

PEDIATRIC NEPHROLOGY

FIFTH EDITION

PEDIATRIC NEPHROLOGY

FIFTH EDITION

Edited By

ELLIS D. AVNER, M.D.

*Associate Dean for Research
Professor of Pediatrics and Physiology
Medical College of Wisconsin
Director, Children's Research Institute
Children's Hospital Health System of Wisconsin
Milwaukee, Wisconsin*

WILLIAM E. HARMON, M.D.

*Associate Professor of Pediatrics
Harvard Medical School
Director, Division of Nephrology
Children's Hospital Boston
Boston, Massachusetts*

PATRICK NIAUDET, M.D.

*Professor of Pediatrics
Department of Pediatric Nephrology
Hôpital Necker Enfants Malades
Paris, France*

with 132 contributing authors

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of health care providers to ascertain the FDA status of each drug or device planned for use in their clinical practice.

CONTENTS

Contributing Authors ix
Preface and Dedication xv

SECTION I: DEVELOPMENT 1

- 1 Embryology** 3
Adrian S. Woolf
- 2 Glomerular Circulation and Function** 25
Valentina Kon and Iekuni Ichikawa
- 3 Tubular Function** 45
Deborah P. Jones and Russell W. Chesney
- 4 Perinatal Urology** 73
David A. Diamond and Craig A. Peters
- 5 Renal Dysplasia/Hypoplasia** 83
Paul R. Goodyer
- 6 Syndromes and Malformations of the Urinary Tract** 93
Chanin Limwongse and Suzanne B. Cassidy

SECTION II: HOMEOSTASIS 123

- 7 Sodium and Water** 125
Howard Trachtman
- 8 Potassium** 147
George J. Schwartz
- 9 Acid-Base Homeostasis** 189
James C. M. Chan and Robert H. K. Mak
- 10 Calcium and Phosphorus** 209
Anthony A. Portale
- 11 Disorders of Phosphorus, Calcium, and Vitamin D** 237
Craig B. Langman
- 12 Nutrition and Metabolism** 255
Corina Năilescu, Phyllis J. Kaskel, and Frederick J. Kaskel
- 13 Fluid and Electrolyte Therapy in Children** 275
Michael J. G. Somers

SECTION III: RESEARCH METHODS 299

- 14 Molecular Biology** 301
Francesco Emma and Gian Marco Ghiggeri
- 15 In Vitro Methods in Renal Research** 317
Patricia D. Wilson
- 16 Animal Models** 335
Jordan A. Kreidberg
- 17 Clinical Investigation** 347
Susan L. Furth and Jeffrey Fadrowski
- 18 Genetics** 363
Lisa M. Guay-Woodford
- 19 Tissue Engineering** 373
Anthony Atala

SECTION IV: CLINICAL METHODS 385

- 20 Clinical Evaluation** 387
T. Martin Barratt and Patrick Niaudet
- 21 Laboratory Investigations** 399
Jean-Pierre Guignard and Fernando Santos
- 22 Evaluation of Growth and Development** 425
Sandra L. Watkins and Gail E. Richards
- 23 Diagnostic Imaging** 449
Fred E. Avni and Michelle Hall
- 24 Renal Pathology** 475
Agnes B. Fogo

SECTION V: GLOMERULAR DISEASE 501

- 25 Congenital Nephrotic Syndrome** 503
Christer Holmberg, Karl Tryggvason, Marjo K. Kestilä, and Hannu J. Jalanko
- 26 Inherited Glomerular Diseases** 517
Marie Claire Gubler, Laurence Heidet, and Corinne Antignac

- 27 Steroid-Sensitive Idiopathic Nephrotic Syndrome in Children** 543
Patrick Niaudet
- 28 Steroid-Resistant Idiopathic Nephrotic Syndrome in Children** 557
Patrick Niaudet
- 29 Immune Mechanisms of Glomerular Injury** 575
Allison A. Eddy
- 30 Acute Proliferative Glomerulonephritis** 601
Endre Sulyok
- 31 Immunoglobulin A Nephropathy** 615
Norishige Yoshikawa
- 32 Membranoproliferative Glomerulonephritis** 629
C. Frederic Strife, Michael C. Braun, and Clark D. West
- 33 Membranous Nephropathy** 641
Sudesh Paul Makker
- 34 Crescentic Glomerulonephritis** 655
Michael J. Dillon

SECTION VI: TUBULAR DISEASE 663

- 35 Nephronophthisis-Medullary Cystic Kidney Disease** 665
Friedhelm Hildebrandt
- 36 Polycystic Kidney Disease** 675
Katherine MacRae Dell, Ruth A. McDonald, Sandra L. Watkins, and Ellis D. Avner
- 37 Aminoaciduria and Glycosuria** 701
Israel Zelikovic
- 38 Tubular Disorders of Electrolyte Regulation** 729
Juan Rodríguez-Soriano
- 39 Renal Tubular Acidosis** 757
John T. Herrin
- 40 Nephrogenic Diabetes Insipidus** 777
Nine V. A. M. Knoers and Leo A. H. Monnens
- 41 Cystinosis and Fanconi Syndrome** 789
John W. Foreman
- 42 Primary Hyperoxaluria** 807
Pierre Cochat and Laure B. D. E. Collard
- 43 Tubulointerstitial Nephritis** 817
Uri S. Alon

SECTION VII: SYSTEMIC DISEASE 833

- 44 Renal Vasculitis** 835
Rudolph P. Valentini and William E. Smoyer

- 45 Henoch-Schönlein Purpura** 851
Rosanna Coppo and Alessandro Amore
- 46 Systemic Lupus Erythematosus** 865
Patrick Niaudet and Rémi Salomon
- 47 Hemolytic Uremic Syndromes** 887
Chantal Loirat and C. Mark Taylor
- 48 Sickle Cell Nephropathy** 917
Jon I. Scheinman
- 49 Diabetic Nephropathy** 931
Leonard G. Feld
- 50 Renal Manifestations of Metabolic Disorders** 941
William G. van't Hoff
- 51 Infectious Diseases and the Kidney** 955
Amitava Pahari, Sam Walters, and Michael Levin
- 52 Nephrotoxins** 987
Russell W. Chesney and Deborah P. Jones

SECTION VIII: URINARY TRACT DISORDERS 1005

- 53 Urinary Tract Infection** 1007
Sverker Hansson and Ulf Jodal
- 54 Vesicoureteral Reflux and Scarring** 1027
H. Gil Rushton, Jr.
- 55 Obstructive Uropathy** 1049
Robert L. Chevalier and Jonathan A. Roth
- 56 Bladder Dysfunction** 1077
Dawn L. McLellan and Stuart B. Bauer
- 57 Urolithiasis** 1091
Dawn S. Milliner
- 58 Pediatric Renal Tumors** 1113
Christopher S. Cooper and Jack S. Elder

SECTION IX: HYPERTENSION 1123

- 59 Epidemiology of Hypertension** 1125
Jean U. Bender, Melvin A. Bonilla-Felix, and Ronald J. Portman
- 60 Pathophysiology of Hypertension** 1153
Joseph T. Flynn and Robert P. Woroniecki
- 61 Evaluation of Hypertension in Childhood Diseases** 1179
Eileen D. Brewer
- 62 Treatment of Hypertension** 1199
Beth A. Vogt and Ira D. Davis

SECTION X: ACUTE RENAL FAILURE 1221

- 63** Pathogenesis of Acute Renal Failure 1223
Norman J. Siegel, Scott K. Van Why, and Prasad Devarajan
- 64** Clinical Evaluation and Management 1233
Sharon P. Andreoli
- 65** Management of Acute Renal Failure 1253
Mark R. Benfield and Timothy E. Bunchman

SECTION XI: CHRONIC RENAL FAILURE 1267

- 66** Pathophysiology of Progressive Renal Disease 1269
Agnes B. Fogo and Valentina Kon
- 67** Conservative Management of Chronic Renal Insufficiency 1291
Richard N. Fine, Dilys A. Whyte, and Ivy I. Boydston
- 68** Endocrine and Growth Disorders in Chronic Renal Failure 1313
Franz Schaefer
- 69** Renal Osteodystrophy 1347
Beatriz D. Kuizon and Isidro B. Salusky
- 70** Peritoneal Dialysis 1375
Bradley A. Warady, Bruce Z. Morgenstern, and Steven R. Alexander
- 71** Hemodialysis 1395
Stuart L. Goldstein and Kathy Jabs
- 72** Transplantation Immunobiology 1411
Alan M. Krensky and Carol Clayberger

- 73** Pediatric Renal Transplantation 1437
William E. Harmon

- 74** Ethical Considerations 1469
Michel J. C. Broyer

SECTION XII: PEDIATRIC NEPHROLOGY AROUND THE WORLD 1479

- 75A** Overview 1481
Matthias Brandis and Ira Greifer
- 75B** Europe 1485
Jochen H. H. Ehrlich and Anita Amina Elgendi
- 75C** Japan 1491
Koichi Nakanishi, Masataka Honda, and Norishige Yoshikawa
- 75D** North America 1495
Sharon P. Andreoli
- 75E** Africa 1499
Bahia Hassan Moustafa, Felicia Eke, and Rajendra Bhimma
- 75F** Latin America 1507
Ramon Alfonso Exeni
- 75G** Australia and New Zealand 1513
John R. Burke and William Wong
- 75H** Asia 1517
Carmelo A. Alfiler, Hui-Kim Yap, and Man-Chun Chiu
- Index** 1525

CONTRIBUTING AUTHORS

Steven R. Alexander, M.D. Professor of Pediatrics, Stanford University School of Medicine; Chief of Pediatric Nephrology, Lucile Packard Children's Hospital at Stanford, Stanford, California

Carmelo A. Alfiler, M.D. Professor of Pediatrics, University of the Philippines Manila College of Medicine, Manila, Philippines

Uri S. Alon, M.D. Professor of Pediatrics, Department of Pediatric Nephrology, University of Missouri—Kansas City School of Medicine, Children's Mercy Hospital, Kansas City, Missouri

Alessandro Amore, M.D. Professor of Nephrology, Department of Nephrology, Dialysis, and Transplantation, Regina Margherita Children's Hospital, Torino, Italy

Sharon P. Andreoli, M.D. Professor of Pediatrics, Indiana University School of Medicine, James Whitcomb Riley Hospital for Children, Indianapolis, Indiana

Corinne Antignac, M.D., Ph.D. Professor of Medicine, Inserm U574 and Department of Genetics, Paris 5 University, Hôpital Necker Enfants Malades, Paris, France

Anthony Atala, M.D. Surgeon, Associate Professor of Surgery, Department of Urology, Children's Hospital, Boston, Massachusetts

Ellis D. Avner, M.D. Associate Dean for Research; Professor of Pediatrics and Physiology, Medical College of Wisconsin, Director, Children's Research Institute, Children's Hospital Health System of Wisconsin, Milwaukee, Wisconsin

Fred E. Avni, M.D., Ph.D. Professor of Radiology, Department of Medical Imaging, Erasme Hospital, Brussels, Belgium

T. Martin Barratt, M.B., F.R.C.P. Emeritus Professor of Paediatric Nephrology and Honorary Consulting Nephrologist, Institute of Child Health, Great Ormond Street Hospital for Children, London, England, United Kingdom

Stuart B. Bauer, M.D. Professor of Surgery, Department of Urology, Harvard Medical School; Senior Associate in Urology, Children's Hospital, Boston, Massachusetts

Jean U. Bender, M.D. Fellow in Nephrology and Pediatric Nephrology, Division of Pediatric Nephrology and Hypertension, University of Texas—Houston Medical School, Houston, Texas

Mark R. Benfield, M.D. Associate Professor of Pediatrics, University of Alabama School of Medicine, Birmingham, Alabama

Rajendra Bhimma, M.D., M.B.Ch.B., D.C.H., M.Med., F.C.P.P. Associate Professor of Pediatrics and Principal Specialist, Department of Pediatrics and Child Health, University of Natal, Durban, South Africa

Melvin A. Bonilla-Felix, M.D. Associate Professor of Pediatrics, University of Puerto Rico School of Medicine, San Juan, Puerto Rico

Ivy I. Boydston, M.D. Assistant Professor, Department of Pediatrics, SUNY at Stony Brook School of Medicine Health Sciences Center, Stony Brook, New York

Matthias Brandis, M.D. Professor of Medicine, Department of Pediatrics and Adolescent Medicine, Freiburg University Hospital, Freiburg, Germany

Michael C. Braun, M.D. Assistant Professor of Pediatrics, The Institute of Molecular Medicine, University of Texas—Houston Medical School, Houston, Texas

Eileen D. Brewer, M.D. Professor of Pediatrics, Head, Renal Section, Department of Pediatrics, Baylor College of Medicine, Texas Children's Hospital, Houston, Texas

Michel J. C. Broyer, M.D. Professor Emeritus, Department of Pediatric Nephrology, Hôpital Necker Enfants Malades, Paris, France

Timothy E. Bunchman, M.D. Professor of Pediatrics, University of Alabama School of Medicine, Pediatric Nephrology and Transplantation, Children's Hospital of Alabama, Birmingham, Alabama

John R. Burke, M.B., F.R.A.C.P. Associate Professor of Medicine, Department of Nephrology, Royal Children's Hospital, Mater Children's Hospital, Princess Alexandra Hospital, Brisbane, Australia

Suzanne B. Cassidy, M.D. Professor of Pediatrics, University of California, Irvine, College of Medicine, Irvine, California

James C. M. Chan, M.D. Professor of Pediatrics, University of Vermont College of Medicine, Burlington, Vermont; Director of Research, Barbara Bush Children's Hospital, Maine Medical Center, Portland, Maine

Russell W. Chesney, M.D. Le Bonheur Professor and Chair, Department of Pediatrics, University of Tennessee, Memphis College of Medicine, Memphis, Tennessee

Robert L. Chevalier, M.D. Professor and Chair, Department of Pediatrics, University of Virginia Medical Center, Charlottesville, Virginia

Man-Chun Chiu, M.B.B.S., F.R.C.P., F.R.C.P.C.H., F.H.K.A.M. (Paed) Doctor, Department of Pediatrics and Adolescent Medicine, Princess Margaret Hospital, Hong Kong, China

Carol Clayberger, Ph.D. Professor of Pediatrics and Cardiothoracic Surgery, Stanford University School of Medicine, Stanford, California

Pierre Cochat, M.D. Professor of Pediatrics, Hôpital Edouard-Herriot, Lyon, France

Laure B. D. E. Collard, M.D. Department of Pediatrics, Division of Pediatric Nephrology, University of Liège—CHU, CHR, CHC, Liège, Belgium

Christopher S. Cooper, M.D. Chief of Pediatric Urology, Associate Professor of Urology, University of Iowa College of Medicine, Iowa City, Iowa

Rosanna Coppo, M.D. Professor of Pediatric Nephrology, Department of Nephrology, Department of Dialysis and Transplantation, Regina Margherita Hospital, Torino, Italy

Ira D. Davis, M.D. Associate Professor of Pediatrics, Case Western Reserve University School of Medicine; Director of Pediatric Nephrology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Katherine MacRae Dell, M.D. Assistant Professor of Pediatrics, Case Western Reserve University School of Medicine; Attending Pediatric Nephrologist, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Prasad Devarajan, M.D. Louise M. Williams Endowed Professor of Pediatrics and Developmental Biology, Director of Nephrology and Hypertension, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

David A. Diamond, M.D. Associate Professor of Surgery, Department of Urology, Harvard Medical School, Children's Hospital, Boston, Massachusetts

Michael J. Dillon, M.B.B.S., F.R.C.P., F.R.C.P.C.H., D.C.H. Professor of Pediatric Nephrology, Nephro-Urology Unit, Institute of Child Health, Great Ormond Street Hospital for Children, London, England, United Kingdom

Allison A. Eddy, M.D. Professor of Pediatrics, University of Washington School of Medicine, Children's Hospital and Regional Medical Center, Seattle, Washington

Jochen H. H. Ehrich, M.D., D.C.M.T. (London) Professor of Pediatrics, Hannover Medical School, Children's Hospital, Hannover, Germany

Felicia Eke, M.D. Professor of Pediatrics, University of Port Harcourt, Port Harcourt, Rivers, Nigeria

Jack S. Elder, M.D. Carter Kissell Professor of Urology, Case Western Reserve University School of Medicine, Director of Pediatric Nephrology, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Anita Amina Elgendi, M.D. Department of Pediatric Nephrology, Children's Hospital, Hannover, Germany

Francesco Emma, M.D. Pediatric Nephrologist and Co-Director of the Pediatric Nephrology Laboratory, Department of Nephrology and Urology, Bambino Gesù Children's Hospital and Research Institute, Rome, Italy

Ramon Alfonso Exeni, M.D. Professor of Pediatrics, Department of Pediatric Nephrology, University of Buenos Aires, Hospital de Niños de San Justo, Beccar, Buenos Aires, Argentina

Jeffrey Fadrowski, M.D. Fellow, Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland

Leonard G. Feld, M.D., Ph.D., M.M.M. Professor of Pediatrics, UMDNJ—New Jersey Medical School, Newark, New Jersey; Chairman of Pediatrics, Atlantic Health System, Morristown, New Jersey

Richard N. Fine, M.D. Professor and Chair, Department of Pediatrics, SUNY at Stony Brook School of Medicine Health Sciences Center, Stony Brook University Hospital, Stony Brook, New York

Joseph T. Flynn, M.D. Associate Professor of Clinical Pediatrics, Division of Pediatric Nephrology, Albert Einstein College of Medicine of Yeshiva University, Montefiore Medical Center, Bronx, New York

Agnes B. Fogo, M.D. Professor of Pathology, Medicine, and Pediatrics, Department of Pathology, Vanderbilt University Medical Center, Nashville, Tennessee

John W. Foreman, M.D. Professor of Pediatrics, Chief of Pediatric Nephrology, Duke University Medical Center, Durham, North Carolina

Susan L. Furth, M.D., Ph.D. Assistant Professor, Department of Pediatrics and Epidemiology, Johns Hopkins University School of Medicine, Baltimore, Maryland

Gian Marco Ghiggeri, M.D. Nephrology Unit, Researcher, Laboratory on Pathophysiology of Uremia, Department of Pediatrics and Basic Science, G. Gaslini Children's Hospital, Genoa, Italy

Stuart L. Goldstein, M.D. Assistant Professor, Department of Pediatrics, Baylor College of Medicine, Houston, Texas

Paul R. Goodyer, M.D. Professor of Pediatrics, McGill University Faculty of Medicine, Montreal, Quebec, Canada

Ira Greifer, M.D. Professor of Pediatrics, Albert Einstein College of Medicine of Yeshiva University Monte Fiore Medical Center, Bronx, New York

Lisa M. Guay-Woodford, M.D. Professor of Medicine and Pediatrics, University of Alabama School of Medicine, Birmingham, Alabama

Marie Claire Gubler, M.D. Directeur de Recherche, Hôpital Necker Enfants Malades, Paris, France

Jean-Pierre Guignard, M.D. Professor of Pediatrics, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland

Michelle Hall, M.D. Professor of Pediatric Nephrology, Queen Fabiola Brussels Free University; Pediatric Nephrologist, Dialysis and Transplantation, Children's Hospital, Brussels, Belgium

Sverker Hansson, M.D., Ph.D. Associate Professor of Pediatric Nephrology, Pediatric Uro-Nephrologic Center, Queen Silvia Children's Hospital, Göteborg, Sweden

William E. Harmon, M.D. Associate Professor of Pediatrics, Harvard Medical School; Director, Division of Nephrology, Children's Hospital Boston, Boston, Massachusetts

Laurence Heidet, M.D., Ph.D. Hôpital Necker Enfants Malades, Paris, France

John T. Herrin, M.B.B.S., F.R.A.C.P. Associate Clinical Professor of Pediatrics, Harvard Medical School; Director of Dialysis, Children's Hospital Boston, Boston, Massachusetts

Friedhelm Hildebrandt, M.D. Professor of Pediatrics and Human Genetics, Department of Pediatrics and Communicable Diseases and Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan

Christer Holmberg, M.D., Ph.D. Professor of Pediatrics, University of Helsinki, Pediatric Nephrologist, Hospital for Children and Adolescents, Helsinki, Finland

Masataka Honda, M.D. Vice President, Department of Pediatrics, Division of Pediatric Nephrology, Tokyo Metropolitan Hachioji Children's Hospital, Hachioji, Tokyo

Iekuni Ichikawa, M.D., Ph.D. Professor of Pediatrics and Medicine, Department of Pediatric Nephrology, Vanderbilt University Medical Center, Nashville, Tennessee

Kathy Jabs, M.D. Associate Professor of Pediatrics, Director of Pediatric Nephrology, Vanderbilt University Medical Center, Nashville, Tennessee

Hannu J. Jalanko, M.D. Department of Pediatric Nephrology and Transplantation, University of Helsinki, Hospital for Children and Adolescents, Helsinki, Finland

Ulf Jodal, M.D., Ph.D. Professor of Pediatric Nephrology, Pediatric Uro-Nephrologic Center, Queen Silvia Children's Hospital, Göteborg, Sweden

Deborah P. Jones, M.D. Associate Professor of Pediatrics, Memphis College of Medicine, Memphis, Tennessee

Frederick J. Kaskel, M.D., Ph.D. Professor of Pediatrics, Albert Einstein College of Medicine of Yeshiva University; Chief, Section on Nephrology, Vice Chair, Affiliate and Network Affairs, Children's Hospital at Montefiore, Bronx, New York

Phyllis J. Kaskel, M.A., R.D., C.D.N. Director, Department of Clinical Nutrition, Mount Sinai Hospital of the Mount Sinai Medical Center, New York, New York

Marjo K. Kestilä, Ph.D. Senior Research Scientist, Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland

Nine V. A. M. Knoers, M.D., Ph.D. Clinical Geneticist, Professor in Clinical Genetics, Department of Human Genetics, University Medical Centre Nymegen, Nymegen, The Netherlands

Valentina Kon, M.D. Associate Professor of Pediatric Nephrology, Vanderbilt University Medical Center, Nashville, Tennessee

Jordan A. Kreidberg, M.D., Ph.D. Assistant Professor of Pediatrics, Department of Medicine, Harvard Medical School, Children's Hospital, Boston, Massachusetts

Alan M. Krensky, M.D. Shelagh Galligan Professor, Department of Pediatrics, Stanford University School of Medicine, Stanford, California

Beatriz D. Kuizon, M.D. Department of Pediatrics, Kaiser Permanente Los Angeles Medical Center, Los Angeles, California

Craig B. Langman, M.D. Isaac A. Abt, M.D., Professor of Kidney Diseases, Department of Pediatrics, Northwestern University Medical School; Director of Nephrology, Children's Memorial Hospital, Chicago, Illinois

Michael Levin, Ph.D., M.B.B.C.H., F.R.C.P. Professor of Pediatrics, Imperial College London Faculty of Medicine, London, England, United Kingdom

Chanin Limwongse, M.D. Assistant Professor of Medicine, Mahidol University Faculty of Medicine, Siriraj Hospital, Bangkok, Thailand

Chantal Loirat, M.D. Professor of Pediatrics, Department of Pediatric Nephrology, Hôpital Robert Debré, Paris, France

Robert H. K. Mak, M.D., Ph.D. Professor and Chief, Division of Pediatric Nephrology, Oregon Health Sciences University School of Medicine, Portland, Oregon

Sudesh Paul Makker, M.D. Professor and Chief of Pediatric Nephrology, Department of Pediatrics, University of California, Davis, School of Medicine, Davis, California

Ruth A. McDonald, M.D. Associate Professor of Pediatrics, Department of Nephrology, University of Washington School of Medicine, Children's Hospital and Regional Medical Center, Seattle, Washington

Dawn L. McLellan, M.D., F.R.C.S.C. Fellow in Urology, Children's Hospital Boston, Boston, Massachusetts

Dawn S. Milliner, M.D. Professor of Pediatrics and Medicine, Division of Pediatric Nephrology, Mayo Clinic, Rochester, Minnesota

Leo A. H. Monnens, M.D., Ph.D. Professor, Department of Pediatric Nephrology, Nymegen University, Nymegen, The Netherlands

Bruce Z. Morgenstern, M.D. Associate Professor, Department of Pediatric and Adolescent Medicine, Division of Pediatric Nephrology, Mayo Clinic, Rochester, Minnesota

Bahia Hassan Moustafa, M.D. Professor of Pediatrics, Pediatric Nephrology Unit, Cairo University, Children's Hospital, Cairo, Egypt

Corina Nailescu, M.D. Fellow in Pediatric Nephrology, Department of Pediatrics, Albert Einstein College of Medicine of Yeshiva University, Children's Hospital at Montefiore, Bronx, New York

Koichi Nakanishi, M.D. Instructor of Pediatrics, Wakayama Medical University, Wakayama City, Japan

Patrick Niaudet, M.D. Professor of Pediatrics, Department of Pediatric Nephrology, Hôpital Necker Enfants Malades, Paris, France

Amitava Pahari, M.D.D.C.H., D.N.B., M.R.C.P., F.R.C.P.C.H. Senior Consultant, Department of Pediatric Nephrology, Apollo Gleneagles Hospital, Kolkata, India

Craig A. Peters, M.D. Associate Professor of Surgery, Department of Urology, Harvard Medical School, Children's Hospital Boston, Boston, Massachusetts

Anthony A. Portale, M.D. Professor of Pediatrics, University of California, San Francisco, School of Medicine, San Francisco, California

Ronald J. Portman, M.D. Professor and Director, Division of Pediatric Nephrology and Hypertension, University of Texas—Houston Medical School, Houston, Texas

Gail E. Richards, M.D. Professor of Pediatrics, University of Washington School of Medicine, Children's Hospital and Regional Medical Center, Seattle, Washington

Juan Rodríguez-Soriano, M.D. Professor of Pediatrics, Basque University School of Medicine, Hospital de Cruces, Baracaldo, Spain

Jonathan A. Roth, M.D. Assistant Professor of Urology, University of Virginia School of Medicine, Charlottesville, Virginia

H. Gil Rushton, Jr., M.D., F.A.A.P. Professor of Urology and Pediatrics, George Washington University School of Medicine and Health Sciences, Chairman, Department of Pediatric Urology, Children's National Medical Center, Washington, D.C.

Rémi Salomon, M.D., Ph.D. Pediatric Nephrology, Hôpital Necker Enfants Malades, Paris, France

Isidro B. Salusky, M.D. Professor of Pediatrics, Department of Pediatric Nephrology, University of California, Los Angeles, UCLA School of Medicine, Los Angeles, California

Fernando Santos, M.D. Professor of Pediatrics, Hospital Universitario Central de Asturias and School of Medicine, Asturias, Spain

Franz Schaefer, M.D. Professor of Pediatrics, Pediatric Nephrology Division, University of Heidelberg, Children's Hospital, Heidelberg, Germany

Jon I. Scheinman, M.D. Professor of Pediatrics; Chief, Pediatric Nephrology, University of Kansas Medical Center, Kansas City, Kansas

George J. Schwartz, M.D. Professor of Pediatrics and Medicine, University of Rochester School of Medicine and Dentistry, Rochester, New York

Norman J. Siegel, M.D. Professor of Pediatrics and Medicine, Yale University School of Medicine, New Haven, Connecticut

William E. Smoyer, M.D. Robert C. Kelch Professor, Director, Pediatric Nephrology Division, University of Michigan Medical School, Ann Arbor, Michigan

Michael J. G. Somers, M.D. Assistant Professor of Pediatrics, Division of Nephrology, Harvard Medical School, Children's Hospital, Boston, Massachusetts

C. Frederic Strife, M.D. Professor of Medicine, Department of Nephrology and Hypertension, University of Cincinnati College of Medicine, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Endre Sulyok, M.D., Ph.D., D.Sci. Director and Professor of Pediatrics, County Children's Hospital, Pécs, Hungary

C. Mark Taylor, F.R.C.P. (London), F.R.C.P.C.H. Consultant Pediatric Nephrologist, Senior Clinical Lecturer, Department of Nephrology, Birmingham Children's Hospital, Birmingham, England, United Kingdom

Howard Trachtman, M.D. Professor of Pediatrics, Albert Einstein College of Medicine of Yeshiva University, Schneider Children's Hospital, Bronx, New York

Karl Tryggvason, M.D., Ph.D. Professor of Medical Chemistry, Department of Medical Biochemistry and Biophysics, Karolinska Institutet, Stockholm, Sweden

Rudolph P. Valentini, M.D. Assistant Professor, Director of Dialysis Services, Department of Pediatrics, Wayne State University School of Medicine, Children's Hospital of Michigan, Detroit, Michigan

Scott K. Van Why, M.D. Associate Professor, Department of Pediatrics, Medical College of Wisconsin, Milwaukee, Wisconsin

William G. van't Hoff, M.D., F.R.C.P., F.R.C.P.C.H. Consultant Pediatric Nephrologist, Great Ormond Street Hospital for Children, London, England, United Kingdom

Beth A. Vogt, M.D. Associate Professor of Pediatrics, Case Western Reserve University School of Medicine, Rainbow Babies and Children's Hospital, Cleveland, Ohio

Sam Walters, M.B., F.R.C.P. Senior Lecturer in Pediatric Infectious Diseases, Department of Pediatrics, Imperial College London, London, England, United Kingdom

Bradley A. Warady, M.D. Professor of Pediatrics; Chief, Section of Pediatric Nephrology, Director of Dialysis and Transplantation, Department of Pediatric Nephrology, University of Missouri—Kansas City School of Medicine, Kansas City, Missouri

Sandra L. Watkins, M.D. Professor of Pediatrics, University of Washington School of Medicine, Children's Hospital and Regional Medical Center, Seattle, Washington

Clark D. West, M.D. Emeritus Professor of Pediatrics, Department of Nephrology and Hypertension, University of Cincinnati College of Medicine, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Dilys A. Whyte, M.D. Assistant Professor of Pediatrics, Stony Brook University Hospital, Stony Brook, New York

Patricia D. Wilson, Ph.D. Professor, Department of Medicine, Mount Sinai School of Medicine of the City University of New York, New York, New York

William Wong, M.B.Ch.B., F.R.A.C.P. Pediatric Nephrologist, Starship Children's Hospital, Grafton, Auckland, New Zealand

PREFACE AND DEDICATION

Through its past four editions, *Pediatric Nephrology* has become the standard medical reference for health care professionals treating children with kidney disease. This new edition is focused on providing critical information regarding the evaluation of children with symptoms of renal disease, the molecular and cellular pathophysiology of renal disorders, and the diagnosis and therapy of specific renal diseases in children. The text is particularly targeted to pediatricians, pediatric nephrologists, pediatric urologists, and physicians in training. It is also targeted to the increasing number of allied health professionals involved in the care of children with renal disease, including geneticists, genetic counselors, nurses, dialysis personnel, nutritionists, social workers, and mental health professionals. It is designed to serve the needs of primary care physicians (internists and family practitioners), as well as internist nephrologists who are increasingly involved in the initial evaluation and/or longitudinal care of children with renal disease under the managed care systems of health care delivery evolving throughout the world.

The fifth edition includes a total reorganization of content from previous editions and begins with an overview of the basic developmental anatomy, biology, and physiology of the kidney, which is critical to understanding the developmental nature of pediatric renal diseases. This is followed by a comprehensive presentation of the evaluation, diagnosis, and therapy of specific kidney diseases of childhood, including extensive clinical algorithms. Of particular note is the emphasis on how rapidly evolving research advances in molecular genetics and evidence-based medicine are being translated into new, effective clinical approaches to many children's kidney diseases. To keep pace with the dramatic evolution of pediatric renal medicine since the previous edition, the content of the fifth edition has been extensively revised, with approximately 40% of the chapters being entirely new and the remainder being revised by previous and/or new authors.

As has been the tradition of previous editions, the former senior editor of the text, Professor Martin Barratt, has stepped down, and Professor Ellis D. Avner serves as senior editor of the fifth edition. Professor William E. Harmon continues as second editor, and Professor Patrick Niaudet joins the editorial troika as junior editor for this edition. This rotation of editors continues to provide a dynamic

mixture of continuity, new ideas, and new perspectives. The current editors are nationally and internationally recognized leaders in complementary areas of pediatric nephrology and reflect the international nature of the text and the subspecialty it serves. Professor Avner's focused interest is in developmental renal biology and congenital/genetic diseases of the kidney. He serves as Chairman of the Department of Pediatrics at Case Western Reserve University School of Medicine and Chief Medical Officer at Rainbow Babies and Children's Hospital in Cleveland, Ohio, and is the current President of the American Society of Pediatric Nephrology. Professor Harmon is a leading expert in the field of chronic renal failure and its therapy in children. He serves as the Director of Nephrology at Harvard Medical School and The Children's Hospital, Boston, Massachusetts, and is the current President of the American Society of Transplantation and Director of the North American Pediatric Renal Transplant Collaborative Study. Professor Niaudet is an internationally recognized educator and clinician-scientist in the evaluation and treatment of kidney disease in children, with a particular focus on childhood nephrosis. Professor Niaudet directs the Pediatric Nephrology Unit at The University of Paris and the Hôpital Necker Enfants Malades, is the former President of the European Society of Pediatric Nephrology, and currently directs the Continuing Medical Education Programs of the International Pediatric Nephrology Association.

The editors of *Pediatric Nephrology* take pleasure in dedicating the fifth edition of the text to the senior editor of the previous edition, Professor Martin Barratt, C.B.E., F.R.C.P., F.R.C.P.H. Over an extraordinarily productive career as one of the first pediatricians in the United Kingdom to specialize in nephrology, Professor Barratt has held leadership positions in the British Association for Pediatric Nephrology and the International Pediatric Nephrology Association and is internationally recognized for his scientific contributions in the fields of childhood nephrotic syndrome and hemolytic uremic syndrome. His distinguished career predominantly evolved at the Institute of Child Health and the Great Ormond Street Hospital for Children in London, where he served as Director of Clinical Services from 1989 to 1994. In 1992, he was awarded the coveted James Spence Medal of the Royal College of Pediatrics and Child Health. Professor Barratt has the reputation of being

the “clinician’s clinician” in recognition of his extraordinary clinical skills and acumen as a pediatrician and pediatric nephrologist. His work is distinguished for its clarity and logic—characteristics that he used well in reengineering and guiding *Pediatric Nephrology* through its second, third, and fourth editions. On a personal note, he has an extraordinary sense of humor and the ability to turn the most tedious of editorial tasks into an exciting adventure. He is a keen observer of human nature, finds pleasure in the extraordinary aspects of seemingly ordinary events, and takes great pride in mentoring trainees and junior col-

leagues. He has been an inspiration to all of the current editors of *Pediatric Nephrology*, as well as to countless trainees, colleagues, patients, and their families.

The editors also wish to acknowledge the outstanding editorial assistance of Shelly Parkhurst (Cleveland), Corinne Fleming (Boston), and Denise Martin, formerly of Lippincott Williams & Wilkins. Their dedicated efforts were essential in the publication of the fifth edition.

DEVELOPMENT

EMBRYOLOGY

ADRIAN S. WOOLF

In the last two decades, considerable advances have been made in understanding the mechanisms that control kidney development (1,2). In previous years, nephrogenesis was described in purely anatomic terms, but we can now interpret many of the key anatomic events as dynamic processes driven by the expression of specific genes. Although our long-term aim is to understand human kidney development, most functional studies have been performed in murine species; therefore, these animal experiments are described in some detail. As is obvious to any pediatric nephrologist, developmental disorders account for a wide spectrum of kidney diseases that cause considerable morbidity and mortality in the first years of life (3–5). Renal malformations, such as agenesis (absence of the kidney) and dysplasia (failure of normal renal differentiation), represent major defects of development, whereas enhanced proliferation, a characteristic of undifferentiated cells, occurs in Wilms' tumor and cystic kidney diseases. Although these diseases are described in detail elsewhere in this book, they are alluded to as illustrative examples of "nephrogenesis gone wrong": In some of these disorders, defined aberrations of cell biology and genetics shed light on normal human kidney development.

ANATOMY OF KIDNEY DEVELOPMENT

Overview

Potter has provided the most complete anatomic description of human kidney development (6). The reader is also referred to more recent reviews (1,2). Three sets of "kidneys" form in mammalian embryos: the pronephros, mesonephros, and metanephros. The metanephros is the direct precursor of the adult kidney, whereas the others essentially involute before birth. The anatomic events of human and mouse nephrogenesis are similar, but the timetable of development differs. Human gestation is 40 weeks, but mouse gestation is 20 days. The metanephros appears 5 to 6 weeks after fertilization in humans and on day 11 in mice. The first metanephric glomeruli form by 9 weeks in humans and day 14 in mice. The final layer of nephrons forms by 36 weeks' gestation in humans, whereas nephro-

genesis continues for 1 to 2 postnatal weeks in mice. In addition, there are some anatomic differences. The human mesonephros contains glomeruli with capillary loops, but mouse mesonephric tubules have rudimentary glomerular tufts. Humans have approximately 0.9×10^6 glomeruli in each kidney (7), with a rather large normal range, from 0.7 to 1.0×10^6 ; mice and rats (8) have proportionately fewer glomeruli per kidney. Finally, whereas the human renal pelvis has multiple papillae, the murine kidney has one. An illustration of the early stages of human metanephric development is depicted in Figure 1.1, and a histologic analysis is shown in Figure 1.2. Figure 1.3 indicates the major cell lineages derived from the metanephros, and Figure 1.4 addresses the formation of blood vessels in the metanephros.

Pronephros and Mesonephros

The mesoderm forms during gastrulation, and embryonic kidneys subsequently develop from nephrogenic cords; masses of intermediate mesoderm, located behind the embryonic coelom between the dorsal somites; and the lateral plate mesoderm. At the height of their development, the pronephros and the mesonephros extend in series from the cervical to lumbar levels. They develop in a segmental manner as tubules that are induced to differentiate from mesoderm by the adjacent pronephric and mesonephric (or wolffian) duct. In humans, the pronephros develops from the third embryonic week and contains rudimentary tubules opening into the pronephric duct. The human mesonephros begins to develop in the fourth week of gestation and contains well-developed nephrons comprising vascularized glomeruli connected to proximal and distal-type tubules draining into the mesonephric duct, a continuation of the pronephric duct. The mesonephric duct extends to fuse with the cloaca, the urinary bladder precursor, at the end of the fourth week. The pronephros and mesonephros can be regarded as a single unit, and as the wave of differentiation spreads caudally, the cranial end of this organ complex begins to regress. By one-third of the way through human gestation, most cells in these organs have involuted. In the male, mesonephric tubules in the area of the gonad

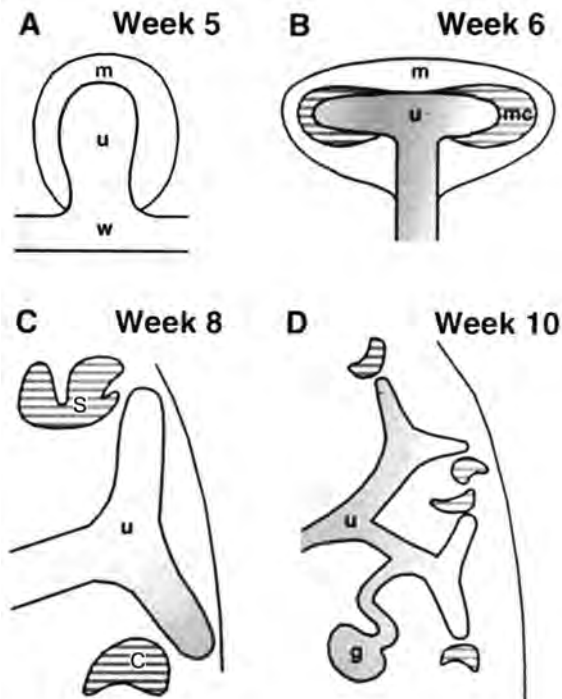

FIGURE 1.1. Early development of the metanephros. Cross-sectional diagrams of the human metanephros at approximately 5 weeks' (A), 6 weeks' (B), 8 weeks' (C), and 10 weeks' gestation (D). form the efferent ductules, and the mesonephric duct gives rise to the epididymis and ductus deferens. In the female, some mesonephric tubules persist as the epoophoron and para-oophoron.

Metanephros

The metanephros is the last embryonic kidney to develop and is identified in humans and consists of two components (2). These are the ureteric bud epithelium, which branches from the caudal part of the mesonephric duct at approximately 4 weeks of gestation, and the metanephric mesenchyme, which condenses from the intermediate mesoderm around the enlarging tip, or ampulla, of the bud. The human metanephric kidney can be first identified at approximately weeks 5 to 6 of gestation. The ureteric bud and its branches form epithelia of the collecting ducts, renal pelvis, ureter, and bladder trigone, whereas the metanephric mesenchyme differentiates into nephron tubules (glomerular, proximal tubule, loop of Henle, and distal tubular epithelia) and interstitial fibroblasts. These lineages may be more plastic than previously considered, as discussed later in this chapter. In humans, the renal pelvis and major calyces are apparent by the tenth to twelfth weeks of gestation. The pelvis forms from remodeling of the first six genera-

FIGURE 1.2. WT1 immunostaining in human fetal kidneys. A: Normal human fetal kidney shows a gradient of WT1 immunoreactivity (black) from nephrogenic cortex (right) to maturing nephrons (left). Cells in condensates and vesicles (larger arrowheads) are weakly positive for WT1. Expression increases in the mesenchymal (m) to epithelial transition, with high WT1 levels in the proximal limb of S-shaped bodies (s; smaller arrowheads) and the podocytes of fetal glomeruli (g). A ureteric bud branch tip (u) is negative. B: Intense WT1 expression is maintained in the podocytes of maturing glomeruli. Bars are 10 μ m. (Courtesy of Dr. P. J. D. Winyard, Institute of Child Health, London.)

tions of ureteric bud branches, and the minor calyces arise from the next generation of branches. Each minor calyx is associated with 20 ampullae, which will form the papillary collecting ducts: These indent the calyx to form the familiar cup shape seen in intravenous urograms (2).

Up to 14 weeks' gestation, the formation of each new collecting duct is associated with the induction of a nephron from adjacent metanephric mesenchyme. The differentiation of each nephron starts with mesenchymal cell aggregation around ureteric bud branch tips. Each condensate subsequently forms a lumen (the vesicle stage) and elongates to form a tubule (the comma-shaped body), which then shows regional specialization into primitive glomerular and proximal tubular epithelia (the S-shaped body). The proximal end of each S-shape becomes the glo-

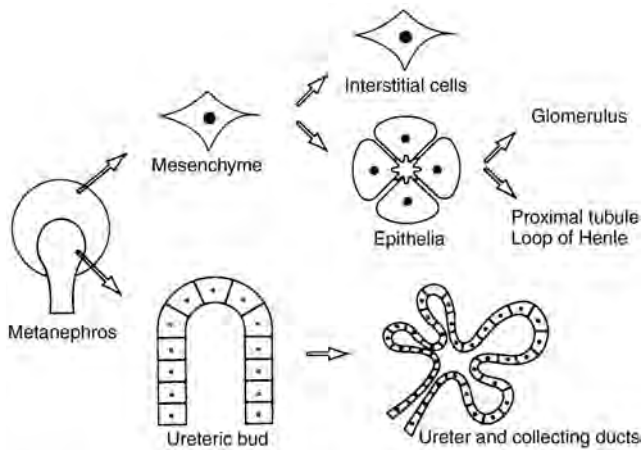

FIGURE 1.3. Main cell lineages arising in the metanephros. (Modified from Hardman P, Kolatsi M, Winyard PJD, et al. Branching out with the ureteric bud. *Exper Nephrol* 1994;2:211–219.)

merular epithelium, whereas the distal end of each tubule fuses with the adjacent branch of the ureteric bud. With each division of the ureteric bud, a new layer of nephrons is induced from stem cells in the periphery of the organ. Between 14 and 20 weeks, each ampulla induces three to six nephrons without dividing. During this process, the connecting tubule of the older, innermost nephron shifts the position of its point of attachment away from the ampulla to the connecting tubule of the next-formed nephron so they are joined together in arcades of four to seven nephrons. Up to 34 to 36 weeks' gestation, the ureteric bud branch tips advance further outward, and another four to seven nephrons form and attach separately just behind the ampullary tips. Thereafter, no new nephrons form, although each tubule continues to mature into the postnatal period. These changes include the elongation of the loops of Henle toward the medulla as well as convolution of the proximal tubule.

The adult kidney is highly vascular and receives approximately 20% of the cardiac output. However, at the inception of metanephric development, no mature vessels are present in the renal mesenchyme. The first patent capillaries are evident around the stalk of the ureteric bud, when it has branched once or twice, and capillaries later appear in the glomerular crevices of the S-shaped bodies (9). The primitive, multilayered, visceral glomerular epithelium subsequently forms a monolayer of podocytes, which abut glomerular capillary loops. At 9 to 10 weeks' human gestation, the most mature nephrons, located toward the center of the metanephros, are the first to acquire capillary loops and a patent Bowman's space. The forming glomerular basement membrane is believed to be synthesized by both the endothelium and epithelium (10). The fusion of the two embryonic membranes and its subsequent biochemical maturation correlate with the progressive restriction of filtration of macromolecules. At its inception, the human

metanephros receives its blood supply from the lateral sacral branches of the aorta. As development proceeds, the organ is located at progressively higher levels and is supplied by higher branches of the aorta. By 8 weeks' gestation, the metanephros is located in the lumbar position, and ultimately, the definitive renal arteries arise from the aorta at the level of the second lumbar vertebra (2).

Ureter and Urinary Bladder

The lower urinary tract forms in synchrony with the metanephric kidney (1). The urogenital sinus is the urinary bladder rudiment, and it separates from the rectum by 4 weeks of human gestation. At this time, its epithelium fuses with that

of the mesonephric duct, and the ureteric bud arises as a diverticulum from the posteromedial aspect of the mesonephric duct near where it enters the forming bladder. Between 4 and 5 weeks, the human ureter is patent, and it has been assumed because the cloaca is imperforate at that time, mesonephric urine maintains ureteral patency by increasing intraluminal pressure. The mesonephric duct above the ureteric bud becomes the vas deferens in males but involutes in females. At 5 weeks of gestation, the mesonephric duct below the ureteric bud, the “common excretory duct,” is absorbed into the urogenital sinus to form the trigone; thereafter, ureteric orifices migrate cranially and laterally. Over the next few weeks, the ureter apparently becomes occluded and then recanalizes, the latter event perhaps coinciding with urine production from the first metanephric glomeruli. The embryonic “ascent” of the metanephros from the level of the sacral segments to the lumbar vertebrae is partly associated with ureteric elongation. The urinary bladder becomes a recognizable entity by approximately 6 weeks of gestation, and the urogenital membrane ruptures at approximately week 7, providing a connection between the bladder and outside of the body. The allantois, another potential outflow tract on the anterior of the developing bladder, involutes by 12 weeks. Toward the end of the first trimester, the ureteric urothelium assumes a pseudo-multilayered arrangement, and its walls become muscularized; by this time, the bladder wall has differentiated into circular and longitudinal smooth muscle fibers which continue to mature in the second trimester. The murine urinary bladder develops in a similar fashion, in synchrony with the metanephros (11).

METHODS USED TO STUDY THE BIOLOGY OF NEPHROGENESIS

Descriptive Studies of Gene Expression

Patterns of cell division, death, differentiation, and morphogenesis can be correlated with changes in spatial and temporal patterns of gene expression in terms of messenger RNA (mRNA) and protein by using *in situ* hybridization and immunohistochemistry (Figs. 1.2 and 1.5). Recently, “gene chip” technology has been used to study the spectrum of genes expressed during murine and human kidney development (12,13). These observations provide the essential data for the generation of hypotheses regarding the molecular control of nephrogenesis; the hypotheses can be tested by studying the effects of diverse interventions during normal development. These functional experiments can be performed in the intact animal, *in vivo*, or “in the test tube,” *in vitro*.

Functional Studies *In Vitro*

Experiments performed by Grobstein several decades ago are classic examples of *in vitro* studies (14). Grobstein

found that the mouse metanephros forms a small kidney in organ culture over days. Of note, other branching organs, such as the lung and the salivary gland, can also be grown in the same manner (Fig. 1.6). If either the renal mesenchyme or the ureteric bud were cultured in isolation, however, Grobstein noted that they failed to differentiate. This clearly demonstrated that embryonic tissue interactions are critical for kidney development, and we now know that growth factors are important signaling molecules involved in these inductive processes. Growth may be modulated in organ culture with antisense oligonucleotides that impair the transcription of metanephric mRNAs or with antibodies that block the bioactivity of secreted or cell surface proteins (15–17). Other technologic advances have made it feasible to transfer new genes into the metanephros *in vitro* (18–20). Qiao and Herzlinger used retroviral transduction to introduce a reporter gene into renal mesenchymal cells; they subsequently demonstrated that these precursors not only formed nephron tubules, as expected, but also differentiated into a minor proportion of cells within collecting duct epithelia (20). Finally, the generation of metanephric cell lines has made it feasible to study the expression of multiple genes in homogeneous populations of precursors (16) as well as in normal and abnormal differentiation of these cells in response to defined stimuli (21).

Functional Studies *In Vivo*

In vivo experiments on developing kidneys have used physical, teratogenic (e.g., chemical), and genetic strategies. For example, surgical interruption of the avian mesonephric duct prevents the conversion of intermediate mesoderm into mesonephric tubules and also prevents the formation of the metanephros (22). Complete obstruction of the sheep fetal ureter in midgestation generates hydronephrotic kidneys, with generation of cysts and disruption of nephrogenesis resembling human renal dysplasia (23,24). With regard to teratogenic studies, an example is the generation of urinary tract malformations after exposure to ethanol (25). Welham et al. (8) reported that the imposition of mild (9%) dietary protein restriction during rat pregnancy reduced numbers of glomeruli per kidney of offspring when measured postnatally. This was associated with enhanced apoptotic deletion of renal mesenchymal precursors at the start of metanephrogenesis (8). In humans, the equivalent developmental time frame is 5 to 7 weeks' gestation, and this might represent a critical window when fetal kidney morphogenesis is susceptible to maternal dietary influences.

The most powerful *in vivo* experiments, however, alter the expression of metanephric molecules by genetic engineering using transgenic animal technology. First, levels of a specific protein can be increased by inserting a coding DNA sequence, linked to a strong promoter, into the genome of early embryos. This is usually done by microin-

FIGURE 1.5. Early human metanephros (mt) and the mesonephros (ms). Sections are stained with antibody to PAX2 transcription factor: Positive nuclei appear black, whereas others are counterstained with methyl green and appear gray. **A:** Transverse section of a 5- to 6-week gestation of human embryo showing, on each side of the embryo, a mesonephros, a metanephros, and a gonadal ridge (g) ($\times 5$). Also shown is the central notochord (n) in a mass of cartilage that will form the vertebral body, and the coelom (c). **B:** Enlarged view of **A**. Note the mesonephros duct (arrowhead) stains for PAX2, as does the flanking paramesonephric duct ($\times 10$). **C:** High power of metanephros containing the first branches of the ureteric duct with adjacent mesenchymal condensates. The mesonephros duct (arrowhead) is nearby ($\times 20$). **D:** Medulla of an 11-week human kidney shows a major branch of the fetal ureter (arrowhead) branching to form collecting ducts: Most nuclei in these structures stain for PAX2 ($\times 20$). **E:** Cortex of an 11-week human fetal kidney shows presence of a nephrogenic outer cortex with increasingly mature nephrons and glomeruli (arrowhead) toward the center of the organ. Note that PAX2 is down-regulated in more mature elements ($\times 20$). **F:** High-powered image of **E**. jection into the male pronucleus of fertilized ova. The phenotype of such mice illustrates the effects of an excess of a molecule (26). Even more informative is the technique of homozygous recombination in which the function of a gene can be ablated. Here, mouse embryonic stem cells are

genetically engineered *in vitro* and then incorporated into early embryos that develop into chimeric mice. If the altered cells contribute to the germline, animals with homozygous and heterozygous gene deletions can be generated by further breeding (27). The phenotypes of these null

FIGURE 1.6. Growth of mouse embryonic tissues in organ culture. Branching out with the ureteric bud. *Exp Nephrol* 1994;2:211–219.)

mutant or “knock-out” mice, which include the complete absence of metanephric development, have so far suggested that approximately 30 genes are essential for normal nephrogenesis *in vivo* (Table 1.1). Many of these animal models also have defects in nonrenal systems because the same genes are expressed in, and critical for, the normal development of organs other than the kidney.

Hundreds of molecules are known to be expressed during nephrogenesis (28), and tens of these have been considered to be functionally important based on organ culture studies. However, mice with null mutations of the same genes sometimes have normal kidney development *in vivo*. Hence, we can speculate that numerous metanephric molecules are of little functional significance or are redundant in the intact fetus. It also follows that organ culture must constitute a relatively stressful milieu in which it is comparatively easy to disrupt development by altering levels of a single molecule. Of note, the genetic background, or strain, of mice with defined mutations can affect the kidney phenotype, suggesting the presence of modifying genes (29). When two structurally similar molecules are expressed at identical locations in the metanephros, both loci may have to be ablated to generate a renal malformation *in vivo* (30,31).

CELL BIOLOGY OF NEPHROGENESIS

Cell Proliferation and Cell Death

Proliferation is prominent in the tips of the ureteric bud branches and in the adjacent mesenchymal cells in the nephrogenic cortex of the metanephros (32). Renal mesen-

<i>Neuronal NOS</i> (bladder outflow impairment)
<i>RARα/$\alpha\beta_2$^a</i> (small or absent kidneys)
<i>Uroplakin III</i> (hydronephrosis and vesicoureteric reflux)

Note: Many mutants have aberrations of other organ systems: Please see references for details. Unless otherwise stated, the renal abnormalities are detected only in homozygous null mutant animals (i.e., both alleles of one gene are nonfunctional).

^aNull mutations of two homologous but separate genes are required to produce the malformation.

^bIn these cases, heterozygous null mutations produce kidney malformations that are less severe than the homozygotes. In all other cases, heterozygotes appear to have normal nephrogenesis.

chymal stem cells are believed to reside within this area, and such cells are believed to divide to generate a copy of themselves and also another cell. These cells subsequently differentiate into nephron epithelia or interstitial cells (21). More recent evidence, discussed later in this chapter, suggests that cells in the renal mesenchymal compartment can also differentiate into glomerular capillaries and juxtaglomerular cells. Stem cells are generally considered to be absent from the mature kidney; although if they did exist, they might provide a source of cells for the regeneration of nephron epithelia after injury.

Not all cells born in the developing kidney are destined to survive the fetal period. In 1926, Kampmeier reported

that the first layers of metanephric nephrons “disappeared” before birth (33), a process likely to be associated with the remodeling of the first divisions of the ureteric bud during formation of the pelvis. More recently, others have reported the normal occurrence of cell death in the mesenchyme adjacent to primitive nephrons, where it may regulate the number of cells in each tubule or the number of nephrons formed (8). These cells die by apoptosis, a process accompanied by nuclear condensation and fragmentation. These deaths are sometimes called *programmed* because they are part of the normal program of development, and each cell “commits suicide” by an active program of biochemical events, including digestion of genomic DNA into fragments of approximately 200 nucleotides by calcium-dependent endonucleases. Apoptosis also occurs in the developing medulla (Fig. 1.7) and it has been suggested that this process is implicated in the morphogenesis of the thin ascending limb of the loop of Henle (34) and also in deleting excess beta intercalated cells in the collecting duct (35).

FIGURE 1.7. Cell death in normal nephrogenesis. **A:** Apoptotic cell death is detected in the outer medulla of the human metanephros, as assessed by bright, condensed, propidium-iodide-stained nuclei (between the *white bars*) in primitive loops of Henle and other tubules, probably collecting ducts ($\times 63$). (Courtesy of Dr. P. J. D. Winyard, Institute of Child Health, London.) **B,C:** Electron microscope images of the medulla of a mouse metanephros to show apoptotic nuclei (*curved arrows*) being engulfed by epithelial cells (**B**) and cells within the interstitium (**C**).

Therefore, normal nephrogenesis involves a fine balance between cell proliferation and death. Excessive proliferation is associated with the generation of neoplasms (e.g., Wilms’ tumor) and cysts (e.g., polycystic kidney diseases) (36). Conversely, excessive apoptosis would cause a reduction of kidney growth resulting in an organ with fewer nephrons than normal (e.g., a hypoplastic kidney) or even involution of a metanephric kidney (e.g., some dysplastic kidneys) (37,38).

Differentiation

As individual renal precursor cells become specialized, they undergo differentiation. For example, some renal mesenchymal cells differentiate into primitive nephron epithelia, whereas others differentiate into stromal cells or interstitial fibroblasts (39). Precursor cells later become “terminally differentiated” to enable them to perform specific functions of the adult organ. For example, cells within a nephron precursor form the glomerular parietal and visceral epithelia as well as the cells that comprise the proximal tubule and loop of Henle. The term *lineage* describes the series of phenotypes as a precursor differentiates into a mature cell.

Morphogenesis

Morphogenesis describes the developmental process by which groups of cells acquire complex three-dimensional shapes. Examples include the formation of nephron tubules from renal mesenchymal cells and the serial branching of the ureteric bud to form the collecting duct system. The process of morphogenesis also occurs during angiogenesis and vasculogenesis; modes of renal capillary formation is discussed later in this chapter (9). Angiogenesis also involves the fundamental cellular process of directional movement or migration.

MOLECULAR CONTROL OF NEPHROGENESIS

Overview

Three main classes of molecules are expressed during nephrogenesis: transcription factors, growth/survival factors, and adhesion molecules. Note that italics are used when referring to genomic sequences, whereas regular typescript is used for gene products (e.g., *PAX2* gene and PAX2 mRNA or protein). The following criteria should be satisfied for a molecule to be definitively involved in normal nephrogenesis: It must be expressed by the metanephros in an appropriate spatial or temporal manner; functional experiments should demonstrate that its absence perturbs kidney development in organ culture and *in vivo*; and the molecule should have appropriate bioactivity on isolated populations of precursor cells. At present, few molecules have been shown to fulfill all three criteria.

Transcription Factors

Transcription factor proteins bind to DNA and regulate expression of other genes. Because they can enhance or switch off the transcription of mRNAs, transcription factors have been likened to conductors of an orchestra during normal development. These molecules can be classified into families that share similar DNA-binding protein motifs and domains. One such motif is called the *zinc-finger*, which describes a projection of the molecule that intercalates with DNA. An example of a transcription factor with multiple zinc-fingers is the WT1 protein, which is expressed at the inception of the metanephros (32). Other examples of transcription factors expressed during nephrogenesis include members of the HOX family, which contain DNA-binding homeodomains, as well as the PAX family, which contain DNA-binding paired domains (40). At present, little is known about the specific targets of many of the transcription factors expressed in the developing kidney.

Growth Factors

The metanephros is rich in growth factors that modulate cell survival, proliferation, differentiation, and morphogenesis (41). Factors that have a positive effect on growth are epidermal growth factor (EGF), transforming growth factor (TGF) α , fibroblast growth factor (FGF)-2, glial cell line-derived neurotrophic factor (GDNF), hepatocyte growth factor (HGF), insulin-like growth factor (IGF)-1 and -2, keratinocyte growth factor (KGF; also called *FGF-7*), leukemia inhibitory factor, neurotrophin 3, pleiotrophin, and TGF β . Factors that have been reported to have a negative effect on growth include activin, TGF β , and tumor necrosis factor- α (TNF- α). In some cases, a single factor can have multiple effects by virtue of binding to more than one different receptor; for example, angiotensin (AT) II generally acts to promote growth through its type 1 receptor but also stimulates apoptosis through the AT 2 receptor (42).

When acting on the neighboring cell, growth factors are *paracrine* factors, but when acting on the producing cell, they are *autocrine* factors. Growth factors bind to cell-surface receptors, many of which are receptor tyrosine kinases that, after ligand binding, dimerize and become phosphorylated, thereafter transducing signals into the cell. Factors acting via receptor tyrosine kinases include angiopoietin, EGF, TGF α , FGFs, HGF, IGF-1 and -2, KGF, neurotrophin 3, nerve growth factor, platelet-derived growth factor A and B chains, and vascular endothelial growth factor (VEGF). Others, including bone morphogenetic proteins (BMP) types 4 and 7 and TGF β , bind receptors with threonine and serine kinase activity. GDNF is a distant relative of TGF α but signals through a receptor tyrosine kinase after binding to an accessory receptor. Yet, other metanephric growth factors, including

AT, leukemia inhibitory factor, and TNF- α , signal through different classes of receptors.

Adhesion Molecules

The third major class of molecules comprises the adhesion molecules (43). Some mediate the attachment of cells to one another, whereas a second group mediates attachment of cells to the surrounding matrix. Examples of the former include neural cell adhesion molecule, whose adhesive properties are independent of calcium, and E-cadherin, whose adhesive properties depend on calcium. Molecules in the second group include collagen, fibronectin, laminin, nidogen, and tenascin. Many bind to cell surfaces via integrin receptors to provide a physical framework for epithelial tubules and endothelia. Some of these interactions also modulate growth and differentiation in an analogous fashion to the binding of growth factors to their receptors. Proteoglycans, including syndecan and heparan sulfate, constitute another type of adhesion molecule. They also bind growth factors, such as FGFs and VEGF, hence sequestering and storing these molecules as well as modulating their binding to receptor tyrosine kinases.

CONVERSION OF METANEPHRIC MESENCHYME INTO NEPHRON EPITHELIA

Uninduced Metanephric Mesenchyme Is Preprogrammed to Form Nephrons

Isolated metanephric mesenchyme can be induced to form nephrons *in vitro* by recombination with the ureteric bud or by apposition to embryonic spinal cord. However, mesenchyme from other embryonic organs cannot be stimulated to produce nephrons by either the ureteric bud or heterologous inducers (14). Hence, by the time the metanephros can first be detected, the renal mesenchyme has already been programmed to form nephrons, but it requires additional, inductive signals from the ureteric bud to permit its differentiation. The molecules responsible for this preprogramming of the renal mesenchyme are currently undefined. The transcription factor LIM1 is expressed in the intermediate mesoderm before it forms the renal mesenchyme, and the metanephros fails to form in mice, which lack LIM1 (44). However, the embryonic expression of this gene is widespread, and diverse nonrenal organs are malformed in null mutants.

Uninduced Metanephric Mesenchyme Is Preprogrammed to Die

When cultured in isolation, murine renal mesenchyme fails to survive. In contrast, the recombination with either ureteric bud epithelium or embryonic spinal cord rescues mesenchymal cells from death and induces them to form nephrons.

Koseki et al. demonstrated that death of the isolated renal mesenchyme was mediated by apoptosis and that it was an active process, as assessed by a requirement for mRNA and protein synthesis (45). They also reported that isolated renal mesenchyme could be rescued from death by the addition of EGF (the adult homolog of TGF α) or by phorbol ester (a chemical that enhances the activity of protein kinase C). Perantoni et al. reported that FGF-2 could also facilitate survival of isolated renal mesenchyme (46)—an important observation considering that the ureteric bud secretes this factor (47). Barasch et al. (48) have reported that metalloproteinase-2 stimulates mesenchymal growth by preventing this cell population from dying.

The *WT1* gene produces multiple transcripts, some of which act as transcription factors, whereas others are likely to affect splicing of mRNA before export from the nucleus (49). *WT1* is expressed at low levels in metanephric mesenchyme, and levels are upregulated during differentiation into nephron precursors (32) (Fig. 1.2). *In vivo*, absence of *WT1* protein causes fulminant death of the intermediate mesoderm, which would normally form the metanephric mesenchyme, producing renal agenesis (50). A similar final phenotype can be generated in mice that are homozygous null mutants for *PAX2*, *formin*, or *GDNF/RET*. In these cases, the primary defect is a failure of outgrowth of the ureteric bud from the mesonephric duct: The defect in the renal mesenchyme is secondary to the loss of its normal inducing tissue *in vivo*. Nishinakamura et al. (51) have recently reported that mesenchymal expression of the *SALL1* transcription factor is necessary for early inductive events in the murine kidney; the human homologue is mutated in the Townes-Brocks syndrome, a disorder associated with urinary tract malformations.

Condensation of Renal Mesenchyme

The first morphologic step in nephron formation is the aggregation of renal mesenchymal cells to form a condensate. At the same time, these nephrogenic precursor cells undergo a burst of proliferation and upregulate the expression of the transcription factors *WT1* (32), *PAX2* (Fig. 1.5) (32), and *N-MYC*. Other genes that are switched on or upregulated include *MET* (the HGF receptor) (Fig. 1.8) (52), $\alpha_8\beta_1$ integrin (53), and *BCL2* (32). Inhibition of *PAX2* by antisense oligonucleotides prevents condensation in metanephric organ culture (54), and mice lacking one copy of the *PAX2* gene are born with small kidneys (27,55). Mice with homozygous mutations of *N-MYC* have malformed mesonephric tubules but die before development of the metanephros (56). HGF induces epithelioid characteristics in *MET*-transfected 3T3 embryonic fibroblasts (57), a model for the conversion of mesenchymal into epithelial cells. This growth factor also induces the expression of epithelial markers in a murine renal mesenchymal cell line (58). Mice deficient in α_8 integrin have small, severely malformed kidneys,

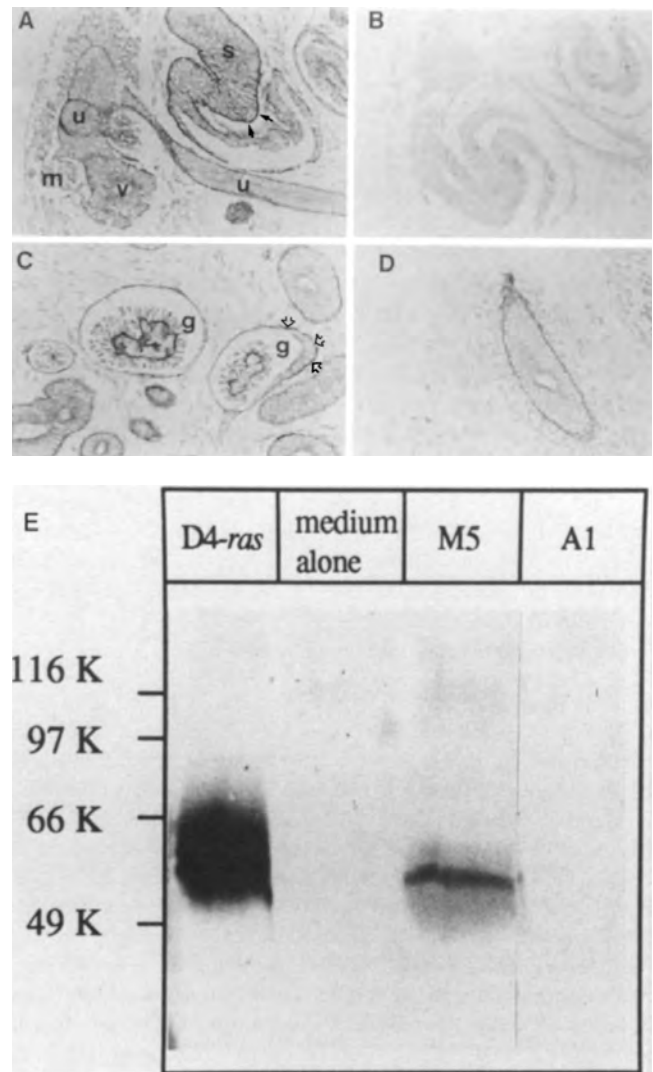

FIGURE 1.8. Hepatocyte growth factor and its receptor, MET, in the normal metanephros. **A–D:** Nine-week gestation of human metanephros. **A:** Positive MET staining in ureteric bud branches (u) and primitive nephrons, such as vesicles (v) and S-shaped bodies (s). Note marked staining on basal surface of primitive epithelia (arrows). Condensing renal mesenchyme (m) expresses a much lower level of MET in the cytoplasm. **B:** Similar field as **A**, after primary antibody was preabsorbed with MET peptide: no specific staining. **C:** MET staining in basal surface of epithelia of Bowman's capsule (open arrows) of fetal glomeruli (g). Mesangial and endothelial cells in the fetal glomeruli are MET-positive. **D:** The stalk of the ureteric bud shows positive MET immunostaining on the basal epithelial surface (immunostaining appears black). **E:** By Western blot, HGF protein is detected at 62 kDa in conditioned media from D4-ras NIH 3T3 cells (positive control) and from a mouse renal mesenchyme cell line (M5) but was not present in media from a more mature metanephric clone (A1) or in unconditioned medium. [Panels **A–D** from Kolatsi-Joannou M, Moore R, Winyard PJD, et al. Expression of hepatocyte growth factor/scatter factor and its receptor, MET, suggests roles in human embryonic organogenesis. *Pediatr Res* 1997;41:657–665; panel **E** from Woolf AS, Kolatsi-Joannou M, Hardman P, et al. Roles of hepatocyte growth factor/scatter factor and the MET receptor in early development of the metanephros. *J Cell Biol* 1995;128:171–184, with permission.]

with defective nephron formation and impaired ureteric bud branching (53). A ligand for $\alpha_8\beta_1$ integrin dimers is expressed on the surface of ureteric bud branches; therefore, these molecules most likely coordinate morphogenetic interactions between the mesenchymal condensate and the ureteric bud epithelium. BCL2 is located in the nuclear and mitochondrial membranes and prevents apoptosis, perhaps by interfering with lipid peroxidation. Homozygous null mutant mice have fulminant renal apoptosis during development and are born with small kidneys containing fewer nephrons than normal (renal hypoplasia) (37,59).

