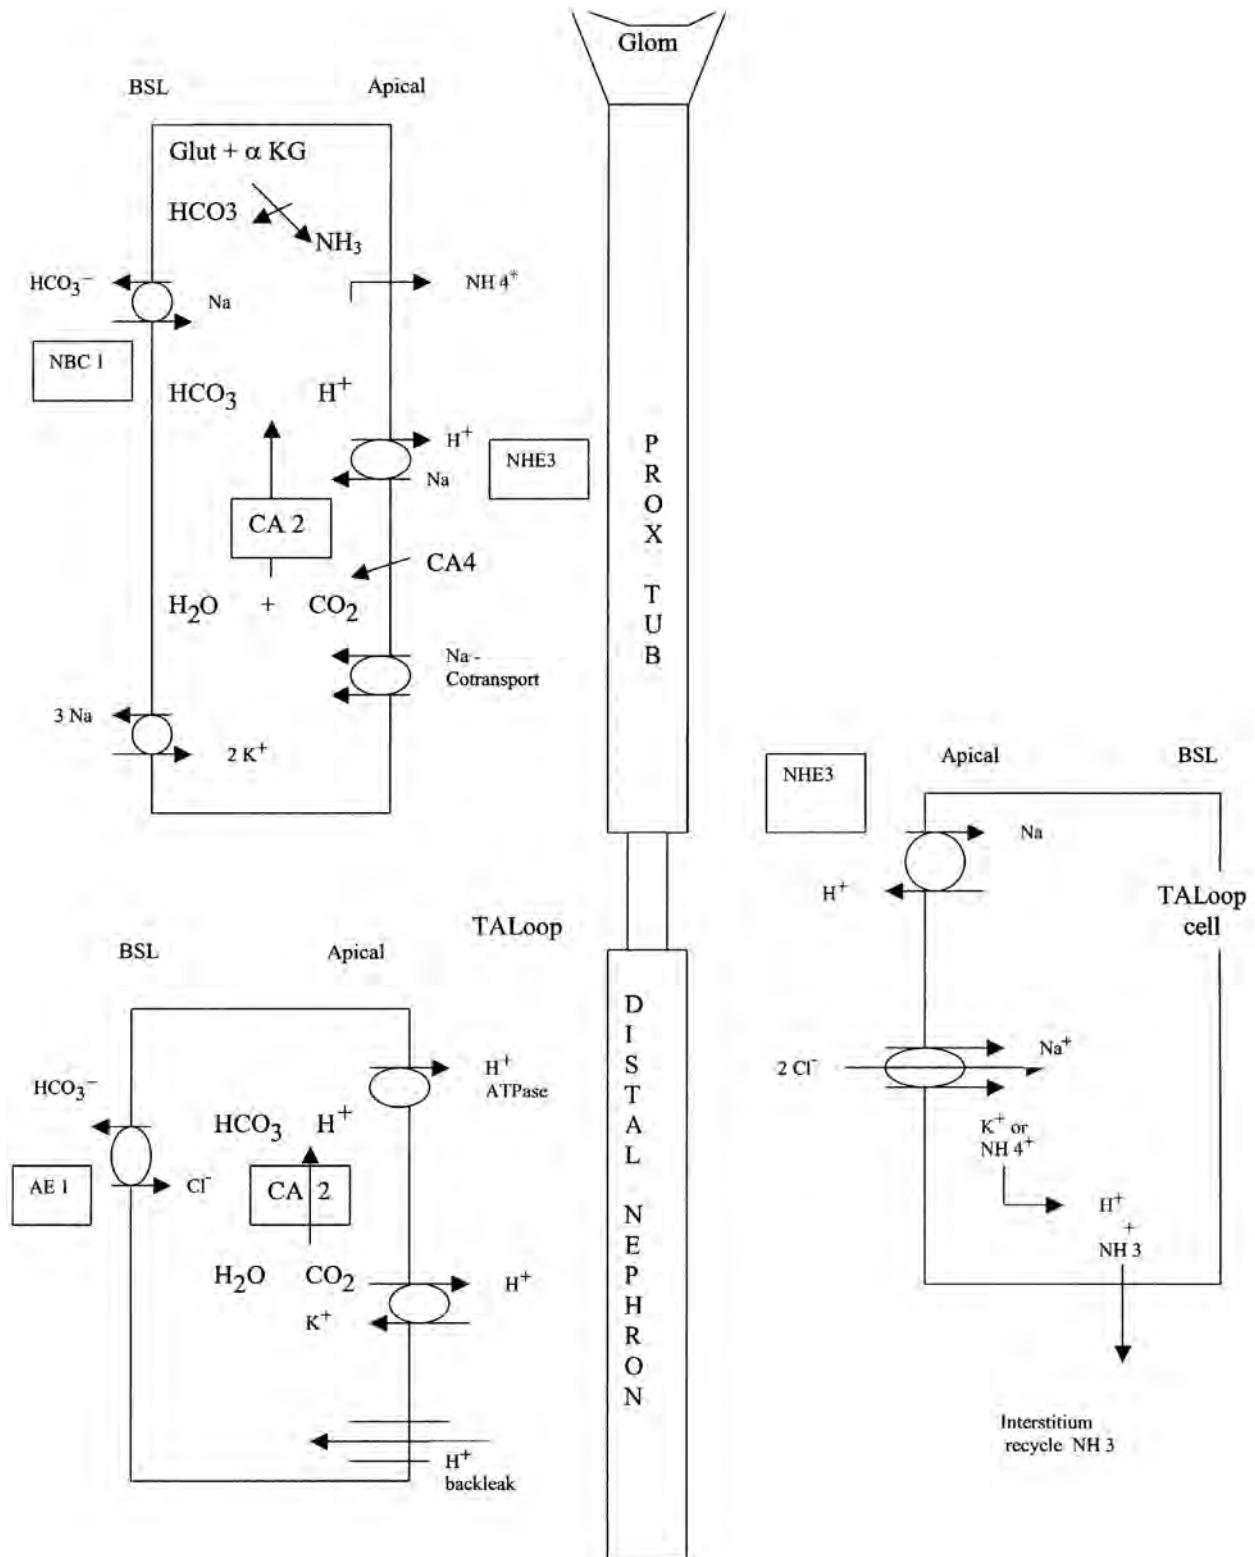

FIGURE 39.1. The schema outlines the major mechanism of acidification and the nephron site of activity for inherited and acquired defects in acidification. α KG, α -ketoglutarate; AE 1, anion exchanger Cl^- and HCO_3^- ; Apical, apical surface (lumen) of cell; ATPase, adenosine triphosphatase; BSL, basolateral surface of the cell; CA 2, carbonic anhydrase 2; CA 4, carbonic anhydrase 4; Glom, glomerulus; Glut, glutamine; Na-Cotransport, Na cotransport at the apical surface of the cell with H^+ (includes Na- amino acid, Na- phosphate, Na- glucose, and Na- citrate); NBC 1, Na, bicarbonate cotransporter; NHE 3, sodium hydrogen ion exchanger; PROX TUB, proximal tubule; TALoop, thick ascending loop of Henle.

In chronic MA, an increase in formation of ammonia from glutamine occurs with little change in phosphate excretion (phosphate released from bone is used in blood buffering during acidosis). NH_4^+ is secreted into the first portion of proximal tubule, substituting for H^+ in the $\text{Na}^+\text{-H}^+$ -antiporter on the apical membrane (43,56,57). Increase in direct proximal convoluted tubule (PCT) ammonium secretion increases delivery distally. In the S3 segment of the proximal straight tubule, ammonium is increased by an acid disequilibrium pH. As fluid leaves the PCT to the loop of Henle, ammonium and ammonia efflux leads to an increased medullary gradient for ammonia. As fluid is removed from the thin loop, leading to alkalinization, efflux of ammonia can occur as a result of nonionic diffusion (58,59).

Direct ammonium transport across the medullary thick ascending limb apical membrane occurs by substitution of NH_4^+ for K^+ in the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter (46). Countercurrent reentry of NH_4^+ in the proximal straight tubule thus correlates with flow. Ammonium is secreted from the interstitium into the medullary collecting ducts by a combination of diffusion of ammonia and H^+ secretion (active transport by H^+ ATPase and $\text{H}^+\text{-K}^+\text{-ATPase}$) (39,59,60).

Relationship of K^+ and NH_4^+

Hyperkalemia is a determinant of changes in acid-base balance by both direct and indirect effects on distal acidification. Serum potassium is a determinant of aldosterone secretion and thus of distal proton secretion (45). Chronic potassium deficiency increases NH_4^+ secretion, whereas hyperkalemia suppresses ammonium production (59). Hyperkalemia has no effect on ammonium transport in the PCT but impairs absorption from the thick ascending limb where NH_4^+ may substitute for K^+ in the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ exchanger (59,60).

Interactions of Sodium and Potassium Handling

Sodium and potassium handling are homeostatically regulated processes. Potassium secretion across the apical membrane of principal cells in the cortical collecting duct is tightly regulated (61). Quantitative potassium secretion depends on the apical membrane potassium conductance and the electrochemical driving force (EDF) across the apical membrane. Potassium conductance is the sum of the collective K channels in the apical membrane, so K secretion is regulated by urine flow and Na delivery and by factors that regulate EDF (e.g., K balance, transepithelial potential difference, pH and bicarbonate concentration of tubular fluid, systemic acid balance, and aldosterone) (61). The EDF for K^+ exchange is maintained by the basolateral $\text{Na}^+\text{-K}^+\text{-ATPase}$. The sodium pump generates a negative luminal potential and a high intracellular potassium con-

centration that augments potassium secretion. Na^+ absorption through the apical Na^+ -selective channel (affected by aldosterone) maintains the negative potential difference in the tubular lumen. Aldosterone increases apical Na^+ -selective channel activity, and with time, aldosterone can also increase the basolateral $\text{Na}^+\text{-K}^+\text{-ATPase}$ to produce changes, which parallel systemic K balance. Measurement of the transtubular K^+ gradient can thus be a clinical tool to assess K^+ excretion and direct therapy.

Factors Influencing Reabsorption of Bicarbonate

Nearly all of the bicarbonate filtered at the glomerulus is reabsorbed. Urinary excretion of acid results in generation of new bicarbonate equal in amount to that lost in buffering the endogenous load of noncarbonic acid generated from diet and metabolism.

In the proximal tubule, secretion of H^+ results in absorption of 80 to 90% of filtered bicarbonate, by combining with H^+ to form carbonic acid, which, in the presence of CA (isoenzyme 4 in the brush border), dissociates to form CO_2 and H_2O (62–64). Luminal CO_2 diffuses into the cells. In the presence of cytoplasmic CA (isoenzyme 2), hydroxylation occurs to form bicarbonate (63,64). Bicarbonate exits the basolateral membrane of the cell by a sodium-coupled mechanism (39). Hydrogen ion secretion in the proximal tubule is mediated by electroneutral $\text{Na}^+\text{-H}^+$ exchange at the luminal membrane. This exchange is driven by the lumen to cytoplasm sodium concentration gradient maintained by the basolateral $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity. In the presence of acetazolamide, carbonic acid (H_2CO_3) accumulates in the lumen, with an increase in H^+ concentration, leading to a decrease in H^+ secretion and bicarbonate reabsorption. Because factors that regulate sodium reabsorption alter bicarbonate reabsorption as a secondary effect, luminal bicarbonate concentration and pH, luminal flow rate, peritubular PCO_2 , and angiotensin II are important determinants of bicarbonate reabsorption. H^+ secretion proximally varies inversely with peritubular bicarbonate, pH, and, to a lesser extent, potassium balance.

Factors Influencing Hydrogen Ion Secretion

In the distal nephron, H^+ secretion is responsible for reabsorption of the remaining 10 to 15% of filtered bicarbonate (not absorbed proximally), decreasing the pH to less than 6.1. As the luminal pH decreases further, secreted H^+ is titrated to the urinary buffers (phosphate and ammonium), completing a process initiated in the proximal tubule (33). In the adjacent cortical and medullary collecting tubules (MCTs), secretion of H^+ is mediated by a proton translocating ATPase (H^+ ATPase) located on the luminal surface of the α -intercalated cells (46). In the cortical collecting tubules (CCTs), principal cells mediate electrogenic transfer of sodium, thus creating a

transepithelial electrical potential difference that is lumen negative and favors H^+ secretion. The principal cells are responsible for the secretion of potassium. Sodium transfer does not occur in the MCT. Secretion of H^+ by the distal tubule is influenced by aldosterone, sodium delivery, buffer delivery, changes in pH and PCO_2 , luminal pH, and potassium (65–67). Aldosterone directly stimulates H^+ ATPase in the intercalated cells and sodium reabsorption by principal cells. The resulting luminal electronegativity further stimulates H^+ secretion. [Increased sodium delivery to the distal tubule when the avidity for sodium is high (e.g., volume depletion; administration of mineralocorticoid hormone) leads to sodium reabsorption, or when sodium is excreted with poorly absorbed anions such as sulfate, phosphate, ferrocyanide, or penicillin, an increased luminal negativity is generated.] If sodium is accompanied by chloride, the stimulus for H^+ secretion is lower because the chloride is passively reabsorbed by the paracellular pathway, dissipating the electrical gradient. An increase in distal delivery of buffer (e.g., phosphate loading or β -hydroxy butyrate during ketoacidosis) leads to stimulation of H^+ secretion and an increased formation of TA. H^+ secretion is stimulated by acidosis and inhibited by alkalosis. H^+ secretion is inhibited when the luminal pH reaches 4.5. Potassium depletion directly stimulates intercalated cells to secrete H^+ and stimulates ammonia production, distal delivery, and H^+ ion excretion.

CLINICAL SPECTRUM

Patients with RTA may have nonspecific symptoms such as anorexia, vomiting, constipation, polyuria, and polydipsia. Untreated children are characteristically growth retarded. Hyperchloremic MA (HCMA) with increased urinary pH, a lack of ammonia secretion ($+U_{AG}$), and even life-threatening acidosis, may occur in infants and young children. Nephrocalcinosis (68), renal calculi (69), and musculoskeletal complaints (myalgia, arthralgia) (70) are the most common presentations of adult type 1 RTA. Rickets may occur in type 1 (71) classic DRTA, although this is more commonly seen in association with PRTA resulting from Fanconi syndrome (72,73). A subgroup of children present with RTA in the course of adrenal insufficiency (aldosterone deficiency or tubular resistance) with signs of volume depletion. In adults, hyporeninemia and hypoaldosteronism more commonly occur in patients with decreased renal function in the presence of diabetes mellitus and interstitial disease (59).

Proximal Renal Tubular Acidosis Type 2

Symptoms

Characteristic symptoms include growth retardation, failure to thrive (FTT), and recurrent vomiting.

Epidemiology

PRTA occurs in a variety of conditions, most often associated with multiple tubular dysfunction (e.g., Fanconi syndrome) as part of cystinosis, galactosemia, tyrosinemia, Wilson's disease, Lowe's syndrome, and mitochondrial myopathies. Isolated transient or persistent proximal tubular defects in bicarbonate reabsorption have been described, predominantly in males (71,74).

Adult-onset persistent type 2 RTA and isolated PRTA defects have been associated with cyanotic congenital heart disease (75) and renal vascular accidents (76). A familial autosomal dominant form that presents in early childhood (74) and a congenital form associated with growth retardation, mental retardation, and ocular and dental abnormalities in two brothers has been described (77).

Genetics

Genetically transmitted forms include persistent PRTA (both autosomal dominant and autosomal recessive forms), an isolated familial transmitted PRTA (74), or as a PRTA syndrome in association with mental retardation and ocular and dental abnormalities (77). PRTA may also be associated with other genetically transmitted disorders (Table 39.3) such as osteopetrosis with CA2 deficiency (30), pyruvate carboxylase deficiency, familial forms associated with other hereditary dysfunction of proximal tubules (hereditary fructose intolerance) (2), mitochondrial myopathies, and glycogen storage disease.

Pathophysiology and Complications

Mechanisms suggested for the defective bicarbonate absorption include abnormality of the Na^+H^+ exchanger, an impaired basolateral $Na^+HCO_3^-$ exchanger, decreased Na^+,K^+ -ATPase activity attenuating the sodium gradient from lumen to cell, and inhibition of CA activity. Decrease in bicarbonate reabsorption in the proximal tubule results in increased delivery of bicarbonate to the distal tubule, overwhelming the distal tubular reabsorption capacity (normally approximately 15% of the filtered load) (26). Bicarbonate loss results in a decrease in NAE and secondary MA. As MA increases and plasma bicarbonate levels fall, the filtered load of bicarbonate falls below the distal tubular capacity and bicarbonate losses cease so that the urinary pH falls below 5.5 (2). Therefore, PRTA is characterized by MA, with a urinary pH above 5.5 under mild to moderate MA, and the ability to lower urinary pH below 5.5 under maximal stress.

In the isolated proximal lesion, other proximal tubular functions are intact (i.e., glycosuria, phosphaturia, and aminoaciduria, which characterize Fanconi syndrome, are absent); sodium bicarbonate losses stimulate aldosterone secretion, and loss of potassium by the principal cells in the CCT results in hypokalemia. Renin and aldosterone levels

generally are elevated as a result of volume contraction (78). Hypokalemia, although common, is less prominent in isolated PRTA. Polyuria is common and appears early in the disorder with hypokalemia and solute diuresis (bicarbonate and sodium loss) (79). Acidosis leads to vomiting, lower caloric intake, and a decrease in growth rate that is reversed when acidosis is corrected (21). Bone age may be retarded.

Serum calcium, phosphorus, and vitamin D levels usually are normal despite persistent acidosis and rickets or osteomalacia (71,74). Abnormalities do not occur in primary isolated RTA unless vitamin D or calcium intake is marginal (73), but disturbances are common in secondary forms of RTA with multiple tubular defects (Fanconi syndrome) and in patients with osteopetrosis and a mixed RTA pattern (80). Nephrocalcinosis and nephrolithiasis are rare in PRTA as increased citrate excretion occurs together with increased calcium reabsorption in the distal tubule.

Treatment and Prognosis

Alkali supplement should be provided in amounts sufficient to offset the losses, which are variable and may be as high as 2 to 20 mmol/kg/day (59). Sodium restriction or hydrochlorothiazide, 1.5 to 2 mg/kg/day, may decrease alkali requirements by enhancing proximal reabsorption of sodium and bicarbonate.

Patients with Fanconi syndrome may require potassium, phosphate, and vitamin D supplementation in addition to specific therapy aimed at the underlying cause, such as cysteamine in cystinosis, chelating agents (i.e., penicillamine) in Wilson's disease, or dietary manipulation in galactosemia and tyrosinemia.

Prognosis in PRTA depends on the etiology. In transient DRTA, supplementation to preserve growth is all that is required. Adequate chronic alkali therapy protects against growth abnormalities in those with persistent lesions. Outcome in secondary lesions is determined by the underlying process and its response to treatment. Early treatment of galactosemia has an excellent prognosis, whereas patients with Lowe's syndrome (81) or mitochondrial myopathies (82,83) have less favorable outcomes.

Renal Tubular Acidosis Type 4

Symptoms

RTA type 4 is the most common nonazotemic form of RTA and may result from a number of disorders (Table 39.4). Patients usually present with hyperkalemia and mild MA. Ability to acidify the urine to a urinary pH below 5.5 is intact and signs of aldosterone deficiency or resistance may be present. Infants may have FTT, hyperkalemic MA with associated salt wasting (in aldosterone deficit), or resistance (pseudohypoaldosteronism) (13,16). In pseudohypoaldosteronism, renal sodium loss and potassium retention usually

remit by 4 or 5 years of age, although renin and aldosterone levels remain elevated. In adults, mild renal insufficiency and hyperkalemic acidosis out of proportion to the renal functional abnormalities is common (59). In the rare syndrome of chloride shunt-associated disorder (9,10,15,17), infants have FTT (16), whereas adolescents have hypertension and increased blood volume associated with hyporeninemia and lowered aldosterone levels (15,17).

In critically ill patients, a new syndrome of isolated hypoaldosteronism has been noted. This is believed to follow hypoxia, cytokine release, and atrial natriuretic peptide inhibition of aldosterone synthase. It is characterized by elevated adrenocorticotropic hormone and cortisol levels with decreased aldosterone and hyperkalemic MA, which is potentiated by K⁺-sparing diuretics, K⁺ load from parenteral nutrition, and heparin (54).

Genetics

Inherited defects resulting in type 4 RTA include absence of aldosterone and glucocorticoid hormones (e.g., congenital adrenal hypoplasia with salt wasting) (11) and isolated hypoaldosteronism (Table 39.4). Possible inheritance is suggested by familial cases of a form of early childhood hyperkalemic RTA (27).

Pathophysiology

RTA 4 results from deficiency of aldosterone or tubular unresponsiveness to its effects. Aldosterone stimulates H⁺ secretion by intercalated cells and sodium absorption in the principal cells. This process increases luminal electronegativity, further enhancing sodium and potassium secretion. Increased potassium secretion by principal cells leads to enhanced ammonium production and distal delivery. In experimental aldosterone deficiency there is a decrease in NAE secondary to decreased ammonium formation; studies in human subjects after adrenalectomy confirm decreased ammonium secretion, which is corrected with mineralocorticoid supplementation (84). This suggests that renal acidification is under tonic stimulation by physiologic levels of mineralocorticoids (84).

As a result of aldosterone deficiency, hyperkalemia results from decreased potassium excretion (59,85). Bicarbonate excretion is reduced if plasma bicarbonate is returned to normal by supplementation. Reduced bicarbonate excretion allows a urinary pH of 5.5 to be attained under acidotic stimulation. Exclusion of other proximal tubular dysfunction is necessary to differentiate between PRTA and RTA 4. However, a decrease in urinary ammonium secretion leads to decreases in NAE and MA, with marked hyperkalemia after any increase in dietary potassium intake.

Citrate excretion usually is high in patients with RTA 4, and nephrocalcinosis and nephrolithiasis do not occur despite the acidosis. In patients with the early childhood

form of RTA 4, calcium reabsorption is increased, further protecting against nephrocalcinosis (86).

Treatment of hyperkalemic RTA includes exclusion of excess dietary potassium intake or removal of potential offending drugs and correction of volume contraction. If restriction of dietary potassium intake does not produce correction, a trial of furosemide to ameliorate the acidosis and hyperkalemia should be undertaken (59,87). In an emergency, mineralocorticoid (fluorohydrocortisone) or sodium bicarbonate may be necessary to correct the acidosis, promote intracellular translocation of potassium, and increase potassium excretion. However, long-term use of sodium bicarbonate in mild renal insufficiency leads to volume overload and hypertension (6). In adrenal insufficiency, mineralocorticoid supplementation leads to correction of underlying pathophysiology. With pseudohypoaldosteronism, sodium chloride supplementation alone most often leads to correction; however, some patients additionally require sodium bicarbonate (86). In the small subgroup with a chloride shunt, possibly as a result of a defective $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ transporter system, concurrent hypertension is present. Treatment includes salt restriction and thiazide or furosemide administration to correct both the hypertension and hyperkalemia by increasing sodium delivery to the distal tubule, resulting in increased H^+ , K^+ , and water excretion.

Prognosis

Prognosis depends on the underlying cause. Pseudohypoaldosteronism appears to result from a relative decrease in receptor number, leading to end-organ resistance that remits by 4 to 5 years of age (86). Primary adrenal lesions usually require permanent supplementation. Drug-induced changes may remit with removal of the drug and further avoidance of such agents. Hyporeninemic hypoaldosteronism from tubulointerstitial nephritis occurs in adult patients with diabetes or hyperuricemia and is likely to be associated with progressive renal insufficiency.

Distal Renal Tubular Acidosis Type 1, Classic Renal Tubular Acidosis

Symptoms

Symptoms differ in children and adults. Childhood presentation includes vomiting, FTT, and life-threatening acidosis. Nephrocalcinosis, renal calculi, or bone disease, including rickets or osteomalacia, are less common as presenting symptoms in younger children but are regularly present in older untreated patients (87). Adults have recurrent renal calculi and musculoskeletal complaints such as arthralgia, myalgia, and bone pain (70).

Genetics

A reduced rate of H^+ secretion may occur as a primary condition—DRTA inherited as either an autosomal dominant

or autosomal recessive trait (26)—or secondary to nephrocalcinosis (88,89–91), autoimmune disease (84–86), or exposure to drugs such as amphotericin (91) (Table 39.5). The inherited forms may be present as an isolated defect (68) or associated with genetically transmitted systemic disease, such as CA2 deficiency (76,80), erythrocyte CA B deficiency, Ehlers-Danlos syndrome, hereditary elliptocytosis, hereditary fructose intolerance with nephrocalcinosis, Marfan's syndrome, sickle cell anemia, osteopetrosis (30), sensorineural deafness, carnitine palmitoyl transferase type 1 deficiency, and idiopathic hypercalciuria (89).

Pathophysiology

Disordered H^+ secretion in the CCT and MCT leads to decreased bicarbonate reabsorption in the distal tubule with consequent decrease in TA and ammonium secretion. The subsequent decrease in NAE leads to MA. Disordered H^+ secretion results in the inability to reduce urinary pH even with spontaneous or induced acidosis. Bicarbonate excretion in early childhood is greater than in adults, and FE_{HCO_3} may range from 5 to 15% (4,78). This large bicarbonate loss, in addition to the inability to secrete H^+ , leads to potentially life-threatening acidosis and a much larger requirement for bicarbonate supplementation in the younger age group. Functional immaturity of the proximal tubule has been suggested as the cause for this increased bicarbonate loss (4,26). Further increases in bicarbonate requirements may occur during periods of subsequent growth when H^+ is produced during bone formation. At approximately 4 to 5 years of age, there is usually a decrease in bicarbonate supplementation to levels similar to those required for correction in adults. Bicarbonate excretion does not vary with filtered load over a wide range of plasma bicarbonate levels and results from the inability to reduce urinary pH below 7, even with severe acidosis. This phenomenon is consistent with impaired distal tubular bicarbonate reabsorption (26).

Most adults show a constant FE_{HCO_3} below 5% over a wide range of serum bicarbonate levels. However, some patients have been described with net base excretion resulting from FE_{HCO_3} exceeding $\text{TA} + \text{NH}_4^+$ (26).

Concurrent sodium and potassium wasting occur. Sodium wasting is a result of decreased reabsorption in both proximal and distal tubules with bicarbonate or other anions (94,95). Volume depletion stimulates renin-aldosterone secretion and leads to increased delivery of bicarbonate and poorly absorbed anions such as sulfate to the distal tubule. This promotes sodium and potassium wasting and consequent hypokalemia. Supplementation with alkali increases urinary pH and decreases the EDF for H^+ secretion, allowing correction of acidosis. Urinary sodium and potassium excretion subsequently fall, leading to improvement in electrolyte

TABLE 39.5. DISTAL RENAL TUBULAR ACIDOSIS (RTA)

Inability to secrete H⁺ (secretory defect)	
Primary distal RTA (persistent classic syndrome)	Primary biliary cirrhosis
In infancy, associated HCO ₃ wasting	Thyroiditis
In adolescence, secondary hyperparathyroidism	Fibrosing alveolitis

CA, carbonic anhydrase.

balance. Volume correction decreases aldosterone secretion and leads to retention of potassium and correction of the hypokalemia (51). A small group of patients have continued potassium wasting despite correction of the acidosis, a condition that may be associated with persisting hyperaldosteronism. MA is associated with an increased excretion of calcium and phosphorus (88) and a decrease in citrate excretion (5,31,96,97). In acidosis (spontaneous or induced by ammonium chloride), citrate enters the mitochondria through stimulation of a citrate carrier in the inner mitochondrial membrane (96,97). This leads to a decrease in cytosolic citrate and a gradient for reabsorption from lumen to cell. Medullary nephrocalcinosis and recurrent calcium phosphate or oxalate nephrolithiasis occur in the alkaline urine as a result of hypercalciuria and the reduced intraluminal citrate.

Nephrocalcinosis, which was, historically, a universal finding in patients with DRTA, has become rare with recognition and early institution of adequate alkali therapy. Persisting MA leads to buffering of hydrogen ion by bone

(alkaline buffer salts) with development of metabolic bone disease (98). Correction of the acidosis leads to correction of bone disease, whereas nephrocalcinosis and nephrolithiasis tend to persist (69,99).

Some patients with DRTA appear to have impaired gastrointestinal absorption of calcium (100), as well as increased renal excretion of calcium, leading to hypocalcemia, hyperparathyroidism, hypophosphatemia, and rickets. This occurs in patients with untreated disease and is uncommon in patients receiving adequate alkali supplementation (68). MA itself may impair vitamin D metabolism and lead to intestinal malabsorption of calcium, with secondary bone disease with RTA. In acidotic children and adults with RTA and radiographic evidence of rickets (101,102), serum levels of 1,25-dihydroxyvitamin D (1,25-OH vitamin D) have been reported to be normal (101,102). However, in phosphorus-restricted healthy men, in whom basal levels of 1,25-OH vitamin D were increased twofold, a decrease occurred when acidosis was induced with ammonium chloride (103). The decrease was mediated by decreased production and increased clearance of 1,25-OH vitamin D (101). Thus, aci-

dosis in humans can impair the renal production of 1,25-OH vitamin D.

Polyuria is always present in patients with DRTA and has been attributed to hypokalemia, nephrocalcinosis, solute excretion in untreated patients (e.g., hypercalciuria, phosphaturia, excess sodium, potassium, and bicarbonate excretion), or a primary tubular defect (79).

Treatment

Therapy is directed at correction of acidosis at a rate commensurate with risk of electrolyte and acid-base abnormality. Severe hypokalemia presents a risk to cardiac and respiratory muscle function (104) and should be at least partially corrected before correction of the acidosis (because the latter can aggravate the degree of hypokalemia) (3). Sodium and potassium supplementation may be supplied as citrate or bicarbonate, with one-third to one-half of the supplement provided as the potassium salt. Increased growth velocity is expected to follow appropriate therapy in 2 to 3 weeks in the infant, and increased bone formation is followed by an increase in acid production (68). Increased supplementation is required until stabilization occurs with normal growth rate (68). A longer period of therapy is required to restore growth

in previously untreated older children. After age 4 to 5 years, there is reduced bicarbonate loss, and, therefore, lower dosages of alkali supplementation (1 to 2 mEq/kg/day or 2 to 4 mEq per 100 calories) maintain correction.

Prognosis

Growth rates can be restored and bone disease prevented by early and consistent therapy. Early treatment is also necessary to prevent nephrocalcinosis, which can lead to chronic interstitial nephritis with scarring and glomerulosclerosis (105).

DIAGNOSIS OF RTA

Diagnosis of RTA is based on clinical findings, assessment of plasma acid-base status, assessment of urine acidification (urinary pH), urinary ammonia or urine anion gap, and urine PCO_2 . Tools for characterization are outlined in Table 39.6 and include acid loading (106), bicarbonate titration (107), urine to blood carbon dioxide tension during bicarbonate titration (18,108), neutral sodium phosphate infusion (101), and furosemide challenge (18,59,108). Urine-blood

^cIncreased back-diffusion of secreted H⁺.

carbon dioxide tension may be used as a specialized laboratory test to define impaired H⁺ secretion by the collecting tubule. Urine-blood PCO₂ is the most sensitive test for distal tubular H⁺ excretion. Impaired excretion is associated with a urinary CO₂ tension (PCO₂) that does not increase to expected higher-than-plasma values after loading with sodium bicarbonate. Under normal circumstances, urinary pH and bicarbonate are increased by administration of sodium bicarbonate, and urinary PCO₂ rises to values considerably higher than those of blood (normally more than 20 mm above blood levels) (109,110). The difference in PCO₂ between urine and blood (U PCO₂ to B PCO₂ gradient) varies directly with the urine bicarbonate concentration. Increase in PCO₂ in alkaline urine reflects an increase in H⁺ secretion in the collecting tubule, augmented by the high, intraluminal bicarbonate concentration (18). The secreted H⁺ and luminal bicarbonate combine to form carbonic acid, which dissociates to carbon dioxide and water at an uncatalyzed rate (CA is not present in the lumen of the distal nephron). Because carbon dioxide generation occurs in the distal segments of the collecting duct, where medullary trapping of carbon dioxide can occur, and in the renal pelvis and bladder, where conditions are unfavorable for reabsorption of carbon dioxide into blood, carbon dioxide appears in increased amounts in the urine. Similar findings follow the administration of neutral sodium phosphate, which enhances the distal delivery of buffer. This stimulates H⁺ secretion and increases the U PCO₂ to B PCO₂ gradient. This can also be used as a test of distal tubular H⁺ secretion. Furosemide challenge (Table 39.7) may be used to assist in differentiation of site and mechanism of the defect in acidification (18). Delivery of sodium and reabsorption in the CCT is followed by an increase in luminal electronegativity. A similar increase in negativity can be produced by sodium

sulfate infusion, which increases the sodium delivery; because the sulfate ion is impermeable, the gradient is maintained. In normal subjects with MA acid, urinary pH is further lowered by furosemide or sodium sulfate infusion and potassium excretion is increased.

Patients with diffuse impairment of H⁺-ATPase from a decrease in glomerular filtration rate (GFR) or nephron number have a persistent alkaline urine with increased potassium excretion because principal cell function is usually intact (Table 39.7). Patients with a pump defect limited to the MCT have a normal increase in both H⁺ and K⁺ because cortical function is stimulated by intraluminal electronegativity. Patients with impairment in cortical sodium reabsorption (voltage defect) have baseline hyperkalemia and after challenge there is no increase in H⁺ or K⁺ because there is no increased intraluminal electronegative gradient.

Differential Diagnosis

1. Other causes of metabolic acidosis

(a) Gastrointestinal bicarbonate loss (e.g., diarrhea, fistula) or administration of drugs [e.g., CaCl₂, MgSO₄, cholestyramine (U Cl greater than Na + K)] (Fig. 39.2).

In chronic MA, ammonia generation from glutamine is stimulated with little change in phosphate excretion (phosphate released from bone is used in blood buffering during acidosis). Thus, it is helpful to focus on ammonia generation and excretion as the expected response in acidosis, and review of ammonia excretion is the key to understanding RTA. Urinary pH values taken alone may be misleading in chronic MA from gastrointestinal loss, particularly if hypokalemia is present. Here the increase in ammonia excretion buffers most of the secreted H⁺, leading to a urinary pH of 5.5 to 6.0. Thus, if pH alone is considered

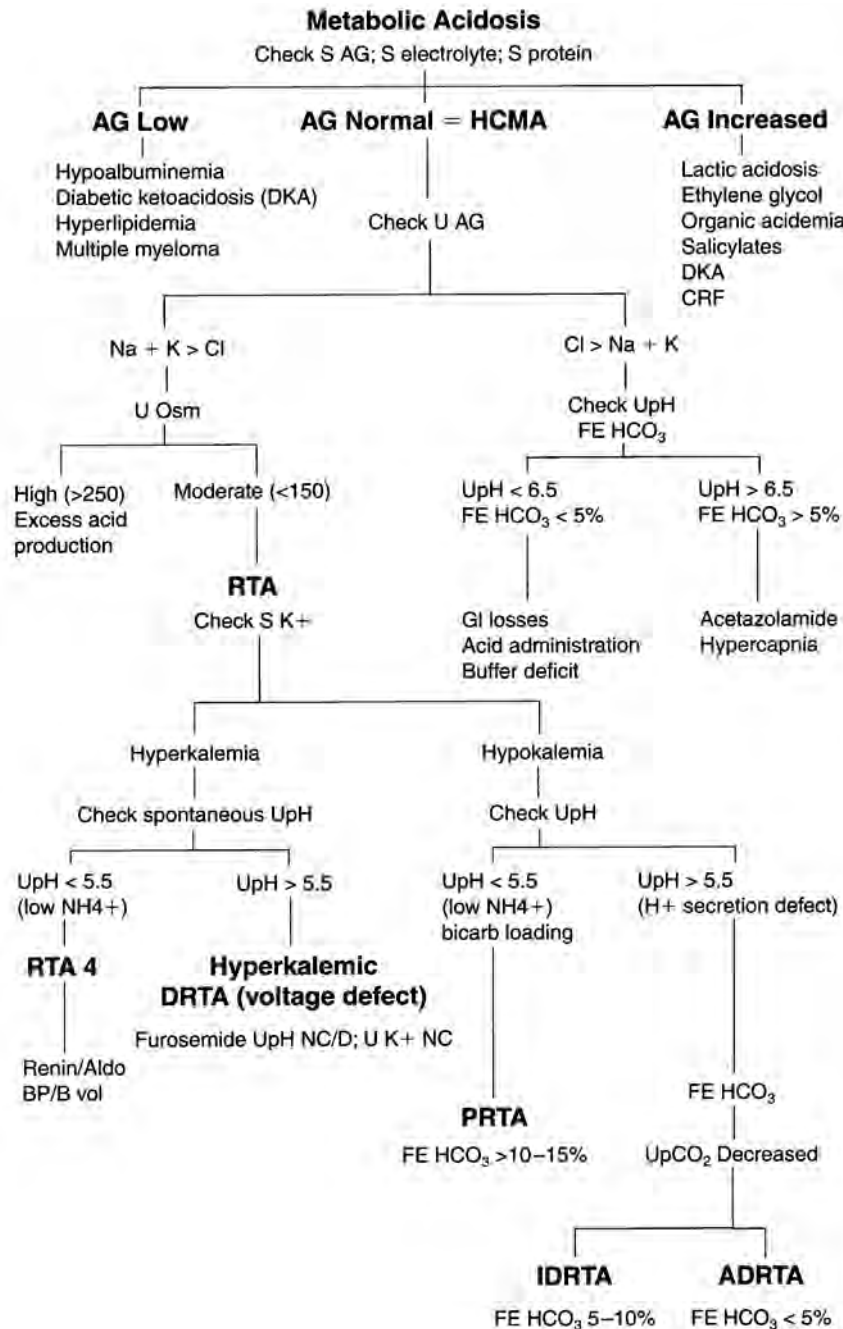

FIGURE 39.2. This algorithmic approach to the patient with metabolic acidosis illustrates the differential features leading to a diagnosis of renal tubular acidosis (RTA). Useful confirmatory tests and features of differing types of RTA are outlined at the steps in which they are used clinically. ADRTA, adult distal renal tubular acidosis; AG, anion gap; Aldo, aldosterone; BP, blood pressure; B Vol, blood volume; CRF, chronic renal failure; GI, gastrointestinal tract; HCMA, hyperchloremic metabolic acidosis; IDRTA, infantile distal renal tubular acidosis; PRTA, proximal renal tubular acidosis; S, serum; UpH, urine pH.

without consideration of urine AG, DRTA is suggested (24,111). In aldosterone deficiency, ammonia secretion is significantly impaired and H^+ secretion as ammonium is reduced. Here, incomplete buffering of secreted H^+ leads to low urinary pH even in patients with DRTA (112,113).

(b) Acid loading that may occur with NH_4Cl , acidic amino acids in parenteral nutrition, or ingestion of acid ingestion (e.g., HCl , NH_4Cl , lysine, arginine, sulfur, and phosphorus from food). HCMA is associated with a negative U_{AG} .

2. Anion gap acidosis (Fig. 39.2)

3. Pseudo-RTA: In malnourished patients, the catabolic state produces increased acid, ketones, a decrease in GFR, and a decrease in phosphate output. This limits both TA (decreased capacity to excrete H^+ with an acid urine), a decreased generation of ammonia from a glutamine deficit that further limits H^+ excretion, and increased ketone excretion (or potential loss of bicarbonate), thereby producing a pseudo-RTA syndrome.

4. Urinary diversion or augmentation of the bladder using segments of ileum or colon leads to hypokalemia with severe acidosis, particularly if there is poor drainage leading to prolonged mucosal contact with urine.

5. Uremic acidosis usually is associated with an increased anion gap (from phosphate and sulfate retention), whereas reduced nephron number is followed by severely decreased ammonium excretion and reduced bicarbonate reabsorption (associated with a relative solute diuresis in remaining nephrons) (114).

6. Urinary infection with urea-splitting organisms (e.g., *Proteus*), an alkaline urine, and, if there is parenchymal infection, MA. Urinalysis and culture are necessary to exclude such factitious RTA patterns, particularly in patients with obstructive uropathy.

7. Hyperkalemic DRTA is a condition in which low K^+ excretion is present together with a decreased ability to acidify the urinary pH to less than 5.5 during spontaneous or induced acidosis (18). Concurrent sodium wasting is common, so salt-losing congenital adrenal hyperplasia, pseudoaldosteronism, must be considered in the differential diagnosis. Furosemide or sodium sulfate testing demonstrates typical low potassium excretion.

8. Abnormal anions, certain drugs, or toxic substances may lead to decrease in value of U_{AG} (e.g., ketonuria), and D lactic acidosis and toluene (glue sniffing) are associated with a (+) net charge, which may be misinterpreted. Formal measurement of NH_3 may be necessary to check anion gap if the history suggests these are potential causes. Glue sniffing leads to a high NH_3 , U_{AG} , and $U_{osmolar}$ gap (from conversion of toluene to hippurate). Check for D lactic acidosis if MA is associated with central nervous system confusion, particularly if there is history of bowel disease or resection. A trial of antibiotics to decrease production is then warranted.

9. Functional RTA secondary to marked decrease in sodium delivery (U_{Na} less than 10) limits distal H^+ excretion.

Other considerations in differential diagnosis include tubular dysfunction (which may occur as a result of extrinsic renal factors such as hyperkalemia, extracellular fluid expansion, and loss of potential bicarbonate during recovery from chronic hypocapnia), with volume expansion (dilutional) acidosis, or secondary hyperparathyroidism.

Practical Approach to Diagnosis

Symptoms often are nonspecific and a high index of suspicion is necessary. If HCMA with a normal anion gap is

present, RTA should be suspected. Initial studies should include repeat blood gas, S_{K_2} , U_{AG} , urinary pH (by pH electrode measurement, not indicator strips, which are notoriously inaccurate), and urinalysis to identify proximal tubular dysfunction (e.g., proteinuria glycosuria, aminoaciduria) (Figs. 39.2 and 39.3).

Serum K^+ is helpful in classification because hypokalemia occurs in PRTA (type 2) and DRTA (type 1). Hyperkalemia suggests aldosterone deficit or resistance (type 4), voltage defect, or obstructive uropathy. Normal S_{K_2} occurs in RTA with renal insufficiency, uremia, and the McSherry syndrome (86).

If preliminary studies suggest HCMA with RTA, serum, and urine, chemistries should be evaluated with blood gases to rule out respiratory alkalosis and other potential causes of bicarbonate loss. Additional history should be obtained to check for potential HCl administration (e.g., parenteral nutrition, drug administration), renal or gastrointestinal losses of bicarbonate, or the presence of a bowel segment augmenting bladder capacity or used as a urinary diversion. Exclude concurrent or underlying renal disease with uremia or retention rather than tubular acidosis. In the patient with HCMA, urinary pH and urinary ammonia excretion should be evaluated by direct measurement or U_{AG} (calculate urinary net charge, $U_{AG} + U_{Na} + U_K - U_{Cl} - U_{HCO_3}$) to evaluate the site of renal tubular lesion. A positive U_{AG} reflects low H^+ secretion and low ammonium excretion, whereas a negative U_{AG} reflects urinary bicarbonate loss.

Low NH_4^+ production ($U_{AG} +$) suggests DRTA, PRTA with low NH_4^+ production, D lactic acidosis, or failure to lower NH_4^+ in the lumen of the collecting duct because of excess distal delivery of HCO_3^- from the PCT (22).

High NH_4^+ production with acidosis makes it necessary to check for loss of metabolizable organic anions in the urine (these equal potential HCO_3^-). Here, the cause of acidosis is overproduction of organic acids, and the renal lesion does not cause the acidosis, which may be U_{AG}^+ . Loss of metabolizable anion is suspected when there is an excessive rate of urinary excretion of organic anions shown by $Na^+ + K^+$ greater than Cl^- (22,48).

If there is a low NH_4^+ excretion, urinary pH should be evaluated. If the urinary pH is above 6.0, bicarbonate excretion should be evaluated by examining the urinary PCO_2 in alkaline urine to examine for distal lesions and fractional excretion of bicarbonate for proximal lesions. Evaluation for other features of Fanconi syndrome should be performed.

Low ammonium secretion is rare. It may occur with a urinary pH of 4 to 5 and a defect in NH_3 availability in the renal medullary interstitium with a decrease in buffering ability (22). This occurs with a low GFR (22), hyperkalemia (22), decreased levels of blood glutamine (e.g., decreased substrate for ammoniogenesis) (115), or high levels of fat-derived fuels (e.g., total parenteral nutrition)

FIGURE 39.3. The figure shows the expected correlation between urine pH (UpH) and arterial pH. Captions highlight the most useful testing at different points in the spectrum. Alkali loading is most useful in the patient with marked acidosis; here comparison of the serum and urine pH allows differentiation between normals, proximal renal tubular acidosis (PRTA), and renal tubular acidosis (RTA) type 4. Acid loading is most useful in patients with normal serum pH (SpH) or mild acidosis. Estimations of net acid excretion from urine anion gap (Urine AG) or osmolar gap (Osm G) or ammonium excretion measurement is most useful at serum pH below 7.4. Urinary Pco_2 measurement requires an alkaline urine. Fractional excretion of bicarbonate is helpful in differentiating between PRTA and the infantile form of distal RTA. Serum K^+ is helpful in differentiating RTA type 4 from other forms. ADRTA, adult distal renal tubular acidosis; IDRTA, infantile distal renal tubular acidosis.

competing with glutamine as a source for regeneration of ATP in the cells of the PCT with decrease in ammoniogenesis and in the hypothetical alkaline cell pH (22). The pH falls even with minimal H^+ transfer (22). A high urinary NH_4^+ or a negative net charge, negative U_{AG} , is consistent with normal distal acidification occurring in the older child (116).

Advantage should always be taken of any episode of spontaneous acidosis to screen for H^+ excretion. Standard treatment in RTA is base replacement; careful selection of testing during correction makes it possible to obtain information, which otherwise requires bicarbonate titration and correction of sodium deficit. This often allows characterization of RTA without the need for formal provocative testing. Formal testing, if subsequently required, should be delayed after correction of acidosis and a period of caloric adjustment to avoid the confounding effects of malnutrition, volume depletion, and other acid-base abnormalities.

The patient suspected of having RTA (Fig. 39.3) who is not overtly acidotic requires formal acid loading to induce an acidosis. A dose of 0.1 g/kg ammonium chloride (110 mEq/m²) or 2.0 mEq/kg calcium chloride is administered orally or intravenously. Ammonia excretion and urinary pH are measured at 1, 2, and 8 hours. If secondary RTA from a metabolic disorder is possible, hyperammonemic syndromes must be excluded before administration of ammo-

nium chloride to prevent life-threatening complications of hyperammonemia.

If the initial urinary pH is above 6.5 and serum bicarbonate is normal or only mildly depressed, evaluation for PRTA is necessary. Proximal tubular function should be evaluated because the defect (failure of bicarbonate reabsorption) in PRTA is, more commonly, part of a multiple defect syndrome (Fanconi syndrome) than an isolated defect.

If MA is present and the serum potassium is high (above 5 mEq/L) with a urinary pH below 5.5, one must consider RTA 4 (Table 39.8). Evaluation includes review of serum AG and U_{AG} (NAE), pH, assessment of volume and circulatory status (e.g., blood pressure, pulse, weight), and plasma renin and aldosterone measurement under stress (e.g., volume depletion or furosemide challenge). Persistently high urinary sodium loss suggests hypoaldosteronism or pseudohypoaldosteronism (117). Urine osmolality should be greater than isotonic and U_{Na} greater than 20 mmol/L for transtubular potassium gradient to be valid in assessing response to mineralocorticoid administration and furosemide challenge.

If U_{Na} is below 15 mmol/L, it is important to exclude an exchange defect because reduced H^+ may result from reduced sodium delivery. This is sometimes called *functional RTA* because of its transient nature and relationship to limited H^+ ion secretion by sodium delivery and poten-

TABLE 39.8. RENAL TUBULAR ACIDOSIS TYPE 4, HYPERKALEMIC ACIDURIA PHYSIOLOGIC SUBTYPING

Subtype	Plasma renin activity	Urine aldosterone/serum aldosterone	Clinical blood pressure	Finding blood volume/plasma volume	Salt-wasting
Aldosterone deficiency ± renal disease

Early childhood type 4	E	E	N	L/N	L

E, elevated; E/N, elevated or normal; L, low; L/N, low or normal; M/E, markedly elevated; N, normal; S/E, significantly elevated.

tial aldosterone effect rather than a true tubular defect. If this defect is suspected, the patient should be carefully assessed for dehydration, severe cardiac failure, and sodium chloride (deficit from vomiting, diuretic abuse, or overuse). If present, dehydration or sodium deficit should be corrected with appropriate hydration or salt supplementation before U_{pH} and U_{AG} are reassessed. If volume deficit is not apparent, a trial dose of furosemide or response to sodium sulfate infusion to increase sodium delivery to the distal tubule (with the consequent enhanced transepithelial voltage) should be administered. Expected response to furosemide administration in healthy subjects includes a decrease in urinary pH and increase in ammonia and U_K excretion. In patients with hyporeninemic hypoaldosteronism, urinary pH is decreased.

Therapy

In the patient with significant spontaneous acidosis, initial correction based on an exact diagnosis is not necessary, nor is it necessary to delay therapy until investigation is complete. Bicarbonate administration and titration are effective in correcting the acidosis with RTA regardless of type. However, in DRTA type 1 with hypokalemia, and likely hypocalcemia, partial correction of potassium and calcium should be carried out before total correction of serum bicarbonate to prevent muscle weakness, respiratory failure, arrhythmia, or painful tetany. Care should be taken to obtain appropriate diagnostic samples of blood and urine under spontaneous acidosis and during base supplementation to allow diagnosis without the need for formal acid loading or bicarbonate.

Acute Correction of Acidosis

First, serum potassium and calcium should be assessed and significant deficits should be partially replaced before cor-

recting bicarbonate deficit. The bicarbonate deficit is replaced over 1 to 2 days depending on presenting symptoms. Initial correction to serum pH 7.25 to 7.30 is made using the Henderson equation ($H^+ = 24 PCO_2/HCO_3^-$) to assess the desired bicarbonate supplementation. Remaining deficits should be calculated after equilibration with bicarbonate space of 0.6 body weight/kg (i.e., HCO_3^- required = $0.6 - \text{body weight/kg} - [\text{desired } HCO_3^- - \text{measured } HCO_3^-]$), to which maintenance dosing is added. The adequacy of replacement is checked and the dosage of administered bicarbonate is titrated.

Maintenance Therapy

Once a deficit is corrected, it is necessary to provide sufficient base supplementation to balance nonvolatile acid production (DRTA) and to replace any continuing losses (PRTA). Base may be supplied as sodium bicarbonate (55 mEq/teaspoon), sodium citrate, or mixed sodium and potassium citrate depending on the presence or absence of continuing potassium losses. The aim is to maintain CO_2 greater than 20 to 22 mEq/L.

In DRTA, replacement covers the production of 2 to 4 mEq of acid/kg from the diet equivalent to 2 mEq per 100 kcal (Table 39.6). In young children, after treatment is commenced, an extra 2 to 3 mEq/kg acid may be generated from bone formation, as hydroxyl and phosphate groups are incorporated into hydroxyapatite. In PRTA, dosages as high as 4 to 15 mEq/kg/day are sometimes required to compensate for continuing losses secondary to the low tubular bicarbonate threshold.

Patients with RTA 4 require treatment for hyperkalemia (59). This may include correction of acidosis, sodium repletion, mineralocorticoid replacement, and, in some patients, glucocorticoid replacement (59,87). It is particularly important to review drug and dietary intake in patients

with RTA type 4. Common contributing factors to hyperkalemia include low urine flow; decreased sodium delivery; rapid decline in GFR, particularly in acute or chronic renal failure; hyperglycemia or hyperosmolality; and unsuspected intake of potassium salt supplements or medications. Calculation of transtubular potassium gradient and response to furosemide and fluorohydrocortisone allow clinical correction of hyperkalemic syndromes while awaiting formal assessment of renin-aldosterone status. If there is a low transtubular potassium gradient (below 5) in a patient with hyperkalemia and no response to mineralocorticoid supplementation, a furosemide challenge and treatment with sodium or bicarbonate to increase excretion is appropriate.

NEPHROGENIC DIABETES INSIPIDUS

NINE V. A. M. KNOERS
LEO A. H. MONNENS

HISTORY

The renal type of diabetes insipidus was appreciated as a separate entity more than 50 years ago, when it was described independently by two investigators: Forssman (1) in Sweden and Waring et al. (2) in the United States. Families with this type of defect, however, had been described previously (3) without clear differentiation of nephrogenic diabetes insipidus (NDI) from the central or neurohormonal form of the disorder. In 1947, Williams and Henry (4) noticed that injection of antidiuretic hormone (ADH) in doses sufficient to induce systemic side effects could not correct the renal concentrating defect in some patients. They coined the term *NDI*. Subsequent studies revealed active hormone in the serum and urine of affected persons and lent further support to the theory of renal unresponsiveness to vasopressin. NDI is synonymous with the terms *vasopressin-* or *ADH-resistant diabetes insipidus* and *diabetes insipidus renalis*.

DEFINITION AND CLINICAL MANIFESTATIONS

Congenital NDI is a rare inherited disorder, characterized by insensitivity of the distal nephron to the antidiuretic effects of the neurohypophyseal ADH, arginine vasopressin (AVP). As a consequence, the kidney loses its ability to concentrate urine, which may lead to severe dehydration and electrolyte imbalance (hypernatremia and hyperchloremia). The defect in NDI is present from birth, and manifestations of the disorder generally emerge within the first weeks of life. With breast milk feedings, infants usually thrive and do not develop signs of dehydration. This is because human milk has a low salt and protein content, and therefore a low renal osmolar load. With cows' milk formula feedings, the osmolar load to the kidney increases, resulting in an increased demand for free water. If cow's milk feedings are not supplemented by hypotonic fluids in infants with NDI, hypernatremic dehydration appears. Irritability, poor feed-

ing, and poor weight gain are usually the initial symptoms (5). Patients are eager to suck but may vomit during or shortly after the feeding. Dehydration is evidenced by dryness of the skin, loss of normal skin turgor, recessed eyeballs, increased periorbital folding, depression of the anterior fontanelle, and a scaphoid abdomen. Intermittent high fever is a common complication of the dehydrated state, particularly in very young children. Body temperature can be normalized by rehydration. Seizures can occur but are rare and most often seen during therapy, particularly if rehydration proceeds too rapidly. Obstipation is a common symptom in children with NDI. Nocturia and enuresis are common complaints later in childhood.

Untreated, most patients fail to grow normally. In a retrospective study of 30 male NDI patients, most children grew below the 50th percentile, most of them having standard deviation (SD) scores lower than -1 and showing no clear catch up growth after the first year of life. Weight for height SD scores were initially low, followed by global normalization at school age (6). The exact reasons for the failure to thrive seen in NDI are unknown. Initial feeding problems and the ingestion of large amounts of low-caloric fluid resulting in a decreased appetite may play roles (7,8). Furthermore, it is possible that repeated episodes of dehydration have some as yet undetermined negative effects on growth.

Mental retardation has long been considered an important complication of untreated NDI and assumed to be a consequence of recurrent episodes of severe brain dehydration and cerebral edema caused by overzealous attempts at rehydration (9,10). Additional evidence underscoring the assumption that NDI has adverse effects on the cerebrum is provided by several reports describing intracranial calcifications in NDI patients (11,12). Such lesions are generally considered to be the result of hemorrhage or necrosis. Most of the reported patients with cerebral calcifications were mentally retarded.

Currently, mental retardation is considered to be rare due to earlier recognition and treatment of NDI. The frequency of mental retardation under modern treatment regimens is

FIGURE 40.1. Intravenous pyelogram of a patient with congenital nephrogenic diabetes insipidus and severe hydronephrosis.

unknown, but in the largest psychometric study ever reported, only 2 of the 17 male NDI patients (aged 3 to 30 years) tested had a total intelligence quotient more than 2 SDs below the norm. Fourteen patients had an intelligence score within or above the normal range, and one patient had a general index score between -1 and -2 SD (13).

The psychological development of patients with NDI is influenced by a persistent desire for drinking and the need for frequent voiding, which compete with playing and learning. Therefore, many NDI patients are characterized by hyperactivity, distractibility, short attention span, and restlessness. In the psychometric study mentioned earlier, the criteria for attention deficit hyperactivity disorder were met in 8 of 17 tested NDI patients (13).