Putting the above experiments together, the following scenario can be envisaged: WT1 appears necessary for the induction and survival of renal mesenchymal cells; PAX2 and HGF/MET may drive the proliferation of nephron precursors; BCL2 may protect cells in the condensate stage from an untimely programmed death; and $\alpha_8\beta_1$ integrin plays a role in aggregation of nephron precursor cells around the ureteric bud branch tips. The application of either FGF-2 or lithium ions to uninduced renal mesenchyme *in vitro* appears to stimulate differentiation up to but not beyond this stage of mesenchymal condensation (46,60).

Morphogenesis into Nephron Tubules

Next, the mesenchymal condensate forms a lumen and differentiates into an increasingly mature nephron via the vesicle, comma shaped, and S-shaped stages. This process is associated with the replacement of the intermediate filament vimentin by cytokeratin in all segments apart from glomerular podocytes. In addition, there are profound changes of expression of adhesion molecules. The neural cell adhesion molecule becomes downregulated (61), whereas E-cadherin appears at sites of cell-cell contact (adherens junctions) in the primitive nephron (17). Numerous studies have implicated the latter molecule as playing a part in the genesis of epithelia (62,63). At the same time, the expression of the extracellular matrix molecules, collagen I and fibronectin, are downregulated, and primitive tubular epithelia begin to synthesize a basement membrane containing collagen IV, laminin, heparan sulfate, and nidogen (17,43). Evidence from organ culture experiments supports the concept that the interaction of laminin-1, a cruciform trimeric molecule, with a cell-surface receptor, $\alpha_6\beta_1$ integrin, is essential for lumen formation of the primitive nephron (17,64). Other interactions of laminin-1 with the α -dystroglycan complex (located on the cell surface) and with nidogen (a mesenchymal-derived matrix protein) are also critical for epithelial morphogenesis (65,66). As the nephron epithelia differentiate further into specific segments, other integrins are expressed: α_3 subunit is found in glomerular podocytes and binds laminin, and the α_2 subunit is expressed by distal tubules and collecting ducts and interacts with collagen IV and laminin (43). As the glomerular epithelium matures, the basement membrane becomes rich in s-laminin, the β_2 chain of laminin. Mice without the

gene encoding this protein develop an infantile nephrotic syndrome, despite the presence of grossly normal-appearing glomeruli at birth (67).

Other types of molecules have been implicated in the growth of primitive nephrons. WNTs are glycoproteins, which are believed to be secreted signaling factors. WNT4, a member of this family, is upregulated in renal mesenchymal cells as they differentiate into nephrons and may have an autocrine role in this process. Mice with WNT4 homozygous null mutations have metanephroi in which the renal mesenchyme is induced but "frozen" at the condensate stage (68). BMPs are members of the TGF β superfamily and transduce growth signals through types 1 and 2 receptor serine/threonine kinases. BMP-7 is expressed by the branches of the ureteric bud and is also upregulated in primitive nephrons (69,70). Nephrogenesis is impaired in BMP-7 null mutant mice with formation of only a few nephrons and ureteric bud branches. Recent data suggest that leukemia inhibitory factor, a member of the interleukin-6 family, is secreted by the ureteric bud and can transform renal mesenchyme into epithelia, including proximal tubules and glomeruli, acting together with FGF-2 and TGF α (71). Indeed, several growth factors may have a permissive effect on epithelial growth at this stage, including HGF, FGF-2, IGF-1, IGF-2, and TGF α (16,71–73).

At present, little is known about the molecular controls of differentiation of primitive nephrons into the specialized cells in the mature mammalian nephron. However, this type of detailed analysis has been performed for cells in the Malpighian excretory tubule of embryonic *Drosophila* fruit flies (74). In mammals, there is evidence that expression of WT1 is essential for the maintenance of the mature podocyte (32), where it downregulates the transcription of PAX2 (75). In humans, mutation of a single WT1 allele causes the Denys Drash syndrome in which nephrotic syndrome and structural glomerular abnormalities are key features (76), whereas the transgenic overexpression of PAX2 causes epithelial overgrowth and a congenital nephrotic syndrome in mice (26).

Negative Regulators of Nephrogenesis

The final form of the kidney is determined by not only growth but also negative processes, such as programmed cell death and as yet poorly defined mechanisms that terminate morphogenesis. In organ culture, TNF- α , a classical inflammatory cytokine, inhibits nephron differentiation and morphogenesis at the stage of mesenchymal condensation (77). This protein is localized at mesenchymal/epithelial interfaces and is expressed by renal mesenchymal cells and possibly also by macrophages that populate the metanephros from its inception. Rogers et al. reported that these *in vitro* actions of TGF β are similar to those of TNF- α (78). Another factor that can inhibit nephrogenesis in organ culture is activin, a TGF β -like molecule (79).

STROMAL CELL LINEAGE

Little is known about the mechanisms that control the differentiation of renal mesenchyme into stromal cells, or interstitial fibroblasts (80), but there is evidence that stromal cells are essential for epithelial development. For example, the G_{D3} ganglioside is expressed by stromal cells surrounding the stalk of the ureteric bud, and antibodies to this molecule prevent bud morphogenesis (81). Metanephric stromal cells also express the BF2 winged-helix transcription factor. Mice that were homozygous null mutants for this gene have impaired branching of the collecting ducts and also perturbed conversion of renal mesenchyme to nephrons (82). Other evidence emphasizes that metanephric stromal and epithelial cells are involved in complex reciprocal signaling loops, with expression of retinoic acid receptors in the stroma, playing important roles (83). A subset of metanephric stromal cells has neuronal characteristics, staining positively with neurofilament markers (84). The role of these cells is unknown, but their survival can be modulated by neurotrophin 3 (84). Although fibroblasts in the mature kidney are heterogeneous (e.g., only some make the hormone erythropoietin), it is not understood how this diversity is generated.

BRANCHING MORPHOGENESIS OF THE URETERIC BUD

Mesenchymal Factors and Ureteric Bud Growth

When the mouse ureteric bud is grown in organ culture with its adjacent renal mesenchyme, it undergoes branching morphogenesis; however, it fails to differentiate when cultured in isolation (14,85). It is established that the epithelia of the ureteric bud express various receptors, mostly tyrosine kinases that transduce differentiation signals by binding to mesenchyme-derived growth factors (85,86). The most important signaling system involves RET, a receptor tyrosine kinase expressed in mesonephric duct, ureteric bud, and its branching tips. GDNF causes tyrosine phosphorylation of RET after binding to a membrane-linked accessory receptor called GDNF receptor α (87). The ligand is expressed by condensing renal mesenchyme, whereas GDNF receptor α is expressed in the same cells as RET (85). Lower levels of the accessory receptor are found in renal mesenchyme, where it may concentrate the ligand and also prevent its diffusion with initiation of ectopic ureteric bud branches (85). Mice with homozygous null mutations of *RET* or *GDNF* do not develop kidneys because of deficient outgrowth of the ureteric bud (88–92). Experiments using culture of whole metanephric rudiments with blocking antibodies to GDNF demonstrate that this signaling system is critical for stimulation branching after initial outgrowth of the ureteric bud (85). Equally impressive, the addition of recombinant GDNF to cultured metanephroi induces ectopic ureters

(85). When the ureteric bud is cultured as a monolayer, it dies by apoptosis over a few days, but GDNF can partially reverse this process (85). The factor also stimulates survival and morphogenesis of RET-transfected collecting duct cells (93). Hence, GDNF is a survival factor and morphogen for the ureteric bud epithelium.

Other metanephric growth factors affect ureteric bud growth. HGF induces branching morphogenesis of Madin-Darby canine kidney collecting duct cells grown in a collagen I matrix. This model system mimics ureteric bud morphogenesis (94). HGF is secreted by renal mesenchymal cells, whereas its receptor, tyrosine kinase MET, is located on the basal surface of ureteric bud epithelia (16,52) (Fig. 1.8). Functional studies demonstrate that HGF is required for growth and branching in metanephric organ culture (16,95,96) (Fig. 1.9). Transgenic mice overexpressing HGF commonly develop renal failure, although details of renal histopathology have not yet been reported (97). Mice with homozygous *HGF* or *MET* null mutations die at embryonic day 13 or 14 with placental, liver, and muscle pathologies, but early nephrogenesis is surprisingly normal (98,99). ROS is another receptor tyrosine kinase expressed in the ureteric bud lineage (100). Its ligand is unknown but is likely to be a mesenchymally derived factor, using the GDNF/RET and HGF/MET signaling systems as paradigms. Antisense oligonucleotides to ROS mRNA cause impaired growth in organ culture (100), but mice with homozygous *ROS* null mutations have normal nephrogenesis *in vivo* (101). Antisense experiments in metanephric organ culture have also implicated low-affinity nerve growth factor receptor in branching (15), but again, mice genetically engineered to lack this molecule have grossly normal nephrogenesis (102). Thus, it is easy to perturb branching morphogenesis in organ culture, but the process is more robust when the whole animal is challenged *in vivo*.

EGF and its embryonic homolog, TGF α , bind to the EGF receptor. EGF induces limited branching of isolated ureteric buds in collagen I gel (103), whereas blocking antisera to TGF α inhibit metanephric development in organ culture (73). Mice with homozygous null mutations of *EGFR* have collecting duct dilation and kidney failure, a strain-dependent phenotype, implicating the activity of modifying genes (29). An isoform of FGF receptor-2 with high affinity for KGF (FGF-7) is expressed in mesonephric duct and its derivatives (104). Furthermore, administration of KGF enhances proliferation of adult urothelial cells *in vivo* (105), whereas the factor modulates ureteric bud morphogenesis in organ culture (106). Finally, pleiotrophin, a heparin-binding protein, has recently been identified as a renal mesenchymal-secreted factor involved in ureteric bud branching (107).

Cell Adhesion Molecules and Ureteric Bud Growth

The stalk of the ureteric bud is surrounded by a basement membrane composed of laminin-1 and collagen IV, as well

FIGURE 1.9. Blockade of hepatocyte growth factor in metanephric organ culture. **A–C:** Mouse rudiments after 3 days of culture in basal media (**A**), nonimmune immunoglobulin G (**B**), and anti-HGF immunoglobulin G (**C**). Ureteric bud (u) branching and nephron formations are limited in organs treated with anti-HGF antibody. **D,E:** Photomicrographs of sections of a metanephros grown for 3 days in basal medium (**D**) or in the presence of anti-HGF antibody (**E**). Note the condensations of mesenchyme (m) around the tips of the ureteric bud in **D** compared with the cystic dilation of the bud surrounded by loose mesenchyme with pyknotic nuclei in **E**. Arrowheads indicate the tips of the ureteric bud, and arrows indicate mesenchyme condensates (**D**). Bars are 100 μm . Arrowheads in **A**, **C**, and **E** indicate ureteric bud branch tips. (Modified from Woolf AS, Kolatsi-Joannou M, Hardman P, et al. Roles of hepatocyte growth factor/scatter factor and the MET receptor in early development of the metanephros. *J Cell Biol* 1995;128:171–184.)

as nidogen/entactin and tenascin. As assessed by electron microscopy, the basement membrane is attenuated around the tips of the ureteric bud, and branching epithelia may be exposed to a renal mesenchymal matrix rich in collagen I and fibronectin. There is evidence that matrix molecules affect branching morphogenesis *in vitro*. In monolayer culture of ureteric bud epithelia, proliferation is enhanced by a fibronectin versus laminin substrate (85), consistent with the observation that cells at the branching tips have a high proliferation rate (32). Collagen I appears permissive for branching of Madin-Darby canine kidney cells, whereas some components of the basement membrane are inhibitory (108). Using the Madin-Darby canine kidney model, HGF-induced branching into collagen I is accompanied by an increase in matrix degrading molecules (e.g., collagena-

ses, such as matrix metalloproteinases, and plasminogen activating proteases, such as urokinase) (109). TGF β inhibits branching and decreases the ratio of matrix-degrading molecules versus others that inhibit this process (e.g., tissue inhibitor of metalloproteinase-1 and plasminogen activator inhibitor-1) (109). Further evidence that the basement membrane plays a critical role in collecting duct morphogenesis is provided by experiments that disrupt the signaling of extracellular matrix molecules to the cell surface. Mice genetically engineered to lack α_3 integrin, which forms functional dimers with β_1 subunits, have a reduced number of medullary collecting ducts (110). Finally, galectin-3 is a cell adhesion molecule expressed in the ureteric bud lineage, which may regulate the growth of collecting duct epithelia by interaction with laminin and other extra-

cellular matrix molecules (111,112), whereas polycystin 1, the product of a gene mutated in autosomal-dominant polycystic kidney disease, is a putative cell adhesion molecule expressed in the ureteric bud lineage (113).

Transcription Factors and Ureteric Bud Growth

As yet, little is known about how the expression of transcription factors orchestrates the expression of growth factors and matrix molecules that directly affect the morphogenesis of the ureteric bud lineage. PAX2 appears to be particularly important because it is expressed in the mesonephric duct and in the ureteric bud branch tips (32,112). The expression of PAX2 in the human ureteric bud lineage correlates with proliferation, and both are downregulated as the ducts mature (32). In mice genetically engineered to lack PAX2, the ureteric bud fails to branch from the mesonephric duct, producing renal agenesis (27). Finally, mice lacking the expression of formin show no outgrowth of the ureteric bud from the mesonephric duct. The function(s) of this gene, which produces multiple transcripts, is unclear (114).

Further Differentiation of Collecting Ducts

As the bud branches, the stems mature into the collecting ducts, which contain three types of cells: the potassium-handling principal cells and the proton-handling α and β intercalated cells (115). Corticosteroids enhance collecting duct differentiation, and there is also some plasticity regarding the lineage of these cells based on *in vitro* studies (116,117). During this period of maturation, the Na⁺-K⁺-adenosine triphosphatase becomes relocated from the apical to basal plasma membrane, and this process is perturbed in some polycystic kidney diseases (118). Other cells that arise from the ureteric bud differentiate into the pseudostratified urothelium, which lines the renal calyces, pelvis, and ureter: The KGF receptor is expressed by these cells and the administration of KGF enhances urothelial proliferation *in vivo* (106). The human fetal ureter is not patent in early gestation, but the mechanisms of its canalization are unknown (119): a failure of this process is believed to occur in human multicystic dysplastic kidneys (3). AT II, acting through its AT 1 receptor, has recently been shown to be important for maturation of the ureter, partly by enhancing peristalsis and partly by a direct effect on morphogenesis (120).

FORMATION OF GLOMERULAR CAPILLARIES

Embryonic blood vessels arise by vasculogenesis or angiogenesis (9). In vasculogenesis, mesenchyme differentiates *in situ* to form capillaries. In contrast, angiogenesis involves ingrowth from existing capillaries. The first embryonic ves-

sels of the yolk sac, endocardium, and dorsal aorta arise by vasculogenesis, but thereafter, descriptive studies alone cannot ascertain the origin of embryonic vessels. When avascular murine renal mesenchyme is induced to differentiate in organ culture, the glomeruli that develop lack capillaries as assessed by light and electron microscopy (121), a result used to argue against the possibility of glomerular vasculogenesis. When mouse metanephroi were transplanted onto avian chorioallantoic membranes, forming glomeruli acquired capillary loops but these were of host origin as assessed by a quail-specific nuclear marker and antisera to chick collagen IV, a component of endothelial basement membrane (10,122). These results were used to argue that glomerular vessels form by angiogenesis *in vivo*. However, neither organ culture nor chorioallantoic membrane is likely to provide a normal environment for growth of glomerular capillaries.

During endothelial differentiation, cells in the lineage express a defined sequence of receptor tyrosine kinases (9): VEGF receptor (VEGFR)-2, VEGFR-1, TIE2, and TIE1. VEGF is expressed at sites of embryonic vessel formation and is a ligand for VEGFR-1 and VEGFR-2, whereas angiopoietin 1 is a ligand for TIE2. VEGFR-1/-2 and TIE1 are expressed by uninduced metanephric mesenchyme, hence suggesting the presence of endothelial precursors (123). When a *TIE1/LACZ* transgenic mouse was used, in which a β -galactosidase reporter gene product can be detected histochemically, endothelial precursors were visualized in intermediate mesoderm condensing around the caudal end of the mesonephric duct, with a similar pattern noted in renal mesenchyme at the ureteric bud stage (123,124). Later in nephrogenesis, *TIE1/LACZ* was expressed by all endothelia, including glomerular endothelia. Loughna et al. (123) determined whether these precursors could differentiate into endothelia using a model in which metanephroi form filtering glomeruli after transplantation into the neonatal nephrogenic cortex (125). When transgenic avascular metanephroi were transplanted into wild-type hosts, differentiated donor tissue contained transgene-expressing glomerular arterioles and capillary loops (123) (Fig. 1.10). Other experiments support the conclusion that glomerular capillaries originate from endothelial precursors present at the inception of nephrogenesis. When wild-type mouse metanephroi were grafted into the anterior eye chamber of adult *ROSA26* transgenic mice, a strain in which the β -galactosidase reporter gene is expressed in all cells, glomerular endothelia were found to be of donor origin (126). Moreover, exposure of murine metanephroi to hypoxia increases endothelial growth in organ culture, whereas other experiments in mice and rats have demonstrated that addition of VEGF or angiopoietin-1 enhance the formation of metanephric capillaries in organ culture (127,128). One can speculate that capillary formation within the metanephros is at least in part driven by hypoxia and that low oxygen tension increases expression of diverse vascular growth factors and their receptors.

FIGURE 1.10. Transplantation of *TIE1/LACZ* metanephroi into wild-type neonates. **A:** After 1 week, the E11 transplant differentiated (arrows) in the host cortex (c). Transgene expression (black) was confined to the transplant. No staining was detected in host cortex or medulla (m). **B:** Donor glomeruli expressed the transgene intensely. **C:** Positive capillary loops in glomeruli are visible. Podocytes (open arrow) do not express the transgene. Bars: 120 μm in **A**; 30 μm in **B**; and 10 μm in **C**. (From Loughna S, Hardman P, Landels E, et al. A molecular and genetic analysis of renal glomerular capillary development. *Angiogenesis* 1997;1: 84–101, with permission.)

Other molecules are implicated in vascular growth within the metanephros. These include the Eph/ephrin family of membrane receptors, which appear to be critical in cell-cell recognition (129). Renin is widely expressed in perivascular cells in the arterial system of the metanephros but becomes restricted to juxtaglomerular cells during maturation. Recent evidence suggests that the metanephric mesenchyme contains renin-expressing precursor cells (130). In addition, other molecules required to generate bioactive AT are expressed in the metanephros, as are AT 1 and AT 2 receptors. In rats, there is evidence that AT II may enhance glomerular endothelial growth *in vivo* (131,132). This axis is also important in fetal glomerular hemodynamics, as discussed elsewhere in this text (see Chapter 2).

MESANGIAL CELL LINEAGE

It has been speculated that mesangial cells arise from the same lineage as glomerular capillaries because neither cell forms when the metanephros is cultured under standard organ culture conditions (121). It was assumed that mesangial cells were derived from cells outside the embryonic kidney. However, mesangial cells develop when metanephroi are grown *in oculo* (126), and thus, mesangial precursor cells may be present in renal mesenchyme. Whatever their origin, platelet-derived growth factor B and its receptor, tyrosine kinase platelet-derived growth factor receptor β , are crucial for the differentiation of mesangial cells *in vivo*. Mice with null mutations of either of these genes lack mesangial cells and develop bizarre, malformed glomeruli (133,134). Platelet-derived growth factor B is expressed by primitive nephron epithelia, and mesangial precursors express the receptor, suggesting a paracrine mode of action. As mesangial cells mature, both ligand and receptor are coexpressed, suggesting autocrine activity. Other growth factor–signaling systems may play roles in development of this lineage. For example, HGF and MET are coexpressed by immature mesangial cells (135).

NEURONS IN EARLY NEPHROGENESIS

Grobstein found that when an embryonic spinal cord was placed on the opposite side of a filter from metanephric mesenchyme, nephrons were induced to differentiate (14). Further investigations showed that neurons had penetrated the mesenchyme through the microscopic pores of the filter, and if the neurons in the spinal cord were destroyed, induction did not occur (136). As assessed by antibodies against neurofilaments and neural cell surface gangliosides, neuronal cell bodies can be observed around the ureteric bud *in vivo*, and their terminals surround mesenchymal condensates (137). These observations support the hypothesis that kidney development may partly depend on innervation. It is also interesting that embryonic neural tissues are capable of inducing the formation of mesonephric tubules from intermediate mesoderm (138).

HUMAN RENAL MALFORMATIONS: NEPHROGENESIS GONE WRONG

Overview

Renal malformations are the major causes of end-stage renal failure in children (3–5) (see Chapter 6). The term *renal malformation* encompasses a heterogeneous group of developmental aberrations. In the most extreme example, renal agenesis, the kidney is absent. *Renal dysplasia* describes an organ comprised of undifferentiated and metaplastic cells

FIGURE 1.11. Histology of a human dysplastic kidney. **A:** Typical histology of a human dysplastic kidney. Primitive ducts, believed to be branches of the ureteric bud (u), are surrounded by undifferentiated tissue that superficially resembles normal renal mesenchyme (m). Note that no nephrons have differentiated from the mesenchyme compartment. **B:** For comparison, this plate shows a normal human metanephros or embryonic kidney at 10 weeks after fertilization. Note that there is a superficial similarity to the dysplastic kidney depicted in **A** because both structures contain primitive ureteric bud ducts and mesenchyme. In the normal embryonic kidney, however, there is evidence of conversion of mesenchyme to epithelial nephron precursors (n). (Courtesy of Dr. P. J. D. Winyard, Institute of Child Health, London.)

surrounding poorly branched ureteric bud derivatives (Fig. 1.11). These organs may be tiny (renal aplasia) or large enough to distend the abdomen (multicystic dysplastic kidneys). A hypoplastic kidney is small and has fewer nephrons than normal. These nephrons may be grossly enlarged in oligomeganephronia. Associated malformations of the urinary tract include agenesis, duplications, obstruction, and vesicoureteric reflux.

Renal Malformations as Dynamic Processes

The above classification of renal malformations is based on pathologic end points. Yet it is now known that normal kid-

ney development is a highly dynamic process of proliferation, death, morphogenesis, and differentiation controlled by the temporal and spatial expression of specific genes (discussed above). It is interesting to reassess multicystic dysplastic kidneys with these perspectives in mind. Serial ultrasound scans performed both prenatally and postnatally have shown that some of these organs can increase to a massive size only to subsequently regress and even involute completely (139). Epithelia lining dysplastic cysts have a high rate of proliferation and overexpress both PAX2, a potentially oncogenic transcription factor, and BCL2, a survival molecule (32). Other evidence also suggests that mesenchymal-derived growth factors, such as TGF β , HGF (Fig. 1.12), and IGFs, are involved in dysplastic epithelial growth (52,140,141). Conversely, undifferentiated tissues around cysts have a high rate of apoptosis associated with a lack of BCL2 expression, and these cells fail to form nephrons (38). Hence, phases of growth and involution correlate with cellular events and aberrant expression of nephrogenesis genes. An understanding of the dynamics that underlie these malformations now allows potential therapies, especially the administration of growth factors that prevent apoptosis and enhance normal differentiation into nephrons, to be envisaged (19). The deregulated expression of genes such as PAX2, BCL2, and TGF β , although intriguing, is likely to be a secondary event. A major question remains: What are the primary causes of human malformation? To date, there are at least three answers: teratogens, physical obstruction of the urinary tract, and sporadic or inherited mutations of genes expressed in the developing kidney (2,142).

Teratogens

As discussed, animal experiments have implicated a wide variety of agents, including vitamin A and ethanol, as renal teratogens. In humans, both glucose (i.e., mothers with diabetes) (143) and AT-converting enzyme inhibitors (used to treat maternal hypertension) are associated with renal malformations. It is unusual, however, to elicit a history of exposure to known teratogens from the parents of children with renal malformations, but it remains possible that occult exposure is important. For example, a recent study suggested that the incidence of various malformations, including those of the genitourinary tract, was increased with a daily intake of vitamin A over 10,000 IU (144).

Physical Obstruction of the Developing Urinary Tract

It has long been recognized that a significant minority of kidney malformations in girls and perhaps half of all malformations in boys are associated with obstructed lower urinary tracts (3–5). Obstruction during the last third of gestation is associated with hydronephrosis, poor renal parenchymal growth, and subcortical cysts, whereas kid-

FIGURE 1.12. Hepatocyte growth factor (HGF) and MET immunohistochemistry in a dysplastic kidney. **A:** A dysplastic tubule within a postnatal human kidney malformation. HGF immunostaining is localized to the epithelium and also to scattered cells in the surrounding undifferentiated stromal/mesenchymal tissues. **B:** In a section adjacent to that depicted in **A**, MET immunostaining was confined to the epithelium. **C:** Other parts of the same organ contained large cysts. Faint HGF/SF immunoreactivity was noted in three locations: stromal; around the cyst, apparently coating the lining of the cyst; and in amorphous material inside the cyst. **D:** In a section adjacent to that depicted in **(C)**, MET immunostaining was prominent in epithelium, lining the cyst (cy). Bar is 50 μm . SF, scatter factor; dt, dysplastic tubule. (From Kolatsi-Joannou M, Moore R, Winyard PJD, et al. Expression of hepatocyte growth factor/scatter factor and its receptor, MET, suggests roles in human embryonic organogenesis. *Pediatr Res* 1997;41:657–665, with permission.)

neys associated with obstruction during early gestation are often dysplastic. Data suggest that experimental obstruction of murine kidneys in the neonatal period causes enhanced cell death by apoptosis, as well as aberrant expression of BCL2, TGF- β 1, AT II, and EGF (145). Similar molecules are implicated in the pathogenesis of renal dysplasia, a phenotype that can be generated in animals, such as sheep, by ureteric obstruction much earlier during development (23,24). All of these molecules have been functionally implicated in metanephric growth in various other experiments using organ culture or transgenic mice.

Genetic Causes: Malformations Confined to the Urinary Tract

Primary vesicoureteric reflux (VUR) affects approximately 1% of white infants, and associated reflux nephropathy causes up to 15% of end-stage renal failure in children and adults (4,146). There is a 20- to 50-fold increased risk of VUR in immediate relatives of probands (147). Feather et al. (148) reported the first genome-wide search of VUR in seven fami-

lies with dominant inheritance. Polymorphic markers were used, spaced at 10 centiMorgan (cM) through the genome, with affecteds-only parametric and nonparametric linkage analyses. The most positive locus spans 20 cM on chromosome 1p13, with a nonparametric lod score of 5.76 ($p = .0002$) and a parametric lod score of 3.16. Hence, VUR maps to chromosome 1, although the gene has yet to be defined. There was also evidence of genetic heterogeneity, and 12 additional loci were identified with $p < .05$. The results support the hypotheses that VUR is a genetic disorder and offers the future prospect of genetic screening to replace invasive cystograms for diagnosis. Other loci, yet to be defined, might be implicated in the rare families reported with inherited nonsyndromic kidney aplasia and dysplasia (149,150).

Genetic Causes: Multiorgan Malformation Syndromes

In some cases, congenital kidney or lower urinary tract disorders occur with a multiorgan malformation syndrome commonly affecting central nervous, cardiovascular, and skeletal systems. For a listing of such syndromes, see Chapter 6 and reference 151. Although individually rare, malformation syndromes collectively account for significant morbidity. Some are associated with gross chromosomal anomalies, such as monosomies, trisomies, 4p- syndrome, and dup (10p)/del (10q); however, gross cytogenetic defects are absent in most cases of children born with syndromic renal tract malformation. Many renal malformation syndromes are inherited in Mendelian patterns, and in some, specific mutations have been defined (Table 1.2) (151). Here, four such syndromes are highlighted.

The ablation of a single *PAX2* allele in mice causes impaired metanephric growth as well as megareter, a finding consistent with gross VUR (27,55). These animals are blind because of maldevelopment of the retina, another site of embryonic *PAX2* expression. There is a human syndrome that is strikingly similar to these mouse models, namely the renal-coloboma syndrome. This comprises blindness caused by optic nerve colobomas and renal failure and hypertension associated with vesicoureteric reflux and small, malformed kidneys. This resemblance was noted by a New Zealand-based laboratory that described heterozygous mutations of *PAX2* in individuals with this syndrome (152). These mutations most likely result in haploinsufficiency (a partial lack of functional protein), and they can arise *de novo* or be inherited in an autosomal-dominant manner. *PAX2* mutations have also been implicated in human inherited renal hypoplasia with a very mild ocular phenotype, emphasizing the utility of careful examination of the optic fundus in such cases (153).

X-linked Kallmann syndrome is caused by mutations of *KAL-1* (154,155). Anosmia and hypogonadotrophic hypogonadism occur in affected male patients because of defective prenatal elongation of axons of olfactory neurons and migration of gonadotrophin-releasing hormone-synthesizing neurons from the nasal placode into the forebrain.

TABLE 1.2. EXAMPLES OF HUMAN RENAL MALFORMATION SYNDROMES WITH A GENETIC BASIS

Associated with syndromes
Apert syndrome (<i>FGFR2</i> mutation)
Bardet Biedl syndrome (several loci and <i>BBS</i> genes defined)
Beckwith-Wiedemann syndrome (<i>p57KIP2</i> mutations in a minority of patients)
Branchio-oto-renal syndrome (<i>EYA1</i> mutation)
Camptomelic dysplasia (<i>SOX9</i> mutation)
Denys Drash syndrome (<i>WT1</i> mutation)
Di George syndrome (locus on 22q11, possibly several genes mutated)
Glutaric aciduria type II (<i>glutaryl-coenzyme A dehydrogenase</i> mutation)
Fanconi anemia (<i>FAA</i> mutation)
Kallmann syndrome (<i>KAL-1</i> mutation) ^a
Meckel syndrome (locus on 17q21–q24)
Nail-patella syndrome (<i>LMX1B</i> mutation)
Oral-facial-digital syndrome type 1 (<i>OFD1</i> mutation)
Renal-coloboma syndrome (<i>PAX2</i> mutation) ^a
Renal cysts and diabetes syndrome (<i>HNF1β</i> mutation) ^a
Simpson-Golabi-Behmel syndrome (<i>GPC3</i> mutation) ^a
Townes-Brocks syndrome (<i>SALL1</i> mutation)
Smith-Lemli-Opitz syndrome [$\delta(7)$ - <i>dehydrocholesterol reductase</i> mutation]
WAGR syndrome (<i>WT1</i> and <i>PAX6</i> contiguous gene defects)
Zellweger syndrome (peroxisomal protein mutation)
Nonsyndromic
Congenital anomalies of the kidney and urinary tract (<i>AT2</i> polymorphism)
Renal adysplasia (locus not defined)
Primary vesicoureteric reflux (locus on 1p13 but condition is genetically heterogeneous) ^a

^aConditions discussed in more detail in the current text. For updated information on the genetics of these and other renal and urinary tract malformation syndromes, see reference 151.

Moreover, the olfactory bulb fails to grow and is hypoplastic. Approximately 30 to 40% of patients have a solitary functioning kidney, with presumed renal agenesis (156). Patients with urinary tract agenesis also lack the vas deferens, a structure derived from the mesonephric duct which also gives rise to the ureteric bud and its derivatives. Two children with X-linked Kallmann syndrome and unilateral multicystic dysplastic kidney have been reported (157): Perhaps the apparent “agenesis” phenotype seen in older individuals with the syndrome might be the result of spontaneous involution of multicystic organs, as is known to occur in non-Kallmann patients. *In vitro* studies demonstrate an adhesive role for the protein coded by *KAL-1*. *In vivo* *KAL-1* is expressed in the embryonic human central nervous and excretory systems (Fig. 1.13) (155,157). The protein, called *anosmin-1*, immunolocalizes to the epithelial interstitial matrix and basement membranes of the mesonephric collecting tubules and mesonephric duct and to the first generations of metanephric collecting duct branches of the ureteric bud (158). It is possible that failure of growth of either the ureteric bud or its first branches, perhaps due

FIGURE 1.13. *KAL* expression in the developing human metanephros. **A:** Bright-field photomicrograph of section of the organ at 11 weeks' gestation counterstained with hematoxylin and eosin, showing the cortex (c) and medulla (m). **B:** *In situ* hybridization with dark field illumination: *KAL* antisense probe shows moderate signal over the nephrogenic cortex (arrows) with a weak signal from deeper tissues. **C:** Background signal from *KAL* sense probe. Bar is 40 μ m. (From Duke V, Winyard PJD, Thorogood PV, et al. *KAL*, a gene mutated in Kallmann's syndrome, is expressed in the first trimester of human development. *Mol Cell Endocrinol* 1995;110:73–79, with permission.)

to alterations in cell adhesion, would lead to a failure of metanephric formation with consequent renal agenesis.

The Simpson-Golabi-Behmel syndrome is an X-linked condition characterized by prenatal and postnatal overgrowth with visceral and skeletal abnormalities. Affected males are often very tall with nephromegaly, renal cysts, hydronephrosis, double renal pelvis, dysplastic kidneys, and Wilms' tumor. The disease superficially resembles Beckwith-Wiedemann syndrome, an autosomal-dominant disorder linked to 11p, and the Perlman syndrome, which is inherited in an autosomal-recessive manner. Mutations of the *GPC3* gene (Xq26) have recently been reported in the Simpson-Golabi-Behmel syndrome (159). This gene encodes a putative extracellular proteoglycan, called *glypican 3*, that is expressed in the fetal kidney and other tissues that are derived from embryonic mesoderm. There is preliminary evidence that the protein product may bind to IGF-2 and modulate its action. This factor is made by the embryonic kidney and enhances metanephric growth in organ culture (72). It is overexpressed in some Wilms' tumors, perhaps because of loss of genetic imprinting of a normally silent *IGFII* allele or to derepression of transcription associated with *WT1* mutations. It has also been demonstrated that mice with *GPC3* null mutations have an overgrowth syndrome accompanied by deregulated metanephric cell turnover and malformed kidneys (160).

It has long been recognized that glucose is teratogenic for kidneys and other organs, with embryopathy associated with free radicals and vasculopathy (143,161). Recently, a genetic link was established between diabetes mellitus and renal cystic malformations, based on a spectrum of disorders associated with mutations of *hepatocyte nuclear factor 1 β* ; collectively, these have been called the renal cysts and diabetes syndrome (162–164). Human mutations were initially associated with maturity onset diabetes mellitus of the young; these individuals have a failure of pancreatic insulin secretion. Mutations in the DNA binding and transactivating domains of this transcription factor have been reported in patients with kidney malformations, including agenesis, dysplasia, hypoplasia, and glomerulocystic disease, a form of cystic kidney disease in which glomerular cysts predominate (see Chapter 38). The gene is expressed in human embryos: Hepatocyte nuclear factor 1 β mRNA can be detected in normal human metanephroi, with the highest levels of transcripts localized to fetal medullary and cortical collecting ducts and low levels of expression in nephrogenic cortex mesenchyme, primitive nephron tubules, and immature glomeruli. The gene is also expressed in the embryonic pancreas, liver, gut, and lung. Most likely, this is an example of a gene involved in epithelial differentiation and branching in several organ systems.

GLOMERULAR CIRCULATION AND FUNCTION

VALENTINA KON
IEKUNI ICHIKAWA

The essential function of the kidney is to preserve constancy of body fluid and electrolytes by removing water and potentially harmful metabolic end-products (e.g., uric acids, sulfates, phosphates) while preserving blood pressure (BP) and essential solutes (e.g., sodium, chloride, bicarbonate, sugars, amino acids). The process begins in the renal glomerulus, where plasma is ultrafiltered under pressure through a semipermeable glomerular capillary wall. The ultrafiltration separates plasma water and crystalloids from blood cells and protein macromolecules, which remain in the glomerular circulation. The magnitude of this filtration process is enormous and requires a high rate of renal blood flow (RBF). Indeed, the entire plasma volume is cycled through the glomerular system 20 times per hour. The RBF and glomerular filtration rate (GFR) are interrelated such that maintenance of an adequate RBF is crucially important for optimal GFR while the glomerulus is an active participant in determining the RBF.

RENAL BLOOD FLOW

Blood flow to the kidneys comprises 20 to 30% of cardiac output (CO) and is determined by two factors: renal perfusion pressure (RPP), which is approximately equal to the systemic arterial BP, and renal vascular resistance (RVR), which is determined primarily by the afferent and efferent arterioles. The relationship can be expressed as $RBF = BP/RVR$. Although RBF is the parameter usually discussed, it is the renal plasma flow (RPF) that is clinically relevant. Thus, at a given level of RBF, RPF may vary with the volume of packed red cells. For example, RPF increases with anemia. Lambs bled to decrease their hematocrit from 33 to 14% double their RPF (1). Because RBF is partly determined by the need for oxygen delivery, RPF may be high with severe chronic anemia such as occurs with sickle cell disease. In such circumstances, both the RPF and the GFR are elevated because of decreased volume of red blood cells.

Like most organs, the kidneys possess intrinsic autoregulatory mechanisms that adjust local RVR when RPP changes. This autoregulation maintains RBF relatively constant in the face of changing BP and RPP under physiologic conditions (2). Many hormonal systems regulate RVR and, hence, RBF. The nature and magnitude of their effects are often age specific because anatomic factors (innervation), presence and distribution of receptor subtypes [angiotensin (AT) II receptors], and post-receptor signaling events change with development (3–6). In addition, autoregulatory efficiency is impaired in several conditions, including extracellular fluid depletion, diuretic exposure, congestive heart failure, and renal parenchymal damage (7–10). Each of these conditions makes the organism more susceptible to acute renal failure in the face of relatively minor changes in BP that cause substantial changes in RBF (see later).

Development of Renal Blood Flow

Prenatal Renal Blood Flow

Fetal RBF is low but increases with gestational age. Doppler ultrasound at 25 weeks of gestation shows the RBF to be 20 mL/min, whereas at 40 weeks, the RBF is 60 mL/min (11). Within the kidney, the relative perfusion varies with cortical depth, with deeper nephrons of the cortex receiving more blood flow than nephrons in the superficial layers (12). This distribution of blood flow parallels morphologic maturation because deeper nephrons are the first to form and mature; superficial nephrons are not completed until near term (13).

Although the kidneys in the human embryo produce urine by 12 weeks' gestation, the role of kidneys in fetal homeostasis is minor compared to the placenta. The percentage of CO perfusing the kidneys is low during intrauterine life. During late gestation, the kidneys of fetal lambs receive only approximately 2.5% of the CO whereas the placenta receives 40%. The kidneys of 10- to 20-week

human fetuses receive only 3 to 7% of CO (14). Thus, the clinical relevance of intrauterine RBF and also glomerular filtration is less for the clearance of fetal plasma than for the formation of urine and, hence, amniotic fluid.

Fetal hemodynamics and urine formation are affected by maternal factors such as the maternal volume status, drugs, and vasoactive substances that cross the placenta. For example, acute oral hydration, which is sufficient to decrease plasma osmolality of healthy pregnant women, increases fetal urine production in near-term fetuses (15). Furosemide given to pregnant women induces diuresis in the fetus; likewise, maternally administered indomethacin lessens urine production and may lead to glomerular hypofiltration even after the baby is born (16,17). AT II has distinct effects on the maternal, uteroplacental, and fetal hemodynamics. Maternal circulation appears to be most sensitive to the vasoconstrictive effects of AT II, which would tend to preserve uteroplacental and fetal circulations (18,19). However, this fetoprotective effect disappears with long-term exposure to elevated levels of AT II. Thus, although the first 4 hours of AT II infusion into pregnant ewes did not compromise uteroplacental/fetal perfusion, more than 20 hours of heightened AT II caused a dramatic decrease in the placental perfusion and compromised fetal gas exchange (20). These observations illustrate the important effect of AT II on the uteroplacental circulation and, by extension, on fetal well-being. AT's actions to maintain BP *in utero* and at the same time maintain RVR at a high level can be compromised by inhibitors of its actions. AT-converting enzyme inhibitors (ACEIs) (e.g., captopril) lead to a decrease in fetal BP, RVR, and GFR in ewes, resulting in oligoanuria (21) and have been observed to cause anuria in the human fetus and newborn (22,23). These hemodynamic changes may result from decreased AT II synthesis or accumulation of bradykinin. AT II receptor antagonism did not affect BP or RVR in fetal piglets or puppies (24,25), whereas bradykinin receptor antagonism attenuated renal vasodilation after AT II receptor antagonism of neonatal rats (26). These findings indicate a role for vasodilatory role of kinins offsetting AT II-modulated vasoconstriction in the maturing kidney and complement the observations that the developing kidney expresses high levels of immunoreactive bradykinin and receptors (27,28). It is interesting that the kinin components localize to the deeper parts of the kidney (29), promoting preferential perfusion of the deeper rather than superficial nephrons characteristic of the fetal kidney.

Another vasodilator that likely plays an important role in fetal renal hemodynamics is nitric oxide (NO) (30). Basal production of NO in third-trimester fetal sheep maintains baseline RBF; its inhibition increased RVR by 50% and blocked the increase in GFR and the natriuresis that accompany volume loading. The NO effects may be direct or mediated by modulation of AT II actions. Overall, the low RBF *in utero* reflects incomplete renal mass that

increases exponentially during fetal life, structural immaturity of resistance vessels (narrower vascular lumina), as well as unique modulation by vasoactive compounds (e.g., AT II, prostaglandins, kinins, and NO).

Postnatal Renal Blood Flow

RBF, measured as a clearance of paraamino hippurate (CPAH) and corrected for body size, is low in human neonates and correlates with gestational age. For example, CPAH is 10 mL/min/m² in babies born at 28 weeks and 35 mL/min/m² in those born at 35 weeks of gestation (31). After birth, RBF increases steadily, doubling by 2 weeks and reaching mature levels by 2 years of age (32). The postnatal change in RBF primarily reflects the considerable increase in the relative RBF to the outer cortex (33–35).

RBF is governed by two factors: CO and the ratio of renal to systemic vascular resistance. After birth, both an increase in CO and a decrease in RVR favor an increase in RBF. Furthermore, RVR decreases much more than systemic vascular resistance (12) allowing for a progressive increase in the renal fraction of CO. For example, RBF increases 18-fold in newborn pigs during the first 5 weeks of life, whereas CO (corrected for body surface area) increases only 7.2 times during the same period (Fig. 2.1). RVR is a function of the arteriolar resistance offered not only by the sum of the glomerular vessels, but also by the number of existing vascular channels. New nephron formation increases the number of channels and, hence, decreases RVR. New nephron formation contributes to the postnatal decrease in RVR and increase in RBF only in premature infants born before 36 weeks of gestation (13).

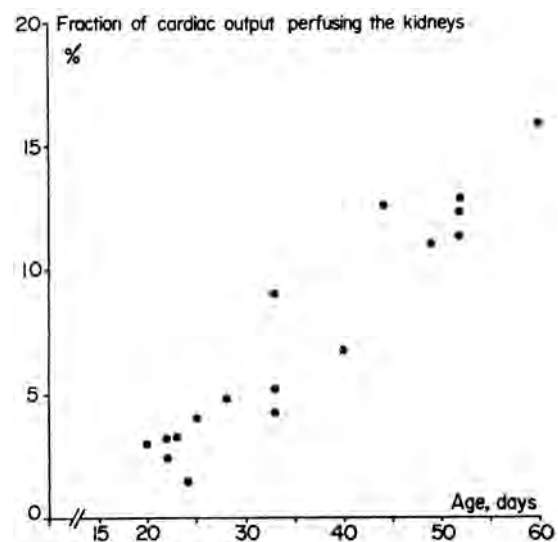

FIGURE 2.1. Renal blood flow as a percentage of cardiac output, plotted versus age, in growing rats between 17 and 60 days of age. (From Aperia A, Herin P. Development of glomerular perfusion rate and nephron filtration rate in rats 17 to 20 days old. *Am J Physiol* 1975;228:1319, with permission.)

Other factors that control the postnatal decrease in RVR largely affect the resistance of glomerular arterioles. In rats, both afferent and efferent arteriolar resistances decrease by a factor of three between 40 days of life and maturity (36). This decrease in RVR may be linked to a decrease in vasoconstrictors or activation of potent vasodilators. Catecholamines, but especially components of the renin-angiotensin system, are high in the early postnatal period of premature and term infants (37–41). The role of the renin-angiotensin system has been extensively studied. Angiotensinogen undergoes a dramatic postnatal increase in liver expression before decreasing and settling to adult levels (42). Renin production in neonates is robust and expands beyond the juxtaglomerular apparatus to include more proximal segments of the renal arterial tree (43). ACE is also abundant. Renal ACE increases postnatally such that within 2 weeks of birth the renal level surpasses the adult level as does the level of circulating ACE (44). Both the AT 1 and AT 2 receptor subtypes are expressed in the neonatal kidney (3,39–46). The AT 2 receptor is believed to play an important role in the apoptotic processes during organogenesis, which wanes postnatally (45,47). Expression of AT 1 receptors peaks postnatally at twice that of adult levels (46). Overall, the substrate, receptors, and the enzymes required for production and actions of AT II are abundantly expressed in the neonatal kidney and contribute to the vasoconstriction of the neonatal kidney. In addition, AT II has been shown to have an important role in the development and function of the renal outflow tract by inducing the development of the renal pelvis and by stimulating the proliferation and differentiation of smooth muscle cells around the ureters, thereby promoting ureteral peristalsis (48). Absence of these AT II-mediated effects promotes hydronephrosis.

Counteracting these vasoconstrictive effects are postnatal increases in the activities of prostaglandins, NO, and kinins, which contribute to the maturational increase in RBF. Indomethacin (which inhibits prostaglandin) lowers RBF in newborn rabbits (49) and decreases renal function in infants indicating an important role for vasodilator prostaglandins (49–52). Endothelium-derived NO release by the renal artery, as well as constitutive NO synthase activity in the renal microvasculature, increases with fetal and postnatal maturation of guinea pigs (53). This increase in NO production is paralleled by increased sensitivity of vascular smooth muscle to NO after birth, which contributes to NO's modulation of postnatal RBF. As *in utero*, vasodilators contribute to the maturational increase in RBF. However, as in the fetus, it may be linked to the renin-angiotensin system through the AT 2 receptor, a potent stimulator of prostaglandin, NO, and kinins (54).

Measurement of Renal Blood Flow

Concept of Clearance

Substances reaching the kidney through circulation may undergo glomerular filtration, tubular reabsorption, or

tubular secretion. Most solutes are freely permeable across the glomerular capillary and undergo filtration, followed by tubular reabsorption or secretion along the various nephron segments. Renal clearance of a substance X (C_x) is the volume of plasma from which X is removed (or "cleared") by the kidney within a period of time. Glomerular filtration and tubular secretion facilitate clearance of a solute, whereas tubular reabsorption impedes it. Clearance is calculated as follows:

$$C_x = (U_x \times V) / P_x$$

where U_x and P_x are the concentrations of X in urine and plasma, respectively, and V is the urine flow. The units of clearance are volume per unit time, usually in milliliters per minute. For example, if $P_x = 40$ mg/mL, $U_x = 80$ mg/mL, and $V = 100$ mL/min, then $C_x = 200$ mL/min. Clearance is a more appropriate concept in describing the renal handling of a certain substance than is urinary excretion rate (i.e., $U_x \times V$) because clearance takes into account the plasma level of X.

If a plasma substance is totally excreted on a single passage through the kidneys, it can be used as a marker of RPF. However, in reality, only approximately 92% of the total RPF passes through the functioning excretory tissue, a fraction termed *effective RPF*. Effective RPF is commonly measured as a CPAH, a weak acid that is almost completely extracted by the renal tubule cells and eliminated in the urine (55). Measurement of effective RPF as CPAH requires a constant infusion of paraamino hippurate and multiple plasma and urine specimens. A simplified modification using a single injection technique, although less accurate, can be used. The use of CPAH as an estimate of RBF has a major limitation in young infants because the renal tubular extraction of paraamino hippurate is incomplete; it is 65% in infants younger than 3 months of age and reaches adult levels only by 5 months of age (56). Thus, CPAH underestimates RBF in infants younger than 5 months of age.

Indirect Assessment of Renal Blood Flow

Radionuclide markers and radiographic techniques can be used to assess RBF. Radiopharmaceuticals used in imaging of the kidneys can provide estimates of RBF or GFR. They have gained wide use in clinical studies of both children and adults because they do not require biochemical assays. The markers are usually labeled with radioactive iodine or technetium. Because of concern that radioactive iodine may accumulate in the thyroid, noniodine radioactive tags are preferred in children. A major value of nuclear methods is the ability to obtain "split" renal function (i.e., separate measurements for each kidney).

Radioactive hippuran is another agent used for assessing renal function. It is excreted by glomerular filtration (20%) and tubular secretion (80%), both governed by RPF. After intravenous injection, timed images are obtained and a

computer-generated time activity curve is obtained for the region of interest drawn around each kidney. Split renal function is also calculated from the renogram by computer analysis. Other markers include iothalamate (57), orthoiodohippurate (handled by the kidney in a manner similar to paraamino hippurate and, hence, a marker of RBF), pentaacetic acid, and dimercaptosuccinic acid (58,59). Although the risk of radiation injury from most radionuclide agents in use is minimal, they are usually reserved for selected cases when accurate estimation of renal function is necessary, such as in the evaluation of a child before urologic surgery (e.g., nephrectomy) or in the follow-up of renal transplantation.

Doppler ultrasonography is a radiologic method that assesses blood velocity in the renal vessels. Although limited in its sensitivity, this method can provide screening information regarding the patency and flow through the renal vessels and detect significant arterial stenosis (60). The resistive index is a crude index of the resistance of the kidneys to blood flow. It takes into account systolic and diastolic blood flow in the renal vessels, as measured by Doppler, and may be helpful in the diagnosis and follow-up of some forms of acute renal failure, such as transplant rejection.

GLOMERULAR FILTRATION

Whole kidney GFR represents filtration occurring in both kidneys and is the product of single-nephron glomerular filtration rate (SNGFR) and the number of filtering nephrons. Formation of new nephrons (nephrogenesis) occurs mainly during intrauterine life and proceeds at different rates in different species. In humans, it is complete by 36 weeks' gestation and proceeds at the same pace when infants are born prematurely (13). Nephrogenesis continues postnatally in rats until 1 week (33), in dogs until 3 weeks (61), and in guinea pigs until 6 weeks of age (62). However, regardless of the species, once nephrogenesis is complete, it is not reactivated even in the face of reduction in the functional renal mass (i.e., disease or surgical resection). Any increase in GFR after nephrogenesis reflects increased filtration of residual nephrons. The degree of this compensatory increase correlates with the magnitude of the initial loss and is more pronounced in the young (63–72). Apart from lack of new nephron formation after nephron loss, compensatory renal growth reflecting increased tubule length and interstitial expansion can start *in utero*. For example, in the model of unilateral obstruction in fetal lambs at 60 days and contralateral kidney, weight increased by 50%, together with an increase in indices of cell proliferation (hyperplasia); however, there is no increase in glomerular number (66,67). The increase in single nephron function that follows a loss of other nephrons early in life is greater in glomeruli in the outer cortex; however, when loss occurs later in life, the increase is more evenly distributed among all residual nephrons (73).

The number of glomeruli in healthy humans has been taken to be, on the average, approximately 1 million in each kidney. However, new observations indicate that there is considerable interindividual variability in the total number of nephron units. The final complement of nephrons has been shown to be affected by an assortment of prenatal factors. For example, low birth weight, especially fetal growth retardation; protein malnutrition; vitamin A deficiency; drugs, such as gentamicin, amino-penicillins, cyclosporine A, and glucocorticoids; as well as metabolic disorders, such as maternal hyperglycemia, have all been shown to cause a significant nephron deficit in the fetus (74–81). Due to the very large number of individual nephron units contributing to the filtration process and the capacity to increase filtration within a single glomerulus, it is unlikely that this interindividual variability in nephron number impacts whole kidney GFR, although no studies exist on this possibility. Instead, the relevance of these findings stems from observations that individuals who have even a modest decrease in the complement of number of nephrons are at an increased risk of developing hypertension and progressive chronic renal dysfunction (74,82,83).

Theoretic Considerations of Glomerular Filtration

As a filtering structure, the glomerulus is essentially a tuft of capillaries, and filtration is transudation of fluid across the capillary wall into Bowman's space (Fig. 2.2). Two characteristics distinguish glomerular ultrafiltration from transcapillary exchange in other organs: (a) The glomerular capillary wall exhibits an extraordinarily high net permeability to water and small solutes, with up to 33% of intraglomerular plasma being filtered; and (b) the glomerulus almost completely excludes plasma proteins the size of albumin and larger from its filtrate. The filtration rate is determined by the same Starling forces governing movement of fluid across other capillary walls (i.e., imbalance between transcapillary hydraulic and oncotic pressure differences). These can be summarized as follows:

1. Mean glomerular transcapillary hydraulic pressure difference [$\Delta P = (P_{GC} - P_{BS})$]
2. Systemic plasma colloid osmotic pressure (π_A)
3. Glomerular plasma flow rate (Q_A)
4. Glomerular capillary ultrafiltration coefficient ($K_f = k \times S$)

When the individual pressures are expressed as average values over the entire length of the capillary, SNGFR is given by the equation:

$$\begin{aligned} \text{SNGFR} &= (k \times S) \times (\Delta P - \Delta\pi) \\ &= K_f \times P_{UF} \end{aligned}$$

FIGURE 2.2. Schematic representation of a glomerulus. Blood enters the glomerular capillaries through the afferent arteriole, courses through the capillary tuft, and exits through the efferent arteriole. Filtration takes place across the capillary wall into Bowman's space. Mesangial cells are strategically located to control the filtration surface area. The juxtaglomerular apparatus, one of the sites of glomerulotubular feedback regulation, is depicted. Terminals from the renal nerve are also shown. (From the artist, Dr. W. Kriz, with permission.)

where P_{GC} is the glomerular capillary hydraulic pressure and P_{BS} is the hydraulic pressure in the tubule; $\Delta P - \Delta\pi$ are the mean glomerular transcapillary hydraulic and colloid osmotic pressure differences, respectively; k is the permeability of the glomerular capillary, and S is the total surface area available for filtration; and K_f , the glomerular ultrafiltration coefficient, is the product of k and S . In this equation, average values are used for $\Delta P - \Delta\pi$ because ΔP decreases and $\Delta\pi$ increases as the plasma flows from the beginning to the end of the capillary within a given glomerulus.

Effect of Perturbation in Determinants of Single-Nephron Glomerular Filtration Rate

Mean Glomerular Transcapillary Hydraulic Pressure Difference

Changes in ΔP seldom play a significant role in altering SNGFR because the autoregulatory mechanism in the afferent arteriole sustains glomerular capillary pressure despite large changes in systemic BP (Fig. 2.3). For example, P_{GC} remained unchanged in Munich-Wistar rats despite a drop in RPP from 115 to 80 mm Hg induced by aortic constriction (8). Similarly, GFR in patients with mild to moderate hypertension is usually normal (84). As BP rises, spontaneously hypertensive rats maintain normal P_{GC} by increased afferent arteriolar resistance (85). However, when BP changes outside the autoregulatory range, both P_{GC} and GFR change accordingly. In circulatory collapse, GFR is severely reduced. Significant reductions in P_{GC} and SNGFR are noted in rats when BP falls below 80 mm Hg (8). As ΔP becomes equal to systemic plasma osmotic pressure (π_A), fil-

FIGURE 2.3. Schematic portrayals of the process of ultrafiltration as it proceeds from the afferent (A) to efferent (E) arteriole. **A:** Glomerulus with reduced mean transcapillary hydraulic pressure difference (ΔP). **B:** Increased systematic colloid osmotic pressure (π_A). **C:** Reduced glomerular plasma flow rate (Q_A). **D:** Reduced ultrafiltration coefficient (K_f). The shaded areas represent normal mean net ultrafiltration pressure (P_{UF}), determined by the normal profiles of hydraulic (ΔP) and oncotic ($\Delta\pi$) pressure differences. The altered ΔP profile as a consequence of each of the above changes is given by an interrupted curve in each panel. Curve 1 in C and curve 3 in D represent conditions of filtration pressure disequilibrium, whereas curve 3 in C and curve 1 in D represent equilibrium. The Starling equation is also given and describes the determinants for single-nephron glomerular filtration rate (SNGFR).

tration diminishes to zero. Conversely, when an increase in BP is extreme, P_{GC} and filtration increase despite a marked concurrent increase in preglomerular vascular resistance. During a decrease (or increase, respectively) in RPP, autoregulation of P_{GC} is largely determined by the ability of the afferent arteriole to constrict/dilate and of the efferent arteriole to respond conversely. It is important to note that the autoregulatory range is not fixed. For example, renal autoregulation is impaired by volume contraction. In volume-depleted animals, lowering BP leads to a reduction in P_{GC} and GFR at a relatively high RPP, whereas little or no change occurs in euvoletic animals (8). This effect and low circulating volume play significant roles in the reduction in GFR that accompanies hypovolemic shock. Renal autoregulation is also readjusted in severe chronic hypertension in which

acute hypotensive treatment may lead to a decrease in GFR and a rise in serum creatinine (S_{Cr}). Such a phenomenon in the setting of chronic hypertension might reflect a structural (i.e., not readily reversible) rather than functional narrowing of arteriolar lumen as a consequence of long-standing elevation in RPP. Although this change may be beneficial in maintaining P_{GC} and GFR in the steady state, it leads to a loss of responsiveness of the renal vasculature and to an acute reduction in RPP.

Changes in ΔP can also occur because of changes in P_{BS} . These occur with acute urinary tract obstruction and some forms of acute renal failure. Early in acute ureteral obstruction, whether partial or complete, SNGFR is well maintained despite marked elevation in P_{BS} due to compensatory increases in both P_{GC} and Q_A . Twenty-four hours after complete ligation of a ureter, P_{BS} returns to near normal, yet GFR remains low as a result of a low Q_A secondary to vasoconstriction. In chronic, mild unilateral ureteral obstruction, total kidney GFR, SNGFR, P_{BS} , and Q_A are nearly the same as values in unobstructed control kidneys. This preservation of GFR is a result of the development of two opposing changes in SNGFR determinants: an increase in P_{GC} and a reduction in K_f .

Systemic Plasma Colloid Osmotic Pressure

Derived primarily from serum proteins, π_A is a function of the number of molecules of protein present per unit volume of solution. At the same concentration, a small protein (e.g., albumin) contributes more to oncotic pressure than does a large protein (e.g., globulin). An isolated change in systemic plasma protein concentration (C_A), and hence in π_A , would theoretically be expected to change SNGFR in an opposite direction (Fig. 2.3). However, this does not occur. Acute reductions in C_A from 5.5 g/dL to 3.5 g/dL, induced by infusion of colloid-free solutions into rats, did not increase SNGFR because the fall in π_A and, hence, the rise in P_{UF} elicited a decrease in K_f ; the opposing influences of an increase in P_{UF} and a decrease in K_f maintained SNGFR nearly constant (34). Whether changes in π_A occurring chronically are also accompanied by changes in K_f is unknown. In the experimental rat model of nephrotic syndrome, K_f decreases significantly, accounting for a large decrease in SNGFR (86). This reduction of K_f observed in the nephrotic syndrome may account for the low or normal GFR rather than higher values that would be predicted when C_A is low and circulation volume is not appreciably affected (87).

Hypoproteinemia, in association with severe malnutrition, is often accompanied by a decrease in GFR (88,89). This decrease in GFR may be overlooked because S_{Cr} may not be elevated, consequent to a low muscle mass and creatinine production. GFR is reduced in protein malnutrition even when C_A is normal. The reduction in SNGFR is a result of reduced filtering surface area because glomerular size is smaller in protein-malnourished animals.

Glomerular Plasma Flow Rate

The impact of a change in Q_A on SNGFR depends on whether the other determinants of SNGFR have been concurrently modified (Fig. 2.3). For example, infusion of isoosmotic plasma selectively increases Q_A , whereas constriction of the aorta or the renal artery decreases both Q_A and ΔP (8). Under certain circumstances, filtration does not occur along the entire length of the glomerular capillary but ceases at some point before its end. This is because plasma oncotic pressure increases progressively from the beginning to the end of the glomerular capillary. This progressive rise in oncotic pressure is accelerated when K_f is high or Q_A is low. Thus, a decrease in Q_A results in cessation of glomerular filtration at an earlier portion of the glomerular capillary tuft and, hence, a reduction in GFR. Experimental administration of renal vasodilators, such as prostaglandin E1, acetylcholine, bradykinin, or histamine causes substantial increase in RBF and RPF in humans or in animals, but GFR is unaffected. SNGFR remains constant because of the opposing influences of an increase in Q_A and a decrease in K_f that occur in response (90). The unexpected decrease in K_f could represent a direct action of these substances on the glomerular capillary, distinct from their known dilatory effects. Conversely, vasoconstrictors, such as AT II and norepinephrine, are capable of producing substantial reductions in RPF but little resultant change in GFR. Again, this is a result of a significant compensatory increase in P_{GC} as a consequence of the pressor-induced increase in efferent arteriolar resistance (91).

Glomerular Capillary Ultrafiltration Coefficient

Glomerular capillary ultrafiltration coefficient is the product of the glomerular capillary permeability to water (k) and the surface area available for filtration (s). Because changes in K_f inevitably lead to directionally similar changes in D_p (Fig. 2.3), changes in K_f , unless extreme, are not expected to cause major changes in SNGFR. Nevertheless, a profound fall in K_f can affect GFR as demonstrated in rats with various experimental conditions. Many of these are disease models, such as minimal change nephrotic syndrome, acute renal failure, acute and chronic extracellular fluid depletion, and congestive heart failure in which a reduction in K_f is the main factor in decreasing SNGFR (10,89,91). A variety of hormones and vasoactive substances, including antidiuretic hormone, adenosine, AT II, endothelin, catecholamines, prostaglandins, acetylcholine, and histamine, modulate SNGFR by reducing K_f (10,89,92). The mesangial cells are believed to be the main locus of their actions because they appear to have a capillary surface area-regulating function. They possess intracellular contractile myofilaments, bear receptors to vasoactive agents, and visibly contract in response to these agents (Fig. 2.4) (93). It is speculated that hormones and vasoactive substances regulate glomerular capillary filtering surface areas, and hence GFR, by affecting mesangial contractility.

FIGURE 2.4. Structural expression of a reduction in the glomerular capillary ultrafiltration coefficient (K_f). The top panel represents the cast of a normal glomerulus; the bottom panel represents a glomerulus after a stimulus (renal nerve stimulation known to induce contraction of mesangial cells and a decrease in K_f) is applied. Mesangial cell contraction leads to obliteration of some of the glomerular capillaries (i.e., anatomic reduction in the surface area available for filtration), reflected as a decrease in the functional parameter K_f . (From Ichikawa I, Kon V. *Fed Proc* 1983;42:3078, with permission.)

Defense of Glomerular Filtration Rate

Nonmammalian vertebrates have effective homeostatic mechanisms to drastically alter GFR, which is critically important to maintain hydration in these species (94). They can afford to markedly alter GFR because toxic nitrogenous wastes are excreted through nonrenal organs such as gills, skin, and cloacae. In contrast, mammals, with their highly and variable fluid intake, have developed a greater capability to conserve and eliminate water from the body, largely through an expanded and highly regulated reabsorptive capacity of the renal tubules. However, because glomeruli are the only route for elimination of metabolic wastes and toxins, the GFR in mammals is remarkably constant and high relative to other species. Mammals have developed specific mechanisms that maintain GFR stable over a wide range of BP and extracellular fluid volume, which ensures an effective removal of large amounts of nitrogenous waste that are constantly pro-

duced. The mechanisms that maintain GFR stable depend on adjustments at the glomerular loci, namely the afferent and efferent arterioles, and likely also in the glomerular capillary bed itself (Fig. 2.5). Two mechanisms, namely the myogenic reflex and tubuloglomerular feedback, are important for the autoregulation of GFR during changes in BP. In the young, autoregulation of RBF is maintained through the same mechanisms but over a lower range of RPP that reflects the lower prevailing BP in the young (2,24).