Persistent polyuria can result in the development of megacystis, hydroureter, and hydronephrosis (14) (Fig. 40.1). We have recently found that this complication is rare in patients with NDI. Dilatation of the urinary tract occurred in only 2 of 30 patients studied (6).

DIAGNOSTIC PROCEDURES

The observation of polyuria in a dehydrated infant, together with the finding of a high serum sodium concentration, provides presumptive evidence of a renal concentrating defect. To confirm the concentrating defect and to distinguish the renal from the central form of diabetes insipidus, a vasopressin test is performed with 1-desamino-8-D-arginine vasopressin (DDAVP), a synthetic analogue of natural AVP that produces a high and prolonged antidiuretic effect. In the test, DDAVP

TABLE 40.1. COMMON CAUSES OF ACQUIRED OR SECONDARY NEPHROGENIC DIABETES INSIPIDUS

Sickle cell anemia and trait

(10 mg for infants, 20 mg for children) is administered intranasally. Urine is collected during the subsequent 5.5 hours. The first collected portion of the urine should be discarded. The maximal urine osmolality in any collected aliquot is chosen as a measure of the concentrating capacity (15). After DDAVP administration, NDI patients are unable to increase urinary osmolality, which remains below 200 mOsm/kg H_2O (normal greater than or equal to 807 mOsm/kg H_2O) and cannot reduce urine volume or free-water clearance.

Plasma vasopressin levels are normal or only slightly increased in affected children. Other laboratory findings have been described, which mainly result from chronic dehydration. Serum sodium concentration is generally elevated and may be as high as 170 mmol/L. There is also an increase in serum chloride concentration and retention of urea and creatinine. All values are normalized by adequate rehydration. In addition, reduced glomerular filtration rate and renal blood flow return to normal when a state of normal hydration has been achieved.

The primary congenital form of NDI must be differentiated from the secondary or acquired forms, which are much more common. In our experience, the urinary osmolality obtained after DDAVP administration in these disorders is always higher than in NDI. Several secondary causes, some of which are discussed later, are listed in Table 40.1.

CELLULAR PHYSIOLOGY OF ARGININE VASOPRESSIN'S ANTIDIURETIC ACTION IN THE DISTAL NEPHRON

The physiologic action of vasopressin on the renal collecting duct has been one of the most intensively studied processes in the kidney. AVP (ADH) is synthesized on the ribosomes of the magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus as a large, biologically inactive bound form, and transported down the neuronal axons to the posterior pituitary where it is stored. After appropriate

FIGURE 40.2. Schematic view of the antidiuretic arginine vasopressin (AVP) signaling pathway in collecting duct cells and the proteins (microtubule, dynein-dynactin) and vesicle targeting receptors (VAMP-2, syntaxin-4, NSF) that might participate in the specificity of aquaporin-2 (AQP2) water channel targeting to the luminal plasma membrane. AC, adenylyate cyclase; AQP3, aquaporin-3 water channel; AQP4, aquaporin-4 water channel; G, stimulatory guanine nucleotide binding protein; NSF, *N*-ethylmaleimide-sensitive fusion protein; PKA, protein kinase A; V_2 , vasopressin type-2 receptor. (See Color Plate 40.2.)

stimuli, AVP is secreted from the posterior pituitary into the circulation as biologically active hormone. AVP release is primarily regulated by changes in plasma osmolality (by more than 2%) but can also occur in response to nonosmotic stimuli. These nonosmotic stimuli are generally related to changes in either total blood volume or the distribution of extracellular fluid. In addition, physical pain, emotional stress, and certain drugs (e.g., nicotine) influence the release of AVP. In its effector organ, the kidney, AVP binds to vasopressin type-2 receptors (V_2 R) on the basolateral membrane of the principal inner medullary collecting duct cells and of the arcade cells (Fig. 40.2). The arcades are long, highly branched renal tubule segments that connect distal convoluted tubules of several deep and midcortical nephrons to the origin of cortical collecting ducts. V_2 R occupancy results, via the intermediacy of a stimulatory G protein (G_s), in activation of adenylyate cyclase and an increase in intracellular cyclic adenosine monophosphate (cAMP) from adenosine triphosphate. The elevated cAMP levels stimulate protein kinase A (PKA), which in turn initiates a redistribution of aquaporin (AQP)-2 water channels from intracellular vesicles to the apical plasma membrane, rendering this membrane water permeable. Phosphorylation of a PKA consensus site in AQP2 (serine at position 256 in the cytoplasmic carboxy terminus) has been shown to

be essential for AQP2 delivery to the apical membrane (16,17). In addition, it has been shown that anchoring of PKA to PKA-anchoring proteins, which ensures targeting of PKA to AQP2-bearing vesicles, is another prerequisite for AVP-mediated AQP2 translocation (18). The identity of the PKA-anchoring proteins involved has not yet been elucidated. The increase in apical membrane permeability allows water to flow from the tubule lumen, via AQP2 in the apical membrane and via AQP3 and AQP4, constitutive water channels in the basolateral membrane, to the hypertonic medullary interstitium. This then leads to the formation of concentrated urine. Withdrawal of vasopressin triggers the endocytosis of AQP2-containing vesicles and restores the water-impermeable state of the apical side of the cell.

The molecular machinery for the docking and fusion of AQP2-containing vesicles with the apical membrane is most likely similar to the process of synaptic vesicle fusion with the presynaptic membrane and involves vesicle (v) SNAREs (soluble NSF attachment protein receptors) and target membrane (t) SNAREs (Fig. 40.2). Thus, in subcellular fractions from rat kidney, enriched for AQP2-containing vesicles, the v-SNARE synaptobrevin (VAMP-2) was found, as well as the fusion-mediating protein SNAP23 (19–22). The potential t-SNARE syntaxin-4 was identified at the apical plasma membrane of rat kidney collecting duct principal cells (23). Rab3A, a member of the Rab family of guanosine triphosphatases, involved in exo- and endocytotic membrane trafficking, is also believed to play a role in AQP2 translocation to the apical membrane (21,24). In addition, it has been shown that both the microtubule-associated motor protein dynein and the associated dynactin-complex, which catalyze transport of vesicles along microtubules, are important in vasopressin-regulated trafficking of these vesicles (Fig. 40.2) (25). Recently, a critical role for calcium as an intracellular mediator of the vasopressin-induced trafficking of AQP2 has been established (26). The translocation of AQP2 from the intracellular vesicle to the plasma membrane can also be stimulated by cAMP-independent pathways. Thus, Bouley et al. have shown that nitric oxide and atrial natriuretic factor stimulate the insertion of AQP2 into renal epithelial cell membranes via a cyclic guanosine monophosphate-dependent pathway (27). The importance of this pathway is as yet unclear.

Long-term adaptation to circulating AVP levels, for instance, in a dehydrated state, is accomplished by increasing the expression of AQP2 messenger RNA (mRNA) and protein. A cAMP-responsive element in the AQP2 promoter has proven to be a key element in cAMP-dependent transcriptional regulation of this gene, and as such for the long-term regulation of water permeability (28).

GENETICS

Three different inheritance patterns of NDI have been recognized. In most cases (approximately 90%), NDI is trans-

mitted as an X-linked recessive trait (MIM304800). In these families, female carriers who are clinically unaffected transmit the disease to sons, who display the complete clinical picture (1,4,29). In 1988, the major NDI locus was mapped to the distal region of the long arm of the X chromosome (Xq28) (30), and in 1992, mutations in the V_2R gene were shown to underlie X-linked NDI (31–33). In a minority of families (approximately 10%), the transmission and phenotypic characteristics of NDI are not compatible with an X-linked trait. In these families, females display the complete clinical picture of NDI and are clinically indistinguishable from affected male family members (34–36). In addition, linkage analysis in these families has excluded linkage between NDI and polymorphic DNA markers from the Xq28 region. Family pedigrees suggested the existence of both an autosomal recessive (MIM 222000) and an autosomal dominant form (MIM 125800) of NDI. In recent years, it has been demonstrated that both autosomal forms of NDI are caused by mutations in the AVP-sensitive AQP2 water channel (37,38). The prevalence of NDI is not exactly known, but the disease is assumed to be rare. Even in large pediatric and nephrology clinics, it is observed infrequently. In the Dutch population of approximately 15 million, 35 different families are known.

X-LINKED NEPHROGENIC DIABETES INSIPIDUS: MUTATIONS IN THE VASOPRESSIN TYPE-2 RECEPTOR GENE

The V_2R had long been considered a prime candidate for the defective step in the AVP-mediated response in X-linked NDI. The reason for this belief was the observation that in patients with X-linked NDI, not only the antidiuretic but also the vasodilatory coagulation and fibrinolytic responses to the V_2R -specific agonist DDAVP were lacking (39). This finding suggested a general V_2R defect in these patients. Independent support for the V_2R being involved in X-linked NDI was provided by the finding that a gene conferring V_2 -like binding activity colocalized with the NDI locus in the subterminal region of the X chromosome long arm (Xq28) (40). Soon after the identification of the human V_2R gene and complementary DNA in 1992 (41), the role of the V_2R in the pathogenesis of NDI was finally proven by the demonstration of mutations in the encoding gene in affected individuals (31–33,42,43). The V_2R gene (AVPR2; Genbank association number L22206) is relatively small and consists of three exons separated by two short intervening sequences (introns). The mRNA has been found exclusively in the kidney, specifically in the cortical and medullary collecting ducts. The complementary DNA encodes a receptor protein of 371 amino acids, has a predicted molecular mass of approximately 41 kDa, and shares the general structure of a G protein-coupled receptor consisting of seven hydrophobic transmembrane helices, con-

nected by extracellular and intracellular loops. The receptor contains one unique consensus sequence site for N-linked glycosylation in the extracellular amino-terminus (44) and phosphorylation sites for G protein-coupled receptor kinases represented by a serine cluster in the carboxy-terminus (45,46). The amino-terminal part of the protein including the first transmembrane domain and the positively charged first intracellular loop are important for proper insertion and orientation in the membrane (47). A conserved glutamate or dileucine motif in the intracellular carboxy terminal part of the receptor is essential for receptor transport from the endoplasmic reticulum (ER) to the Golgi apparatus (48). Two conserved adjacent cysteines in the C-terminus are palmitoylated, thereby anchoring the carboxy-tail to the plasma membrane and controlling the tertiary structure of this region of the receptor (49).

To date, more than 180 distinct putative disease-causing mutations in the V_2R gene have been detected in families with X-linked NDI (see <http://www.medicine.mcgill.ca/nephros>). Remarkably, the mutations are not clustered in one domain of the V_2R but are scattered throughout the protein, except for the part coding for the N- and C-terminal tails of the receptor. Approximately 50% of the mutations are missense mutations. Nucleotide deletions and insertions causing frame shifts (27%), nonsense mutations (12%), large deletions (5%), in-frame deletions or insertions (4%), and splice-site mutations (2%) account for the remainder of mutations (42). Several mutations are recurrent, as evidenced by the fact that these mutations were found on different haplotypes in ancestrally independent families. The most frequent of these recurrent mutations (D85N, V88M, R113W, R137H, S167L, R181C, and R202C) occur at potential mutational hotspots.

The impact of more than 80 mutations on the function of the V_2R has been studied in *in vitro* expression systems, such as COS-7 cells (monkey kidney cells), allowing further classification of the genotypes based on the cell-biologic outcome, similar to what has been done for other proteins (50–52). The first class of mutations (class I) yields defects in the synthesis of stable mRNA, which precludes the formation of sufficient amounts of protein. Mutations resulting in aberrant splicing, frame shifts, and premature termination of translation belong to this first category. Most of the truncated receptor proteins found in NDI patients result in a complete lack of receptors present on the cell surface and, consequently, preclude specific function of the receptor. The majority of mutations found in X-linked NDI belong to the second class (class II), in which the translation of the protein is completed, but the abnormal protein is misfolded or improperly assembled and trapped in the ER.

Subsequently, such mutant proteins are often targeted to proteosomes for degradation. Therefore, class II mutations also lead to severely reduced or absent receptor expression on the cell surface. Most missense mutations and in-frame

deletions and some nonsense mutations in the V₂R fall in class II, and, except for some mutations in the extra- and intracellular loops (R104C, R113W, R143P, G201D, R337stop, E242stop), most of these mutations are located in transmembrane domains (L44P, I46K, L59P, L62P, L62-64del, L83P, L83Q, A84D, I130F, R137H, R143P, W164S, S167T, S167L, S167A, I209F, V287del, Y280C, L292P, A294P) (43,53–60). Recently, Morello et al. demonstrated a prolonged interaction time between the molecular chaperone calnexin and several class II V₂R mutant proteins and suggested that calnexin could play a role in the intracellular retention of misfolded V₂R proteins (61). This finding is consistent with the dual role proposed for calnexin. On the one hand, this chaperone is believed to assist folding of neosynthesized wild-type proteins, whereas on the other hand it targets the incompletely synthesized or misfolded proteins toward the degradation pathway (62).

A few of the missense and frame-shift mutations, however, have been shown not to significantly alter protein abundance at the cell surface, but either impair the coupling efficiency of the receptor to the stimulating G protein (class III mutations) or reduce AVP-binding affinity (class IV mutations). As yet, only a few mutations have been identified that belong to class III. These mutations are found in the lower half of the transmembrane regions (D85N, P322S/P) and within the second intracellular loop (R137H) (58,63). The study by Rosenthal et al. (63) demonstrating disturbed G protein activation of the *in vitro*-expressed R137H mutation, stresses the importance of the highly conserved DRY/H motif in the second intracellular loop for G protein activation, which is also known for other G protein-coupled receptors (64). In conflict with the study by Rosenthal, others have reported that the R137H mutant is almost completely retained in the cell interior (55).

Class IV mutations are mainly found in the first, second, sixth, and seventh transmembrane domains (L44F, A84D, V88M, Y128S, P286R, F287L, V277A, S315R) and in the first and second extracellular loops (W99R, R106C, F105V, R181C, G185C, ΔR202, R202C, T204N, Y205C, V206D, R113W) (43,53,56,59,61,65). It is well known that the conserved disulfide bridge between Cys112 in the first and Cys192 in the second extracellular loop ensures correct folding of these loops and, as a consequence, the establishment of the ligand-binding domain. It is assumed that the introduction of additional cysteine residues as a result of mutations found in NDI (R106C, R181C, G185C, R202C, Y205C) might impair receptor function by altering disulfide bonding of the conserved cysteine residues (58) or, more likely, by introducing an additional disulfide bond (66). Based on the finding of class IV mutations in transmembrane domains (I, II, VI), it can be concluded that several amino acids in these domains are involved in forming the conformation of the receptor for agonist binding.

Genotype-Phenotype Correlations in X-Linked Nephrogenic Diabetes Insipidus?

Almost all mutations in the V₂R gene result in a uniform clinical NDI phenotype with polyuric manifestations in the first weeks of life and poor growth. There are, however, a few exceptions to this rule. Three mutations (D85N, G201D, and P322S) are associated with a milder form of NDI, characterized by a later clinical presentation, around the age of 10, and without growth retardation. Functional studies of these mutations by *in vitro* expression systems have confirmed the partial phenotype of the NDI. P322S is the most remarkable of these three mutations, since another mutation substituting proline 322, namely P322H, is associated with a severe phenotype. By *in vitro* expression of both P322H and P322S in COS-7 cells, Ala et al. (58) have shown that the P322H mutant had totally lost the ability to stimulate the Gs/adenylate cyclase system, whereas the P322S mutant was able to stimulate adenylate-cyclase, albeit less than the wild-type receptor. Thus, the *in vitro* experiments closely correspond to the clinical phenotype. On the basis of three-dimensional modeling of the P322H and P322S mutant receptors, a plausible hypothesis to explain the molecular basis for the mild phenotype of the P322S has been proposed. Based on this modeling it is suggested that complete loss of function of the P322H receptor could be due, in part, to hydrogen bond formation between the His322 side chain and the carboxyl group of Asp85, which does not occur in the P322S receptor (58).

Recently, a family was reported in which the R137H mutation was associated with severe NDI in the proband but with very mild NDI in his affected brother (67). Genetic or environmental modifying factors are likely to account for this intrafamilial phenotype variability.

AUTOSOMAL RECESSIVE AND AUTOSOMAL DOMINANT FORMS OF NEPHROGENIC DIABETES INSIPIDUS: MUTATIONS IN THE AQUAPORIN-2 WATER CHANNEL

Both the autosomal recessive and the autosomal dominant types of NDI are caused by mutations in the AQP2 water channel gene (Genbank accession number z29491). The human AQP2 gene is a small gene consisting of 4 exons, comprising 5 kb genomic DNA. The 1.5-kb mRNA encodes a protein of 271 amino acids, which has a predicted molecular weight of 29 kDa (68). AQP2 belongs to a family of membrane integral proteins, AQPs, which function as selective water transporters throughout the plant and animal kingdom. In mammals, ten different AQPs have been identified to date, seven of which (AQPs 1 to 4 and 6 to 8) are highly expressed in the kidney. Like other AQPs, AQP2 is assembled in the membrane as a homotetramer in which each 29-kDa monomer, consisting of six membrane-spanning α-helical domains and intracellular

FIGURE 40.3. Schematic representation of the postulated mechanisms in a collecting duct cell to explain recessive and dominant forms of nephrogenic diabetes insipidus (NDI) caused by aquaporin-2 (AQP2) water channel mutations. Normal AQP2 proteins are transported from the endoplasmic reticulum via the Golgi apparatus to the luminal side of the cell. In case of a recessive NDI mutation, AQP2 is retained in the endoplasmic reticulum due to misfolding and is subsequently broken down by proteasomes. In case of a dominant NDI mutation, there is a change in the transport signal of the AQP2 protein and consequent misrouting to the Golgi network or late endosomes/lysosomes. (Adapted from Knoers NVAM, Deen PMT. Van Gen naar Ziekte; van vasopressine-V2-receptor en aquaporine-2 naar nefrogene diabetes insipidus. *Dutch J Med* 2000;144:2402-2404.) (See Color Plate 40.3.)

N- and C-termini, is a functional water channel. The six transmembrane domains are connected by five loops (A through E). In the hourglass hypothesis, loops B and E are assumed to fold back into the membrane and to interact via their highly conserved motifs asparagine-proline-alanine (NPA boxes) to form the water pore (69). Cryo-EM analysis of AQP1 crystals at atomic resolution revealed that this was indeed the case (70). AQP2 is exclusively localized in the apical membrane and a subapical compartment of collecting duct cells. It is upregulated by dehydration or AVP, indicating that it is the AVP-regulated water channel.

To date, 29 putative disease-causing mutations in AQP2 have been identified in families with autosomal recessive NDI (42,43,71,72). These include 23 missense mutations, two nonsense mutations, two small deletions, and two splice-site mutations. Approximately one-half of these mutations are found in the B and E loops of the protein, where it is likely that they will destroy the pore function of the protein. Expression studies in *Xenopus laevis* oocytes have revealed that all 23 AQP2 missense mutations that cause recessive NDI are class II mutations. Thus, these mutations lead to misfolding of the mutant protein and retention in the ER (71,73,74) (Fig. 40.3). At high expression levels in oocytes and Chinese hamster (CHO) cells, six of these AQP2 mutants (A147T, T126M, G64R, L22V, A47V, and T125M) confer water per-

meability (71,73,75,76). This indicates that at high expression levels, these AQP2 mutant proteins escape from the ER and are routed to the plasma membrane, where they are functional.

Several families have been described with autosomal dominant NDI, based on the transmission of the disease from father to son. In one of these families, a point mutation (G866A) in one allele of the AQP2 gene, resulting in the substitution of a lysine for a glutamic acid at position 258 (E258K) in the C-terminal tail of AQP2, was identified. Expression studies in *X. laevis* oocytes have shown that this E258K-AQP2 mutant is a properly folded functional water channel but is retained in the Golgi region (38) (Fig. 40.3). In coexpression studies with wild-type AQP2, a dominant-negative effect was observed, caused by impaired routing of wild-type AQP2 to the plasma membrane after hetero-oligomerization with the E258K mutant (77). Subsequently, a similar impairment of wild-type AQP2 in its routing to the plasma membrane of oocytes was reported for three other dominant AQP2 mutants (721delG, 763-772del, 812-818del) (78). Very recently, a novel AQP2 mutant (727delG) identified in a family with dominant NDI was shown to interfere with the routing of wild-type AQP2 to the apical membrane by its mistargeting to the late endosomes or lysosomes (79).

Remarkably, all mutations causing dominant NDI are located in the C-terminal tail of AQP2. The cell-biologic basis of dominant NDI, as revealed by *in vitro* expression of the mutations, underscores the importance of the C terminus of AQP2 in trafficking to the cell surface.

Kanno et al. (80) showed that AQP2 is detectable in the urine of normal individuals and, after treatment with DDAVP, in the urine of patients with central diabetes insipidus but not in that of patients with NDI. These initial findings, together with additional examinations of AQP2 excretion (81), raised the possibility of assessing AQP2 levels in the kidney by the measurement of urinary AQP2 levels. However, because the amount of AQP2 in the urine appears to be determined largely by trafficking of AQP2 to the apical membrane of collecting duct cells in response to vasopressin, rather than their content of AQP2 (82), AQP2 excretion in the urine must be interpreted with caution with respect to predicting AQP2 expression levels.

Differential Diagnosis between the X-Linked and the Autosomal Forms of Nephrogenic Diabetes Insipidus

Patients with X-linked NDI can be discriminated from patients with autosomal NDI on the basis of their extrarenal reaction to administration of the synthetic V_2 -vasopressin analogue 1-DDAVP. Patients with autosomal NDI show normal increases in von Willebrand factor, factor VIII, and tissue-type plasminogen activator levels, whereas in patients with X-linked NDI, these extrarenal responses are absent as a result of an extrarenal mutant V_2R (83).

NEPHROGENIC DIABETES INSIPIDUS IN FEMALES

Several families have been described in which females show classic clinical and laboratory features of NDI. After the identification of AQP2 mutations as a cause for autosomal recessive NDI, and in some cases for autosomal dominant NDI, a satisfying explanation for the complete manifestation of the disease in some females had been found. However, several families have been reported in which symptomatic females do not have an AQP2 defect but are heterozygous for a V_2R defect (84–87). In some of these women, maximal urinary osmolality after DDAVP administration does not exceed 200 mOsmol/L. Of interest, in some of the reported families, asymptomatic female family members shared the same V_2R mutation with the manifesting females (84,88). The most likely explanation for the existence of different phenotypes in carriers of a V_2R mutation, varying from no symptoms to complete manifestation of the disorder, is skewed X-inactivation. This hypothesis was underlined by the study of Nomura et al., investigating the X-inactivation patterns of female carriers belonging to one family via the detection of a methylated trinucleotide repeat in the human androgen receptor gene (88). The V_2R mutation carriers in this family displayed different degrees of manifestation of NDI. One woman, who had no symptoms at all, showed random X-inactivation, whereas her grandmother with complete NDI showed extremely skewed methylation of one X chromosome. One should keep in mind that this skewed X-inactivation pattern in blood cells does not necessarily reflect the situation in renal collecting duct cells.

ACQUIRED NEPHROGENIC DIABETES INSIPIDUS

Although the hereditary forms of NDI are relatively rare, a wide range of pathologic conditions and drug treatments can lead to acquired NDI (Table 40.1). In a variety of these acquired forms of NDI, AQP2 expression is downregulated. For example, it has been shown that prolonged treatment of rats with therapeutic doses of lithium causes a 95% reduction in AQP2 expression in the inner medullary collecting duct principal cells, concomitant with the development of severe polyuria (89,90). Cessation of lithium infusion or DDAVP treatment for 1 week only partially reversed this downregulation, consistent with the clinical observation of slow recovery from induced NDI in patients treated with lithium. It is assumed that the inhibition of vasopressin-induced adenylate cyclase activity by lithium is the cause of the reduced expression of AQP2.

It has recently been demonstrated that there is also marked downregulation of AQP3, but not of AQP4, expression in kidneys of rats treated with lithium (90). It is assumed that

reduced AQP3 expression also plays a crucial role in the development of lithium-induced polyuria. The mechanism of AQP3 downregulation remains to be elucidated.

Other polyuric states that have been associated with downregulation of AQP2 expression in rat renal medulla include chronic hypokalemia, hypercalcemia, bilateral ureteral obstruction, low-protein diet, chronic renal failure, and puromycin aminonucleoside- or doxorubicin-induced nephrotic syndrome (91–95).

In some families with autosomal primary nocturnal enuresis, linkage analysis has revealed cosegregation of this disorder with polymorphic microsatellite markers from 12q, in the region where the AQP2 gene maps (96). Deen et al. sequenced the AQP2 coding region in affected primary nocturnal enuresis individuals from these dominant families but did not identify any significant mutations. Thus, the AQP2 gene could be excluded as a candidate for autosomal primary nocturnal enuresis. (97).

TREATMENT

The treatment of NDI has been challenging since the original description of the disorder. Replacement of urinary water losses by adequate supply of fluid is the most important component of therapy. However, most infants with NDI cannot drink the required amounts of fluid. One approach to reduce urine output is provision of a low-solute diet to reduce the renal osmolar load and decrease obligatory water excretion. Initially, a diet low in sodium (1 mmol/kg/day) as well as protein (2 g/kg/day) was recommended. However, severe limitations of dietary protein may introduce serious nutritional deficiencies. Therefore, it is preferable to prescribe dietary restriction of sodium only.

Diuretics, such as hydrochlorothiazide (2 to 4 mg/kg per 24 hours), were the first class of drugs shown to be effective in lowering the urine volume in NDI (98). When combined with a reduction of salt intake, hydrochlorothiazide reduces urine volume by 20 to 50% of baseline values. However, thiazide-induced hypokalemia may cause further impairment of urine-concentrating ability in patients with NDI. Another possible risk associated with hypokalemia is cardiac arrhythmia. Simultaneous administration of potassium salt is therefore advised in most cases.

There is ample evidence that the combined administration of hydrochlorothiazide with either a prostaglandin-synthesis inhibitor such as indomethacin (2 mg/kg/24 hr), or the potassium-sparing diuretic amiloride, is much more effective in reducing urine volume than the thiazide diuretic alone (99–103). Prolonged use of prostaglandin-synthesis inhibitors, however, is often complicated by gastrointestinal and hematopoietic side effects. Gastrointestinal complaints and complications include anorexia, nausea, vomiting, abdominal pain, ulceration, perforation, and hemorrhage. Hematopoietic reactions include neutropenia, thrombocyto-

penia, and, rarely, aplastic anemia. In addition, renal dysfunction has been described during indomethacin therapy, most often consisting of a slight reduction in glomerular filtration rate.

Amiloride counterbalances the potassium loss from prolonged use of thiazides and thus prevents hypokalemia. Because amiloride appears to have only minor long-term side effects, the combination of hydrochlorothiazide (2.0 to 4.0 mg/kg/24 hr) with amiloride (0.3 mg/kg/24 hr) is the treatment of choice for most patients. Our personal experience of more than 12 years with the amiloride-hydrochlorothiazide combination, however, indicates that amiloride is less well tolerated in young children below the age of 4 to 6 years because of persistent nausea. Therefore we recommend the use of the combination of indomethacin-hydrochlorothiazide in these young children.

For a long time, the following mechanism for the paradoxical effect of thiazides in NDI has been proposed; thiazides reduce sodium reabsorption in the distal tubule by inhibition of the NaCl cotransporter. This subsequently results in increased sodium excretion, extracellular volume contraction, decreased glomerular filtration rate, and increased proximal sodium and water reabsorption. Consequently, less water and sodium reach the collecting tubules, and less water is excreted (104,105). Recently, this long-standing hypothesis has been challenged by Magaldi, who reported new insights into the possible mechanism of thiazide action, based on microperfusion studies in rat inner medullary collecting duct (106,107). In these studies it was shown that in the absence of vasopressin, luminal hydrochlorothiazide increased osmotic and diffusional water permeabilities. Increased permeability facilitates water reabsorption in the collecting duct, and, thus, decreases water excretion. When prostaglandins were added, the effect of thiazides decreased. This finding may explain why indomethacin potentiates the effect of thiazides in NDI. The results of these microperfusion studies indicate that thiazides may act in nephron segments beyond the distal tubule. Because the effect of thiazides was only seen when they were applied to the luminal side of the inner medullary collecting duct, they do not apparently interact with the basolaterally located V_2R directly. Magaldi proposed that these drugs act at some point in the vasopressin cascade inside the cell, because an inhibitor of PKA blocked thiazide effects (107).