Myogenic Reflex

The *myogenic reflex* describes the theory that an increase in transmural pressure increases vascular tone. In the renal circulation, this is particularly important in the afferent arteriole, which dilates in response to a decrease in RPP. This dilation also serves to preserve P_{GC} . At the same time, P_{GC} (and GFR) is also maintained in the adult animal through stimulation of renin release and the selective vasoconstrictor effect of AT II on the efferent renal arteriole (10). This reflex is independent of renal nerves or macula densa mechanisms and reflects the inherent characteristics of the vessel (24,95–97). This response has been demonstrated in isolated perfused renal vessels in which a change in vasomotor tone occurs in response to changes in the perfusion pressure in mature animals. However, a definitive role of the myogenic reflex during gestation and early life has not been defined.

Tubuloglomerular Feedback

Constancy of GFR is also determined by the tubuloglomerular feedback system, which describes the coupling of the distal nephron flow and SNGFR. In each nephron, the distal tubule returns to the parent glomerulus and contributes to the formation of the macula densa, which consists of specialized cells of the ascending loop of Henle located between the afferent and efferent arterioles and the glomerulus. In this system, the stimulus to adjust SNGFR is related to the rate of distal flow and also to the composition of the tubular fluid, particularly the chloride concentration and the tubule fluid osmolality (98–102). The signal is perceived in the macula densa and transmitted to the vascular structures of the nephron, particularly the afferent arteriole, but also to the efferent arteriole and the glomerular capillaries, which in concert adjust the rate of filtration. This feedback system is well suited to adjust the rate of filtration and maintain constancy of salt and water delivery to the distal nephron where tubular reabsorption is precisely regulated. Thus, an inverse relationship between filtration and tubular flow is established such that a decrease in tubular flow is anticipated to increase the rate of SNGFR and vice versa. The vascular response has been linked to several vasoactive substances, including adenosine, thromboxane A_2 , endothelin, NO, and particularly AT II (103–106).

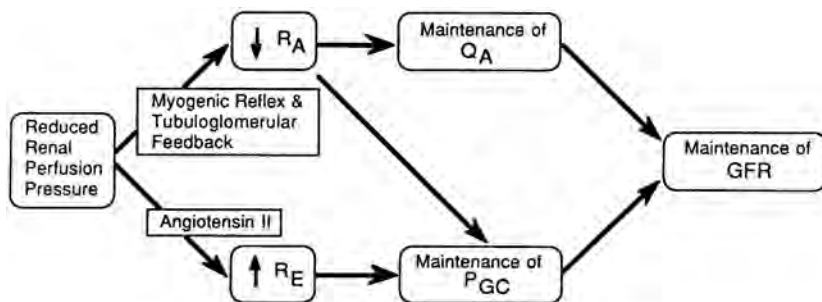

FIGURE 2.5. Mechanisms contributing to the autoregulatory maintenance of renal blood flow and glomerular filtration rates (GFR) in the face of a reduction in renal perfusion pressure. In the young animal, high baseline levels of angiotensin II, the inability to maximally activate the renin-angiotensin system on stimulation under certain circumstances, and low responsiveness of the vasculature to the constrictor action of angiotensin II may limit the ability to autoregulate GFR. P_{GC} , glomerular capillary hydraulic pressure; Q_A , glomerular plasma flow rate; R_A , afferent arteriolar resistance; R_E , efferent arteriolar resistance. (From Badr KF, Ichikawa I. Prerenal failure: a deleterious shift from renal compensation to decompensation. *N Engl J Med* 1988;319:623, with permission.)

The existence of a tubuloglomerular feedback mechanism has been established in the superficial nephrons of young (30-day-old) rats (107). Its sensitivity (i.e., the change of SNGFR induced by a given change in tubule flow rate) is maximal around the values of SNGFR and tubule flow rate prevailing under normal undisturbed conditions. As SNGFR and tubule flow rates increase with growth, adjustments in the tubuloglomerular feedback mechanism take place to maintain this relationship, and the relative sensitivity of the system remains unaltered.

As noted earlier, afferent arteriolar dilation and RBF adjust to decreasing RPP in both adults and immature animals. However, one study found that although decreasing the RPP by approximately 30% from baseline was accompanied by a minimal fall in the GFR in adult rats; in young rats, GFR plummeted by more than 80% (108). Micropuncture experiments revealed that the profound hypofiltration in the young rats reflected decreased glomerular capillary pressure. Because glomerular capillary pressure, in large part, reflects efferent arteriolar vasoconstriction maintained by AT II, the autoregulatory decompensation observed in the young animals likely reflects incompetence in the AT II-mediated vasoconstriction of the efferent vessels. In this connection, a similar degree of water deprivation causes a greater increase in the plasma renin activity in adult animals than in immature animals, and a higher dose of AT II is required in immature animals than in adult animals to effect a similar increase in glomerular capillary pressure (108). Taken together, it appears that the young have limited ability to activate AT II and that the immature efferent arteriole has a limited responsiveness to AT II. Thus, even in the face of afferent vasodilation after decreasing RPP, young animals develop hypofiltration. These observations provide a mechanism for dissociation between RBF and the GFR in that dilation in the afferent arteriole without sufficient vasoconstriction in the efferent arteriole is insufficient to maintain a transcapillary pressure that promotes glomerular hypofiltration in the young (Fig. 2.5).

As noted above, of the two currently recognized receptors for AT II, AT 1 and AT 2, the AT 1 is most abundantly expressed and transduces the bulk of the recognized actions of

AT II including efferent arteriolar constriction (3,109). Glomerular AT II hyporesponsiveness in the neonatal kidney does not appear to reflect inadequate AT 1 receptor density, as kidney AT 1 expression peaks postnatally at twice the adult level (46). Further, as noted above, AT II availability is also maximized, reflecting an abundance of renal angiotensinogen, renin, and ACE (42–44). The observed hyporesponsiveness of the neonatal kidney, therefore, appears to reflect inadequate postnatal maturation of post-receptor processes. It is possible, however, that the blunted vasoconstriction of the neonatal efferent arteriole in response to AT II reflects the vasodilatory contribution of the AT 2 receptor, which is abundant during development but wanes with maturation. This may occur through a direct effect of the AT 2 receptor or through AT 2-mediated stimulation of NO and bradykinin (54).

Development of Glomerular Filtration Rate

Prenatal Glomerular Filtration Rate

GFR in the fetus correlates with gestational age and body weight and parallels the increase in renal mass (110,111). There remains controversy as to whether this increase continues throughout gestation (112) or plateaus between 28 and 35 weeks of gestation (113). However, even corrected for body weight, prenatal GFR at every stage of development is much lower than that in adults. For example, creatinine clearance (C_{Cr}) measured within 24 to 40 hours of birth in 30-week premature infants is less than 10 ml/min/1.73 m² body surface area (11); at 34 weeks, it is less than 15 mL/min/1.73 m², whereas at 40 weeks, it ranges between 10 and 40 mL/min/1.73 m² (Fig. 2.6) (114). Direct measurement of intrauterine glomerular function is obviously limited, and creatinine is not an ideal indicator of fetal renal function because it freely crosses the placenta such that the fetal level actually reflects maternal levels. Recently, endogenous low-molecular-weight proteins such as β_2 -microglobulin and cystatin C have been shown to be useful in assessing renal function of adults, children, and infants and have been used to assess prenatal renal function (115–121). Cordocentesis measurements of β_2 -

FIGURE 2.6. Creatinine clearance measured within 24 to 40 hours of birth in 30-week premature to 40-week full-term infants. [From Chevalier RL. Developmental renal physiology of the low birth weight preterm newborn. *J Urol* 1996;156(2 Pt 2):714–719, with permission.]

microglobulin and cystatin C have generated reference values in fetuses with normal amniotic fluid volume, normal chromosomes, and absence of sonographic evidence of renal/extrarenal abnormalities as well as fetuses with abnormalities in these parameters or postnatal evidence of renal dysfunction (115). The study found that β_2 -microglobulin has higher sensitivity, and cystatin C has higher specificity of predicting impaired postnatal renal function, suggesting that these measurements may be a useful adjunct to the analysis of prenatal renal/urinary tract abnormalities.

Postnatal Glomerular Filtration Rate

At birth, the placental function of regulating fetal homeostasis becomes shifted to the kidneys. Compared to the adult, the GFR of a term newborn baby is less than 10% of the adult level whether expressed per gram of kidney weight, body weight, or surface area and correlates closely with the gestational age (Figs. 2.6 and 2.7) (122,123). However, during the first 2 weeks of life, the GFR doubles and continues to increase, reaching adult levels by 2 years of age (112,123). This increase lags in premature babies (124). As with RBF, development of GFR proceeds centrifugally, and the maturational increase in whole kidney GFR reflects primarily an increase in the SNGFR within superficial nephrons and less in the juxtamedullary nephrons (33,125,126).

All four determinants of SNGFR— ΔP , π_A , Q_A , and K_f —contribute to the maturational increase in GFR to varying degrees. In early stages, the systemic BP in humans averages 40 to 70 mm Hg, which is below the autoregulatory range (126,127) and likely contributes to a low P_{GC} and DP that has

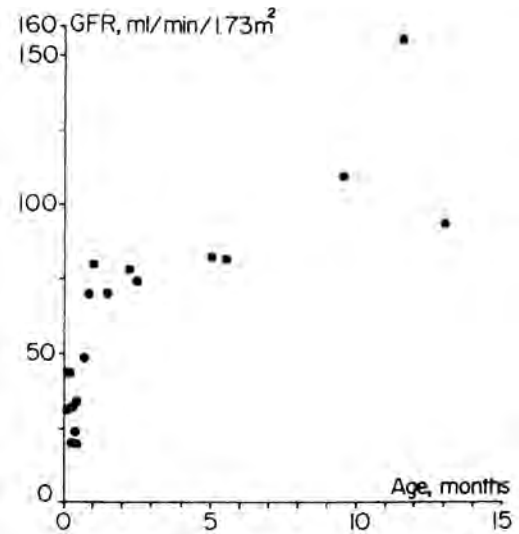

FIGURE 2.7. Glomerular filtration rate (GFR) during the first year of life. (From Aperia A, Broberger O, Thodenius K, et al. Development of renal control of salt and fluid homeostasis during the first year of life. *Acta Paediatr Scand* 1975;64:393.)

been shown in immature animals (36). Indeed, the BP in babies born at 28 to 43 weeks of gestation predicted their C_{Cr} (33,38). Plasma protein concentration, and therefore the resultant π_A , is lower in newborns than in older children (5 to 6 g/dL vs. 6 to 8 g/dL) and is a factor that increases ultrafiltration. However, the maturational increase in π_A that hinders ultrafiltration is offset by a more profound increase in P_{GC} having the net effect on P_{UF} to promote ultrafiltration. Experimental studies during later postnatal maturation indicate that π_A and P_{GC} are at adult levels and remain constant (36). The further increase in SNGFR is attributable to an increasing plasma flow rate, Q_A , that reflects an increasing caliber of afferent and efferent arterioles and decreasing resistances in these arterioles. Experimental and human observations support the parallel increase in plasma flow and GFR. Thus, increasing circulating blood volume by delayed clamping of the umbilical cord or intravenous fluid infusion increases inulin clearance (128,129). Finally, rising hydraulic conductivity as well as surface area of the glomerular capillaries likely contributes to maturational increase in the capillary ultrafiltration coefficient, K_f . Glomerular size, glomerular capillary basement membrane surface area, and capillary permeability to macromolecules all increase from neonatal period to adulthood (130–132). However, neither human nor animal data can provide the precise contribution of such changes to the increasing GFR.

CLINICAL ASSESSMENT OF GLOMERULAR FILTRATION RATE

Inulin Clearance

Assessment of GFR is the single most important measurement of renal function. Substances reaching the kidney

may undergo one of several processes, including glomerular filtration, tubule reabsorption, tubule secretion, and intrarenal metabolism. These considerations necessitated the search for an “ideal GFR marker.” Among various substances considered, inulin emerged and has remained the standard against which all other techniques of measuring GFR are compared to validate their accuracy (133). Inulin is a polymer of fructose, containing, on average, 32 fructose residues and has a molecular weight of approximately 5700 daltons. Natural inulin is derived from plant tubers such as dahlias, chicory, and Jerusalem artichokes. Although the molecular configuration of inulin varies depending on the source, the Stokes-Einstein radius that affects filtration is constant at approximately 5.0 nm. Inulin fulfills the following criteria:

1. It is freely and completely filterable at the glomerulus.
2. It is neither secreted nor reabsorbed by tubules.
3. It is neither metabolized nor synthesized by the kidney.
4. It is not bound to plasma proteins, or if it is, the free unbound as well as the bound components can be measured separately.
5. It is physiologically inert.

Because of these characteristics of inulin, the rate of inulin filtered into Bowman’s space equals the urinary excretion of inulin. Moreover, inulin concentration in Bowman’s space equals that of plasma. Thus, the flow rate of the fluid filtered into Bowman’s space is

$$\text{GFR} = C_{\text{In}} = U_{\text{In}} \times V / P_{\text{In}}$$

where C_{In} is the clearance of inulin; U_{In} and P_{In} are the inulin concentrations in the urine and plasma, respectively; and V is the urinary flow rate. For example, if $P_{\text{In}} = 0.5 \text{ mg/mL}$, $U_{\text{In}} = 50 \text{ mg/mL}$, and $V = 1.1 \text{ mL/min}$, then $\text{GFR} = C_{\text{In}} = 110 \text{ mL/min}$. Although this is a straightforward relationship, there are several points worth emphasizing. It is plasma, not urine, that is being cleared of inulin. In the above example, all inulin is removed from 110 mL of plasma each minute. The inulin clearance is independent of the rate of urinary flow rate. Thus, the concentration of inulin in the urine increases as the volume decreases and vice versa at a given GFR. The inulin clearance is also independent of the concentration of inulin in the plasma; thus, as plasma inulin concentration increases, its appearance in the urine increases as more is filtered. Although inulin clearance remains the most accurate method of assessing GFR, it is cumbersome in routine clinical settings. The drawbacks include difficulty in obtaining the inulin, the preparation of the inulin, and requirement for continuous intravenous infusion to maintain constancy in its plasma concentration. Moreover, measurements of inulin levels are not routinely available in hospital clinical laboratories. These drawbacks have led to the development of other methods to estimate GFR.

Creatinine as a Marker of Glomerular Filtration Rate

In clinical practice, GFR is most often estimated from measurements of S_{Cr} concentrations and the clearance of endogenously produced creatinine. These require only collections of urine or blood samples. Most commonly, renal function is estimated simply by obtaining an S_{Cr} measurement as the initial screening assessment and in monitoring the increase as an estimate of the rate of deterioration of renal function. In the steady state, $U_{\text{Cr}} \times V$ (creatinine excretion rate) equals creatinine production rate, which is constant. GFR is inversely proportional to plasma creatinine concentration because $\text{GFR} = (U_{\text{Cr}} \times V) / P_{\text{Cr}}$. Thus, an increase in plasma creatinine from 1 to 2 mg/dL or from 4 to 8 mg/dL represents a functional loss of 50% of GFR between measurements, although the absolute decline in function is less in the latter as is the fractional residual function. The utility of S_{Cr} measurement stems from the relatively constant production of daily creatinine and is independent of diet, protein catabolism, and physical activity. Creatinine production is a function of muscle mass. Approximately 1 g creatinine is derived from 20 kg muscle mass in 1 day (i.e., 50 mg/kg muscle) (134). In individuals of average proportions, creatinine production is 15 to 20 mg/kg/day in boys and 10 to 15 mg/kg/day in girls and infants. This is the amount that is expected to be found in a complete 24-hour urine collection. Thus, if GFR completely ceases (e.g., acute renal failure), the plasma creatinine concentration is expected to increase by approximately 1.5 mg/mL/24 hr.

C_{Cr} is a well-accepted estimate of GFR (as measured by C_{In}) in patients who are older than 1 month of age (135) who have normal or have only moderately decreased renal function. However, in some settings, C_{Cr} is an unreliable estimate of GFR. C_{Cr} overestimates GFR with severely decreased renal function; when GFR falls below 20 mL/min/1.73 m², C_{Cr} overestimates C_{In} by approximately 20%. C_{Cr} has been shown to overestimate C_{In} in adults with nephrotic syndrome (136) and in kidney transplant donors and recipients (137,138). Both C_{Cr} and C_{In} underestimate GFR in some forms of acute renal failure in which the functional integrity of the renal tubule is disrupted. Under these conditions, filtered creatinine and inulin can be reabsorbed by passive back diffusion. In acute tubular necrosis after cardiac surgery, 50% of filtered inulin undergoes tubular back leak (139). Thus, measurements of GFR in the setting of acute renal failure with tubule injury are invalid. Notably, although the value of GFR is relatively preserved in this setting, the clearance of creatinine, inulin, and the toxic metabolic wastes represented by these markers is compromised. In practice, therefore, changes in GFR are reflected by changes in S_{Cr} with sufficient accuracy to follow the course of patients with acute renal failure.

Values for S_{Cr} in human newborns are somewhat higher than the maternal S_{Cr} level, reflecting a gradient that allows fetal creatinine to be cleared largely by the maternal kidneys. Over the first few days of life, S_{Cr} decreases and represents GFR maturation, which eliminates both the maternal creati-

FIGURE 2.8. Plasma creatinine values during the first 3 months of life in low-birth-weight infants (less than 2000 g). (From Stonestreet BS, Oh W. Plasma creatinine levels in low-birth-weight infants during the first three months of life. *Pediatrics* 1978;61:788, with permission.)

nine and the newborn's endogenous creatinine production (Fig. 2.8). In normal premature infants, S_{Cr} values in the first 10 days of life range between 0.1 and 1.8 mg/dL with a mean of 1.3. During the first month of life, S_{Cr} declines gradually and becomes less than 1 mg/dL after 1 month of age (140). Low-birth-weight infants have daily urinary creatinine excretion rates during the first 2 weeks of life that correlate with birth weight, gestational age, and body length (141). S_{Cr} concentration in normal infants and children increases with age and is slightly higher at any age in male patients than in female patients (Fig. 2.9) (142). Estimation of GFR by C_{Cr} entails obtaining an accurately timed urine collection over a long period, ideally two 24-hour periods (see above). Investigators have attempted to derive formulas to estimate C_{Cr} from S_{Cr} level, in conjunction with anthropometric measurements such as height, weight, or body surface area. The following formula, derived by Schwartz and others, yields values of GFR that correlate with those obtained from C_{Cr} and C_{In} (143):

$$GFR = \delta L / S_{Cr}$$

where GFR is expressed in milliliters per minute per 1.73 m^2 ; L represents body length in centimeters; S_{Cr} is S_{Cr} in mil-

ligrams per deciliter; and δ , a constant of proportionality, is age and sex dependent. Although this formula is useful in day-to-day management, a more precise measurement of GFR (using C_{In} or iothalamate clearance) should be obtained whenever a high accuracy is desirable. New equations have been developed from the Modification of Diet in Renal Disease study that more accurately estimate GFR in adults than GFR measurements obtained by C_{Cr} (144). The equations take into account the individual's age, gender, race, and body size; however, the utility of these equations have not been tested in children.

Modifications of the Standard Clearance Method

Because of the difficulty in maintaining intravenous access and obtaining urine samples in newborn infants and young children, various modifications of the standard clearance tests have been used to yield indirect assessments of GFR. One modification uses an intravenous infusion of a GFR marker but does not require urine collection. Because at steady state the amount of marker infused per unit time (I)

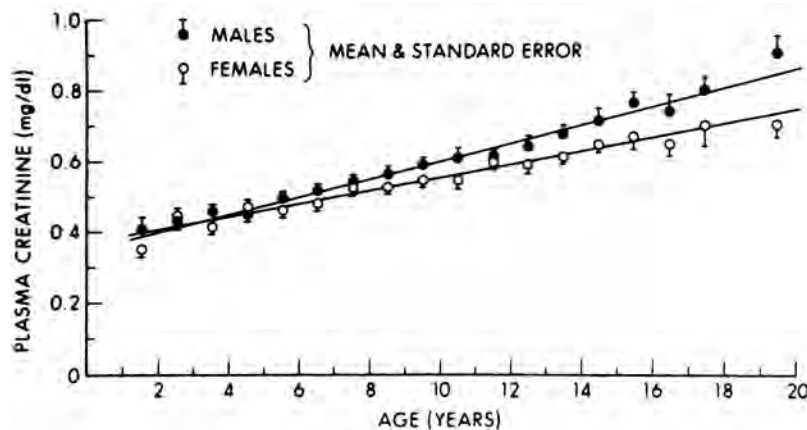

FIGURE 2.9. Mean plasma creatinine concentration (mg/dL) plotted against age for both sexes. The regression equations are for males: $y = 0.35 + 0.025 \times \text{age}$, and for females: $y = 0.37 + 0.018 \times \text{age}$. (From Schwartz GJ, et al. Plasma creatinine and urea concentration in children: normal values for age and sex. *J Pediatr* 1976;88:828, with permission.)

equals the amount excreted in the urine, as well as the amount filtered,

$$\begin{aligned} U_x \times V &= I \\ &= \text{GFR} \times P_x \\ \text{hence, GFR} &= I/P_x \end{aligned}$$

Thus, only blood sampling is required, together with accurate knowledge of infusion parameters (infusion rate and marker concentration) and certainty that a steady state has been attained. The method uses unlabeled iothalamate infused subcutaneously via a portable minipump (145). After steady state (8 to 24 hours), the marker clearance can be calculated, assisted by a computer program to correct for the child's age, gender, and body size. Some advantages of this method include its suitability for use in infants, in terms of its accuracy, simplicity, safety, and low cost.

Clearance of a marker has also been measured by a single injection of that marker, followed by analysis of its disappearance rate as assessed from repeated plasma samples. This method bypasses the necessity of continuous intravenous infusion and urine collection. A dose of inulin or polyfructosan (0.5 mL/kg of a 25% solution) is given intravenously, and seven or eight capillary blood samples are collected at 5, 10, 15, and 20 minutes, and then after 10- to 15-minute intervals; clearance of the marker is calculated using a mathematic model (146,147). Radiolabeled markers such as chromium-51-ethylene diaminetetraacetic acid (147) or iodine-125-iothalamate (57) have been used because they do not require biochemical assays. However, they remain costly and are still reserved for selected cases when accurate estimation of renal function is necessary.

Cystatin C as a Marker of Glomerular Filtration Rate

Although inulin clearance remains the gold standard and S_{Cr} concentration and C_{Cr} are currently most widely used to estimate GFR, a new endogenous marker has emerged that may obviate some of the limitations of the traditional methodologies. Cystatin C is a 13.6 kDa protease inhibitor constitutively synthesized by all nucleated cells that is freely filtered through the glomerulus and essentially completely reabsorbed and catabolized by tubular cells. Its measurement can now be performed by readily available immunoassay (118,148–151). Studies in adults and children, including premature babies, show that serum concentrations are not affected by gender, height, or muscle mass. It is important to note that the assay is also free from analytical interference from bilirubin and hemoglobin, which represent considerable confounders of S_{Cr} in newborns with jaundice or hemolysis from difficult blood draws.

A reference range has been established for adults (152–154). Recently, a pediatric reference range for cystatin C together with levels of S_{Cr} was published based on measurements in 291 children aged 1 day to 17 years, including

infants with gestational age ranging from 24 to 36 weeks (154). The data are shown in Figure 2.10. The data obtained in this study reiterate the high creatinine values at birth and during the first week of life (see above) and the fall that occurs over the first month. Creatinine levels then remain constant until 2 years of age when they rise to adolescent values. The authors emphasize that, by contrast, cystatin C values more closely parallel functional clearance studies. Thus, premature babies have the highest levels of cystatin C (0.43 to 2.77 mg/L; mean, 1.56), followed by infants less than 1 year of age reflecting kidney immaturity (0.59 to 1.97 mg/L; mean, 1.20). By 1 year of age, the range 0.50 to 1.27 mg/L (mean, 0.82) approximates levels found in adults of 0.51 to 0.98 mg/L and indicates essentially constant cystatin C concentration beyond 1 year of age. Recent studies also find that cystatin C may be a more accurate serum marker than creatinine in individuals with impaired renal function (155–157). Finally, even fetal serum concentrations of cystatin C appear to be useful predictors of postnatal renal function suggesting that this may well become a more universal marker of glomerular function (115).

GLOMERULAR SIEVING OF MACROMOLECULES

The enormity in the quantity of filtration generated by the glomerulus underscores specific features of the glomerular capillary bed that allows high permeability to water and small molecules while at the same time providing efficient selectivity that bars cells, proteins larger than albumin, and charged molecules (158,159). This barrier function of the glomerular capillaries is influenced by the size, shape, and charge of the macromolecules. Micropuncture studies and urinary clearance analyses that compare concentration of a given macromolecule in Bowman's space/urine to plasma have been used to obtain the glomerular sieving coefficient for a variety of macromolecules. Sieving coefficients are inversely correlated with the effective radius of the macromolecules. Thus, clearance of the larger proteins, such as albumin and globulin, is markedly less than that of smaller proteins such as monomeric immunoglobulin light chains (160,161). Molecules without charge, including dextran and polyvinylpyrrolidone, that are neither reabsorbed nor secreted (unlike proteins), have been used extensively to study glomerular capillary size selectivity both in experimental settings and in human diseases (160–170). Greater restriction of anionic than of neutral or cationic molecules suggests an electrostatic barrier that is charge selective. The observation that for a given chromatographic radius and charge density, the protein sieving coefficient is smaller than that of neutral dextrans suggests that the glomerular capillary barrier is also shape selective. Thus, proteins are believed to behave as rigid spheres, whereas dextrans are more compliant so as to have a smaller effective radii (161).

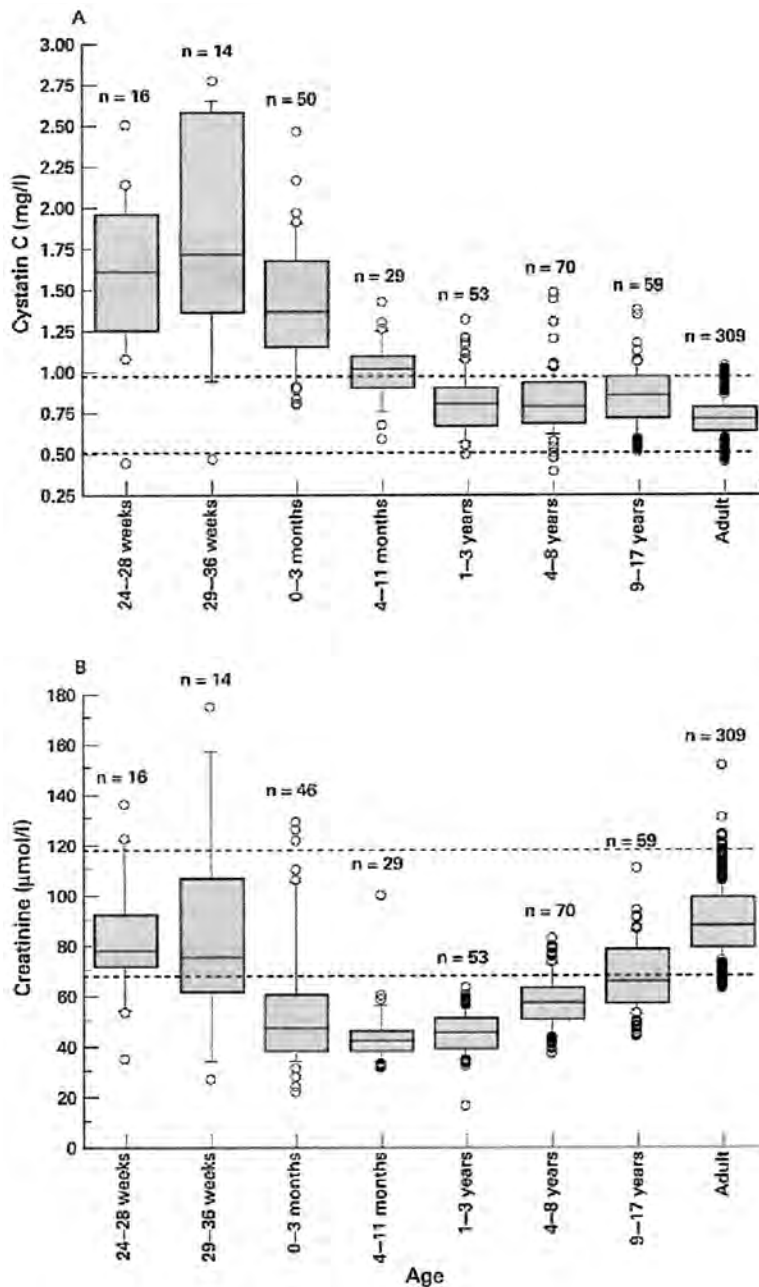

FIGURE 2.10. Range for cystatin C (A) and creatinine (B) measured in 291 children aged 1 day to 17 years. [From Finney H, Newman DJ, Thakkar H, et al. Reference ranges for plasma cystatin C and creatinine measurements in premature infants, neonates, and older children. *Arch Dis Child* 2000;82(1):71-75, with permission.]

It appears that each of the three major components of the glomerular capillary wall (endothelial cells, basement membrane, and epithelial cells with their podocytes and slit diaphragms) provide impedance to macromolecular filtration (Fig. 2.11). Both endothelial cells and epithelial cells are important in this barrier function as evidenced by the observation that permeability of the isolated glomerular basement membrane (GBM) is much higher than in the intact glomeruli (171). Indeed, native anionic ferritin particles accumulate in the endothelial fenestrae and in the lamina rara externa of the basement membrane. The GBM is increasingly being recognized as providing an important barrier to macromolecular

passage. The composition of the GBM includes type IV collagen, laminin, and proteoglycans that provide size and charge-selective restriction to glomerular filtration. Type IV collagen is a trimeric basement membrane specific protein that represents six genetically distinct forms that assemble in specific combinations *in utero* and in different combinations postnatally (172). Defects in adult collagen IV lead to distortion of the GBM that characterizes Alport's syndrome (172). Laminin plays a role in basement membrane structure, cellular differentiation, and adhesion. Laminin also provides sieving impedance, as mice deficient in laminin-2 chain develop nephrotic syndrome (173). Perlecan and agrin are the major proteogly-

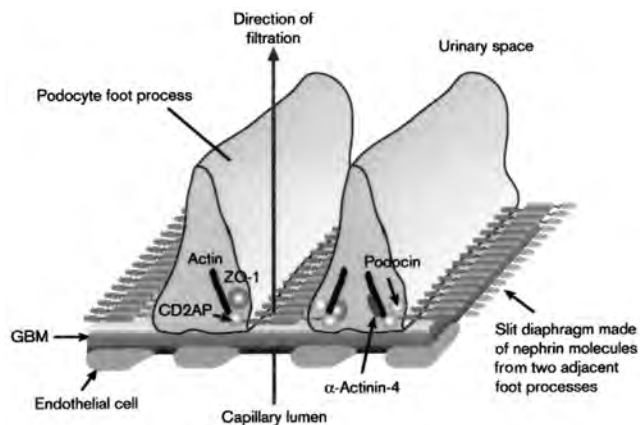

FIGURE 2.11. Molecular model of the glomerular filtration barrier. The three layers of the barrier are the fenestrated endothelial cells lining the inside of the glomerular capillary, the glomerular basement membrane (GBM), and the podocyte foot processes with their intervening slit diaphragm. CD2AP, CD2-associated protein; ZO-1, zonula occludens-1. (From Tryggvason K, Wartiovaara J. Molecular basis of glomerular permselectivity. *Curr Opin Nephrol Hypertens* 2001;10:543, with permission.)

cans in the GBM that contain high levels of negatively charged heparan sulfate moieties (174–176). Overall, it is currently believed that the endothelial cells together with the basement membrane components provide electrostatic impedance for negatively charged components of glomerular filtrate.

The epithelial cell layer of the glomerular capillary network is the site of restrictive size selection of macromolecular filtration. Indeed, the epithelial cells appear to provide the most significant element in glomerular permselectivity, and loss of epithelial podocytes has been shown to parallel the degree of proteinuria in patients with immunoglobulin A and diabetic nephropathies (177,178). Significant proteinuria is typically accompanied by dissolution of the normal interdigitation of epithelial podocytes. Notably, infusion of exogenous polycations, which cause proteinuria, also produce this podocyte lesion (179). Recent studies have clarified the molecular structure and functional implications of the epithelial podocyte slit diaphragms. Positional cloning has identified the gene mutated in congenital nephrotic syndrome of the Finnish type. The NPHS1 gene product, nephrin, is a transmembrane glycoprotein similar to immunoglobulin-like cell adhesion molecules, and nephrin is located in the podocyte slit diaphragms such that two adjacent molecules form the porous filter (180–184). Intracellularly, nephrin interacts with CD2-associated protein as well as other proteins such as podocin and zonula occludens-1 that connect with actin (185). Mice deficient in nephrin or CD2-associated protein have massive proteinuria and early death (173,181). These studies underscore the recent appreciation of the pivotal role of the podocyte and slit diaphragm in the glomerular filtration barrier function.

In addition to the structural characteristics of the capillary wall components that determine its permeability, indi-

FIGURE 2.12. Schematic representation of the relationship between glomerular capillary pressure (P_{GC}), functional pores in the glomerular capillary wall, and glomerular macromolecular sieving. An increase in P_{GC} as induced by angiotensin II, increases nonselective pores on the capillary wall allowing the bulk of macromolecules to escape into Bowman's space and then the urine. When the high P_{GC} is attenuated by saralasin, an angiotensin II antagonist, the abnormal presence of large nonselective pores and the sieving defect are largely corrected. (From Ichikawa I, Harris RC. Angiotensin actions in the kidney: renewed insight into the old hormone. *Kidney Int* 1991;40:586, with permission.)

vidual determinants of SNGFR also impact filtration of macromolecules (Fig. 2.12). Glomerular capillary flow rate, but particularly the glomerular capillary pressure, modulates membrane pore structure such that an increase in glomerular pressure augments proteinuria. The mechanism for this effect has been attributed to AT II–induced proteinuria. Thus, infusion of AT II, or endogenous stimulation of AT II activity, increases the fractional excretion of protein, whereas decreasing the pressure has the opposite effect (186–188). These studies underscore that glomerular hemodynamic changes, through increasing the large nonselective pores in the glomerular membrane, can allow macromolecules to escape into the urinary space (Fig. 2.12). It is of interest that acute exercise-induced proteinuria, in which the sieving defect is believed to be linked to increased intraglomerular pressure, is lessened by pretreatment with ACEI (189). Conversely, antagonism of AT II actions by ACEI or AT II receptor antagonist acutely lessens proteinuria and is well documented to decrease protein excretion in many different chronic settings (190–196). The mechanism for this antiproteinuric effect is in part related to decreased efferent arteriolar resistance and there-

fore glomerular capillary pressure (197). This effect occurs, at least in part, because of a decrease in AT II. However, it also occurs because of an increase in bradykinin, which is also elevated during ACE inhibition and can be abolished by bradykinin antagonism. It should be emphasized that although hemodynamic effects are important in modulating proteinuria, it is likely that more chronic antagonism of AT II activity by ACEI or AT II antagonists also therapeutically preserves glomerular structure and lessens proteinuria.

RUSSELL W. CHESNEY

ANATOMIC ORGANIZATION

The renal tubule forms an epithelial surface that, through the processes of reabsorption and secretion, adjusts glomerular filtrate so that excretion balances input and body composition is kept close to normal. In particular, this function maintains extracellular fluid (ECF) volume and electrolyte and acid-base homeostasis, maintains substrate levels, and excretes a wide variety of organic solutes, including drugs.

The renal tubule is divided into 12 segments; each has distinct morphologic and functional characteristics. The differences that set apart each segment result from the changes in distribution of transport systems on the apical and basolateral surface of the epithelial cells of each of these segments and to the anatomic arrangement in which cells from one segment influence the environment and function of another segment. The membrane properties of segments change as the tubule progresses from its proximal origin to its distal terminus. A series of at least 16 different tight junction proteins, termed *claudins*, are found in segment-specific expression patterns along the nephron in each of these 12 segments (1). Changes in the volume and composition of peritubular capillary fluid and of tubular luminal fluid also influence these transport processes.

Reabsorption is the net transfer of solutes from luminal fluid to pericapillary fluid; secretion is the reverse. The transfer may be transcellular across apical and basolateral membranes or paracellular across epithelial tight junctions into intercellular spaces. In many cases, it is bidirectional, and the net transfer may change from reabsorptive to secretory as conditions dictate.

Some solutes, particularly organic substrates and phosphates, are reabsorbed almost exclusively in the proximal convolution. Electrolytes, including hydrogen ions, are transferred by segments along the entire nephron, sometimes being reabsorbed and then secreted, or the reverse. Often, there are different transport systems for the same solute, such as glucose or organic acids. The proximal segments reabsorb the bulk of glomerular filtrate. The distal segments effect more precise adjustments of solutes, partic-

ularly electrolytes, and water. This fine-tuning preserves ECF and whole-body composition within the narrow margins we describe as normal and buffers change in ECF composition through disease.

Developmental Pattern

At birth, the infant is transformed from an organism dependent on the maternal placenta to an independent organism that relies largely on renal function to maintain homeostasis. From midgestation, the kidney develops rapidly so as to be able to fulfill its function at birth. Nephrogenesis is complete by 36 weeks' gestation; tubular maturation begins early in the second trimester, is very active during weeks 32 to 36 of gestation, and continues well into postnatal life (2,3). Factors that affect this maturation and transport capacity include the density, structure, and turnover of specific transporter proteins, in particular, the activity of Na⁺-K⁺-ATPase; the electrochemical gradient across the cell membrane; hormone responsiveness; membrane surface area, phospholipid content, and fluidity; and cell metabolic activity (3).

This chapter reviews the transport functions of the individual classes of solutes that are transferred, beginning with those specific to the proximal segments and proceeding to those transferred along the 12 segments of the nephron from origin to terminus. In each case, we consider overall tubular handling and the cellular mechanisms and regulatory systems involved in solute transfers. We also describe developmental features affecting each class of solutes.

Before describing the transport mechanisms for each class of solute, we note that three levels of active transport operate along the nephron. The *primary* active transport systems are those in which energy derived from adenosine triphosphate (ATP) hydrolysis is used. The major component of this primary system is Na⁺-K⁺-ATPase. Others include H⁺-ATPase and Ca²⁺-ATPase. *Secondary* active transporters are those in which sodium transport is coupled to the antiport or cotransport of another solute. These include Na⁺-H⁺ exchange; the Na⁺-K⁺-2Cl⁻ cotransporter;

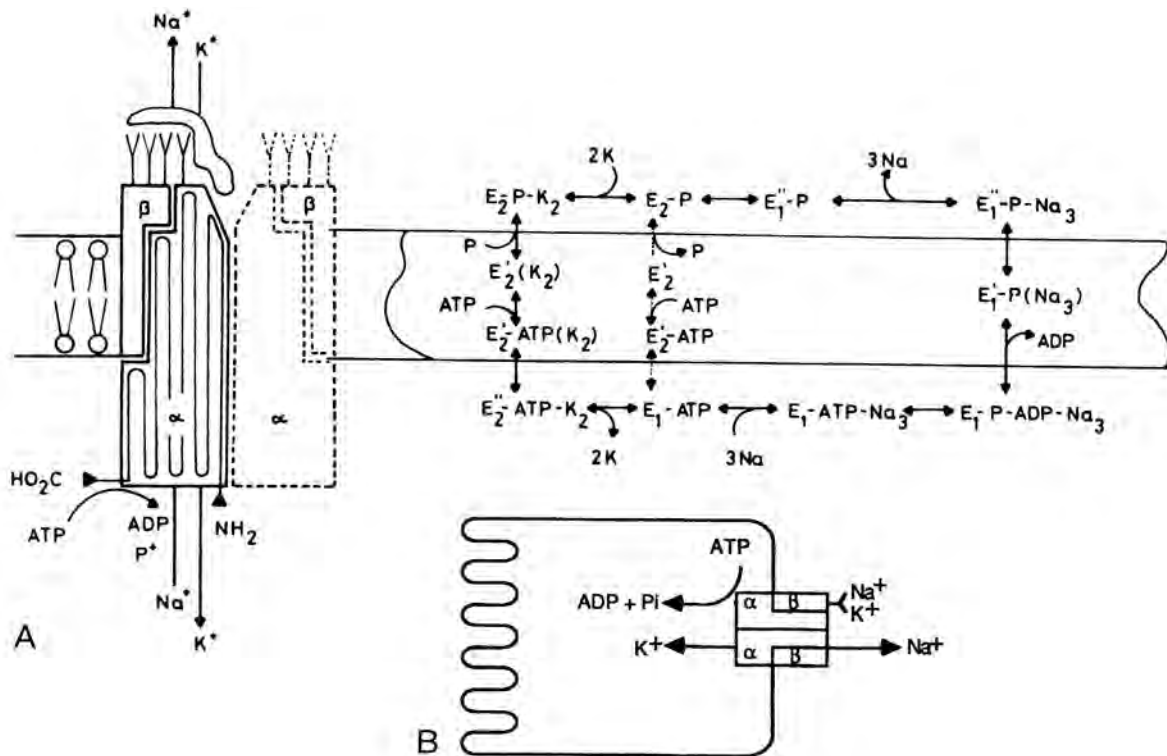

FIGURE 3.1. A: Model of Na⁺-K⁺-adenosine triphosphatase (ATPase) and biochemical reactions involved in the sodium-driven conformational changes of the α subunit. The 3 Na⁺ bind to E₁-ATP to form phosphorylated E₁-P, which releases the 3 Na⁺ at the outer surface and undergoes a conformational change to the E₂ form, then binds to 2 K⁺ and is dephosphorylated at the inner surface, where it binds to ATP and releases the 2 K⁺. The intermediate pathway represents reactions in the absence of extracellular K⁺. B: Model of the cellular orientation of the Na⁺-ATPase. ADP, adenosine diphosphate. (From Guder WG, Morel F. Biochemical characterization of individual nephron segments. In: Windhager EE, ed. *Handbook of physiology: renal physiology*. New York: Oxford University Press, 1992:2120–2164, with permission.)

and the amino acid, glucose, and phosphate cotransporters. These symport and antiport systems couple the downhill influx of sodium with the uphill flux of the other solute. *Tertiary* active transport systems are those that are coupled to secondary active transport processes. Examples are the Cl⁻-formate exchanger, which is coupled to Na⁺-H⁺ exchange, and the organic anion exchanger, which is coupled to ketoglutarate exchange. Selective ion channels enable ions to diffuse down their concentration gradients.

The use of human cell lines with extended *in vitro* growth potential, especially if they are fully differentiated, have permitted new insights into tubular transport function (4). Likewise, the use of tissue-engineered bioartificial renal tubules, in which porcine proximal tubule cells are seeded into the intraluminal space of a high-flux hollow-fiber hemofiltration cartridge, has permitted study of differentiated transport as well as the metabolic and endocrine functions of the kidney (5).

Na⁺-K⁺-ATPase

Na⁺-K⁺-ATPase transports sodium from cells in exchange for potassium uptake into cells. In the renal tubule, this activity

is located on the basolateral cell membrane and is the energy-dependent step that regulates sodium chloride reabsorption. Sodium reabsorption begins with its passive transport from luminal fluid across the apical membrane into the intracellular space by secondary transporters (see earlier). It is actively transported out of the cell into peritubular fluid by Na⁺-K⁺-ATPase (Fig. 3.1). This step creates the favorable electrochemical gradient necessary for continued transport of solutes from luminal fluid into the cell and then into pericapillary fluid, which completes the reabsorptive process. The high level of renal Na⁺-K⁺-ATPase activity accounts for the high level of renal oxygen consumption and energy expenditure (6). With the hydrolysis of ATP, this pump exchanges three intracellular sodium ions for two extracellular potassium ions, thus maintaining a low intracellular sodium concentration and creating a sodium concentration gradient from lumen to cell. In addition, the high intracellular potassium concentration establishes a cell membrane potential difference (PD) of -60 mV inside the cell.

Na⁺-K⁺-ATPase is composed of two subunits, α and β, which link the hydrolysis of ATP to the translocation of Na⁺ and K⁺ (Fig. 3.1). The phosphorus from ATP phos-

phorylates an amino acid residue of the α subunit, which binds to potassium on the extracellular face. This binding site is the same as that for ouabain. Na^+ binds to the internal cell surface of the α subunit and is translocated to the extracellular face of the membrane along with adenosine diphosphate. The stoichiometry of the process is 3Na^+ exchanged for 2K^+ per ATP hydrolyzed. Three isoforms of the α subunit (α_1 , α_2 , and α_3) and two isoforms of the β subunit (β_1 and β_2) have been identified (7). The α_1 and β_1 forms are found in the mature kidney.

Regulation of $\text{Na}^+\text{-K}^+\text{-ATPase}$ Activity

Agents with a natriuretic action, such as dopamine, atrial natriuretic factor (ANF), parathyroid hormone (PTH), endothelin, and prostaglandin E_2 , inhibit $\text{Na}^+\text{-K}^+\text{-ATPase}$, whereas agents such as norepinephrine, α -adrenergic receptor agonists, insulin, and angiotensin (low dosages) stimulate $\text{Na}^+\text{-K}^+\text{-ATPase}$. In the dopaminergic system, CA1 receptors are coupled to adenylate cyclase such that dopaminergic agonists simultaneously increase cyclic adenosine monophosphate (cAMP) and phospholipase C_2 with activation of protein kinases, which phosphorylate a regulatory protein and potentially specific phosphorylation sites on the α subunit of $\text{Na}^+\text{-K}^+\text{-ATPase}$. Phosphorylation of the α subunit reduces ATP hydrolysis and changes the equilibrium between sodium binding E_1 and potassium binding E_2 forms (8).

Developmental Changes in $\text{Na}^+\text{-K}^+\text{-ATPase}$ Activity

The activity of the $\text{Na}^+\text{-K}^+\text{-ATPase}$ increases during development, as does the expression of the α and β subunits. Striking increases occur during weanling (9). The activity of the $\text{Na}^+\text{-K}^+\text{-ATPase}$ in homogenized whole rabbit kidney and isolated tubules from rabbit is lower in neonatal kidney than in the adult kidney; however, the distribution and the affinity constants for Na^+ and K^+ are identical (10,11). The increase in $\text{Na}^+\text{-K}^+\text{-ATPase}$ that occurs during development parallels the increase in sodium reabsorption. In developing rats, an increase in sodium reabsorption precedes an increase of $\text{Na}^+\text{-K}^+\text{-ATPase}$ (12). Studies performed in guinea pig renal cortex demonstrate that pump activity increases fourfold to fivefold during transition from fetus to newborn. Most of the postnatal increase in basolateral pump activity was related to increased pump synthesis rather than redistribution of preformed pumps from internal stores. The increase in pump protein abundance was greater than the increase in mRNA for both α and β subunits, leading to the conclusion that posttranscriptional upregulation might account for the marked increase in pump abundance (13). Inhibition of the $\text{Na}^+\text{-H}^+$ pump, the major mechanism for active sodium entry into the cell, reduces the activity of the $\text{Na}^+\text{-K}^+\text{-ATPase}$ in weanling rats,

and manipulations that increase the $\text{Na}^+\text{-H}^+$ exchanger activity stimulate $\text{Na}^+\text{-K}^+\text{-ATPase}$ (14). The rate of sodium entry into cells and intracellular sodium concentration regulate transcription of both subunits of $\text{Na}^+\text{-K}^+\text{-ATPase}$ (15). Inhibition of $\text{Na}^+\text{-K}^+\text{-ATPase}$ leads to an increased cell sodium concentration, which, within hours, stimulates synthesis of $\text{Na}^+\text{-K}^+\text{-ATPase}$ (15). Glucocorticoid hormones increase transcription of both subunits of $\text{Na}^+\text{-K}^+\text{-ATPase}$ in the newborn rat kidney (16). $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity is acutely affected by other hormones and intracellular second messenger systems. The immature kidney has a blunted response to dopamine and protein kinase C activation (17).

PROXIMAL TRANSPORT SYSTEMS

The proximal tubule has three nephron segments (S1, S2, and S3), which differ from each other morphologically. Cells of the early, or S1, segment have a greater density of microvilli and deeper basolateral membrane infoldings, as well as an abundance of mitochondria. Transport capacity for most solutes (NaCl , bicarbonate, glucose, amino acids, and phosphate) is greatest in the S1 and less in the S2 and S3 segments. This difference may result from the high permeability of the epithelium to solutes and water or to intrinsic differences in the density or kinetic properties of specific transport processes. Changes in the transport rate do not automatically imply a greater intrinsic transport capacity; for example, a decrease in transport rate may follow decreasing substrate concentration as luminal fluid moves distally along the proximal tubule (5,18). Later segments may be described as having less surface area and decreased capacity for transport, both transcellular and paracellular. However, these later segments are also less permeable to solutes and fluid because they have tighter junctional complexes; backleak is minimal in the region of these segments, and a higher concentration gradient is thereby achieved. This illustrates a common theme: The arrangement of transcellular transporters and intercellular permeability characteristics in series in the proximal tubule favors a higher flux in the proximal segment and creation of steeper concentration gradients in the later segments. This arrangement achieves almost complete absorption of nutrients and organic solutes as luminal fluid passes through the proximal tubule (5,18).

Functionally, the proximal tubule performs two major functions: the reabsorption of almost all of the filtered glucose, amino acids, phosphate, and bicarbonate and reabsorption of more than one-half of the sodium, chloride, and water. Figure 3.2 describes the relative reabsorption of various solutes along the length of the proximal tubule. The tubular fluid (TF):plasma (P) ratio of each solute relative to that of inulin is represented; a TF:P ratio less than 1 denotes a drop in TF concentration and indicates net reabsorption. The PD across the proximal tubular epithelium is lumen negative and that of the later (S3) is lumen positive (18).

FIGURE 3.2. Reabsorption of solutes along the proximal tubule in relation to the TF:P ratios and potential difference (PD) across the tubular epithelium. TF/P represents the ratio of tubule fluid to plasma concentration. The area above the line denotes that the substance is secreted, and below the line that the solute is reabsorbed. OSM, osmolality; PAH, *p*-aminohippurate. (Adapted from Rector FC Jr. Sodium, bicarbonate, and chloride absorption by proximal tubule. *Am J Physiol* 1983;244:F461.)

Glucose

Glucose is almost completely reabsorbed by the proximal tubule; less than 0.05% of the filtered load appears in urine when the serum level is within the normal range. As the filtered load of glucose increases, the quantity of glucose reabsorbed also increases until the maximum rate of glucose reabsorption (Tm_G) is achieved. The plasma level of glucose at which glucose reabsorption is maximal is known as the *threshold for glucose*. The transport capacity (milligrams per minute) when the threshold is reached is called the Tm_G . The limited capacity for glucose transport is probably related to the number of carrier or transport molecules on the brush-border membrane surface and the basolateral membrane. These carrier systems work in series to transport glucose from the luminal fluid to the intracellular space and then into the pericapillary fluid. The transport maximum for glucose may be modified by factors other than the number of glucose transporters: ECF volume, glom-

ular filtration rate (GFR), intracellular sodium concentration, and the electrical potential across the tubular epithelium (19). A number of membrane-associated polypeptides are also found at the inner side of the plasma membrane. These influence incorporation and/or retrieval of transporters into the membrane, a process which alters membrane capacitance (20). The membrane protein, termed *RSI*, also influences the organic cation transporter (OCT2).

Heterogeneity of Glucose Transport Along the Tubule

The bulk of filtered glucose is reabsorbed by the first 3 mm of the proximal tubule (S1), with negligible reabsorption by S2 and S3 segments (Fig. 3.2). There are two components of glucose flux: nonsaturable, passive paracellular diffusion and saturable, active transport, which is transcellular. The rate-limiting step in glucose reabsorption is the activity of the glucose transporter, which is located on the brush-border membrane surface. The kinetic properties of the glucose transporter vary among the segments of the proximal tubule: in the S1 segment, there is a high-capacity (J_{max}), low-affinity (Km) system; in the S2 segment, a high-affinity, lower-capacity system; and in the S3 segment, an even higher-affinity, lower-capacity system (Table 3.1) (21). The permeability of the diffusion pathway decreases with increasing distance along the proximal tubule. Hence, the rate of glucose reabsorption decreases along the length of the proximal tubule as the character of the transport proteins change, the permeability of the diffusive pathway changes, and the concentration of glucose in luminal fluid declines. This diversity allows high glucose flux in the early proximal tubule and then a steep uphill reabsorption as the affinity for glucose increases along the late proximal tubule, where backleak is minimal. A question still remains: Do these heterogeneous functions of the uphill glucose transporter (SGLT1) indicate two independent transporters or different transport modes through an oligomeric protein? The most likely explanation is that heteroassociation with regulatory subunit(s) contribute to this heterogeneity of glucose handling (22).

TABLE 3.1. COMPARISON OF KINETIC PARAMETERS FOR GLUCOSE TRANSPORT IN PROXIMAL TUBULE SEGMENTS

Segment	V_{max} (pmol/min/mm)	Km (mM)
Convoluted (S1)	83.2 ± 5.0	1.64 ± 0.19
Early straight (S2)	12.9 ± 1.1	0.70 ± 0.12
Late straight (S3)	7.9 ± 0.5	0.35 ± 0.05

FIGURE 3.3. Model of glucose transport by the proximal tubular cell. (1) Glucose enters the proximal tubular cells by an apical brush-border cotransporter along with either one or two sodium ions, depending on the location of the transporter along the proximal tubule. (2) A transporter for other hexose sugars in addition to glucose is present on the apical surface. (3) Exit across the basolateral membrane of the cell occurs through a sodium-independent transporter. The $\text{Na}^+\text{-K}^+\text{-ATPase}$ is also illustrated.

Cellular Processes Involved in Glucose Reabsorption

Three steps are involved in the reabsorption of glucose: uptake of glucose into the cell by a sodium-dependent glucose transporter in the apical membrane, diffusion of free glucose in the intracellular fluid, and exit from the cell via a specific sodium-independent transport process in the basolateral membrane (Fig. 3.3). The transport of glucose across the apical membrane is by secondary active transport dependent on the electrochemical sodium gradient that is produced by $\text{Na}^+\text{-K}^+\text{-ATPase}$. The transport is carried out by two structurally and kinetically distinct apical glucose transporter proteins (19,23): One has a high capacity and a low affinity (SGLT2) and the other a low capacity and high affinity (SGLT1) for glucose. The transporter-coupling ratios of sodium to glucose are 1:1 for the S1 segment and 2:1 for the S2 and S3 segments (24). The sensitivity of the two systems to phlorizin, a competitive inhibitor of the glucose transporter, also differs. Phlorizin binding appears to influence both the glucose- and Na^+ -binding sites (25). The transitional steps involved in glucose uptake at the brush-border membrane have been elucidated. The initial binding of sodium at the luminal outside surface induces a conformational change that increases affinity of glucose binding. This is followed by presentation of sodium and glucose to the cytoplasmic side, in which the low sodium concentration favors disassociation of sodium, which reduces the affinity of the transporter for glucose that is then released into the cytosol. Then, the transporter orients sodium- and glucose-binding sites back toward the extracellular domain for repeated transport (26).

Molecular Studies of Sodium-Dependent and Sodium-Independent Systems

The distribution of the two apical sodium-dependent glucose transport systems may account for the kinetic differences men-

tioned earlier. There are two distinct sodium-dependent luminal sugar transporters in the proximal tubule. The SGLT2, which is localized to the early proximal segment, is specific for glucose, has a 1:1 stoichiometry with sodium, and accounts for approximately two-thirds of glucose absorption. The SGLT1 transporter accepts galactose as well as glucose, has a 2:1 stoichiometry ($\text{Na}:\text{sugar}$), and is found along the brush border of all proximal segments (22,26). The gene for the sodium-dependent glucose transporter has been localized to chromosome 16. The human transporter protein is 664 amino acids in length, with ten transmembrane helical domains and a molecular weight of approximately 73 kDa (26). The renal cortical, sodium-dependent glucose transporter is similar to that found in small intestine (27).

The basolateral glucose transport systems (GLUT) do not require Na^+ and are not inhibited by phlorizin. At least five distinct GLUT transporters are distributed among numerous tissues, with two predominantly expressed in renal tubule and intestine (28). One has higher affinity and lower capacity (GLUT 1), and the other has lower affinity and higher capacity (GLUT 2). These two systems are distributed differently along the renal tubule: GLUT 1 is present in the glomerulus and along the entire proximal tubule, whereas GLUT 2 is localized exclusively to the basolateral membrane of early proximal convoluted tubule (S1) (29). The specific locations of the two basolateral glucose transport systems parallel those of the apical, sodium-dependent systems. The basolateral glucose transporter system of renal cells is structurally similar to that of erythrocytes and hepatocytes (23,29).

Developmental Changes in Glucose Transport

The increase in glucose reabsorption during late fetal life through infancy and childhood parallels the increase in GFR. However, glucosuria is more common among neonates, and the levels of glucose in urine are highest in preterm infants (65 ± 78 mg/dL), lower in term infants (15 mg/dL), and even lower in adults (6 ± 2 mg/dL) (24). Tm_{G} , when adjusted to standard surface area and to GFR, tends to be lower in preterm and term infants (Table 3.2) than it is in adults (30).

Factors that increase the glucose absorptive capacity during growth from fetal life to maturity include development of new nephrons, increases in cell membrane surface area and in basolateral $\text{Na}^+\text{-K}^+\text{-ATPase}$, and changes in expression and density of transporter proteins (31–34). The maximal rate of glucose transport into brush-border vesicles is lower in preparations from fetal kidneys than in those from adult kidneys (Fig. 3.4); the density of transporter proteins is higher in adults (31). Age-related differences in glucose transport capacity correlate with differences in sodium conductance. Changes in membrane permeability to sodium affect membrane potential, a factor that modifies glucose reabsorption.

TABLE 3.2. NORMAL VALUES FOR TUBULAR MAXIMUM FOR GLUCOSE

	Tm_G^a (mg/min/1.73 m ²)	Tm_G/GFR^b (mg/mL)
Adults	290–375	2.3–2.7
Children	250–400	1.8–2.9
Infants		
Term	35–290	0.9–2.9
Premature	25–190	2.3

^aMaximum tubular reabsorption of glucose.

^bMaximum tubular reabsorption of glucose per mL glomerular filtration rate (GFR).

Adapted from Brodehl J, Franken A, Gelissen K. Maximal tubular reabsorption of glucose in infants and children. *Acta Paediatr Scand* 1972;61:413–420.

Maturation of the glucose transport system parallels maturation of bicarbonate flux, fluid absorption, and basolateral surface area of the proximal tubule (Fig. 3.5). The reduced capacity for glucose absorption that characterizes the immature kidney is related to a less-developed basolateral membrane, in addition to the previously mentioned differences in membrane transporter density (35). In summary, the maturational increase in the capacity for tubular reabsorption of glucose is related to an increased number of apical symporter proteins, a more favorable electrochemical gradient, decreased turnover rate of transporter proteins, and decreased membrane fluidity (31). In addition, the membrane of the immature animal is leakier; nearly one-

third of the glucose reabsorbed by the neonatal animal leaks back across the tubular membrane, compared with one-sixth of that in the adult (3,36).

AMINO ACIDS

The bulk of amino acid reabsorption occurs within the first 2 mm or the proximal one-third of the proximal tubule (S1 segment) (Fig. 3.2) (37). The luminal fluid concentration of amino acids drops as it passes this portion of the tubule and then remains fairly constant. This is indirect evidence for reabsorption of amino acids along the entire length of the proximal tubule. Under normal conditions, amino acids other than glycine, histidine, and taurine are completely reabsorbed. The capacity for amino acid reabsorption along the entire proximal tubule is high. The renal tubule has a mechanism to increase reabsorption in the event that the filtered load of any amino acid increases (38,39).

Although the loop of Henle is difficult to study, bidirectional amino acid transport for neutral amino acids and acidic amino acids has been reported (40,41). The physiologic role of loop amino acid transport has not been elucidated, and it seems unlikely that it would make a significant contribution

to total tubular reabsorption because delivery of amino acids to the loop is minimal under normal conditions.

Cellular Mechanisms of Amino Acid Transport

The transepithelial transport of amino acids is an active, concentrative, sodium-requiring process that involves several specific steps (Fig. 3.6) (37). Luminal cell-surface transport is performed by specific amino acid transport systems that operate by secondary active transport, cotransporting amino acids uphill against their concentration gradient along with sodium. The electrochemical sodium gradient created by $\text{Na}^+\text{-K}^+\text{-ATPase}$ enables amino acids to be accumulated. Once inside the cell, the amino acids may be used by the cell or may exit the cell by passive, downhill transport. Together, the apical and the basolateral amino acid

transporters achieve the net reabsorption of amino acids from luminal to peritubular fluid. There is also bidirectional movement of amino acids. At the apical membrane, backleak occurs via a paracellular route, through the leaky “tight junctions” of the proximal tubule or via a transepithelial route, using the apical amino acid transporters. Studies in brush-border membrane vesicles (BBMVs) indicate that the transporters located on the brush border are stimulated by intravesicular, or cytoplasmic, amino acids (transstimulation). Therefore, the transport system on the apical membrane is probably bidirectional.

Amino acids may be coupled to sodium in a 1:1 or a 2:1 ratio, which allows the transport process to rely on the luminal to cellular transmembrane potential (E_m) and the chemical potential for sodium. In addition to cellular accumulation of amino acids from the luminal membrane, amino acids may be taken up by cells from the basolateral surface to provide substrate, especially in the portions of the nephron that do not have high flux of amino acids via a luminal system (42).

The kinetics of glycine transport (43) in the convoluted tubule differ from those in the straight tubule. The transport maximum and the K_m are lower in the straight portion. This allows the tubule to drastically reduce the intraluminal concentration of an amino acid by increasing the affinity of the transporter for substrate. In addition, the forces that favor backleak of amino acids are progressively reduced from convoluted to straight tubule.

Amino Acid Transport Systems

Seven specific transport systems for amino acids have been identified (Table 3.3). Most of the amino acid transport processes are sodium dependent and have some degree of substrate specificity. The electrogenic properties of the sodium–amino acid transporter complex depend on the charge of the amino acid, the coupling ratio for sodium, the charge on the protein carrier complex, and the ionic dependence (Cl^- or K^+) (38). Acidic amino acids require potassium for transport (44). The anionic or acidic amino acids L-glutamate and L-aspartate are reabsorbed by a transporter that is stereospecific, requiring a primary two-amino group along with a positively charged two- to four-carbon chain for transport to occur (45,46). The glutamate transport system is unique in that it requires 2 Na^+ and a proton, which are exchanged for a potassium ion after the transporter undergoes a conformational change. The β -amino acid transport system requires chloride in addition to sodium (47). Protein kinase C activation may also modify taurine transporter activity by phosphorylation of a critical serine residue (48). Dibasic amino acids L-arginine and L-lysine and L-ornithine share at least one transport system (49,50); the luminal uptake step is sodium independent and passive. A sodium-dependent, electrogenic system on the basolateral membrane allows amino acid exit.

A large number of amino acid transport systems have now been cloned and characterized by structural homolo-

FIGURE 3.6. Proposed factors responsible for the physiologic aminoaciduria of the immature animal. Factors include decreased activity of the amino acid-sodium cotransporter, increased $\text{Na}^+\text{-H}^+$ exchange at the luminal membrane, and decreased activity of the $\text{Na}^+\text{-K}^+\text{-ATPase}$ at the basolateral membrane. (From Zelikovic I, Chesney RW. Development of renal amino acid transport systems. *Semin Nephrol* 1989;9:49–55, with permission.)

gies to be members of distinct gene families: the glycine transport system, the neutral amino acid transport system A, the basic amino acid transport system y^+ , and the acidic amino acid transport system X⁻.

A sodium-independent amino acid transport system (rBAT) for the dibasic amino acids, neutral amino acids, and cystine has been identified (51). As a member of the type II membrane glycoproteins, this transporter is found in the brush-border membrane of both the intestine and the kidney proximal tubule, in which it enables electrogenic exchange of neutral and dibasic amino acids. It shares sequence homology with a variety of amino acid transporters and α glucosidases as part of a family of transport regulators. The gene is located on human chromosome 2. Mutations of this protein have been identified in patients with cystinuria, a transport defect of ornithine, lysine, cystine, and lysine. This transport system is inhibited by heavy metals such as lead and mercury (52). These heteromeric amino acid transporters (HATs) have interesting biologic properties (53). If mutated, they form the molecular basis of the primary aminoacidurias cystinuria and lysinuric protein intolerance (54). They are composed of two polypeptides, a heavy and light subunit, which also may play a role in integrin activation. The genes encoding these transporters are SLC 3A1, SLC 7A6, and SLC 7A7 (54).

Developmental Changes in Amino Acid Transport

In general, urinary amino acid levels are higher in neonates than in mature animals, and the fractional excretion of all

but a few amino acids is greater in immature animals. The increased excretion of amino acids results from reduced reabsorption. Factors that might account for the immaturity of the reabsorptive process include differences in the luminal transport system, decreased efflux of the amino acid from the contraluminal membrane, increased backleak through paracellular or transepithelial pathways, or nonspecific maturational differences in the cell membrane or cell metabolism (Fig. 3.6) (55). Altered renal amino acid handling is a highly sensitive marker for nephrotoxicity in immature rats (56).

The aminoaciduria that occurs in preterm and term neonates probably is not caused by a generalized abnormality, because not all of the filtered amino acids are wasted to the same degree (55). The excretion of glycine, imino acids (proline, hydroxyproline), dibasic amino acids, and taurine is preferentially higher than that of other amino acids (57–61). Acquisition of mature reabsorptive capacity of the amino acid system and the glycine transporter occurs at different developmental stages (57). When compared, the renal cortical accumulations of glycine, leucine, and glutamic acid are lower than those of lysine and alanine (55,62–64). Lysine uptake is similar in adult and neonatal animals, whereas cystine accumulation into cortical slices from neonatal kidney is lower than it is in adult kidneys until the age of 2 to 3 weeks (65). Urinary levels of proline are decreased by the postnatal age of 7 days, whereas those of glycine remain elevated until 3 weeks of age (66,67).

Most studies thus far have failed to demonstrate a change from one transporter protein isoform to another with maturation. Early studies of glycine and proline transport led investigators to conclude that the specific, high-affinity transporter was not present at birth but appeared at the time that amino acid reabsorption capacity reached mature levels. Later studies found that both a common glycine-proline transport system and individual transport systems were present from birth and that no new systems were acquired with maturation (55,66,67).

Intrinsic differences in the activity and transport capacity for certain individual transport systems exist. There is evidence of a decreased rate of efflux (66). Analysis of kinetic studies involving the uptake of proline by rat renal BBMVs reveals that the magnitude of proline uptake is reduced in neonates and that the characteristic uptake pattern is less pronounced in vesicles from young rats. This phenomenon is explained by differences in membrane permeability to sodium. The sodium gradient that is necessary for cellular or vesicular uptake of an amino acid is dissipated more rapidly in the vesicles from 7-day-old rats than in those from older rats (66).