Because the majority of V_2R mutations found in X-linked NDI and all AQP2 mutations found in autosomal recessive NDI result in protein retention within the ER (class II mutations), a treatment aimed at restoring the plasma membrane routing of ER-retained, but otherwise functional, V_2R or AQP2 mutants becomes an interesting potential. Indeed, Morello et al. have recently shown *in vitro* that selective, nonpeptide cell-permeant V_2R antagonists increased cell-surface expression and rescued the function of V_2R mutants by promoting their maturation and targeting to the plasma membrane (108). Thus, these V_2R antagonists function as pharmacologic chaperones. The fact that eight distinct

mutants could be rescued by the same treatment is promising, given the diversity of mutations identified in NDI.

Similarly, it has been shown that treatment of cells expressing ER-retarded AQP2 mutants with chemical chaperones, such as glycerol, facilitated the translocation of these mutants to the plasma membrane (76). The feasibility of treatment with pharmacologic and chemical chaperones awaits *in vivo* testing. It is important to appreciate that the exact ER-retention mechanisms of NDI causing V_2R and AQP2 mutants remain to be elucidated. *In vitro* studies have suggested that, in the future, gene therapy for NDI may become technically feasible (109). There are, however, questions as to whether gene therapy would be the treatment of choice for this disorder. Development of gene-transfer vectors and gene-delivery techniques as well as analysis of gene-therapy safety need to be pursued. Such studies determine the feasibility of gene therapy in renal diseases such as NDI. In this respect, recently developed transgenic mice carrying a functionally inactive V_2R receptor protein (110) and AQP2 knock-in mice (111) will be important reagents for preclinical testing.

CYSTINOSIS AND FANCONI SYNDROME

JOHN W. FOREMAN

In the 1930s, de Toni (1), Debré et al. (2), and Fanconi (3) independently described several children with the combination of renal rickets, glucosuria, and hypophosphatemia. The name of this clinical entity has been shortened to *Fanconi syndrome*. Fanconi syndrome is a dysfunction of the proximal tubule leading to excessive urinary excretion of amino acids, glucose, phosphate, bicarbonate, and other solutes handled by this nephron segment. These losses lead to the clinical problems observed in this syndrome (e.g., acidosis, dehydration, electrolyte imbalance, rickets, and growth failure). Numerous disorders, ranging from inborn errors of metabolism to exogenous toxins, are associated with Fanconi syndrome.

PATHOPHYSIOLOGY

Currently, the sequence of events underlying Fanconi syndrome is incompletely defined. A number of possible mechanisms exist that could lead to diminished net solute reabsorption in the proximal tubule (Fig. 41.1). At the membrane level, at least six possibilities exist:

1. An intrinsic defect in carrier function could be the cause. Because there are many different carriers, this is unlikely except for a defect in sodium binding common to most or all of the carriers.
2. There may be a generalized defect in the insertion or recycling of these carriers into the brush-border membrane or in a membrane lipid-protein carrier interaction necessary for their complete function.
3. Solute reabsorption may be normal, but the resorbed solute quickly leaks back into the lumen. This mechanism has been implicated in the experimental Fanconi syndrome induced by maleic acid (4).
4. There may be impairment in solute movement out of the cell at the basolateral membrane—this would lead to solute accumulation intracellularly, which would augment solute efflux across the luminal membrane, decreasing net transepithelial transport.

5. Dysfunction of the Na^+, K^+ -adenosine triphosphatase (ATPase) pump would increase the intracellular Na concentration, diminishing the electrochemical gradient for Na influx at the luminal membrane and its coupling to other solute transport.

6. Finally, there could be a significant paracellular backflux of solute from increased permeability of the tight junctions between proximal tubule cells.

In addition to membrane defects, abnormalities in cellular organelle function could impair net solute reabsorption. Examples include the apical endosome in Dent's disease and the lysosome in cystinosis. Numerous filtered proteins are reabsorbed through binding to the endocytic receptors, megalin and cubilin (Fig. 41.2). The protein-receptor complex is then incorporated into an endosome. In the endosome, the ligand and the receptor are disassociated and the receptor is recycled back to the luminal membrane and the reabsorbed protein into lysosomes for further processing. This disassociation process is dependent on acidification of the endosome by an H^+ -ATPase and the ClC-5 chloride channel. The importance of this pathway in Fanconi syndrome is underscored by the finding of low urinary levels of megalin in patients with Fanconi syndrome due to Dent's disease and Lowe syndrome but not all causes of Fanconi syndrome (5). An abnormal endocytic pathway may affect the recycling of transport proteins, other than megalin, back to the luminal membrane, leading to decreased solute reabsorption. Furthermore, disturbances in energy generation could impair net transepithelial transport. Energy is necessary for operation of the Na^+/K^+ -ATPase pump and intracellular Na^+ regulation and may be involved with solute reabsorption in other undefined ways as well. A defect in energy generation has been raised as the underlying cause of Fanconi syndrome observed in a diverse group of disorders, including hereditary fructose intolerance (HFI), galactosemia, cytochrome-*c*-oxidase deficiency, and heavy metal poisoning. In experimental models of Fanconi syndrome (including those induced by maleic acid, succinylac-

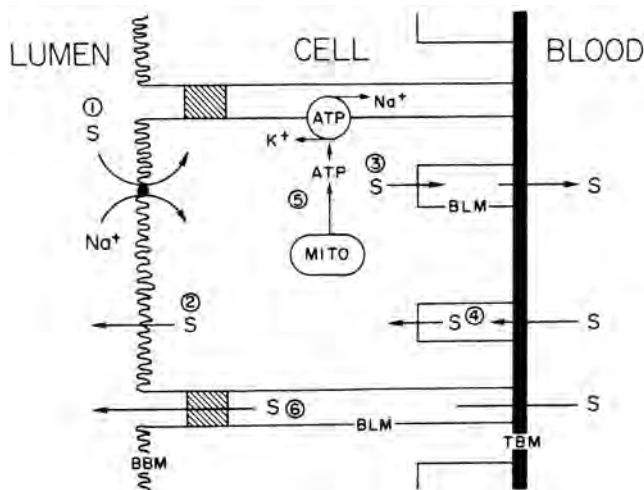

FIGURE 41.1. Model of solute (S) transport by the human renal proximal tubule cell. S uptake by the brush-border membrane (BBM) from the lumen is coupled to Na^+ influx. A favorable electrochemical driving force for luminal Na^+ is maintained by the Na^+ - K^+ -adenosine triphosphatase pump. Transported S is then either used by the cell or returned to the blood across the basolateral membrane (BLM). Fanconi syndrome could arise because of a defect of influx (1), leakage back into the lumen after influx (2), decreased flux out of the cell across the BLM (3), a defect in energy generation or transduction to the plasma membrane (4), an increase in backflux across the tight junctions between the cells (5), and, finally, defective transporter recycling (6). ATP, adenosine triphosphate; TBM, tubular basement membrane; MITO, mitochondrion.

etone, and cystine dimethylester), decreased adenosine triphosphate (ATP) production has been related to impaired solute reabsorption.

Experimental Models of Fanconi Syndrome

Maleic acid, the *cis* isomer of fumaric acid, has been used extensively to produce an experimental model of Fanconi syndrome (4,6–9). Injection of maleic acid in dogs and, especially, rats leads to a reversible Fanconi syndrome with aminoaciduria, glucosuria, phosphaturia, proteinuria, and bicarbonaturia. Maleic acid has been shown to inhibit Na^+ - K^+ -ATPase (6,7) and decrease cellular ATP levels (6–8). The low ATP levels were associated with low kidney tissue coenzyme A levels (8), leading to the speculation that maleic acid irreversibly bound to coenzyme A and impaired tricarboxylic acid cycle function. Maleic acid also has been shown to impair the incorporation of phosphate into the cell membrane (7). Maleic acid also disrupts the apical endocytic pathway of the renal tubule mediated by megalin, a receptor for a number of filtered proteins (9) (Fig. 41.2). Whether any or all of these effects underlies Fanconi syndrome induced by maleic acid is unclear.

Cadmium (10), lead (11,12), mercury (13), and uranium (14) have been used to induce experimental Fanconi syn-

drome. Animals given cadmium or lead have abnormal ATP levels and decreased Na^+ - K^+ -ATPase levels. Pathologically, experimental heavy metal toxicity is associated with significant abnormalities in renal tubule mitochondria. Outdated tetracycline, with the formation of anhydro-4-epitetracycline, causes reversible experimental Fanconi syndrome (15) associated with decreased mitochondrial respiration (16).

An experimental model of cystinosis and Fanconi syndrome has been created by injecting rats and incubating renal tubule cells with cystine dimethylester. Treated tubules had significantly increased cystine levels, decreased tubular transport, decreased metabolic fuel and O_2 consumption, decreased ATP levels, increased intracellular K^+ concentrations, and decreased mitochondrial respiration (17–19). ATP added to the incubation media partially restored the tubular transport function of the cystine-loaded cells, suggesting that cystine storage in cystinosis impairs mitochondrial function and ATP generation, leading to Fanconi syndrome. Succinylacetone has been proposed as the presumed toxin in tyrosinemia because of its structural similarity to maleic acid. Normal rats injected with this compound develop proteinuria, glucosuria, and aminoaciduria (20). Renal tubules incubated with succinylacetone have reduced amino acid, sugar, and phosphate transport; ATP levels; and O_2 consumption. Succinylacetone inhibits renal brush-border membrane transport and alters membrane fluidity (21). Thus, succinylacetone may be the cause of Fanconi syndrome in tyrosinemia.

Spontaneous Fanconi syndrome has been observed in several dog breeds, especially the Basenji (22,23). These dogs developed polyuria, polydipsia, glucosuria, aminoaciduria, and acidosis. The glomerular filtration rate (GFR) was normal in most of the dogs, although some went on to develop renal failure. Renal biopsies from affected dogs were normal except for large nuclei in a few tubular cells. Solute uptake by renal cortical slices from the affected dogs was also decreased. This model resembles the idiopathic human Fanconi syndrome.

SIGNS AND SYMPTOMS

Hyperaminoaciduria

Aminoaciduria is one of the major characteristics of Fanconi syndrome (Table 41.1). Virtually every amino acid is found in excess in the urine, giving rise to the designation of *generalized aminoaciduria*. Reabsorption rates vary for each amino acid, with some approaching the GFR. The easiest method for determining the renal handling of amino acids is to assess the percentage of tubular reabsorption (T_{aa}):

$$T_{aa} = 1 - \left[\frac{U_{aa} \times P_{aa}}{U_{cr} \times P_{cr}} \right] \times (100\%)$$

where U_{aa} and P_{aa} are the urine and plasma amino acid concentrations and U_{cr} and P_{cr} are the urine and plasma creati-

FIGURE 41.2. Megalin-endocytic pathway. Low-molecular-weight proteins in the luminal fluid bind to megalin and are endocytosed. The recycling of megalin and further catabolism of these proteins are dependent on acidification of the vesicle by a proton pump. The ClC-5 chloride channel provides an electrical shunt for efficient functioning of the proton pump. This endocytosis pathway may also play a role in membrane transporter recycling, and disruption of this pathway could interfere with absorption of other luminal solutes.

nine concentrations. Normally, T_{aa} for most amino acids is more than 98%, except for glycine (95%) and histidine (92%). The urinary amino acid losses in Fanconi syndrome do not cause any clinical consequences because the losses are trivial in relation to dietary intake. However, plasma amino acid levels tend to be lower than normal.

Glucosuria

Glucosuria is one of the originally recognized features of Fanconi syndrome. Glucosuria is the result of impaired tubular reabsorption of glucose and is present despite normal plasma glucose concentrations. It is often an early feature of Fanconi syndrome and indicates that the renal threshold (i.e., the plasma level of a solute when it first appears in the urine) is reduced.

Hypophosphatemia

Hypophosphatemia secondary to impairment in phosphate reabsorption is another important feature of Fanconi syndrome. Impaired phosphate reabsorption is usually not

reflected by the excessive excretion of phosphate, except when Fanconi syndrome first develops. At a steady state, urinary phosphate excretion simply reflects dietary intake similar to that observed in X-linked hypophosphatemic rickets, vitamin D deficiency, and normals. Excessive phosphate excretion is observed only when plasma phosphate is above its steady-state level. Phosphate handling can be assessed by measuring the percentage of tubular reabsorption of phosphate, as described for amino acids. The tubular reabsorption of phosphate ranges from 80 to 95% in normal children (24), with much lower values in patients with Fanconi's syndrome. A preferred way of estimating the

TABLE 41.1. FEATURES OF FANCONI SYNDROME

Acidosis	Hypokalemia
Dehydration	Hypophosphatemia
Glucosuria	Hypouricemia

Hypocarnitinemia	Rickets

renal handling of phosphate is to derive the tubular maximal rate of phosphate reabsorption (Tm_p) related to GFR:

$$Tm_p/GFR = S_p - (U_p \times S_{cr}/U_{cr})$$

where S_p is serum phosphate, U_p is urine phosphate, S_{cr} is serum creatinine, and U_{cr} is urine creatinine, determined on simultaneous blood and urine specimens (25).

Phosphate handling by the kidney is affected by a number of factors, including parathyroid hormone (PTH) and vitamin D levels. PTH levels have been found to be both normal and elevated in patients with Fanconi syndrome (26,27). Low levels of 1,25-dihydroxy vitamin D have been found in some patients with Fanconi syndrome (28,29). Furthermore, patients with the Fanconi syndrome appear to have impaired conversion of 25 vitamin D to 1,25-dihydroxy vitamin D (30). Metabolic acidosis, another feature of Fanconi syndrome, also impairs the conversion of 25 vitamin D to 1,25-dihydroxy vitamin D. This may, in part, explain why alkali therapy may heal rickets in some patients with Fanconi syndrome. Bone disease is common in patients with long-standing untreated Fanconi syndrome (31).

Acidosis

Hyperchloremic acidosis, another feature of Fanconi syndrome, results from impaired bicarbonate reabsorption by the proximal tubule [proximal renal tubular acidosis (RTA)]. In Fanconi syndrome, more than 30% of the normal filtered bicarbonate load may be excreted when plasma levels are normal, leading to low plasma bicarbonate levels (usually between 12 and 18 mEq/L), and a reduction in extracellular fluid volume. Occasionally, there is an associated defect in distal acidification, usually in association with long-standing hypokalemia or nephrocalcinosis. Ammoniogenesis usually is normal or increased because of the hypokalemia and acidosis, unless there is associated impairment of GFR.

Sodium and Potassium Losses

Na^+ and K^+ losses may give rise to major clinical problems in patients with Fanconi syndrome. Far less than the normal 60 to 80% of the filtered Na^+ load is reabsorbed in the proximal tubule in Fanconi syndrome. Part of this loss is related to impaired bicarbonate reabsorption, with the subsequent urinary excretion of $NaHCO_3$ and $KHCO_3$. In some cases, Na^+ and K^+ losses are so great that metabolic alkalosis and hyperaldosteronism result, simulating Bartter's syndrome despite the lowered bicarbonate threshold (32). The clearance of K^+ may be twice that of the GFR, and resultant hypokalemia has caused sudden death (33).

Dehydration

Polyuria, polydipsia, and frequent bouts of severe dehydration are common symptoms in patients with Fanconi syn-

drome. Despite dehydration, the urine is typically dilute. Recurrent febrile episodes, as a consequence of the dehydration, are often the first sign of Fanconi syndrome in infants with cystinosis. Polyuria is secondary to the osmotic diuresis from the excessive urinary solute losses. In some patients, there also appears to be an associated defect in renal concentrating ability, especially with prolonged hypokalemia.

Growth Retardation

Growth retardation is another common feature of Fanconi syndrome in children (34). The cause is multifactorial. Hypophosphatemia, disordered vitamin D metabolism, and acidosis can impair growth. Chronic hypokalemia and extracellular volume contraction may be additional factors, but glucosuria and aminoaciduria probably are not. However, even with correction of all of these metabolic abnormalities, most patients fail to grow, especially those with cystinosis.

Uricosuria

Impairment in renal handling of urate is often present in Fanconi syndrome, leading to hypouricemia, especially in adults. Urolithiasis from the uricosuria has rarely been reported (35). This is probably because the urine flow and pH are increased, inhibiting uric acid crystallization.

Proteinuria

Proteinuria, another feature of Fanconi syndrome, is usually minimal, except when the Fanconi syndrome develops in association with the nephrotic syndrome. The proteins lost in Fanconi syndrome (e.g., enzymes, immunoglobulin light chains, and hormones) are of low molecular weight (1900 to 30,000 d) (36).

ETIOLOGIES

Patients with Fanconi syndrome can be classified into two main categories: inherited and acquired (Table 41.2). In adults, the most common cause of a persistent Fanconi syndrome is an exogenous toxin, such as a heavy metal, whereas in children, the most common cause is an inborn error of metabolism, such as cystinosis.

Inherited Fanconi Syndrome

Cystinosis

Cystinosis, or cystine storage disease, is an enigmatic disorder characterized biochemically by excessive storage of cystine in the lysosomes of numerous organs, including the kidney (37). Three different types of cystinosis have been distinguished on the basis of the clinical course and the

TABLE 41.2. CAUSES OF FANCONI SYNDROME

intracellular cystine content (38). Benign or ocular cystinosis is associated with cystine crystals only in the cornea and bone marrow and the smallest increase in intracellular cystine levels (39). There is no renal disease. Infantile or nephropathic cystinosis is most common and is associated with the highest intracellular levels of cystine (5 to 10 nmol/mg protein) in leukocytes or cultured fibroblasts. Autopsy kidney specimens contained 150 to 2000 nmol/mg protein of 0.5 cystine (40). Children with nephropathic cystinosis develop renal failure by late childhood. Patients with adolescent cystinosis tend to have intracellular cystine levels between those of the infantile and the ocular forms. Renal involvement occurs but does not appear until later and progresses more slowly (41).

Cystinosis arises from a defect in the egress of cystine from lysosomes (42). Heterozygotes for cystinosis have rates of lysosomal cystine egress that are one-half as fast as those from normal individuals, while homozygotes for nephropathic cystinosis have very low rates (42). This is due to a mutation in the CTNS gene, encoding the protein cystinosisin, which is located on the short arm of chromosome 17 (43). Cystinosisin is an integral lysosomal membrane protein composed of 367 amino acids with seven transmembrane domains and a C-terminal GYDQL sorting motif that directs it to the lysosomal membrane (43). It mediates the egress of cystine from the lysosome (44). Cystine transport is stimulated by an outwardly directed pH gradient (44). ATP also stimulates cystine egress through lysosomal acidification (45). The origin of lysosomal cystine in cystinosis is mainly from lysosomal protein degradation (46), but it is also from plasma cystine (47). There is no defect in cystine reduction or degradation in cystinosis (48).

Nephropathic cystinosis, with an estimated incidence of 1 in 200,000 births, is caused by a severe mutation on both chromosomes that leads to no functional protein (43). The

most common mutation is a 57-kb deletion, but numerous other mutations have also been described. Ocular cystinosis is associated with one severe and one mild mutation leading to the production of some functional protein (49). Presumably there is enough lysosomal cystine transport to prevent the kidney and other organ dysfunction, but not enough to prevent corneal crystal formation. Patients with later onset or slower disease progression have been shown to have mutations that result in some functional protein, which results in less lysosomal cystine transport than occurs in ocular cystinosis (50).

The mechanism(s) by which increased intracellular cystine levels lead to renal injury and dysfunction remains unexplained in cystinosis. Lysosomal cystine concentration rises to levels sufficient to form crystals, which presumably cause cell injury and death. Foreman et al. (17) have shown that loading normal rat renal tubules with cystine impairs solute transport. Furthermore, cystine-loaded tubules have reduced metabolic fuel and O₂ consumption, ATP levels, and mitochondrial oxidation (18,19,51). These studies suggest that the intracellular storage of cystine may impair energy generation, which leads to defects in solute reabsorption.

In nephropathic cystinosis, high intracellular cystine concentrations can be found in virtually every cell and organ, including bone marrow, leukocytes, cornea, conjunctiva, retina, lymph nodes, liver, spleen, intestine, thyroid, muscle, and kidney. The brain was previously believed not to be affected in cystinosis, but a few patients surviving into their 20s have developed neurologic disorders in association with increased cystine levels in brain tissue (52,53). The definitive method of making the diagnosis of cystinosis is the demonstration of elevated intracellular levels of cystine, usually in polymorphonuclear leukocytes or fibroblasts. A prenatal diagnosis can be made by measuring the cystine content of amniotic cells (54). Finding needle-shaped, tinsel-like refractile opacities in the cornea by slit-lamp examination is also usually diagnostic (Fig. 41.3). Such ocular findings are invariably present after 2 years of age.

FIGURE 41.3. Tinsel-like refractile opacities in the cornea of a patient with cystinosis under slit lamp examination.

The first clinical signs and symptoms of cystinosis are polyuria, polydipsia, anorexia, failure to thrive, dehydration, and hyperchloremic metabolic acidosis, which usually appear in the latter half of the first year of life (55). Subtle abnormalities of tubular function can be demonstrated earlier in families with index cases, including glucosuria, generalized aminoaciduria, and mild proteinuria. Tubular reabsorption of phosphate is decreased with the development of hypophosphatemia and rickets. The renal threshold for bicarbonate is usually between 12 and 15 mEq/L. Hypokalemia and hypouricemia are common. Rarely, hyponatremia and metabolic alkalosis have been observed (32). Medullary calcinosis detected by renal ultrasound is relatively common (56), and a few patients have developed renal calculi (35). Children with cystinosis usually have fair complexion and blond hair, but this is not uniform. Cystinosis occurs in blacks but is less common than in whites.

Before the use of cysteamine, the GFR always declined in patients with nephropathic cystinosis, and end-stage renal disease developed between 7 and 10 years of age. Chronic dialysis and transplantation are well tolerated by children with cystinosis. Successful renal transplantation reverses the renal failure but does not improve the other symptoms of cystinosis (57). Cystine accumulates in the monocytes and interstitial cells of transplanted kidneys, but symptoms of proximal tubule dysfunction typical of cystinosis have not been noted. Photophobia is common and usually appears between 3 and 6 years of age. The severity of this symptom increases with age. In addition to corneal and conjunctival crystal deposits, a peripheral retinopathy can occur. The appearance of this is variable, with either hyperpigmented areas or the juxtaposition of hypopigmented and hyperpigmented areas in a salt-and-pepper pattern. Retinopathy affects the temporal more than the nasal side but occurs symmetrically in both eyes. Retinopathy tends to appear later in the course of the disease and to be progressive, although it has been observed in the first year of life. A few patients have developed visual impairment and blindness (55,57).

Growth failure is another major feature of cystinosis and, usually, is evident during the first year of life and before a significant decline in GFR. It occurs despite careful attention to electrolyte and mineral deficiencies. The appearance of renal failure and hypothyroidism further aggravates growth failure. Some patients have had improved growth after renal transplantation; however, the final height of patients with cystinosis is reduced. Recombinant growth hormone has improved linear growth (58), as has reducing intracellular cystine levels with cysteamine (59).

The morphologic features of the kidney in cystinosis vary with the stage of the disease (60). Early in the disease, cystine crystals are present in tubular epithelial cells, interstitial cells, and, rarely, glomerular epithelial cells. A swan-neck deformity or thinning of the first part of the proximal tubule can be observed, but this is not unique to cystinosis. Later in the course of the disease, pronounced tubular atro-

phy, interstitial fibrosis, and abundant crystal deposition occur. In the glomerulus, there is giant-cell formation of the visceral epithelium, segmental sclerosis, and eventual obsolescence. Hyperplasia and hypertrophy of the juxtaglomerular apparatus have been noted and probably are related to abnormalities of the renin-angiotensin system. Electron microscopy studies have demonstrated crystalline inclusions surrounded by a single limiting membrane, which electron diffraction has shown to be cystine. Peculiar dark cells, unique to the cystinotic kidney, have also been observed. These cells have a uniform darkening of their cytoplasm, probably reflecting a reaction between osmium tetroxide and cystine. These cells appear principally in the interstitium and visceral glomerular epithelium, but also in the loop of Henle, collecting duct, capillary endothelium, mesangium, and arteriolar smooth muscle layer.

Symptomatic treatment of nephropathic cystinosis involves early management of the tubulopathy and later management of renal failure. Acidosis and hypokalemia can be treated with potassium citrate. Rickets responds to vitamin D and phosphate supplementation. Low plasma and muscle carnitine levels have improved with prolonged supplementation (61). Careful attention to fluid and electrolyte replacement during gastroenteritis is particularly important.

The specific therapy for cystinosis is to lower tissue cystine levels. The best agent for this is cysteamine, which has been shown to lower intracellular cystine levels (Fig. 41.4) and to slow the decline in GFR, particularly in children with normal renal function treated before 2 years of age (59,62) (Fig. 41.5). Cysteamine therapy also improves linear growth (59,62) but does not improve the Fanconi syndrome. The most common problems associated with cysteamine are nausea, vomiting, and a foul odor and taste. These problems preclude its use in some patients. The best formulation is cysteamine bitartrate (Cystagon). Absorption of this formulation is equal to cysteamine

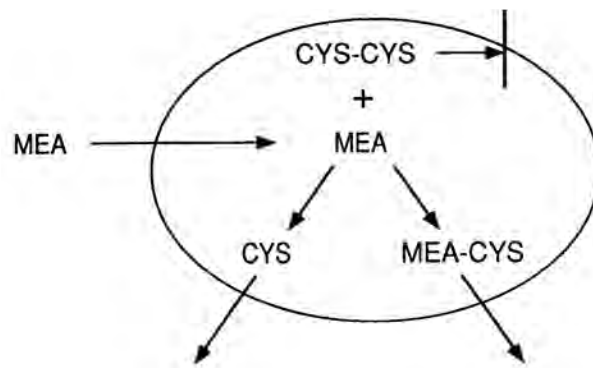

FIGURE 41.4. Effect of cysteamine (MEA) on lysosomal cystine (CYS-CYS). In cystinosis, the transporter for cystine egress from the lysosome is defective. Cysteamine can easily enter the lysosome and combine with cystine, forming cysteine (CYS) and the mixed disulfide cysteamine–cysteine (MEA-CYS). Both of these compounds can exit the lysosome via a transporter different from the cystine carrier.

FIGURE 41.5. Mean creatinine clearance as a function of age in normal subjects, 17 patients with cystinosis who had received adequate therapy with cysteamine (started before 2 years of age and leukocyte cystine level less than or equal to 2 nmol of 0.5 cystine/mg protein), 32 who had received partial treatment, and 67 who had not received treatment. (From Markello TC, Bernardini IM, Gahl WA. Improved renal function in children with cystinosis treated with cysteamine. *N Engl J Med* 1993;328:1157-1162, with permission.)

HCl, and leukocyte cystine levels were lower after 3 weeks of therapy compared with cysteamine HCl, possibly reflecting better patient compliance with this formulation (63). The current recommendation for treatment of cystinosis is to initiate cysteamine soon after the diagnosis is made and to increase dosage over 4 to 6 weeks to 1.3 g/m²/day in four divided doses. Slowly increasing the dosage minimizes the risk of a serum sickness–like reaction. Leukocyte cystine levels should be checked every 3 to 4 months to monitor effectiveness and compliance. The goal of therapy is to maintain cystine levels below 1.0 nmol 0.5 cystine/mg protein (63).

With the use of dialysis and renal transplantation to improve survival, a number of new complications of cystinosis have been recognized (57). Common problems include hypothyroidism, splenomegaly, hepatomegaly, decreased visual acuity, and corneal ulcerations. A few patients have developed insulin-dependent diabetes mellitus after renal transplantation in association with cystine crystal deposition in the pancreas (64). Of greater concern, several patients have developed progressive neurologic disorders (52,53). Cortical atrophy has also been noted (65). A generalized myopathy and swallowing difficulties attributed to muscular dysfunction have been observed in most patients older than 20 years (66). Patients also have a restrictive ventilatory defect attributable to this myopathy (67). Hypogonadism is common in adult male patients with cystinosis (68). These

late-onset complications highlight the need to continue cysteamine therapy throughout life.