Studies using isolated renal tubule preparations reveal that the initial transport rate of proline into neonatal rat tubules equals that of adults, yet the cellular amino acid levels are higher in the neonatal rats (60). This phenomenon is partially explained by metabolic studies. Metabolism

of proline by tubules from adult rats is twice that of tubules from neonates. The maturational changes in the excretion of proline are related to metabolic changes within the cell as well as to changes in the transport system.

Two cystine transport systems have been detected in isolated proximal renal tubules from neonatal dogs. Both systems are present from birth, yet the activity of both systems, as judged by the transport maximum (J_{\max}), is less in the tubules from puppies; these increase to adult levels by 3 weeks of age. The authors speculate that the postnatal increase in transport capacity is secondary to an increase in the number of transport sites for the sulfur amino acids (65).

Changes in the phospholipid composition of the membrane during maturation also affect the ionic and amino acid permeability characteristics. The change in composition of rat tubular brush-border membranes parallels change in membrane permeability to sodium (55). This may impair the ability of the immature renal tubular cell to maintain the electrochemical gradient necessary for reabsorption of amino acids.

The steady-state renal cell accumulation of the amino acids glycine, proline, and taurine is greater in young animals than it is in adults, probably because of slower egress of amino acids from immature animals (55). The intracellular concentration of amino acids is higher in younger animals. Although the luminal transport process is similar, the efflux step at the basolateral membrane is reduced. The net effect is decreased net transepithelial amino acid transport.

The kinetic characteristics of taurine accumulation by BBMV's have been extensively studied and are similar in adult and 28-day-old rats (68). The young rats responded to alterations in the supply of the substrate amino acids with changes in accumulation that were identical to responses in adults. Despite this, the urinary excretion of taurine is much greater in the immature animals. This probably is related to differences in the membrane permeability to taurine or reduced basolateral efflux in the immature rats. An age-related increase in the accumulation of the amino acid into BBMV's was found in younger rats (59). Taurine transport into vesicles isolated from nursing rats of three different ages (7, 14, and 21 days) was measured to examine the influence of dietary supply on uptake. Taurine uptake by the vesicles from 7-day-old rats was significantly lower than that of the older rats; there was little response to changes in dietary taurine intake (59). The efflux of taurine from cortical slices is decreased in the 7-day-old pups (69). Taurine accumulation increased as a function of age, being lower in the 14- and 21-day-old animals and increasing to adult levels by 28 days of age. These results suggest that age-related differences in taurine reabsorption and urinary excretion are related to reduced intrinsic apical transporter activity early in development and to differences in membrane permeability to taurine and Na^+ later in development, when the transporter capacity is at adult levels. The ability of the renal tubular cell to respond to dietary taurine

is attained at 1 to 2 weeks of age in the rat. The maturational factors responsible for this capacity are unknown.

The urinary levels of taurine in low-birth-weight neonates are significantly elevated, with fractional excretion ranging from 38 to 68% (70). These infants were receiving parenteral nutrition devoid of taurine and had low plasma taurine levels. Therefore, immature animals cannot reabsorb as much filtered amino acids and are less able to adapt to deficiency, predisposing them to significantly reduced plasma taurine values. Because taurine is needed for normal retinal and CNS development, this may have deleterious consequences in the developing preterm infant.

PEPTIDE AND PROTEIN REABSORPTION

Peptides are reabsorbed in the proximal tubule by a variety of processes, including reabsorption by endocytosis, luminal hydrolysis with reabsorption as free amino acids, carrier-mediated reabsorption of small intact peptides, and peritubular uptake. Peptides reabsorbed by the proximal tubule include angiotensin II, bradykinin, and glucagon. These peptides are rapidly hydrolyzed by peptidases found along the brush-border membrane and are then reabsorbed as single amino acids. Certain properties confer resistance to peptidases, because peptides with disulfide bonds or β -amino acids may not undergo hydrolysis (37).

Dipeptides and tripeptides that are resistant to hydrolysis in the gastrointestinal tract are presented to the brush-border membrane, in which they are encountered by enzymes that may be reabsorbed by a Na^+ -independent, electrogenic peptide transporter. The peptide transporter is located in cortex and medulla and shares similarities with the intestinal peptide transport system (71). Peptide transport is sodium independent and energized by an inwardly directed transmembrane proton gradient that depends on the inward negative membrane potential. This type of system is unique to the renal tubule, is more commonly found among prokaryotic cells, and remains the only example of uphill solute transport energized primarily by proton movement. Two distinct dipeptide transport systems have been characterized: a high-affinity system that is highly dependent on proton gradient and a lower-affinity system that may operate in the absence or presence of substrate concentration or inward proton gradient (71). A diverse group of dipeptides or tripeptides and xenobiotics with a peptide backbone are accepted by these systems, but free amino acids, or peptides with more than three amino acids, do not interact. Hydrophobicity seems to favor binding to transporter. Specific basolateral systems for peptide transport have not been demonstrated. However, many of these substances interact with basolateral systems for organic cations or anions. The *p*-aminohippurate (PAH) transporter reveals significant affinity for dipeptides and tripeptides and also seems to favor hydrophobic compounds. Peritubular uptake of peptides appears to be negligible.

Although not filtered freely like smaller peptides, proteins may reach the urinary space through glomerular filtration, in which they are reabsorbed by nonspecific adsorptive endocytosis or receptor-mediated endocytosis, or undergo hydrolysis by brush-border membrane enzymes such as peptidases (72). Handling of proteins by the brush-border membrane depends on size. The low-molecular-weight proteins are 10 to 44 kDa. Examples include growth hormone, PTH, many enzymes, immunoprotein fragments such as Bence Jones, and tissue-specific antigens such as β_2 -microglobulin. These proteins are absorbed and then undergo hydrolysis.

Intermediate-molecular-weight proteins of 44 to 90 kDa (e.g., albumin) are normally filtered to a very small degree and are subsequently endocytosed and then hydrolyzed within lysosomes (72). Larger proteins, such as fibrinogen and immunoglobulins, normally do not reach the urinary space. If the normal barrier to filtration of high-molecular-weight proteins is disrupted, they may undergo endocytosis.

Examples of low-molecular-weight proteins that undergo hydrolysis by a nonspecific system are angiotensin II and bradykinin. Peptides such as insulin, PTH, and ANF are absorbed by specific receptor-mediated endocytosis hydrolysis. The nonspecific system is a high-capacity, low-affinity system, whereas the specific systems are usually low-capacity, high-affinity systems (72).

Phosphate

The fraction of plasma phosphate that is filtered depends on the plasma phosphate concentration and the distribution of ionized phosphate as determined by the Donnan equilibrium. In the rat, 92 to 98% of phosphate is present in the aqueous phase of plasma, and 90% of total plasma phosphate is filterable. The ultrafilterability of phosphate declines with increases in plasma calcium (73).

Phosphate reabsorption occurs primarily in the proximal tubule, in which approximately 76% of the filtered phosphate is reabsorbed (Table 3.4). Phosphate reabsorption occurs in both the convoluted and the straight portions of the proximal tubule (73). A small fraction of phosphate is reabsorbed in the distal tubule under conditions of sodium loading and in the absence of PTH. Phosphate reabsorption rates are three to four times greater in the early proximal tubule than in the S2 portion of the convoluted tubule and are lower still in the straight tubule (74). This axial heterogeneity in phosphate transport is postulated to be the result of TF acidification, which decreases the ratio of the divalent form (preferred substrate) to monovalent form (75) (see Peptide and Protein Reabsorption, Cellular Mechanisms). There are differences in the affinity and capacity for phosphate transport between the straight and convoluted portions of the proximal tubule (74,75). Affinity of the transporter for phosphate is low in the S1 and increases as one travels distally. This characteristic, which enables a

large substrate flux proximally and more complete absorption distally, has been alluded to in the discussion of glucose transport. Higher affinity of the transporter for substrate allows more complete absorption by increasing the transporter efficiency in the face of lower tubular substrate concentrations.

Cellular Mechanisms

Phosphate reabsorption is a unidirectional, transcellular movement of phosphate across the proximal tubule from luminal to peritubular fluid (Fig. 3.7A). Phosphate is reabsorbed by a sodium-dependent, cotransport system located on the apical, or brush-border, membrane. Uptake occurs against a small chemical gradient and a large electrical gradient (76). Phosphate uptake is driven by the electrochemical gradient for sodium, with a sodium-coupling ratio of 3:1 (77). The rate-limiting process for transepithelial phosphate reabsorption is the apical transport step (76,78). The transporter prefers the divalent form (HPO_4^{2-}) of inorganic phosphate to the monovalent form (H_2PO_4^-), although both are candidates for transport. Luminal fluid pH influences the activity of the Na^+ -phosphate cotransporter; kinetically distinct transporter proteins also cause the rate of phosphate transport to vary.

Sodium is required for cotransport with phosphate and is postulated to activate the binding of phosphate to its transport site (78). The Na^+ -phosphate cotransporter probably functions in a "glide symmetry" model, as illustrated in Figure 3.7C: Na^+ binds to the transporter protein first and then induces a conformational change to increase affinity of the protein for phosphate. The substrate-transporter complex is translocated to the interior of the cell, in which sodium and then phosphate dissociates (76).

Phosphate transport is stimulated by decreased intracellular pH (an outwardly directed proton gradient) (75). Two

FIGURE 3.7. **A:** Model for sodium-phosphate cotransport by the proximal tubular cell (1). Both monovalent and divalent phosphates are cotransported with sodium at the brush-border membrane. Phosphate exits the basolateral membrane by a sodium cotransport process (2), or by anion exchange (3). **B:** Model for conformational changes and ionic interactions of the sodium-phosphate cotransporter. At high intratubular sodium concentrations, sodium binds to the transporter first and favors binding of phosphate to the transport site, followed by movement of the transporter-substrate complex to the cytoplasmic side of the cell where sodium dissociates first, decreasing protein affinity for phosphate, which then dissociates (glide symmetry model). **C:** Secondary structure prediction for the type II Na- P_i cotransporter. Eight transmembrane spanning regions are proposed. The transporter is N-glycosylated at the two positions indicated. (From Murer H. Cellular mechanisms in proximal tubular P_i reabsorption: some answers and more questions. *J Am Soc Nephrol* 1992;2:1649–1665, with permission.)

factors are responsible: Increasing the luminal fluid pH increases divalent phosphate, which is more readily transported; and there appears to be a direct effect of pH on the transporter protein, which alters its binding properties (79). Protons and sodium compete for binding sites of the transporter both inside and outside the cell. A decrease in the external pH reduces the affinity of the transporter and the rate of transport, whereas a decrease in intracellular pH increases the rate of transport (75,76,79).

Intracellular phosphate has many important functions in oxidative metabolism, protein synthesis, and enzyme action. The mechanism of phosphate exit has not been as clearly characterized; there is probably a passive component leading to phosphate transfer down its electrochemical gradient. Phosphate also exits the cell by the sodium-independent system, using a phosphate- OH^- antiport system (anion exchanger) (76,80). A basolateral, Na^+ -phosphate cotransport system has been proposed that is based on the

demonstration of sodium-coupled phosphate uptake into basolateral BBMVs; however, these findings may have resulted from contamination of the basolateral vesicles with vesicles from apical membranes (76).

Molecular Characterization

Structural characterization of at least two distinct Na-phosphate cotransport systems (NPT1 and NPT2) in the kidney indicates that the two classes are different, sharing only 20% homology. The NPT1 transporters are 465 amino acids in length, with a predicted seven to nine transmembrane domains. The NPT2 transporters have 635 amino acids and eight transmembrane domains (Fig. 3.7). Both transporters have been localized to the brush-border membrane of the proximal tubular cell, although the NPT1 is homogeneously found throughout, whereas the NPT2 is most concentrated in the S1 segment (81). NPT1 trans-

porter is less specific for phosphate and also accepts anions such as probenecid, chloride, and penicillin. The NPT2 is the PTH- and hormone-sensitive transporter that also responds to changes in dietary phosphate. The type II (NPT2) transporter forms the rate-limiting step in brush-border membrane transport (82). In addition to these two systems, Na-independent phosphate transporters have been identified that are also cell surface viral receptors Glvr-1 and Ram-1 and are widely expressed in mammalian tissues, in which they are proposed to serve a housekeeping function (81).

Hormonal Regulation

PTH is the principal hormone regulator of Na⁺-phosphate transport. PTH reduces the transport maximum without changing the affinity of the transporter for substrate (76). PTH inhibits Na-dependent phosphate transport by mechanisms dependent on AMP protein kinase A and protein kinase C-phosphoinositide pathways. Other factors that stimulate cAMP production also inhibit phosphate transport (83). Apical and basolateral PTH receptors mediate the effect of PTH to reduce phosphate transport through an acute mechanism dependent on endocytosis or phosphorylation (81). Growth hormone, insulin-like growth factor-I, insulin, thyroid hormone, and 1,25-dihydroxyvitamin D₃ stimulate phosphate absorption, whereas PTH-related peptide, calcitonin, ANF, epidermal growth factor, transforming growth factor α , and glucocorticoids inhibit this process. Hormonal effects may be mediated through ligand-activated receptors that bind to response elements in the promoter region of the transporter gene.

Two major circulating factors also greatly influence phosphate reabsorption. The first, a membrane-bound endopeptidase encoded by the PHEX (protein with homology to endopeptidases on the X chromosome) gene, serves as an enzyme to degrade a protein, fibroblast growth factor 23, which in the absence of PHEX acts to massively reduce phosphate reabsorption (84). PHEX also appears to degrade PTH related peptide (85). Mutations of PHEX and fibroblast growth factor 23 have been associated with a number of hereditary or tumor-induced phosphaturic syndromes (84,86).

Developmental Changes in Phosphate Reabsorption

In contrast to most other transport processes, fractional reabsorption of phosphate is greater in the immature or neonatal animal than it is in the adult (Table 3.4) (87). Clearance studies performed in infants and children initially suggested that the increased plasma phosphate levels and reduced fractional excretion of phosphate during infancy are related, in part, to the lower GFR during the first year of life (88). However, subsequent studies per-

FIGURE 3.8. Relationship between the filtered load of phosphate and phosphate reabsorption in isolated perfused kidneys from mature and newborn guinea pigs. At a comparable filtered load, the reabsorption of phosphate is significantly greater in newborn animals than in adult animals. (From Johnson V, Spitzer A. Renal reabsorption of phosphate during development: whole-kidney events. *Am J Physiol* 1986;251:F251-F256, with permission.)

formed in the rat, guinea pig, and dog indicate that enhanced tubular reabsorption of phosphate is the primary contributing factor to the greater reabsorption and positive phosphate balance that characterize early extrauterine life (87). The tubular maximum for the reabsorption of phosphate is high in infants at a time when the accretion of phosphate is highest; it declines when the accretion of phosphate declines (89). The rate of phosphate reabsorption at any given filtered load of phosphate is greater in newborn guinea pigs than in adults (Fig. 3.8).

The mechanisms responsible for higher phosphate reabsorption by the neonatal kidney are intrinsic ones controlling the renal handling of phosphate and differences in hormonal regulation of phosphate transport. Investigators have used microperfusion techniques, the isolated perfused kidney, and BBMVs to assess whether the increased tubular reabsorption of phosphate is related to differences in the transport of phosphate at the brush-border surface of the proximal tubule. The fractional reabsorption of phosphate is higher in the newborn than it is in the adult guinea pig (Table 3.4) (90,91). The proximal tubular reabsorption is 77% of the filtered load in the newborn and 67% in the adult guinea pigs. The distal reabsorption of phosphate in newborns is 16% and in mature guinea pigs is 11%. Both proximal and distal tubular phosphate reabsorption are greater in newborns. This

is remarkable in light of the relative structural immaturity of the newborn proximal tubule. Compared with adults, the maximum rate of phosphate reabsorption is greater in newborn guinea pigs (92). There is no significant difference in affinity (K_m) of the transporter for phosphate. BBMVs from 2-month-old and 8- to 9-month-old rats demonstrate no difference in the activity of sodium phosphate cotransport (89). However, newborn rats have enhanced phosphate uptake due to changes in the affinity of the transporter (K_m) for phosphate (90). Therefore, greater apical membrane density rather than conformational changes or structural isomers of the sodium phosphate cotransporter probably accounts for the greater phosphate absorption characteristic of the developing animal.

Increased phosphate reabsorption by the developing animal or child might be explained by relative insensitivity to the phosphaturic effect of PTH. The fractional excretion of phosphate after administration of PTH was lower in 6-week-old rats than in 20-week-old rats. However, studies indicate that the greater phosphate reabsorption characteristic of the newborn is intrinsic to the immature tubule and is independent of PTH. In parathyroidectomized rats, the capacity for phosphate reabsorption was greatest in the immature, or 3-week-old, animals and decreased with growth and development (91). Parathyroidectomy is accompanied by a greater increase in the maximal tubular reabsorption of phosphate in immature rats than in the mature rats (89). In the presence of parathyroid glands, the phosphate reabsorptive capacity was lower in all groups, but a decline in capacity was still noted as rats matured. Therefore, it appears that there is an enhanced intrinsic ability of the immature kidney to reabsorb phosphate, which is not simply related to noted maturational differences in PTH action on the renal tubule. PTH receptor-associated adenylate cyclase is less responsive to PTH stimulation in the immature renal tubule than in mature controls; however, hormone responsiveness in the rat increases threefold during the first several weeks of life (93).

The rate of phosphate transport is also regulated by the availability of phosphate. Dietary phosphate deprivation results in enhanced reabsorption of phosphate (92). A parallel has been drawn between the phosphate-replete state of the immature kidney and the adult kidney during phosphate depletion, because in both conditions phosphate reabsorptive capacity is enhanced independent of PTH (91,94). Factors observed to contribute to the enhanced reabsorption of phosphate during dietary deprivation include increased activity of the brush-border transport system, significant phosphate reabsorption in both distal and proximal tubules, and decreased responsiveness to PTH (90). As mentioned, these same factors contribute to the greater increase in phosphate reabsorption observed in the young kidney.

Conflicting results have been obtained from the study of the response of the newborn rat and guinea pig kidney to

FIGURE 3.9. Age-related changes in the effect of dietary phosphate on maximal capacity for phosphate reabsorption in thyroparathyroidectomized rats given low-, normal-, and high-phosphate diets. GFR, glomerular filtration rate; Pi, inorganic phosphate; RPI, resting pressure index. (From Mulrone SE, Lumpkin MD, Haramati A. Antagonist to GH-releasing factor inhibits growth and renal Pi reabsorption in immature rats. *Am J Physiol* 1989;257:F29-F34, with permission.)

either low- or high-phosphate diets, depending on whether the whole organ or the proximal tubule is studied. Studies of whole-kidney phosphate reabsorption in the rat indicate that the immature kidney has enhanced capacity to respond to both decreases and increases in dietary phosphate and the filtered load of phosphate (Fig. 3.9) (89,91,95). Immature rats receiving low-phosphate diets had greater phosphate reabsorption than either immature animals receiving normal dietary phosphate or mature animals on low-phosphate diets. In contrast, a low-phosphate diet did not induce any changes in phosphate uptake by BBMVs from the newborn guinea pig, nor did a high-phosphate diet decrease phosphate uptake. The newborn animals experienced greater fluctuations in plasma phosphate (92). Proximal phosphate transport by immature rats, as assessed by BBMV studies, is greater than that of adults, yet there is diminished ability of the developing rat to sustain plasma phosphate as dietary phosphate is changed. These developmental changes in phosphate handling are analogous to those described for taurine (see earlier). Although immature animals have similar intrinsic transporter function with greater relative capacity, the ability of the renal proximal tubule to adapt to its environment is diminished.

The ability to respond to alterations in the filtered load of phosphate does not require PTH (91,95,96). The stimulation of phosphate reabsorption in the immature animal may be related to reduced intracellular levels of phosphate (97). Intracellular phosphate as measured by nuclear magnetic resonance is lower in 3-week-old rats than in 12-week-old rats (97). The investigators postulate that a low intracellular phosphate concentration in developing rats may stimulate synthesis and expression of phosphate transporter proteins.

Growth hormone also may regulate renal phosphate reabsorption during the neonatal period (96). Long-term administration of the growth hormone antagonist (GRF-AN) to immature and mature rats resulted in growth failure and increased urinary phosphate excretion in the immature rats only. Immature rats (4 weeks old) receiving GRF-AN exhibited decreased tubular capacity for phosphate reabsorption, whereas adult animals did not. These data indicate that the release of growth hormone during development may contribute to the elevated phosphate reabsorption characteristic of this period (95,98). Insulin-like growth factor-1 induces the increase in activity of the sodium phosphate transporter and prevents the decrease observed after GRF-AN administration (98,99). Preliminary studies suggest a role for tyrosine kinases in transduction of hormone-transporter events (99).

In summary, the renal retention of phosphate in the newborn is not an expression of an immature transport system; rather, it is an appropriate physiologic adaptation to the demands for phosphate during a period of rapid growth. The postnatal changes in phosphate reabsorption do not necessarily depend on GFR, PTH, or dietary phosphate. They may be regulated by growth hormone and insulin-like growth factor-1, as well as by intracellular phosphate concentration.

ORGANIC ANIONS

The proximal renal tubule is the primary site for the major organic anion transporters hOAT1 and hOAT3 (100). PAH is the prototypical substrate for the organic anion transport pathway. Organic anions may be filtered, reabsorbed, and secreted by the nephron. Excretion of a given anion is the sum of filtration and secretion less reabsorption. There is a great deal of variability in the renal handling of organic anions, depending on the species and organic anion studied (101). In humans, the major transporters are in the proximal tubule (100), whereas in mice, they are present in proximal tubule, Henle's loop, and cortical collecting duct (102). These anions may undergo bidirectional transport, with secretion being the predominant direction of flux. Many of the organic anions are highly protein bound and are not filtered to any extent at the glomerulus. Rather, these compounds may reach luminal fluid via transcellular transport movement across basolateral and apical membranes. PAH is secreted at a very high rate; as much as 90% is extracted from plasma by the proximal tubule in a single pass through the kidney. Because of this characteristic, PAH is used as a marker of renal blood flow. The urinary levels of PAH increase along the length of the proximal tubule (Fig. 3.2).

Tubular capacity for the secretion of organic anions increases as the plasma concentration increases, up to a maximum at which the transport system is saturated (101).

TABLE 3.5. ORGANIC ANIONS

A wide variety of organic anions are secreted by this transport system (Table 3.5). Although the secretion of all organic anions occurs in the proximal tubule, the rate of secretion by different proximal segments varies, depending on the compound and on the species studied (103). In the rat and the rabbit, PAH secretion is greatest in the straight tubule, specifically the S2 segment, whereas in the pig, it is greater in the convoluted portion of the proximal tubule (103). These differences in the secretory patterns probably are related to differences in transporter density on the basolateral membrane of the tubule (104).

Other factors that influence the excretion of organic anions include the degree of protein binding, the competition by other similar compounds for the same basolateral transport system, and the metabolic state of the animal, because many of these compounds are metabolic intermediates (103).

Cellular Mechanisms

Secretion of organic anions is accomplished by the cooperative interaction of several cotransport and countertransport systems located on the basolateral and apical membrane surfaces (Fig. 3.10A) (101,103). As the interior of the cell has a substantial net negative charge, the uptake of anions occurs against a steep electrochemical gradient. The basolateral transport of PAH is sodium- and energy-dependent but, as a tertiary active transport system, is not directly coupled to either sodium or energy expenditure. PAH enters the basolateral cell surface via an anion exchanger; ketoglutarate is thought to be the principal anion exchanged for PAH. This anion exchanger is coupled to a basolateral sodium-anion (ketoglutarate) cotransporter that allows the energy from ATP hydrolysis to be coupled to that of the anion exchanger through the recycling of ketoglutarate at the basolateral membrane. This process is similar to the apical Cl⁻-formate exchanger (see Sodium and Chloride: Whole Nephron). Once inside the cell, the organic anion diffuses through the cytoplasm and exits the apical side of the cell through another anion exchanger. The substrate specificity of the apical anion exchanger differs from that of the basolateral anion exchanger. Ketoglutarate is the preferred substrate for exchange with PAH on the basolateral surface, but many anions (lactate, pyruvate, hydroxybutyrate,

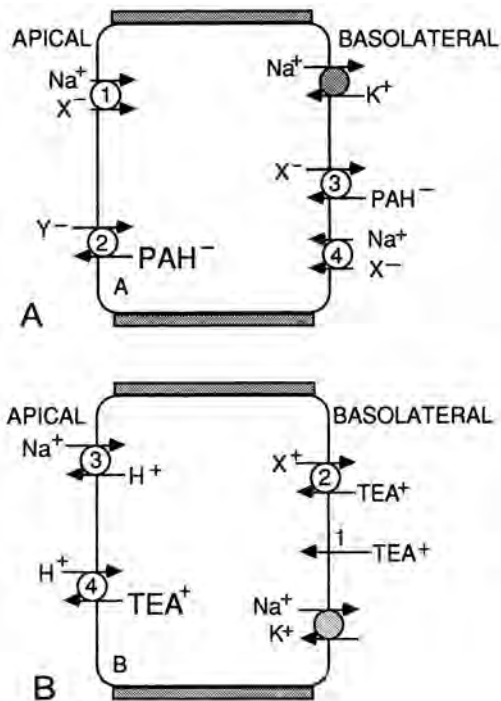

FIGURE 3.10. A: Organic anions [*p*-amino hippurate (PAH)] enter the proximal tubular cell on the basolateral surface by an anion exchanger (3) in association with a sodium anion cotransporter (4), which allows recycling of the anion across the basolateral membrane. PAH exits the cell by another anion exchanger (2) with different substrate specificity than the basolateral system. The apical anion exchanger is also associated with an anion sodium cotransport system (1). **B:** Organic cations [tetraethylammonium (TEA)] enter the proximal tubular cell on the basolateral surface by one of two mechanisms: cation exchange (2) or passive, facilitated diffusion (1). TEA exits the luminal membrane via a proton exchanger (4) that operates in association with a sodium-proton exchanger to allow recycling of a proton across the luminal membrane. (Adapted from Roch-Ramel F, Besseghir K, Murer H. Renal excretion and tubular transport of organic anions and cations. In: Windhager EE, ed. *Handbook of physiology: renal physiology*. New York: Oxford University Press, 1992:2179–2262.)

acetoacetate, succinate, ketoglutarate, urate, hydroxyl ions, bicarbonate, and chloride) may be exchanged for PAH by the apical exchanger. In addition to the anion exchanger on the apical surface, there is a sodium-coupled anion transporter that reabsorbs organic substances such as ketoglutarate for the reabsorption of metabolic substrates, as well as one specific for ketoglutarate that may be exchanged for PAH by the basolateral anion exchanger. Therefore, the net movement of PAH is from peritubular fluid to luminal fluid, and the net movement of the anion ketoglutarate is the reverse. Lithium inhibits the sodium-organic anion cotransporters, and probenecid inhibits the anion exchangers.

Molecular Characterization

The basolateral organic anion transporter system accomplishes organic anion-dicarboxylate exchange and is found

on the basolateral membrane (100,102). The rat kidney transporter (OAT1) has 551 amino acid residues with 12 proposed transmembrane domains (105). OAT1 has wide substrate specificity, including cyclic nucleotides, prostaglandins, uric acid, and a variety of drugs. Expression is limited to an isolated basolateral segment of the proximal tubule (105). OAT1 shows approximately 38% structural homology to the organic cation transporter (OCT1). The human kidney transporter (hOAT3) has 543 amino acids and is localized to the basolateral membrane (106), with comparable structural homology.

Developmental Changes in Organic Anion Transport

The secretion of organic acids is low during the neonatal period; it increases gradually over the first few years of life (107,108). Limitations on the excretion of organic acids include low GFR, anatomic immaturity, reduced number of transporter sites, and incomplete metabolic capacity. In addition, the limited distribution of blood flow to the deep cortical structure reduces the concentration of organic acids available for secretion.

The kidney's ability to produce a concentration gradient of organic anions is present before birth and increases with maturation. Studies in newborn humans, dogs, and rats demonstrate a gradual increase in renal extraction of PAH with age (109–111). When PAH transport is examined using tissue slices, the slice:medium ratios (in rats) peak at approximately 1 month of age and then decline to adult values. The PAH extraction (GFR) of infants 3 months or younger is approximately 30% that of older children.

The increased secretory ability that occurs with maturation is the result of the intrinsic ability of the proximal tubule to transport organic acids without appreciable changes in the membrane permeability to PAH. When organic acid transporter activity is standardized for tubule length, an almost fivefold increase in transport capacity occurs with maturation (108). Both increased transporter density and tubular length contribute to the increased capacity for organic acid secretion that occurs with development.

In addition to age-related changes in transporter capacity, organic anion transport is regulated by substrate availability and hormones (112,113). The administration of organic acids induces the transport system (112,114). Administration of penicillin to 2- and 4-week-old rabbits resulted in enhanced basolateral uptake and excretion of PAH in the 2-week-old, but not in the 4-week-old, rabbits (112). Administration of the drugs to pregnant rabbits during the later part of pregnancy results in enhanced newborn PAH transport. The ability to induce transport activity depends on the species and the anion studied.

Premature infants have a reduced renal ability to excrete organic anion drugs because of the immaturity of the organic anion transport system. Thyroxin administration to

TABLE 3.6. ORGANIC CATIONS

young rats increases PAH uptake (115). This increased uptake is blocked by inhibitors of protein synthesis, suggesting that the thyroxin effect depends on synthesis of regulatory or transporter proteins.

ORGANIC CATIONS

Organic cations include endogenous primary, secondary, tertiary, and quaternary amines in addition to many drugs that are secreted by the proximal tubule (103). A partial list of organic cations is found in Table 3.6. Tetraethylammonium (TEA) is the model substrate for describing the organic cation system. The clearance of TEA is similar to that of PAH; there is nearly complete extraction with a single pass through the kidney. Secretory fluxes are greatest in the proximal convoluted (S1) segment and decrease in S2 and S3 (116). Changes in the activity of the organic cation transport system appear to be related to regional differences in luminal permeability to TEA along the proximal tubule and are not caused by changes in basolateral cation uptake (101).

Cellular Mechanisms

Organic cations move into the negatively charged cell interior by a saturable, electrogenic process that is located on the basolateral cell surface. Some organic cation uptake is through facilitated diffusion (Fig. 3.10B) (101,103). A luminal organic cation-proton antiporter that uses potential energy stored in a pH gradient to drive uphill movement of cations has been demonstrated in human, snake, dog, rat, and rabbit BBMVs. Cations diffuse through the cell cytosol and are either taken up into cell organelles or vesicles or exit through a luminal proton exchanger. At the luminal membrane, TEA is exchanged for a proton. This is another example of a tertiary transport process: The energy-requiring process is the $\text{Na}^+\text{-K}^+\text{-ATPase}$, which creates the major driving force for the apical $\text{Na}^+\text{-H}^+$ exchanger. In turn, the $\text{Na}^+\text{-H}^+$ exchanger provides protons for apical exchange with TEA. The luminal proton-TEA exchange is electroneutral. Therefore, the net movement of TEA is from the capillary fluid to the lumen; protons recycle across the apical membrane.

The fetal kidney is able to secrete organic cations; the ability to do so is probably less than that in adult animals (108,109,117,118). In general, the capacity to secrete organic cations precedes that of organic anions (101,103).

URIC ACID

Uric acid, a weak organic acid, is the biologic end-product of dietary and endogenous purine metabolism. Approximately 75% is excreted by the kidney. Urate is freely filtered at the glomerulus and is transported exclusively by the proximal tubule (119). In a number of species (human, monkey, rat, mongrel dog), the fractional excretion of urate is less than 100%, indicating net reabsorption. In other species (pig and rabbit), the fractional excretion of urate exceeds 100%, indicating net secretion. The degree to which there is secretion or reabsorption varies and depends on the species studied (119). Urate reabsorption is inhibited by probenecid, high luminal fluid flow rate, hexose, and anion exchange inhibitors. Urate secretion is inhibited by pyrazinoic acid, the active metabolite of the antituberculous drug pyrazinamide (120). The decrease in urinary excretion of urate after the administration of pyrazinamide or its metabolite pyrazinoate was initially thought to be related to a selective effect of the drug on the secretory component of urate excretion. However, recent work suggests that pyrazinoate may inhibit the reabsorptive component in addition to the secretory pathway. Thus, the pyrazinoate-suppressible excretion of urate is not totally caused by inhibition of the secretory component (120,121). Urate handling along the proximal tubule is theorized to proceed as follows: Initial reabsorption of urate occurs in the early proximal convoluted tubule (S1), and secretion occurs in the late convoluted, early straight tubule (S2) via a secretory pathway similar to that for PAH (121). Postsecretory reabsorption may occur but has not been well characterized. Clearance studies performed in human subjects demonstrated that blocking reabsorption prevented an increase in excretion that would be expected to follow probenecid administration (103).

Cellular Mechanisms

Because of the bidirectional nature, axial heterogeneity, and species-related variability of urate transport, any model describing urate transport is complex. Most likely, passive, paracellular, and active transcellular transport mechanisms affect urate secretion and reabsorption. A urate anion exchanger has been demonstrated in rat and dog BBMVs (121–123). This system may use the hydroxyl, Cl^- , HCO_3^- , lactate, or succinate anion in exchange for urate. This system is specific for urate, but PAH is also accepted. Probenecid inhibits urate transport by this system (121–123). A sodium-urate cotransport system has been proposed, because the reabsorption of urate is closely coupled to sodium in studies

involving intact animals and isolated perfused tubules. Such a system has not been demonstrated in isolated BBMVs. Most likely, urate transport is sodium dependent through the sodium-dependent cotransport of organic anions or dicarboxylates and is linked as a tertiary transport process to sodium flux.

An anion exchange system for urate has been described in basolateral membrane vesicles from the rat; this transport system is postulated to be distinct from the apical transport system because PAH and other organic anions do not interact with it (124).

The initial step for urate reabsorption is the anion exchanger at the apical membrane, with exit on the basolateral membrane by another anion exchanger or by a passive mechanism. Secretion of urate occurs by basolateral exchange of urate for chloride, with secretion by the apical anion exchanger. The differential distribution of these two systems along the proximal tubule probably determines the net flux of urate in a given segment. In the S1 segment, reabsorption predominates; in the S2 segment, secretion (pyrazinamide-sensitive) predominates. Both fluxes could be present in the S3 segment, with the net flux being in the direction of reabsorption in the human (119).

The human urate transporter (uHAT) has been cloned and it has two membrane-spanning domains. It acts as a highly selective urate ion channel. A second urate transporter (uHAT2) has also been cloned (125).

Developmental

The fractional excretion of urate is much higher in infants than in adults or older children. Plasma levels tend to be higher in premature and term newborns than in older children and adults (126). Urate fractional excretion is 70% at a gestational age of 29 to 31 weeks and 38% at term (127–129). The fractional excretion of urate decreases further during the early postnatal period, and this effect appears to be independent of gestational age (Fig. 3.11). Uptake of urate by neonatal kidney slices and by fetal and neonatal mouse kidney cortex slices is lower than uptake by slices from adult animals (128). This probably indicates decreased ability for urate secretion in the immature rodent (127,129). Therefore, the increased fractional excretion probably is not related to increased secretion. Instead, increased excretion of urate could be related to the relative volume-expanded state of the infant, as well as to the potential immaturity of reabsorptive pathways (130). Maturation of the superficial renal cortex, with its greater reabsorptive capacity, could also contribute to the postnatal decline in fractional urate excretion (127).

SULFATE

Sulfate and thiosulfate are freely filtered at the glomerulus. Both are reabsorbed by the proximal tubule; fractional excretion

FIGURE 3.11. Fractional excretion of uric acid (clearance of uric acid/creatinine clearance $\times 100$) during the first day of life. A significant inverse relationship was observed between the fractional excretion of urate and gestational age. (From Stapleton FB. Renal uric acid clearances in human neonates. *J Pediatr* 1983;103:290–294, with permission.)

tion is approximately 10% (131). Sulfate is transported into the proximal tubular cell by a luminal, sodium-dependent process with a stoichiometry of 2 Na^+ to 1 SO_4^- (Fig. 3.12). The system is electroneutral and requires a proton. The proton acts as an allosteric activator of the transport system and modifies the stoichiometry of the transporter with respect to sodium. With an acidic internal pH, stoichiometry is 2:1; in an alkaline environment, it is 1:1 (132,133). On the basolateral cell surface, sulfate is transported by an anion exchanger that is sodium independent. Sulfate is exchanged for another anion (hydroxyl radical, bicarbonate, or thiosulfate). This anion exchanger does not accept Cl^- , phosphate, or other organic anions such as PAH or lactate, but it is inhibited by

FIGURE 3.12. Model of sulfate transport by the proximal tubule. Sulfate is cotransported with two sodium ions at the brush-border membrane (1) and exits the cell by way of passive, facilitated diffusion on the apical membrane (backleak, 2) or by a sulfate-anion exchanger (3) on the basolateral surface of the cell. (From Murer H, Manganel M, Roch-Ramel F. Tubular transport of monocarboxylates, Krebs cycle intermediates and inorganic sulfate. In: Windhager EE, ed. *Handbook of physiology: renal physiology*. New York: Oxford University Press, 1992:2164–2188, with permission.)

typical anion transporter inhibitors, SITS and DIDS. Luminal sodium sulfate cotransport enables significant luminal chloride transport in the proximal tubule, through the coordinated luminal oxalate-sulfate exchanger and oxalate-chloride exchange systems.

CARBOXYLATES

The renal tubule has several specific transport systems for the reabsorption and absorption of monocarboxylates, dicarboxylates, and tricarboxylates (131). These substrates are divided into the monocarboxylates (lactate, pyruvate, acetoacetate, hydroxybutyrate, and fatty acids) and dicarboxylates/tricarboxylates (citrate, succinate, ketoglutarate, oxaloacetate, and fumarate) (131). Most of these compounds are metabolic intermediates or substrates that are important energy sources, hence the need for absorption and reabsorption, respectively.

Reabsorption of these compounds is predominantly in the proximal tubule. In general, tubular reabsorption is incomplete, which may be the combined result of incomplete absorption by the apical membrane surface or the efflux of these substrates from the cell back into the lumen when the intracellular concentrations are high (131).

Cellular Mechanisms

Monocarboxylates

There are both apical and basolateral transport processes for the monocarboxylates (Fig. 3.13A). Reabsorption from luminal fluid is by an apical-specific transporter that is sodium dependent and is not inhibited by other organic compounds such as PAH, urate, or dicarboxylates. The transporter requires a single carboxyl group, but it accepts both the D- and the L-isomer of the carboxylate. Studies using BBMVs indicate that there may be both a high-affinity/low-capacity system and a low-affinity/high-capacity system (131,134).

In addition to the sodium-monocarboxylate cotransport system, there is an apical anion exchange system. This system accepts a variety of anions (Cl^- , hydroxyl, bicarbonate, urate, PAH, and dicarboxylates). It is sensitive to SITS and DIDS, as well as furosemide and probenecid, indicating that this organic anion exchanger is nonspecific. This system probably functions to facilitate exit of metabolic intermediates and the shuttling of protons (formate- Cl^- exchanger), which are necessary for the electroneutral absorption of NaCl .

The basolateral system is sodium independent and specific for the D-isomer of lactate. The basolateral system is thought to be an anion exchanger that exchanges lactate for the hydroxyl ion or bicarbonate in a fashion similar to that described for sulfate (135–137). This system is bidirec-

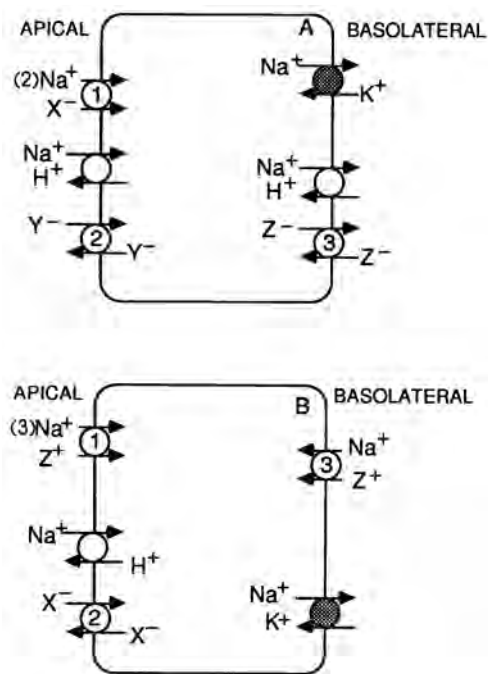

FIGURE 3.13. A: Model for monocarboxylate transport. Monocarboxylates enter the proximal tubular cell by one of two mechanisms: either a sodium cotransporter (1), where X = lactate, pyruvate, acetoacetate, or β hydroxybutyrate, or by an anion exchanger (2) with different substrate specificity (Y = OH^- , Cl^- , urate, bicarbonate, *p*-aminohippurate, ketoglutarate, lactate, pyruvate, acetoacetate, or β hydroxybutyrate). On the basolateral membrane, an anion exchanger enables the exit of these substances (3) (Z = lactate, pyruvate, OH^- , formate, Cl^- , sulfate, phosphate, or oxalate). B: Model for dicarboxylate/tricarboxylate transport. The substances enter the luminal membrane of the cell by a sodium cotransport system (1) (Z = pyruvate, succinate, citrate, malate, fumarate, or ketoglutarate) or an anion exchanger (2) (bicarbonate, lactate, pyruvate, acetoacetate, β hydroxybutyrate, malate, or succinate). In addition, a sodium cotransport system (3) similar to the apical system enables the basolateral transport of these substrates. (From Murer H, Manganel M, Roch-Ramel F. Tubular transport of monocarboxylates, Krebs' cycle intermediates and inorganic sulfate. In: Windhager EE, ed. *Handbook of physiology: renal physiology*. New York: Oxford University Press, 1992:2164–2188, with permission.)

tional and allows the entry as well as the exit of monocarboxylates. This system can affect the net reabsorption of monocarboxylates from luminal fluid and release into pericapillary fluid, as well as effect basolateral uptake of these compounds as substrate for cell metabolism. The basolateral transport system is located in the S2 and S3 segments, which do not have an apical transport system for the monocarboxylates. In these segments, the transport system is crucial to the uptake of monocarboxylates as substrates needed for cell energy metabolism.

Dicarboxylates/Tricarboxylates

The model substrate for the transport of dicarboxylates/tricarboxylates is α -ketoglutarate. Approximately 75% of

the filtered load is reabsorbed by the proximal tubule, 20% of which is by the S3 segment. Secretion also has been demonstrated in the rat (138). Ketoglutarate reabsorption is effected by cotransport with sodium (stoichiometry 3:1) (Fig 3.13B) (139). This system accepts all the Krebs cycle intermediates as well as pyruvate, which is actually a monocarboxylate (140). Sodium must bind to the transporter protein to induce a conformational change that facilitates binding and transport of substrates. Lithium inhibits this process by binding in place of sodium (141,142). The same system is located on the basolateral surface of the cell to effect uptake of key substrates from peritubular fluid. The presence of arginine-349 and aspartate-373 of the Na⁺/dicarboxylate cotransporter is important in the conformational states of the transport cycle (143). There is an additional anion exchanger that has affinity for many substrates and is probably the same transport system as that previously mentioned for the monocarboxylates.

Sodium and Chloride: Whole Nephron

Approximately 60% of the filtered sodium and 50% of filtered chloride is reabsorbed by the proximal tubule (144). The preferential reabsorption of amino acids, glucose, phosphate, and bicarbonate in the early proximal tubule creates a TF NaCl concentration greater than the plasma concentration. This augments the reabsorption of NaCl through both active and passive processes (144,145). The passive reabsorption of NaCl through a paracellular pathway accounts for two-thirds of the total NaCl flux in the S2 and S3 segments (144). In the early proximal tubule, a lumen-negative potential resulting from sodium-coupled absorption of substrates such as glucose and amino acids favors passive paracellular Cl transport. Sodium bicarbonate reabsorption via the luminal Na-H exchange is accompanied by fluid absorption so that the luminal Cl concentration increases in the late proximal tubule favoring Cl absorption, which creates a positive luminal charge that favors passive transcellular sodium absorption in the late proximal tubule (145). Additional Cl absorption is achieved via apical Cl exchange with formate or oxalate. This chloride-formate exchanger, expressed in the brush-border membrane, can also be found in the pancreas and heart (146).

Cellular Mechanisms: Proximal Tubule

Three apical transport systems operate in conjunction with the basolateral Na⁺-K⁺-ATPase transport system to effect sodium reabsorption (Fig. 3.14) (147): the Na⁺-H⁺ exchanger; the sodium-coupled transport with amino acids, phosphate, glucose, sulfate, and organic acids; and the sodium channels. The Na⁺-H⁺ exchanger accounts for the greatest fraction of reabsorbed sodium in the S1-3 segment. Sodium-coupled transport mechanisms are more important

in the S1, and sodium channels are more important in the S2 and S3 segments (144). Active Na⁺ transport occurs across the apical membrane by the coupling of Na⁺-H⁺ exchange and the Cl⁻-formate exchanger (147).

A significant amount of chloride reabsorption occurs in the proximal tubule by passive diffusion of Cl; the rate of reabsorption is lower in the early proximal tubule, in which sodium and bicarbonate reabsorption are favored. As TF moves distally, it becomes acidified, and the chloride concentration rises to a level greater than that of plasma (Fig. 3.2). The transtubular PD is negative in the early proximal tubule, but it becomes lumen positive later in the proximal tubule. In the early proximal tubule, the major driving force for passive Cl reabsorption is the lumen-negative PD and, in the later proximal tubule, an outwardly directed Cl⁻ concentration gradient. Active Cl reabsorption also occurs in the proximal tubule by tertiary active transport, because the driving force is generated by one of two secondary active transport systems: the Na⁺-H⁺ exchanger in parallel with Cl⁻ formate or the Na-sulfate exchanger in parallel with Cl⁻ oxalate. Cl⁻ transport is coupled indirectly to H⁺ transport because the cell concentration of formate is affected by pH, and hydrogen ions are pumped out of the cell in exchange for sodium. In the case of Cl-oxalate exchange, oxalate is accumulated in exchange for sulfate, which is cotransported with sodium. Renal potassium-chloride cotransporters, which are electroneutral, are found in the proximal tubule and thick ascending limb (148).

Because Na-H exchange is vital in both NaHCO₃ and NaCl reabsorption, regulation of Na-H activity could be expected to affect both processes. In the setting of metabolic acidosis, a need for enhanced NaHCO₃ absorption results in upregulation of Na-H exchange via increased expression of NHE3 protein. NaCl transport would be expected to increase as well, but decreased formate-induced NaCl transport, decreased oxalate-induced NaCl transport, and Na-sulfate cotransport are observed during acidosis, thereby counteracting the increase in Na-H exchange activity on net Cl reabsorption (149). Phosphorylation of serine-982 in the Na⁺ bicarbonate cotransporter shifts the HCO₃⁻:Na⁺ stoichiometry from 3:1 to 2:1 (150).

Na⁺-H⁺ Exchanger

The Na⁺-H⁺ exchanger is responsible for the bulk of NaHCO₃ and NaCl reabsorption in the proximal tubule (147). The Na⁺-H⁺ exchanger requires Na⁺ and H⁺ and is inhibited by amiloride in concentrations lower than those required for inhibition of the Na⁺-K⁺-ATPase but higher than those required for inhibition of sodium channels (149). The antiporter accepts NH₄⁺, Li⁺, Na⁺, and H⁺ but does not accept K⁺, Rb⁺, Cs⁺, or choline (23). Na⁺, Li⁺, NH₄⁺, and H⁺ compete for the external binding site. There are two internal cation-binding sites; one is for transport and the other binds hydrogen ions as a means of regulating

FIGURE 3.14. The Na-(K)-Cl cotransporters. **A:** Localization of cloned Na-(K)-Cl cotransporters along the mammalian nephron. **B:** Schematic model of the topology of the Na-(K)-Cl cotransporters. The proposed membrane-spanning helices are numbered 1 to 12. Putative N-glycosylation sites on the loop between membrane spans 7 and 8, and the amino-(NH₂) and carboxy-(COOH) termini are indicated. DCT, distal convoluted tubule; IMCD, inner medullary collecting duct; TAL, thick ascending limb. [From Hebert SC, Gamba G, Kaplan M. The electro-neutral Na⁺-(K⁺)-Cl-cotransport family. *Kidney Int* 1996:1638–1641, with permission.]

the activity of the transporter (151). Increases in the hydrogen ion concentration induce protonation of the regulatory site and activation of the antiporter. Increasing intracellular pH inactivates the exchanger (23). Therefore, acidification of the cell cytosol activates the Na⁺-H⁺ exchanger by provision of protons and by allosteric activation.

The activity of the exchanger is regulated by acidosis, renal ablation, thyroxine, glucocorticoids, angiotensin II, catecholamines, and PTH (145,147). Activation of the Na⁺-H⁺ exchanger occurs either through the action of tyrosine-specific kinases or through activation of protein kinase C. Epidermal growth factor, platelet-derived growth factor, and insulin activate the Na⁺-H⁺ exchanger through the tyrosine-specific kinase. Thrombin, angiotensin II, vasopressin, and α -adrenergic agonists activate the Na⁺-H⁺ exchanger via protein kinase C (152–154). The Na⁺-H⁺ exchanger also maintains intracellular pH and the regulation of cell growth. The Na⁺-H⁺ exchanger is regulated in parallel with regulation of the basolateral system that is involved with bicarbonate reabsorption and the Na-3HCO₃ cotransporter. The latter also increases its transport capacity in response to chronic acidosis (155). The turnover of both transporters probably is regulated by the need for transepithelial bicarbonate transport or proton secretion.

Several isoforms of the Na⁺-H⁺ exchanger have been characterized. The eukaryotic housekeeping isoform gene, NHE1, encodes a protein that is composed of 10- to 12-membrane-spanning α helical segments and a large hydrophilic C-terminal domain with potential phosphorylation sites (145). The housekeeping form is expressed only on the basolateral membrane of proximal tubule segments. A total of five isoforms, NHE1-5, have been identified, with predicted proteins that have highly conserved sequences except for the C-terminal domains. All isoforms except NHE5 are found in the kidney and intestine. NHE3 is specifically expressed on the brush-border membrane of the proximal tubule, and expression is increased after acid loading (145). This isoform appears to be unique in that it is resistant to amiloride. In addition, apical membrane expression of NHE3 increases during maturation and after administration of glucocorticoids (156).

Chloride Formate Exchanger

The Cl⁻-formate exchanger is a tertiary transport system that recycles a base across the membrane and couples proton secretion and sodium reabsorption with chloride reabsorption. The base, which is usually formate, reenters the

cell, dissociates, and is again available for exchange with Cl^- . The Cl^- -formate exchanger has been studied in both BBMVs and intact proximal tubules (157–159). Addition of formate to luminal fluid increases NaCl reabsorption when the lumen pH is lower than the intracellular pH. The effect of pH is related to the H^+ gradient between luminal fluid and cell fluid and the recycling of the necessary base. Other bases have been considered as substrates for this exchanger, such as OH^- , bicarbonate, HCO_3^- , and oxalate (160). Oxalate has recently been noted to contribute to net Na reabsorption in a manner similar to formate, with anion exchange at the apical membrane of the proximal tubule. Oxalate is recycled via oxalate-sulfate exchange in parallel with oxalate- Cl exchange.

Basolateral

Several different pathways for Cl exit at the basolateral membrane include KCl cotransport, Na -dependent Cl - HCO_3^- exchange, and Cl channels. Basolateral SITS—an anion exchange inhibitor—reduces NaCl reabsorption in rat proximal tubule by 50%; this suggests a role for a Cl^- -base exchange in the basolateral Cl^- exit (147,161). The process is sodium dependent with a stoichiometry of $\text{Na}:2\text{HCO}_3^-:\text{Cl}^-$ and probably is responsible for most basolateral Cl^- exit (147). Recent evidence indicates that the largest component of Cl movement across the basolateral membrane is via Cl channels (sensitive to diphenylamine-2-carboxylate) (145).

Cellular Mechanisms: Thick Ascending Limb of the Loop of Henle

Sodium reabsorption in this segment proceeds via a luminal $\text{Na}^+/\text{K}^+/\text{Cl}^-$ transporter that couples the reabsorption of 1 Na^+ and 1 K^+ with 2 Cl^- (Fig. 3.14) (128). Chloride leaves the cell via a basolateral Cl channel or KCl cotransporter (162,163). Potassium is recycled via K channels located on the apical membrane. These K channels are inhibited by choline, ammonium, ATP, and verapamil and are not regulated by Ca^{2+} (162). In addition, there is a mechanism for potassium exit from the basolateral membrane either by K^+ channels or by the previously mentioned KCl cotransport system (164). Polarization of most K^+ conductance on the apical membrane and most Cl channels on the basolateral membrane generates a lumen-positive charge that drives as much as 50% of total sodium reabsorption through passive paracellular pathways (162).

The $\text{Na}^+/\text{K}^+/\text{Cl}^-$ cotransporter is an electroneutral transport system and is located on the apical surface of the thick ascending limb of the loop of Henle and the inner medullary collecting duct. In the presence of sodium and potassium, two Cl^- ions are transported with 1 Na^+ and 1 K^+ . Lithium may be transported instead of sodium; however, other cations may not substitute for sodium (165). Rb^+ ,

Cs^+ , and NH_4^+ may be transported instead of K^+ . The high-affinity site is specific for Cl^- or Br^- . Once the high-affinity site is occupied, the remaining site is a low-affinity site that may accept Br^- , Cl^- , I^- , nitrate, or thiocyanate (166). This transport system provides the energy for countercurrent multiplication, which concentrates solutes in the renal medullary interstitium, allowing generation of a concentrated urine. Regulation of urinary-concentrating ability is, in part, a function of this system. The $\text{Na}^+/\text{K}^+/\text{Cl}^-$ transporter is inhibited by furosemide and bumetanide. A separate secretory isoform of the $\text{Na}^+/\text{K}^+/\text{Cl}^-$ cotransporter (NKCC1) (BSG-2) localizes to the basolateral membrane of the ∞ intercalated cell of the collecting duct. This form of the transporter serves to regulate cell volume, as well as to facilitate electrolyte and water transport (167).

The transporter gene (NKCC2) has recently been cloned (168). Homozygous mutations have been found to account for the Bartter's syndrome in numerous kindreds (168). As a member of the electroneutral cation-chloride cotransporter family, this transport system serves both an absorptive and a secretory function (cell volume regulation) (169). Sequence analyses show that these cotransporters are structurally similar, with 12 transmembrane-spanning helices and variable-length amino and carboxyterminal segments, which are cytosolic (Fig. 3.14). A long extracellular loop is proposed to be located between the seventh and eighth transmembrane domains with potential glycosylation sites. There is approximately 50% homology between the two $\text{Na}^+/\text{K}^+/\text{Cl}^-$ cotransporters and the thiazide-sensitive Na - Cl cotransporter found in the distal tubule. Two isoforms of the $\text{Na}^+/\text{K}^+/\text{Cl}^-$ cotransporter are found within the kidney. One is the absorptive form (BSC1), which is localized to the apical membrane of the cortical thick ascending limb of the loop of Henle. The more ubiquitous basolateral form, BSC2, is found in chloride secretory epithelia (169). In the kidney, BSC2 is localized to the basolateral membrane of the inner medullary collecting duct and to the extraglomerular mesangium (juxtaglomerular) and to a subpopulation of smooth muscle cells in the afferent arteriole (167,169). The function of the BSC2 cotransporter in the inner medullary collecting duct may be NaCl secretion through an ANF-inducible response. In addition, this transporter may enable H^+ and/or NH_3^+ secretion. The role of the BSC2 transporter in the afferent arteriole and juxtaglomerular region could be that of tubuloglomerular feedback. Increased Cl delivery to the cortical thick ascending limb has been postulated to be detected by a furosemide-inhibitable $\text{Na}^+/\text{K}^+/\text{Cl}^-$ cotransporter, suggesting a direct role of chloride as the signal between cortical thick ascending loop chloride delivery and response from the macula densa to alter afferent arteriolar tone (170). Recent studies have indicated the precise distribution pattern of transport proteins in the human distal tubule (171).

The main regulating factors for the $\text{Na}^+/\text{K}^+/\text{Cl}^-$ cotransporter are the cAMP/cyclic guanosine monophosphate system,

the state of phosphorylation (phosphorylation stimulates), and cell shrinkage. Antidiuretic hormone stimulates the adenylate cyclase system, which increases the rate of NaCl reabsorption in the medullary thick ascending limb of the mouse. Enhanced luminal transport of NaCl occurs after insertion of additional transporter units into the plasma membrane (23). In addition, urea at high concentration inhibits the Na⁺-K⁺-Cl⁻ cotransporter independent of changes in cell volume (172). This is prevented by prior phosphorylation, which suggests that exposure to urea results in dephosphorylation of the cotransporter or a closely linked regulatory protein. Urea appears to alter cotransporter activity by decreasing the number of functional transporters. Long-term saline administration to rats increases the expression of the gene (BSC1) for the Na⁺-K⁺-Cl⁻ cotransporter. Long-term furosemide use also increases gene expression, as well as possibly inducing glycosylation of the cotransporter (173).

Cellular Mechanisms: Distal Convuluted Tubule

The thiazide-sensitive NaCl cotransporter of the distal collecting tubule is the primary source of active Na reabsorption distal to the loop of Henle. This transporter has structural homology with the Na⁺-K⁺-Cl⁻ cotransporter, as previously mentioned.

Also contributing to luminal sodium entry are the sodium channels. A ubiquitous class of transporters sensitive to amiloride, Na channels are regulated acutely by cAMP-dependent hormones such as vasopressin; G-proteins; and intracellular Na⁺, Ca⁺, and H⁺, and chronically by aldosterone. There is a great deal of heterogeneity among amiloride-sensitive sodium channels. They may be characterized by their conductance, amiloride-binding affinity, and epithelial origin (174). Na channels are multimeric, with various combinations of subunits. Channel activity has been shown to be modified by phosphorylation (cAMP dependent). The guanosine triphosphate-binding protein, G α I-3, is associated with the channel protein complex and directly participates in channel activity. The G protein pathway is activated through phospholipase- and lipoxygenase-generated phospholipids. Nonphosphorylated channels are primarily closed. Exposure to protein kinase A in the presence of ATP shifts channel activity to a more open position (174). Other covalent modifications of the Na channel that affect its activity include pertussis toxin-induced ribosylation and aldosterone-mediated carboxyl methylation. All covalent modifications are induced by exposure of the channel complex from the internal surface and the opposite site of amiloride binding and depend on the state of phosphorylation (174).

Cellular Mechanisms: Collecting Tubule

In this segment, sodium is reabsorbed by transcellular pathways only (Fig. 3.14). The energy is provided by the basolat-

erally located Na⁺-K⁺-ATPase. Sodium enters the principal cell by way of highly selective, low-conductance Na⁺ channels located on the apical membrane (147). Sodium reabsorption is regulated acutely by antidiuretic hormone (175) and chronically by aldosterone and dietary sodium intake (176). The reabsorption of sodium in this segment creates a lumen-negative charge. There is no chloride reabsorption by the principal cell; rather, chloride is reabsorbed by a paracellular route or via a transcellular pathway through intercalated cells. In addition, both arginine and lysine enhance cortical collecting duct Na⁺ transport. Because lysine is not a nitrous oxide (NO) precursor, this is a cationic amino acid effect rather than a vasodilatory effect (177).

Comparison of the mechanisms of sodium reabsorption in the proximal tubule (S1-S3), loop of Henle, and the collecting duct reveals major differences. In the proximal tubule, a large amount of sodium is reabsorbed at low energy cost to the tubule because there is a substantial component of passive paracellular sodium flux; however, the ability of this segment to generate a concentration gradient is limited by the high sodium conductance (147). Therefore, a large fraction of sodium and chloride reabsorption takes place; however, because the luminal concentrations of Na⁺ and Cl⁻ are similar to their plasma concentrations, a significant concentration gradient is not generated. In contrast, sodium reabsorption in the collecting duct occurs by a transcellular route that is expensive with respect to cellular energy. However, in the absence of a significant paracellular conductive pathway, the tubule can generate a large sodium concentration gradient. The thick ascending limb is a compromise between the proximal and collecting tubules; up to 50% of sodium reabsorption is passive.

Developmental Changes in Sodium and Fluid Transport

The reabsorptive capacity for fluid in the proximal tubule increases approximately twofold from 3 to 6 weeks of age in the rat (178) in parallel with increased luminal and basolateral membrane surface area. The postnatal increase in reabsorptive ability can be attributed to the increased activity of the Na⁺-K⁺-ATPase. The sodium-dependent proton flux in isolated, perfused tubules from rabbits is approximately one-third of adult levels at 2 weeks of age and increases to adult levels by 6 weeks of age (179). Studies in both proximal tubular cells in culture and BBMVs confirm that the Na⁺-H⁺ exchange system is less active in immature animals than it is in adults (180,181). This is related to differences in the abundance of the transport protein, because the Na⁺-H⁺ exchanger from newborn rats has characteristics identical with those of the adult rats except that the transport maximum (V_{max}) is one-fourth that obtained from adult rats (Fig. 3.15). Increases in V_{max} occur after the administration of glucocorticoids, indicating an increase in abundance of the transport protein (181).

FIGURE 3.15. Developmental changes in $\text{Na}^+\text{-H}^+$ exchanger activity. Kinetic analysis of initial rate of amiloride-sensitive ^{22}Na uptake into brush-border membrane vesicles from adult and fetal rabbits. (From Ives HE, Chen PY, Verkman AS. Mechanism of coupling between C1 and OH transport in renal brush-border membranes. *Biochem Biophys Acta* 1986;863:91–100, with permission.)

This chapter has outlined various renal tubular transport processes that are vital to homeostasis. Subsequent chapters on water, acid-base, and potassium homeostasis detail those tubular transport systems. Transepithelial movement of solute and fluid tends to be massive in the early parts of the nephron with most of the renal tubular fine-tuning occurring in the more distal segments. Recent advances in the ability to characterize transporter proteins using molecular techniques has provided invaluable insights into the unique proteins that are arranged along the nephron in a polarized and highly segment-specific distribution. Distinct differences in protein structure allow kinetic variation along the proximal tubule so that an impressive concentration gradient from cell to lumen is maintained, allowing nearly complete reabsorption of a substrate.

Maturation changes in transporter protein abundance, metabolism, and regulational responses, in addition to less specific alterations in the cell membrane, explain the decreased functional capacity of the immature kidney. The exception to this generalized functional immaturity is phosphate transport, which is more active in the immature nephron than in the adult counterpart. The ability of both the adult and immature renal tubule to respond to changes in the external milieu through modification of gene transcription or protein trafficking and turnover at the plasma membrane serves as a means of adaptation to our external environment.

PERINATAL UROLOGY

DAVID A. DIAMOND
CRAIG A. PETERS

The routine use of maternal-fetal ultrasound has introduced the field of perinatal urology. Fetal hydronephrosis, with an incidence of 1:100 to 1:500 maternal studies, is the most common abnormality detected. Other urologic abnormalities have been diagnosed prenatally as well, including renal cystic disease, renal agenesis, and even stones and tumors. For the pediatric urologist, these prenatal findings have opened a Pandora's box of questions that challenge our understanding of normal and abnormal renal embryology and physiology. In this chapter, we discuss the diagnosis of prenatal urologic abnormalities, the rationale behind prenatal intervention, and our clinical experience in managing children with prenatal urologic abnormalities.

DIAGNOSIS

In a large prospective Swedish study, the incidence of prenatally detected renal anomalies was 0.28% (1). Of these, two-thirds (0.18%) were hydronephrosis. A British study (2), in which 99% of the pregnant population in Stoke-on-Trent were scanned at 28 weeks' gestation, demonstrated hydronephrosis prenatally in 1.40% of cases, which was confirmed postnatally in 0.65% (2). These authors defined *prenatal hydronephrosis* as an anteroposterior (A-P) diameter of the renal pelvis greater than 5 mm but noted the lack of consensus on the definition of *antenatal hydronephrosis* (3–5).

When an abnormality of the urinary tract is determined by maternal-fetal ultrasound, several questions should be raised by the ultrasonographer and consulting urologist. Combinations of specific findings direct the differential diagnosis and permit more accurate prognosis and tailoring of postnatal evaluation. The principal findings and their implications are listed in Table 4.1.

Diagnostic Accuracy

The importance of accurate diagnosis is dependent on the context of the case. If intervention is to be considered, diagnostic accuracy needs to be high. In most cases, the detec-

tion of some degree of hydronephrosis permits appropriate postnatal evaluation, even if the responsible mechanism and precise level of obstruction are not discernible. Diagnostic accuracy of hydronephrosis in the fetus remains imperfect. An early report by Hobbins et al. suggested that the correct prenatal identification of the site of obstruction could be confirmed postnatally in 88% of cases (6). Subsequent studies reported fairly high false-positive rates ranging from 9 to 22% (3). The majority of false positives in these studies was nonobstructive causes of hydronephrosis, such as high-grade reflux or large, nonobstructed, extrarenal pelves or transient hydronephrosis.

Accurate diagnosis of posterior urethral valves (PUV), in which intervention might be considered, has proven difficult. In one series, the false-positive rate was as high as 58% (7), but the criteria for diagnosing valves were quite liberal and perhaps inappropriate. In another population-based series, the sensitivity in detecting valves was as low as 23% (3). Diagnosis of obstructive conditions based on the criteria of increased renal echogenicity and decreased amniotic fluid is very accurate (8). The distinction between mild and moderate degrees of obstruction and conditions such as reflux may be more challenging. The clinical impact of these distinctions depends on whether intervention should be considered for anything less than severe.

Ureteropelvic Junction Obstruction

The basic features of ureteropelvic junction obstruction (UPJO) in the fetus include dilation of the renal pelvis and collecting system with no evidence of ureteral dilation (Fig. 4.1). The best way to detect ureteral dilation is at the level of the bladder, preferably in transverse view. The degree of dilation becomes the critical issue determining postnatal recommendations. The threshold for recommending postnatal follow-up is largely arbitrary, yet most would agree that a unilateral A-P diameter over 7 or 8 mm in the third trimester (5 to 6 mm with bilateral dilation) mandates postnatal follow-up (9). In the case of unilateral UPJO, there is little

TABLE 4.1. MAJOR DIAGNOSTIC FINDINGS IN PRENATAL IMAGING

	Finding	Comment
Kidney	Hydronephrosis	Assess degree
	Unilateral vs. bilateral	May be different degrees
	Parenchymal echogenicity	Should be less than spleen or liver; if increased and organ enlarged, suggests autosomal recessive polycystic kidney disease
	Duplication	Often with dilation of upper pole; may be lower pole dilation
	Cysts	Small cysts associated with dysplasia; simple cyst of upper pole suggests duplication with ureterocele or ectopic ureter; genetic cystic disease
Ureter	Urinoma	Perinephric or subcapsular
Bladder	Dilation/tortuosity	Obstruction or reflux
	Distended	Variation with time
Bladder	Wall thickness	In relation to filling status
	Intravesical cystic structure	Ureterocele
	"Keyhole" pattern	Dilated posterior urethra; PUV
	Not visible	Exstrophy
Amniotic fluid	Absence; oligohydramnios	Impaired urine output
	Polyhydramnios	May be seen with mild-moderate hydronephrosis
Gender	Penis/scrotum/testes	Sex-associated conditions (e.g., PUV)
Spine	Meningocele	Neural tube defect

PUV, posterior urethral valves.

rationale for *in utero* intervention. In a few cases with massive dilation, therapeutic aspiration has been recommended for dystocia. In the case of bilateral UPJO, the efficacy of *in utero* intervention is difficult to assess.