Galactosemia

Galactosemia is an autosomal recessive inherited disorder of galactose metabolism. The most common type is the result of deficient activity of the enzyme galactose-1-phosphate uridyl-transferase, known as *transferase deficiency galactosemia*, with an incidence of 1 in 62,000 live births. The gene for galactose-1-phosphate uridyl-transferase is found on the short arm of chromosome 9 (69). This enzyme catalyzes the reaction of galactose-1-phosphate (Gal-1-PO₄) plus uridine diphosphate glucose to uridine diphosphate galactose plus glucose-1-phosphate. Uridine diphosphate galactose can then be further metabolized to either glucose or CO₂ and H₂O via glycolysis. Deficiency of this enzyme leads to the intracellular accumulation of galactose-1-phosphate with damage to the liver, proximal renal tubule, ovary, brain, and lens. A less common cause of galactosemia is a deficiency of galactose kinase, which forms galactose-1-phosphate from galactose. Cataracts are the only manifestation of this form of galactosemia.

Affected infants ingesting milk containing lactose, the most common source of galactose in the diet, rapidly develop vomiting, diarrhea, and failure to thrive. Most also manifest jaundice and unconjugated hyperbilirubinemia and may have severe hemolysis. Continued intake of galactose leads to hepatomegaly and cirrhosis. Cataracts appear within days after birth, although they often are detectable only by a slit-lamp examination. Mental retardation may develop within a few months. Fulminant *Escherichia coli* sepsis has been described in a number of infants (70); it may be a result of inhibition of leukocyte bactericidal activity.

In addition to these clinical findings, galactose intake in patients with galactosemia leads, within days, to hyperaminoaciduria and albuminuria. Melituria, which is a cardinal feature of Fanconi syndrome, is principally a result of galactosuria and not glucosuria. There seems to be little or no impairment in glucose handling by the renal tubule. Galactosemia should be suspected when there is a urinary reducing substance that does not react in a glucose oxidase test. However, finding galactose in the urine does not establish the diagnosis because it can be seen in severe liver disease, in the first week of life in normal newborns (71) and even for longer periods in premature infants (72), and in some children with a high consumption of milk (73). Galactosuria disappears in affected infants after the withdrawal of galactose, which can obscure the diagnosis. Confirmation of a suspected diagnosis should be made by demonstrating deficient transferase activity in red blood cells, fibroblasts, leukocytes, or hepatocytes.

The relationship of biochemical abnormalities to specific symptoms of galactosemia is not clear. Accumulation of Gal-1-PO₄ with the ingestion of galactose can inhibit a number of

pathways for carbohydrate metabolism and correlates with some clinical symptoms. Defective galactosylation of proteins has also been postulated. Formation of galactitol from galactose by aldose reductase has been proposed as a pathogenetic mechanism and is at least responsible for cataract formation. As to the renal tubular abnormalities, aminoaciduria has been induced in normal rats fed a high-galactose diet (74) and in normal human subjects given galactose intravenously (75). Experimentally, galactose inhibits amino acid uptake by slices of kidney cortex (76).

Galactosemia is treated by eliminating galactose from the diet. Acute symptoms and signs resolve within a few days. Cataracts also regress to some extent. However, even with early elimination of galactose, developmental delay, speech impairment, ovarian dysfunction, and growth retardation are common outcomes in galactosemia. Profound intellectual deficits are rare even in suboptimally treated infants (77).

Hereditary Fructose Intolerance

HFI is another disorder of carbohydrate metabolism associated with Fanconi syndrome (78,79). Patients with HFI experience nausea, vomiting, and symptoms of hypoglycemia shortly after ingesting fructose, sucrose, or sorbitol. These symptoms may progress to convulsions, coma, and even death, depending on the amount consumed. Concomitant serum biochemical findings include decreases in serum glucose, phosphate, and bicarbonate and increases in serum uric acid and lactic acid after fructose ingestion. Chronic exposure to fructose leads to failure to thrive, hepatomegaly, jaundice, hepatic cirrhosis, and nephrocalcinosis.

HFI is inherited as an autosomal recessive trait with an incidence estimated to be 1 in 20,000. It is caused by a deficiency of the enzyme fructose-1-phosphate aldolase B, which cleaves fructose-1-phosphate into D-glyceraldehyde and dihydroxyacetone phosphate for further conversion into glucose or CO_2 and H_2O . The gene for aldolase B is found on the long arm of chromosome 9 (79). Aldolase B is present in liver, small intestine, and proximal renal tubule cells. Symptoms of HFI appear at weaning when fruit, vegetables, and sweetened cereals that contain fructose or sucrose are introduced. Symptoms appear in the newborn period if the infant is fed a formula containing sucrose. Young infants with this disorder may have a catastrophic illness, with severe dehydration, shock, acute liver impairment, bleeding, or acute renal failure, with exposure to fructose. The diagnosis should be suspected when characteristic symptoms develop after the ingestion of fructose. Confirmation can be made either by performing a fructose tolerance test or by assaying the activity of fructose-1-phosphate aldolase in a liver biopsy specimen.

Abnormalities associated with Fanconi syndrome appear rapidly after the ingestion of fructose (80,81). Proximal bicarbonate reabsorption falls by 20 to 30%, leading to

RTA. The development of lactic acidosis adds significantly to the metabolic acidosis (82). Chronic fructose ingestion may lead to nephrocalcinosis, impairing distal tubular function as well. Although the onset of proximal tubule dysfunction is rapid after fructose loading, resolution of these symptoms may take days or weeks (83).

Acute fructose loading in the rat has been used as a model for HFI (84–86). Fructose loading leads to depletion of intracellular phosphate as fructose-1-phosphate accumulates and adenine deaminase is activated. Adenine deaminase converts adenosine monophosphate to inosinic monophosphate and ultimately to uric acid. A fall in adenosine monophosphate causes a drop in adenosine diphosphate and ATP, because these levels are maintained at or near equilibrium by adenylate kinase. Therefore, a drop in intracellular phosphate can cause a depletion of ATP. Furthermore, phosphate depletion impairs ATP regeneration by mitochondria. Fructose infusion induces a fall in tissue ATP in normal humans as well (87), and to an even greater extent in patients with HFI. This fall in ATP may be the cause of Fanconi syndrome because, experimentally, ATP depletion impairs substrate reabsorption in the proximal tubule.

Treatment of this disorder is strict avoidance of foods containing fructose and sucrose. Most patients develop a strong aversion to such foods, making this interdiction easy. The greatest risk occurs during infancy.

Glycogenesis

A number of patients have been described with Fanconi syndrome and glycogen storage in the liver and kidney (88–91). The syndrome is inherited as an autosomal recessive trait and is characterized by heavy glucosuria along with other features of Fanconi syndrome. This has led to the name *renal glucose losing syndrome* or *Fanconi-Bickel syndrome* because the glucose losses can be massive. Fanconi syndrome may appear in the first few months of life and precede the development of hepatomegaly from glycogen storage. The degree of renal tubular dysfunction is often severe, and rickets, osteoporosis, and growth retardation are common. Glucose tolerance tests are diabetic in pattern, but glucagon stimulation leads only to a slight increase in blood sugar. Galactose metabolism also is impaired, but the activities of the enzymes associated with galactose metabolism are normal. Ketonemia, ketonuria, elevations in plasma lactate and pyruvate, and hyperlipidemia are also observed as in type I glycogen storage disease. A few patients with type I glycogen storage disease have been described with mild Fanconi syndrome (92).

Fanconi-Bickel syndrome is caused by a deficiency of the transporter, GLUT2, that facilitates the exit of glucose and other hexoses from the basolateral side of the proximal tubule and intestinal cell and the entry and exit of these sugars from the hepatocyte and pancreatic β -cell (93). The therapy of this disorder is directed at the renal solute losses;

treatment of rickets, which can be severe; and frequent feeding to prevent ketosis. Uncooked cornstarch has been shown to lessen hypoglycemia and improve growth (94).

Tyrosinemia

Hereditary tyrosinemia type I, also known as *hepatorenal tyrosinemia*, is an autosomally inherited defect of tyrosine metabolism affecting the liver, kidneys, and peripheral nerves (95). The liver is the major organ affected in tyrosinemia, and liver dysfunction may be evident in the first month of life. Clotting abnormalities can be the initial sign of liver disease, with little elevation in transaminases. Infants may also have obvious and severe signs of liver disease, and those presenting at younger than 2 months of age have a high likelihood of dying during the first year of life. Some children are not diagnosed until after infancy; they have more indolent liver disease but are at risk for acute exacerbations of liver dysfunction. All children eventually develop macronodular cirrhosis, and many develop hepatocellular carcinoma. Acute, painful peripheral neuropathy may appear and can lead to transient paralysis. Autonomic dysfunction with hypertension and tachycardia can be associated with this acute neuropathy. Some renal tubular dysfunction is evident in all patients with tyrosinemia, especially those presenting after infancy. Rickets, secondary to the renal phosphate loss, can be severe. Generalized aminoaciduria, renal tubular acidosis, and mild proteinuria are also often seen, whereas glucosuria is less common because plasma glucose levels are usually low. Nephromegaly is common, and nephrocalcinosis may be seen. Glomerulosclerosis and impaired GFR may be seen with time. Plasma tyrosine and methionine levels usually are elevated in untreated patients. The hypermethioninemia imparts a cabbage-like odor to affected patients. In association with these amino acid abnormalities, *p*-hydroxyphenolic compounds, as a result of *p*-hydroxyphenyl pyruvate dioxygenase inhibition, are elevated in the urine. The presence of succinylacetone in blood or urine is diagnostic of hereditary tyrosinemia type I.

A deficiency of fumarylacetoacetate hydrolase activity is the cause of hereditary tyrosinemia type I (96). The gene coding for this enzyme resides on the long arm of chromosome 15 (97,98). Patients with early onset of severe symptoms tend to have no immunologically detectable fumarylacetoacetate hydrolase peptide, whereas patients with a more chronic course usually have detectable peptide. Decreased or absent activity of fumarylacetoacetate hydrolase leads to accumulation of maleylacetoacetate and fumarylacetoacetate in affected tissues. These compounds can react with free sulfhydryl groups and reduce intracellular levels of glutathione. They also may be capable of acting as alkylating agents. Maleylacetoacetate and fumarylacetoacetate are not detectable in plasma or urine but are converted to succinylacetoacetate. Succinylacetone, a metabolite of succinylacetoacetate, is structurally similar to maleic acid, which is known to induce Fan-

coni syndrome and may be the cause of the tubular dysfunction of tyrosinemia. Experimentally, succinylacetone administration to rats leads to Fanconi syndrome (20,21). Succinylacetone is also a potent inhibitor of D-aminolevulinic acid dehydratase, leading to the accumulation of D-aminolevulinic acid. This compound is neurotoxic and probably causes the acute porphyria-like symptoms of tyrosinemia.

Treatment with a low-phenylalanine and low-tyrosine diet dramatically improves the renal tubule dysfunction (99). In chronic cases, this diet leads to a rise in plasma phosphate, healing of rickets, a decrease in aminoaciduria, and the disappearance of glucosuria and proteinuria. However, its efficacy in halting the liver disease is uncertain. There is a risk of inducing deficiencies of phenylalanine or tyrosine. There is evidence for hepatic involvement prenatally, before any elevations of tyrosine or methionine are evident, and this raises doubt that elevated levels of these amino acids are the cause of liver injury (100). Liver transplantation has been successfully used to treat patients with severe liver failure and to prevent the development of hepatoma. Liver transplantation leads to rapid correction of Fanconi syndrome (101). Nitrotrifluorobenzoylcyclohexadione, which blocks *p*-hydroxyphenyl pyruvate dioxygenase and the formation of maleylacetoacetate and fumarylacetoacetate, dramatically improves the renal and hepatic dysfunction (95).

Wilson's Disease

Wilson's disease is a disorder of copper metabolism that affects numerous organ systems. Approximately 40% of patients present with liver disease, 40% with extrapyramidal symptoms, and 20% with psychiatric or behavioral abnormalities (102). Although symptoms rarely occur before 6 years of age, the most common presentation in children is with chronic active hepatitis or cirrhosis with little or no neurologic findings except those ascribable to hepatic failure. Greenish-brown rings at the limbus of the cornea, independently described by Kayser (103) and Fleischer (104), are usually present and are pathognomonic of Wilson's disease.

The underlying problem in Wilson's disease is a defect in a P-type copper transporting ATPase in the liver. This leads to a severe impairment in biliary copper excretion, the major excretory route for copper, and in the incorporation of copper into ceruloplasmin (105). These abnormalities cause excessive intracellular accumulation of copper in the liver, with subsequent overflow into other tissues such as brain, cornea, and renal proximal tubule. The gene for this enzyme has been localized to chromosome 13q14.3, and multiple mutations have been described in patients with Wilson's disease (105).

Excessive storage of copper in the kidney leads to renal tubular dysfunction in most patients and a full-blown Fanconi syndrome in some (106). Hematuria also has been noted. Renal plasma flow and GFR decrease as the disease progresses, but death from extrarenal causes occurs before the onset of renal failure. Tubular dysfunction overshadows the

glomerular disease. Fanconi syndrome usually appears before the onset of hepatic failure and is characterized by intermittent glucosuria; aminoaciduria; decreased phosphate reabsorption leading to hypophosphatemia, osteomalacia, and rickets; and mild proteinuria. Hypouricemia secondary to a significant uricosuria is common and is a clue to the diagnosis (107,108). Hypercalciuria (109), with the development of renal stones and nephrocalcinosis (110), also has been reported. Besides proximal tubular dysfunction, abnormalities in distal tubular function, decreased concentrating ability, and distal RTA have also been observed.

Histologically, the kidney in untreated Wilson's disease shows either no alterations on light microscopy or only flattened proximal tubule cells without recognizable brush borders (107). Electron microscopy shows loss of the brush border, disruption of the apical tubular network, electron-dense bodies (probably representing metalloproteins) in the subapical region of tubule cell cytoplasm, and cavitation of the mitochondria with disruption of the normal cristae pattern. Rubeanic acid staining shows intracytoplasmic copper granules. The copper content of kidney tissue is significantly elevated.

The diagnosis of Wilson's disease should be suspected in children and young adults with unexplained neurologic disease, chronic active hepatitis, acute hemolytic crisis, behavioral or psychiatric disturbances, or the appearance of Fanconi syndrome. In such patients, the presence of Kayser-Fleischer rings is an important clue in making the diagnosis, but slit lamp examination may be necessary. Serum ceruloplasmin levels are decreased in 96% of patients with Wilson's disease, making this a useful screening test. However, normal values may be seen in young children with severe liver disease. A significantly increased urinary copper level is also useful in making the diagnosis, especially if it increases significantly with D-penicillamine. Liver copper levels are increased in untreated patients; however, in advanced cirrhosis this may not be the case.

Treatment with D-penicillamine reverses the renal dysfunction and may reverse the hepatic and neurologic disease, depending on the degree of damage before the onset of therapy (111). Recovery, however, is slow. Trientine can also chelate copper and is indicated in patients who cannot tolerate penicillamine. Tetrathiomolybdate is a potent agent in removing copper from the body and may be the drug of choice for patients with neurologic disease to prevent the immediate worsening of symptoms that can occur with penicillamine. Zinc salts, which induce intestinal metallothionein and blockade of intestinal absorption of copper, are useful in maintenance therapy. Liver transplantation has been successful in some patients but should be reserved for those with liver failure (112).

Lowe Syndrome

Lowe syndrome (oculocerebrorenal syndrome) is characterized by congenital cataracts and glaucoma, severe mental

retardation, hypotonia with diminished to absent reflexes, and renal abnormalities (113,114). Initially, the renal abnormalities are those of Fanconi syndrome but, later, GFR is impaired. The disorder is transmitted as an X-linked recessive trait mapped to Xp24-p26 (115). This gene codes for a phosphatidylinositol bisphosphate phosphatase (116) localized in the Golgi complex (117). A few females have been reported (118,119). This may be explicable by the Lyon hypothesis, or there are several modes of inheritance. Cataracts and punctate lens opacities have been noted in mothers of affected males, and these findings have been proposed as a method of carrier detection (120). Generalized aminoaciduria with relative sparing of the branched-chain amino acids is a constant feature of Lowe syndrome after the first several months of life. Proteinuria is present from infancy and often exceeds 1 g/m² body surface area per day. Glucosuria is minimal and only intermittently present. Phosphate reabsorption is variably impaired, but this impairment appears to worsen with age. Potassium reabsorption is also impaired and some patients require supplementation. Proximal RTA, polyuria, and impaired concentrating ability are common. The GFR usually only slowly declines with the appearance of end-stage renal failure in the fourth decade of life.

The histology of the kidney by light microscopy is normal early in the disorder (121,122). Swelling of endothelial cells with thickening and splitting of the glomerular basement membrane and fusion of the epithelial foot processes were observed by electron microscopy. In the proximal tubule cells, there was shortening of the brush border and enlargement of the mitochondria, with distortion and loss of the cristae. With progression of the disease, there was further thickening of the basement membrane, increased cellularity of the glomeruli, glomerular fibrosis, tubular atrophy, dilation, and interstitial fibrosis.

Treatment of Lowe syndrome is only symptomatic. The eye abnormalities usually require therapy early in infancy. Electrolyte and vitamin D supplements are needed by many patients for treatment of Fanconi syndrome. Renal insufficiency usually develops in adulthood.

Dent's Disease

Dent's disease is an X-linked recessive disorder characterized by low-molecular-weight proteinuria, hypercalciuria, nephrolithiasis, nephrocalcinosis, and, in some cases, rickets (123). Affected males also have aminoaciduria, phosphaturia, and glucosuria. They also excrete β_2 -microglobulin in amounts that are 100-fold greater than normal. Another characteristic of affected males is severe hypercalciuria that leads to recurrent stone formation. These stones are usually made up of calcium phosphate or a mixture of calcium phosphate and oxalate. In addition, most affected males and some females have medullary nephrocalcinosis. Rickets is a frequent problem in children and osteomalacia in adults. Hypokalemia is

also common. Renal failure is common and may occur by late childhood. The renal pathology is not pathognomonic and mainly shows interstitial nephritis with scattered calcium deposits. Hemizygous females usually only have low-molecular-weight proteinuria and mild hypercalciuria.

X-linked recessive hypophosphatemic rickets, X-linked recessive nephrolithiasis, and Japanese idiopathic low-molecular-weight proteinuria have similar features, and all are part of the clinical spectrum of an absent or inactive renal ClC-5 chloride channel from a mutation in the CLCN-5 gene located at Xp11.22 (124). A number of mutations have been described, and the same mutation may result in a different phenotype in different patients, indicating that there are other genetic or environmental modifiers. The ClC-5 chloride channel resides in the membrane of endocytic vesicles just below the luminal membrane of the proximal tubule. Entry of Cl⁻ via this channel is necessary for acidification of the vesicle by the H⁺-ATPase pump. Inactivation of this channel interferes with protein reabsorption and cell surface receptor recycling, which may explain the hypercalciuria, phosphaturia, glucosuria, and aminoaciduria. Targeted disruption of the ClC-5 channel in a mouse led to a phenotype that was quite similar to that of patients with Dent's disease (125).

Treatment of Dent's disease is largely supportive. High fluid intake is helpful for the stone disease. Calcium restriction reduces calcium excretion but probably adds to the bone disease. A pharmacologic dose of vitamin D heals the rickets but may worsen the hypercalciuria. Thiazide diuretics reduce the hypercalciuria, but these patients are quite sensitive to them and may develop dehydration and hypotension.

Mitochondrial Cytopathies

In 1977, Biervliet et al. (126) described a family in which three infants died from a mitochondrial myopathy in association with lactic acidemia and Fanconi syndrome. Subsequent to this report, two more infants with similar clinical presentations were reported (127,128). The infants were noted to have weak cries and a poor suck, with generalized hypotonia in the neonatal period. The hypotonia and weakness progressed in all affected infants, leading to respiratory failure and death. Examination of muscle cells from these babies showed lipid-filled vacuoles in type I fibers and swollen mitochondria with abnormal cristae. Cytochrome-*c*-oxidase activity, an important enzyme in the electron-transport chain, was very low in both muscle and kidney. This deficiency, with its consequent impairment of oxidative phosphorylation, appeared to underlie the myopathy and renal tubulopathy.

After these reports, it has been recognized that there is a diverse group of diseases related to dysfunction of mitochondria in various tissues, termed *mitochondrial cytopathies* (129,130). Most are caused by abnormalities in mitochondrial DNA that lead to impaired oxidative phosphorylation.

TABLE 41.3. MITOCHONDRIAL CYTOPATHIES

MERRF	Myoclonic epilepsy with ragged red fibers
NARP	Neuropathy, ataxia, and retinitis pigmentosa
MELAS	Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes
LHON	Leber hereditary optic neuropathy
Leigh syndrome	Maternally inherited Leigh syndrome (somnolence, blindness, deafness, peripheral neuropathy, degeneration of brainstem)
Pearson syndrome	Pancytopenia, exocrine pancreatic deficiency, hepatic dysfunction
Kearns Sayre syndrome	Ophthalmoplegia, pigmentary retinopathy, heart block, ataxia
Alpers syndrome	Intractable epilepsy, liver disease, neuronal degeneration

The mitochondrion has its own DNA, which encodes for 13 protein subunits of 4 biochemical complexes; 2 ribosomal RNAs; 22 transfer RNAs; and machinery for DNA replication, transcription, and translation. Mitochondrial DNA mutates ten times more often than nuclear DNA; has no introns, so mutations are more likely to affect DNA coding sequences; lacks protective histones; and has an ineffective repair system. Mitochondria with their DNA are inherited maternally and multiple mitochondria are present in each egg. Therefore, normal and mutant mitochondria can coexist within a cell, a condition termed *heteroplasmy*, and this proportion can vary from cell to cell and tissue to tissue. This allows otherwise lethal mutations to exist and gives rise to the variation in the phenotype of a particular mutation. Some mitochondrial DNA mutations, mainly missense mutations, can be homoplasmic (i.e., affecting every mitochondrion).

Mitochondrial cytopathies most often present with neurologic disorders such as myopathy, myoclonus, ataxia, seizures, external ophthalmoplegia, stroke-like episodes, and optic neuropathy. Other manifestations include pigmentary retinitis, diabetes mellitus, exocrine pancreatic insufficiency, siderocrestic anemia, sensorineural hearing loss, pseudoobstruction of the colon, hepatic disease, cardiac conduction disorders, and cardiomyopathy. These various manifestations tend to group together in specific syndromes and reflect specific mutations in mitochondrial DNA (Table 41.3).

The most common renal manifestation associated with mitochondrial cytopathies is Fanconi syndrome, although a few patients have had focal segmental glomerulosclerosis with nephrotic syndrome. All of the patients with renal abnormalities have had extrarenal disorders, mainly neurologic diseases. Most patients presented in the first months of life and died soon after.

A clue to these disorders is an elevated serum or cerebrospinal fluid lactate level, especially if associated with an altered lactate to pyruvate ratio, suggesting a defect in

mitochondrial respiration. The presence of ragged red fibers, a manifestation of abnormal mitochondria, in a muscle biopsy is another clue, especially with large abnormal mitochondria on electron microscopy of muscle tissue. Specific abnormalities of respiratory chain enzyme activity are best made by spectrographic analysis of isolated mitochondria, tissue homogenates, circulating lymphocytes, or cultured fibroblasts. Analysis of the mitochondrial DNA for deletions, duplications, or point mutations adds further insight into the nature of the abnormality.

There is little to offer these patients in terms of definitive therapy (131). Low electron transport chain complex III activity can be treated with menadione or ubidecarenone. Deficient complex I activity may be treated with riboflavin and ubidecarenone. Ascorbic acid has been used to minimize oxygen free-radical injury. A high-lipid, low-carbohydrate diet has been tried in cytochrome-*c*-oxidase deficiency.

Idiopathic Fanconi Syndrome

A number of patients develop complete Fanconi syndrome in the absence of any known cause. These cases have been called *idiopathic* or *primary Fanconi syndrome* (26–28,34,132–139). Originally, only adults were believed to be affected; hence, it was called *adult Fanconi syndrome*. However, it is now clear that idiopathic Fanconi syndrome occurs in children as well. All of the features of Fanconi syndrome may not be present when the patients are first studied. Idiopathic Fanconi syndrome can be inherited in an autosomal dominant (27,132), autosomal recessive (29), and even an X-linked pattern (134). However, most cases occur sporadically, without any evidence of genetic transmission. The possibility of an underlying enzymatic or other abnormality that has not yet been described as causing Fanconi syndrome should be kept in mind, especially in those in whom the syndrome is inherited. A number of patients, in whom the known causes of Fanconi syndrome have been excluded, still appear to have an underlying metabolic abnormality (136,137). Deal et al. (138) described six infants from consanguineous marriages with idiopathic Fanconi syndrome, ichthyosis, dysmorphism, jaundice, and diarrhea who failed to thrive and died in infancy.

Children with idiopathic Fanconi syndrome usually exhibit growth failure, recurrent dehydration, and rickets, despite an adequate intake of vitamin D. They often have the other features of Fanconi syndrome, including polyuria, polydipsia, hypokalemia, hypophosphatemia, RTA, aminoaciduria, glucosuria, and proteinuria. The GFR, usually, is normal in childhood. The prognosis is variable. These patients require careful management to prevent death from dehydration and electrolyte imbalance. However, some develop chronic renal failure 10 to 30 years after the onset of symptoms (26,132,135,139).

Renal morphologic descriptions of such cases are scanty. In some reports, no abnormalities were found, and others

reported tubular atrophy with interstitial fibrosis interspersed with areas of tubular dilation. Significantly dilated proximal tubules with swollen epithelium and grossly enlarged mitochondria with displaced cristae have also been noted.

Therapy for idiopathic Fanconi syndrome remains symptomatic. Careful follow-up of these patients is necessary to prevent serious dehydration and electrolyte imbalance as well as severe bone disease. Renal transplantation has been done in a few patients who have reached end-stage renal disease (140). Fanconi syndrome has recurred in the allograft without evidence of rejection, suggesting that in some cases, there is an extrarenal cause of idiopathic Fanconi syndrome.

Acquired Causes

Exogenous Intoxications

Numerous substances can injure the proximal renal tubule, and this injury can range from an incomplete Fanconi syndrome to acute tubular necrosis and renal failure. The extent of the tubular damage is variable and depends on the type of toxin, the amount, and the host. A detailed history, therefore, is important in patients with tubular dysfunction to discover whether a toxin is the cause.

A major cause of proximal tubular dysfunction is heavy metal intoxication. Lead poisoning induces Fanconi syndrome, principally in children (141,142). However, the tubular dysfunction usually is overshadowed by the involvement of other organs, especially the central nervous system. Generalized aminoaciduria is regularly present in children with moderate lead poisoning. Glycosuria and hypophosphatemia with impaired phosphate reabsorption can also occur, but not as often. There is a rough correlation between the severity of the intoxication and the completeness of Fanconi syndrome. In acute lead poisoning, the alterations in renal histology are mainly in the proximal tubule and include eosinophilic intranuclear inclusions with mitochondrial swelling (143).

Cadmium intoxication also leads to Fanconi syndrome (142,144), usually after a long exposure to the toxin. This poisoning was dramatized by a large number of cases appearing in the Jintsu River Basin in Japan after World War II. It was characterized by severe bone pain, which gave rise to the name *Itai-Itai (ouch-ouch)* disease. Aminoaciduria, glucosuria, hypophosphatemia with impaired phosphate reabsorption, hyposthenuria, and RTA were also observed. The cause was traced to industrial contamination of the soil and water with cadmium.

Certain organic compounds cause Fanconi syndrome in humans. Outdated tetracycline causes a reversible Fanconi syndrome even in therapeutic doses (15,145,146). Affected patients experience dizziness, muscular weakness, acidosis, and, occasionally, neurologic symptoms. They have a generalized aminoaciduria, renal glucosuria, hypophosphatemia,

RTA, hypokalemia, proteinuria, and hypouricemia. The GFR is moderately reduced in some. Recovery is rapid when the degraded drug is stopped. The compound responsible for the tubular dysfunction is anhydro-4-tetracycline formed from tetracycline by heat, moisture, and a low pH.