Attempts to correlate prenatal ultrasound appearance with postnatal outcomes have been complicated by the long-standing controversy regarding postnatal evaluation and management of UPJO. Grignon et al. developed a system of grading hydronephrosis secondary to UPJO based on the diameter of the renal pelvis (RPD) and degree of calyceal dilatation (10). Mandell et al. attempted to correlate the degree of A-P RPD pelvic diameter relative to gestational age with subsequent need for postnatal surgical intervention (Fig. 4.2) (11). They found the "at risk" diameter to be greater than or equal to 5 mm at 15 to 20 weeks' gestation, greater than or equal to 8 mm at 20 to 30 weeks' gestation, and greater than 1 cm at over 30 weeks' gestation. An alternative system proposed by Kleiner et al. defined *hydronephrosis* as the ratio of A-P RPD to A-P diameter of kidney as being greater than 0.5 cm (12); caliectasis was later added as an additional indicator of significant hydronephrosis. Mild degrees of renal pelvic dilatation may resolve *in utero*. Mandell et al. noted this to occur in 23% of cases, with 66% remaining stable and 9% worsening over the course of the pregnancy (11). Severe forms of UPJO may be associated with urinary ascites or perinephric urinomas, which often precede nonfunction of the kidney (13).

Cystic Kidneys

The distinction between severe unilateral hydronephrosis and a multicystic dysplastic kidney may occasionally be

unclear. The findings of multiple noncommunicating cysts, minimal or absent renal parenchyma, and the absence of a central large cyst are diagnostic of a multicystic dysplastic kidney. Bilaterally enlarged echogenic kidneys, particularly if associated with hepatobiliary dilatation or oligohydramnios, suggests autosomal recessive polycystic kidney disease (Fig. 4.3). A more challenging finding is normal-sized, diffusely echogenic kidneys that are not associated with other urologic lesions. Estroff et al. described 19 cases (14 bilateral), including 10 with normal function who survived and 4 with autosomal recessive polycystic kidneys who died (14).

FIGURE 4.1. Bilateral ureteropelvic junction obstruction manifested as symmetric hydronephrosis with caliectasis and no ureteral dilation in a fetus.

FIGURE 4.2. Prenatal renal pelvic diameter in operative and non-operative patients with hydronephrosis. [From Mandell J, Blyth BR, Peters CA, et al. Structural genitourinary defects detected in utero. *Radiology* 1991;178(1):193–196, with permission.]

Ureterovesical Junction Obstruction

Less common than UPJO, ureterovesical obstruction is characterized by ureteral dilation along with varying degrees of renal pelvic and calyceal dilation. More extreme cases may be confused with single system ectopic ureters, particularly in males. In general, the differentiation can be made postnatally.

Duplication Anomalies

Duplication anomalies, among the most interesting of prenatal urologic findings, are recognized on the basis of upper

FIGURE 4.3. Markedly enlarged echogenic (“bright”) kidneys (arrows) in a fetus with oligohydramnios, consistent with autosomal-recessive polycystic kidney disease.

FIGURE 4.4. Fetal image of duplex kidney with marked upper pole hydronephrosis (open arrow) in contrast to a normal lower pole (closed arrows). This image is consistent with either ectopic ureter or ectopic ureterocele with duplication.

pole hydroureteronephrosis, associated with an obstructing ureterocele within the bladder or ectopic ureter, inserting outside of the bladder (15) (Fig. 4.4). Lower pole hydronephrosis may be present as a result of reflux or UPJO. Occasionally, lower pole dilation is due to upper and lower ureteral obstruction by a large ureterocele.

Vesicoureteral Reflux

One cannot make a firm diagnosis of vesicoureteral reflux based on prenatal ultrasound, although intermittent hydronephrosis or hydroureter is highly suggestive. Vesicoureteral reflux may be present in as many as 38% of children with prenatal hydronephrosis (16). Reflux occurred in 42% of children in whom postnatal imaging revealed persistent upper tract abnormalities and in 25% of those with normal findings on postnatal ultrasound but having a history of prenatal dilation. Tibballs and Debrun reported that in patients with prenatal dilation and postnatally normal renal units by ultrasound, 25% had grade III–V reflux (17). The incidence of high-grade reflux was greater in males than in females as noted in previous studies.

Posterior Urethral Valves

Perhaps the most important diagnosis to be made prenatally is that of PUV in the male fetus—a disorder that, at the very least, mandates prompt postnatal surgical correction. In some cases, prenatal intervention may be warranted. Fetal sonographic findings of PUV include bilateral hydroureteronephrosis, a thick-walled bladder with dilated posterior urethra, and, in more severe cases, dysplastic renal parenchymal changes with perinephric urinomas and urinary ascites (Figs. 4.5 and 4.6) (18). When characteristic

FIGURE 4.5. Image of fetal bladder associated with posterior urethral valves showing bladder wall thickening and a dilated posterior urethra (arrow), "keyhole sign."

sonographic findings are present, the differential diagnosis includes prune belly syndrome (with or without urethral atresia), massive vesicoureteral reflux, and certain cloacal anomalies (in genetic females) (19,20). Prenatal diagnostic accuracy for PUV is far from perfect but is probably better than the 40% reported by Abbott et al. (7).

RATIONALE FOR PRENATAL INTERVENTION

The scientific rationale for prenatal treatment of hydronephrosis is to maximize normal development of renal and pulmonary function. These two aspects of fetal development are closely linked because urine comprises 90% of amniotic fluid volume, and oligohydramnios during the third trimester has been causally related to pulmonary hypoplasia.

Before prenatal surgical intervention for obstructive uropathy, it is critical to assess the risk-benefit ratio. The most widely accepted indicator of salvageable renal function is analysis of fetal urine. When the urinary sodium is less than 100 mg/dL and urine osmolarity less than 200 mOsm/dL, renal function appears to be salvageable with *in utero* intervention (Table 4.2) (21). The accuracy of these predictors has been challenged (22,23). More recently, serial aspirations of fetal urine have been reported to yield more valuable results (24). Guez et al. (25) reported ten fetuses who underwent multiple urine samplings and in whom severe obstruction reduced sodium and calcium reabsorption. They concluded that fetal urinary chemistries were reasonably predictive of severe but not moderate postnatal renal impairment. Other investigators have suggested the use of fetal urinary β_2 -micro-

FIGURE 4.6. Echogenic hydronephrotic kidney (arrow) associated with posterior urethral valves in a 20-week fetus.

globulin as an indicator of tubular damage. Using this parameter, poor renal outcome has been predicted with a specificity of 83% and sensitivity of 80% (26).

The time of onset of oligohydramnios has been shown to be an important determinant of outcome by Mandell et al. (27). In fetuses in which adequate amniotic fluid was documented at up to 30 weeks' gestation in association with a urologic abnormality, pulmonary outcomes were satisfactory, and postnatal clinical problems were related to renal disease. It seems inappropriate to recommend late urinary tract decompression from a pulmonary or renal basis. It is unclear whether early delivery, to permit earlier postnatal urinary decompression, is beneficial.

CLINICAL EXPERIENCE WITH INTERVENTION FOR PRENATAL HYDRONEPHROSIS

The ability to diagnose severe prenatal hydronephrosis and knowledge of its outcomes has led to our desire to treat it. In 1982, Harrison et al. described the initial report of fetal surgery in a 21-week-old fetus with bilateral hydroureteronephrosis due to PUV (28). More interventions followed. After the 1986 report of the International Fetal Surgery Registry (29) in which outcomes did not seem to justify risk, a de facto moratorium on *in utero* urinary tract shunting evolved. More recently, with improved technology and renewed interest in fetal shunting, most cases have been referred to a small number of highly specialized centers actively engaged in prenatal surgery. The initial method of decompression with open surgery has largely been replaced by *in utero* shunt

TABLE 4.2. PRENATAL ASSESSMENT OF RENAL FUNCTIONAL PROGNOSIS

	Good		Poor	
Amniotic fluid	Normal to moderately decreased		Moderate to severely decreased	
Sonographic appearance of kidneys	Normal to echogenic		Echogenic to cystic	
Fetal urine	Glick et al. (21)	Johnson et al. (24)	Glick et al. (21)	Johnson et al. (24)

Output (mL/h)	>2	—	<2	—
Sequential improvement in urinary values	—	X	—	—

X, only in this series was the criterion used.

placement, although this has been complicated by technical problems of shunt dislodgement and, in the case of the double-J shunt, bowel herniation (30). Some investigators have explored the use of fetoscopic methods for direct intervention to provide prolonged bladder drainage (31–33), whereas others have attempted direct endoscopic valve ablation (34).

Harrison et al. have clearly outlined the indications and contraindications of intervention for prenatal obstructive uropathy (Table 4.3). (35) The principal reason for considering vesicoamniotic shunting is to prevent early neonatal pulmonary insufficiency and death. The risks that one accepts with intervention include induction of premature labor, perforation of fetal bowel and bladder, as well as hemorrhage and infection in the fetus and mother.

The need to consider *in utero* intervention for obstruction is rare. In a recent study, only 9 of 177 fetuses with a diagnosis of hydronephrosis were considered to have PUV, and only 3 warranted serious consideration of intervention (11).

The results of prenatal intervention for fetal hydronephrosis between 1982 and 1985 were reported by the International Fetal Surgery Registry (29). The largest group of fetuses that were treated had an indeterminate cause of their prenatal hydronephrosis (45%). Among those fetuses with a clear etiology of their hydronephrosis, PUV was the leading cause (29%). Surgical intervention in these cases led to a survival rate of 76%. Among the several reports of outcomes with fetal intervention for obstructive uropathy, true benefit is difficult to assess. This is due to variability in diagnosis, length of follow-up, and documentation of postnatal care. A compilation of these reports is shown in Figure 4.7. These data demonstrate improvement in survival and reduction in renal failure in patients with both good and poor prognostic features (36–38). Longer follow-up periods have demonstrated a high incidence of later renal failure and growth retardation (39). No direct, prospective trial of prenatal intervention for fetal hydronephrosis has been performed.

More recently, the ability to influence renal outcome in male patients with PUV but without oligohydramnios has

been suggested as a possible indication for *in utero* intervention. The principal goal of intervention is not to prevent pulmonary hypoplasia and deaths but to prevent or delay end-stage renal failure. Although some reports have shown the ability to distinguish those fetuses with likely early renal failure from those with later-onset failure (40,41), the specificity and accuracy of methods using a combination of ultrasound and urinary chemistries (sodium, β_2 -microglobulin, and calcium) has not been well defined. In summary, precise identification of those situations in which intervention may benefit the fetus with obstructive uropathy remains unclear.

POSTNATAL MANAGEMENT OF INFANT WITH PRENATALLY DIAGNOSED HYDRONEPHROSIS

A child with a prenatal diagnosis of hydronephrosis should be carefully evaluated and followed by a pediatric

TABLE 4.3. PRENATAL INTERVENTION FOR HYDRONEPHROSIS

Indications (prerequisites)	Contraindications
Presumed obstructive hydronephrosis, persistent or progressive, bilateral or in solitary unit	Unilateral hydronephrosis with an adequately functioning contralateral kidney
Otherwise healthy fetus	Chromosomal abnormalities or presence of associated severe anomalies
Oligohydramnios	Bilateral hydronephrosis without oligohydramnios
No overt renal dysplasia	Severely dysplastic kidneys
Adequate renal functional potential based on urinary indices (see text)	Evidence of urethral atresia
Informed consent	Presence of a normal twin

FIGURE 4.7. Survival and renal function in fetal interventions for bladder outlet obstruction comparing treated and untreated fetuses with good and poor prognostic indices. C.I., confidence interval; Rx, treatment. [Data from Crombleholme TM, Harrison MR, Golbus MS, et al. Fetal intervention in obstructive uropathy: prognostic indicators and efficacy of intervention. *Am J Obstet Gynecol* 1990;162:1239-1244; Johnson MP, Bukowski TP, Reitleman C, et al. In utero surgical treatment of fetal obstructive uropathy: a new comprehensive approach to identify appropriate candidates for vesicoamniotic shunt therapy. *Am J Obstet Gynecol* 1994;170(6):1770-1776; discussion 1776-1779; and Coplen DE, Hare JY, Zderic SA, et al. 10-year experience with prenatal intervention for hydronephrosis. *J Urol* 1996;156(3):1142-1145.]

urologist from birth. The vast majority of these children (with unilateral hydronephrosis and a contralateral normal kidney) appear entirely healthy and, in the absence of prenatal ultrasound findings, would not have any indications for regular urologic follow-up. Parental anxiety is common and should be addressed directly with prenatal counseling and education. The presence of unilateral dilation of the kidney warrants postnatal evaluation in a timely but nonurgent fashion (3 to 8 weeks of life) with an ultrasound (42). Early ultrasound is unlikely to miss a significant abnormality, but a normal result adds confusion as to the need for further evaluation (43). The precise indications for antibiotic prophylaxis (amoxicillin, 10 mg/kg/day or 50 mg/day) are unclear. A reasonable rule of thumb is that if a voiding cystourethrogram is requested, prophylactic antibiotics should be used. There are no outcomes-based assessments of follow-up protocols for children with mild to moderate dilation. An approach that seems reasonable and safe is to recommend functional imaging (diuretic renography or intravenous pyelography) if there is calyceal dilation followed by serial ultrasonography. Serial ultrasonography with some plan for extending the interval between imaging studies seems reasonable but unproven.

For the child with bilateral hydronephrosis suggestive of bladder outlet obstruction, an ultrasound and voiding cystourethrogram should be performed promptly. In boys, PUV is the most important diagnosis to be ruled out. In girls, an obstructing ectopic ureterocele would be the most likely cause for bladder outlet obstruction. In the event that an obstructive lesion is discovered, it should be corrected promptly. If high-grade reflux is noted, antibiotic prophylaxis with appropriate radiologic follow-up is indicated.

The timing of postnatal cystography in the setting of prenatally detected unilateral hydronephrosis remains controversial. Although some groups advocate postnatal cystography in any child with a history of prenatal hydronephrosis, others have questioned the value of this approach (44). A practical threshold for performing cystography used in many programs has been the presence of caliectasis, a dilated ureter, or variable hydronephrosis.

In a neonate with prenatally detected hydronephrosis, the importance of diagnosing vesicoureteral reflux remains controversial. Several studies have demonstrated that a high incidence of reflux is a major factor contributing to prenatally detected hydronephrosis, although its clinical significance is unclear. In several studies, the incidence of reflux is approximately 20 to 30% in all grades of hydronephrosis (45-50). The grade of hydronephrosis does not predict the likelihood or grade of reflux, and the absence of hydronephrosis does not rule out high-grade reflux. As with hydronephrosis in the neonatal period, reflux (and particularly high-grade reflux) occurs more commonly in boys. The natural history is less well defined, with some series demonstrating rapid resolution of higher grades of reflux (48,51). When neonates with grades 4 and 5 and higher reflux are studied with dimercaptosuccinic acid (scintigraphy) renal scanning, renal abnormalities are detected in up to 50% of children with no history of infection (49,52-54). This challenges current dogma that renal injury associated with reflux is only due to infection. It may be argued that the observed renal abnormalities are dysplastic and will not progress postnatally, yet this remains unproven. The relationship of bladder function to neonatal reflux is currently being defined and may be of critical importance, particularly in boys. Significant bladder instability has been documented in infants with high-grade reflux (55-57), and for this reason, managing bladder dysfunction is appropriate.

URETEROPELVIC JUNCTION OBSTRUCTION

Perhaps the most challenging aspect of managing prenatal hydronephrosis is determining when postnatal surgical correction for obstruction is appropriate. Despite the improved anatomic detail afforded by real-time ultrasound and the

FIGURE 4.8. Renal pelvic dilation and occurrence of surgical intervention (based on declining function, increasing hydronephrosis, or symptoms). [Adapted from Dhillon HK. Prenatally diagnosed hydronephrosis: the Great Ormond Street experience. *Br J Urol* 1998;81(Suppl 2):39-44.]

increasing experience with functional nuclear medicine studies (mercaptotriglycylglycine) (see Chapter 25), no gold standard for physiologically significant obstruction exists. Over time, some kidneys have been seen to improve, whereas others appear to lose function. The natural history of prenatal hydronephrosis remains to be clearly defined.

The debate over the appropriate management of infants with prenatally detected unilateral hydronephrosis remains unsettled and will ultimately be determined by three key factors. It will be necessary to define the degree of hydronephrosis in a reproducible way to correlate initial presentation with outcome. Next, the natural history of various degrees of hydronephrosis must be defined in current clinical terms, as well as using novel means of marking the progression of renal function or response to the hydronephrotic condition. Finally, clinically useful indicators of the state of the developing kidney in the hydronephrotic state need to be defined to permit identification of “at risk” patients.

At present, it is commonly considered that a unilaterally hydronephrotic kidney with significantly reduced relative uptake on a renogram (i.e., less than 30%) should be considered for surgical repair. The group of kidneys with uptake

from 30 to 40% are controversial: The London group recommends surgical repair based on a high incidence of later functional loss (58), whereas Koff and colleagues observe these patients with frequent diuretic renograms (59,60). Indeed, Koff has recommended scans as frequently as every 2 weeks for those with significantly reduced uptake. In kidneys with less than 10 to 15% uptake on renogram, it is questionable whether any attempt to salvage renal function is appropriate. The greatest difficulty lies in those patients with a unilateral kidney having severe dilation and normal uptake (i.e., greater than 45%). Some are found to have uptakes greater than 50%, which is as yet unexplained (61). The most predictive clinical parameter identified to date is the degree of renal pelvic dilation (A-P diameter). Dhillon et al. have shown that with increasing A-P diameter, there is a progressive risk of decrease in relative renal function or development of symptoms (Fig. 4.8) (62). These are minimal risks if the A-P diameter is less than 20 mm, whereas in those with dilation greater than 50 mm, it is almost 100%. It remains unknown if this relationship is time dependent and whether the risk of deterioration will increase at lesser degrees of dilation with increasing time. The few reports of prospective assessments of the risk of renal injury (functional deterioration, infection, or symptoms) are listed in Table 4.4 and indicate a 20 to 25% likelihood of patients with unilateral, significant UPJO warranting pyeloplasty by objective criteria. In most cases, functional loss was corrected by surgical intervention. A retrospective study by Chertin et al., however, observed that the functional status of comparable kidneys was better if the children had undergone earlier rather than delayed pyeloplasty (63).

Other indicators of potential deterioration have been proposed. Koff attempted using contralateral renal growth as an indirect indicator of ipsilateral obstructive injury, but this has not proved to be clinically useful (64). Urinary markers, including *N*-acetyl- β -D-glucosaminidase (65) and transforming growth factor- β 1 (66), have been explored in limited series with suggestive but as yet clinically unproven predictive value. All of these markers have suggested that affected kidneys are not normal, but few data have been rigorously correlated with functional outcomes.

TABLE 4.4. REPORTS OF NONOPERATIVE MANAGEMENT OF UNILATERAL URETEROPELVIC JUNCTION OBSTRUCTION

Author (reference)	No. of patients	Study type	Crossover to pyeloplasty (%)
Ransley et al. (58)	100	Prospective, single arm	23
Cartwright et al. (68)	41	Prospective, single arm	15
Palmer et al. (69)	16	Prospective, double arm, randomized	25
Ulman et al. (60)	104	Prospective, single arm	22

From a practical standpoint, the clinician must balance possible spontaneous resolution of hydronephrosis without impairment of renal development with losing the opportunity to maximize potential renal function through surgical intervention. As in all of pediatric practice, the emphasis should remain on permitting maximal childhood growth and development while minimizing medical intrusion (67). Our current approach is to consider surgical repair in the setting of impaired relative renal function (i.e., less than 40%), marked or increasing dilation, decreasing function on serial radionuclide imaging, or the development of symptoms. Also critical is parental preference, with many parents remaining uncomfortable with a "watchful waiting" approach. Early counseling by all members of the pediatric healthcare delivery team can help avoid confusion and allay anxiety.

ACKNOWLEDGMENT

The authors acknowledge the assistance of Beryl Benacerraf, M.D., for providing many of the fetal ultrasound images.

RENAL DYSPLASIA/HYPOPLASIA

PAUL R. GOODYER

During normal kidney development, interactions between the branching ureteric bud and the metanephric mesenchyme generate the nephrons of each kidney. Nephrons eventually hang like apples, each on its own branch of the arborized collecting system. At birth, this crop of nephrons constitutes the individual's nephron endowment for life and ranges widely among normal humans from 0.3 to 1.1 million nephrons per kidney (1). "Normal" children at the low end of this nephron endowment spectrum are thought to be at increased risk for hypertension and renal insufficiency after an acquired renal insult later in life; suboptimal nephron number may also influence longevity of renal allografts (2–4). On occasion, renal hypoplasia may be more extreme. In one antenatal ultrasound screening study, it was estimated that approximately 1 in 400 neonates are born with at least one hypoplastic kidney (5). When renal hypoplasia is bilateral, nephron number may be insufficient for normal extrauterine life. As somatic growth outstrips nephron endowment, these children develop progressive renal insufficiency, generating approximately 20% of the pediatric end-stage renal disease population (6).

In this chapter, those clinical settings in which primary nephron number is suboptimal from birth are considered. In some, nephron number may be reduced even though the structure and function of nephrons is normal (pure renal hypoplasia). More often, renal hypoplasia is associated with histopathologic evidence of aberrant developmental fates of the metanephric mesenchyme and profound disturbances of the normal patterning of renal tissue (renal dysplasia). As suggested by Pohl et al., current approaches to classification of human kidney hypoplasia/dysplasia must integrate recent advances in the understanding of nephrogenesis with clinicopathologic observations (7). Because the former field is so rapidly evolving, any classification system should be considered a work in progress. In this chapter, primary renal agenesis and pure renal hypoplasia are considered in the context of key molecules that are either essential for initial steps in renal development or which optimize the rate of branching nephrogenesis. Then, renal dysplasia, which is often linked to aberrant outgrowth of the primary ureteric bud and/or disturbed interactions of bud with metanephric mesenchyme, is

described. Although syndromes involving marked renal dysplasia are categorized in Chapter 6, examples of renal dysplasia and the evidence that obstruction of the fetal urinary tract can disturb mesenchymal cell fate during kidney development are considered in this chapter. Abnormalities of kidney position and macroscopic patterning, particularly multicystic/dysplastic kidneys (MCKDs), are reviewed in regard to failure of mechanisms normally involved in the terminal differentiation of renal epithelia.

RENAL AGENESIS

Bilateral Renal Agenesis

Bilateral failure of primary nephrogenesis during fetal life causes a characteristic pattern of facial compression and pulmonary hypoplasia (Potter syndrome) due to the absence of amniotic fluid. When severe, oligohydramnios is evident clinically or by ultrasonography in the second trimester (21 to 23 weeks), and should raise major concern about the postnatal viability of the infant (8). High-resolution color Doppler ultrasonography is helpful in detecting the fetal renal arteries and distinguishing renal hypoplasia from renal agenesis (9). Complete absence of renal parenchyma (renal agenesis) and amniotic fluid predicts severe pulmonary hypoplasia, often resulting in pneumothorax and/or inability to oxygenate in the newborn period. In those who initially survive, the decision about whether to embark on chronic peritoneal dialysis is usually based on whether: (a) lung development is sufficient to allow oxygenation without respiratory support beyond the perinatal period; (b) there is any functional renal parenchyma [identifiable by mercaptoacetyl triglycerine (MAG-3) imaging and/or ultrasonography]; (c) urine volume is sufficient to permit minimal long-term oral nutrition (100 kcal/kg/day); and (d) family and institutional resources can sustain dialytic therapy long enough to achieve growth and development sufficient to permit successful renal transplantation.

The causes of renal agenesis in humans are not well understood, but reports of absent renal arteries during the second trimester suggest arrest of kidney development at an early

stage. Study of homozygous knock-out mice has identified a number of critical developmental genes causing experimental BRA. For example, inactivation of either glial cell line-derived neurotrophic factor (a growth factor expressed in the undifferentiated mesenchyme) or *c-ret* (the glial cell line-derived neurotrophic factor receptor, which is expressed at the surface of ureteric bud cells) results in failure of primary outgrowth of the ureteric bud (10,11). Knock-out mice lacking key transcription factor genes, such as *PAX2* or *WT1*, are also anephric (12,13). Presumably, homozygous mutations for any one of these genes could account for occasional sporadic cases of complete renal agenesis in humans, but this has not yet been demonstrated. Most cases of Potter syndrome are associated with obstruction of the urinary tract or severe bilateral renal hypoplasia rather than complete BRA. Antenatal ultrasonography of 4000 normal Japanese pregnancies uncovered no examples of BRA, indicating its rarity (5).

Unilateral Renal Agenesis

In a recent study of American infants, the incidence of unilateral renal agenesis (URA) was 1 per 2900 births and was more common in infants of diabetic mothers and among black mothers than in others (adjusted odds ratio of 4.98 and 2.19, respectively) (14). In a screening study of normal Japanese newborns, 52 of 4000 newborns (1.3%) had evidence of unilateral hypoplastic/dysplastic kidneys (5). During follow-up of three of these cases, the abnormal renal tissue involuted in early postnatal life so that eventually no detectable kidney was evident (5). Thus, adults with congenital absence of one kidney may be born with at least some partial, though abortive, renal tissue that regresses at an early stage. In murine models, knock-out of both copies of the *c-ret* gene usually results in anephric fetuses. However, a small percentage manage to achieve outgrowth of the ureteric bud and generate a small, though suboptimal, kidney on one side (10). This suggests that some cases of URA may be caused by inherited mutant genes. Occasional cases of autosomal dominant URA have been reported (15).

At birth, nephron number is suboptimal in children with URA, and the contralateral kidney is stimulated to undergo postnatal compensatory hypertrophy. In most cases, plots of renal length or volume versus body length demonstrate gradual compensatory hypertrophy of the unaffected contralateral kidney over the first 3 to 4 months postnatally, crossing percentiles established for normal populations. Failure to undergo compensatory hypertrophy usually indicates contralateral renal dysplasia and may predict progressive renal insufficiency. In addition to monitoring contralateral growth, it is important to screen for residual functional renal tissue by nuclear dimercaptosuccinic acid (DMSA) or MAG-3 scanning. The presence of severely hypoplastic/dysplastic tissue is sometimes associated with hypertension, which might require excision of the dysplastic kidney.

URA has been associated with developmental abnormalities of other tissues, particularly the ear, genital tract, and axial skeleton. Among 40 girls with URA, 4 out of 40 (10%) had an ipsilateral mild-moderate sensorineural hearing deficit and 14 (35%) had mullerian duct abnormalities (16). In a retrospective study of patients with mullerian duct abnormalities, 30% had URA (17); this association was particularly strong for girls with uterus didelphys (13 of 16 cases), uterine agenesis (two of five cases), and unicornuate uterus (two of seven cases). URA was seen in all 11 cases of obstructed uterus didelphys, ipsilateral to the side of the obstructing transverse hemivaginal septum. The incidence of genital tract anomalies in boys with URA is not precisely known, but ipsilateral cystic dysplasia or seminal vesicle cysts and bilateral absence of the vas deferens (with ipsilateral syndactyly) have all been described (18–20). In a prospective study of 202 patients with congenital vertebral abnormalities, 54 (26.7%) had at least one genitourinary abnormality detected by intravenous pyelography or ultrasonography; the most frequent being URA (16). Although the pathogenetic mechanisms are not well understood, it is evident that defective developmental pathways or genes may disturb morphogenesis of mesenchyme in the ear, genital tract, and skeleton, and it is not unreasonable to screen children with URA for these associated anomalies.

PRIMARY RENAL HYPOPLASIA

Normal mature kidneys contain approximately 617,000 glomeruli with mean glomerular size of approximately $6 \mu\text{m}^3$ (21). In the 1970s, pediatric nephrologists recognized a familial form of oligomeganephronia in which renal hypoplasia and progressive proteinuric renal failure in childhood were associated with unusually large but otherwise normal-appearing glomeruli (22). During the same period, an autosomal dominant syndrome of renal hypoplasia associated with colobomas of the optic nerve [renal-coloboma syndrome (RCS)] was also characterized (23). In 1995, Eccles showed that RCS was caused by heterozygous mutations of the *PAX2* gene and drew attention to the high frequency of vesicoureteral reflux (VUR) in affected families (24–26). When patients with oligomeganephronia were subsequently reinvestigated, these patients also proved to have heterozygous *PAX2* mutations, though the optic nerve abnormality was often barely detectable (27–29). Approximately 15 different inactivating mutations of the *PAX2* gene have been described, and the most common (a single base-pair insertion in the second exon of *PAX2*) also causes RCS in the inbred *INeu* mouse strain (30). Studies of fetal kidney development in *INeu* mice have led to the hypothesis that a critical function of the *PAX2* gene is to prevent apoptosis of cells in the branching ureteric bud during kidney development (31,32). Absence of one *PAX2* gene is sufficient to permit increased ureteric bud cell apoptosis,

FIGURE 5.1. Hypoplastic kidney bisected to show presence of ureter and symmetric collecting system derived from initial branches of the ureteric bud. The thin outer rim of renal cortex has normal architecture, but nephron number is dramatically reduced.

compromising nephron number by slowing the rate of branching nephrogenesis. Presumably, PAX2 function also influences structure of the ureterovesical junction. In pure primary renal hypoplasia, there is little evidence of dysplasia, and glomerular hypertrophy is presumably the normal compensatory response to the deficit in nephron number (Fig. 5.1).

At least one other form of hereditary renal hypoplasia, branchiootorenal (BOR) syndrome (OMIM 113650), can be attributed to mutation of a single gene. The autosomal dominant BOR syndrome, involving variable degrees of renal hypoplasia, congenital lateral cervical fistulas or cysts, and ear abnormalities (preauricular tags or pits, a malformed auricle, atresia of the canal, anomalies of the middle ear, and hypoplasia of the cochlea or semicircular canals) is caused by mutations of the EYA1 gene (32,33). More than 20 different EYA1 mutations have been reported; end-stage renal failure may develop anywhere between 12 and 36 years of age. EYA1 is the human homolog (chromosome 18q13.3) of a small family of transcription factors originally identified in *Drosophila* because of their importance to eye development, but in humans the eye is unaffected. Within the same family, heterozygous mutations of EYA1 may cause renal defects ranging from BRA to mild unilateral hypoplasia (34). During normal renal development EYA1 is expressed in the metanephric mesenchyme, and homozygous EYA1 knock-out mice lack primary outgrowth of the ureteric bud with subsequent failure of nephron induction (35).

The otic defects in BOR syndrome can usually be delineated by computed axial tomography, but nuclear magnetic resonance imaging may be useful in diagnosis (36). It has been argued that renal defects are not common enough in children with external ear anomalies alone to warrant routine renal ultrasonography (37). On the other hand, several other syndromes involve renal anomalies and external ear deformities (38). Although renal hypoplasia can be quite variable in BOR, branchial arch defects with normal kidneys (BO syndrome) probably result from mutations of a different gene on chromosome 1q31 (39).

In the 1940s and 1950s, Wilson reported that severe vitamin A (retinol) deficiency caused renal agenesis (40,41). More recent observations indicate that even modest maternal retinol deficiency (50% reduction in circulating levels of retinol) can cause significant renal hypoplasia in rodents. In such studies, postnatal kidney weight is decreased by 24%, and nephron number is reduced by 20% (42). In these rodent studies, nephron number correlated with kidney size and varied directly with circulating retinol concentration. Normally, the fetus acquires retinol from the maternal circulation and converts it to an active metabolite, all-*trans*-retinoic acid, in the kidney and other peripheral tissues (43). In fetal rat kidneys cultured *ex vivo*, all-*trans*-retinoic acid (0.1 to 1.0 μmol) accelerates new nephron formation by two- to threefold (44,45). Vitamin A deficiency is widespread (15 to 25% of pregnant women) in many third world regions, and in North America a small but significant fraction (1%) of pregnant women have retinol levels in the low-normal range that could effect nephron number. As yet, however, it is unknown whether human maternal vitamin A deficiency limits nephrogenesis as it does in rats.

RENAL DYSPLASIA/HYPOPLASIA AND VESICoureteral REFLUX

During early fetal life, the two nephric (wolffian) ducts arise in the pronephric region of the intermediate mesoderm and migrate caudally. Just before arrival at the cloaca (approximately somite 25 in the mouse), ureteric buds emerge from the nephric ducts at a site corresponding to the future vesicoureteral junction and induce the metanephric kidneys from laterally adjacent metanephric mesenchyme. In 1975, Mackie and Stephens observed (by ureteroscopy) that many children born with duplex collecting systems and/or VUR also had malpositioned ureteric orifices (46). In Japanese perinatal screening studies, renal hypoplasia (approximately 1 in 400 normal births) was strongly correlated with VUR (5). Among neonates investigated for VUR, renal hypoplasia (reduced renal length by ultrasonography and reduced DMSA uptake by scintigraphy) was frequent, being symmetric in approximately one-third of cases and involving patchy scars of the renal parenchyma in others (47,48). Thus, disturbance of the

FIGURE 5.2. Renal hypoplasia associated with ipsilateral vesico-ureteral reflux in a 2-year-old boy who presented with his first lower urinary tract infection. Dimercaptosuccinic acid scintigraphy demonstrates normal reniform appearance of the hypoplastic parenchyma, which contributes only approximately 10% of total renal function.

factors that regulate the proper timing or positioning of ureteric bud outgrowth appear to lead to ectopic ureteric orifices, abnormalities of ureter structure, and faulty induction of metanephric mesenchyme by the ectopic ureteric bud (Fig. 5.2). This hypothesis is supported by knock-out mouse experiments in which homozygous inactivation of a single transcription factor gene (*Foxc2*) may cause various anatomic abnormalities of the ureters associated with renal hypoplasia in approximately 60% of offspring (49). *Foxc2* is normally expressed in the metanephric mesenchyme and is thought to be involved in guiding outgrowth of the ureteric bud (49). The gross abnormalities were often unilateral (70 to 85% of offspring) and were highly dependent on the genetic background of the mice (49). To date, single gene mutations causing VUR and renal hypoplasia/dysplasia have not been identified in humans, but putative VUR loci have been reported (50).

RENAL HYPOPLASIA/DYSPLASIA AND FETAL URINARY TRACT OBSTRUCTION

Numerous observations indicate that antenatal obstruction of the urinary tract (UTO) may be associated with disturbances of normal nephrogenesis. Most commonly, renal hypoplasia/dysplasia is reported in males with posterior urethral valves but is also evident in other UTO settings such as prune-belly syndrome and urethral atresia (51–53) (Fig. 5.3). Dysplastic areas containing cysts, fibrotic interstitial zones, and even islands of cartilage may be scattered amid fairly normal-appearing renal tubules. In fetal monkeys, obstruction produced by injection of agaral beads into the collecting system at mid-gestation causes progressive diminution in renal size associated with evidence of apoptosis (particularly of collecting duct and glomerular cells), cysts with pericyclic fibrotic collars, and a defect in branching of the ureteric bud (54). Thus, although the molecular mechanisms are not yet

FIGURE 5.3. A: Renal dysplasia: peritubular fibrous cuff. B: Renal dysplasia: island of cartilage amid dysplastic tissue represents aberrant cell fate of metanephric mesenchyme.

well understood, fetal UTO appears to modify survival of selected cell lineages and affect signals regulating developmental cell fates. Timing of the fetal obstruction may be important; very early (50 days' gestation) obstruction of the urinary tract in lambs causes severe hypoplasia and interstitial fibrosis, whereas obstruction at 60 days results in a larger, cystic kidney with less fibrosis (55). In humans, striking obstruction has sometimes been reported in association with normal renal histology, prompting the speculation that UTO late in fetal life may have less effect on determinants of developmental cell fate (56).

As in other forms of renal hypoplasia/dysplasia, the risk of progressive renal insufficiency due to congenital UTO is highly influenced by the number of functioning nephrons at birth. The likelihood of developing end-stage renal disease ranges from 22 to 70% in various studies of boys with posterior urethral valves. A key predictor of long-term outcome is serum creatinine level 1 year after relief of obstruction (53,57). In 29 patients with prune-belly syndrome (deficient abdominal musculature, evidence of UTO, and cryptorchidism), approximately one-third die in the perinatal period from Potter syndrome, and most survivors develop end-stage renal disease (58,59).

SYNDROMIC RENAL HYPOPLASIA/DYSPLASIA

Renal dysplasia is associated with many different recognizable patterns of malformation, presumably involving genes or developmental pathways shared by multiple organs. Although a more complete list appears in Chapter 6, several syndromes of interest are mentioned briefly here. Mutations in the hepatocyte nuclear factor-1 β gene (TCF2) are responsible for an autosomal dominant syndrome characterized by maturity-onset diabetes of the young, nondiabetic progressive nephropathy, genital malformations, and liver dysfunction (60). The hepatocyte nuclear factor-1 β gene is normally expressed in the wolffian duct, metanephric tubules, and mullerian duct during fetal life; its absence results in a form of cystic renal dysplasia in which glomerular number is significantly reduced (61,62). Early-onset progressive nephropathy may be seen without evidence of diabetes mellitus in some cases, and renal dysplasia is quite variable, producing unilateral renal hypoplasia with cystic dysplasia in the contralateral kidney (62).

Renal dysplasia is also part of the autosomal dominant HDR syndrome (hypoparathyroidism, deafness, and renal anomalies) caused by mutations of another transcription factor gene, GATA3 (63) and is part of the Bardet-Biedl syndrome caused by mutations at six different loci, including the MKKS gene (64). Other monogenic syndromes with renal dysplasia include Townes-Brock syndrome (SALL1 gene) (65) and nail-patella syndrome (LMX1B gene) (66).

Variable degrees of renal dysplasia have been described in numerous syndromes for which the etiology is unknown. The causes of the VATER syndrome (*vertebral defects, anal atresia, trachio-esophageal fistula, and renal dysplasia*) are thought to be heterogeneous but presumably identify a common developmental pathway in these tissues (67). In the VACTERL syndrome (with additional limb and cardiac defects), the majority of patients have renal dysplasia, which may be associated with vesicoureteral reflux (39%), unilateral aplasia (23%), or unilateral multicystic dysplasia (7%) (68). Similarly, renal dysplasia may be seen in association with developmental defects of the pancreas and liver (Ivemark syndrome) (69), jejunal atresia (70), and encephalocele (Meckel syndrome) (71), and with pancreatic fibrosis, liver dysgenesis, and *situs inversus* (72). In Perlman syndrome, renal dysplasia and Wilms' tumor are associated with fetal gigantism and multiple congenital anomalies (73,74).

MULTICYSTIC/DYSPLASTIC KIDNEY

Classically, MCKDs have been identified as unilateral multiloculated abdominal masses with thin-walled cysts that do not appear to connect (Fig. 5.4), distinguishing them from hydronephrotic kidneys. Nuclear scans often show no functional parenchyma, and ureters are usually atretic, indicat-

FIGURE 5.4. Nonfunctional multicystic/dysplastic right kidney and grossly normal-appearing left kidney from an infant who died in the perinatal period of nonrenal causes.

ing little or no urine formation from early fetal life. The cystic mass usually lacks a reniform shape; scanty tissue between cysts is hyperechoic, and there is usually no detectable renal artery by Doppler ultrasonography. Microscopic analysis reveals disorganized renal architecture with islands of undifferentiated mesenchymal cells, occasional bizarre differentiation (e.g., cartilage), and few if any normal-appearing nephrons. Cysts are often rimmed by collars of fibromuscular cells. The incidence of unilateral MCKD is approximately 1 in 4000 live births (75). Rarely, bilateral MCKD has been reported and is fatal in the newborn period (76).

More recently, antenatal detection and long-term follow-up studies of unresected MCKDs have suggested that the pathogenesis and prognosis for this entity are more complex than was initially appreciated. In approximately 15% of unilateral cases, postnatal nuclear scans show some minimal functional renal tissue amid the dysplastic areas, so complete absence of renal function is no longer the *sine qua non* (77). Numerous cases of localized (restricted to one pole) cystic dysplasia have been reported (78,79). More important, the contralateral kidney often (20 to 30% of cases) exhibits some form of limited dysplasia (80–83). Approximately one-fourth of contralateral kidneys exhibit VUR, and this may be associated with recurrent urinary tract infections and progressive renal insufficiency (84). Careful evaluation of contralateral renal growth by serial postnatal ultrasonography, DMSA nuclear scans to detect foci of dysfunctional parenchyma, and voiding cystourethrography to identify contralateral VUR may be considered to identify cases with significant contralateral dysplasia (85).

Because experimental obstruction may produce cystic dysplasia, it has been proposed that first-trimester UTO might account for MCKD (75,86). However, the putative obstruction would have to be intrarenal as MCKD ureters are atretic, and lower tract obstruction could not explain cases of localized dysplasia. Furthermore, there are reports

of autosomal dominant MCKD and chromosomal anomalies (87,88), suggesting that failure of key genes can lead to MCKD by perturbing the normal pattern of nephrogenesis. A high incidence of subtle genital and other nonrenal abnormalities suggests aberrations in shared developmental programs rather than UTO as the primary etiology (81,82).

On occasion, unilateral MCKD has been associated with hypertension; in some cases, hypertension resolves when the dysplastic tissue is resected (89). Ectopic renin gene expression has been documented in macrophage-like interstitial cells (90). Although hypertension is not commonly identified in children with unilateral MCKD (less than 5%), its prevalence may be underestimated. Subtle abnormalities of blood pressure were found in 5 of 25 such children when studied by ambulatory blood pressure monitoring (91).

It has long been appreciated that MCKDs may undergo complete or partial involution, but the significance of this observation is not yet clear (92). Involution of MCKD tissue has been observed during fetal life, and 20 to 25% of MCKDs involute completely in the first 1 to 2 years of postnatal life (93–95). When involution does not occur, the specter of rare malignant transformation is raised. Multiple cases of Wilms' tumor (approximately three- to tenfold increased incidence over the normal population) (96,97) and renal cell carcinoma (98–101) arising from within the cystic tissue have been reported. On the other hand, because Wilms' tumors grow rapidly, effective ultrasound screening would have to be done approximately every 3 months for 8 years (102); renal carcinomas may arise in adulthood. Several recent reports advise conservative management, and routine early excision of MCKDs has become much less common than in the past (102,103). However, the approach to MCKD tissue that does not involute is still made on an individual basis after discussion with the family.

ABNORMALITIES OF KIDNEY POSITION AND PATTERNING

Variations in the gross architecture of the kidney are fairly common. Nearly 1% of patients undergoing ultrasonography are found to have duplex kidneys; of these, 80% have ureteral duplication as well (104). However, there is no evidence that isolated duplication of the collecting system is associated with morbidity. Rarely, ectopic kidneys have been reported in the thorax, but these are usually nonfunctional and are identified when an unidentified chest mass is spotted incidentally (105).

Horseshoe kidneys represent the most common renal fusion abnormality and occur in every 400 to 800 individuals (106). They are unusually common (30%) in Turner syndrome (107). Horseshoe kidneys are usually detected by ultrasonography, but other imaging modalities are required to identify the anomaly in approximately one-third of cases. In one series, vesicoureteral reflux was noted in 32%

and uretero-pelvic junction obstruction in 23% (108). The risk of Wilms' tumor is slightly increased in children with horseshoe kidney, and there are more than 40 reports of this association in the literature (109). However, regular screening for this complication is probably unwarranted. Although 0.5% of Wilms' tumors arise within a horseshoe kidney, this is only approximately three times the expected incidence. The arterial supply to the horseshoe kidney is highly variable, presenting a special technical challenge for transplantation. Nevertheless, horseshoe kidneys can be transplanted into recipients *en bloc* or after division of the isthmus, and the success rate is equivalent to normal cadaveric transplantation with either approach (106).

SYNDROMES AND MALFORMATIONS OF THE URINARY TRACT

**CHANIN LIMWONGSE
SUZANNE B. CASSIDY**

Birth defects involving the kidney and urinary system are common and often occur in association with other structural abnormalities. A congenital urinary tract anomaly may provide the first clue to the recognition of multiorgan developmental abnormalities. Nevertheless, many renal anomalies remain asymptomatic and undiagnosed.

Although the number of single malformations involving the kidney and urinary system is limited, combinations of such malformations with anomalies involving other organ systems are found in more than 500 syndromes. In addition, many well-known sequences and associations involve the kidney and urinary tract. This chapter discusses common malformations, sequences, and associations involving the kidney and urinary tract and provides a summary of conditions that have these anomalies as one of their features. In addition, Tables 6.1 through 6.3 summarize more detailed information about a large number of disorders associated with urinary tract anomalies. These tables can be used to (a) provide readily available information about potential urinary tract anomalies in patients with a diagnosed genetic syndrome and (b) develop a differential diagnosis when specific anomalies are identified. Readers interested in additional details about a specific syndrome are referred to standard reference textbooks and databases for further reading (4–7).

To understand the pathophysiologic basis of structural abnormalities, it is important to define certain terms used in describing malformations and syndromes.

Malformation refers to a single structural anomaly that arises from an error in organogenesis. Such an error may be due to the failure of cells or tissues to form, to regress (programmed cell death), or to induce others' anlagen. Examples include renal agenesis, horseshoe kidney, and bladder exstrophy.

Deformation refers to a single structural anomaly that arises from mechanical forces (e.g., intrauterine constraint). Examples include metatarsus adductus, torticollis, and congenital scoliosis. The underlying tissue may be normal or

abnormal, and sometimes a malformation (e.g., renal agenesis) can predispose patients to a deformation (e.g., Potter's sequence from oligohydramnios).

Disruption refers to a single structural anomaly that results from a destructive event after normal morphogenesis. Such events can be caused by lack of vascular supply, infectious process, or mechanical factors. Examples include limb amputation from amniotic bands and abdominal wall defects from vascular insufficiency related to maternal cocaine use.

Sequence refers to a cascade of abnormalities that results from a single initiating anomaly. Sequences can be malformational, deformational, or disruptive, and they sometimes represent more than one of these categories. Obstruction of urine flow at the level of the ureter during early gestation, for example, can cause malformation of the kidneys, intestines, and abdominal wall—a malformation sequence. At the same time, decreased urine flow produces oligohydramnios, fetal compression, and multiple deformities of the face, limbs, and chest wall—a deformation sequence.

Syndrome refers to a consistently observed pattern of multiorgan anomalies consisting of malformations, deformations, or disruptions. Examples include Turner syndrome and fetal alcohol syndrome.

Association refers to a constellation of anomalies that occur together more often than expected by chance alone but cannot be explained by a single cause or sequence of events. Vertebral, anus, tracheoesophageal, radial, and renal (VATER) association, which is discussed later in this chapter, is a common example.

PREVALENCE OF URINARY TRACT ANOMALIES

The true incidence of urinary tract anomalies is difficult to ascertain because they are asymptomatic and, therefore, remain undetected. The reported incidence of many anoma-

TABLE 6.1. SYNDROMES AND DISORDERS THAT HAVE URINARY TRACT ANOMALIES AS A FREQUENT FEATURE

Syndromes	Urinary tract abnormalities										Other associated anomalies	Inheritance pattern	Reference	
	Renal agenesis	Ectopia/horseshoe	Cystic/dysplasia	Duplication	Hypoplasia	Hydronephrosis/ureter	Diverticulae	Atresia/stenosis	Reflux	Nephritis/sclerosis				Tumor/nephromegaly
Abruzzo-Erickson		H										Coloboma, cleft palate, hypospadias, deafness, short stature	Uncertain	44
Acrocephalopolydactylous dysplasia (Elejalde syndrome)			+		+	+						Acrodactyly, hand hexadactyly, overgrowth, visceromegaly, globular body, redundant neck skin	AR	45
Acrorenal (Dieker)	1	E		+	+		Ua					Ectrodactyly, oligodactyly, hypoplastic carpal/tarsal bones	Sporadic	46
Acrorenal (Johnson-Munson)	1, 2						U, Ua					Aphalangy, hemivertebrae, genital/intestinal/anal dysgenesis	AR	46
Acrorenal (Siegler)		E				+		U	+			Short stature, hypoplastic radii/ulnae/humeri, oligodactyly	Uncertain	46
Acro-renal-mandibular	1		+									Ectrodactyly, hypoplastic mandible	AR	47
Acro-renal-ocular	1	E			+		B					Hypoplastic thumb, optic coloboma, cleft lip/palate	AD	48
Adrenoleukodystrophy, neonatal												See Pseudo-Zellweger		
Aglossia-adactylia	1											Micrognathia, cranial nerve palsy	Sporadic	49
Agnathia-holoprosencephaly		H				+						Arrhinencephaly, situs inversus, midline defects	Sporadic	50
Alagille	1		+	+						+		Cholestasis, peripheral pulmonic stenosis, characteristic face	AD	51
Alport										+		Nephritis, proteinuria, deafness	AD, X-linked	52
Alsing										+		Nephritis, nephronophthisis, optic coloboma, hip dislocation	AR	53
Alstrom										+		Diabetes mellitus, retinopathy, short stature, deafness	AR	54
Amelogenesis imperfecta										+		Enamel hypoplasia, nephrolithiasis, enuresis	AR	55
Amyloidosis type 5										+		Nephropathy, proteinuria, cranial nerve palsy, cutis laxa	AD	56
Angiotensin converting enzyme inhibitor, maternal use										+		IUGR, oligohydramnios, patent ductus arteriosus, limb anomalies, renal artery stenosis, progressive renal failure	Sporadic	57
Aniridia-Wilms' tumor											+	Aniridia, ambiguous genitalia, hypospadias, short stature	AD	58

Axial mesoderma dysplasia	1								Bladder exstrophy, vertebral anomalies, Goldenhar-like	Uncertain	59
Baldellou	1								Hypoparathyroidism, ocular coloboma, MR, seizures	Uncertain	60
Baller-Gerold	+	E	+	+					Craniostenosis, radial aplasia, malformed ear, anal atresia	AR	61
Barakat									Mesangial sclerosis, MR, optic atrophy, nystagmus	AR	62
Bardet-Biedl			+	+	+				Obesity, polysyndactyly, MR, retinopathy, hypogonadism	AR	63,64
Beckwith-Wiedemann		E	+	+	+			+	Overgrowth, macroglossia, omphalocele, embryonal tumors	Sporadic, AD	65-68
Berardinelli								+	Insulin resistance, lipodystrophy, acanthosis nigricans, MR	AR	69
Brachymesomelia-renal			+						Micrognathia, corneal opacity, craniofacial dysmorphism	Uncertain	70
Braddock-Carey			+						Robin sequence, thrombocytopenia, ACC	Uncertain	71
Branchio-oculo-facial	1								Philtrum hypertrophy, cleft lip/palate, branchial remnant	AD	72
Branchio-oto-renal	1, 2	E	+	+	+				Branchial remnant, preauricular pit/tag, microtia, deafness	AD	73
Branchio-oto-ureteral									Branchial remnant, preauricular pit/tag, microtia, deafness	AD	74
Braun-Bayer								U	Deafness, bifid uvula, digital anomalies	Uncertain	75
Cat eye									See Table 6.3	Chromosomal	
Caudal duplication	1, 2	E	+	+	+				Duplication of colon, sacrum, genitalia, vertebral defects	Sporadic	76
Caudal regression	1, 2	E, H	+	+	Ua				Atresia of colon, anus, genitalia, vertebral defects, transesophageal fistula	Sporadic, AR	77,78
Cerebro-hepato-renal (Pas-sarge)									Hypotonia, abnormal ear, hepatomegaly, hypospadias	AR	79
Cerebro-oculo-hepato-renal			+						Cerebellar hypoplasia, hepatic fibrosis, Leber amaurosis	AR	80
Cerebro-osteo-nephro-dysplasia			+					+	Rhizomelic limb shortening, cerebral atrophy, MR, seizures	AR	81
CHARGE association	+	E	+	+	+			U	See text for details		30-33
Chondroectodermal dysplasia (Ellis van Creveld)	1		+	+	+				Acromelic dwarfism, polydactyly, nail dystrophy, tooth hypoplasia narrow thorax, CHD	AR	82,83
Cocaine, maternal use	1, 2							Ua	Vascular disruption anomalies affecting multiple organs	Sporadic	84
Cornelia de Lange	1		+	+	+				SS, microcephaly, limb defect, hirsutism, synophrys	Uncertain	87
Crossed renal ectopia-pelvic lipomatosis		E						U	Clubbing of fingers, gynecomastia	Uncertain	85
Czeizel								U	Electroductyly, spina bifida, megacystis	AD	86

CHARGE, coloboma, heart disease, atresia choanae, retarded growth and development, genital hypoplasia, and ear anomalies; MURCS, müllerian, renal, cervicothoracic somite abnormalities; VATER, vertebral, anus, tracheoesophageal, radial, and renal.

^aRates include 39 other syndromes with related anomalies.

^bRates include 34 other syndromes with related anomalies.

lies reflects ascertainment bias because data are often derived from symptomatic individuals. Reliable data have been reported from several birth defects registries. In the United States, these include the Metropolitan Atlanta Congenital Defects Program, California Birth Defects Monitoring Program, and the Washington State Birth Defects Registry (1,2). Table 6.4 summarizes prevalence data for a number of distinct urinary anomalies reported from these registries.

When adjusted for race, sex, and maternal age, the prevalence of renal agenesis, cystic kidney, exstrophy of the bladder, and obstruction of the bladder or urethra do not show differences between geographic areas (1). In contrast, there appears to be a higher prevalence of obstruction of the kidney or ureter in California and Washington compared with Atlanta. It has been suggested that these differences are due to ascertainment bias; however, differences in prenatal teratogenic exposures (e.g., alcohol and cocaine) and differences in the genetic background of individuals in these geographic areas cannot be discounted. Overall, renal anomalies are found in approximately 3 to 6 per 1000 births (1,3). Genitourinary anomalies are responsible for approximately 6.8% of infant deaths in the United States (March of Dimes Perinatal Data Center 2002; <http://www.marchofdimes.com/aboutus/1523.asp/>).

APPROACH TO THE CHILD WITH A URINARY TRACT ANOMALY

The clinical approach to the child with a urinary tract anomaly is similar to that for other birth defects. The initial step is to establish a specific diagnosis if possible based on history, physical examination, and laboratory investigation. A thorough family history for both urinary tract anomalies

and for any other type of congenital or developmental anomalies must be obtained. Many genetic disorders have variable expression even within the same family. A careful physical examination looking specifically for major and minor anomalies should be performed. Sometimes, a pattern of multiple anomalies can be recognized immediately as a well-described syndrome. Patterns of anomalies that cannot be recognized may require a literature or database search or referral to an expert in syndrome recognition. The search for a specific diagnosis is optimally accomplished by identifying the least common and most distinctive anomalies, thereby limiting the list of possible differential diagnoses. To aid in this effort, refer to Tables 6.1 through 6.3 in addition to tables listing the differential diagnosis that accompanies the description of each of the major urinary tract anomalies below (see Tables 6.5 through 6.15). For example, it is preferable to search for syndromes with urethral agenesis (22 syndromes) rather than renal dysplasia (more than 80 syndromes) when the two anomalies coexist. A search based on the more common anomalies can be performed if the first search does not reveal a match. Even after careful evaluation, a substantial number of children with multiple congenital anomalies remain undiagnosed.

A chromosome analysis is indicated in any child who has at least two major congenital anomalies or one isolated anomaly that is particularly associated with a defined chromosomal abnormality [e.g., aniridia (microdeletion 11p)]. Growth or developmental delay, dysmorphic features, or lack of familial resemblance should also prompt a chromosomal analysis. Chromosome abnormalities are found in approximately 10 to 12% of all renal anomalies (3,8). Table 6.3 lists common and distinct chromosomal disorders with their reported urinary tract anomalies.

For a child with no known urinary tract anomaly, findings that should prompt an evaluation of the urinary tract

include oligohydramnios, undefined abdominal mass, abnormal genitalia, aniridia, hypertension, preauricular pits or tags, branchial cleft cyst or sinus, imperforate anus, symptoms indicative of renal dysfunction, urinary tract infection, or obstructive uropathy (3). For patients with known syndromes, the types of associated urinary tract anomalies are listed in Tables 6.1 and 6.2.

Ultrasonography is recommended in screening for urinary tract anomalies. It is noninvasive and provides excellent anatomic information. It is also the only method routinely used for the prenatal diagnosis of urinary tract anomalies. Additional radiographic studies and specialized genetic testing may then follow as part of a staged diagnostic evaluation. Corrective or reparative treatments are available for many anomalies (stenosis or atresia, bladder exstrophy, duplication, diverticula, and tumors).

Once a child with a urinary tract anomaly is identified, a search for related anomalies in first-degree relatives is indicated only when the proband has renal agenesis (9). Otherwise, the decision to investigate family members should be based on a thorough family history and whether the identified anomaly is part of a well-described inherited syndrome. Genetic counseling should be provided to the family, and reproductive options should be discussed in a nondirective fashion. For an isolated anomaly without a family history of similar or related anomalies, an empiric risk can be provided. Accurate risk figures can be determined for mendelian disorders, and estimated risks are available for associations.

All children with congenital anomalies need long-term follow-up. This is especially the case for children with undiagnosed multiple congenital anomalies, for whom follow-up examination may lead to a specific diagnosis. Additional relevant family information should be specifically sought for any newly affected member. Finally, for patients with a urinary tract anomaly who reach reproductive age, the recurrence risk for their offspring and reproductive options should be discussed.

DEVELOPMENT OF THE URINARY TRACT

Renal organogenesis is reviewed in Chapter 1. Embryogenesis of the lower urinary tract includes development of the mesonephric duct and urogenital sinus. The mesonephric duct inserts into the lower allantois, just above the terminal part of the hindgut, the cloaca. During the fourth to seventh weeks, mesoderm proliferates and forms the transverse mesodermal ridge, the urorectal septum. The urorectal septum divides the cloaca into the anterior portion (the primitive urogenital sinus) and the posterior portion (the cloacal sinus or anorectal canal). The mesonephric ducts open into the urogenital sinus and later become the ureters. The urorectal septum develops caudally and fuses with the cloacal membrane, dividing it into the urogenital membrane

(anterior) and the anorectal membrane (posterior) by the end of the seventh week. The primitive perineal body forms at the site of fusion.

The primitive urogenital sinus develops primarily into the urinary bladder. The superior portion, originally continuous with the allantois, later becomes a solid fibrous cord (the urachus or median umbilical ligament), which connects the bladder to the umbilicus. The inferior portion of the urogenital sinus in the male divides into a pelvic portion, containing the prostatic and membranous urethra, and the long phallic portion, containing the penile urethra. The inferior portion in the female forms a small portion of the urethra and the vestibule. At the same time, the distal portion of the mesonephric ducts is incorporated into the endodermal vesicoureteral primordium, forming the trigone of the bladder. A part of the distal end of both mesonephric ducts just proximal to the trigone develops into the seminal vesicles and ductus deferens in the male. Finally, at the end of the twelfth week, the epithelium of the superior portion of the prostatic urethra proliferates to form buds that penetrate the surrounding mesenchyme. In the male, these buds form the prostate gland; in the female, they form the urethral and paraurethral glands.

URINARY TRACT ANOMALIES

Kidney Defects

Renal Agenesis

Renal agenesis refers to complete absence of one or both kidneys without identifiable rudimentary tissue. Renal agenesis is usually associated with agenesis of the ipsilateral ureter. The pathogenesis of renal agenesis is failure of formation of the metanephros. Causal heterogeneity has been shown, both by animal studies and by human observations (10–12), including failure of ureteric bud formation, failure of the bud to reach the metanephric blastema, or failure of the bud and the metanephric blastema, to create mutual inductive influence on one another (see Chapter 1). In addition, interruption in vascular supply and regression of a multicystic kidney can lead to renal agenesis in the fetal period (11).

Unilateral renal agenesis is usually asymptomatic and detected incidentally, whereas bilateral renal agenesis results in severe oligohydramnios and fetal or perinatal loss. Several studies have demonstrated that unilateral renal agenesis is associated with an increased frequency of anomalies in the contralateral kidney (9,13). Renal agenesis is often associated with anomalies of other organ systems. These anomalies can occur both in contiguous structures (e.g., vertebrae, genital organs, intestines, and anus) and in noncontiguous structures (e.g., limbs, heart, trachea, ear, and central nervous system). The diagnosis of renal agenesis is made by abdominal ultrasound. Care must be taken to

LEOPARD, lentiginos, electrocardiographic abnormality, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and deafness; VACTERL, vertebral, anal, cardiac, tracheal, esophageal, renal, limb; VATER, vertebral, anus, tracheoesophageal, radial, and renal.

exclude the possibility of ectopic kidney. Intravenous pyelography, computed tomography, and radionuclide studies can be helpful in equivocal cases.

The recurrence risk for renal agenesis can be estimated if the pattern of inheritance is known or if the proband has a recognizable syndrome. For nonsyndromic renal agenesis,

CHARGE, coloboma, heart disease, atresia choanae, retarded growth and development, genital hypoplasia, and ear anomalies.

an empiric risk of 3% can be used for families in which renal anomalies in first-degree relatives (siblings, parents) have been excluded (3). First-degree relatives of patients with nonsyndromic renal agenesis have an increased prevalence of related urogenital anomalies. In one study, 9.0% of first-degree relatives of infants with agenesis or dysgenesis of both kidneys had a related urogenital anomaly, and 4.4% had an asymptomatic renal malformation (13). Therefore, renal sonography is recommended for the first-degree relatives of the proband, unless renal agenesis in the proband is clearly sporadic or a specific cause without an increased recurrence risk is identified.

Tables 6.5 and 6.6 list the syndromes commonly associated with unilateral and bilateral renal agenesis, respectively. For more information about these disorders and other less common conditions with renal agenesis, see Tables 6.1 through 6.3.

Ectopic Kidney

Ectopic kidneys result from an error(s) of ascent. Most are pelvic kidneys that fail to ascend out of the pelvic cavity. Rare case reports of thoracic kidneys exist (14). Ectopic kidneys can be unilateral or bilateral. Bilateral pelvic kidneys often fuse into a midline mass of renal tissue, with two pelvises and a variable number of ureters, which is referred to as a *pancake* or *discoid kidney*. *Crossed renal ectopia* refers to an ectopic kidney whose ureter crosses the midline. Ectopic kidneys are usually hypoplastic and rotated and contain numerous small blood vessels and ureteric anomalies. Ectopic kidneys may be asymptomatic, but complications from ureteral obstruction, infection, and calculi are common. Table 6.7 provides a list of syndromes that include ectopic kidney, also described in Tables 6.1 through 6.3.

Horseshoe Kidney

Horseshoe kidney refers to a condition in which the kidneys are fused at the lower poles with a renal parenchymal or, less commonly, fibrous isthmus. The embryopathogenesis of horseshoe kidney with parenchymal isthmus is believed to be abnormal migration of nephrogenic cells across the primitive streak before the fifth gestational week. Horseshoe kidney with fibrous isthmus is believed to originate from fusion after the fifth week, before renal ascent (15). Most horseshoe kidneys are located in the pelvis or at the lower lumbar vertebral level, as ascent is further prevented when the fused kidney reaches the junction of the aorta and inferior mesenteric artery.

Complications of horseshoe kidneys include obstructive uropathy, calculi, and urinary tract infection. Horseshoe kidneys are associated with other genitourinary anomalies as well as renal tumors (16). Wilms' tumor is the most common, but renal cell carcinoma, adenocarcinoma, transitional cell carcinoma, malignant teratoma, oncocytoma, angiomyolipoma, and carcinoid have all been reported.

Table 6.8 lists syndromes associated with horseshoe kidney. For more details of these disorders, see Tables 6.1 and 6.2.

Dysplasia and Polycystic Kidney

Renal dysplasia (17–19) and polycystic kidney disease are extensively covered in Chapters 5 and 36, respectively. Table 6.9 summarizes well-known syndromes with renal dysplasia/cystic kidney. (See Tables 6.1 through 6.3.)

Obstruction and Hydronephrosis

Urinary obstruction is a complication of a primary anomaly, which can be stenosis or atresia of the ureteropelvic junction, ureter, or urethra; a poorly functional bladder causing stasis or reflux; a malformed dilated ureteral end (ureterocele); or extrinsic compression by other structures (e.g., anomalous blood vessels or tumors). Hydronephrosis and pelvocaliectasis are the most common urinary tract abnormalities detected by prenatal ultrasound examination (20). (See Chapter 4.)

Table 6.10 provides a list of syndromes commonly associated with obstruction and hydronephrosis. (See Tables 6.1 through 6.3.)

Ureter Defects

Duplication

Double ureters or collecting systems are caused by duplication of the ureteric bud. Early duplication results in a duplicated kidney, which is usually smaller and fused with

the ipsilateral kidney and has ureters that enter into the bladder separately. Duplication that occurs later results in double ureters that may have separate openings into the bladder. On rare occasions, one of the ureters may have an ectopic opening into the vagina, vestibule, or urethra. Most double ureters are crossed, and the ureter from the higher pelvis enters the bladder more caudally. Duplication anomalies are common but usually asymptomatic; therefore, they often remain undetected. One autopsy study reported the prevalence of duplication anomalies to be as high as 1 in 25, with females approximately four times more likely to be affected than males (21). Unilateral duplication is five to six times more common than bilateral duplication (3). Double ureters are commonly associated with vesicoureteral reflux due to their ectopic opening into the urinary bladder or the ureterocele (22). In addition, ureteric obstruction can occur at the level of the vesicoureteric junction or that of the ureteropelvic junction.

Table 6.11 summarizes syndromes associated with duplication, and Tables 6.1 through 6.3 provide clinical information about these disorders.

Hydroureter

Hydroureter, or megaloureter, is caused by distal obstruction and is usually found with hydronephrosis, except in ureteropelvic junction obstruction. Hydroureter has the same etiology as hydronephrosis (see Obstruction and Hydronephrosis).

Bladder Defects

Anomalies of the bladder are rare. These include agenesis, hypoplasia, diverticulae, and dilatation or megacystis caused by distal obstruction or by nonobstructive causes. Agenesis of the bladder is usually associated with severe developmental anomalies of the urinary tract, such as in sirenomelia and caudal regression syndrome. Hypoplastic bladder can be found in conditions associated with bilateral renal agenesis because no urine is produced. Bladder diverticulae have heterogeneous causes. They may result from an intrinsic defect in the bladder wall (e.g., in cutis laxa or Ehlers-Danlos, Ochoa, occipital horn, and Williams syndromes). They can also be caused by increased intravesicular pressure from distal obstruction or by persistent urachus. For information about specific syndromes associated with bladder diverticulae, see Tables 6.1 through 6.3.

OEIS, omphalocele-cloacal exstrophy-imperforate anus-spinal dysraphism.

Bladder exstrophy refers to a urinary bladder that is open anteriorly because of the lack of abdominal wall closure. It is usually associated with anomalies of the contiguous structures including epispadias and separation of the pubic rami. Exstrophy is believed to result from an overdeveloped cloacal membrane that interferes with inferolateral abdominal mesenchymal closure. Therefore, when the cloacal membrane ruptures, the inferior abdominal wall has not completely closed and the bladder cavity is exposed. It has been suggested that bladder exstrophy belongs to the spectrum of omphalocele-cloacal exstrophy-imperforate anus-spinal dysraphism complex (23,24). The extent of anomalies is determined by the timing of the cloacal membrane rupture. Rupture that occurs after the separation of cloaca by the urorectal septum results in bladder exstrophy, whereas one that occurs before the separation results in the more severe cloacal exstrophy and omphalocele-cloacal exstrophy-imperforate anus-spinal dysraphism complex. Bladder exstrophy is six times more common in males.

Table 6.12 lists syndromes associated with bladder exstrophy, and Tables 6.1 through 6.3 provide information about these disorders.

Urethral Defects

Agenesis and Atresia

Urethral agenesis is rare. It predominantly occurs in males, reflecting the complex embryogenesis of the male urethra. Urethral agenesis is often associated with the bladder obstruction sequence. Table 6.13 lists syndromes associated with urethral agenesis, and clinical information about these disorders is summarized in Tables 6.1 through 6.3.

Duplication

Duplication refers to complete or partial duplication of the urethra, which is a rare anomaly, found only in a few syn-

dromes. Those syndromes associated with urethral duplication are listed in Table 6.14, and their findings are provided in Tables 6.1 through 6.3.

Posterior Urethral Valves

Posterior urethral valves refer to abnormal mucosal folds that obstruct urine flow. Posterior urethral valves can be suspected prenatally when a dilated bladder is seen in association with obstructive uropathy. Recently, the “keyhole sign” has been demonstrated by prenatal ultrasonography in fetuses with subsequently confirmed posterior urethral valves (25). A voiding cystourethrogram or endoscopy is usually required for a definitive diagnosis. The embryogenesis of posterior urethral valves is unknown. Proposed hypotheses include an overdeveloped posterior urethral fold, a remnant of the mesonephric duct, and an anomalous opening of the ejaculatory duct. Table 6.15 lists syndromes in which posterior urethral valves can be seen, and the other findings in these disorders are provided in Tables 6.1 through 6.3.

VATER (VACTERL) association

OEIS, omphalocele-cloacal exstrophy-imperforate anus-spinal dysraphism; VACTERL, vertebral, anal, cardiac, tracheal, esophageal, renal, limb; VATER, vertebral, anus, tracheoesophageal, radial, and renal.

ASSOCIATIONS AND SEQUENCES INVOLVING THE URINARY TRACT

A number of associations and sequences involve anomalies of the urinary tract that are important for both diagnosis and clinical management. For this reason, such conditions are described in more detail in this section in addition to the information presented in Tables 6.1 and 6.2.

Association of Vertebral, Anus, Tracheoesophageal, Radial, and Renal Anomalies

VATER is an acronym used to designate a nonrandom occurrence of vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal anomalies (26,27). *VACTERL* (vertebral, anal, cardiac, tracheal, esophageal, renal, limb), another acronym, has been proposed to broaden the spectrum of *VATER* to include cardiac defects and limb anomalies. The term *VATER* is not a diagnosis per se, but the designation provides clues for potentially associated anomalies and for recurrence risk counseling when no specific syndromic diagnosis can be made. Causes of *VATER* association include chromosomal disorders (e.g., trisomy 18), genetic syndromes (e.g., Goldenhar and Holt-Oram syndromes), and teratogenic exposures (e.g., infants of diabetic mothers and fetal alcohol syndrome). Recently, a family with a mitochondrial DNA mutation was identified in which the daughter was born with *VACTERL* association, and her mother and sister had classic mitochondrial cytopathy (28). Thus, all patients suspected to have *VATER* association should have a chromosome analysis, a careful family and prenatal exposure history, and a thorough examination for dysmorphic features. The spectrum of anomalies

seen in VATER is broad. Associated renal anomalies are usually agenesis, ectopy, or obstruction (26,27).

Because there is apparent causal heterogeneity for VATER association, the inheritance pattern and recurrence risk vary with the cause. VATER association is usually sporadic, with an empirical recurrence risk of 1 to 3% when a specific cause cannot be identified (29). Autosomal recessive and X-linked inheritance have been reported for subsets of patients (e.g., for VATER with hydrocephalus), in which recurrence risk can be as high as 25% (28).

Association of Coloboma, Heart Disease, Atresia Choanae, Retarded Growth and Development, Genital Hypoplasia, and Ear Anomalies

CHARGE is an acronym used to designate an association of coloboma of iris, choroid or retina, heart defects, atresia choanae, retarded growth and development, genital anomalies or hypogonadism, and ear anomalies or deafness (30–33). In addition, unilateral facial palsy is a common finding. Renal anomalies found in *CHARGE* association include ectopy, dysplasia, renal agenesis, and ureteric anomalies. The presence of two or more anomalies associated with *CHARGE* association should prompt a search for the others. To prevent overuse of the term, it was suggested that at least three anomalies are required for the term *CHARGE* to be applied, and one of the anomalies should be either coloboma or choanal atresia (31). *CHARGE* association has phenotypic overlap with VATER association. Similar to VATER, a specific cause should be sought, although familial forms of *CHARGE* have been reported more often than for VATER, with recessive, dominant, and X-linked inheritance patterns identified. Conditions with anomalies in the spectrum of *CHARGE* include trisomy 13, trisomy 18, Wolf-Hirschhorn (deletion 4p), cat-eye, Treacher-Collins, velocardiofacial, Apert, Crouzon, and Saethre-Chotzen syndromes. Therefore, a careful physical examination for malformations and dysmorphic features should be conducted, and chromosome analysis including specific fluorescence *in situ* hybridization probes for velocardiofacial syndrome (deletion 22q) and 4p deletion should be performed. Because most cases of *CHARGE* association are sporadic, the empirical recurrence risk is low (30,33). In familial forms of *CHARGE* association, the recurrence risk is substantially higher and can be as much as 25%.

Association of Müllerian, Renal, Cervicothoracic Somite Abnormalities

MURCS refers to the rare association of müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia (34). Anomalies include absence of the proximal two-thirds of the vagina, uterine hypoplasia or aplasia, unilateral renal agenesis, ectopic kidney, renal dysplasia, C5-T1 vertebral anomalies (hypoplasia of vertebrae, fusion, hemivertebrae,

and butterfly vertebrae), and short stature. Additional anomalies are common, including rib defects, facial asymmetry, limb anomalies, hearing loss, and brain anomalies (e.g., encephalocele and cerebellar cysts) (35).

The pathogenesis of *MURCS* association is unknown, but it is believed to be related to defects in the paraxial mesoderm, which gives rise to the cervicothoracic somites and the adjoining intermediate mesoderm. Most patients are diagnosed because of primary amenorrhea or infertility associated with normal secondary sexual characteristics, followed by recognition of reproductive organ atresia. *MURCS* association is usually sporadic. A report of vertebral and renal anomalies associated with azoospermia was proposed to represent the male version of *MURCS* association (36).

Oligohydramnios Sequence

Oligohydramnios of whatever cause leads to a recurrent pattern of abnormalities that has been called the *oligohydramnios sequence* (3,5). Oligohydramnios may be caused by decreased production of fetal urine from bilateral renal agenesis or dysplasia or by urinary obstruction, or it can result from amniotic fluid leakage. When oligohydramnios is prolonged and severe, the condition is lethal because of pulmonary hypoplasia. Moderate oligohydramnios from amniotic fluid leakage may result in a liveborn child with multiple congenital anomalies. These anomalies are both malformations and deformations. Intrauterine constraint leads to mechanical compression that leads to the characteristic flat facial profile (Potter's facies), limb deformities (e.g., talipes equinovarus), and intrauterine growth retardation. Decreased fetal movement as a result of intrauterine constraint causes multiple joint contractures (arthrogryposis). Breech presentation is common. Pulmonary hypoplasia can be the consequence of compression of the chest cavity coupled with decreased inspiration of amniotic fluid. Because the initial defect has many causes, recurrence risk is based on the underlying defect. When oligohydramnios is due to nonsyndromic bilateral renal agenesis or dysgenesis, related renal malformations occur at an increased frequency in first-degree relatives (13), and recurrence risk can be as high as 4 to 9%. The recurrence risk can be as high as 25% for an autosomal-recessive disorder causing bilateral renal agenesis or dysplasia.

Urethral Obstruction Sequence

The initial defect in this sequence is obstruction of the urethra leading to dilation of the proximal urinary tract, bladder distension, and hydroureter (3,5,37). Obstruction of urine flow interferes with normal nephrogenesis, resulting in renal dysplasia. Other potential anomalies related to bladder distension include cryptorchidism, malrotation of colon, persistent urachus, and limb deficiency caused by iliac vessel compression. In addition, oligohydramnios results from lack of urine and leads to the oligohydramnios sequence.

Prune-belly syndrome (37,38) is a rare entity referring to a constellation of anomalies that includes megacystis, abdominal wall muscle deficiency, hydroureter, renal dysplasia, and characteristic wrinkled abdominal skin. This condition, previously believed to be a form of urethral obstruction sequence, is, in fact, a nonobstructive cause of bladder distension that results from a malformation, thus now being properly designated a syndrome (25).

The most common cause of urethral obstruction is posterior urethral valves, but urethral agenesis/atresia or bladder neck obstruction can also be the cause. This anomaly occurs more often in males, with a male to female ratio of 20:1. Survival is rare in fetuses with complete obstruction, and severe urinary tract anomalies are always present in those who are liveborn. Prenatal diagnosis by ultrasound examination can detect the abnormally dilated bladder at the beginning of the second trimester (39), and intrauterine urinary decompression procedures, such as vesicoamniotic shunts, are options for treatment to decrease the occurrence of pulmonary hypoplasia, although their benefits have not been unequivocally shown (40,41). (See Chapter 4.)

Sirenomelia Sequence

Sirenomelia is a malformation characterized by the presence of a single lower extremity with posterior alignment of the knees and feet, sacral agenesis and other lower vertebral defects, imperforate anus and rectal agenesis, and absence of external and internal genitalia (42). The current view of the embryogenesis is that sirenomelia results from a vascular steal phenomenon (43). This is supported by the presence of abnormal vasculature in the caudal part of affected embryos. A single large vessel originating from the aorta, a derivative of the vitelline artery complex, connects the iliac arteries to the placenta rather than the two normal umbilical arteries. The area caudal to the origin of this vessel has minimal blood supply because of the lack of aortic branches. Therefore, a "vascular steal phenomenon" is generated, leading to a vascular disruption sequence.

Sirenomelia is a rare condition and has a broad spectrum of anomalies. Virtually any urinary tract anomaly can occur in sirenomelia sequence. Renal agenesis occurs in two-thirds of cases, and a variable degree of renal dysplasia is present in one-third of cases (3). Absence of the ureter and bladder are common. All cases of sirenomelia are sporadic and almost uniformly fatal because of pulmonary hypoplasia. Sirenomelia has been noted with an increased frequency among monozygotic twins in which only one of the twins is usually affected.

HOMEOSTASIS

SODIUM AND WATER

HOWARD TRACHTMAN

You may not discontinue the salt of your God's covenant from upon your meal offerings. . .

Leviticus 2:13

For the life of any creature—its blood represents its life. . .

Leviticus 17:14

This chapter reviews the physiologic mechanism involved in the control of sodium and water homeostasis. Using this knowledge as a basis, the common diseases that arise when these systems malfunction are analyzed, and a discussion of the optimal therapy for these conditions is presented.

BODY FLUID COMPARTMENTS AND THEIR COMPOSITION

Total Body Water and Its Compartments

On average, water comprises 60% of total body weight in adults. This proportion is higher in infants and even greater in babies born prematurely and very low birth weight neonates. Total body water (TBW) declines during early infancy and reaches the adult proportion by the end of the first year (1). The percentage of body weight that is water is higher in individuals who have lower adipose levels and higher muscle levels. In addition, TBW may be altered in disease states that are associated with altered salt handling, such as cystic fibrosis.

In general, the TBW is divided into two principal components: the intracellular water (ICW) and the extracellular water (ECW) spaces (2). These spaces are divided in a 2:1 ratio. In those states in which there is an increase in the TBW, the increase is manifested clinically by the increase in the ECW space. The ECW compartment is further divided into the interstitial and plasma spaces, which are separated in a 3:1 ratio. A component of the ECW, namely the interstitial fluid in skin and connective tissue, may serve as a reservoir that can mobilize water into the plasma volume to sustain circulation during conditions of hypovolemia (3). Finally, there are transcellular

water compartments, such as the gastrointestinal lumen or cerebrospinal fluid, which need to be considered in a distinct category. They are not in direct contact with the rest of the fluid spaces and are separated by an epithelial membrane. Water and electrolytes enter these spaces via active transport processes.

Composition of Body Water Compartments

All of the major fluid compartments in the body are separated by semipermeable membranes (2,3). This type of barrier permits free passage of the solvent but may limit the movement of selective solutes across the membrane. Therefore, the solvent will always move down its concentration gradient to ensure that the osmolality of the solution is the same on both sides of the membrane. Despite marked differences in the makeup of the cationic and anionic solutes in the various body water compartments, under equilibrium conditions, osmolality or tonicity is always equal in all body fluids.

Because of the presence of active transporters and selective channels for various solutes within the cell membrane, there is an uneven distribution of solutes in the ICW and ECW compartments. The presence of the Na-K-adenosine triphosphatase (ATPase) pump in the cell membrane ensures that potassium is the principal cation in the intracellular compartment, and sodium is the primary ECW cation (4). Similar limitations in membrane permeability to chloride and bicarbonate result in these anions being found almost exclusively in the ECW space, whereas proteins and phosphate constitute the major intracellular anions. The differences in cell permeability and binding characteristics of specific ions are reflected in the coefficients that are used to determine the volume of distribution for individual solutes. For example, because of the permeability of cell membranes to water, the volume of distribution for sodium is equal to the TBW compartment, although sodium is confined to the ECW space. In contrast, the volume of distribution of bicarbonate is $0.3 \times \text{TBW}$. These considerations are important in formulating therapeutic regimens to treat specific disorders of sodium and water homeostasis (5).

Besides the presence of distinctive membrane permeability characteristics for specific solutes, the unequal distribution of ions across the membrane is, in part, due to the Gibbs-Donnan effect, which arises because of the presence of impermeant, negatively charged proteins, primarily albumin, in the intravascular space (3). Nonetheless, there is electroneutrality in all body fluids, and the osmolality, or the sum of all osmotically active particles, is equal in all body water compartments.

Under normal conditions, the serum osmolality is 286 ± 4 mOsm/kg water. Because sodium is the major cation in the ECW, osmolality can be estimated by the following formula:

$$\text{Serum osmolality} \approx 2 \times [\text{serum sodium concentration}]$$

A reflection coefficient of 1.0 indicates a totally non-permeant solute, whereas freely permeable molecules have a reflection coefficient of zero. The reflection coefficient for urea is approximately 0.4. Similarly, in the absence of insulin, the reflection coefficient for glucose is 0.5. Thus, in circumstances in which there is a pathologic elevation in the serum urea nitrogen (e.g., acute renal failure or glucose concentration) (diabetic ketoacidosis), these solutes will also contribute to osmolality, and the following formula should be used to calculate serum osmolality:

$$\text{Serum osmolality} = 2 \times [\text{serum sodium concentration}] + [\text{serum urea nitrogen}]/2.8 + [\text{serum glucose concentration}]/18$$

This formula is based on the molecular weights of urea nitrogen (28 d) and glucose (180 d) and the standard practice of reporting these serum concentrations as mg/100 mL. The calculated serum osmolality is normally within 1 to 2% of the value obtained by direct osmometry in clinical chemistry laboratories. However, there are circumstances in which the calculated serum osmolality is significantly lower than the value obtained by measurement with an osmometer. This "osmolal gap" reflects the accumulation of unmeasured osmoles such as organic solutes that are produced after an ingestion of ethanol or ethylene glycol (antifreeze) (6,7).

MAINTENANCE SODIUM AND WATER REQUIREMENTS

Sodium

It is established that sodium is an essential component of the diet. Not only is this cation necessary for the maintenance of the size of the extracellular fluid (ECF) space (see later), it is also required for normal growth. Wassner (8) has demonstrated that somatic growth of experimental animals is impaired if they are fed a sodium-deficient diet. This effect is independent of protein or calorie content of the diet.

Balance studies indicate that the daily sodium requirement is 2 to 3 mmol/kg body weight. This quantity is nearly two- to threefold higher in term and very low birth

weight premature infants (9). This is a reflection of immaturity in renal tubular function coupled with the increased need for sodium to achieve the high rate of growth that is normally observed during the first few years of life. The sodium requirement is exaggerated by intrinsic (diarrhea, increased losses in children on chronic peritoneal dialysis, genetic defect in tubular sodium transport) or exogenous (administration of diuretics) factors that enhance losses of sodium. In most developed countries, the daily sodium intake is well in excess of the amount needed to promote growth or maintain body function. Under normal circumstances, the principal anion that accompanies sodium in the diet is chloride. In certain disease states, such as renal tubular acidosis, metabolic acidosis associated with chronic renal insufficiency, or urolithiasis, it may be advisable to provide a portion of the daily sodium requirement as the bicarbonate or the citrate salt.

Water

The daily requirement for water has traditionally been expressed as a quantity of mL per metabolic kg (10). However, in clinical practice, this is a very cumbersome and impractical method, and all calculations are based on body weight and size. Currently, three methods are used to estimate the daily fluid requirement. The first is a direct extension of the use of metabolic kg and uses the following formula:

$$\begin{aligned} \text{Daily water requirement} &= 100 \text{ mL/kg for a child weighing} \\ &\quad \text{less than 10 kg} \\ &+ 50 \text{ mL/kg for each additional kg up to 20 kg} \\ &+ 20 \text{ mL/kg for each kg in excess of 20 kg} \end{aligned}$$

The second method is based on body surface area and uses the following formula:

$$\text{Daily water requirement} = 1500 \text{ mL/m}^2 \text{ body surface area}$$

The last method is a refinement of the second and uses the following formula:

$$\text{Daily water requirement} = \text{Urine output} + \text{insensible water losses}$$

Based on clinical experience, under normal circumstances, urine output is approximately 1000 mL/m²/day, and insensible losses amount to 500 mL/m²/day.

Thus, consider a child weighing 30 kg and 123 cm in height with a body surface area of 1 m². According to the first method, the daily water requirement is 1700 mL, whereas the second method yields 1500 mL/day. This example illustrates the relative benefits of these two methods. Although the first is easier to apply, it tends to overestimate the water requirement as body weight increases. The third method is the most precise and should be applied in more unusual circumstances, such as when the patient has oliguria secondary to acute renal failure or increased insen-

sible losses (e.g., diarrhea, increased ambient temperature, tachypnea, burns, or cystic fibrosis) (11). In addition to the daily energy requirement and insensible losses that are represented in the formulas, the amount of water excreted daily is dependent on the solute load. Because the urine has a minimum osmolality—approximately 50 mOsm/kg H₂O, even in the absence of arginine vasopressin (AVP)—increased dietary intake of solute will result in a larger obligatory urine volume to accommodate the larger solute load (12).

The daily sodium and water requirement are generally provided enterally. Intravenous administration of fluids and electrolytes should be used only under clinical circumstances that interfere with normal feeding, such as persistent vomiting or gastrointestinal tract surgery.

DISTINCT ROLES OF SODIUM AND WATER IN BODY FLUID HOMEOSTASIS

Sodium and water are inextricably linked in the determination of the serum sodium concentration. However, it is critical to recognize that sodium and water serve two distinct functions within the body. Sodium is instrumental in the maintenance of the size of the ECF space, whereas water is critical to the maintenance of the size of individual cells. The regulation of sodium and water homeostasis represents two distinct processes with discrete sensing and effector mechanisms. Although these systems may overlap from a physiologic and clinical perspective, a complete understanding of body fluids and electrolytes mandates separate evaluation of sodium and water.

As mentioned earlier, sodium is confined primarily to the ECW compartment as a consequence of active transport mechanisms in the cell membrane. Because sodium is the principal cation in this space, disturbances in total body sodium content are reflected by expansion or contraction in the ECW compartment. Adequacy of the ECW compartment is essential to maintain the intravascular space and sustain perfusion of vital organs. The primary step in the pathogenesis of disturbances in ECW compartment size is a perturbation in sodium balance. Under normal circumstances when TBW and sodium content are within the normal range, sodium balance is zero. This means that the daily intake of sodium is matched by the net losses in the urine, stool, and other insensible losses. Provided kidney function is normal, the dietary sodium intake can be as low as 0.1 mmol/kg or in excess of 10 mmol/kg without any derangement in ECF compartment size. If the alterations in diet are not abrupt, then sodium balance is maintained, even when kidney function is markedly impaired (13). In contrast, if the daily input of sodium exceeds the normal losses, then there is expansion of the ECF space that may manifest as edema. If the input does not match the daily losses, there will be symptoms and signs related to ECW space contraction. These dis-

turbances are not associated with any obligatory changes in the serum sodium concentration.

Water homeostasis is a prerequisite for the normal distribution of fluid between the ICW and ECW compartments. Cell function is dependent on stabilization of cell volume to keep the cytosolic concentration of enzymes, cofactors, and ions at the appropriate level. Perturbations in water balance result in fluctuations in serum osmolality. Because cell membranes are semipermeable and generally permit free movement of water down an osmolal gradient, changes in osmolality will cause obligatory shifts in water between the cell and the ECW space. Any disorder that alters the 2:1 ratio of water volume in the ICW:ECW spaces will be reflected in changes in cell size and subsequent cellular dysfunction. Thus, under hypoosmolar conditions, water will move from the intravascular compartment into the cell, causing relative or absolute cell volume expansion. Conversely, if the serum osmolality is elevated, water will exit from the cell to the ECW space, resulting in absolute or relative cellular contraction (14).

Disturbances in cell function related to abnormalities in cell size occur throughout the body. However, this problem is especially prominent in cerebral cells. There are two reasons for this phenomenon. First, the blood-brain barrier, which is constituted by tight junctions between adjacent endothelial cells, limits the movement of solute between the ICW and ECW compartments, while permitting unrestricted flow of water down an osmolal gradient (15). Second, because the brain is contained within the skull, which is a closed, noncompliant space, and is tethered to the cranial vault by bridging blood vessels, it has limited tolerance of cell swelling or contraction. Thus, alterations in water balance and serum osmolality are dominated by clinical findings of central nervous system dysfunction, including lethargy, seizures, and coma (14).

Similar to the situation noted earlier in which disturbances in sodium balance do not necessarily imply specific abnormalities in serum sodium concentration, the presence of a disturbance in water balance and serum osmolality is not linked to a specific abnormality in the ECW compartment. The independent nature of disturbances in sodium and water balance is illustrated in Table 7.1. It is apparent that alterations in ECW size can occur in patients with hypoosmolality, isotonicity, or hypertonicity. Similarly, each alteration in serum osmolality can develop in patients with contraction or expansion of the ECW compartment.

Disturbances in sodium and water homeostasis need to be addressed separately in the clinical evaluation of patients with abnormalities in sodium and/or water. The clinical approach to these problems is outlined below.

SENSOR MECHANISMS: SODIUM AND WATER

For both sodium and water homeostasis, the sensor mechanisms that maintain the equilibrium state are primarily

TABLE 7.1. CLINICAL DISEASES OF SODIUM AND WATER HOMEOSTASIS: RELATIONSHIP BETWEEN EXTRACELLULAR WATER (ECW) SIZE AND TONICITY

ECW volume	Tonicity		
	Low	Normal	High
Low	Addison's disease <i>Salmonella</i> diarrhea Mannitol infusion	Isotonic dehydration	Hypertonic diarrheal dehydration Diabetes insipidus
Normal	SIADH	No disease	Acute sodium bicarbonate infusion
High	Acute renal failure Nephrotic syndrome Cirrhosis Congestive heart failure	Nephrotic syndrome	Salt intoxication Saltwater drowning

SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

designed to be responsive to the secondary consequences of abnormalities in sodium or water balance (i.e., changes in ECW and cell size, respectively) rather than measuring the primary variable. They operate using negative feedback loops in which deviations from normal are detected, counterregulatory mechanisms are activated that antagonize the initiating event, and the system is restored to its original state.

Sodium

The detection of abnormalities in sodium balance is based on systems that sense the consequences of these changes. Thus, net sodium deficit is detected as a decrease in ECW space size, whereas net sodium excess is perceived as an obligatory expansion of the ECW space. These receptors, which are influenced by the filling pressure within the circulation, are called *baroreceptors* or *mechanoreceptors*. It is important to note that these signals are supplemented in certain instances by chemoreceptors that respond directly to changes in the serum sodium concentration and trigger adaptive modifications in renal sodium handling. These receptors may effect change by altering nervous system activity or by activating upstream promoter elements and stimulating the expression of relevant genes (16).

Atrial Receptors

There are ECW volume receptors on the venous (low pressure) and arterial (high pressure) sides of the circulation. Within the right atrium, there are sensors that possess the distensibility and compliance needed to detect alterations in intrathoracic blood volume by maneuvers such as negative intrathoracic pressure or head-out water immersion. Both of these maneuvers, which increase the central blood volume and raise central venous and right atrial pressures, are followed by a brisk natriuresis and diuresis (17). These changes are triggered even in the absence of concomitant change in

the total ECW space size. Neural receptors that respond to mechanical stretch or changes in right or left atrial pressure convey the signal via the vagus nerve (17,18).

Hepatic Receptors

The enhanced effect on renal sodium excretion of saline infusions directly into the hepatic vein versus the systemic circulation suggests that there are also low-pressure sensors within the portal vein or hepatic vasculature. The hepatic responses to changes in sodium balance have been divided into two categories (19). The "hepatorenal reflex" involves direct activation of sodium chemoreceptors and mechanoreceptors in the hepatoportal region via the hepatic nerve and causes a reflex decrease in renal nerve activity. The "hepatointestinal reflex" uses chemoreceptors to respond to changes in sodium concentration and modulate intestinal absorption of sodium via signals conveyed along the vagus nerve. Activation of these hepatic volume sensors may contribute to the sodium retention and edema states that develop secondary to chronic liver disease and cirrhosis with their associated intrahepatic hypertension.

Pulmonary Receptors

There may also be pressure sensors within the pulmonary circulation that are activated by changes in pulmonary perfusion or mean airway pressure (20). The receptors in the lung may be located in the interstitial spaces and may influence the physical forces that modulate paracellular absorption of sodium and water. Similar receptors in the renal interstitium may also influence paracellular absorption of fluid and solutes along the nephron, especially in the proximal tubule segment (21).

Carotid Arch Receptors

There are also volume-dependent sensors on the high-pressure side of the circulation, including the carotid arch, the brain,

and the renal circulation. Thus, occlusion of the carotid leads to increased sympathetic nervous system activity and alterations in renal sodium handling (18). The responsiveness of the carotid arch receptors may be modulated by chronic changes in ECF volume. For example, head-down bed rest and a high-salt diet blunt carotid baroreceptor activity and lead to natriuresis (22).

Cerebral Receptors

Alterations in the sodium concentration of the cerebrospinal fluid or brain arterial plasma lead to increased renal sodium excretion (23). Various lesions in discrete anatomic areas of the brain, such as the anteroventral third ventricle, alter renal sodium reabsorption and buttress the contention that there are central mechanisms of sensing changes in sodium balance and ECF volume. Derangements in the sensing system within the brain in patients with long-standing central nervous system diseases may contribute to the cerebral salt-wasting syndrome.

Of interest, if the arterial sensors perceive underfilling of the vascular space, this activates counterregulatory mechanisms to replete the ECW compartment size, even if the receptors in the venous system detect adequate or even overfilling of the venous tree. Despite normal or even excess total body sodium and net positive sodium balance, there are conditions in which the body perceives an inadequate circulating plasma volume. This has given rise to the notion of the "effective" intravascular volume, a concept that is applicable in the edema states such as congestive heart failure, cirrhosis, and nephrotic syndrome (24). For example, in patients with cardiac pump failure, the perceived underfilling of the arterial tree may occur despite significant venous distention and TBW overload (25). Similarly, women who develop edema during pregnancy may have primary peripheral vasodilatation and excess total body sodium (24).

In summarizing the sensor mechanisms that are involved in the regulation of sodium balance, there are those that are directly linked via mechanoreceptors to the status of the ECF volume. These sensor systems are activated by decreased size of the ECW compartment and respond to "underfilling" of the vasculature tree. However, there are other mechanisms that may be activated by chemoreceptors or localized intra-organ disturbances in perfusion that are dissociated from the ECF volume. These sensors can cause overfilling of the vascular compartment by stimulating renal sodium reabsorption. Correct interpretation of the balance between these two processes involved in sodium balance is critical to the proper diagnosis and management of the edema states (see later).

Water: Arginine Vasopressin

The receptors that are responsible for regulating water homeostasis are primarily osmoreceptors and are sensitive

to alterations in cell size (26). These osmoreponsive cells are located in the anterolateral regions of the hypothalamus, adjacent to but distinct from the supraoptic nuclei. They shrink or swell in response to increases or decreases in plasma tonicity, and this change in cell size triggers the release of AVP and/or the sensation of thirst.

AVP is a peptide containing nine amino acids and has a molecular weight of 1099 d. It is synthesized by the cells in the hypothalamus, transported down the axon, and stored in the posterior pituitary in conjunction with larger proteins, called *neurophysins* (27). The gene for AVP is located on chromosome 20 and has a cyclic adenosine monophosphate response element in the promoter region. Prolonged stimulation of AVP release leads to upregulation of the AVP gene; however, synthesis does not keep up with the need for the peptide, because pituitary levels of AVP are usually depleted in states such as chronic salt loading and hypernatremia (28).

The principal solute that provokes the release of AVP is sodium. The infusion of sodium chloride to increase plasma osmolality results in increased secretion of AVP in the absence of parallel changes in ECW volume. This underscores the primary role of fluctuations in plasma osmolality per se in stimulating AVP release (26). Mannitol, an exogenous solute that is used in clinical practice to treat increased intracranial pressure, is nearly as effective as sodium in stimulating AVP release. Urea and glucose are less than 50% as effective as sodium in provoking AVP secretion, presumably because they are more permeable than sodium and cause less pronounced changes in osmoreceptor cell volume. However, in disease states such as acute renal failure or diabetic ketoacidosis in which urea or glucose act as osmotically active molecules or after the exogenous administration of mannitol, these solutes can also stimulate increases in AVP release. Likely there is coupling between mechanical changes in membrane structure and hormone release. However, the exact mechanism and the neurotransmitters that mediate the actions of the osmoreceptors on the cells of the posterior pituitary have not been identified.

There are a variety of nonosmotic stimuli to AVP release that may contribute to water handling in various disease states (26). Vomiting and acute hypoglycemia promote AVP release by neural-hormonal pathways that are not well defined. Stress associated with pain or emotional anxiety, physical exertion, high body temperature, acute hypoxia, and acute hypercapnia are other conditions that lead to increased secretion of AVP in the absence of a primary disturbance in water balance. There are numerous drugs that directly influence the hypothalamic release of AVP, including carbamazepine, cyclophosphamide, and vincristine. Finally, hemodynamic changes arising from primary alterations in sodium balance and the ECW space can trigger AVP release. If the ECW volume disturbance is mild, then the stimulation of AVP release is modest. However, in the face of severe ECW volume contraction, there is marked secretion of AVP. Under

these circumstances, the imperative to protect the effective circulating blood volume takes precedence over the need to maintain plasma osmolality, and ECW volume is restored at the expense of hypoosmolality. This clinical observation indicates that despite rigorous intellectual attempts to separate sodium and water homeostatic mechanisms, these two factors are closely linked *in vivo*, and there can be significant overlap in sensor and effector mechanisms in the regulation of ECW and ICW compartment size. Table 7.2 lists the factors that modulate AVP release.

In addition to AVP release, the osmoreceptor cells also respond to the changes in serum osmolality in an independent manner to stimulate thirst and increase drinking (29). The stimuli for thirst are generally the same as those for AVP release, among which hypernatremia is the most potent trigger. The osmotic threshold for thirst in humans appears to be higher than for AVP secretion, namely 295 mOsm/kg. The sensing mechanism that leads to this increase in water intake is even more obscure than that for AVP release. It is likely that changes in ECW volume are also involved in this process, because angiotensin II, which rises in states of ECW volume contraction, is a potent dipsogen (30).

EFFERENT MECHANISMS: SODIUM AND WATER

The efferent mechanisms involved in maintaining sodium and water balance include a variety of neural and endocrine-humoral systems. There often is an overlap in the action of these effectors, with an individual effector having distinctive effects on sodium and water balance.

Sodium

Renin-Angiotensin-Aldosterone Axis

The major components of this system—renin, angiotensinogen, and angiotensin-converting enzyme—are found within the kidney and within the vasculature of most organs. Thus,

these elements are linked in a large feedback loop involving the liver, kidney, and lung, as well as smaller loops within individual organs. This complex system accounts for the often-disparate data that have been accumulated about plasma renin activity and the expression of these components within the kidney during disturbances in ECW compartment size.

Angiotensin II is the major signal generated by this axis (3). The peptide interacts with two different receptors, and most of its biologic activity is mediated by the angiotensin type 1 (AT1) receptor. The AT2 receptor is expressed more prominently in the fetal kidney; however, interaction of angiotensin II with the AT2 receptor postnatally may stimulate the release of molecules, such as nitric oxide, that counteract the primary action of the peptide (31). The best-known effects of angiotensin II include peripheral vasoconstriction to preserve organ perfusion and stimulation of adrenal synthesis of aldosterone to enhance renal sodium reabsorption. These two actions serve to restore the ECW space to normal. However, angiotensin II also has direct actions on tubular function and stimulates both proximal and distal sodium reabsorption. The proximal tubule cells contain all of the elements needed to synthesize angiotensin II locally, and the peptide increases the activity of the sodium-hydrogen exchanger (32). In the distal tubule, angiotensin II modulates this exchanger as well as the amiloride-sensitive sodium channel (33). The effects of aldosterone on the renal tubule include both an immediate effect to increase apical membrane permeability to sodium and more extended effects that involve enhanced gene transcription and *de novo* synthesis of Na-K-ATPase. Aldosterone may also stimulate the synthesis of other enzymes involved in renal cell bioenergetics (e.g., citrate synthase) that are needed to sustain maximal tubular sodium transport (34).

Endothelin

This vasoactive molecule is part of a family of three peptides of which endothelin-1 is the most important in humans (35). It is converted in two steps from an inactive precursor to a biologically active 21-amino acid peptide. Endothelins react with two receptors, ETA and ETB, and cause vasoconstriction, which result in a decrease in renal blood flow (RBF) and glomerular filtration rate (GFR). With regard to sodium balance, the primary effect of endothelin is sodium retention mediated by the reduction in GFR. This would suggest that endothelin acts in concert with angiotensin II to protect ECW compartment size under conditions of sodium deficit. However, the situation may be more complicated, because direct exposure of proximal tubule and medullary collecting duct cells to endothelin *in vitro* inhibits sodium absorption.

Renal Nerves

There is abundant sympathetic nervous innervation of the renal vasculature and all tubular segments of the nephron

(36). The efferent autonomic fibers are postganglionic and originate in splanchnic nerves. The renal innervation is primarily adrenergic and involves α_1 adrenoreceptors in the blood vessels and both α_1 and α_2 receptors along the basolateral membrane of the proximal tubule. Renal sympathetic nervous system activity contributes to preservation of ECF volume by promoting renal vasoconstriction and lowering GFR and by increasing sodium reabsorption. Among the catecholamines involved in adrenergic transmission, norepinephrine exerts an antinatriuretic effect. The fact that dopamine, another sympathetic nervous system neurotransmitter, promotes a natriuresis suggests that there may be internal regulation of the effect of nerve activation on renal sodium handling (37).

Renal sympathetic nervous activity is inversely proportional to dietary salt intake (36). Drug-induced sodium retention and volume-dependent hypertension (e.g., with the use of cyclosporine) is mediated in part by activation of the sympathetic nervous system (38). In addition, increased adrenergic nervous signaling within the kidney is instrumental in the initiation of hypertension in experimental animals by causing a right-shift in the pressure-natriuresis curve (36). However, the observation that sodium balance is normal and ECF volume is maintained in the denervated transplanted kidney implies that the role of the sympathetic nervous system in maintaining sodium homeostasis is redundant and can be taken over by other regulatory mechanisms (36).

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is a 28-amino acid peptide that is a member of a group of proteins that includes brain natriuretic peptide and C-type natriuretic peptide (39). It is synthesized as a prohormone that is stored in granules in the cardiac atria. Increases in right atrial pressure provoke cleavage and release of the mature peptide. For each 1-mm Hg rise in central venous pressure, there is a corresponding 10- to 15-pmol/L increase in circulating ANP levels. Conversely, declines in atrial pressure secondary to sodium depletion or hemorrhage reduce ANP release. There are two receptors for ANP, and both are coupled to guanylate cyclase. The activation of this enzyme results in cytosolic accumulation of cyclic guanosine monophosphate, which, in turn, appears to diminish agonist-stimulated increases in intracellular calcium concentration. The principal effects of ANP are to promote an increase in GFR, diuresis, and, most important, natriuresis. The increased renal sodium excretion is, in part, mediated by an increase in filtered load secondary to the rise in GFR. However, ANP also exerts direct actions on renal tubular cells to diminish sodium reabsorption, including inhibition the Na-K-Cl cotransporter in the loop of Henle and the amiloride-sensitive sodium uptake in the medullary collecting duct. Finally, ANP antagonizes the action of several

antinatriuretic signals in the kidney, including sympathetic nervous system activity, angiotensin II, and endothelin. The overall effects of ANP to counteract increases in ECF volume have been demonstrated by short-term studies in which acute infusions of ANP improved cardiac status in patients with congestive heart failure and promoted a diuresis in patients with acute renal failure (40).

Prostaglandins

The kidney contains the enzymes required for constitutive (COX-1) and inducible (COX-2) cyclooxygenase that are necessary for the conversion of arachidonic acid to prostaglandins (PGs) (41). The major products of these pathways are PGE₂, PGF_{2 α} , PGD₂, prostacyclin (PGI₂), and thromboxane (TXA₂). In the cortical regions, PGE₂ and PGI₂ predominate, whereas PGE₂ is the major PG metabolite in the medulla. These two compounds increase GFR and promote increased urinary sodium excretion. In addition, they antagonize the action of AVP. These actions may mediate the adverse effects of hypercalcemia and hypokalemia on renal tubular function (41). The natriuretic effects of PGs in response to alterations in dietary sodium intake under normal circumstances are unclear. However, the role of PGs as efferent signals is more apparent in conditions associated with increased vasoconstrictor tone, such as congestive heart failure or reduced renal perfusion. In these conditions, PGs act to counteract the vasoconstrictor and sodium-retaining effects of angiotensin II and norepinephrine. Inhibition of PGs with cyclooxygenase inhibitors can be associated with dramatic declines in GFR and profound sodium retention and edema (42).

Kinins

Kinins are produced within the kidney and act via β_2 receptors. Their principal action is to promote renal vasodilation and natriuresis. The kinins act in the distal tubule to reduce sodium reabsorption (43).

Nitric Oxide

The kidney contains all three isoforms of nitric oxide synthase (NOS) that are involved in NO synthase—neuronal NOS in the macula densa, inducible NOS in renal tubules and mesangial cells, and endothelial NOS in the renal vasculature. The neuronal and endothelial isoforms are calcium-dependent enzymes and produce small, transient increases in NO production. The inducible isoform is upregulated by various cytokines and inflammatory mediators, resulting in large, sustained elevations in NO release.

Activation of eNOS within the kidney increases the activity of soluble guanylate cyclase and causes vasodilation and an increase in GFR. In addition to its effect on RBF and GFR, NO has direct effects to inhibit Na-K-

ATPase in cultured proximal tubule and collecting duct cells (44,45). The specific isoform of NOS that is responsible for modulating urinary sodium excretion is not as well known. Recent studies using inducible NOS, neuronal NOS, and endothelial NOS knock-out mice suggest that only the first two isoforms are involved in the regulation of sodium and water reabsorption in the proximal tubule (44). There is evidence to support a role of NO in maintaining sodium balance under normal conditions, because alterations in dietary salt intake are associated with parallel changes in urinary excretion of nitrite, the metabolic byproduct of NO release (46). In normotensive Wistar-Kyoto rats and spontaneously hypertensive rats, increased dietary sodium intake is associated with a modest increase in urinary nitrite excretion (47). This effect is less well documented in pediatric patients. Along with ANP and bradykinin, NO is part of the defense system against sodium excess and expansion of the ECW compartment. Derangements in renal NO synthesis and responsiveness to cyclic guanosine monophosphate may be instrumental in the pathogenesis of salt-dependent hypertension in experimental animals (47).

Adrenomedullin

Adrenomedullin is a 52-amino acid peptide that was isolated from human pheochromocytoma cells (48). It reacts with a G-protein cell receptor and causes vasodilatation, an effect that may be mediated by increased synthesis of NO. The resultant natriuresis secondary to the increase in GFR is accompanied by direct inhibition of tubular sodium reabsorption. Its role in sodium balance is under investigation.

Water

Arginine Vasopressin

The primary efferent mechanism in the maintenance of water homeostasis is AVP. This peptide fosters water retention by the kidney and stimulates thirst. The plasma AVP concentration is approximately 1 to 2 pg/mL under basal conditions (26). It is not known whether there is tonic release of AVP or whether there is pulsatile secretion in response to minute fluctuations in plasma osmolality. The set point, or osmotic threshold for AVP release, ranges from 275 to 290 mOsm/kg H₂O. The circulating hormone concentration rises approximately 1 pg/mL for each 1% increase in plasma osmolality. The sensitivity of the osmoreceptors in promoting AVP release varies from person to person, with some individuals capable of responding to as small as a 0.5 mOsm/kg H₂O increase in osmolality and others requiring greater than a 5 mOsm/kg H₂O increment to stimulate AVP release. Patients with essential hypernatremia possess osmoreceptors that have normal sensitivity, but the osmotic threshold for AVP release is shifted to the right. Because the relative distribution of water

between the ECW and ICW compartments is undisturbed, these patients are clinically unaffected by their abnormally high-serum sodium concentration. Although there may be gender-related differences in AVP secretion in response to abnormal water homeostasis with increased sensitivity in women, this is not a relevant clinical concern in prepubertal children.

Angiotensin

Angiotensin II serves as an efferent system in water homeostasis primarily by stimulating drinking (30). Its role in water handling within the kidney is minor and may be related to modulation of the renal response to AVP.

Thirst

Thirst, or the consciously perceived desire to drink, is a major efferent system in water homeostasis (29). It is estimated that for each 1-pg/mL increase in the circulating plasma AVP level, there is a parallel rise of 100 mOsm/kg H₂O in urinary concentration. If the basal plasma osmolality and AVP concentration are approximately 280 mOsm/kg H₂O and 2 pg/mL, respectively, and the steady state urine osmolality is 200 mOsm/kg H₂O, then as soon as the plasma osmolality and AVP concentration reach 290 mOsm/kg H₂O and 12 pg/mL, respectively, the urine is maximally concentrated. Beyond this point, the only operational defense against further increases in plasma osmolality is increased free water intake. This underscores the essential role of thirst as an efferent mechanism in water homeostasis. Moreover, it highlights the increased risk of hyperosmolality developing in patients who do not have free access to water such as infants, those who are physically or mentally incapacitated, or the elderly (49).

Thirst is a very difficult biologic function to quantitate, because it is an expression of a drive rather than an actual behavior. At present, visual analog scales using colors or faces are the most useful tools for quantitating thirst under controlled condition. There can be dissociation between water intake and the sensation of thirst, as in patients with psychogenic polydipsia (e.g., schizophrenia, neurosis). It is not known whether specific drugs directly stimulate the dipsogenic response. The role of diet (e.g., high salt intake) in the regulation of thirst is unknown. The osmotic control of thirst may be suboptimal in both newborn infants and in the elderly (49).

Thirst and drinking behavior are stimulated by significant contraction of the ECF space or by hypotension. In addition, thirst and drinking behavior are modulated by signals that originate in the oropharynx and upper gastrointestinal behavior. Thus, in animals with hypernatremia, those that are given free access to water as the sole means of correcting the hyperosmolal state will stop drinking sooner than animals, which are corrected in part with

supplemental intravenous fluid. This is most likely due to oropharyngeal stimuli that curtail drinking before complete normalization of the plasma osmolality (50).

EFFECTOR MECHANISMS: SODIUM AND WATER

The kidney is the principal organ that acts in response to sensory input, delivered via neural or humoral signals, to restore ECW volume size to normal after the full range of clinical problems. These are supplemented by specific anatomic features of the effector organ to achieve normal homeostasis. Although absorption of sodium and water across the intestinal epithelium may be modulated by chemoreceptors in the hepatic vasculature, the role of the gastrointestinal tract in the control of sodium balance is clearly secondary to the function of the kidney.

Sodium

Glomerular Filtration Rate

In children with normal kidney function, changes in GFR are generally associated with parallel alterations in sodium balance. This is accomplished by glomerular-tubular balance, in which proximal tubule sodium absorption and delivery of filtrate to the distal tubule is modulated in response to GFR (51). Thus, tubular sodium reabsorption increases in parallel with an increase in GFR. This, in part, reflects the load-dependent nature of sodium reabsorption in the proximal tubule. In addition, changes in GFR lead to changes in the oncotic pressure within the peritubular capillaries that also influence sodium reabsorption (52). Thus, an increased GFR is associated with higher hydrostatic pressures in the peritubular capillary network that retard fluid and solute reabsorption in the proximal tubule changes. Finally, tubuloglomerular feedback is activated by alterations in solute delivery to the distal nephron to bring GFR in line with alterations in tubular function. Many of the efferent signals, including renin, angiotensin, NO, and PGs, participate in this particular pathway. The release of these effector molecules is activated via myogenic stretch receptors and chemoreceptors located in the macula densa region of the distal nephron. Even in children with compromised renal function (GFR <20 to 30 mL/min/1.73 m²) in whom there are adaptive changes in tubular function [e.g., increased fractional excretion of sodium (FE_{Na})], glomerulotubular balance is maintained in the face of gradual changes in GFR. However, patients with chronic renal failure are unable to respond to abrupt changes in sodium balance and ECF volume changes as rapidly as healthy children. Therefore, they are susceptible to volume contraction or hypervolemia if sodium intake is substantially reduced or increased over a short period of time (13).

Most of the neural and humoral factors described previously can modulate GFR. Agents that lower GFR may act

predominantly on the vascular tone of the afferent arteriole and cause substantial reduction in RBF and the filtration fraction. Agents in this category include adrenergic nerve stimulation and endothelin. In contrast, angiotensin II acts primarily on efferent arteriolar tone and tends to preserve GFR more than RBF. Therefore, filtration fraction (GFR/RBF) is increased. This pattern is most evident in states of compromised effective perfusion such as congestive heart failure, cirrhosis, and nephrotic syndrome (24,25,53). The critical role of angiotensin II in maintaining GFR and sodium excretion in these conditions is manifest during the functional decline in GFR that occurs after the administration of angiotensin-converting enzyme inhibitors (54). This phenomenon also explains the reversible reduction in kidney function and sodium retention that are observed in patients with a critical renal artery stenosis in a kidney transplant after initiation of angiotensin-converting enzyme inhibitor therapy (54).

Proximal Tubule

Nearly 60 to 70% of the filtered sodium and water load are reabsorbed in the proximal tubule. Sodium and fluid reabsorption are isosmotic in this segment of the nephron. These processes are driven by Na-K-ATPase activity along the basolateral membrane surface with secondary active transport of solute across the apical membrane. The bulk of sodium reabsorption is driven by the sodium-hydrogen exchanger, with a lesser contribution by other cotransport systems for glucose, phosphate, organic anions, and amino acids. The linkage between disturbances in ECF volume and sodium reabsorption in the proximal tubule is created, in part, by changes in the physical forces that govern fluid and solute movement. These include changes in peritubular capillary hydrostatic pressure, peritubular capillary protein concentration and oncotic pressure, and changes in renal interstitial pressure that modulate water and solute movement across cells (transcellular) and along the paracellular pathway.

It is now evident that sympathetic nervous stimulation, norepinephrine release, and both filtered and locally synthesized angiotensin II stimulate the activity of the sodium-hydrogen antiporter and promote sodium reabsorption in conditions associated with decreased ECF volume. Conversely, ANP and the kinins act on proximal tubular cells to inhibit sodium reabsorption and limit expansion of the ECW space.

Distal Nephron Including Collecting Duct

This portion of the nephron is responsible for the reabsorption of approximately 10 to 25% of the filtered sodium and water load. Under most circumstances, it can adapt to changes in delivery arising from alterations in proximal tubule function. This segment of the nephron is responsive to virtually all of the humoral efferent signals and accom-

plishes the final renal homeostatic response to fluctuations in sodium balance. Sodium reabsorption in the distal tubule and connecting segment is responsive to circulating levels of aldosterone (34). In the collecting tubule, there are mineralocorticoid-responsive sodium reabsorptive pathways that are responsible for the final modulation of sodium excretion in response to alterations in sodium intake. The most prominent of these is the epithelial sodium channel (ENaC). This transepithelial protein is composed of three distinct chains— α , β , and γ —each of which is encoded by a separate gene (55). The complete protein has two membrane-spanning domains with an amino and carboxyl terminus within the cell. The α -chain appears to constitute the actual sodium-conducting pathway, whereas the β - and γ -chains may represent regulatory components that control the open/closed status of the channel. Genetic defects in each of the individual components have been described and linked to human disease. Thus, pseudohypoaldosteronism has been mapped to mutations in the α -, β -, and γ -chains, and Liddle's syndrome has been attributed to truncation in the β -chain (55).

Water

Arginine Vasopressin

AVP acts along several segments of the nephron. However, its primary site of AVP action for maintenance of water homeostasis is the collecting tubule (56). In the segment of the nephron, AVP reacts with a V2 receptor—a 371-amino acid protein that is coupled to a heterotrimeric G-protein—along the basolateral membrane of cells along the distal tubule and the collecting duct. The V2 receptor gene has been localized to region 28 of the X chromosome. This epithelial cell receptor is distinct from the V1 receptor in the vasculature that is linked to Ca-activation of the inositol triphosphate cascade, which mediates vasoconstrictor response to the hormone (56).

Binding of AVP to the V2 receptor activates basolateral adenylate cyclase and stimulates the formation of cyclic adenosine monophosphate within the cytosol. This intracellular second messenger then interacts with the cytoskeleton, specifically microtubules and actin filaments, and promotes fusion of intramembrane particles that contain preformed water channels with the apical membrane of principal cells in the collecting duct. The AVP-induced entry of preformed water channels involves clathrin-coated pits. Withdrawal of AVP is followed by endocytosis of the membrane segment containing the water channels into vesicles that can be localized to the submembrane domain of the cell. This results in termination of the hormone signal. The recycling of water channels from vesicles to the apical membrane and then back into vesicles has been demonstrated in freeze-fracture studies of cells exposed to AVP (56). The importance of the V2 receptor in water homeostasis has been confirmed by the documentation of numer-

ous mutations in the gene and corresponding abnormalities in protein structure in children with X-linked congenital nephrogenic diabetes insipidus (57).

The water channels that mediate increased transmembrane movement of water across the collecting tubule in response to AVP have been identified and are called *aquaporins* (58). There are nine known members of this group of transmembrane water channels, all of which contain six membrane-spanning domains. The first member to be identified was aquaporin-1 (AQP-1; originally called channel-forming integral membrane protein of 28 kDa or CHIP-28). It is a transmembrane protein that mediates water movement across the erythrocyte membrane and along the proximal tubule. Mice that do not express AQP-1 have a normal phenotype and concentrate their urine normally. Aquaporin-2 (AQP-2) is the major AVP-sensitive water channel in the collecting tubule (59). Immunogold electron microscopy studies have confirmed that AQP-2 represents the water channel that is present within the cytosolic vesicles that fuse with the apical membrane after exposure of principal cells in the collecting duct to AVP. The contribution of AQP-3 and AQP-4 to the normal urinary-concentrating mechanism has been confirmed in mice that have been genetically manipulated and do not express these two proteins (60).

The importance of AQP-2 in mediating the normal response to AVP has been verified by the discovery of mutations in the AQP-2 gene in children with non-X-linked, autosomal recessive forms of nephrogenic diabetes insipidus (61). Moreover, alterations in AQP-2 protein expression have been documented in other states associated with a urinary-concentrating defect, such as lithium exposure, urinary tract obstruction, hypokalemia, and hypercalcemia (58).

It is important to acknowledge that water reabsorption in the collecting duct is not completely dependent on the presence of AVP. Thus, even in animals that are genetically deficient in AVP (Brattleboro rats) or in patients with central diabetes insipidus, the urinary osmolality does increase slightly above basal levels in the face of severe ECF volume contraction. This concentration may be the consequence of reduction in urinary flow rate along the collecting duct that enables some passive equilibration to occur between the luminal fluid and the hypertonic medullary interstitium.

Although the collecting duct is the primary site of regulation of net water reabsorption, the proximal tubule may contribute to water balance under circumstances of decreased ECW compartment size. Whereas the proximal tubule normally reabsorbs approximately 60% of the filtered water load, this proportion may exceed 70% when the ECF volume is diminished. Furthermore, by decreasing fluid delivery to the distal nephron, this may enhance the AVP-independent reabsorption of water along the collecting tubule. These combined effects may explain the beneficial effects that have been observed after administration of thiazide diuretics to patients with nephrogenic diabetes insipidus (62).

Countercurrent Mechanism

The primary locus of the urinary-concentrating mechanism is the medulla and involves the thin descending limb of Henle, the medullary thick ascending limb of Henle, the cortical thick ascending limb of Henle, and the collecting duct (63). Sodium and water reabsorption are isosmotic in all segments of the nephron proximal to the loop of Henle. To concentrate or dilute the urine, water and solute must be separated to enable excretion of free water or urine that is hyperosmolar relative to plasma. This process begins in the medullary and cortical thick ascending limb of Henle in which NaCl is reabsorbed independently of water, generating a hypotonic luminal fluid. This action is linked in series to the low water permeability of the distal tubule and the connecting segment, which together with continued sodium reabsorption enhances the hypotonicity of the urine in this segment. In a secondary step, the permeability to water along this segment of the nephron is much lower than in the descending limb of the loop of Henle. This enables water to move down its osmolal gradient from the tubule lumen into the interstitium as it enters the medulla in the descending limb. Finally, the third critical component of the countercurrent mechanism is the presence of vasa recta, which perfuse the inner medulla via vascular bundles that contain hairpin loop-shaped blood vessels. This facilitates the efficient removal of the water that exits in the descending limb of Henle from the medullary interstitium without washing out the solute gradient that passively drives water reabsorption in the collecting tubule. The final effector mechanism is the alteration in the water permeability of the collecting tubule in response to AVP and the generation of a concentrated urine or the excretion of solute free water in the absence of AVP (Table 7.3).

Osmoprotective Molecule (Compatible Osmolytes)

Besides the presence of effector mechanisms to maintain water balance, cells possess a wide range of adaptive mechanisms to counteract the undesirable movement of water between the cell and the ECW during hypotonic and hypertonic states and prevent neurologic dysfunction. These mechanisms include early response genes that result in the immediate accumulation of chaperone molecules

that counteract the adverse effects of altered cell size on protein function (14). This immediate response is followed in short order by the uptake or extrusion of electrolytes as an acute response to the altered size cell. Because there are inherent limits on the ability to regulate cell volume exclusively with inorganic electrolytes, this is followed by a more extended response involving the membrane transport or synthesis/degradation of a variety of compatible solutes, called *osmolytes*, whose cytosolic concentration can be safely altered within the cell without perturbing cell function. These osmoprotective molecules include various carbohydrates (sorbitol, myo-inositol), amino acids (taurine, glutamate), and methylamines (betaine, glycerophosphorylcholine) (14). The osmolytes accumulate in the cytosol to preserve cell function during chronic osmolal disturbances. The cell volume regulatory response can be activated by electrolytes such as sodium or neutral molecules (e.g., urea and glucose) (14). The adequacy of the cell volume regulatory response and the accumulation of osmoprotective molecules in cerebral and renal cells may be dependent on the rate of rise in osmolality, as well as the magnitude of the absolute change (64).

Experimental data in animals and clinical experience in premenopausal women suggest that estrogens may impair the cell volume regulatory response to disturbances in plasma osmolality. This increases the risks associated with both the untreated abnormalities and therapy (65). Although there are some who assert that adaptive control of cell size is inadequate during development, it has been demonstrated that the accumulation of osmoprotective molecules during chronic hyponatremia is normal in preweaning rats and, in fact, there is a higher set-point to preserve the increased brain cell water content (66).

Failure to adequately account for the cell volume regulatory response to osmolal disorders contributes to some of the adverse effects associated with inappropriate correction of abnormalities in plasma osmolality. These effects include neurologic dysfunction, specifically seizures, during the treatment of hyponatremia; osmotic demyelinating syndrome during rapid reversal of hyponatremia; dialysis disequilibrium syndrome that occurs during the initiation of dialysis in patients with acute or chronic renal failure; and cerebral edema and brain herniation in patients with diabetic ketoacidosis (67,68).

TABLE 7.3. FACTORS THAT CONTRIBUTE TO THE COUNTERCURRENT MECHANISM

Na-Cl-K-mediated solute absorption in the medullary thick ascending limb of Henle

LABORATORY ASSESSMENT OF SODIUM AND WATER BALANCE

There are no normal values for sodium and water intake or excretion, reflecting the wide range of normal daily intake for both sodium and water as a consequence of differences in dietary composition. Healthy individuals are in balance, and the excretion of sodium and water matches the daily intake. Therefore, laboratory assessment of sodium and water homeo-

stasis is confined to disease states in which the clinicians must determine whether renal sodium and water handling are appropriate for the clinical circumstances, will maintain balance, and will prevent disturbances in ECF volume or water distribution between the ICW and ECW compartments.

Sodium

The urine sodium concentration is not a valid index of sodium balance, because the value may vary depending on the volume and concentration of the sample. Therefore, the renal handling of sodium is best evaluated using the FE_{Na} . After obtaining a random urine sample and a simultaneous blood sample and measuring the sodium and creatinine concentrations in both specimens, the FE_{Na} is calculated using the following formula:

$$\begin{aligned} FE_{Na} &= \text{Excreted sodium/Filtered sodium} \\ &= \text{Urinary sodium concentration} \times \text{urine flow rate/Plasma} \\ &\quad \text{sodium concentration} \times \text{GFR} \\ &= \frac{\text{Urine sodium concentration/Plasma sodium concentration}}{\text{Urine creatinine concentration/Plasma creatinine concentration}} \end{aligned}$$

This formula is based on the insertion of the creatinine clearance as a measurement of GFR in the second equation and the cancellation of the urine flow rate term in the numerator and denominator. Therefore, the determination of the FE_{Na} is a particularly useful test in clinical practice, because the measurement does not require a timed urine collection. In healthy individuals, this value varies depending on the daily sodium intake. However, in patients with ECF volume contraction who are responding appropriately to retain sodium, the FE_{Na} is less than 1% (less than 3% in neonates). Conversely, in patients with expansion of the ECW compartment, the FE_{Na} typically will exceed 3% unless there is concomitant renal disease.

Water

Determination of the urine-specific gravity or osmolality in a random sample will vary depending on the water intake in the past 2 to 4 hours. Therefore, the assessment of water handling is best judged by determining these values under more controlled conditions such as in the water-deprived state or after administration of a water load (10 to 20 mL/kg body weight) to evaluate the urinary concentrating or diluting capacity, respectively.

The functional aspects of renal water handling are best assessed by determining the free water clearance. This represents the amount of solute-free water excreted by the kidney. It is calculated using the following formula:

$$\begin{aligned} \text{Free water clearance} &= \text{Urine volume} - \text{osmolal clearance} \\ &= \text{Urine volume} - [\text{Urine osmolality} \times \text{urine flow rate}] / \\ &\quad \text{Plasma osmolality} \end{aligned}$$

If the free water clearance is a positive number, then the urine/plasma osmolality ratio is less than 1, the urine is dilute, and the kidney is in a diuretic mode. When a water diuresis is maximal, the free water clearance measures the capacity of the kidney to excrete free water. In contrast, patients who are in an antidiuretic mode with urine:plasma osmolality ratio greater than 1 and who are able to concentrate their urine will have a negative free water clearance. As the solute excretion rate increases, both the maximum values for free water clearance and free water reabsorption increase. At any given solute excretion rate, the free water clearance greatly exceeds the free water reabsorption. This indicates that the renal water homeostatic mechanisms designed to protect against overhydration and dilution of the ECW are more robust than those used to defend against water deficit and dehydration.

OVERVIEW OF THE EVALUATION OF FLUID AND WATER ABNORMALITIES

In practice, the clinical information and laboratory data that are used to evaluate patients overlap with one another. However, in view of the different physiologic roles of sodium and water balance in body fluid homeostasis, the distinct regulatory mechanisms used to control these factors, and the varied therapeutic strategies that must be used to restore sodium and water balance to normal in disease states, it is essential that disturbances in sodium and water balance be evaluated separately. In realtime, these separate assessments are done in parallel, a reflection of the body's own method of operation.

When confronted with a child with a sodium and water disturbance, the first question that must be addressed is whether there is a life-threatening compromise in the size of the ECF volume. Thus, it is necessary to clarify whether the ECF volume is decreased or expanded. By implication, this is an assessment of sodium balance. Such patients have a life-threatening disease and may require emergency therapy such as volume resuscitation or acute ultrafiltration, reflecting the vital importance of a normal ECF volume to maintain intravascular volume within the normal range to sustain perfusion of vital organs.

After making this emergency determination and instituting appropriate therapy, it is important to grade the magnitude of the disturbance in ECF volume. Unfortunately, there are no laboratory tests that can reliably substitute for clinical judgment. Because acute changes in body weight always reflect alterations in sodium balance and ECW compartment size, serial measurements in body weight are the most reliable indicator of the presence and severity of disturbances in ECF volume. However, these measurements are often unavailable and, therefore, the evaluation of sodium balance is based on a wide range of clinical findings, including changes in mental status, level

of alertness, irritability, presence of thirst, pulse rate, blood pressure, orthostatic changes, fullness of the anterior fontanelle in infants, the presence of tears, dryness of the mucus membranes, skin color, elasticity of the skin or tenting, capillary refill or turgor, peripheral edema, shortness of breath, and the presence of rales on auscultation of the chest. Some investigators have documented that capillary refill may be the most useful test to rapidly and accurately assess ECF volume and the response to treatment (69). Other findings on clinical examination include urinary-specific gravity and central venous pressure. Laboratory investigations include BUN, serum creatinine, and bicarbonate concentrations.

It is important to emphasize that assessment of ECF volume is a clinical determination. There is no laboratory test that is a valid surrogate marker. Moreover, despite the frequency of clinical disturbances in sodium balance, especially ECF volume contraction, no suitable scoring has been devised based on any combination of the previously mentioned elements that can be used to accurately and reliably distinguish different degrees of ECF volume contraction or expansion. This deficiency is in contrast to the Glasgow coma score or APACHE (acute physiology and chronic health evaluation) score that have been successfully applied to the initial assessment of patients with acute neurologic or multisystem illnesses.

The third step in the evaluation of a patient with a sodium and water disturbance is to evaluate the plasma osmolality. This evaluation indicates whether there will be an abnormal distribution of water between the ECW and ICW compartments. The most likely symptoms that will be present in affected patients will arise secondary to central nervous dysfunction. These include confusion, irritability, lethargy, obtundation, and seizures. These manifestations overlap significantly in patients with hyperosmolality or hyposmolality. Moreover, there is no obligatory change in ECF volume. Therefore, unlike disorders of ECF volume, disturbances in water balance and distribution require a laboratory determination for confirmation and grading. The steps involved in the initial evaluation of a child with a disturbance in sodium and water balance are outlined in Table 7.4.

TABLE 7.4. STEPS IN THE INITIAL EVALUATION AND TREATMENT OF A CHILD WITH A DISTURBANCE IN SODIUM AND/OR WATER BALANCE

Step 1: Determine whether there is a life-threatening alteration in ECF volume.
Volume resuscitation if there is ECF volume contraction.
Consider ultrafiltration if there is ECF volume expansion.
Step 2: Grade severity of defect in sodium balance.

SODIUM BALANCE DISTURBANCES: DEFICIT AND EXCESS

Sodium Deficit

Diagnosis and Evaluation

In children with normal kidney function, consumption of a diet that is low or high in sodium does not generally cause a net negative or positive sodium balance, because the kidney can adaptively modify sodium reabsorption to parallel fluctuations in salt intake if the changes are not too abrupt or massive in nature.

Sodium deficits and ECF volume contraction are dangerous because decreased size of the intravascular fluid can lead to reduced perfusion and ischemia in organs such as the brain, heart, and kidneys. In children, the absence of concomitant atherosclerosis disease or endothelial dysfunction secondary to essential hypertension, smoking, hyperlipidemia, and diabetes decreases this risk. However, there are groups of pediatric patients who may be more susceptible to the adverse consequences of hypovolemia. These include newborn babies in whom high circulating levels of vasoconstrictor hormones and impaired autoregulation render the glomerular microcirculation particularly sensitive to reduced perfusion (70). In addition, underlying diseases or medications may hinder the counterregulatory responses to ECF volume contraction and enhance the risks of hypovolemia.

Diseases that cause sodium deficiency can originate outside the kidney or within the kidney. It is unfortunate that the word *dehydration* is often used to describe these states because it deflects attention from the primary defect, namely a net negative sodium balance, and suggests that water deficit is the major pathophysiologic problem in these conditions (71,72). The critical role of the ECF space and sodium balance in the pathogenesis of states of volume contraction is highlighted by comparing them with diabetes insipidus. When sodium balance is perturbed, >60% of the fluid loss is derived from the ECW compartment, provoking the rapid onset of symptoms. In contrast, only 8% of the pure water loss that occurs in diabetes insipidus is derived from the ECF, accounting for the rare evidence of ECF volume contraction. Use of the term *denaturation* may provide a more accurate depiction of what is occurring in patients with primary deficits in sodium balance and contraction of the ECF volume (71).