A number of other compounds also may give rise to Fanconi syndrome, often in association with a reduced GFR, but the renal injury usually is reversible. For example, a few patients ingesting methyl-3-chromone (diachrome) (147), 6-mercaptopurine (148), toluene (glue sniffing) (149), Chinese medicine (150), valproate (151), suramin (152), and Lysol (153) have developed Fanconi syndrome. Gentamicin (154), streptozotocin (155), and ranitidine (156) have caused Fanconi syndrome and renal failure. Tubular dysfunction during recovery from acute renal failure from any cause can occur, diminishing the significance of some toxins as inducers of Fanconi syndrome.

A number of cancer chemotherapy agents have been associated with Fanconi syndrome and renal tubule dysfunction, especially cisplatin and ifosfamide. The nephrotoxicity of cisplatin is dose dependent and often irreversible (157). Renal cisplatin toxicity is manifested by tubular proteinuria, aminoaciduria, hypercalciuria, hyperphosphaturia, and, especially, hypermagnesuria. The hypermagnesuria can be severe, persistent, and difficult to treat. Reductions in GFR are common with prolonged use of cisplatin. Cisplatin principally affects the tubule, especially the proximal and distal tubules at the corticomedullary junction. Strict attention to hydration and avoidance of other nephrotoxins are helpful in preventing cisplatin nephrotoxicity.

Ifosfamide is another useful chemotherapeutic agent against solid tumors. However, nephrotoxicity is a well-documented side effect of this drug (158–162). Fanconi syndrome may appear at any time but seems more likely to appear after doses greater than 60 g/m² body surface area in children under 2 years of age, in those with reduced renal mass, and in those treated previously with cisplatin. Hypophosphatemic rickets as a consequence of Fanconi syndrome has occurred in a number of these children long after cessation of the drug, as has a reduced GFR. Experimentally, the perfusion of isolated rat kidneys with chloroacetaldehyde, a metabolite of ifosfamide, caused Fanconi syndrome, although this was not observed with ifosfamide or acrolein, another metabolite of ifosfamide (163).

Other Acquired Disorders

Dysproteinemia associated with a number of diseases is a cause of Fanconi syndrome. This cause is mainly observed in adults because the diseases are rare in children. Dysproteinemia and Fanconi syndrome are associated with multiple myeloma (164), light-chain proteinuria (165), Sjögren's syndrome (166), and amyloidosis (167). The appearance of tubular dysfunction is correlated with specific light chains

or light-chain fragments (Bence Jones proteins) that crystallize within the tubule cells (164,168).

Hypophosphatemia has been well described in patients with benign and malignant mesenchymal tumors of bone. A single patient was also reported who had Fanconi syndrome, as well as hypophosphatemia, in association with a nonossifying fibroma of bone (169). Removal of the tumor led to resolution of the tubular dysfunction, indicating a humoral substance that impaired tubular transport.

The nephrotic syndrome has rarely been associated with Fanconi syndrome (170). The renal pathology in most cases is focal segmental glomerulosclerosis, and Fanconi syndrome heralds a poor prognosis. These patients have hypokalemia, RTA, rickets, and growth retardation. Hypocalcemia and tetany can be significant problems in these children.

Fanconi syndrome has appeared rarely after renal transplantation (171). The pathogenesis probably is multifactorial (e.g., sequels of acute tubular necrosis, rejection, nephrotoxic drugs, ischemia from renal artery stenosis, and residual hyperparathyroidism) (172).

THERAPY

Therapy, when possible, should be directed at the underlying cause, such as avoidance of the offending nutrient in galactosemia, HFI, and tyrosinemia. Wilson's disease can be treated with penicillamine and other copper chelators. Heavy metal intoxication can be treated with chelation therapy. In these cases, resolution of Fanconi syndrome usually is complete.

In other instances, therapy is directed at the biochemical abnormalities secondary to the renal solute losses and the bone disease often present in these patients. Proximal RTA usually requires high dosages of alkali (2 to 10 mEq/kg/day given in divided doses throughout the day) for correction. Some patients require even higher dosages that may lead to volume expansion and further bicarbonate wasting. In this situation, 1 to 3 mg/kg/day of hydrochlorothiazide to prevent volume expansion may lessen the dose of alkali needed. Hydrochlorothiazide aggravates the potassium losses, however. Potassium supplementation is also commonly needed, especially if there is significant RTA. The use of potassium citrate, lactate, or acetate corrects hypokalemia as well as acidosis. A few patients require sodium supplementation, as well as potassium. Again, the use of a metabolizable anion aids in the correction of the acidosis. Rare patients require NaCl supplementation. Usually these patients manifest alkalosis when untreated because of large urinary NaCl losses leading to volume contraction, which overrides the RTA. Magnesium supplementation is required in those patients who manifest hypomagnesemia. Ensuring adequate fluid intake is essential, especially during gastrointestinal diseases. This is of greater importance in the infant who does not have free access to fluid. Correction of hypokale-

mia and its effect on the concentrating ability of the distal tubule may decrease polyuria.

Bone disease is another important aspect of managing patients with Fanconi syndrome. Often, complaints referable to this problem (e.g., pain, fractures, rickets, or growth failure) are the presenting feature. Factors implicated in bone disease include hypophosphatemia, decreased synthesis of calcitriol, hypercalciuria, and chronic acidosis. Both low and normal plasma levels of calcitriol have been found in patients with Fanconi syndrome. Moreover, healing of rickets has occurred in patients receiving supplemental vitamin D without phosphate and in some receiving phosphate without supplemental vitamin D. In the presence of hypophosphatemia, oral phosphate should be started with the goal of normalizing serum phosphate levels. This often requires 1 to 3 g/day of supplemental phosphate. This is best given in divided doses, and the dosage should be slowly increased over several weeks to reduce the gastrointestinal intolerance. With regard to vitamin D supplementation, it is unclear whether standard vitamin D (i.e., ergocalciferol) or a vitamin D metabolite is better. Currently, most clinicians would use a vitamin D metabolite, such as calcitriol or dihydrotachysterol. This obviates concern of inadequate hydroxylation by proximal tubule mitochondria and reduces the risk of prolonged hypercalcemia because of the shorter half-life of these metabolites. Vitamin D therapy improves the hypophosphatemia and lessens the risk of hyperparathyroidism. Supplemental calcium is indicated in those with hypocalcemia after supplemental vitamin D has been started.

Hyperaminoaciduria, glucosuria, proteinuria, and hyperuricosuria usually do not lead to clinical symptoms and do not require specific treatment. Carnitine supplementation has been utilized in patients with Fanconi syndrome to improve muscle function and lipid profiles (61). Urinary carnitine is incompletely reabsorbed in patients with Fanconi syndrome, leading to both low plasma and muscle levels of carnitine (173).

Despite correction of all of these metabolic factors, some patients continue to grow poorly, especially those with cystinosis. Supplemental growth hormone has been used successfully in a few such patients. Although there is concern that growth hormone therapy may hasten renal failure, growth hormone therapy in children with renal failure from a variety of causes does not appear to worsen their renal function (174).

PRIMARY HYPEROXALURIA

PIERRE COCHAT
LAURE B. D. E. COLLARD

First report on oxalosis by Lepoutre, reprinted from *Journal d'Urologie Médicale et Chirurgicale* 1927;20:424, with permission.

Calculs multiples chez un enfant; infiltration du parenchyme rénal par des dépôts cristallins. — Chez un enfant de quatre ans et demi, opéré ou soigné pour calculs multiples de l'urètre, de l'uretère et des deux reins, une biopsie fait découvrir un parenchyme rénal bourré de concrétions cristallines d'oxalate de chaux. Ce cas réalise en clinique l'expérience d'Ebstein et Nicolaier, qui, faisant ingérer de l'oxamide à des chiens, voyaient de développer des calculs urinaires et de multiples formations cristallines dans le parenchyme rénal.

Primary hyperoxaluria (PH) results from endogenous overproduction of oxalic acid, as opposed to secondary hyperoxaluria, which is attributable to increased intestinal absorption or excessive intake of oxalate. Such derangement leads to accumulation of oxalate within the body. The main target organ is the kidney because oxalate cannot be metabolized and is excreted in the urine, leading to nephrocalcinosis, recurrent urolithiasis, and subsequent renal impairment. Hyperoxaluria, the hallmark of any kind of PH, is associated with increased urinary excretion of either glycolate in PH type 1 (PH1) or L-glycerate in PH type 2 (PH2).

OXALATE METABOLISM

Oxalate is a poorly soluble end-product of the metabolism of a number of amino acids, particularly glycine, and of other compounds such as sugars and ascorbic acid (Fig. 42.1). The immediate precursors of oxalate are glyoxylate and glycolate. The main site of synthesis of glyoxylate and oxalate is the liver peroxisome, which can also detoxify glyoxylate by reconversion into glycine, catalyzed by alanine:glyoxylate aminotransferase (AGT). In the cytosol, glyoxylate can be converted into oxalate by lactic acid dehydrogenase. It can also be converted into glycolate by glyoxylate reductase (GR) and into glycine by glutamate:glyoxylate aminotransferase. Glycolate can also be formed from hydroxypyruvate, a catabolite of glucose and fructose. Hydroxypyruvate can be con-

verted into L-glycerate by lactic acid dehydrogenase, and into D-glycerate by hydroxypyruvate reductase (HPR), which also has a GR activity.

PRIMARY HYPEROXALURIA TYPE 1

PH1, the most common form of PH, is an autosomal recessive disorder caused by the functional defect of the hepatic, peroxisomal, pyridoxal phosphate-dependent enzyme AGT, the protein product of a gene that has been identified on chromosome 2q37.3. The disease occurs because AGT activity is undetectable or because AGT is mistargeted to mitochondria, which may explain clinical and enzymatic heterogeneity.

Metabolic Derangement

PH1 is due to a deficiency of the liver-specific pyridoxal phosphate-dependent enzyme AGT (EC 2.6.1.44, 392 amino acids, 43 kDa) (Fig. 42.1) (1). The resulting decreased transamination of glyoxylate into glycine leads to subsequent increase in its oxidation to oxalate, a poorly soluble end-product. In patients with a presumptive diagnosis of PH, 10 to 30% are identified as non-PH1 because AGT enzymatic activity and immunoreactivity are normal (2). Among PH1 patients, 75% have undetectable enzyme activity (*enz*⁻) and the majority of these also have no immunoreactive protein (cross-reacting material, *crm*⁻). In the rare *enz*⁻/*crm*⁺ PH1 patients, a catalytically inactive but immunoreactive AGT is found within the peroxisomes. The remaining PH1 patients have AGT activity in the range of 5 to 50% of the mean normal activity (*enz*⁺), and the level of immunoreactive protein parallels the level of enzyme activity (*crm*⁺) (2). In *enz*⁺/*crm*⁺ patients, the disease is caused by a mistargeting of AGT: approximately 90% of the immunoreactive AGT is localized in the mitochondria instead of in the peroxisomes, where only 10% of the activity is found; almost all patients who are pyridoxine-responsive are in this group (3,4). Of interest, human hepatocyte AGT, which is

FIGURE 42.1. Human hepatocyte. Major reactions involved in oxalate, glyoxylate, and glycolate metabolism in the human hepatocyte. AGT, alanine:glyoxylate aminotransferase; DAO, D-amino oxidase; GGT, glutamate:glyoxylate aminotransferase; GO, glycolate oxidase; GR, glyoxylate reductase; HPR, hydroxyypyruvate reductase; LDH, lactate dehydrogenase; PH1, primary hyperoxaluria type 1; PH2, primary hyperoxaluria type 2; X, metabolic block in PH1; O, metabolic block in PH2.

normally exclusively localized within the peroxisomes, is unable to function when diverted to the mitochondria, its normal localization in several other species (e.g., cat, dog, frog) (3). In addition, patients with a primary peroxisomal disorder (e.g., Zellweger syndrome) do not exhibit hyperoxaluria (5).

Different AGT crystal forms have been recently obtained for some polymorphic variants [AGT, AGT (P11L), AGT (P11L, I340M)] (6).

Genetics

PH1 is the most common form of PH (1:60,000 to 1:120,000 live births) (7,8). Due to autosomal recessive inheritance, it is much more frequent when parental consanguinity is present (9–11). Indeed, it is responsible for less than 0.5% of pediatric end-stage renal failure (ESRF) in Europe versus 13% in Tunisia (7).

Human liver AGT complementary DNA and genomic DNA have been cloned and sequenced; the normal AGT gene (*AGXT*) is a single copy gene, which maps to chromosome 2q37.3 (11 exons spanning approximately 10 kb) (2). Polymorphic variations have been identified in *AGXT* (2); the two best-studied polymorphic variants are those encoded by the major *AGXT* allele (80% frequency in the European and North American populations) and the minor *AGXT* allele, which has a frequency of 20%.

More than 40 mutations in the *AGXT* gene have been identified to date. However, some of them are more frequent and may play a role either in enzyme trafficking or in expression of a specific clinical or biochemical phenotype (12–16). The G630A mutation leading to a G170R substitution is found in one-third of European and North American patients and appears to act together with the P11L polymorphism leading to peroxisome-to-mitochondrion AGT mistargeting. Double heterozygous patients seem to present at a younger age and demonstrate a more aggressive disease. The T444C mutation is more frequent in the severe forms; the G630A mutation is more frequent in less severe cases (17). In addition, G630A mutation homozygotes have higher AGT residual activity (17). In any condition, the P11L polymor-

phism, which has a high allelic frequency (approximately 20%) plays an important role in determining the phenotypic manifestations of specific mutations (15).

DNA analysis among different ethnic groups has revealed the presence of specific mutations, founder effects, and phenotype-genotype correlations among North African, Japanese, Turkish, and Pakistani populations (2,18,19).

Prenatal diagnosis using a combination of linked polymorphism and detection of the two most common mutations has an accuracy of more than 99% and can be performed from chorionic villi or amniocytes according to gestational age (20).

Clinical Presentation

PH1 has four general clinical presentations: (a) a rare infantile form with early nephrocalcinosis and rapid kidney failure, (b) a rare late-onset form with occasional stone passage in late adulthood, (c) the most common form with recurrent urolithiasis and progressive renal failure leading to a diagnosis of PH1 in childhood or adolescence, and (d) a rare condition where PH1 is diagnosed after the prompt recurrence of the disease after kidney transplantation (7,21,22). In addition, some patients are asymptomatic, and PH1 may be discovered by family history.

Renal Involvement

PH1 presents with symptoms referable to the urinary tract in more than 90% of cases [e.g., loin pain, hematuria, urinary tract infection, passage of stones, evidence of nephrocalcinosis (Fig. 42.2), uremia, metabolic acidosis, growth delay, anemia]. Calculi—multiple, bilateral, and radiopaque—are composed of calcium oxalate. Nephrocalcinosis, best demonstrated by ultrasound, is evident on plain abdomen x-ray at an advanced stage. The median age at presentation is 5 years, ranging from birth to the sixth decade; ESRF is reached by the age of 25 years in one-half of patients (23). The infantile form of PH1 often presents as a life-threatening condition because of rapid progression to ESRF due to both early oxalate load and immature glomerular filtration rate (GFR); one-half of the patients experience ESRF at the time of diagnosis, and 80% develop ESRF by the age of 3 years (9).

FIGURE 42.2. Plain abdomen x-ray in a 20-month-old primary hyperoxaluria type 1 boy: bilateral nephrocalcinosis, 13 months after starting hemodialysis ($5 \times 3/\text{wk}$).

Extrarenal Involvement

When GFR falls to below 40 to 50 mL/min per 1.73 m^2 , continued overproduction of oxalate by the liver along with reduced oxalate excretion by the kidneys leads to a critical saturation point for plasma oxalate (plasma oxalate concentration greater than 30 to 50 $\mu\text{mol/L}$) so that oxalate deposition occurs in many organs (24,25). Bone is the major compartment of the insoluble oxalate pool (Fig. 42.3), and bone oxalate content is higher (15 to 910 μmol oxalate per gram bony tissue) than that observed in ESRF patients without PH1 (2 to 9 $\mu\text{mol/g}$) (26). Calcium oxalate crystals accumulate first in the metaphyseal area and form characteristic, dense suprametaphyseal bands on x-ray (27). Later on, oxalate osteopathy leads to pain, erythropoietin-resistant anemia, and spontaneous fractures, sometimes in infancy (Fig. 42.4). Along with the skeleton, systemic involvement includes many organs

FIGURE 42.3. Bone histology from a 13-year-old girl with primary hyperoxaluria type 1 on hemodialysis for 2 years: oxalate crystals on polarized light microscopy.

FIGURE 42.4. Spontaneous fracture of the left tibia in a 25-month-old boy on hemodialysis.

because of progressive vascular lesions—heart (e.g., cardiomyopathy, arrhythmias, heart block), nerves (e.g., polyradiculoneuropathy, mononeuritis multiplex), joints (e.g., synovitis, chondrocalcinosis), skin (e.g., ulcerating calcium oxalate nodules, calcinosis cutis, livedo reticularis), soft tissues (e.g., peripheral gangrene), retina (e.g., flecked retinopathy, choroidal neovascularization), and other visceral lesions (e.g., intestinal infarction, hypothyroidism) (7,28–33).

Systemic involvement, named *oxalosis*, is responsible for poor quality of life leading to both disability and severe complications. Indeed, PH1 is one of the most life-threatening hereditary renal diseases, mainly in developing countries where the mortality rate approaches 100% in the absence of adequate treatment (34).

Diagnosis

The combination of both clinical and radiologic presentation is a strong argument for PH1 in a large number of patients. In addition, family history may bring additional information (e.g., other affected siblings, parental consanguinity, and unexplained death in siblings) (34). Physicochemical investigation is of major interest in diagnosis, and infrared spectroscopy is helpful for the identification and the quantitative analysis of stones, showing calcium oxalate monohydrate crystals (type Ic whewellite, $\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$) (35). Such crystals can also be identified in urine or biopsy

TABLE 42.1. PLASMA AND URINE CONCENTRATIONS OF OXALATE, GLYCOLATE, AND L-GLYCERATE: NORMAL VALUES

Urine	Oxalate per day	Child	<0.46 mmol/1.73 m ²

tissues (e.g., kidney, bone, marrow) by polarized light microscopy or infrared spectroscopy (36). Funduscopy may also show flecked retina as early as infancy. In patients with normal or significant residual renal function, concomitant hyperoxaluria and hyperglycoluria are indicative of PH1 (Table 42.1), but 20 to 30% of PH1 patients do not present with hyperglycoluria (37). In dialysis patients, the biochemical assessment may include plasma oxalate or glycolate to creatinine ratio, and oxalate or glycolate measurement in dialysate (34,35,22).

A definitive diagnosis requires assessments of AGT activity and immunoreactivity in hepatic tissue (from a freshly frozen liver biopsy specimen, minimum of 4 mg). Nevertheless, there is controversial information about the relationship between AGT activity and the severity of the disease (17). Liver biopsy is mandatory if liver transplantation is being considered (see below). In selected populations, a direct molecular diagnosis can be performed, such as the search for the I244T mutation in patients from Maghreb (Basmaison, *submitted*). However, in most clinical settings, the search for frequent mutations (G630A, T853C, G170R) cannot currently replace enzymology in the diagnosis of PH1 (34,38). Prenatal diagnosis can be performed from DNA obtained from chorionic villi (10 to 12 weeks' gestation) or amniocytes (13 to 17 weeks' gestation). It is based on either mutational analysis using polymerase chain reaction amplification, or linkage analysis using the various intragenic and extragenic polymorphisms; the latter is more generally applicable, provided DNA

from the index case and parents is available (20). Such a procedure identifies normal, affected, and carrier fetuses. In the absence of identified mutations in an index case, the two most common mutations (G170R and I144T) can be checked (2). The detection of *AGXT* mutations using simplified reliable technology can be proposed to identify healthy carriers among family members, and sometimes for screening of polymorphisms in patients with nephrolithiasis (16).

Treatment and Prognosis

Supportive Treatment

Conservative measures should be started as soon as the diagnosis of PH1 has been made or even suspected. The aims are to decrease oxalate production and to increase the urinary solubility of calcium oxalate. The risk of stone formation is increased when urine oxalate exceeds 0.4 to 0.6 mmol/L, especially if urine calcium exceeds 4 mmol/L. Therefore, therapy should keep the concentrations of oxalate and calcium below these limits (39). This should be accomplished by maintaining a high fluid intake (greater than 2 L/m²/day), sometimes requiring a nasogastric tube or gastrostomy in infants, complemented by administration of calcium-oxalate crystallization inhibitors. Citrate (potassium or sodium), 100 to 150 mg/kg/day in three to four divided doses (8,40,41), has been shown to be effective in PH1 patients. When it is not available, crystallization inhibition may be accomplished by sodium bicarbonate (aiming at keeping pH greater than or equal to 7), magnesium or orthophosphate (20 to 60 mg/kg body weight per day) administration (40). Diuretics require careful management: furosemide maintains a high urine output but increases the risk of calciuria, whereas the diuretic effect of hydrochlorothiazide is less marked but is associated with an appreciable decrease of calcium excretion. The combination of both loop agents and thiazides is recommended in most instances.

Restriction of dietary oxalate intake (e.g., beet roots, strawberries, rhubarb, spinach, coffee, tea, nuts) has very limited influence on the disease because dietary oxalate contributes very little to hyperoxaluria in PH (40). Calcium restriction is not recommended, because dietary calcium is required to bind oxalate and form insoluble calcium oxalate complexes in the gut. Vitamin C supplementation is not recommended because ascorbic acid is a precursor of oxalate. The effects of conservative measures can be assessed by serial determinations of crystalluria score and calcium oxalate supersaturation software (41,42).

Pyridoxine (cofactor of AGT, see Fig. 42.1) sensitivity is found in 10 to 40% of patients, so that it must be tested early at a daily dose of 2 to 5 mg/kg with stepwise increase up to 10 to 20 mg/kg (8). Response to pyridoxine may delay the progression to ESRF. Pyridoxine sensitivity can be detected by monitoring of both oxalate and glycolate and can be tested at any stage of the disease (2,3,41). However,

one should keep in mind that large doses of pyridoxine might induce sensory neuropathy. Patients most likely to respond are those with residual AGT activity (43), but pyridoxine responsiveness is still poorly understood at the molecular level. An attempt to inhibit hepatic synthesis of oxalate by using (L)-2-oxothiazolidine-4-carboxylate has been reported without clinically significant changes in urinary oxalate excretion (44).

The treatment of stones should avoid open and percutaneous surgery because further renal parenchymal damage alters the GFR (45). The use of extracorporeal shock wave lithotripsy may be an available option in selected patients, but the presence of nephrocalcinosis may be responsible for parenchymal damage. Bilateral nephrectomy is recommended in most patients on renal replacement therapy to limit the risk of infection, obstruction, and passage of stones.

Renal Replacement Therapy

Dialysis

Conventional dialysis is unsuitable for PH1 patients who have reached ESRF because it cannot clear sufficient amounts of oxalate (3). In such patients, plasma oxalate levels range between 80 and 160 $\mu\text{mol/L}$ (normal is less than 7 $\mu\text{mol/L}$) (Table 42.1). Therefore, daily hemodialysis (6 to 8 hours per session) using high-flux membranes would be required. Such a strategy cannot be routinely used (46). A reasonable therapeutic goal is to keep predialysis plasma oxalate concentration below 50 $\mu\text{mol/L}$ to limit the progression of systemic oxalosis. Daily hemodialysis in infants raises major technical and developmental problems and its association with nighttime peritoneal dialysis may be sometimes proposed. Conventional long-term hemodialysis is generally regarded as contraindicated because it prolongs a deteriorating quality of life because of unabated progression of extrarenal oxalate deposition.

The benefit of pre- and posttransplantation hemodialysis is still debated and should be limited to patients with either oliguria or severe systemic oxalate loads.

Kidney Transplantation

Successful kidney transplantation allows significant removal of soluble oxalate. However, because the biochemical defect is in the liver, overproduction of oxalate and subsequent deposition in tissues continues unabated. High urinary oxalate excretion originates from both ongoing oxalate production from the native liver and oxalate deposits in tissues. Due to oxalate accumulation in the transplanted kidney, overall graft survival is limited. Therefore, isolated kidney transplantation is no longer recommended in most pyridoxine-unresponsive patients (see later). The long-term outcome of PH1 after renal transplantation remains uncertain, with a 5- to 10-year patient survival rate ranging from 10 to 50% (47). In addition, renal transplantation does not prevent the progression of skeletal and vascular complications. Outcome of renal transplantation is unrelated to residual

AGT activity (48), but graft survival is improved if transplantation is performed when there is substantial renal function (i.e., a GFR ranging from 20 to 30 mL/min/1.73 m²), and in the absence of major extrarenal involvement. In selected patients, good results have been reported after early renal transplantation and vigorous perioperative dialysis (49,50). However, at this point in time, living-related donors should be avoided because the overall results are poor (47). Isolated kidney transplantation may be a temporary solution for PH in developing countries before managing the patient in a specialized center for further (combined) liver, if required, kidney transplantation. Even with previous pyridoxine resistance, it is recommended to retest vitamin B₆ responsiveness after isolated renal transplantation (49).

Enzyme Replacement Therapy

Ideally, any kind of transplantation should precede accumulation of large systemic oxalate loads. Assessment of the oxalate burden therefore needs to be regularly monitored by measurement of serial GFR, plasma oxalate (Table 42.1), calcium oxalate saturation, and systemic involvement (assessment of bone mineral density by quantitative measures, such as bone histology and computed tomography) (34,51–54).

Rationale for Liver Transplantation

Because the liver is the only organ responsible for glyoxylate detoxification by AGT, the excessive production of oxalate continues as long as the native metabolically defective liver is left in place. Therefore, any form of enzyme replacement succeeds only when the deficient host liver is concomitantly removed (55). Successful liver transplantation can supply the missing enzyme in the correct organ (e.g., liver), cell (e.g., hepatocyte), and intracellular compartment (e.g., peroxisome) (2,55). The ultimate goal of organ replacement is to reduce endogenous oxalate synthesis and provide good oxalate clearance via either the native or the transplanted kidney.

Of interest, the removed native liver from a PH1 patient has been used for domino transplantation in a high-risk 69-year-old marginal recipient with initially a favorable postoperative clinical outcome but evolution toward progressive renal insufficiency due to hyperoxaluria (56).

Combined Liver-Kidney Transplantation

In Europe, eight to ten combined liver-kidney transplantations per year have been reported in the PH1 Transplant Registry Report (47). The results are encouraging. Patient survival approximates 80% at 5 years and 65 to 70% at 10 years. In addition, despite the potential risks for the grafted kidney due to oxalate release from body stores, kidney survival is approximately 95% at 3 years posttransplantation, and the GFR ranges between 40 and 60 mL/min/1.73 m² after 5 to 10 years (47,54,55).

Isolated Liver Transplantation

Isolated liver transplantation might be considered initial therapy in selected patients before advanced chronic renal failure has occurred (i.e., at a GFR between 60 and 40 mL/min/1.73 m²) (18,58). Such a strategy has a strong rationale but raises ethical controversies. Approximately 20 patients have received an isolated liver transplant to date. Overall outcome is difficult to evaluate because the course of the disease is unpredictable and a sustained improvement can follow a phase of rapid decrease in GFR (57–59).

Posttransplantation Reversal of Renal and Extrarenal Involvement

Deposits of calcium oxalate in tissues can be remobilized according to the accessibility of oxalate burden to the blood stream (55). After combined liver-kidney transplantation, plasma oxalate returns to normal before urine oxalate does, and oxaluria can remain for several months posttransplantation (3,47,49). Therefore, there is still a risk of recurrent nephrocalcinosis or renal calculi that might jeopardize renal graft function. Glycolate, which is more soluble than oxalate and does not accumulate, is excreted in normal amounts immediately after liver transplantation. Thus, independent of the transplantation strategy, the kidney must be protected from damage induced by the systemic oxalate load suddenly released from tissues. Forced fluid intake (3 to 5 L/1.73 m²/day) supported by diuretics and the use of crystallization inhibitors is the most important strategy. Plasma oxalate concentration, crystalluria, and calcium oxalate saturation are helpful tools in renal graft management after combined liver-kidney transplantation (42,53,60). The benefit of daily high-efficiency pre- and posttransplant hemodialysis or filtration is still debated; it provides a rapid drop in plasma oxalate but also an increased risk of urinary calcium-oxalate supersatura-

tion and therefore should be limited to patients with anuria or with evidence of significant systemic oxalate involvement (34,52,60).

Combined transplantation should be planned when the GFR ranges between 20 and 40 mL/min/1.73 m² because, at this level, oxalate retention increases rapidly (22,59). In patients with ESRF, vigorous hemodialysis should be started and urgent liver-kidney transplantation should be performed. Even at these late stages, damaged organs other than the kidney, such as the skeleton or the heart, do benefit from enzyme replacement from the donor liver (57,60,61), which results in an appreciable improvement in quality of life.

Donors for Combined Liver-Kidney Transplantation

The type of donor (i.e., cadaver or living related) depends mainly on the physician and the country where the patient is treated (34,62,63) (Table 42.2). A living related donor must be considered because of the restricted number of potential biorgan donors. A living related donor can be proposed in a preemptive procedure using either isolated liver or synchronous liver-kidney transplantation. In patients with end-stage renal disease and systemic involvement, a metachronous transplantation procedure might be an option because a first-step liver transplantation will then allow oxalate clearance by vigorous hemodialysis before considering further kidney transplantation from the same (living related) donor.

Fate of Primary Hyperoxaluria Type 1 in Infants

PH1 in early childhood raises specific problems due to (a) the severity of the disease in infants (approximately 50% death rate), (b) the access to available diagnostic procedures in this age group, and (c) the adequacy of management, which directly reflects local economic particulars. Infantile PH1 presents two different issues worldwide. It is

TABLE 42.2. SUGGESTIONS FOR TRANSPLANTATION STRATEGIES IN PRIMARY HYPEROXALURIA TYPE 1 PATIENTS ACCORDING TO RESIDUAL GLOMERULAR FILTRATION RATE (GFR), SYSTEMIC INVOLVEMENT, AND LOCAL FACILITIES^a

GFR (mL/min/1.73 m ²)	Estimated oxalate burden	Proposed transplantation strategy	Comments

^aAuthors' personal opinion.

a very rare disease in developed countries where combined liver-kidney transplantation is available in children older than 6 months of age (or 5 to 6 kg body weight). Yet, it is a frequent cause of early end-stage renal disease in developing countries, often due to consanguinity, where therapeutic withdrawal is widely applied (9,58). Management of PH1 is, therefore, a major example of ethical, epidemiologic, technical, and financial dilemmas, which may be raised by recessive, inherited diseases with early life-threatening onset presenting in different socioeconomic contexts.

Future Trends

Although gene therapy has been advocated, many years of research will be required before its potential may be actualized (3). Amino acid changes found in AGT may affect its stability (6). A better understanding of such changes will facilitate design pharmacologic agents that stabilize AGT, leading to appropriate targeting of functional proteins in the potential of PH1 without the need for organ transplantation (Danpure, *personal communication*, 1999).

NON-TYPE 1 PRIMARY HYPEROXALURIA

In patients with overt hyperoxaluria, the pattern of urinary metabolites is indicative but not diagnostic of PH. In patients with a clinical picture of PH1, 10 to 30% have normal AGT activity that may lead to a diagnosis of PH2 or of another disorder causing hyperoxaluria. Enzyme activity measurement in a single-needle liver biopsy can confirm or exclude PH1 and PH2.

Primary Hyperoxaluria Type 2

PH2 is another rare inherited defect of oxalate metabolism causing raised urine oxalate and L-glycerate (Fig. 42.1).

Metabolic Derangement

PH2 is characterized by the absence of an enzyme with GR, HPR, and D-glycerate dehydrogenase activities (Fig. 42.1) (64–66). Analysis of liver and lymphocyte samples from patients with PH2 showed that GR activity was either very low or undetectable, whereas D-glycerate dehydrogenase activity was reduced in liver but within the normal range in lymphocytes (67).

Genetics

There is evidence for autosomal recessive transmission, and the gene encoding the enzyme GR or HPR (*GRHPR*) has been located on chromosome 9q11 (68). Several missense, nonsense, and deletion mutations have been identified (66).

Clinical Presentation

PH2 has been documented in less than 40 published patients (65,69). Median age at onset of first symptoms is 1 to 2 years, and the classical presentation is urolithiasis, including hematuria and obstruction. However, stone-forming activity is lower than in PH1 so that nephrocalcinosis and urinary tract infection are less frequent (41). Glomerular filtration rate is usually maintained during childhood, and systemic involvement is therefore exceptional (69).

Diagnosis

In the presence of hyperoxaluria without hyperglycoluria, a diagnosis of PH2 should be considered, especially when AGT activity is normal. However, hyperoxaluria in PH2 tends to be less pronounced than in PH1. The biochemical hallmark is the increased urinary excretion of L-glycerate (Table 42.1) (70), but the definitive diagnosis requires measurement of GR activity in a liver biopsy (71) as some PH2 patients have normal L-glycericaciduria (72).

Treatment and Prognosis

The overall long-term prognosis in PH2 is better than for PH1. ESRF occurs in 12% of patients between 23 and 50 years of age (69). As in PH1, supportive treatment includes high fluid intake, crystallization inhibitors, and prevention of complications; there is no rationale to use pyridoxine. Kidney transplantation has been performed in some end-stage renal disease patients, often leading to recurrence (nephrocalcinosis), including hyperoxaluria and L-glycerate excretion (69,73,74). The concept of liver transplantation has therefore been suggested, but more data are needed concerning the tissue distribution of the deficient enzyme and the biochemical impact of hepatic GR/HPR deficiency before such a strategy can be recommended.

Non-Type 1 Non-Type 2 Primary Hyperoxaluria

Few reports have shown a possible association of PH (a) without AGT or GR/HPR deficiency, and (b) with hyperglycoluria in the absence of AGT deficiency (75–77). It is therefore likely that there is at least another form of PH yet to be identified; hepatic glycolate oxidase is a candidate enzyme for a third form of inherited hyperoxaluria.

CONCLUSION

Children with nephrocalcinosis or urolithiasis should be screened for hyperoxaluria. Those patients with hyperoxaluria or recurrent calcium oxalate urolithiasis should be referred for diagnosis and management to specialized clinical centers with interest and experience in the conditions

and access to the appropriate biochemical and molecular biologic facilities. Major advances in biochemistry, enzymology, genetics, and management of PH have been achieved during recent years. Further steps will assess genotype-phenotype relationships and underlying metabolic defects of atypical PH. The ongoing analysis of data from multicenter databases will improve transplantation/enzyme replacement strategies and subsequent patient survival and quality of life.

TUBULOINTERSTITIAL NEPHRITIS

URI S. ALON

Involvement of the tubulointerstitial compartment in renal diseases can be either primary or even more commonly secondary to glomerular, vascular, or structural disease (Table 43.1). However, even in the latter disorders the magnitude of involvement and damage to the tubulointerstitium can have a significant effect on the outcome of the primary disease (1,2). This chapter addresses primary tubulointerstitial nephritis (TIN), which is a syndrome in which there is a spectrum ranging from acute to chronic diseases. TIN is characterized histologically by inflammation and damage of tubulointerstitial structures, with relative sparing of glomerular and vascular elements (3,4). Acute TIN is typically associated with marked tubulointerstitial inflammation, varying degrees of edema and tubular epithelial cell damage, and mononuclear cell infiltration (5). In contrast, chronic lesions generally are characterized by evidence of tubular epithelial cell damage and atrophy, with tubulointerstitial fibrosis (5). Although there are important clinical and pathophysiologic distinctions between acute and chronic TIN, they are best viewed as a continuum of manifestations of renal injury (6,7). Acute TIN is often reversible; however, progression to chronic renal disease can occur (8,9).

STRUCTURE AND FUNCTION OF THE TUBULOINTERSTITIAL COMPARTMENT

The tubulointerstitial compartment comprises approximately 80% of the renal parenchyma with the majority of its volume contributed by the tubules (10). The interstitium is made of matrix and cells. Two main types of cells are recognized:

1. Type I interstitial cells are fibroblast-like cells that are able to produce and degrade extracellular matrix, with a subgroup residing in the inner medulla producing prostaglandins.
2. Type II interstitial cells include dendritic antigen-presenting cells located mainly in the cortex.

In addition, a few monocyte-derived macrophages capable of phagocytosis are found in all renal zones (11,12). The

matrix is composed of a fibrillar net of basement membrane and interstitial collagens, glycoproteins, and proteoglycans, as well as interstitial fluid (12). The interstitium provides structural support for the nephrons and capillaries and plays an important role in the transport of solutes. It is also the site of production of cytokines and hormones such as prostaglandins and erythropoietin. The roles of the tubules in maintaining homeostasis of fluid, electrolytes, minerals, and acid-base balance are described in previous chapters. Damage to different segments of the tubules result in metabolic abnormalities related to the affected segments.

PATHOPHYSIOLOGY

The similarity of tubulointerstitial lesions in all forms of TIN, which is characterized by predominantly T-cell lymphocytic infiltrates, suggests immune-mediated mechanisms of renal injury (6,13). Such mechanisms are likely important in either initiating tubular injury or amplifying damage induced by both immune and nonimmune causes. Studies from experimental models of tubulointerstitial disease indicate that both cell-mediated and humoral immune mechanisms are relevant pathways that induce renal injury (14,15).

CELL-MEDIATED IMMUNITY

Historically, abnormalities in cell-mediated immune response have been implicated as central to the pathophysiology of TIN. Analysis of infiltrating mononuclear cells in human TIN of various etiologies demonstrated the majority of them to be T lymphocytes (16–18). The T-cell lymphocytic (CD4⁺ and CD8⁺) interstitial infiltrates generally occur in the absence of antibody deposition (5). Immunohistochemical studies conducted on biopsies obtained in drug-induced TIN also indicate the importance of cell-cell interactions in intrarenal inflammation because there is a significant increase in interstitial expression of cellular adhesion molecules. In human forms of acute TIN, increased expression of lymphocyte function-associated antigen-1 and very late antigen-4 cell-surface receptors, as well

TABLE 43.1. CLASSIFICATION OF TUBULOINTERSTITIAL NEPHRITIS (TIN)**Primary TIN**

Infection (bacterial pyelonephritis, hantavirus, leptospirosis)
 Immune-mediated (antitubular basement membrane disease)
 Drug-induced (antimicrobials, analgesics, lithium, cyclosporine, Chinese herbs)
 Toxins (lead)
 Hereditary (cystinosis, hyperoxaluria, Wilson disease)
 Metabolic disorders (hypercalcemia, hyperkalemia, hyperuricosuria)
 Hematologic disorders (sickle cell disease)
 Miscellaneous (Balkan nephropathy)

Secondary TIN

Glomerular disease
 Vascular disease
 Structural disease
 Cystic diseases
 Obstructive disease
 Reflux

Modified from Rastegar A, Kashgarian M. The clinical spectrum of tubulointerstitial nephritis. *Kidney Int* 1998;54:313–327.

as their respective ligands intercellular adhesion molecule-1 and vascular cell adhesion molecule-1, is seen in areas of mononuclear cell infiltration (19). Further support of cell-mediated events in human disease is derived from the observation of *in vivo* and *in vitro* activation of lymphocytes isolated from affected patients after repeat exposure to specific inciting agents of TIN (20,21). In view of these observations, the role of cell-mediated events in TIN has been extensively studied in murine models of anti-TBM disease and spontaneous TIN (15,22,23). In both of these models, the effector T-cell (T_e) lymphocytes that differentiate in diseased animals are CD8⁺ renal tubular antigen-specific T cells. Nephritogenic CD8⁺ T_e cells induce renal injury in genetically susceptible animals and adoptively transfer renal disease to naïve hosts (14,15,22,23).

Cell-mediated responses are initiated by T-cell recognition of relevant antigen presented in the context of appropriate major histocompatibility complex (MHC) molecules. Class I MHC molecules primarily direct CD8⁺ T cell responses, and class II MHC determinants direct CD4⁺ T cell responses (24). *In vitro* studies show that resident renal cells, such as renal tubular epithelial cells, glomerular epithelial cells, and mesangial cells, have the potential to present a variety of antigens (25,26). Correlation of *in vitro* antigen-presenting activity to disease activity *in vivo*, however, has not been established (27). It is noteworthy that renal tubular epithelial cells express class II MHC determinants in inflammatory renal disease and in culture when stimulated by proinflammatory cytokines such as interferon-gamma and tumor necrosis factor- α (28,29). Moreover, class II MHC expression on renal tubular epithelial cells induces *in vitro* proliferation of antigen-specific T-cell clones and hybridomas and promotes autoimmune renal disease *in vivo*. These findings suggest that induced class II MHC expression on renal tubular epithelial

cells promotes autoimmune injury by facilitating presentation of a self (tubular)-antigen by nonlymphoid cells (27). The cause for antigen expression by the tubular cells is unknown. Tubular epithelial cells normally do not express costimulatory molecules such as CD80 and CD86, which likely limits their ability to present antigen under physiologic conditions (30). Genetic susceptibility may play a factor in antigen expression and consequent immune response (15). Other mechanisms, such as drugs or infectious agents, may serve as inciting antigens of cell-mediated responses targeting the kidney (31,32). In addition, degenerate recognition of peptide antigens by autoreactive T cells in autoimmune disease has been reported (31,33). The potential relevance of such molecular mimicry in autoimmune T-cell activation to renal immune responses, however, awaits further investigation. There is a large body of research focused on analysis of the interaction between effector and suppressor T cells in the inflammatory process in the renal interstitium. However, their definitive role in the pathogenesis of TIN is still unclear (9,10).

ANTIBODY-MEDIATED IMMUNITY

Antibody-mediated TIN is occasionally seen. When antibodies are present on immunofluorescence investigation they are usually associated with the tubulointerstitial cells, along the basement membrane or as immune complexes. Anti-TBM staining often occurs as part of anti-GBM disease but at times it appears to be a primary phenomenon resembling experimental anti-TBM disease. Anti-TBM antibodies can be seen at times in association with drug-induced TIN and more commonly in the setting of renal transplantation due to the presence of foreign antigens in the transplanted kidney (34,35).

Primary immune deposit-mediated TIN is rare. It seems that in such instances the complexes are formed *in situ*, as circulating complexes would have been entrapped in the glomeruli. Indeed, in cases in which immune complexes are detected in the interstitium, they are also observed in the glomeruli as in systemic lupus erythematosus (SLE), immunoglobulin A (IgA) nephropathy, and membranous nephropathy. It is believed that in these disorders immune reactants are delivered to the interstitium through the process of glomerular proteinuria. The presence of interstitial immune complexes might still require cellular immune response genes for the development for complete inflammatory reaction. Most studied experimentally is anti-TBM disease. Other animal models for experimental antibody- and immune complex-mediated TIN include the Heymann nephritis antigen complex in the brush-border disorder (36) and reaction to Tamm-Horsfall protein (37).

LOCAL AND EXTRARENAL ANTIGENS

Antigens presented to the immune system may be derived from resident cells or arrive at the tubulointerstitial compart-

ment from an extrarenal origin. As mentioned previously, resident cells of the tubulointerstitial component and, in particular, tubular epithelial cells have the potential to present antigens. In addition, local antigens may be related to Tamm-Horsfall protein or uromodulin, which is a glycoprotein secreted by the cells of the ascending loop of Henle. The glycoprotein can cause immune deposits at the base of the tubular cell and the lymphatic drainage of the ascending limb and result in binding of neutrophils to the cell-surface anchored glycoprotein (38,39). In Heymann nephritis, antibodies reacting to the tubular brush border have been detected, at times associated with interstitial infiltration (40,41). Most extensively studied is the antigen in antitubular basement membrane (anti-TBM) disease, named *3M-1* (42,43). It was detected both in humans and rodents, showing extensive polymorphic expression (44,45).

Extrarenal antigens may present to the interstitium as isolated antigens or as part of an immune complex. Antigens arriving at the tissue like those originally derived from drugs such as penicillin, cephalosporin, and phenytoin, combine with antibodies and inflammatory cells that initiate the interstitial disease. Another mechanism by which outside antigens initiate an immune response is by mimicking of epitopes. For instance, some antibodies to *Escherichia coli* cross-react with Tamm-Horsfall protein (46). It is also possible that a similar mechanism operates in TIN that follows certain viral illnesses (47,48). It has also been hypothesized that noninfectious, shared epitopes may instigate the immune process, as might be the case in anti-DNA antibodies (49,50).

Circulating immune deposits that settle in the interstitium can cause TIN. This might be the case in SLE, IgA nephropathy, and possibly some cases of chronic idiopathic human tubulointerstitial nephritis (51,52). Experimentally, a model of chronic serum sickness disease in the rabbit results in immune deposits in the interstitium (53).

CYTOKINES AND AMPLIFICATION OF INJURY

Events resulting from infiltration of T cells, deposition of specific antibodies, or immune complexes that augment inflammation and injury are part of the *amplification process*. These processes include the release of cytokines and proteases from T cells; the attraction and activation of non-specific immune effector cells, including eosinophils and macrophages (18), which release various effector products; and the activation of the complement cascade. Interestingly, the presence of complement in TIN is inconsistent and when present is usually associated with deposition of IgG and immune complexes (53–55) or IgE and eosinophils (53,55,56). Even more important seems to be the activation of the alternative passway by ammonia in the absence of antibodies (57). This process may be instrumental in the process of progressive local injury in nonimmune-

mediated TIN. It may also indicate the importance of correction of metabolic acidosis in the prevention of progressive damage to the kidneys by diminishing ammonia production. It is possible that both resident epithelial cells and infiltrating cells further amplify the damage by expressing chemokines. This subclass of structurally related cytokines selectively promotes the chemotaxis, adhesion, and activation of leukocytes (58). After obstruction in the mouse, the most potent recruiter of macrophages is monocyte chemoattractant peptide-1, which is expressed in tubular epithelium (59). The chemokines induce their effect by binding to specific cell-surface receptors on target cells. The various types of leukocytes are activated by different chemokines binding to different receptors. The pharmacologic blockage of chemokines and their receptors may have a potential in controlling the inflammatory response (60). In humans with ureteropelvic junction obstruction, urinary monocyte chemoattractant peptide-1 is increased and decreases after surgical alleviation of the obstruction (61).

FIBROGENESIS AND ATROPHY

Interstitial fibrosis is the final common pathway for a variety of glomerular and tubular disorders, particularly when associated with massive glomerular proteinuria or the presence of inflammatory cells in the tubulointerstitial component (62,63). It seems that both processes induce local cytokines that transform and activate several types of resident cells in the tubulointerstitial compartment to produce new or modified extracellular matrix (64). Some of the activated cells probably change phenotype (65–67). It is unclear why what is usually a self-limited wound repair process continues unabated. It is possible that homeostatic regulatory mechanisms fail to stop or reverse fibrosis during the continuous inflammatory process of chronic TIN.

Tubulointerstitial scars are primarily composed of collagen types I and III, fibronectin, and tenascin (68,69). Other glycoproteins may participate as well. Early in the development of a scar, the fibrotic tissue may contain monocytes, tubular cells, and fibroblasts (63). It seems that the local monocytes release cytokines affecting the activity of their neighboring fibroblasts. The phenotypic expression of the fibroblast and hence the renal glycoprotein synthesized by it may be related to the type of cytokine stimulating the cell (70). Among the strongest morphogenic cytokines driving TIN fibrosis is angiotensin II (71).

The source of the fibroblasts in the tubulointerstitium is yet unknown. There are several lines of evidence that suggest they may arise from transformation of resident cells like the tubular epithelium. This mechanism is called *epithelial-mesenchymal transformation* (72–74). The transformation is probably activated by immune-mediated mechanisms and various cytokines that result in changes in the basement membrane of the tubular epithelial cell. Once

transformed to a mesenchymal cell, it acquires motility and becomes responsive to growth factor stimuli (75). Several local chemoattractants stimulate the migration of the newly formed fibroblasts. These chemoattractants are released by macrophages or the fibroblasts themselves (76,77). Fibroblasts secrete transforming growth factor β (TGF β), which amplifies the process (78). Once fibroblasts migrate to their new location, they begin to deposit fibronectin matrix, which serves as a skeleton for the deposition of other glycoproteins. Concomitantly with the transformation process, the effect of cytokines on tubular cells can result in their atrophy by disturbing their basement membrane synthesis. Additional damage to the tubular cell can be caused by T-cell clones, with cytotoxic activity resulting in tubular cell destruction and atrophy. Thus, tubular atrophy and interstitial fibrosis coexist.

ACUTE TUBULOINTERSTITIAL NEPHRITIS

Epidemiology

Acute TIN accounts for 10 to 25% of reported cases of acute renal failure (ARF) in adults (3) and up to 7% of children with ARF (79). However, in both children and adults, acute TIN may be underreported because many patients with ARF recover spontaneously after removal of the suspected offending agent, and definitive diagnosis based on a renal biopsy is not routinely established (7). Lower reported incidences of acute TIN in children than in adults may reflect more common use of nephrotoxic pharmacologic agents and greater prevalence of preexisting renal abnormalities in older patients.

Clinical, Laboratory, and Radiologic Features

The clinical manifestations of TIN are variable, and many of them are seen in both acute and chronic TIN (Table 43.2). The severity of renal impairment ranges from mild azotemia and asymptomatic urinary abnormalities to oliguric ARF (80). The nonspecific nature of the clinical findings in TIN emphasizes the need for a renal biopsy to make a definitive diagnosis in questionable cases (4,81). In one series of 13 children with biopsy-proven acute TIN, only 6 were suspected of having the diagnosis before the procedure (82). However, in a child suspected to have acute TIN, if improvement in kidney function is noticed after withholding the suspected offending agents and starting treatment, there is no need for a biopsy.

Systemic manifestations of a hypersensitivity reaction, such as fever, rash, and arthralgias, are variable findings. Although these symptoms are more likely to occur in drug-induced acute TIN (79,83), in a series of nine adults with acute TIN caused by medications, components of this classic triad were presenting symptoms in only approximately

one-half of the patients (84). The rash may be maculopapular, morbilliform, or urticarial, and it often is fleeting (84–87). Arthralgias are seldom a prominent feature (84). Acute TIN associated with infection may present with extrarenal manifestations of disease, such as fever and sore throat (82). Nonspecific constitutional symptoms of fatigue, anorexia, weight loss, nausea and vomiting, and flank pain with macroscopic hematuria may occur (85,87). Oliguria can occur, but 30 to 40% of patients with acute TIN have nonoliguric ARF (3). Hypertension and edema are seldom noted,

TABLE 43.3. PATTERNS OF RENAL TUBULAR DYSFUNCTION IN TUBULOINTERSTITIAL NEPHRITIS

Nephron site	Functional defect	Clinical manifestation
Proximal tubule	Decreased HCO ₃ , PO ₄ , amino acid, uric acid, and glucose reabsorption	Fanconi syndrome, hyperchloremic metabolic acidosis
Loop of Henle	Defective NaCl reabsorption, decreased magnesium reabsorption	Polyuria (polydipsia), salt wasting, magnesium losses
Distal tubule	Defective NaCl reabsorption and potassium and hydrogen ion secretion	Hyperkalemia, hyperchloremic metabolic acidosis, salt wasting
Collecting tubule	Defective water reabsorption	Nephrogenic diabetes insipidus

Modified from Toto RD. Review: acute tubulointerstitial nephritis. *Am J Med Sci* 1990;299:392-410.

except in specific drug-induced lesions, such as the nephrotic syndrome associated with nonsteroidal antiinflammatory drugs (NSAIDs) (88) or in TIN secondary to glomerular disease (8,80).

Acute and chronic TIN have quite similar laboratory findings (7). Renal tubular epithelial cell damage is the predominant finding in all forms of TIN, and biochemical abnormalities observed in patients with TIN may reflect injury to specific nephron segments involved in the inflammatory process (Table 43.3) (89). In general, cortical damage may affect mainly the proximal and distal tubules, whereas medullary lesions may affect mainly the loop of Henle and the collecting duct. Proximal tubule injury results in Fanconi syndrome with impaired urinary reabsorption of glucose, bicarbonate, phosphorus, amino acids, and uric acid (90). Damage to the loop of Henle may result in magnesium and sodium losses. Distal tubular lesions result in renal tubular acidosis, impaired potassium excretion, and sodium wasting (91). Biochemical abnormalities in TIN include an elevated serum creatinine concentration with hyperchloremic metabolic acidosis (3,82). If proximal tubular involvement is prominent, serum phosphorus, bicarbonate, uric acid, and potassium concentrations may be decreased. Many patients have nonoliguric renal failure, a urine concentrating defect, and relatively bland changes on urine microscopic examination.

Relevant serologic studies in the investigation of TIN are listed in Table 43.4. Normochromic, normocytic anemia is often associated with TIN (79,89). Hemolytic anemia has also been reported in acute TIN induced by allopurinol, penicillins, and rifampin (4,89). Leukocytosis may occur, and some but not all patients with drug-induced TIN have a peripheral eosinophilia (83,84,87). Drug-induced liver damage is reflected in elevated hepatic enzymes (92,93). Elevated serum IgE titers have been reported in up to 50% of biopsy-proven cases and is suggestive but not diagnostic of drug-induced TIN (80,84). Anti-DNA antibodies, antinuclear antibodies, and complement levels are normal in most forms of TIN, unless associated with a systemic autoimmune disorder (3,85). Circulating anti-TBM antibodies are detected on rare occasions (86).

 Salt-wasting

^aCommon finding in children.

^bCan be massive with nonsteroidal antiinflammatory drugs and less commonly with other drugs.

Urinary abnormalities vary considerably (Table 43.4). Microscopic hematuria is commonly detected, and macroscopic hematuria and sterile pyuria also occur (79,87). Mild to moderate proteinuria (less than 1 g/day) is detected in most patients with TIN (82). Nephrotic range proteinuria is not characteristic of TIN but has been associated with acute TIN induced by certain medications, including NSAIDs, lithium, ampicillin, and rifampin (5,94). Urinary sediment analysis shows granular, hyaline, and white blood cell casts (5). Red blood cell casts are rarely seen in acute TIN (82). *Eosinophiluria*, defined as greater than 1% of urinary leukocytes stained positively with Hansel's or Wright's stain, is suggestive of acute TIN and has been reported in 50 to 90% of patients with drug-induced acute TIN (84,95). However, eosinophiluria can be seen in many inflammatory renal diseases (96). In a study of 51 patients, eosinophiluria had a sensitivity of 40% and specificity of 72%, with a positive predictive value for TIN of only 38% (96).

Renal ultrasound examination usually demonstrates normal or enlarged kidneys, depending on the extent of tubulointerstitial inflammation and edema (3,79). Gallium citrate scanning may be useful in distinguishing acute TIN from other common causes of ARF (84). However, increased uptake on gallium scan is a relatively nonspecific finding and may be seen in cases of allograft rejection, acute pyelonephritis, and severe minimal change nephrotic syndrome (3). A definitive diagnosis of TIN can be made only by renal biopsy (3,4).

Pathology

Typical light microscopy findings in acute TIN consist of tubulointerstitial mononuclear cell infiltration and edema, with varying abnormalities in renal tubular epithelial cells (Fig. 43.1) (80,81). In general, vessels and glomerular struc-

FIGURE 43.1. Acute tubulointerstitial nephritis (TIN). Light microscopy of idiopathic TIN in a 14-year-old girl. Cortical renal parenchyma showing a normal glomerulus, extensive interstitial edema, infiltration by lymphocytes and eosinophils, and cellular epithelial tubular degenerative changes.

tures are unaffected (80,84). Mild mesangial hypercellularity or periglomerular inflammation and fibrosis occasionally are seen (82). Cellular infiltrates, primarily of lymphocytes, often are patchy and are variably distributed throughout the kidney (5,84). Monocytes, macrophages, and plasma cells are also commonly noted in affected areas (82,85). Eosinophils are most commonly seen with drug-induced acute TIN and can comprise up to 10% of the infiltrate (86). Interstitial granulomas occasionally are seen, particularly in drug-induced or infection-related acute TIN (97). Complement and immunoglobulin deposition is not characteristic of acute TIN (5,98,99) but has been noted in children with acute TIN because of SLE, syphilis, hepatitis B, shunt nephritis, and some drug-induced lesions (100).

Tubular epithelial cell damage varies from minimal histologic changes to frank necrosis (83,98). Most often there is flattening of renal tubular cells with atrophy, degeneration, and loss of the brush border in proximal convoluted tubules (5,8). Renal tubules are commonly dilated, with splitting or fracturing of the basolateral membrane. The tubule lumens may contain desquamated cells or blood (8,82). In some instances, infiltrating lymphocytes are observed between tubular epithelial cells (84). Electron microscopy typically reveals striking renal tubular epithelial cell mitochondrial damage, cytoplasmic vacuoles, and significantly dilated rough endoplasmic reticulum (81,82,84).