Extrarenal causes can be attributed to losses of sodium in any body fluid or across any epithelial surface, including the cerebrospinal fluid, pleural fluid, biliary tree, gastrointestinal losses, or the skin. They can represent the result of a disease process, or they may be iatrogenic in nature. Renal diseases can cause sodium deficit as a result of limited homeostatic capacity caused by a compromise in GFR. Alternatively, there may be primary renal sodium loss that is not the consequence of a decrease in kidney function. Finally, renal sodium reabsorption may be diminished

TABLE 7.5. CAUSES OF NET SODIUM DEFICIT

Renal causes
Compromised glomerular filtration rate
Acute decrease in sodium intake or increased losses

Salt-losing congenital adrenal hyperplasia
Addison's disease
Skin losses
Cystic fibrosis
Neuroectodermal diseases
Burns

because of reduced circulating levels of aldosterone or unresponsiveness to the hormone. The major causes of sodium deficiency are summarized in Table 7.5.

The diagnosis of the cause of a disturbance in sodium balance is made based on the history and physical examination. In most cases, this information is adequate to identify the source of the sodium losses. Previously, the degree of ECF volume contraction was categorized as mild, moderate, or severe if the changes in body weight were estimated to be less than 5%, 5 to 10%, or more than 10%, respectively. Life-threatening ECF volume contraction was thought to represent a more than 15% decrease in weight. Recent data, based on systematic body weights at the time of hospitalization and immediately after correction of the sodium deficit, suggest that these numbers overestimate the degree of sodium deficit and that the ECF volume contraction is better estimated to be less than 3%, 3 to 6%, and greater than 6% with a greater than 9% change in body weight representing an emergency (73).

If the losses are primarily extrarenal in nature, then renal sodium retentive mechanisms will be activated, and the specific gravity of the urine will be more than 1.015 and the FE_{Na} will be low, specifically less than 1%. Failure to increase the urine concentration and a high FE_{Na} in the face of clinical signs of ECF volume contraction points toward a renal or adrenal cause for the disorder. A renal ultrasound documenting the presence of small, misshaped kidneys or hydronephrosis may be indicative of congenital

abnormalities of the kidney, such as dysplasia or obstructive uropathy.

Treatment

In the unusual circumstance in which the ECW is so severely contracted that vital organ perfusion is compromised, based on an altered mental status, orthostatic changes, and azotemia, then fluid resuscitation must be initiated on an emergent basis. This treatment is necessary to prevent the development of acute tubular necrosis, which may occur if there is hypotension and renal ischemia secondary to ECF volume contraction. The risk of acute renal failure is higher in children with preexisting renal disease, children who are receiving nephrotoxic medications, or children who have concomitant hemoglobinuria or myoglobinuria. If there is no evidence of cardiac or pulmonary disease, then the optimal therapy under these conditions is infusion of isotonic crystalloid (0.9% NaCl, Ringer's lactate), 20-mL/kg body weight. Although transfusions of whole blood are optimal for treatment of hemorrhagic shock, infusion of crystalloid solutions avoids difficulties caused by extravasation of the colloid into the interstitial compartment. Moreover, a systematic review of the literature does not support the use of colloid solutions for volume replacement in critically ill patients (74). This fluid is appropriate regardless of what the initial serum sodium or osmolality is, and concerns about the advisability of infusing Ringer's lactate are misplaced in view of the low potassium concentration (4 mmol/L) in this solution. A catheter should be placed in the bladder to facilitate monitoring of urine output. The infusion should be as rapid as possible, and the fluid dose should be repeated as often as necessary to achieve some evidence of clinical improvement, such as improved mental status, decrease in pulse, rise in blood pressure, or improved capillary refill.

After addressing and correcting the underlying disease, a fluid repletion plan should be initiated as soon as possible. Preference should be given to correcting sodium and electrolyte deficits with oral rehydration solutions (ORS). In general, patients can be repleted with a rapid (1 to 2 hour) intravenous infusion to restore ECF volume followed immediately by initiation of ORS (75). The only conditions that represent contraindications to the use of ORS are impaired neurologic status, persistent vomiting, or diseases associated with mucosal damage in the gastrointestinal lumen.

ORS fluids introduced by the World Health Organization contain sodium 90; potassium 20; bicarbonate 30; chloride; and glucose (20 g/L), 111 mmol/L. The sodium and glucose are present in a molar ratio that maximizes the secondary active uptake of these solutes via the sodium-glucose cotransporter across the gastrointestinal epithelium. Water is absorbed passively down its osmolal gradient. The presence of other solutes, such as potassium and bicarbonate,

are not critical to the successful use of ORS. These fluids have been used for more than 30 years. They can be administered ad libitum in response to the child's own thirst, and they are effective and safe with minimal occurrence of hypernatremia or hyperkalemia. There is evidence that various alternatives to glucose, such as rice-syrup or amylase-resistant starch, may facilitate sodium and water reabsorption from ORS, decrease fecal fluid loss, and shorten recovery time after an episode of cholera (76,77). However, further clinical studies are needed to confirm the use of these additives because they may increase the cost and decrease the shelf life of ORS. These are important considerations in developing countries where there is a high incidence of infectious diarrhea in infants and children.

In specific circumstances when parenteral therapy is required to correct sodium and water deficits, the following guidelines can be applied when devising a therapeutic plan. First, in the absence of reliable data regarding the acute weight loss, it is easiest to calculate the maintenance and deficit therapy based on the clinical estimate of the percentage decrease in body weight. Second, it is advisable to discount any emergency fluid therapy, such as bolus infusions of isotonic saline, in computing the fluid prescription. Third, if the clinical problem has developed in less than 48 hours, then it should be considered an acute process, and the sodium and fluid losses are derived from the ICW and ECW in the ratio of 80 to 20%. If the patient has been ill for more than 48 hours and the process is chronic, then the sodium and fluid losses are derived from the ICW and ECW in the ratio of 60 to 40%. Under most conditions in which the sodium and water losses are isotonic, the ECW portion of the loss, in liters, can be multiplied by 140 mmol/L to determine the sodium loss. Similarly, the ICW portion of the loss, in liters, can be multiplied by 140 mmol/L to determine the potassium deficit. If the ECW and ICW fluid losses together with the respective sodium and potassium deficits are added to the maintenance requirements, then a total fluid volume can be determined. After selecting a fluid that most closely approximates the total sodium and water losses, the total fluid volume is divided by the time frame of the correction to determine the intravenous infusion rate.

As an example, if a 10-kg child is judged to have a 5% decrease in body weight over 36 hours, then the total fluid deficit of 500 mL can be divided into two components—400 mL ICW with 56 mmol potassium and 100 mL ECW containing 14 mmol sodium. The daily maintenance water and sodium requirements are 1000 mL and 30 mmol sodium. Adding these two quantities together results in a fluid that closely resembles 0.25% saline (37 mmol NaCl/L) containing 30 mmol KCl/L, and the infusion rate is approximately 60 mL/hr if the correction is designed to occur over 24 hours. In all cases, it is important to monitor and replace ongoing losses to insure that there is full resolution of the underlying clinical problem.

Sodium Excess

Diagnosis and Evaluation

These conditions, which generally are less common than sodium deficit, are evidenced by clinical signs of ECF volume expansion. The causes of net total body sodium excess are noted in Table 7.6. They can arise secondary to exogenous addition of sodium or abnormal retention of endogenous sodium. Because the normal kidney can rapidly excrete a sodium load, for the excess sodium to cause clinical symptoms and signs, there must be a concomitant factor that limits natriuresis.

Common causes of excess exogenous sodium are salt-water drowning, ingestion of a diet abnormally high in sodium, or therapeutic infusion of sodium-containing intravenous solutions, such as sodium bicarbonate during the resuscitation after a cardiopulmonary arrest. Examples of dietary excess of sodium include errors in the preparation of infant formulas. The widespread use of premixed baby formulas may decrease the incidence of these accidents.

The conditions associated with excessive endogenous sodium retention include acute renal failure and the edema states, namely nephrotic syndrome, cirrhosis, and congestive heart failure. In the first condition, which may occur owing to glomerulonephritis or tubular necrosis, the sodium retention is directly related to the decrease in GFR and diminished filtration of sodium. In the latter three states, renal sodium and water reabsorption are activated by a combination of mechanisms that are termed *underfill* and *overflow*. A critical review of available evidence in patients with nephrotic syndrome suggests that those diseases that are associated with an inflammatory infiltrate in the kidney develop primary sodium retention and overfilling of the ECF volume. This histopathologic feature is absent in most cases of minimal change nephrotic syndrome (78). Thus, in nephrotic syndrome, the total body sodium excess may be coupled with a diminished, normal, or expanded effective ECF volume, explaining the normal distribution of plasma renin activity values and the variability in measurements of plasma volume in these patients.

The clinical problems that accompany these conditions are mainly related to pulmonary venous congestion, impaired

TABLE 7.6. CAUSES OF NET SODIUM EXCESS

Exogenous sodium

Congestive heart failure

gas exchange in the lung, and difficulty breathing. In idiopathic nephrotic syndrome, the intraalveolar pressure is often sufficient to prevent frank pulmonary edema. However, in other circumstances, there may be intrinsic capillary leak together with lowered plasma oncotic pressure, augmenting the development of pulmonary interstitial fluid. Peripheral edema may be associated with skin infection, peritonitis, or thromboembolic events.

All of the states associated with sodium excess should be evident on physical examination. The FE_{Na} is high if there is sodium loading and renal function is normal. In contrast, in the states associated with abnormal retention of endogenous sodium, the FE_{Na} is very low. The FE_{Na} is more useful than the urinary-specific gravity because it is likely to be elevated in all cases of sodium excess.

Therapy

The optimal therapy is targeted at correcting the underlying disease. This is most important in patients with cirrhosis or congestive heart failure. Ancillary therapies include administration of diuretics to facilitate urinary sodium excretion. Although thiazide diuretics may be adequate, a more potent loop diuretic may be required if the GFR is diminished. Supplemental oxygen may be necessary to alleviate shortness of breath and hypoxemia. In more severe cases, acute dialysis may be necessary to foster rapid clearance of the excess sodium. Patients with nephrotic syndrome may require combinations of diuretic agents that act in the proximal (e.g., metolazone) and distal (e.g., furosemide) segments of the nephron to promote an adequate natriuresis and diuresis. Infusions of albumin (1 g/kg body weight) may be necessary to promote and augment the medication-induced diuresis, especially in those with severe ECF volume contraction, reduced GFR, and azotemia (79). Finally, hemofiltration may be a safe and effective means to rapidly remove sodium and water in severely ECF-overloaded children with nephrotic syndrome (80).

WATER BALANCE DISTURBANCES: DEFICIT AND EXCESS

Hyponatremia

Diagnosis and Evaluation

Patients with hyponatremia have relative or absolute expansion of the ICW compartment. If renal function is normal, excess free water is eliminated within 2 to 4 hours. Therefore, for this problem to occur, two conditions must be satisfied—there must be continued AVP release that is inappropriate to the serum sodium concentration, and the patient must have continued access to free water. The symptoms and signs of hyponatremia, which generally involve central nervous system dysfunction, are vague and

nonspecific. Therefore, laboratory confirmation is required to diagnose this abnormality. Moreover, the presence of hyponatremia has no predictive value about the status of the ECF volume. Therefore, this later issue must be assessed clinically to determine whether the child has hypovolemic hypotonicity, isovolemic hypotonicity, or hypervolemic hypotonicity.

It is important to recognize that the laboratory measurement of serum sodium concentration is no longer susceptible to technical errors. In the past, laboratory analyzers measured sodium concentration in the total supernatant phase obtained after centrifugation of blood samples, including lipids and proteins. Because these molecules are not water soluble, they displace sodium into a smaller aqueous phase, leading to a spurious reduction in the serum sodium concentration. All biochemical analyzers that are currently in use assay sodium concentration only in the aqueous phase and result in an accurate determination of the serum sodium level. Therefore, the entity called *pseudohyponatremia* is no longer clinically relevant. In contrast, the reduced serum sodium concentration noted in patients with increased circulating levels of an impermeant solute, such as mannitol, urea, contrast media, or glucose in patients with diabetic ketoacidosis, is valid and reflects osmotic redistribution of water from the ICW to the ECW space. The phenomenon is reflected in the following formula, which enables adjustment of the serum sodium in patients with severe hyperglycemia:

$$\begin{aligned} \text{“Physiologic” sodium concentration} &= \\ & \text{measured serum sodium concentration} + 1.6 \times \\ & [\text{Each } 100 \text{ mg/dL increment in serum glucose } > 100 \text{ mg/dL}] \end{aligned}$$

The most common clinical causes of hyponatremia are classified by the concomitant ECF volume status in Table 7.7. In some diseases, such as congestive heart failure, the degree of hyponatremia may be a reflection of circulating AVP levels and sympathetic nervous system activation and provides a marker of disease severity. This relationship has not been demonstrated in patients with nephrotic syndrome or cirrhosis.

The syndrome of inappropriate AVP release causes hyponatremia with mild to modest ECF volume expansion. It can occur as a consequence of central neurologic lesions, pulmonary disease, or tumors. In addition, numerous drugs can result in abnormal secretion or action of AVP and lead to chronic hyponatremia. A list of these agents is provided in Table 7.8. The diagnosis of this problem requires confirmation that the urine is excessively concentrated relative to the plasma osmolality without any evidence of ECF volume contraction or adrenal or thyroid insufficiency. The two hormones are required to maintain the low water permeability of the collecting duct in the absence of AVP. Deficiencies of either hormone impair free water clearance, leading to euvoletic hyponatremia. In practice, this requires comparison of the urine-specific gravity or osmolality with the concurrent serum osmolality. The

TABLE 7.7. CAUSES OF HYPONATREMIA

Hypovolemic: ECF volume contraction
Renal
Mineralocorticoid deficiency
Mineralocorticoid resistance
Diuretics
Polyuric acute renal failure

Chronic renal failure
Nephrotic syndrome
Cirrhosis
Congestive heart failure
Psychogenic polydipsia/compulsive drinking

ADH, antidiuretic hormone; ATN, acute tubular necrosis; ECF, extracellular fluid.

urine should normally be maximally dilute if the serum sodium concentration is <130 mmol/L or the plasma osmolality is <270 mOsm/kg H₂O. In addition, if the urinary sodium concentration is >40 mmol/L, there is adequate evidence against ECF volume contraction.

Treatment

In all cases, the first line of therapy should be directed at the underlying cause of the low serum sodium concentration. However, hyponatremia often warrants specific corrective treatment. Much ink has been spilled in detailing the appropriate therapy of this electrolyte abnormality. At times, this issue has been quite contentious, and the nephrology community has been divided into two supposedly distinct camps—those who advocate "rapid" versus "slow" correction of hyponatremia. The former group asserts that hyponatremia has direct adverse effects on central nervous system function, including impaired oxygenation that can

lead to seizures or cardiopulmonary collapse before initiation of therapy (81). This risk may be especially prominent in premenopausal women. In contrast, there are others who emphasize the cerebral cell volume regulatory response to hyponatremia and highlight the risk of brain cell dehydration and osmotic demyelinating syndrome in patients who are corrected too quickly (82).

Taking into account the entire literature on the subject, current evidence suggests that the risk of hyponatremia is more closely related to the acuity of the change rather than the absolute size of the drop in serum sodium concentration (83). Thus, therapy should be guided by the clinical assessment of the time frame in which hyponatremia has developed. If the hyponatremia is acute—that is, less than 12 hours in duration—then the brain will behave as a perfect osmometer, leading to potentially life-threatening cerebral cell swelling. Under these circumstances, there is an urgent need to reverse the hyponatremia to counteract cell swelling. Clinical experience indicates that infusion of a 3% NaCl solution (513 mmol/L) in a volume designed to raise the sodium concentration by 3 to 5 mmol/L is sufficient to halt central nervous system dysfunction (84). The benefits and lack of adverse effects of acute correction have been confirmed in a series of 34 infants and children with acute water intoxication caused by the administration of dilute infant formula (85). After partial correction is achieved, the hyponatremia can be corrected more slowly. For example, if a 6-year-old child weighing 20 kg (TBW = 0.6 L/kg × 20 kg = 12 L) develops a seizure after a tonsillectomy and is noted to have a serum sodium concentration of 115 mmol/L, then 36 to 60 mmol of sodium are needed to raise the sodium concentration by 3 to 5 mmol/L.

This correction is accomplished by infusing 72 to 120 mL of the hypertonic saline.

If hyponatremia has developed over more than 12 hours or the duration of the problem is unclear, especially if the patient has no signs of neurologic dysfunction, then slow correction is the prudent course of action (82,83). The current definition of low correction includes two features:

1. The rate of rise in serum sodium concentration should be less than 0.6 mmol/L/hr throughout the correction phase.
2. The total increment and/or the final serum sodium concentration after 48 hours of treatment should not exceed 25 mmol/L or 130 mmol/L, respectively.

The more cautious criterion should be applied depending on the initial serum sodium level. If the child develops acute changes in mental status or new neurologic findings, during or shortly after the fluid treatment, then a serum sodium concentration should be checked. Imaging studies, specifically an MRI of the brain, may reveal the changes of osmotic demyelinating syndrome.

In patients with syndrome of inappropriate secretion of antidiuretic hormone, if the underlying cause cannot be corrected, then there are several therapeutic options. Restriction of free water intake to match insensible losses and urine output may be adequate to stabilize the serum sodium concentration. If this is not well tolerated, then administration of furosemide, 1 to 2 mg/kg/day, to promote a hypotonic diuresis together with oral administration of NaCl, 1 to 2 g/day, may correct the hyponatremia. If these measures fail, consideration can be given to treatment with lithium or demeclocycline, two drugs that interfere with AVP action in the collecting tubule to foster excretion of free water and raise the serum sodium concentration (86). Finally, orally active nonpeptide vasopressin antagonists have been developed that may be introduced into clinical practice for the treatment of chronic hyponatremia (87,88).

Hypernatremia

Diagnosis and Evaluation

The causes of hypernatremia are listed in Table 7.9. Hypernatremia may arise owing to excessive intake of sodium and ECF volume expansion. However, excessive water loss relative to the sodium deficit with hypovolemia is far more common. In a recent survey of hypernatremia in hospitalized children, the vast majority had significant underlying medical problems, and 76% of the cases were secondary to inadequate water intake (89). The prevalence of this electrolyte abnormality is much lower than hyponatremia. One of the common causes is diarrheal illness in infants; however, the reduction in the sodium concentration of most baby formulas to match the level in human breast milk has resulted in a

TABLE 7.9. CAUSES OF HYPERNATREMIA

Hypovolemic: ECF volume contraction
Gastrointestinal (diarrhea and vomiting)
Evaporative (high fever, high ambient temperature)
Hypothalamic diabetes insipidus (ADH deficiency)
Head trauma
Infarction (Sheehan's syndrome)
Tumors (e.g., craniopharyngioma)
Histiocytosis
Degenerative brain diseases
Infections
Hereditary central diabetes insipidus (usually dominant)
Idiopathic
Nephrogenic diabetes insipidus (ADH resistance)
Chronic renal failure
Hypokalemia
Hypercalcemia
Damage to renal medulla
Sickle cell disease
Nephronophthisis
Renal papillary necrosis
Chronic pyelonephritis (reflux nephropathy)
Euvolemic: normal ECF volume
Unconscious patients
Infants
Lack of access to water (lost in the desert)
Primary adipsia
Essential hypernatremia (osmoreceptor destruction or malfunction)
Hypervolemic: ECF volume expansion
Inappropriate IV fluid therapy
Salt poisoning
Mineralocorticoid excess

ADH, antidiuretic hormone; ECF, extracellular fluid.

dramatic decrease in the incidence of hypernatremic dehydration. Nonetheless, recent changes in medical practice with early discharge of newborn infants after delivery have resulted in a steady occurrence of hypernatremic dehydration in breast-fed babies (90). Patients with hypernatremia have relative or absolute contraction of the ICW compartment. Similar to the situation with hyponatremia, the clinical clues to the presence of hypernatremia are nonspecific. Therefore, laboratory confirmation is required to diagnose this abnormality. Moreover, the presence of hyponatremia must be evaluated in light of the status of the ECF volume.

Those patients with hypernatremia and ECF volume expansion are easy to diagnose. The children who represent a serious problem are those with hypovolemia. They may have some distinct features, including marked irritability, a high-pitched cry, and a doughy skin texture. Because the hyperosmolality of the ECW compartment provokes movement of water from the ICW down its osmolal gradient, these patients tend to preserve ECF volume until late in the disease course. Thus, their illness is usually chronic, and there is a greater contribution of the ICW to the water and electrolyte deficits. Assessment of the FE_{Na} is useful in assessing the ECF volume in these patients.

Treatment

Because children with hypovolemic hyponatremia are usually very ill, they often require substantial infusions of isotonic saline to restore organ perfusion. Once adequate perfusion is accomplished, the fluid regimen should include the maintenance fluids, the estimated deficit with the assumption that 60% is derived from the ECW and 40% from the ICW. In addition, there is a free water deficit that can be calculated from the following formula:

$$\text{Water deficit (in L)} = 0.6 \times \text{Body weight} \times [(\text{Actual serum sodium concentration}/140) - 1]$$

There is some evidence that this formula may overestimate the water deficit, and it has been recommended that the following alternative equation (91) be used to estimate the change in serum sodium concentration that will be achieved after the infusion of 1 L of a given solution:

$$\text{Change in sodium concentration} = [\text{Infusate Na}^+ - \text{serum Na}^+]/(\text{TBW} + 1)$$

Finally, with regard to the rate of correction, it is standard practice to correct hypovolemic hyponatremia gradually over at least 48 hours. After the groundbreaking work of Finberg et al. (92), the risk of cerebral edema after rapid correction of chronic hyponatremia is now attributed to the inability of brain cells to extrude the osmoprotective solutes that accumulate during sustained hyperosmolar conditions in parallel with the decline in plasma osmolality during fluid therapy (93,94). Therefore, the osmolal gradient is reversed with plasma osmolality lower than cerebral cell osmolality, leading to ICW expansion and clinical signs of cerebral edema. This experimental observation was confirmed in a randomized trial, which demonstrated that the safest and most effective fluid therapy for hypovolemic hyponatremia is 0.18% NaCl given slowly over 48 hours, compared to 0.45% saline given slowly or rapidly over the same time period (95). Because hyperosmolality impairs insulin and parathyroid hormone release, patients should be monitored for hyperglycemia and hypocalcemia during the correction period.

POTASSIUM

GEORGE J. SCHWARTZ

Potassium (K^+) is the most abundant intracellular cation. High concentrations of K^+ in the cytosol are required for many normal cellular functions, including metabolism and growth, cell division, optimal enzyme function, protein and DNA synthesis, volume regulation, and intracellular acid-base balance (1). In addition, a steep concentration gradient of K^+ across the cell membranes is required for nerve excitation and muscle contraction. These functions are achieved by maintaining high intracellular and low extracellular K^+ concentrations. The intracellular and extracellular fluids (ECFs) are separately controlled to maintain K^+ homeostasis. Whereas homeostasis in adults seeks to maintain zero K^+ balance, growing infants and children must accumulate K^+ for growth.

The intracellular K^+ concentration, 100 to 150 mEq/L, far exceeds its concentration in ECF, 3.5 to 5 mEq/L. This transcellular K^+ gradient is maintained by the action of the enzyme Na^+-K^+ -adenosine triphosphatase (Na^+-K^+ -ATPase) in the cell membrane, which pumps Na^+ out of and K^+ into the cell in a 3:2 ratio (2–4). Thus, serum potassium level provides only an indirect estimate of total body K^+ status because it represents only 2% of total body K^+ .

BODY COMPOSITION AND INTAKE

Total body K^+ in adult men, estimated from total body counting of potassium-40, is approximately 50 mEq/kg, and 98% is within cells, mainly muscle (5–8). In proportion to muscle mass, total body K^+ is lower in females than in males (8), and the levels in all adults decline gradually after age 40. During growth, total body K^+ increases linearly with either height or weight without sex-related differences for height and weight below 135 cm and 30 kg, respectively (9,10) (Fig. 8.1). By the onset of puberty, gender-related differences in total body K^+ content develop, even when values are corrected for body weight or height. The rate of increase in body K^+ as a function of growth diminishes in girls (9,10). This change from the male pattern reflects the deposition of adipose tissue, which contains little K^+ (6). In boys postnatal growth is accompanied by an increase in total body K^+ from

approximately 8 mEq/cm body height at birth to more than 14 mEq/cm body height by 18 years of age (9). In absolute terms, total body K^+ in infants (approximately 42 mEq/kg) is less than in older children (approximately 51 mEq/kg), and it increases more rapidly during the first 1.5 years of life than after age 3 (9–11) (Fig. 8.1).

The average intake of potassium in adults is quite variable, ranging from 50 to more than 500 mEq/day (12,13). In the healthy adult, K^+ output balances intake, so that constancy of body K^+ content is maintained. For a typical adult K^+ intake of 1.5 mEq/kg body weight, 90 to 95% is excreted in the urine and 5 to 10% in the stool (Fig. 8.2).

The process of growth requires that the growing organism be able to conserve K^+ and exist in a state of positive K^+ balance (14) to facilitate incorporation of K^+ into dividing cells. Infants fed human milk receive only 13 mEq of K^+ /L (corresponding to 1.8 mEq/100 kcal or 1.8 mEq/kg/day), whereas other milk formulas may provide 1.5 to 3 times this amount (15). Under normal physiologic conditions the K^+ content of breast milk is sufficient, because there is little urinary excretion of K^+ . In addition, the renal K^+ clearance (C_K), even corrected for the low absolute glomerular filtration rate of infants (that is, the fractional excretion of K^+ , or FEK*), is less than in the older child (Table 8.1) (16). This tendency to retain K^+ early in postnatal life is observed in infants, who tend to have higher plasma K^+ concentrations than older children and adults. With maturation of renal K^+ excretion, however, adjustments of K^+ intake are essential. Maintenance K^+ intake in children is 2 to 3 mEq/100 kcal, approximately twice that in adults (17).

The 2% of total body K^+ that is located within the ECF is tightly regulated. Because of the dependence of so many vital processes on K^+ homeostasis and the ratio of intracellular to extracellular K^+ , many mechanisms to regulate serum K^+ concentration and total body K^+ homeostasis

*Fractional excretion of K^+ is the percentage of filtered K^+ that appears in the urine:

$$FEK = \frac{\text{urinary } K^+ \text{ (mEq/L)}}{\text{plasma } K^+ \text{ (mEq/L)}} \times 100\% / \left[\frac{\text{urinary creatinine (mg/dL)}}{\text{plasma creatinine (mg/dL)}} \right]$$

FIGURE 8.1. Total body potassium as a function of weight in males and females 3 to 18 years of age. The shaded regions represent the mean \pm 1 standard deviation for 68% of the population of 432 children. (From Flynn MA, Woodruff C, Clark J, et al. Total body potassium in healthy children. *Pediatr Res* 1972;6:239, with permission.)

have evolved. The cellular volume of distribution for K^+ greatly exceeds that of the ECF volume, and the potential for intracellular redistribution provides protection against abrupt changes in serum K^+ concentrations.

Direct chemical analysis of various nonsecreting mature tissues (e.g., skeletal muscle) has provided estimates of intracellular fluid (ICF) K^+ concentration of 100 to 160 mEq/L (18–20). Comparable studies in the tissues of newborn humans and animals have revealed ICF K^+ concentrations that are 15 to 30% lower than those found in adults (19,21) (Fig. 8.3). The more rapid accretion of K^+ in infants probably reflects both a maturation of intracellular chemical composition and actual cellular growth.

DISTRIBUTION BETWEEN INTRACELLULAR AND EXTRACELLULAR FLUID

Potassium is readily absorbed from the gastrointestinal tract and enters the ECF. Relative constancy of plasma K^+ concentration during entry of K^+ into the ECF is maintained by hormonally mediated temporary shifts of this cation into cells, such as muscle, liver, red cells, and bone (Fig. 8.2) (22). To maintain zero K^+ balance, all of the dietary K^+ must be ultimately excreted, primarily by the kidney. However, the renal excretion of K^+ is rather slow, requiring several hours. Only approximately 50% of an oral load of K^+ is excreted during the first 4 to 6 hours after ingestion (23–25). Protection is achieved within minutes by hormonally mediated translocation of extracellular K^+ into cells (22–27).

Na^+ - K^+ -Adenosine Phosphatase Activity

The high ratio of intracellular to extracellular K^+ concentration is sustained primarily by the action of Na^+ - K^+ -ATPase, the sodium pump. This pump, generally present on the basolateral membranes of polarized epithelial cells, consumes energy (adenosine triphosphatase, or ATP) in the process of transporting three Na^+ ions out of and two K^+ ions into the cell, which generates a negative intracellular

FIGURE 8.2. Potassium homeostasis depends on the maintenance of external and internal K^+ balance. External balance of K^+ in adults is determined by the rate of K^+ intake (approximately 100 mEq/day) and the rate of excretion in the urine (approximately 90 mEq/day) and feces (approximately 10 mEq/day). Internal K^+ balance depends on the distribution of K^+ between muscle, bone, liver, red blood cells (RBC), and extracellular fluid (ECF). (From Giebisch G. Renal potassium transport: mechanisms and regulation. *Am J Physiol* 1998;274:F817, with permission.)

voltage. It is comprised of an α (catalytic) and a β (glycoprotein) heterodimer. The activity of Na⁺-K⁺-ATPase in red cells (28,29), kidney (30–33), and intestine (34) is low early in life, perhaps mediating lower cellular K⁺ concentrations (19,21).

Na⁺-K⁺-ATPase activity is regulated by several hormones, namely, insulin, thyroid hormone, catecholamines, and aldosterone. Long-term stimulation of Na⁺-K⁺-ATPase by aldosterone and thyroid hormone is mediated by changes in gene expression, whereas short-term regulation may be mediated by altered phosphorylation of the pump (catecholamines) or by changes in the surface distribution of pumps (insulin, aldosterone) (35,36). A small rise in ECF K⁺ (from dietary intake, exercise, or acute hyperosmolality) stimulates secretion of these hormones, activating Na⁺-K⁺-ATPase to transport more K⁺ into cells.

Hormone Activity

Insulin is the most important hormonal regulator of interrenal K⁺ balance. Insulin reduces serum K⁺ by promoting the cellular uptake of K⁺, probably by directly stimulating Na⁺-K⁺-ATPase activity (3,22,37,38). Basal insulin levels permissively facilitate K⁺ entry into cells. An acute rise in

plasma K⁺ results in a two- to threefold increase in insulin levels (24,25,39–42).

Catecholamines influence K⁺ distribution, with α receptors inhibiting and β_2 receptors stimulating cellular K⁺ uptake. This results in a biphasic response manifested first by an initial increase followed by a prolonged decrease in plasma K⁺ concentration to below baseline (22). The transient initial rise is due to α -adrenergic receptor stimulation, which causes release of K⁺ from cells, whereas the β_2 -receptor stimulation, via stimulation of adenylate cyclase and generation of cyclic adenosine monophosphate, activates Na⁺-K⁺-ATPase and mediates increased K⁺ uptake by liver and muscle cells (22). Basal epinephrine levels are permissive in stimulating K⁺ uptake by liver, skeletal muscle, adipose tissue, and cardiac muscle (22,23,43). Indeed, the increment in plasma K⁺ concentration after a K⁺ load or exercise is greater and more prolonged if the subject has been pretreated with the beta-blocker propranolol (23,44,45). The administration of a β_2 -adrenergic agonist (albuterol) can reduce plasma K⁺ concentration by stimulating K⁺ uptake by cells and by stimulating insulin release, which independently stimulates K⁺ uptake.

Blood levels of aldosterone are sensitively influenced by plasma K⁺ concentration (46–48). The secretion of aldosterone protects against hyperkalemia primarily by increasing uri-

FIGURE 8.3. Comparison of cellular K⁺ concentration (mEq/L) in the skeletal muscle (slashed bars) and cortical collecting duct (CCD, solid bars) of newborn (NB), 1-month-old, and adult rabbits. nary and colonic K^+ excretion but also by promoting cellular K^+ uptake (13,25,49). Thyroid hormone, glucocorticoids, and growth hormone may also promote the cellular uptake of K^+ by chronically stimulating $Na^+-K^+-ATPase$ (22,35,36).

Plasma K^+ Concentration

An increase in plasma K^+ concentration, independent of aldosterone and other factors, promotes K^+ entry into cells, probably by diminishing the K^+ concentration gradient against which the $Na^+-K^+-ATPase$ -dependent sodium pump must function (24,25,50). Thus, plasma K^+ concentration generally varies directly with body K^+ stores (51). In those cells of the kidney and colon responsible for K^+ secretion, the resulting increase in cellular K^+ concentration enhances secretion by favoring increased K^+ diffusion into the tubular fluid down its concentration gradient.

Acid-Base Balance

Acute changes in acid-base balance may have important effects on K^+ distribution. During mineral-acid-induced acidosis, excessive protons are buffered in the cells and K^+ moves into the ECF, which results in an increase in plasma K^+ concentration; hyperkalemia may ensue (13,52,53). A common rule of thumb states that, for every 0.1-U decrease in blood pH, the plasma K^+ concentration increases by approximately 0.6 mEq/L (13,22,51,53).

Increases in plasma K^+ concentration are generally much smaller in acute organic acid acidosis, such as lactic acidosis and diabetic ketoacidosis (13,51,53–55). The concurrent entry into the cell of the anion with the proton may reduce the necessity for K^+ redistribution. Also, the hyperkalemia often observed in ketoacidosis reflects a larger flux of K^+ from cells to ECF due to insulin deficiency and hyperosmolality rather than to acidemia per se (13,26,51,53).

Acute metabolic alkalosis causes K^+ to shift into cells, with a resulting decrease in plasma K^+ concentration. The effect on serum K^+ concentration is generally smaller (0.2 to 0.4 mEq/L), probably due to the smaller degree of intracellular buffering and transcellular movement of protons (53,56). More prolonged alkalosis usually results in hypokalemia (13,51), due to a shift of K^+ into collecting duct cells that results in enhanced urinary excretion of K^+ . Contributing to the variability of proton load and serum K^+ concentration, the concentration of plasma HCO_3^- itself can reciprocally affect plasma K^+ values, independent of a pH effect (13,53,57). Large changes in plasma K^+ concentration are rarely seen with respiratory acid-base disorders (13,52,53,56).

Exercise

Exercise can cause the release of K^+ from muscle, due in part to the discrepancy between the K^+ exit during depolar-

ization and the reuptake of K^+ by the $Na^+-K^+-ATPase$ sodium pump (58,59). With strenuous exercise, the reduction in ATP within muscle cells stimulates the opening of ATP-dependent K^+ channels, which further promotes an increase in K^+ release from cells (60). Finally, the release of K^+ from the myocyte takes place with H^+ exchange, and the exercise-induced hyperkalemia may result from a reduction in nondiffusible intracellular anions, which accompanies phosphocreatine hydrolysis (59).

Other Conditions

Any condition resulting in cell breakdown leads to the release of K^+ into the ECF and potentially to hyperkalemia (61,62). An acute increase in effective plasma hyperosmolality can also cause K^+ to leave cells, so that the plasma K^+ concentration may rise by 0.3 to 0.8 mEq/L for every 10 mOsm/kg elevation (63–67). Hyperglycemia is a common clinical example of this phenomenon, especially because the rise in ECF K^+ concentration may not be effectively modulated in a diabetic patient lacking insulin secretion (64). With permeant solutes, such as urea or ethanol, plasma hyperosmolality does not result in hyperkalemia, because there is no transcellular osmotic gradient.

RENAL POTASSIUM EXCRETION

Overview of the Renal Contribution to Potassium Homeostasis

Renal regulation of urinary K^+ excretion allows for adjustment of output to equal intake over a wide range. The kidney excretes 90 to 95% of the daily K^+ intake (7). Extreme adjustments cannot be achieved as rapidly as for sodium, nor are they as complete. Maximal rates of K^+ excretion may not be observed until several days after K^+ intake is increased (68). Whereas urinary Na^+ can be reduced to less than 1 mEq/day within 3 to 4 days of Na^+ restriction, a minimum urinary K^+ loss of 5 to 15 mEq/day persists in the adult on K^+ restriction (12,26,69–71).

There is a circadian rhythm of renal K^+ excretion in the adult that is independent of changes in serum aldosterone or K^+ concentration (72–74). The cause of this rhythmic K^+ excretion is unclear, but it may be due to hypothalamic oscillators characterized by maximum output during times of peak activity. In children, one study has shown no diurnal variation in urinary K^+ excretion (75).

Growing individuals maintain a state of positive K^+ balance (14,18). The relative conservation of K^+ early in life is generally associated with higher plasma K^+ values* than in

*Serum K^+ concentration runs approximately 0.5 mEq/L higher than in plasma, due to the release of K^+ from cells during clotting (78).

the adult (14,76–78). Our own study of healthy human infants shows that plasma K⁺ concentrations during the first 4 months of life average 1 mEq/L higher than in infants older than 1 year of age (Table 8.1).

FEK (Table 8.2) provides an additional assessment of renal K⁺ handling under various physiologic and pathophysiologic states. Normally, FEK ranges from 10 to 30%, but FEK usually exceeds 40% and urinary Na⁺/K⁺ ratio is less than 1 with enhanced mineralocorticoid activity. During K⁺ conservation FEK is less than 10% with urinary Na⁺/K⁺ ratios exceeding 2 or 3.

Children and adults ingesting a regular diet containing Na⁺ in excess of K⁺ excrete urine with an Na⁺/K⁺ ratio higher than 1 (Table 8.1) (76,77). Although the Na/K ratios of breast milk and commercial infant formulas are approximately 0.5 (15), the urinary Na/K ratio of the newborn also generally exceeds 1, due in part to a physiologic natriuresis, as well as preferential retention of K⁺ as a function of growth. Premature infants may show urinary Na⁺/K⁺ ratios above 4, which reflects a relative hyporesponse-ness of the distal tubule and collecting duct to mineralocorticoid activity in addition to the substantial natriuresis that occurs during this period of gestation (14).

The renal adaptation to chronic K⁺ loading is due primarily to an enhanced capacity for individual nephrons to secrete K⁺. Infants can excrete K⁺ at a rate that exceeds its filtration, which indicates the capacity for net tubular secretion (79); however, they cannot do this as rapidly or as efficiently as can adults (80–82).

Sites of Potassium Transport in the Kidney

The nephron sites of K⁺ handling have been ascertained by micropuncture and *in vitro* micropuncture studies (Fig. 8.4). Filtered K⁺ is reabsorbed mainly in proximal segments of the nephron, whereas the urinary K⁺ is derived primarily from distal K⁺ secretion. Although small amounts of K⁺ are

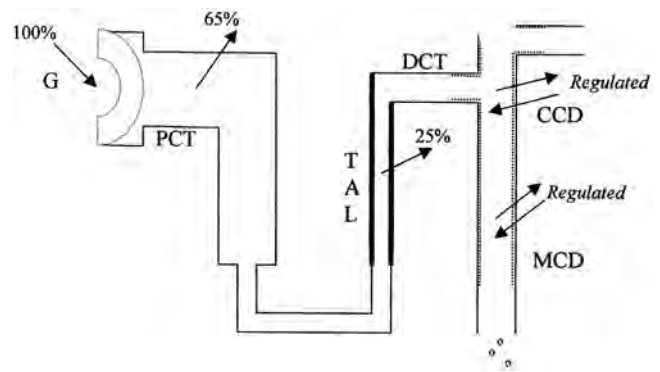

FIGURE 8.4. Schematic of K⁺ transport along the nephron. Reabsorption occurs in the proximal tubule and thick ascending limb of the loop of Henle. The excretion of K⁺ during varied K⁺ intake is mainly regulated by the distal nephron (areas indicated by the dotted lines in the lumens). The handling of K⁺ in the collecting duct during K⁺ depletion is also influenced by reabsorptive processes mediated by H⁺-K⁺-ATPase in the collecting duct, a subject of active investigation. CCD, cortical collecting duct; DCT, distal convoluted tubule; G, glomerulus; MCD, medullary collecting duct; PCT, proximal convoluted tubule; TAL, thick ascending limb of loop of Henle.

lost each day in the stool (5 to 15 mEq) (83,84) and sweat (0 to 10 mEq) (26), K⁺ homeostasis is regulated in large part by the rate of K⁺ secretion in the distal nephron.

Segmental Potassium Transport

The renal handling of K⁺ requires filtration at the glomerulus, reabsorption in the proximal nephron, and secretion by the distal tubule and cortical collecting duct (1,85). Micropuncture studies in adult rats by Malnic et al. (86) (Fig. 8.5) examined the clearance of K⁺ factored by that of inulin. After being freely filtered at the glomerulus, K⁺ is nearly completely reabsorbed in the proximal tubule and thick ascending limb of the loop of Henle, as seen by the progressive decrease in K⁺/inulin (K/In) along the proximal nephron (Fig. 8.5). Proximal K⁺ reabsorption is passive after that of Na⁺ and water; 60 to 65% of the filtered K⁺ load is reabsorbed in the proximal tubule of the adult rat (86) (Fig. 8.6A) (87), a fraction similar to that observed in the immature rat (88–91).

In the adult rat, only 5 to 15% of the filtered load of K⁺ reaches the superficial distal tubule, which reflects further significant net reabsorption by the intervening nephron segments (86). Indeed, an additional 20 to 30% of the filtered load of K⁺ is reabsorbed along the thick ascending limb of the loop of Henle, so that by the time the tubular fluid reaches the distal convoluted tubule, as little as 10% of the filtered K⁺ load remains (K⁺/In of <0.1; Fig. 8.5). The avid reabsorption of K⁺ in the thick ascending limb is mediated by apical uptake through a secondary active electroneutral Na⁺-K⁺-2Cl⁻ co-transporter driven by the electrochemical gradient for Na⁺ that is generated by the basolateral Na⁺-K⁺-ATPase activity (Fig. 8.6B). There is passive K⁺ exit across the

FIGURE 8.5. Determination of tubular fluid to plasma concentration ratios of potassium to inulin $[K/I_n (TF/P)]$ as a function of tubular length along the nephron in rats undergoing hypertonic NaCl administration. (From Malnic G, Klose RM, Giebisch G. Micropuncture study of distal tubular potassium and sodium transport in rat nephron. *Am J Physiol* 1966;211:529, with permission.)

basolateral membrane by diffusion through K^+ channels or by co-transport with chloride or bicarbonate (85). There is also K^+ recycling back across the apical membrane through a K^+ channel, which assures adequate amounts of K^+ for the

$Na^+-K^+-2Cl^-$ co-transporter and generates a positive potential in the lumen. The molecular identification of this apical channel is ROMK (rat outer medullary K^+ channel) (92–94). Mutations in ROMK have been identified in patients with

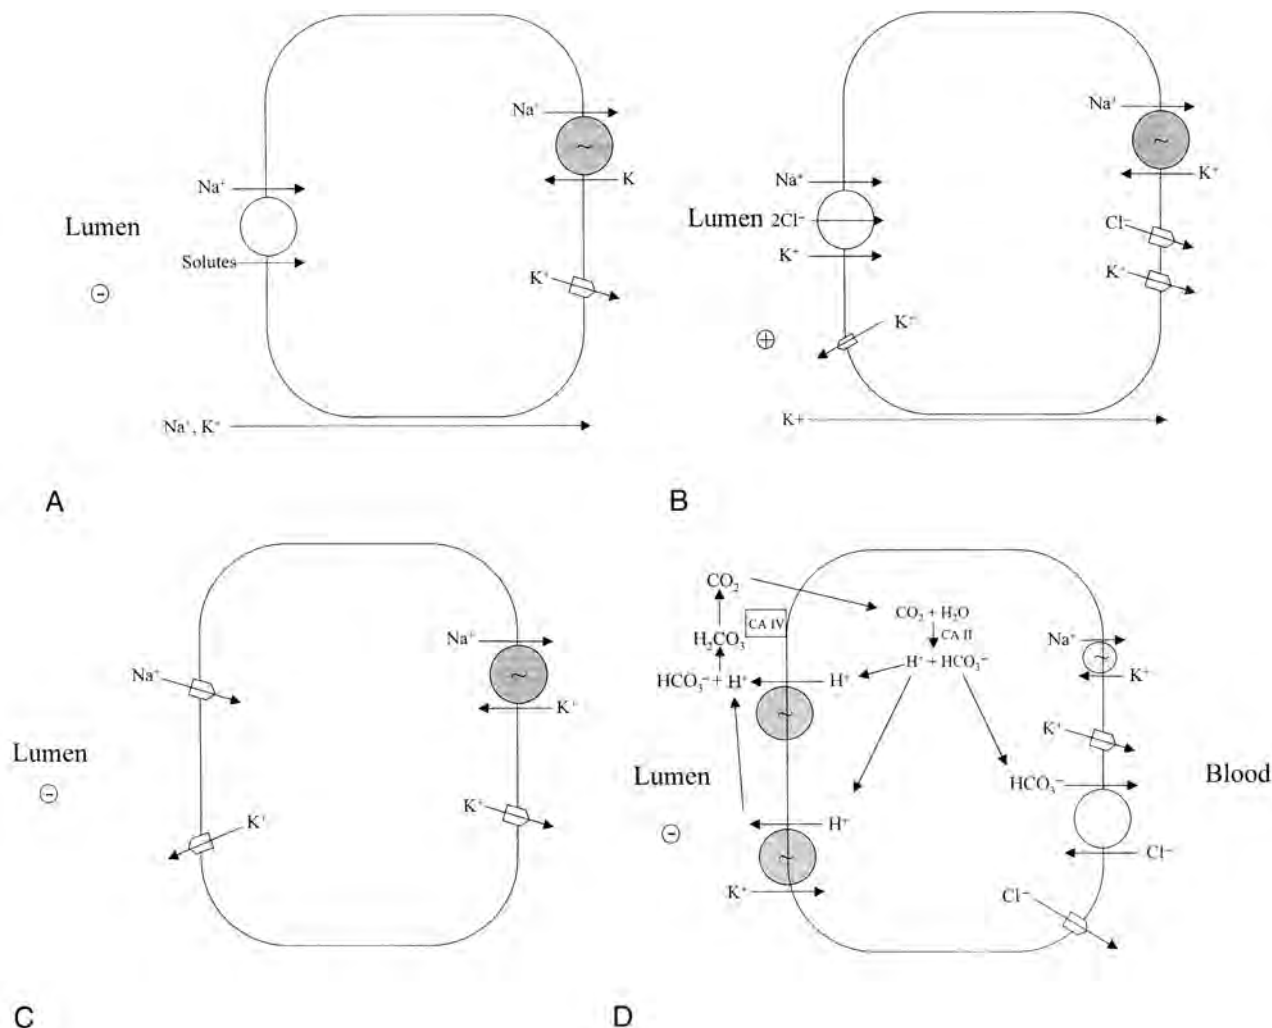

FIGURE 8.6. Cell models of K^+ transport pathways across apical and basolateral membranes and paracellularly through the tight junction. **A:** Proximal tubule. **B:** Thick ascending limb. **C:** Principal cell. **D:** Type A intercalated cell or outer medullary collecting duct cell. The circles enclosing the “~” indicate primary active transport; open circles indicate exchangers. Channels are denoted by the pentagonal figures in the membranes. Bartter's syndrome, an inherited disease characterized by hyperreninemic hypokalemic metabolic alkalosis with secondary hyperaldosteronism and normal blood pressure (95). Significant amounts of K^+ are also reabsorbed via the paracellular pathway across the thick ascending limb, driven by the electropositive potential. The net reabsorption of K^+ in this segment can be changed to net K^+ secretion if the $Na^+K^+2Cl^-$ co-transporter is inhibited by loop diuretics.

The elevation of the K^+/In ratio along the distal tubule indicates that K^+ has been secreted into the tubular fluid. Potassium is secreted by the late distal tubule (initial collecting tubule), connecting segment, principal cells of the cortical and medullary collecting duct (Fig. 8.6C), and, under certain circumstances, the inner medullary collecting duct (7,86,96–100). Under conditions of excessive K^+ intake or depressed glomerular filtration rate, the rate of K^+ secretion may become so high that the net K^+ excretion rate exceeds the filtered load (86,101–103).

Secretion of K^+ in the distal nephron occurs in principal cells by Na^+K^+ -ATPase-mediated active uptake of K^+ across the basolateral membrane (4) and passive diffusion through secretory channels across the apical membrane into the luminal fluid (Fig. 8.6C). The magnitude of K^+ secretion depends on its electrochemical gradient and apical permeability. The electrochemical gradient is generated by the cell to lumen ratio of K^+ concentrations and the lumen-negative potential, which is driven by apical Na^+ entry through epithelial Na^+ channels (ENaCs) and transcellular Na^+ flux. The active cellular uptake of two K^+ ions in exchange for the extrusion of three Na^+ ions (via Na^+K^+ -ATPase at the basolateral membrane) generates a negative intracellular voltage with respect to the blood. Cell K^+ is then secreted passively down a favorable electrochemical gradient into the lumen through apical K^+ -selective channels (104–106). The small conductance channel has a high open probability and is regulated by ATP. Its molecular identification is ROMK (93,94,107), and it is considered to mediate basal K^+ secretion (85,105,106). It has two potential membrane-spanning helices flanking a region that forms part of the channel pore in the voltage-gated K^+ channel (108). The channel has a unitary conductance of 30 to 40 picosiemens, high K^+/Na^+ selectivity, weak inward rectification, sensitivity to external Ba^{2+} , and marked inhibition to decreases in cytosolic pH within the physiologic range (108). The inward rectification permits significant outward K^+ current, as for K^+ secretion from principal cells. This same ROMK channel (105,106,108) is present in the apical membrane of thick ascending limb cells and therein allows the $Na^+K^+2Cl^-$ co-transporter to function optimally by providing readily available substrate, K^+ (109) (Fig. 8.6B). There is also a high-conductance, stretch- and calcium-activated maxi-K channel that is likely to mediate flow-stimulated K^+ secretion (110).

The lumen-negative potential in the cortical collecting duct, generated by apical Na^+ entry and electrogenic baso-

lateral extrusion (via Na^+K^+ -ATPase), promotes both the secretion of K^+ and the paracellular reabsorption of Cl^- . Thus, the major determinants of passive K^+ secretion are the difference between cell and tubular fluid K^+ concentrations, the transepithelial negative voltage driven by Na^+ reabsorption through apical Na^+ channels, and the number of open K^+ channels in the luminal membrane.

Potassium reabsorption has been localized morphologically to collecting duct intercalated cells in the cortex and medulla (111–113). Distal K^+ secretion can be partially offset by this K^+ reabsorptive process in the cortical and medullary collecting ducts (112,114) and in the inner medullary collecting duct (96,115). This process is probably due to a luminal H^+K^+ -ATPase (Fig. 8.6D) in the collecting duct, an enzyme that exchanges a single K^+ ion for a proton while consuming ATP and thereby mediating both H^+ secretion and K^+ reabsorption (116–120). It is likely that both α and β intercalated cells express H^+K^+ -ATPase (1,112,121). Several isoforms of H^+K^+ -ATPases have been identified in the kidney, and they share some identity with the gastric and colonic ATPases (121–123). The activity of H^+K^+ -ATPase is increased by K^+ depletion and reduced by K^+ loading (111,119–121,124). The adaptation with severe K^+ depletion results in net K^+ reabsorption along the distal nephron (86,111,113).

Medullary K^+ recycling occurs when the K^+ reabsorbed in the thick ascending limb enters the medullary interstitium and is then secreted into the late proximal tubule or thin descending limb of the loop of Henle; this additional K^+ is reabsorbed when it enters the outer medullary collecting duct (125–128). This recycling of K^+ in the medulla results in a relatively high concentration of K^+ in the interstitium that tends to favor K^+ excretion by decreasing the gradients for passive K^+ efflux out of the collecting duct and thick ascending limb (7,129).

Factors Affecting K^+ Secretion in the Cortical Collecting Duct

Whereas 90% of filtered K^+ is reabsorbed in the proximal tubule and thick ascending limb, total body K^+ homeostasis is maintained by regulation of K^+ secretion along the distal nephron. The cortical collecting duct is the main regulatory site of K^+ secretion, capable of generating luminal K^+ concentrations in excess of 100 mmol/L in the adult (98). The principal cell of this cortical collecting duct secretes K^+ and absorbs Na^+ . The major regulators of distal K^+ secretion are listed in Table 8.3.

Aldosterone

Aldosterone secretion rises after a K^+ load (130). Mineralocorticoids stimulate net sodium reabsorption and potassium secretion in the principal cells of the cortical collecting duct and adjacent cells of the connecting segment (97,131–134).

TABLE 8.3. FACTORS AFFECTING K⁺ SECRETION IN THE CORTICAL COLLECTING DUCT

Aldosterone activity
Cell K ⁺ concentration
Tubular flow rate
Luminal Na ⁺ concentration
Luminal nonreabsorbable anion
Acid-base balance
Other hormones

Aldosterone binds to mineralocorticoid receptors of principal cells; the hormone-receptor complex is translocated to the nucleus, which results in activation of transcription and synthesis of physiologically active proteins (135). Cellular effects of aldosterone include an early enhancement in apical Na⁺ permeability; this in turn increases the basolateral Na⁺-K⁺-ATPase turnover rate, which results in increased cell K⁺ concentration (132,136–138). Later effects include increases in basolateral membrane infolding, insertion of additional Na⁺-K⁺-ATPase pumps into the membrane, and an increase in the apical K⁺ conductance as K⁺-channel density increases (105,134,136,137,139–142). Stimulation of Na⁺ reabsorption leads to an increase in lumen negative transepithelial voltage, which further favors K⁺ secretion (97,132,134,142). Mineralocorticoids stimulate both the electrochemical gradient and luminal membrane permeability across the principal cell, which results in increased K⁺ secretion and Na⁺ reabsorption (97,132,133,143,144). Prolonged administration of mineralocorticoids leads to a persistent kaliuresis but only a transient phase of Na⁺ retention (143–145). After a significant extracellular volume expansion to a new steady state, there is a subsequent diuresis, which returns plasma volume toward normal (143,146). This “escape” phenomenon is probably due to decreased Na⁺ reabsorption in some other nephron segment (147).

Plasma K⁺ Concentration

The serum K⁺ concentration directly affects renal K⁺ excretion (130). An increase in dietary K⁺ intake results in a transient rise in plasma K⁺ concentration (50), which in turn stimulates renal potassium excretion and the adrenal release of aldosterone (68,99,130,148). The elevation in serum K⁺ concentration favors the entry of K⁺ into principal cells across the basolateral membrane and thereby drives K⁺ secretion across the luminal membrane (149,150). Aldosterone enhances the electrochemical gradient, driving K⁺ secretion in the distal tubule and collecting duct. In addition, plasma K⁺ elevation, through unknown mechanisms, increases Na⁺ reabsorption, luminal Na⁺ permeability, and Na⁺-K⁺-ATPase activity independently of aldosterone (105,151–153). Also, a high-K⁺ diet can induce increases in K⁺ channel density in the apical membranes of principal cells (105,154).

In the first 4 hours after an exogenous K⁺ load, approximately one-half is excreted by the kidneys, whereas the rest

is distributed into cells (22). The rise in plasma K⁺ concentration is transient, because only a small fraction of the K⁺ load remains in the ECF. After the initial cell sequestration of K⁺, the kidneys continue to excrete K⁺ at an accelerated rate until the excess is eliminated and balance is restored (1,22,68). Most of the increase in urinary K⁺ excretion is mediated by a rise in K⁺ secretion by the distal tubule (99,155–158) and cortical collecting duct (159–163). An elevation of plasma K⁺ concentration may also be modulated by K⁺ uptake into cells of the proximal tubule, which results in decreased cellular H⁺ concentration and thereby decreased HCO₃⁻ reabsorption. This proximal effect serves to increase tubular flow rate, which, in combination with increased cellular K⁺ activity and aldosterone-induced effects, serves to increase urinary K⁺ excretion (99).

Habitual ingestion of a high-K⁺ diet leads to an acquired tolerance to K⁺ in the distal nephron, an adaptation that augments the capacity of each individual nephron to secrete K⁺ (164). In the principal cell, the cellular mechanisms underlying this adaptation include increases in basolateral surface area, Na⁺-K⁺-ATPase activity, and density of apical membrane K⁺ and Na⁺ channels; increased cellular K⁺ concentration; and increased transepithelial voltage along the distal nephron (150,152,154,164,165–169)—events that together enhance K⁺ movement from cell to lumen. The morphologic correlate of this adaptation is the major increase in basolateral membrane surface area, the site at which the Na⁺-K⁺-ATPase pumps are inserted (113). Distal K⁺ secretion at comparable levels of serum K⁺ concentration is approximately three times higher in K⁺-adapted rats (99,113). A similar adaptive response seen in chronic renal insufficiency (170,171) allows K⁺ balance to be relatively well maintained during the course of many forms of progressive renal disease. Finally, gastrointestinal excretion of K⁺ can increase in response to K⁺ loading or renal insufficiency to help maintain K⁺ balance (172,173).

When there is chronic K⁺ depletion, there is less K⁺ secretion (86,113,174), due in part to decreased release of aldosterone and, later, diminished cellular K⁺ concentrations (175). There is also an increase in active K⁺ reabsorption by cortical and medullary intercalated cells expressing the luminal H⁺-K⁺-ATPase pump (111,113,124). This response is associated with morphologic alterations to increase luminal surface area in the intercalated cells (112).

Tubular Flow Rate

K⁺ secretion is strongly influenced by the rate of tubular fluid flow and the concentration of K⁺ in the tubular fluid (151,176–178). The higher the distal flow rate, the slower the rate of rise in tubular fluid K⁺ concentration and the larger the driving force favoring additional K⁺ secretion (149,177,178). Thus, volume expansion and diuretics, which increase distal delivery rates, enhance K⁺ secretion in the distal nephron. By causing a concomitant reduction in

extracellular volume, diuretics also stimulate aldosterone secretion, which further favors K^+ secretion.

Increased distal flow is usually associated with increased distal Na^+ delivery. The increased availability of Na^+ at distal sites results in two additional factors favoring K^+ secretion (177,179). First, the increase in Na^+ entry across the apical channels makes the luminal potential more negative, which creates a more favorable electrochemical gradient for K^+ secretion. Second, the increase in Na^+ transport makes more K^+ available to the cell via the basolateral Na^+ - K^+ -ATPase pump; the higher cell K^+ concentration stimulates distal K^+ secretion.

Relevant to flow dependence, the high-conductance maxi-K channel, which is not open at physiologic membrane potentials, can be activated by membrane depolarization, elevation of intracellular Ca^{2+} concentration, membrane stretch, or hypoosmotic stress (180). One study shows that high urinary flow rates and hydrostatic pressure alter intracellular Ca^{2+} or the membrane stretch to which renal epithelial cells are exposed, thereby stimulating apical stretch- and Ca^{2+} -activated maxi-K channels (110). Stimulation of these maxi-K channels is likely to mediate flow-dependent K^+ secretion in the cortical collecting duct, whereas baseline K^+ secretion occurs through the small-conductance ROMK channel.

Na^+ Concentration

The effect of luminal Na^+ concentration on the magnitude of K^+ secretion is determined by the entry of Na^+ into the cell across the apical membrane (149,178,181). In addition to increasing luminal electronegativity, enhanced Na^+ movement from the tubular fluid into the principal cell depolarizes the apical cell membrane, stimulates Na^+ - K^+ -ATPase activity, and accelerates basolateral K^+ uptake (149,181). The net effect of these events is creation of a more favorable electrochemical gradient driving passive diffusion of K^+ from cell to lumen. Maneuvers that decrease active Na^+ transport (e.g., blockers of Na^+ channels, such as the K^+ -sparing diuretic amiloride) attenuate the lumen negative potential difference and thereby reduce K^+ secretion (177).

Once the luminal Na^+ concentration falls below 35 mEq/L, K^+ secretion declines and the transepithelial voltage becomes less negative (162,178,179). The decrease in Na^+ uptake into the principal cell hyperpolarizes the apical membrane and decreases the electrochemical gradient favoring K^+ secretion into the lumen. A reduction in cell Na^+ concentration also reduces the activity of the basolateral Na^+ - K^+ -ATPase pump, thereby further reducing K^+ secretion.

Prolonged increases in Na^+ delivery resulting from long-term diuretic treatment will augment the basolateral membrane area of distal convoluted tubule cells, connecting tubule cells, and principal cells (182–185). This structural adaptation is accompanied by increased Na^+ reabsorption

and K^+ secretion, which results in a downstream attenuation of the diuretic-induced natriuresis and an increase in the kaliuresis.

Nonreabsorbable Anion

Anions are generally reabsorbed in the cortical collecting duct via the paracellular route, after the active transport of Na^+ . The delay in the reabsorption of the anion creates the negative transepithelial difference (186). Distal delivery of Na^+ accompanied by an anion that is less reabsorbable than chloride, such as sulfate, bicarbonate, β -hydroxybutyrate, or carbenicillin, leads to an increase in luminal electronegativity in the cortical collecting duct; this further stimulates K^+ secretion (187–189), occasionally with clinical consequences (190).

Acid-Base Balance

Acute metabolic acidosis causes the urine pH and K^+ excretion to decrease, whereas both acute respiratory alkalosis and metabolic alkalosis result in increases in urine pH and K^+ excretion. Chronic metabolic acidosis has variable effects on urinary K^+ excretion. Metabolic changes in ECF pH produce reciprocal H^+ and K^+ shifts between cells. During acute acidemia, H^+ is taken up by cells while K^+ moves out of cells, and this tends to reduce K^+ secretion; in acute alkalemia, on the other hand, H^+ comes out of cells and K^+ moves into cells, and this tends to increase K^+ secretion (150,191–194). Moreover, a decrease in the pH of tubular fluid, as would be expected during metabolic acidosis, in itself inhibits K^+ secretion in the cortical collecting duct (192,195,196). Data indicate that cell acidification suppresses and cell alkalization stimulates activity of the apical pH-sensitive K^+ secretory channels (176). Furthermore, low pH inhibits Na^+ - K^+ -ATPase activity (1), which reduces K^+ uptake and K^+ secretion in the distal nephron.

The effect of chronic acid-base disturbances on K^+ secretion is more complex and may be overridden by modifications of the glomerular filtrate (e.g., Cl^- and HCO_3^- concentration), tubular fluid flow rate, and circulating aldosterone levels (197–199). Indeed, chronic metabolic acidosis is a potent stimulus of renal K^+ excretion (192,193,200–203). Presumably, the acidosis causes hyperkalemia, which stimulates aldosterone secretion, and this results in the high rate of urinary K^+ excretion in this acid-base disorder. In addition, a reduction in plasma HCO_3^- inhibits fluid and Na^+ reabsorption in the proximal tubule, which leads to increased fluid and Na^+ distal delivery (192). The development of volume depletion that also results from this proximal inhibition stimulates the secretion of aldosterone, which further increases K^+ secretion. Thus, in contrast to acute metabolic acidosis in which K^+ secretion is reduced, chronic acidosis overrides this inhibition by inducing aldosterone- and flow-dependent K^+ secretion. The handling of K^+ in the organic acidurias (lactate, β -hydroxybutyrate) is domi-

nated by the increased distal delivery of Na^+ with a poorly reabsorbable anion, plus volume depletion that stimulates aldosterone secretion—effects that offset those of acute acidosis and stimulate net distal K^+ secretion and ultimately K^+ depletion in the body (26).

Other Hormones

Glucocorticoids stimulate K^+ excretion through their action to enhance glomerular filtration, distal Na^+ delivery, and rate of urinary flow (133,204,205). The administration of vasopressin causes a small increase in urinary K^+ excretion despite a reduction in urinary flow rate, due in large part to an increase in the electrochemical driving force for K^+ secretion across the luminal membrane (206–208). Specifically, there is a vasopressin-induced initial increase in apical Na^+ permeability that leads to apical membrane depolarization, basolateral Na^+ - K^+ -ATPase activation with enhanced K^+ uptake, and increased K^+ secretion into the tubular fluid (155,209). In addition, the vasopressin-induced stimulation of K^+ secretion may also reflect an increase in density of apical K^+ secretory channels in the principal cell (210). Catecholamines decrease urinary K^+ excretion both directly and indirectly through catecholamine-induced alterations in renal hemodynamics and cell K^+ uptake in the liver and muscle (43,211). In addition, β -adrenergic agonists directly inhibit K^+ secretion in the cortical collecting duct via modifications in chloride transport and transepithelial voltage (212,213).

CONTRIBUTION OF THE GASTROINTESTINAL TRACT

In the adult under normal conditions, approximately 10% of daily K^+ intake is excreted in the stool (Fig. 8.2). The gastrointestinal tract normally absorbs approximately 85% of dietary K^+ . This process is substantially more efficient in the neonate, probably related to a higher activity of K^+ -absorptive pumps (214,215). The general pattern of K^+ handling by the intestine parallels that of the nephron, and the primary site of regulation of intestinal K^+ transport is the colon. Most dietary K^+ is absorbed along with water in the small intestine (84,214,216), so that a low volume of fluid with a high K^+ concentration is delivered to the colon. The direction of net K^+ transport in the colon, as in the distal nephron, is determined by the balance between K^+ secretion and K^+ absorption (172,217). In the colon, K^+ secretion requires basolateral uptake of K^+ via the Na^+ - K^+ -ATPase pump and Na^+ - K^+ - 2Cl^- co-transporter and its secretion across the apical membrane via K^+ channels (218). The absorption of K^+ is mediated by apical K^+ -dependent ATPases, including a colonic H^+ - K^+ -ATPase (214,215).

Hormones (aldosterone, glucocorticoids, epinephrine, and prostaglandins) stimulate K^+ colonic secretion (22,219). A high- K^+ diet also stimulates colonic K^+ secretion (220). In

addition, glucocorticoids stimulate maturation of neonatal colon K^+ secretion by opening up apical K^+ channels and increasing the activity of Na^+ - K^+ -ATPase (221,222). On the other hand, colonic K^+ secretion is inhibited by indomethacin and dietary K^+ restriction. Diarrheal illnesses are typically associated with hypokalemia, despite an adaptive reduction in renal K^+ excretion. Mucosal inflammation reduces K^+ absorption, whereas cyclic adenosine monophosphate-stimulated secretion during rotaviral enteritis may contribute to inappropriate colonic K^+ excretion (223).

Potassium adaptation in the colon is demonstrated by increased fecal K^+ excretion under conditions of K^+ loading (trauma, renal tubular K^+ secretory disorders, excessive K^+ intake), especially when exacerbated by renal insufficiency (164). Whereas stool K^+ content averages 5 to 10% of dietary intake in healthy adults, fecal K^+ excretion may triple in patients with severe renal insufficiency (22,172).