Etiology

The causes of acute TIN can be grouped into four broad categories: medications, infections, immunologic diseases, or idiopathic processes (Table 43.5). As described in the Pathology section of this chapter, all forms of acute TIN have similar pathologic features. Unique features of distinct forms of acute TIN are described in more detail.

Medications

Medications, rather than infection, are now the leading cause of acute TIN in children (8). An ever-increasing list of medications is implicated as causing acute TIN (Table 43.6). Establishing a clear link between a medication and acute TIN may be difficult, however, because many case reports of drug-induced acute TIN are in patients who have received several medications simultaneously. Nevertheless, a few categories of drugs are consistently associated with acute TIN in both children and adults: antibiotics, NSAIDs, anti-convulsants, and diuretics (83,84,87). Although symptoms of acute TIN caused by a specific drug can occur within hours or months after starting a medication, they are usually seen 2 to 3 weeks after starting therapy (4). Antimicrobials and NSAIDs are the most common drugs causing acute TIN in children (83,87). The incidence of acute TIN caused by methicillin, which is no longer used, was 16% (87). The incidence of acute TIN with currently available

penicillins is significantly less than that previously observed with methicillin. Systemic manifestations of hypersensitivity with fever, rash, and eosinophilia in the setting of ARF can occur in up to 30% of patients with penicillin-induced acute TIN (4). By contrast, these hypersensitivity manifestations are not typically associated with NSAID-induced acute TIN (88). NSAID-induced TIN may be associated with minimal change nephrotic syndrome (94). Although NSAID-induced acute TIN in children occurs less often than in adults, the increasing availability of over-the-counter NSAID preparations for children may result in an increase in cases in that age group.

Drug-induced acute TIN is an idiosyncratic reaction, and, as such, it is difficult to predict which patients will be affected. No specific risk factors have been consistently identified. Acute TIN has been reported with various routes of administration, including oral, intravenous, intramuscular, and rectal (83,87,98,101). Duration and the dosage of therapy also do not correlate well with the development of disease, although several reports suggest that acute TIN is more common with high-dose therapy (7,87).

The association of drug-induced acute TIN with fever, rash, and eosinophilia suggests an underlying allergic reaction to administered drugs. Reports of accelerated, recurrent TIN on drug rechallenge also implicate drug hypersensitivity (101,102). Administration of structurally similar medications may induce cross-reactivity as evidenced by recurrent acute TIN after cephalosporin administration in individuals with previous penicillin-induced TIN (87).

Drug-induced acute interstitial nephritis was found to be a cause for graft dysfunction in kidney transplant recipi-

ents. Early diagnosis and treatment prevented permanent damage (103).

Infections

In the preantibiotic era, infection, especially streptococcal, was the predominant cause of acute TIN in children. Councilman's initial postmortem findings of TIN involved 42 children who succumbed to scarlet fever (104). With the development of effective antimicrobial therapy, the incidence of *Streptococcus*-associated acute TIN has decreased. Other infectious organisms have become important causes of acute TIN. These include unusual bacteria such as *Rickettsia* species, *Yersinia*, and mycoplasma. Viruses, such as adenovirus and human immunodeficiency virus, and parasites are also causes of acute TIN (Table 43.7) (5,105–107). Infections may induce acute TIN by two distinct processes. Organisms may directly invade the renal parenchyma, producing local renal infection and inflammation. This form of acute TIN may respond to treatment of the underlying infection. Alternatively, organisms may induce “reactive” intrarenal inflammation without evidence of renal infection. The latter mechanism is implicated by the observation that group A streptococcal infections can cause acute TIN in children, even with appropriate antibiotic therapy (82). Mechanisms for the renal inflammatory reaction in the absence of renal infection are not clearly elucidated but are presumed to be immunologically mediated (82).

Immunologic Diseases

Immunologic diseases elicit acute TIN in two distinct settings (Table 43.5). TIN occurs with either a primary glomerular lesion or, less commonly, as an isolated primary TIN. SLE is the most important cause of acute TIN seen in association with glomerulonephritis in children. Tubulointerstitial immune deposits may be present in up to 60% of SLE patients who are biopsied and correlate with both severity of interstitial inflammation and degree of functional renal impairment (108,109). As is the case with other glomerular diseases, severe tubulointerstitial involvement with fibrosis is a poor prognostic indicator for renal function (100). Acute TIN occasionally is seen in children with membranous nephropathy, postinfectious glomerulonephritis, and shunt nephritis (100). IgA nephropathy was associated with significant TIN in 37% of 51 patients (110). At follow-up, patients with renal tubular deposits had significantly worse renal function than those with isolated glomerular findings (110). Immunologic diseases that present with isolated tubulointerstitial involvement are tubulointerstitial nephritis with uveitis (TINU) syndrome, allograft rejection, and rarely SLE (111,112). Allograft rejection is discussed in detail in Chapter 75.

TINU syndrome was first described in 1975 in a report of two adolescent girls who developed ARF with eosino-

philic TIN associated with anterior uveitis and bone marrow granulomas (113). Subsequent reports have highlighted the significant adolescent female predominance (111). The pathogenesis of this syndrome remains unclear, and preliminary evidence suggests roles for both humoral- and cell-mediated immune mechanisms. Circulating or deposited immune complexes were detected in up to 60% of patients (114,115). A significant number of patients, however, have no evidence of tubulointerstitial immune deposits on renal biopsy. Analysis of the lymphocytic infiltrates on biopsies of patients with TINU demonstrated a predominance of activated memory T-helper cells, thus providing further evidence for cell-mediated events (111). A genetic predisposition is suggested by the occurrence of TINU in identical twins within the same year (116).

Patients usually have anorexia, fever, weight loss, abdominal pain, and polyuria. Eye tenderness may not be evident at presentation, as uveitis could occur at any time with respect to the onset of renal disease (117). Laboratory abnormalities include an elevated erythrocyte sedimentation rate, increased serum IgG levels, azotemia, and non-hemolytic anemia. Urinary abnormalities include proteinuria, glucosuria, and sterile pyuria. The interstitial nephritis resolves completely, either spontaneously or after steroid therapy in most cases. In a study of 21 children with acute TIN, TINU patients required a longer period of time for the renal function to recover in comparison with other etiologies (118). The uveitis often requires multiple steroid courses and other immunosuppressives, like methotrexate, azathioprine, and cyclosporin A, and may relapse (100,119).

^aCases reported in children.

^bIncompletely documented or isolated cases.

Modified from Colvin RB, Fang LST. Interstitial nephritis. In: Tischer CC, Brenner BM, eds. *Renal pathology*. Philadelphia: JB Lippincott, 1994:723–768.

Recent case reports described the association of TINU with granulomatous hepatitis (120), hyperthyroidism (121), and Epstein-Barr virus infection (122).

Idiopathic

Idiopathic cases of acute TIN are uncommon in childhood. In a series of 12 children with biopsy-proven acute TIN, only 1 had idiopathic disease (8). These cases are diagnosed

by exclusion of the previously described entities and usually are not associated with hypersensitivity symptoms of fever, rash, or eosinophilia (3).

Treatment and Prognosis

The initial treatment of acute TIN is primarily supportive, with dialysis therapy as indicated (3,4). It is important to immediately discontinue all possible offending medications, which in many patients might be multiple. When replacing the suspected medications, it is important to select medications that are not potentially cross-reactive (e.g., a cephalosporin to replace a β -lactam penicillin) or other potentially nephrotoxic agents (87). In infection-related acute TIN, specific treatment of the underlying infection is indicated (82).

The use of corticosteroid therapy for acute TIN remains controversial (7). Anecdotal case reports and uncontrolled trials with small numbers of patients suggest a therapeutic benefit (9,79,82). However, prospective controlled studies of corticosteroids or other cytotoxic agents in acute TIN are lacking, and it is possible that many reported patients would have recovered merely from the withdrawal of the inciting agent. Various steroid treatment regimens for acute TIN have been reported, primarily in the adult literature (84,123). Some children have been treated with daily prednisone at a dosage of 2 mg/kg/day, which is tapered rapidly over 2 to 4 weeks (82). Pulse methylprednisolone followed by high-dose daily or alternate-day prednisone has also been used in adults (123). In idiopathic cases and in those in whom removal of the offending agent do not result in improvement, we use a similar protocol of pulse methylprednisolone followed by daily oral prednisone of 2 mg/kg (maximum dose, 80 mg) for 4 weeks, then change to alternate day treatment and taper over a period of several months depending on the response.

Prognosis for recovery of renal function in children with acute TIN is excellent (8,79,82,87). Most affected patients recover renal function completely within weeks to months of onset of ARF. The mean renal recovery time of 13 children with acute TIN from various causes was 69.5 ± 34.7 days (82). All patients had normal serum creatinine and urinalysis at follow-up examination 1.5 to 10.0 years after presentation. Of note, the clinical or histologic severity of disease at presentation did not correlate with rate of recovery of renal function. Another study of seven children with acute TIN, 42% of who required dialysis, reported a renal recovery rate of 86% (79). In two studies of adults with acute TIN, poor prognostic factors included the severity of the interstitial inflammation on renal biopsy and the duration of ARF (124,125).

CHRONIC INTERSTITIAL NEPHRITIS

Epidemiology

Chronic TIN in children occurs primarily in the setting of obstructive uropathy, vesicoureteral reflux, and inherited

conditions (3,9). Obstructive uropathy accounts for almost 20% of all children who develop end-stage renal disease (126). Primary chronic TIN from other causes accounts for only 2 to 4% of children with chronic renal failure (126). In a few families, chronic TIN has been described in association with cholestatic liver disease (92,93) and in others with mitochondrial abnormalities (127,128).

Clinical, Laboratory, and Radiologic Features

Chronic TIN tends to progress more slowly than other forms of chronic renal diseases, and therefore, affected individuals often have no clinical evidence of disease until late in the course of renal insufficiency (3). Many patients have nonspecific constitutional symptoms characteristic of chronic renal failure, with weight loss, growth retardation, fatigue, anorexia, vomiting, and occasionally polyuria and polydipsia (129). Hypertension may also occur (130). Patients with the syndrome of chronic TIN associated with cholestatic liver disease may also have symptoms of hepatic dysfunction, such as pruritus and scleral icterus (131). Naturally, in children with chronic TIN, a major manifestation may include growth failure.

The clinical, laboratory, and radiologic findings in chronic TIN are in essence similar to those observed in acute TIN. However, as in other cases of chronic kidney failure, the deterioration in kidney function is insidious, and the medical history might extend back to a longer period. In contrast to some patients with acute TIN, patients with chronic TIN do not have oliguria; on the contrary, some may be polyuric. In advanced cases, renal ultrasonography shows small and hyperechogenic kidneys. Skeletal radiographs may show renal osteodystrophy and in the case of Fanconi syndrome rickets and osteomalacia.

Pathology

Histologic findings in chronic TIN are characterized by tubulointerstitial fibrosis with a lymphocytic infiltrate, as well as tubular atrophy and thickening of the TBM (3,132). When renal damage is associated with high intratubular pressure, as occurs with vesicoureteral reflux and urinary tract obstruction, dilated renal tubules are particularly evident (81). In primary chronic TIN, glomeruli are often normal until late in the course of disease, when periglomerular fibrosis and global sclerosis are seen (Fig. 43.2) (131,132).

Etiology

The causes of chronic TIN are summarized in Table 43.8. Of note, acute TIN from any cause can progress to chronic TIN if the disease process is not abated by removal of the inciting agent or steroid therapy. Secondary chronic TIN

FIGURE 43.2. Chronic tubulointerstitial nephritis (TIN). Light microscopy of idiopathic chronic TIN in a 12-year-old boy. Renal cortex showing moderate interstitial fibrosis, tubular atrophy, and tortuosity. The interstitium is infiltrated by scattered mononuclear cells. A preserved glomerulus with periglomerular fibrosis is seen.

associated with primary glomerular or vascular disorders, especially focal segmental glomerulosclerosis and hemolytic uremic syndrome, is a common histologic finding in patients with progressive renal disease (133).

Chronic TIN in children most commonly is due to obstructive uropathy or high-grade vesicoureteral reflux, especially when associated with urinary tract infections (126). Urinary tract obstruction of only a few weeks' duration may result in irreversible renal damage (7). Isolated vesicoureteral reflux without obstruction might also be associated with chronic TIN in children. Interstitial damage and progressive fibrosis in these disorders may result from renal immune responses that amplify tubulointerstitial injury initially induced by high urinary tract pressures in the setting of infection. Persistent and progressive renal inflammation and damage can occur, however, despite relief of the obstruction or surgical correction of the vesicoureteral reflux (127,134,135).

Treatment and Prognosis

There is currently no known effective therapy for chronic TIN. Naturally, when an offending agent is detected, it should be removed. However, even in such cases the damage may be irreversible and its progression self-perpetuating. Some experimental data indicate the potential for pharmacotherapy in stopping or slowing the inflammatory, apoptotic, and fibrotic mechanisms by blocking their stimulating signals and activity. For instance, in the mouse model of unilateral obstruction, injury to the kidneys starts with increased angiotensin II production, which activates TGF β in a cascade, leading to tubulointerstitial inflammation and fibrosis (59). The use of angiotensin-converting enzyme (ACE) inhibitors in this model dimin-

TABLE 43.8. ETIOLOGIC CLASSIFICATION OF CHRONIC INTERSTITIAL NEPHRITIS

Drug-related	Systemic lupus erythematosus ^a

^aCommon cause in children.

ished transformation of renal cells to interstitial myofibroblasts and decreased migration of inflammatory cells into the interstitium. However, ACE inhibitors do not affect tubular atrophy (59).

In a recent study in the mouse model of unilateral ureteral obstruction, injection of exogenous hepatocyte growth factor blocked myofibroblast activation and dramatically prevented interstitial fibrosis (136). The study suggested that blockage of the transition of tubular epithelial cells to myofibroblasts may provide a novel therapeutic approach in halting fibrosis. In another study on the same animal model, administration of bone morphometric protein-7 prevented tubulointerstitial fibrosis and inhibited tubular atrophy by prevention of apoptosis. The exact mechanism

of action by which bone morphometric protein-7 provides a renoprotective effect is yet unknown (59). Several studies have demonstrated the potential of 3-hydroxy-3-methylglutaryl CoA reductase inhibitors, like simvastatin and fluvastatin, in ameliorating interstitial fibrosis in animal models (137,138). Other studies examined the effect of blocking TGF β and its mediators, like connective tissue growth factor in tissue fibrosis (139). A different direction of investigation is focused on the potential protective effect of nitric oxide in chronic TIN (61,140,141).

At the moment, patients with chronic TIN are treated with supportive therapy. Whether the use of angiotensin-converting enzyme inhibitors or 3-hydroxy-3-methylglutaryl CoA reductase inhibitors in human chronic TIN is

effective as it is in some glomerular diseases associated with proteinuria has yet to be proven.

The prognosis for normalization of renal function in chronic TIN is less favorable than in acute disease. In specific forms of chronic TIN, such as juvenile nephronophthisis, progression to end-stage renal disease is almost inevitable (129,130). By contrast, patients with chronic TIN in the setting of obstructive uropathy have a more variable clinical course (127,134).

SYSTEMIC DISEASE

RENAL VASCULITIS

RUDOLPH P. VALENTINI
WILLIAM E. SMOYER

Renal vasculitis, or inflammation of the blood vessels involving the kidney, is a process mediated by neutrophilic infiltration of vessel walls resulting in fibrinoid necrosis. Its consequences include compromise of the vascular lumen and tissue ischemia. *Renal vascular involvement* is defined as a process affecting the blood supply to the kidney and its vessels within. Therefore, this consists of vessels of various sizes such as the aorta, renal artery, renal arterioles, or glomerular capillaries. Typically, renal manifestations of vasculitis include hypertension and glomerulonephritis.

Pediatric diseases associated with renal vasculitis may be renal-limited, but are more commonly systemic. Those with systemic manifestations may involve other large, medium, and small vessels outside of the renovascular system, such as the subclavian arteries, coronary arteries, alveolar capillaries, and postcapillary venules of the dermis. Depending on the organ systems involved, sinopulmonary, dermatologic, gastrointestinal (GI), and/or musculoskeletal symptoms may develop. In an effort to afford clinicians an easier way to differentiate the various forms of systemic vasculitis, a few classification schemes have been developed. Because no one classification scheme is complete, a combination of various schemata is typically needed.

A clinical classification scheme based on the organs involved can be used to develop a differential diagnosis. For example, a child presenting with glomerulonephritis and pulmonary hemorrhage is considered to have a pulmonary renal syndrome. The differential diagnosis for this clinical entity includes Wegener granulomatosis (WG), microscopic polyangiitis (MPA), anti-glomerular basement membrane (anti-GBM) disease, systemic lupus erythematosus (SLE), and Henoch-Schönlein purpura (HSP) (Table 44.1). This differential diagnosis can be further narrowed after considering further clinical and laboratory data.

Another vasculitis classification scheme relates to the caliber of the vessel(s) involved. The differential diagnosis can be separated into diseases involving small, medium, or large vessels. The small vessel vasculitides with renal involvement (e.g., HSP, SLE, WG, MPA, Churg-Strauss disease, and anti-GBM disease) typically affect the glomerular capillaries and manifest

clinically as glomerulonephritis. The vasculitides involving larger vessels such as classic polyarteritis nodosa (cPAN) (medium vessels) or Takayasu's arteritis (TA) (large vessels) are more apt to result in renal ischemia and hypertension.

Further characterization of a child with a small vessel vasculitis manifesting as a pulmonary renal syndrome requires laboratory testing and in many instances a tissue biopsy. Serologic testing includes C3 and C4, antinuclear antibodies (ANAs), anti-double-stranded DNA antibodies, anti-GBM antibodies, antineutrophil cytoplasmic autoantibodies (ANCA), anti-proteinase 3 (PR3) antibodies, and anti-myeloperoxidase (MPO) antibodies.

A histologic classification scheme uses features of the renal biopsy to differentiate disease states. Light microscopy can point out the presence of a necrotizing glomerulonephritis as can be seen in the small vessel vasculitides. In addition, the presence of granulomas would point further toward WG or Churg-Strauss disease (1). Unfortunately, granulomas, when present, are less likely to be seen on a renal biopsy when compared to a lung biopsy (2,3).

Immunofluorescence is the most useful part of the renal biopsy when classifying forms of renal vasculitis. Immune complex diseases such as HSP and lupus have characteristic glomerular staining patterns. Linear immunoglobulin G staining along the GBM is characteristic of anti-GBM disease. Minimal or absent immunofluorescence staining is seen in the pauciimmune glomerulonephritides, such as WG, MPA, Churg-Strauss disease, and ANCA (+) pauci-immune crescentic glomerulonephritis. A summary of the above classification systems can be seen in Table 44.2.

This background is used as a foundation on which to develop a more detailed comparison of these various forms of renal vasculitis. The reader should note that anti-GBM antibody disease (Goodpasture disease) is not always classified with vasculitis, although it is an immune-mediated process resulting in a focal necrotizing and crescentic glomerulonephritis and pulmonary hemorrhage. For further discussion of anti-GBM antibody disease, see Chapter 34. The forms of vasculitis are discussed by the size of the vessel involved beginning with the small vessel vasculitides.

TABLE 44.1. PULMONARY RENAL SYNDROMES IN CHILDREN

Antineutrophil cytoplasmic autoantibody–associated diseases
Wegener granulomatosis
Microscopic polyangiitis
Churg-Strauss syndrome
Immune complex diseases
Systemic lupus erythematosus
Henoch-Schönlein purpura
Anti-glomerular basement membrane disease (Goodpasture disease)
Other
<i>Legionella</i> infection
Renal vein thrombosis with pulmonary embolus

SMALL VESSEL VASCULITIS

By definition, the *small vessel vasculitides* are diseases with a predilection for involvement of small arteries, arterioles, capillaries, and postcapillary venules. The differential diagnosis for this disease category is quite extensive. As mentioned earlier, the types of small vessel vasculitis can be further classified using immunopathology. When glomerulonephritis is present, the immunofluorescence component of the renal biopsy reveals the presence or absence of significant immunostaining and results in classification as immune complex–mediated disease, anti-GBM disease, or pauciimmune disease.

Immune Complex–Mediated Disease

The two most common systemic forms of immune complex–mediated small vessel vasculitis with renal involvement in pediatrics are HSP and SLE. These two topics are dealt with in Chapters 45 and 46.

TABLE 44.2. RENAL VASCULITIS IN CHILDREN

Systemic diseases with renal involvement
Large vessel vasculitis
Takayasu's arteritis
Medium vessel vasculitis
Polyarteritis nodosum
Kawasaki disease
Small vessel vasculitis
Immune complex diseases
Systemic lupus erythematosus
Henoch-Schönlein purpura
Pauciimmune diseases
Granulomatous
Wegener granulomatosis
Churg-Strauss Disease
Non-granulomatous
Microscopic polyangiitis
Anti-glomerular basement membrane disease
Renal-limited disease
Antineutrophil cytoplasmic autoantibodies (+) pauciimmune crescentic glomerulonephritis

Pauciimmune-Mediated Disease

By definition, pauciimmune vasculitis is a small vessel vasculitis that features minimal or no immune deposits on immunofluorescence on a renal biopsy. Most varieties are ANCA associated, but a small number are ANCA negative (4,5). Based on the Chapel Hill Consensus Conference, ANCA-associated vasculitis is comprised of three systemic diseases and one renal limited disease (1). MPA is an ANCA-associated systemic vasculitis that often involves the skin, lungs, and kidneys. It is characterized by a positive ANCA test [perinuclear ANCA (pANCA) or cytoplasmic ANCA (cANCA)], absence of airway symptoms, and absence of granulomas on biopsy. WG is a systemic vasculitis with multiorgan involvement, including the respiratory tract; is usually cANCA positive; and is characterized by the presence of granulomas on biopsy. Churg-Strauss disease is the third ANCA-associated systemic vasculitis and is characterized by the presence of granulomas on biopsy and clinical asthma and eosinophilia. The renal limited ANCA (+) vasculitis is known as *pauciimmune crescentic glomerulonephritis*. These four entities are described in greater detail later beginning with the granulomatous ANCA (+) systemic vasculitides.

Wegener Granulomatosis

WG is a clinicopathologic entity that is uncommon in children. The triad of generalized WG consists of necrotizing granulomatous lesions of the upper or lower respiratory tract, generalized necrotizing vasculitis involving both small- and medium-sized vessels, and focal necrotizing glomerulonephritis (6,7). Regional WG is distinguished from generalized WG by the absence of renal disease. While the largest case series have been reported in adults, scattered reports of WG exist in the pediatric literature (8–10). Since the advent of ANCA testing, the definitions of WG have been revised. This has enabled clinicians to better distinguish it from MPA, a disease with which it shares much in common.

The definition of WG, as determined by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis, requires evidence of granulomatous inflammation (1). This “new” definition is contrasted from that previously used by the National Institute of Health (NIH) studies of WG patients. At the NIH, patients were required to have a clinical history compatible with WG and histologic evidence of either a vasculitis or granulomatous inflammation in a typical organ system (10). The absence of an absolute need for evidence of granulomatous inflammation in the NIH studies suggests that their WG patient population also included patients who are today classified as MPA. This distinction makes comparison of older studies to more modern ones difficult.

This section focuses on renal manifestations of WG and their treatment. The extrarenal symptoms are discussed

FIGURE 44.1. A: A 10-year-old boy with a history of fever, rash, and arthritis presented with hemoptysis accompanied by hematuria and proteinuria. His c-antineutrophil cytoplasmic autoantibody was positive at 1:512. Chest x-ray revealed opacification of the middle and lower lung fields on the right side. B: Ten weeks later, a follow-up chest x-ray showed complete resolution of the pulmonary infiltrates.

only briefly, as more comprehensive reports exist in the otolaryngology and ophthalmology literature (12,13).

From the outset of its initial descriptions in the literature, the prognosis of patients afflicted with WG was grim. Untreated adults with WG survived an average of only 5 months, with 82% succumbing to the disease within the first year and 90% by the second year (14). Corticosteroid treatment only increased the mean survival time to 12.5 months. The advent of cytotoxic therapy for WG, however, resulted in markedly improved patient survival. At a mean follow-up of 51 months, Fauci et al. reported a patient survival rate of 88% in 85 patients with WG (2).

The most comprehensive report on children with WG was published from the NIH (8). This study did not include any data on ANCA testing but described the clinical presentation, clinical course, and morbidity of children classified as having WG. Affected children were predominantly adolescent (mean age of onset, 15.4 years) and female (16 of 23 patients). There was a median of 8 months from onset of symptoms until a definitive diagnosis was secured. Clinical features at presentation were largely sino-pulmonary, followed later by renal symptoms.

Children with WG usually sought medical attention for symptoms related to the upper and lower respiratory tract. Ear, nose, and throat pathology was present in 87% of patients, with sinusitis occurring most commonly (61%) (8). Large numbers of children developed large airway disease early on and subglottic stenosis later in their courses. The 48% of pediatric patients with subglottic stenosis far exceeded the 10% occurrence reported in adults (11). Pul-

monary involvement in WG can range from asymptomatic to severe and fulminant. Pulmonary infiltrates (61%), pulmonary nodules (43%), and hemoptysis (26%) were the most common lung abnormalities. Radiographic abnormalities may occur in the absence of symptoms. In its most severe form, WG may present as life-threatening diffuse alveolar hemorrhage, which is often accompanied by progressive glomerulonephritis (Fig. 44.1).

Constitutional symptoms at disease onset included fever and weight loss. Other systemic symptoms at presentation included arthralgia/arthritis in approximately one-third of patients and rash in 9%. Eye disease was common and included dacrycystitis, proptosis, eye pain, and episcleritis.

The neurologic and cardiovascular systems can be involved as well. The adult literature states that 4% of patients with WG present with nervous system involvement, but it eventually develops in 10 to 34% (15). A peripheral neuropathy such as mononeuritis multiplex has been the most frequent neurologic manifestation described in adults with WG. Cardiac involvement is rarely detected antemortem but includes pericarditis and coronary arteritis in 10 to 20% of cases. Necrotizing vasculitis of the coronary vessels can result in a myocardial infarction or sudden death (15).

In this same large pediatric WG series, glomerulonephritis was present in only 9% of children at disease presentation, although it ultimately developed in 61% during the course of their disease (8). Hematuria, proteinuria, and renal insufficiency were common, whereas hypertension and gross hematuria were unusual. Fifty-seven percent of

children with renal involvement developed chronic renal insufficiency, and 14% required dialysis.

The incidence of WG in children is difficult to determine, but it is known to occur much less frequently than in adults. According to the 1999 United States Renal Data Systems Annual Data Report, WG was the underlying cause of end-stage renal disease (ESRD) in 40 pediatric patients (age younger than 20) over 5 years (1993 to 1997). The median age of these patients was 16 years. Forty-eight percent were male and 82% were white (16).

Pathogenesis

Necrotizing vasculitis of small arteries and veins together with granuloma formation are the hallmark lesions of WG. Granulomatous necrotizing lesions are most commonly found in the respiratory tract. Lung involvement may include bilateral nodular cavitary infiltrates (15). The renal biopsy lesion is that of a pauciimmune-necrotizing and crescentic glomerulonephritis.

The pathogenesis of WG is still unknown. The role of ANCA has not yet been determined. An autoimmune mechanism seems likely, but direct evidence does not yet exist *in vivo*. It is known that *in vitro* neutrophils from patients with active WG express PR3 on their surface, thus increasing their accessibility to circulating PR3 antibodies. Furthermore, "primed" neutrophils from patients with WG have increased basal superoxide anion production, which enhances their inflammatory potential (17). In addition, *in vitro* tests have shown that neutrophils activated by ANCA are retained within the vessel longer owing to increased endothelial adhesion and reduced transendothelial migration, thereby increasing their ability to induce endothelial injury (18). Finally, ANCA induces endothelial injury *in vitro* through the activation of neutrophils that release reactive oxygen radicals and inflammatory cytokines and proteases (reviewed in 18). Respiratory infections may be part of the inciting event for both the initial onset of disease, as well as for relapses. There is also an increased association of WG and the HLA-B8 and HLA-DR2 gene loci (19,20).