MATURATION OF RENAL K^+ TRANSPORT

Newborns fed breast milk or formula with an Na^+/K^+ ratio of 0.5 to 0.6 demonstrate significant renal K^+ retention with an average urine Na^+/K^+ higher than 1 (Table 8.1). This relative conservation of K^+ in the newborn and immature animal is generally associated with a higher plasma K^+ concentration than in the adult and is a requirement for somatic growth (14,76,77,88,224). Clearance and micropuncture studies in the newborn consistently demonstrate low rates of urinary K^+ excretion under basal conditions (88,225,226) and an inability to excrete an exogenously administered potassium load as efficiently as the adult (14,79–82). Acute K^+ loading of experimental animals results in significantly lower rates of urinary K^+ excretion in weaning than in older rats (Fig. 8.7)

FIGURE 8.7. Renal K^+ excretion after intragastric KCl loading (0.7 mmol/100 g body weight) in unanesthetized infant (PN20) and adult (PN50) rats. Values are means \pm the standard error of the mean; asterisks indicate statistically significant difference between infant and adult rats. bw, body weight.

FIGURE 8.8. Maturation of net K⁺ secretion in cortical collecting ducts obtained from 1-, 2-, 3-, 4-, 6-, and >8-week-old (adult) rabbits. Mean values plus standard error are given for each age group. *, $p < .05$ versus >8-week-old (adult). (Data from the Satlin LM. Postnatal maturation of potassium transport in rabbit cortical collecting duct. *Am J Physiol* 1994;266:F57.)

(215). Whereas infants, like adults, can excrete K⁺ at a rate that exceeds its filtration (79), the rate of K⁺ excretion expressed per unit of body or kidney weight is less than that observed in older subjects (80,82,214).

Micropuncture studies have shown that approximately 50% of the filtered load of K⁺ is reabsorbed in the proximal tubule of both suckling and older rats (88,90). However, up to 35% of the filtered load of K⁺ reaches the superficial distal tubule of the 13- to 15-day-old rat, which far exceeds the distal delivery measured in older animals and indicates functional immaturity of the loop of Henle (88,227). The fractional reabsorption of K⁺ along the loop of Henle, expressed as a percentage of delivered load, increases from 57% at 13 to 15 days to 79% by 30 to 39 days of age (88).

Because the fractional excretion of K⁺ in the immature rat is approximately the same as the percentage of the load delivered to the superficial distal tubule (88), it is likely that there is little net K⁺ secretion along the immature distal nephron. Evidence indicates that the limitation in K⁺ excretion is due, at least in part, to a greatly reduced K⁺ secretory capacity of the cortical collecting duct early in life. Clearance experiments in saline-loaded puppies have provided indirect evidence for diminished capacity of the immature distal nephron to secrete K⁺ (225). Comparison of early distal tubular fluid and final urine in the newborn suggests that the immature distal tubule and cortical collecting duct secrete less K⁺ than do more mature segments (88).

Micropfusion experiments in rabbit cortical collecting ducts have conclusively shown that net K⁺ secretion is absent at birth, first becomes evident at the fourth postnatal week, and increases sharply to reach adult levels by 6 weeks of age (Fig. 8.8) (228). These data indicate that the low rates of K⁺ excretion characteristic of the newborn kidney are due, at least in part, to a low capacity for K⁺ secretion by the immature cortical collecting duct. Whereas K⁺ secretion in the mature cortical collecting duct is strongly stimulated by an increase in luminal flow rate, this is not observed in early life, at least until 6 weeks postnatally. Indeed, the developmental appearance of flow dependence 2 weeks after the appearance of basal K⁺ secretion suggests that basal and flow-stimulated

K⁺ secretion are mediated by distinct channels with different developmental patterns of expression (229).

Ultrastructural comparison of principal cells from newborn and adult cortical collecting ducts lends support to the observation of relative functional immaturity of the K⁺ secretory epithelium early in life (21,230). Whereas the principal cell of the neonatal cortical collecting duct possesses few organelles, smooth apical and basolateral surfaces, varying amounts of intracellular glycogen, and a low volume of mitochondria, the mature principal cell is devoid of glycogen and possesses twice the volume percentage of mitochondria, has more organelles and basolateral infoldings, and has a 35% larger apical perimeter (230).

Factors Limiting K⁺ Secretion in the Cortical Collecting Duct

Several factors may limit urinary K⁺ secretion in the neonatal principal cell, including an unfavorable electrochemical gradient (low cell K⁺, low Na⁺-K⁺-ATPase activity, and/or low transepithelial voltage), high backleak of K⁺ through paracellular routes, limited membrane permeability to K⁺, low tubular fluid flow rates, and diminished principal cell sensitivity to mineralocorticoids. Alternatively, enhanced K⁺ absorption by intercalated cell-rich distal nephron segments (e.g., inner cortical collecting duct, outer medullary collecting duct) may offset much of the distal K⁺ secretion.

Na⁺-K⁺-ATPase

The high cellular potassium concentration is generated and maintained by the activity of Na⁺-K⁺-ATPase. Na⁺-K⁺-ATPase activity in the neonatal cortical collecting duct is only 50% of that measured in the mature segment, when expressed per unit of dry weight (32), in keeping with the smaller number of basolateral infoldings observed in neonatal principal cells (230). This lower level of Na⁺-K⁺-ATPase activity in the immature cortical collecting duct results in a reduced electrochemical K⁺ gradient across the apical membrane. If one assumes that principal cell K⁺

activity is similar in neonatal and mature collecting ducts (21), it is likely that the low rate of Na^+ - K^+ -ATPase activity observed early in life must be accompanied by a proportionally low rate of passive K^+ efflux from immature principal cells. The efflux of K^+ may be limited by an unfavorable electrochemical gradient opposing secretion, reduced apical membrane K^+ permeability, or low tubular flow rates prevailing in the neonate.

Flow Rate

The low distal flow rates characteristic of the newborn (88,231,232) could limit K^+ secretion early in life. To address the role of flow rate on K^+ secretion, Satlin measured the rates of K^+ transport in cortical collecting ducts. Flow-dependent stimulation of K^+ secretion was not observed until 6 weeks postnatally (228). These studies rule out a low *in vivo* tubular flow rate per se as a factor limiting K^+ secretion in the neonatal kidney.

Micropuncture studies in maturing rats show that the early distal tubular fluid concentration of K^+ decreases during maturation from 4.5 to 2.3 mmol/L (88,90). The higher K^+ concentration in the youngest rats reflects, in part, immaturity of K^+ reabsorption by the thick ascending limb of the loop of Henle. These data suggest that only a small increase in distal nephron K^+ secretion could be accounted for by this maturational decrement in chemical gradient along the collecting duct. Thus, the chemical driving force for K^+ secretion across the apical membrane of the principal cell appears to remain relatively constant after birth (228).

Electrical Gradient

The luminal electronegativity of the cortical collecting duct, driven by electrogenic Na^+ absorption (97,162), favors K^+ secretion from principal cell to lumen. Measurements of transepithelial voltage in cortical collecting ducts early in life have shown maturational increases from a few millivolts negative at birth to approximately 10 mV negative in the adult (228,233). These findings suggest that a smaller electrical gradient slightly limits K^+ secretion in the neonatal cortical collecting duct. Microperfused cortical collecting ducts isolated from 1-week-old rabbits show no significant Na^+ absorption (228). By 2 weeks of age the rate of net Na^+ absorption is approximately half that observed in cortical collecting ducts taken from mature animals. Concomitant with the postnatal increase in Na^+ absorption is a parallel increase in negativity of transepithelial voltage (228).

Finally, to secrete K^+ , the principal cell requires functioning apical Na^+ channels to provide Na^+ for the Na^+ pump. The rate-limiting step for Na^+ absorption appears to be the expression of the apical Na^+ channel. Using patch-clamp analysis of the maturing rabbit principal cell, Satlin and Palmer (234) found that by 2 weeks of age the number of open Na^+ channels per patch reached a value similar to

that observed in 5-week-old animals. The increase in the number of conducting channels is due to both an increase in the number of channels present per patch plus an increase in open probability (234). Thus, the presence of conducting Na^+ channels in the maturing cortical collecting duct approximately 1 week before net K^+ secretion is observed suggests that a low rate of Na^+ entry into the principal cell does not limit K^+ secretion early in life, unless little Na^+ is delivered to the distal nephron. *In vivo* measurements of distal tubular Na^+ concentrations in both adult and maturing rats generally exceed 30 mEq/L (86,88,179,232), which rules out the possibility that very low luminal Na^+ concentrations contribute to the reduced rate of distal K^+ secretion in the newborn.

Backleak

Paracellular K^+ conductance may be increased through leaky tight junctions in immature proximal tubules and cortical collecting ducts compared with mature segments (235,236). Thus, at the lower flow rates found in the immature kidney, enhanced tubular backleak of K^+ could severely limit net K^+ secretion. A cortical collecting duct microperfusion study showed that the difference between perfused and collected K^+ concentrations was less than 1.5 mol/L during the first 3 weeks of life (228). However, in the same age group, a lack of active secretion of K^+ over a wide range of flow rates suggests that backleak may not be a limiting factor early in life. Moreover, despite the absence of net K^+ secretion, active Na^+ absorption was evident as early as 2 weeks of age, at a rate that approached 50% of the mature level. Because the difference between perfused and collected Na^+ concentrations was nearly the same in immature and mature segments (228), it is not likely that postnatal development of the tight junctions comprising the paracellular pathway plays a major role in the maturation of K^+ secretion in the cortical collecting duct. On the other hand, data to suggest that backleak may be important in limiting K^+ transport come from the isotopic Na^+ studies performed by Vehaskari in maturing cortical collecting ducts (237), which showed high rates of passive Na^+ permeability during the first 2 weeks of postnatal life before a decrease to adult levels. Thus, a role for backleak in limiting K^+ secretion in the immature cortical collecting duct is still a significant possibility.

Aldosterone

Plasma aldosterone concentrations in the fetus and newborn are high compared with those in the adult (14,238–241). Yet, clearance studies demonstrate that young animals are less sensitive to mineralocorticoids than their mature counterparts (14,242). Both the density of aldosterone binding sites and receptor affinities are similar in mature and immature rats, which suggests that the early hyposensitivity to aldoster-

one is likely to be a postreceptor phenomenon (242). In addition, Vehaskari (237) showed that the administration of mineralocorticoid for 48 hours to 1- and 2-week-old rabbits had no effect on the sodium-22 absorptive flux in cortical collecting ducts isolated from these animals. Thus, the biological responsiveness to aldosterone is minimal early in life and increases with age; this development of aldosterone responsiveness may contribute to the maturation of K^+ secretion in the cortical collecting duct.

Apical K^+ Channels

The most likely explanation for both the low rate of K^+ secretion and the mature level of intracellular K^+ concentration despite the low activity of the $Na^+-K^+-ATPase$ pump is a low apical permeability of the principal cell to K^+ . The passage of K^+ across the apical membrane from the principal cell into the luminal fluid is likely mediated by a low conductance inwardly rectifying K^+ -selective channel (105,106,108,154). Using patch-clamp technology, Satlin and Palmer (243) found a progressive increase with age in mean number of open K^+ channels per patch in rabbit principal cells (Fig. 8.9). This increase was due primarily to a developmental increase in the number of channels per patch, because the open probability remained constant after the second week of life. Because a major increase in net K^+ secretion occurs after the first 3 weeks of life and a major increment in mean number of open channels per patch occurs after the second week, it is likely that the increase in apical K^+ conductance of the

FIGURE 8.9. Maturation of K^+ conductance in split-open cortical collecting ducts obtained from 1-, 2-, 3-, 4-, and 5-week-old rabbits. Mean values of number of open channels per patch plus standard error are given for each age group. Segments from rabbits older than 5 weeks were not examined because the rate of successful patch-clamp experiments was too low. *, $p < .05$ versus 5-week-old. (From Satlin LM, Palmer LG. Apical K^+ conductance in maturing rabbit principal cell. *Am J Physiol* 1997;272:F397, with permission.)

principal cell substantially contributes to the maturational surge in the rate of K^+ secretion.

The secretory K^+ channel characterized by Satlin and Palmer (243) is generally believed to have a major functional subunit called ROMK, based on similarities in biophysical properties (92,107,244,245). Using reverse transcriptase polymerase chain reaction, Benchimol et al. (246) showed that ROMK messenger RNA (mRNA) was regularly expressed by cortical collecting ducts isolated from animals 3 weeks of age and older. Only 30% of ducts from 2-week-old animals expressed ROMK mRNA and none expressed ROMK during the first week of life. Immunodetectable (247) and functional (243) apical low (ROMK) conductance channels, absent in neonatal principal cells, are present in principal cells from maturing rabbits, which indicates that the increase in ROMK mRNA contributes to the development of low-conductance secretory K^+ channels in the maturing cortical collecting duct.

K^+ Absorption by Intercalated Cells

Because net K^+ transport represents the sum of K^+ secretory and K^+ reabsorptive processes, it is possible that some K^+ absorption offsets the limited K^+ secretion in the neonatal cortical collecting duct. Clearance studies in saline-expanded dogs showed that newborn dogs reabsorbed 25% more of the distal K^+ load than did adult animals (80,225). Because micropuncture studies of immature rats indicated little K^+ reabsorption in the loop of Henle (88,90), the collecting duct was considered a likely segment for K^+ reabsorption. This K^+ reabsorption is probably mediated by an apical $H^+-K^+-ATPase$ that couples K^+ reabsorption to H^+ secretion identified in collecting duct intercalated cells (117,118,121,248). Indeed, K^+ deficiency in adult animals is associated with selective hypertrophy of the apical membranes of medullary collecting duct intercalated cells (114). These anatomical changes are accompanied by functional data that show increased K^+ absorption (249) and $H^+-K^+-ATPase$ protein and activity (124,250–252).

Functional studies indicate that neonatal cortical collecting duct intercalated cells possess an apical $H^+-K^+-ATPase$ with activity comparable to that of mature intercalated cells (253). In addition, the higher tubular fluid K^+ concentration of the immature animal (88) should facilitate lumen to cell K^+ absorption mediated by the $H^+-K^+-ATPase$. Although direct studies of K^+ absorption by the immature collecting duct have not been performed, the preceding data suggest that parts of the neonatal collecting duct may absorb K^+ (233,253), which is essential for conserving some of the excessive K^+ presented to the immature distal nephron.

DISORDERS OF POTASSIUM METABOLISM

Hypokalemia

K^+ is predominantly an intracellular cation, yet clinical estimation of K^+ balance usually depends on the measurement of

extracellular (serum or plasma) K^+ concentration. Accurate assessment of body potassium stores can be performed only by total-body counting methods, laborious measurements not readily available to the clinician. Hypokalemia, defined as a serum K^+ concentration below 3.5 mEq/L, usually indicates a deficit in total body potassium but may also represent a shift of K^+ from the extra- to the intracellular space in the setting of normal total body K^+ stores. To a first approximation, each 1 mEq/L decrease in serum K^+ concentration below 3 mEq/L corresponds to a 200- to 400-mEq (approximately 10%) deficit in total body potassium stores in the 70-kg adult. Total body K^+ depletion causing hypokalemia results from inadequate intake or from excessive loss of K^+ from the body via the kidney or gastrointestinal tract. A list of clinical disorders associated with K^+ redistribution and depletion is found in Table 8.4.

Clinical Disorders Associated with Hypokalemia

Insufficient K^+ Intake

Dietary Insufficiency. Potassium is virtually impossible to eliminate from the average diet except by limiting intake to foods containing a high percentage of carbohydrate or refined sugar or by administering K^+ -free parenteral fluids for a prolonged period. The K^+ content of a variety of foods and beverages in the American diet are listed in Table 8.5.

In the adult a sharp reduction in dietary K^+ intake is followed within several days by a decrease in urinary K^+ excretion but only to a minimum rate of approximately 10 mEq/day, as the kidney is unable to produce a K^+ -free urine (69). The combination of the limited ability to maximally conserve urinary K^+ and ongoing obligatory gastrointestinal losses may lead to significant K^+ depletion if dietary deprivation is prolonged.

Chloride Deficiency Syndrome. Dietary chloride deficiency syndrome, first recognized in infants fed chloride-deficient batches of commercial cow's milk formula, is characterized by hypochloremic metabolic alkalosis, hypochloruria, and hypokalemia (254,255). Clinically, these babies presented with failure to thrive, anorexia, muscular weakness, lethargy, vomiting, and dehydration. Renal K^+ excretion was lower in chloride-deficient patients than in age-matched controls offered formula of comparable K^+ content (254). The pathogenesis of the hypokalemia may be related to volume contraction due to lack of adequate chloride and resulting in secondary hyperaldosteronism, reduced intake of formula, pH-induced redistribution of extracellular K^+ , and provision of nonreabsorbable anions.

Increased Entry of K^+ into Cells

Acute Alkalosis. Either metabolic or respiratory alkalosis can be associated with hypokalemia by promoting K^+ entry into cells in exchange for protons. The initial small transcellular shift of K^+ is exacerbated by volume contraction-induced hyperaldosteronism and the delivery of nonreabsorbable anions (bicarbonate) to potassium-secretory sites in the distal nephron.

TABLE 8.4. CLINICAL DISORDERS ASSOCIATED WITH HYPOKALEMIA

Inadequate intake
Dietary insufficiency
Chloride deficiency syndrome
Increased entry of K^+ into cells
Acute alkalosis (metabolic, respiratory)
Insulin administration
Elevated β -adrenergic activity
Hypokalemic periodic paralysis
Increased number of cells in plasma
Barium poisoning
Pseudohypokalemia
Increased renal losses
Renal K^+ wasting disorders with low plasma renin activity
Disorders of excess mineralocorticoid activity
Primary hyperaldosteronism
Aldosterone-producing adenomas
Bilateral adrenal hyperplasia
Cushing syndrome
Primary adrenal disease
Effect of pharmacologic doses of corticosteroids
Secondary effect of nonendocrine tumor
Congenital adrenal hyperplasia
11 β -hydroxylase deficiency
17 α -hydroxylase deficiency
Excessive licorice ingestion
Inhibition of 11 β -hydroxysteroid dehydrogenase
Liddle's syndrome (pseudoaldosteronism type 1)
Pseudoaldosteronism type 2 (mineralocorticoid receptor defect)
Glucocorticoid-remediable aldosteronism
Syndrome of apparent mineralocorticoid excess
Renal K^+ -wasting disorders with high plasma renin activity
Excessive renin production
Bartter's syndrome
Gitelman's syndrome
Diuretic use
Thiazides and loop diuretics
Osmotic diuretics (mannitol, glucose)
Carbonic anhydrase inhibitors
Renal tubular acidosis
Other conditions associated with increased distal nephron flow
Renal diseases (interstitial nephritis, obstructive uropathy, dysplasia, hypercalcemia)
Antibiotic use (carbenicillin, nafcillin, penicillin, gentamicin, amphotericin B)
Leukemia
Miscellaneous
Hypomagnesemia
Vitamin D intoxication
Thyrotoxicosis
Primary polydipsia
Cardiopulmonary bypass
Increased gastrointestinal loss
Gastric (vomiting, nasogastric suction, pyloric stenosis)
Large intestinal (diarrhea, VIPoma syndrome, villous adenoma, chronic laxative abuse, biliary drainage, ureterosigmoidostomy)
Integumental loss
Excessive sweating
Full-thickness burns

VIPoma, vasoactive intestinal polypeptide tumor.

TABLE 8.5. POTASSIUM CONTENT OF VARIOUS FOODS

Food	K ⁺ (mg)	Food	K ⁺ (mg)
Beverages		Cookies/desserts	
Cola, 12 oz	4	Gingersnaps, 1 oz, 4 cookies	98
Pepsi, 12 oz	10	Doughnut, 1	60
Gingerale, 12 oz	4	Chocolate ice cream, 0.5 cup	164
Diet Coke, 12 oz	18	Vanilla ice cream, 0.5 cup	131
Coffee, 6 oz	96	Chocolate ice cream bar with chocolate coating, 1 bar	247
Cranberry-apple juice, 6 oz	50	Apple turnover, 1	33
Hawaiian punch, 8 oz	50	Orange sherbet, 0.5 cup	92
Orange juice, 6 oz	210	Jello, 0.5 cup	239
Black tea, brewed, 6 oz	66	Meals	
Citrus fruit juice drink, 8 oz (from frozen concentrate)	278	Scrambled egg (1) with milk	84
Apple juice, 8 oz	295	Macaroni and cheese, 1 cup	190
Grapefruit juice, 8 oz	378	Cheese pizza, 1 slice	85
Orange juice, 8 oz	436	Chicken pot pie, 1/3 of 9-in. pie	343
Tomato juice, 6 oz	400	Spaghetti with tomato sauce, 1 cup	408
Chocolate shake, 10 oz	566	Cheeseburger, 1 large	644
Candy		Hotdog, 1	143
Golden Almond Hershey's Chocolate 3.2-g bar	429	Mashed potatoes, 1/3 cup	235
Lollipop, 1	0	Fruit, fresh	
Marshmallow, 1	25	Apple, 1 medium	159
Milk chocolate, 1.55-oz bar	169	Banana, 1 medium	451
Snickers, 2.16-oz bar	206	Cantaloupe, 1 cup	494
Twizzlers, 2.5 oz	45	Grapefruit, one-half, medium	175
Cereals		Peach, 1 medium	171
Bran, 100%, 1 oz	277	Raisins, 2/3 cup	825
Cornflakes, 1.06 oz	35	Watermelon, 1 cup	186
Granola, Kellogg's lowfat, 1.7 oz	122	Bread	
Raisin bran, 2.08 oz	380	White, 1 slice	30
Special K, 1.09 oz	54	Whole wheat, 1 slice	71
Shredded Wheat, 1 oz	93	English muffin, with butter	69
Cheese		Vegetables	
American processed, 1 oz	46	Potato, with skin	903
Cream cheese, 1 oz	34	Tomato, 1	273
Chips		Green beans, 0.5 cup	185
Corn chips, 1 oz	40	Carrot, 1 medium	233
Potato chips, 1 oz	361	Lima beans, 1 cup boiled	955
Pretzels, 1 oz	41	Lentils, 1 cup boiled	731

Insulin Administration. Insulin promotes the entry of K⁺ into skeletal muscle and liver cells (37,256), as observed most prominently in the treatment of diabetic ketoacidosis.

Elevated β -Adrenergic Activity. Nonselective β -adrenergic agonists (isoproterenol, epinephrine) and selective β_2 -adrenergic agonists (albuterol, terbutaline) promote K⁺ entry into cells (37). Thus, transient hypokalemia can be produced by stress-induced release of epinephrine, theophylline intoxication, treatment of asthma with albuterol (257), or treatment of premature labor with terbutaline (258). Arrhythmias may result from this hypokalemia when there is volume contraction induced by concomitant diuretic therapy (259) or by poor oral intake (260).

Hypokalemic Periodic Paralysis. Hypokalemic periodic paralysis is a rare disorder characterized by attacks of muscle weak-

ness and episodes of flaccid paralysis of the limbs and thorax lasting 6 to 24 hours (261). Serum K⁺ concentration is normal between attacks. In severe cases death from respiratory failure or cardiac arrhythmia may occur. Both sporadic and familial cases have been reported with a male to female preponderance of 3:1 and generally autosomal dominant inheritance. Familial forms are due to point mutations in the gene encoding the α -1 subunit of the L-type calcium channel, or voltage-gated dihydropyridine receptor (262,263). The dihydropyridine receptor functions as a voltage-gated calcium channel and is critical for excitation-contraction coupling in a voltage-sensitive and calcium-independent manner (264). The defect in hypokalemic periodic paralysis is associated with a reduced sarcolemmal ATP-sensitive K⁺ current (265).

The disorder usually becomes symptomatic during the first or second decade of life. Acute attacks generally occur at night, and the patient awakens paralyzed. Episodes are asso-

ciated with sudden movement of K^+ into cells, which lowers plasma K^+ concentration by 1.5 to 2.5 mEq/L. Attacks are often precipitated by a carbohydrate meal, rest after exercise, or stressful events causing hypokalemia by a shift of K^+ into cells via the release of insulin or epinephrine. The paralysis is characterized by failure of propagation of the muscle action potential (266). After the attack, sequestered K^+ is released from cells and plasma K^+ concentration becomes normal.

Treatment with oral KCl usually aborts symptomatic attacks; intravenous K^+ may be required for severe attacks. Nonselective beta-blockers can reduce the number and severity of attacks, and limit the fall in plasma K^+ concentration (261). In most patients acetazolamide (20 to 40 mg/kg/day divided into four doses) may be more effective than K^+ supplementation or K^+ -sparing diuretics in preventing severe attacks. The metabolic acidosis induced by acetazolamide may decrease the rate of K^+ entry into cells and thereby diminish the severity of the disease (267). Hyperthyroidism may be associated with hypokalemic periodic paralysis, probably because thyroid hormone stimulates Na^+ - K^+ -ATPase activity and sensitivity to catecholamines, and thereby drives K^+ into cells. Restoration of euthyroidism in thyrotoxic patients combined with beta-blockade generally prevents the hypokalemic attacks.

Barium Poisoning. Ingestion of soluble barium salts may result in a severe decrease in plasma K^+ concentration secondary to intracellular shifts of K^+ from the plasma (268). Barium acts on muscle cells to decrease K^+ conductance, thereby impairing outward diffusion of K^+ (269). Thus, the K^+ pumped into the cell via Na^+ - K^+ -ATPase cannot exit.

Increased Number of Cells in Plasma. A rapid increase in hematopoietic cell production associated with new cell K^+ uptake, such as resulting from the administration of folic acid or vitamin B_{12} to patients with megaloblastic anemia, can lead to hypokalemia and potentially to cardiac arrhythmias (270). Similarly, after the administration of granulocyte-macrophage colony-stimulating factor to correct neutropenia, a marked increase in white blood cell production may lead to hypokalemia (271).

Other Cellular Shifts. Hypothermia has been associated with hypokalemia as K^+ enters cells and is reversible on rewarming.

Pseudohypokalemia. Because metabolically active cells continue to take up K^+ after blood has been drawn, patients with very high white blood cell counts may become apparently hypokalemic if their blood has been allowed to stand for prolonged periods at room temperature (271,272).

Increased Renal Losses

Urinary K^+ excretion is determined primarily by K^+ secretion in the cortical collecting duct. Increased urinary losses usually result from increased flow of water and Na^+ to the cortical col-

lecting duct and/or excessive mineralocorticoid. In the setting of adequate distal Na^+ delivery, the urine K^+ concentration is helpful in differentiating among the causes of hypokalemia.

Renal K^+ Wasting Disorders with Low Plasma Renin Activity Disorders of Excess Mineralocorticoid Activity. Because mineralocorticoids stimulate K^+ secretion in the distal tubule and cortical collecting duct, conditions characterized by excessive mineralocorticoid activity are often associated with hypokalemia. The classic disorder of endogenous overproduction, *primary hyperaldosteronism*, may be associated with an adrenal adenoma or bilateral adrenal hyperplasia and is accompanied by hypertension, a variable degree of hypokalemia, and metabolic alkalosis (273,274).

Hypokalemia along with metabolic alkalosis may be observed in some patients with increased cortisol production (*Cushing syndrome*) or in those receiving *pharmacologic doses of corticosteroids*, presumably related to the mineralocorticoid effect of such hormones or to the fact that the rate of delivery of cortisol exceeds its rate of inactivation via 11β -hydroxysteroid dehydrogenase (11β -HSD) (275,276). Tumors of the lung, thymus, and pancreas that produce an adrenocorticotrophic hormone (ACTH)-like substance are less prevalent in children than in adults but may lead to increased production of cortisol, desoxycorticosterone (DOC), and corticosterone, which results in severe hypokalemia (277).

Among the multiple forms of *congenital adrenal hyperplasia*, deficiencies of 11β -hydroxylase and 17α -hydroxylase are associated with hypertension and hypokalemic alkalosis. The 11β -hydroxylase deficiency leads to a block in synthesis of cortisol, enhanced secretion of ACTH, and subsequent stimulation of DOC and adrenal androgen production (278). The excess mineralocorticoid (DOC) activity results in hypokalemia and hypertension. The 17α -hydroxylase deficiency leads not only to a block in cortisol synthesis but also to defective production of adrenal androgens (278,279).

Ingestion of large quantities of European *licorice*, which contains glycyrrhetic acid, a plant steroid with weak mineralocorticoid activity, can lead to a syndrome similar to primary hyperaldosteronism with sodium retention, edema, hypertension, and hypokalemia, except that plasma aldosterone levels are suppressed (280). Licorice and its analogues are also effective inhibitors of 11β -HSD, which converts cortisol to cortisone in the distal nephron (275,281). Cortisol binds to the mineralocorticoid receptors present in the cortical collecting duct with an avidity equal to that of aldosterone but circulates at much higher concentrations in plasma. However, cortisol is converted locally by 11β -HSD to inactive metabolites such as cortisone. This conversion is impaired with licorice-induced inhibition of 11β -HSD, which allows cortisol to activate the mineralocorticoid receptors and produce a clinical picture of primary hyperaldosteronism.

Liddle's Syndrome. Liddle's syndrome is a rare autosomal dominant disorder that presents a clinical picture similar to

that of primary hyperaldosteronism with severe hypokalemic metabolic alkalosis and hypertension accompanied by Na^+ retention and substantial urinary K^+ excretion (282). Plasma renin and aldosterone levels are low, however, which gives rise to the clinical descriptor of pseudoaldosteronism (283).

This disease is caused by mutations in the carboxyterminal of the β or γ subunits of the ENaC (282,284). These gain-of-function mutations result in enhanced channel activity due to increased cell surface expression (and lack of downregulation) of functional Na^+ channels in the cortical collecting duct. The consequent increase in Na^+ reabsorption leads to severe hypertension. The hypokalemia reflects urinary K^+ wasting due to the secondary effects of increased apical Na^+ reabsorption, which results in an increased electrochemical driving force favoring K^+ secretion from the principal cell into the urinary space. The urinary Na^+ and K^+ abnormalities are not affected by spironolactone, a competitive aldosterone antagonist, but rather by the Na^+ channel blockers triamterene and amiloride (285).

Pseudoaldosteronism Type 2. This disorder results from a mutation in the hormone-binding domain of the mineralocorticoid receptor (286). The phenotype resembles that of Liddle's syndrome with autosomal dominant inheritance, hypertension, hypokalemia, suppressed plasma renin activity, and aldosterone secretion. However, a very severe presentation during pregnancy is also seen (284).

A serine to leucine mutation occurs at position 810 in the hormone-binding domain of the mineralocorticoid receptor that changes the affinity of the receptor for a variety of steroids. This mutation results in constitutive mineralocorticoid receptor activity and alters receptor specificity, so that progesterone and other steroids lacking 21-hydroxyl groups, normally mineralocorticoid receptor antagonists, become potent agonists (286).

Progesterone has a very high affinity for the mutated receptor, which accounts for the severe presentation during pregnancy. Because the receptor has constitutively stimulated basal activity and may respond to other endogenous steroids, the clinical phenotype can present in males and nonpregnant females as well. Spironolactone is an agonist for the mutated receptor, and its use is therefore contraindicated in this form of pseudoaldosteronism.

Glucocorticoid-Remediable Aldosteronism. In glucocorticoid-remediable aldosteronism, aldosterone and the weak mineralocorticoids 18-oxo-cortisol and 18-hydroxy-cortisol are produced in excess (287). This is a single-gene disorder that causes hypertension. It results from a relatively common autosomal dominant mutation that creates a chimeric gene comprised of 5' regulatory sequences of the 11β -hydroxylase gene fused to the 3' coding sequences of the gene encoding aldosterone synthase, the rate-limiting enzyme for aldosterone synthesis. This ectopic aldosterone synthesis in the zona fasciculata is under the control of ACTH, rather than the renin-angiotensin system, and results in salt and water retention, hypertension, and dramatic hypokalemia. The level of hypertension appears

to correlate with the level of aldosterone secretion, and glucocorticoids suppress this hypertension (284). The mechanism for urinary K^+ wasting is similar to that observed in Liddle's syndrome.

Syndrome of Apparent Mineralocorticoid Excess. In the syndrome of apparent mineralocorticoid excess, inactivating mutations in the 11β -HSD type II gene allow cortisol to act as the major endogenous mineralocorticoid (284,288). This enzyme normally converts cortisol to cortisone, thereby preventing cortisol from activating the type I mineralocorticoid receptor in the kidney. In this rare autosomal recessive disorder characterized by pre- and postnatal growth failure, juvenile hypertension, hypokalemic metabolic alkalosis, and hyporeninemic hypoaldosteronism, reduced metabolism of cortisol to cortisone results in local cortisol excess and increased mineralocorticoid response, even in the absence of elevations in plasma cortisol level (289). The underlying mechanism for urinary K^+ wasting is similar to that in Liddle's syndrome. Treatment usually includes spironolactone (which competes for the mineralocorticoid receptor), K^+ supplements, and a low-salt diet.

Renal K^+ Wasting Disorders with High Plasma Renin Activity

Bartter's and Gitelman's Syndromes. Bartter's and Gitelman's syndromes are rare autosomal recessive disorders associated with urinary K^+ wasting, hypokalemia and metabolic alkalosis, hyperreninism, and hyperaldosteronism, but with normal blood pressure (282,290). Hypokalemia, chronic volume contraction, and high plasma concentrations of angiotensin, kallikrein, kinins, and vasopressin all stimulate the production of prostaglandin E_2 . The absence of hypertension rules out primary mineralocorticoid excess, and the finding of high urinary chloride excretion rules out secondary hyperaldosteronism due to extrarenal fluid loss. Such findings occur only in Bartter's syndrome and with long-term diuretic therapy (282). The pathogenesis of Bartter's and Gitelman's syndromes is similar to that in long-term treatment with loop and thiazide diuretics, respectively. The genetic defect of Bartter's syndrome involves transporters in the thick ascending limb of the loop of Henle and collecting duct. Clinical disease is attributable to defective NaCl reabsorption in the thick ascending limb, where approximately 30% of the filtered salt is reabsorbed. Gitelman's syndrome presents with milder salt wasting due to abnormal salt transport in the distal convoluted tubule.

At least three phenotypically different subgroups of patients with Bartter's and Gitelman's syndromes can be identified. The neonatal variant, previously called hyperprostaglandin E syndrome, presents with dehydration, failure to thrive, dysmorphic facies, and a history of polyhydramnios and premature delivery (291,292). There is significant Na^+ wasting, polyuria, hypercalciuria, osteopenia, and nephrocalcinosis with normal serum magnesium levels. The pathophysiology is likely due to mutations in the gene encoding the bumetanide-sensitive Na-K-2Cl co-transporter in the thick ascending limb (293) or in

the gene encoding the ATP-regulated K^+ channel (ROMK1) (291) in the thick ascending limb and cortical collecting duct.

The second type is classic Bartter's syndrome, which presents in childhood (younger than 5 years of age), often as failure to thrive with signs of severe intravascular volume depletion. Compared to the neonatal form, urine calcium is elevated less severely and nephrocalcinosis is generally absent (260). The pathogenesis is generally a loss-of-function mutation of the renal basolateral Cl^- channel (ClC-Kb).

The third type of hypokalemic metabolic alkalosis is known as Gitelman's syndrome, which presents in childhood or later and is not associated with salt craving or bouts of dehydration. The presentation is much milder than Bartter's from a clinical and biochemical viewpoint. Gitelman's syndrome is due to mutations in the thiazide-sensitive NaCl cotransporter (NCCT or TSC), which is localized in the distal convoluted tubule (294). This subgroup comprises the Bartter's-type patients with hypomagnesemia and hypocalciuria. Defective NaCl reabsorption in the distal convoluted tubule results in increased delivery to the cortical collecting duct, with consequent mild volume contraction and aldosterone-stimulated K^+ and H^+ secretion, which leads to a mild hypokalemic metabolic alkalosis. The extent of volume contraction and K^+ depletion appear to be less marked than in Bartter's syndrome and are not sufficient to raise prostaglandin E_2 production.

Treatment focuses on correcting the electrolyte abnormalities and preventing dehydration. Potassium chloride therapy is required to fully address the K^+ imbalance and NaCl helps manage the defect in Cl^- reabsorption. Spironolactone is often helpful. Indomethacin inhibits prostaglandin production and decreases renin and aldosterone production; this results in less renal K^+ wasting but can have adverse long-term effects on renal function. Despite treatment, patients with Bartter's syndrome often have persistent hypokalemia. Patients with Gitelman's syndrome need magnesium chloride supplements but rarely need volume resuscitation or prostaglandin synthase inhibition.

Renal Tubular Acidosis. The mechanisms responsible for hypokalemia and renal K^+ wasting differ for proximal (type II) and distal (type I) renal tubular acidosis (RTA). Despite the K^+ depletion, however, the plasma K^+ concentration may be normal because the acidemia promotes K^+ movement out of cells. Failure of intercalated cells in the distal nephron to secrete protons into the urinary fluid results in distal RTA. The defect in H^+ secretion increases tubular electronegativity, thereby enhancing K^+ secretion and limiting Na^+ reabsorption in the cortical collecting duct. Volume depletion and consequent secondary hyperaldosteronism further aggravate urinary K^+ losses. Hypokalemic variants of distal RTA may arise from abnormalities of the luminal $H^+-K^+-ATPase$, which mediates H^+ secretion and K^+ reabsorption in the distal nephron, or a defect in the membrane permeability of the distal nephron. Treatment with alkali to correct the acidosis and volume depletion may diminish urinary K^+ losses and normalize serum K^+ concentra-

tion when dietary intake of Na^+ and K^+ is adequate (295). However, flooding of the distal nephron segments with excessive bicarbonate ion will exacerbate urinary K^+ losses.

Proximal or type II RTA, characterized by a depression in the renal HCO_3^- threshold, may exist as an isolated proximal defect of HCO_3^- reabsorption or may be associated with other proximal tubular transport abnormalities as a Fanconi syndrome, in which patients excrete large amounts of HCO_3^- , phosphate, amino acids, and glucose. Distal deliveries of Na^+ and the poorly reabsorbed anion HCO_3^- are high, which results in excessive K^+ secretion. Secondary hyperaldosteronism due to Na^+ wasting and volume depletion further increases K^+ secretion, as does treatment with sodium bicarbonate. On the other hand, correction of the acidosis and hypokalemia can usually be accomplished by replacing some of the sodium bicarbonate with potassium citrate (296–298).

Diuretic Use. The most common cause of renal K^+ wasting is the administration of diuretics, particularly loop and thiazide diuretics. The major mechanisms for K^+ wasting include increased delivery of loop or distal tubular fluid to the cortical collecting duct, where K^+ secretion is flow dependent, and secondary hyperaldosteronism resulting both from the underlying disease and from the volume contraction induced by the diuretics (298–300). In addition, the metabolic alkalosis that accompanies the use of such diuretics is likely to promote additional K^+ secretion.

Diuretic-induced hypokalemia may be associated with an increased incidence of arrhythmias (301,302) and should be treated in patients with hypomagnesemia or cardiac disease, especially during digitalis therapy (303). Treatment is recommended with KCl supplements or K^+ -sparing diuretics (such as spironolactone or triamterene); the latter will also partially correct diuretic-induced magnesium depletion by diminishing magnesium excretion (304).

Excessive Renin Production. Activation of the renin-angiotensin system provides a major stimulus for adrenal aldosterone synthesis with the development of hypertension and hypokalemia. Such findings may be observed in patients with poor oral intake, diuretic use, vomiting or diarrhea, renal vascular disease, malignant hypertension, and renin-producing tumors, including hemangiopericytomas and Wilms' tumor (298).

Secondary hyperaldosteronism in edema-producing states does not usually result in hypokalemia (305). Edematous patients do not experience increased urinary K^+ losses or become hypokalemic when administered Na^+ loads to ensure adequate distal delivery and flow (306). Thus, the development of significant K^+ depletion in the presence of Na^+ retention (nephrotic syndrome, cirrhosis, congestive heart failure) suggests that additional kaliuretic factors are involved; for example, the administration of potent diuretics or the presence of metabolic alkalosis.

Other Conditions Associated with Increased Distal Nephron Flow. Conditions associated with increased flow of water and salt to the distal nephron may result in hypokalemia. As described for diuretic use and Bartter's and Gitelman's syndromes, the initial renal Na^+ wasting leads to a secondary rise in aldosterone release, which further contributes to the tendency to hypokalemia. A variety of renal diseases, including *chronic interstitial nephritis*, *urinary tract obstruction*, and *dysplasia*, can cause hypokalemia by these mechanisms (271). Similarly, *hypercalcemia* is frequently associated with a urinary concentrating defect and high distal flow, because calcium-induced tubular damage may impair Na^+ reabsorption (307).

Hypokalemia and urinary K^+ wasting may follow administration of various antibiotics, including high-dose *penicillin* and *penicillin analogues*, such as carbenicillin and nafcillin. The penicillins behave as nonreabsorbable anions, enhancing transepithelial electronegativity in the distal nephron, and are often administered as sodium salts, so that they enhance distal Na^+ delivery and thus K^+ secretion (298). Hypokalemia associated with prolonged or high-dose administration of *aminoglycosides* (e.g., gentamicin) has been attributed to development of secondary hyperaldosteronism and drug-induced renal magnesium wasting (308,309). Polyene antibiotics, such as *amphotericin B*, frequently induce renal K^+ wasting by increasing K^+ permeability of the luminal membrane and by causing a distal acidification defect (310).

Renal K^+ wasting and hypokalemia can be seen in patients with various forms of *leukemia*. The elevated urinary excretion of lysozyme (a low-molecular-weight protein present in leukocytes), which is characteristic of these leukemias, may be toxic to the proximal tubule (311,312). The hypokalemia observed in childhood leukemia (acute lymphocytic leukemia, acute myelogenous leukemia) and other adult leukemias (chronic myelogenous leukemia, chronic lymphocytic leukemia) is probably multifactorial in origin and may be attributed to causes such as reduced K^+ intake, antibiotic-induced renal K^+ wasting, the mineralocorticoid effect of high-dose steroid therapy, increased K^+ entry into metabolically active leukemic cells, and the osmotic diuresis (and nephrotoxicity) encountered in the administration of some chemotherapeutic agents (e.g., cisplatin) (271,298,313).

Miscellaneous Factors. *Hypomagnesemia* is a relatively common finding in hypokalemic patients (314,315). Hypomagnesemia can lead to K^+ depletion (314,316). The mechanism for the increased kaliuresis is not clear, but it may reflect decreased reabsorption of K^+ in the loop of Henle and possibly the cortical collecting duct. Magnesium deficiency may result in loss of cell K^+ , either by impairment of Na^+ - K^+ -ATPase activity or alteration of cell membrane permeability to K^+ . Magnesium depletion may enhance renin and thus aldosterone secretion, with the resulting hyperaldosteronism in turn promoting urinary K^+ excretion. Hypocalcemia is also com-

monly found in hypomagnesemic patients due to decreased secretion of parathyroid hormone and skeletal resistance to its effect. Indeed, the combination of hypokalemia plus hypocalcemia is highly suggestive of underlying magnesium depletion (316). Correction of the hypokalemia frequently requires the restoration of magnesium balance (314–316).

Other conditions have been associated with hypokalemia, including *vitamin D intoxication*, *thyrotoxicosis*, *lithium toxicity*, *primary polydipsia*, and *cardiopulmonary bypass* (298). Hypokalemia can also follow transfusion of previously frozen washed erythrocytes, which reflects avid uptake of K^+ by these K^+ -depleted red cells (317).

Increased Gastrointestinal Losses

Gastric Loss. Vomiting and nasogastric suction often lead to hypokalemia despite the fact that gastric secretions contain only 10 to 20 mEq/L of K^+ (318). The major site of K^+ loss is, in fact, the kidney. Volume contraction after prolonged vomiting or nasogastric suction and consequent secondary hyperaldosteronism are primarily responsible for increased distal K^+ and H^+ losses. The metabolic alkalosis that accompanies significant vomiting causes an increase in both distal tubular cell K^+ concentration and distal delivery of HCO_3^- , a nonreabsorbable anion; these two factors, in addition to secondary hyperaldosteronism, stimulate urinary K^+ excretion.

Large Intestine Loss. Fecal excretion of K^+ usually amounts to between 5 and 15 mEq/day. Because gastrointestinal fluids (e.g., from stomach, ileum, cecum) contain approximately 10 mEq/L of K^+ and because colonic mucus is rich in K^+ (100 to 140 mEq/L) (319), diarrhea can induce significant K^+ loss. In cholera, daily stool losses may average 8 L of water, 1000 mEq of Na^+ , and 130 mEq of K^+ (320). Comparable losses may occur in patients with *VIPoma syndrome*, a severe, watery diarrhea and histamine-fast achlorhydria that is usually but not always due to a vasoactive intestinal peptide-producing non- β -cell islet cell tumor (321). When volume contraction ensues, secondary hyperaldosteronism further stimulates renal and colonic K^+ secretion (322).

A similar picture may be seen early in the course of *congenital chloride diarrhea*, a rare autosomal recessive condition characterized by mutations in the downregulated adenoma gene (DRA) that codes for an intestinal Cl^- - HCO_3^- exchanger in the terminal ileum and colon (323). Infants with the disorder have distended abdomens and absence of meconium, and fail to thrive. They develop metabolic alkalosis, dehydration, secondary hyperaldosteronism, and severe electrolyte disturbances, including hypochloremia, hyponatremia, and hypokalemia. Fecal Cl^- concentration always exceeds 90 mEq/L in patients with corrected electrolyte balance (324).

Severe diarrhea and dehydration (10 to 15%) in children can incur losses of between 7 and 14 mEq of K^+ per kilo-

gram of body weight (325). Evaluation of such patients usually reveals a hyperchloremic metabolic acidosis, despite the secondary hyperaldosteronism, due to the marked bicarbonate and organic anion (potential alkali) losses in diarrheal fluid. The metabolic acidosis may induce K^+ to shift from the cells to the ECF, which thereby masks total body K^+ depletion.

Profound large intestine losses of K^+ are commonly observed in patients with villous adenomas of the colon and rectum (326). Ureterosigmoidostomies, surgical diversions performed to relieve chronic urinary tract obstruction, are typically associated with a hypokalemic hyperchloremic metabolic acidosis arising from colonic secretion of K^+ and HCO_3^- in exchange for Na^+ and Cl^- . This complication can be mitigated by implantation of the ureter into the ileum.

Those who habitually abuse laxatives frequently develop marked K^+ depletion (298). These patients, typically overly concerned with body image, may also abuse diuretics. With habitual use of either laxatives or diuretics, Na^+ depletion, volume contraction, secondary aldosteronism, and metabolic alkalosis may develop. Thus, these patients may present with a picture mimicking Bartter's syndrome. The habitual laxative abuser who has not recently taken diuretics usually shows a urinary Cl^- concentration below 25 mEq/L.

Excessive Integumental Losses

The concentration of K^+ in sweat is approximately 5 to 10 mEq/L (327). Vigorous exercise or heat stress usually results in a significant increase in the volume of sweat and its Na^+ concentration (though rarely exceeding 60 mEq/L), which leads to salt losses and volume contraction. The secondary hyperaldosteronism that ensues results in augmented K^+ secretion into both exocrine gland products (327) and urine, and thereby produces additional K^+ deficits. Excessive loss of sweat and its salts in patients with cystic fibrosis may lead to hypokalemia by similar mechanisms (328), with patients occasionally presenting with a picture resembling Bartter's syndrome.

Patients with full-thickness burns who develop volume contraction and consequent secondary hyperaldosteronism from massive integumental fluid losses often demonstrate an enhanced kaliuresis by 48 hours (298).

Clinical Manifestations of Hypokalemia

An acute fall in plasma K^+ concentration generally results in a more severe manifestation than does a chronic K^+ loss, which is often well tolerated.

Neuromuscular

Hypokalemia can induce skeletal muscle weakness and, in severe cases, paralysis (301). Excitable tissues require a specific transmembrane K^+ gradient for optimal function. Briefly, depolarization of excitable cells is characterized by the rapid entry of Na^+ ions and exit of K^+ ions. Repolarization of the membrane involves extrusion of the Na^+ ions in

exchange for the lost K^+ ions. Hypokalemia results in a high intracellular to extracellular concentration ratio for K^+ , which induces a state of electrical hyperpolarization and thereby slows nerve impulse conduction and muscle contraction. Neuromuscular dysfunction is most commonly manifest as skeletal muscle weakness. Usually the muscles of the lower extremities are affected first, followed by the quadriceps, then those of the trunk and upper extremities, and ultimately of respiration (271,301).

Potassium deficiency can also reduce skeletal muscle blood flow. During exercise and muscular contraction, muscle cells normally release K^+ to the interstitial fluid. The increasing concentration of interstitial K^+ is believed to act as a vasodilator (329). It has been suggested that severe K^+ depletion (plasma K^+ concentration lower than 2 mEq/L) leads to failure of the vasodilatory response to exercise, which results in muscle ischemia with subsequent muscle cramps, rhabdomyolysis, and myoglobinuria (330).

Hypokalemia-induced smooth muscle dysfunction is usually manifest as paralytic ileus with abdominal distention, anorexia, nausea, vomiting, and constipation. Impaired pressor responsiveness to angiotensin and catecholamines may lead to postural hypotension (331).

Cardiac

Hypokalemia contributes to cardiovascular morbidity and mortality by its effect on cardiac conduction and arterial blood pressure. The electrical disturbances of conduction and rhythm, manifest on the electrocardiogram as depression of the ST segment, diminished T-wave voltage, and appearance of U waves, are generally observed at plasma K^+ concentrations below 3 mEq/L (Fig. 8.10). Premature atrial and ventricular contractions and atrial arrhythmias may be seen. In patients who have congestive heart failure, cardiac ischemia, or left ventricular hypertrophy, or who are taking digoxin therapy, hypokalemia significantly increases the risk of cardiac arrhythmias (332).

A diet that is low in K^+ , especially in the presence of high salt intake, has been implicated in the genesis of high blood pressure (333). The mechanism for hypokalemia-induced hypertension may relate to intravascular volume expansion as a result of renal Na^+ retention (334). The association between hypokalemia and hypertension is marked in African Americans, a population in whom a reduction in Na^+ intake and supplementation with K^+ may be particularly beneficial.

Metabolic

Potassium depletion interferes with both carbohydrate and protein metabolism. Potassium deficiency suppresses pancreatic insulin release, which results in increased glucose intolerance (335). However, a 10% reduction in body K^+ (corresponding roughly to a decrease in plasma K^+ concentration of 1 mEq/L) in healthy subjects results in only a mild impairment as measured by the glucose tolerance test, which

FIGURE 8.10. Relationship between plasma K^+ concentration and electrocardiographic changes. (From Winters RW. *The body fluids in pediatrics*. Boston: Little, Brown, 1973:134, with permission.)

suggests that more severe glucose intolerance in the presence of hypokalemia is associated with an underlying disorder, for example, subclinical diabetes. In diabetic patients hypokalemia impairs both insulin release and end-organ sensitivity to insulin, which aggravates the hyperglycemia.

Growth failure is commonly observed with chronic K^+ depletion (298). Although the mechanism is unclear, it may be due in part to a disturbance in protein metabolism. Because K^+ is the predominant intracellular cation, body K^+ depletion results in enhanced cellular uptake of other positively charged cations, specifically Na^+ , H^+ , and cationic amino acids (301). Thus, K^+ depletion results in an increase in the ratio of ECF volume to total body water volume, a decrease in the ratio of total body K^+ to body water, and a decrease in body noncollagen protein (8).

Renal

Potassium depletion, regardless of cause, produces a characteristic picture of structural and functional abnormalities in the kidney, known collectively as potassium-depletion nephropathy (301). One function that is preserved is the ability to conserve K^+ (336), mediated by decreased K^+ secretion as well as increased K^+ absorption via the $H^+-K^+-ATPase$ in the collecting duct (111,124). A specific reversible vacuolar lesion of proximal tubular cells has been described in humans (336,337). Interstitial fibrosis, tubular atrophy, and cyst formation in the medulla also may be seen (338).

The most common renal functional abnormality associated with K^+ depletion is impaired urinary concentration, a deficit arising from a reduced osmolar gradient in the medullary interstitium (339). This concentrating defect is resistant to the administration of exogenous vasopressin and prolonged water deprivation (337). Hypokalemia inhibits activation of renal adenylate cyclase, which prevents vasopressin-stimulated urinary concentration in the inner medullary collecting duct. In addition to this direct tubular effect, K^+ depletion stimulates the central thirst center via increased production of angiotensin II (340). Enhanced proximal tubular Na^+ reabsorption (341) in the face of K^+ depletion leads to Na^+ retention, expansion of the ECF, and even frank edema (301).

Potassium depletion would be expected to result in increased net acid excretion because of enhanced cellular uptake of H^+ as a substitute for K^+ ; this leads to intracellular acidosis (and alkalemia) and stimulation of both H^+ secretion and renal ammonia production by renal tubular cells (342). Indeed, moderate K^+ depletion induced by restriction of dietary K^+ (substituting with Na^+ without changing dietary anion content) results in a mild systemic metabolic alkalosis unaccompanied by chloride depletion or hyperaldosteronism (343). The metabolic alkalosis is likely due to enhanced proximal reabsorption of HCO_3^- , mediated by an increase in the activity of the luminal Na^+-H^+ exchanger and basolateral $Na^+-HCO_3^-$ co-transporter. This is manifest by an elevated plasma HCO_3^- concentration and is associated with the paradoxical excretion of an acid urine, possibly via the stimulation of $H^+-K^+-ATPase$ isoforms.

Approach to the Patient with Hypokalemia

Diagnosis

The evaluation of a patient with hypokalemia should begin with taking a detailed history that includes the pattern of childhood growth, occurrence of chronic illness, family history of similar disease, use of medications and special diets, and symptoms associated with the present electrolyte disturbance. Physical examination must include measurement of growth indices and blood pressure and assessment of any evidence of edema and altered neuromuscular function.

The initial laboratory evaluation should include measurement of serum electrolytes and acid-base status and a complete blood count. These routine laboratory studies will identify whether or not the hypokalemia is due to K^+ uptake by abnormal leukocytes or is associated with the redistribution of K^+ from the extra- to the intracellular space. If the laboratory data do not support either of these two possibilities, the hypokalemia likely represents total body K^+ depletion due to K^+ losses via the gastrointestinal tract, skin, or kidney.

To evaluate these possibilities, a urine collection (preferably timed) on a controlled Na^+ and K^+ intake of 2 to 3 mEq/kg/day for each cation should be obtained to yield information on renal function and renal K^+ handling (urinary Na^+/K^+ ratio, absolute and fractional urinary K^+ excretion). A low urinary K^+ concentration (less than 15 mEq/L) in the absence of recent

diuretic use implies near-maximal urinary K^+ conservation, which suggests that the K^+ deficit is secondary to extrarenal losses (gastrointestinal system, skin) or inadequate intake. The measurement of total body K^+ is not readily available to the clinician. Gastrointestinal K^+ losses occur from either vomiting, diarrhea, fistulas, nasogastric suction, or a villous adenoma. Laxative abuse should be considered in patients overly concerned with body image.

A child with a high rate of urinary K^+ excretion (greater than 15 mEq/L or exceeding intake by 0.5 to 1.0 mEq/kg/day, a fractional urinary K^+ excretion exceeding 30%, or a urinary Na^+/K^+ ratio consistently less than 1 in the absence of renal failure) has renal K^+ wasting. Inappropriate urinary K^+ wasting is often associated with hypertension and/or abnormalities of acid-base status. Hypokalemia associated with hypertension and metabolic alkalosis is classically found in hyperreninemic states, such as renal vascular stenosis, and primary hyperaldosteronism. The finding of hypokalemia and metabolic acidosis in a normotensive patient should suggest RTA or diabetic ketoacidosis. Bartter's and Gitelman's syndromes should be considered in patients with hypokalemic metabolic alkalosis, chronic salt wasting with volume depletion, and hyperreninemia and hyperaldosteronism.

Therapy

The choice of K^+ replacement therapy depends primarily on the magnitude of the K^+ deficit. Treatment of the deficit, particularly in the presence of complicating factors that affect the transcellular distribution of K^+ , must be performed cautiously, especially in patients with renal or cardiac disease.

Mild hypokalemia will often respond simply to dietary supplementation with foods having a high K^+ content (Table 8.5). Oral K^+ supplementation is necessary for moderate K^+ depletion (Table 8.6). Among the oral preparations available in liquid, powder, and slow-release preparations are potassium chloride, potassium citrate, and potassium gluconate. Potassium chloride is most commonly used; the citrate and gluconate formulations are ideal for patients with concomitant acidosis in whom the organic anion provides potential alkali. The adverse effects associated with oral therapy, especially after administration of KCl, include gastrointestinal irritation, ranging from vomiting to ulceration, and K^+ intoxication.

Intravenous K^+ supplementation therapy should be reserved for patients with severe hypokalemia, including those patients demonstrating neuromuscular or cardiac disturbances, those receiving amphotericin B, and diabetic patients in ketoacidosis. Administration of K^+ in dextrose-containing solutions may worsen the hypokalemia, because the sugar stimulates insulin secretion, which results in movement of K^+ into cells. Conventionally, parenteral K^+ should be infused in a solution containing no more than 40 mEq/L and infused at a rate not to exceed 0.5 to 1.0 mEq/kg of body weight per hour in children (298,344) or 10 to 20 mEq/hr in adults (334,345). When life-threatening paralysis or ventricular arrhythmias are present, or there are excessive ongoing losses such as with diabetic ketoaci-

Data from Gunn VL, Nechyba C. *The Harriet Lane handbook: a manual for pediatric house officers*, 16th ed. Philadelphia: Mosby, 2002.

dosis, more aggressive K^+ replacement may be appropriate. Under these circumstances, adults have been shown to tolerate K^+ administered in concentrations of 40 to 100 mEq/L and infused at a rate not to exceed 40 mEq/hr, while serial electrocardiograms and frequent measurements of plasma K^+ concentration are monitored (334,346).

In patients with diuretic-induced hypokalemia who require continued use of their diuretic, addition of a potassium-sparing diuretic such as amiloride, triamterene, or spironolactone should be considered. Hypomagnesemia can lead to renal K^+ wasting and refractoriness to K^+ replacement. Magnesium repletion facilitates correction of the coexisting K^+ deficit.

Hyperkalemia

Hyperkalemia is defined as a serum K^+ concentration higher than 6.0 mEq/L in the newborn and 5.5 mEq/L in the older child and adult. Hyperkalemia is an uncommon finding in healthy subjects, because cellular and renal adaptations prevent significant accumulation of K^+ in the ECF. Because the kidney provides the primary means of eliminating excess K^+ , hyperkalemia is frequently observed with major disturbances of renal excretory function. A classification of disorders associated with hyperkalemia is presented in Table 8.7.

Clinical Disorders Associated with Hyperkalemia

Pseudohyperkalemia

Pseudohyperkalemia represents an *in vitro* elevation of serum K^+ concentration in the absence of any clinical evidence of hyperkalemia and is attributable to K^+ movement out of cells

during or after the drawing of the blood specimen. The serum K^+ concentration is normally up to 0.5 mEq/L higher than the plasma value due to release of K^+ by platelets and leukocytes during the *in vitro* clotting process. Potassium leakage by red blood cells, coincident with *in vitro* hemolysis, is readily demonstrable because of simultaneous release of hemoglobin into the plasma or serum. Hematologic disease associated with marked leukocytosis, thrombocytosis [especially with Kawasaki disease (347)], or familial disorders of erythrocyte membrane permeability (348,349) can lead to increases in serum, but not plasma, K^+ concentration. Inappropriate blood drawing can raise the apparent blood or plasma K^+ concentration by more than 2 mEq/L (350,351).

Transcellular Shift of K^+ from Cells to the Extracellular Fluid
Metabolic Acidosis. The relationship between acid-base balance and transcellular distribution of K^+ predicts that acute metabolic acidosis will often be accompanied by an increase in plasma K^+ concentration as excess protons enter the cell to be buffered intracellularly. Metabolic acidosis due to mineral acids such as hydrochloric acid or ammonium chloride is generally accompanied by an increase in plasma K^+ concentration of up to 1.5 mEq/L

for every 0.1 unit reduction in arterial blood pH (53). In contrast, organic acids such as lactic acid, β -hydroxybutyric acid, and methylmalonic acid and respiratory acidosis usually provoke a lesser rise in the plasma K^+ concentration (352).

Hormones. Cellular uptake of K^+ is influenced by several hormones, including insulin, catecholamines, and mineralocorticoids. Impairment of hormonally mediated uptake processes may result in hyperkalemia. Thus, hyperkalemia may complicate insulin deficiency (353), exercise during treatment with beta-blockers such as propranolol and metoprolol (354), and hypoaldosteronism, either hyporeninemic or that which follows administration of angiotensin-converting enzyme (ACE) inhibitors (355) or angiotensin receptor antagonists.

Severe Exercise. Potassium is normally released from muscle cells during exercise (51), and this local release of K^+ plays a vasodilatory role to maintain enhanced blood flow to the exercising muscle (60,356). With more severe exercise and reduction of ATP levels in the cells, the ATP-dependent K^+ channels open, so that K^+ is released from muscle cells.

TABLE 8.7. CLINICAL DISORDERS ASSOCIATED WITH HYPERKALEMIA

Pseudohyperkalemia	Decreased renal excretory capacity
Hematologic disorders: leukocytosis, thrombocytosis, test tube hemolysis	Renal failure
Improper collection of blood	Acute
Transcellular shift of K^+ from cells to the extracellular fluid	Chronic
Metabolic acidosis	Effective circulating volume depletion
Impaired hormone activity	Hypoaldosteronism
Insulin deficiency	Hyporeninemia
Exercise (beta blockade)	Congenital adrenal enzymatic defects
Severe exercise	21-hydroxylase defects
Hyperosmolality	Aldosterone synthase defects
Increased tissue catabolism	Primary adrenal insufficiency
Drug effects	Impaired renal tubular secretion without abnormalities in mineralocorticoid production
Succinylcholine	Pseudohypoaldosteronism type I
Digoxin (overdose)	Mutations in mineralocorticoid receptor (consider new pseudohypoaldosteronism type II)
β -adrenergic blockers and α -adrenergic agonists	Familial hyperkalemia with hypertension (originally pseudohypoaldosteronism type II)
Arginine hydrochloride	Includes Spitzer-Weinstein and Gordon's syndromes
Familial hyperkalemic periodic paralysis	Acquired forms with normal mineralocorticoid production
Increased potassium load	Sickle cell disease
Exogenous	Renal transplantation
Oral or parenteral potassium supplements	Systemic lupus erythematosus
Salt substitutes	Lead nephropathy
Potassium penicillin in high doses	Papillary necrosis
Blood transfusion	Obstructive and reflux uropathy
Addition of KCl to parenteral fluid bags with poor mixing	Distal renal tubular acidosis (voltage-dependent defect)
Endogenous	Drug effects
Intravascular hemolysis	Potassium-sparing diuretics
Rhabdomyolysis	Prostaglandin synthesis inhibitors
Exercise	Angiotensin-converting enzyme inhibitors
Infection	Miscellaneous (trimethoprim-sulfamethoxazole, pentamidine, heparin, cyclosporine A, tacrolimus)
Trauma	
Burns	
Tumor lysis	
Severe starvation	

Hyperosmolality. Hyperosmotic infusion of mannitol or saline, or acute hyperglycemia may lead to an acute increase in plasma K^+ concentration, as K^+ leaks from cells (63,65,67). With the rise in osmolality, there is a fluid shift from intracellular to extracellular space and a resulting increase in intracellular K^+ concentration. K^+ accompanies the fluid shift out of the cells via solvent drag. The higher cellular K^+ gradient stimulates K^+ efflux via K^+ channels in the membrane.

Increased Tissue Catabolism. When an increased rate of tissue breakdown occurs, large amounts of K^+ may be released into the ECF to cause hyperkalemia. Clinical examples of hypercatabolism include the use of cytotoxic drugs causing tumor lysis syndrome (61), extensive trauma (357), and massive hemolysis (358).

Drug Effects. Certain drugs alter the normal distribution of K^+ in the body. Depolarizing muscle relaxants used in general anesthesia such as *succinylcholine* cause release of K^+ from muscle during cellular depolarization (359). In healthy subjects the increment in plasma K^+ concentration is small, but in patients with neuromuscular disease, trauma, burns, tetanus, or renal insufficiency succinylcholine can induce an increase in plasma K^+ concentration of as much as 6 mEq/L (360–362). Patients who have taken an overdose of *digoxin*, a drug that inhibits cellular $Na^+-K^+-ATPase$ so that intracellular K^+ leaks from cells, can also acutely develop marked hyperkalemia (363–365).

Nonspecific β -adrenergic blockade and α -adrenergic stimulation impair extrarenal disposal of K^+ . Although beta-blockers normally produce only a small increment in plasma K^+ concentration, they should be used with caution in patients with renal insufficiency (366). Commonly used α -adrenergic agonists such as phenylephrine can also contribute to hyperkalemia. A relatively pure β_1 -selective adrenergic blocker (metoprolol, atenolol) is safer in these settings (367).

Arginine hydrochloride may cause hyperkalemia as the cationic amino acid enters cells and displaces intracellular K^+ (368). Severe hyperkalemia has been reported in patients with renal and hepatic failure; patients in the latter group are unable to metabolize the arginine (352).

Hyperkalemic Periodic Paralysis. Hyperkalemic periodic paralysis is a rare familial disorder with autosomal dominant inheritance characterized by recurrent episodes of muscle weakness that occur in association with hyperkalemia (369). Episodes are precipitated by rest after strenuous exercise, exposure to cold or glucocorticoids, or ingestion of small amounts (0.5 to 1 mEq/kg) of exogenous K^+ (266), and are often aborted by carbohydrate feeding. Several characteristics of this disorder, aside from the association of

hyperkalemia with the attacks, differ from those of the entity hypokalemic periodic paralysis. Attacks begin at a younger age (first or second decade of life) and are more frequent and of shorter duration (usually less than 2 hours) than those of the hypokalemic disorder.

The disease is associated with a point mutation of the gene encoding the α subunit of the voltage-gated Na^+ channel of human skeletal muscle (SkM1), which results in a single amino acid substitution of a highly conserved residue (369,370). The mutation leads to increased activity of the Na^+ channel (371) or disruption of fast inactivation of these channels after the action potential; this allows Na^+ entry into the cells, which depolarizes the membrane and favors K^+ diffusion out of the cells with the development of hyperkalemia.

Attacks can be aborted by treatment with β -adrenergic agonists such as albuterol, which drive K^+ back into cells (372). Other long-term treatment modalities include limiting exercise, consuming a low- K^+ , high-carbohydrate diet, inducing mild K^+ depletion with a thiazide diuretic or mineralocorticoid, and adding a carbonic anhydrase inhibitor (373).

Increased K^+ Load

Exogenous K^+ Load. The healthy individual is easily able to tolerate an acute K^+ load due to both early cellular uptake, the predominant means of short-term disposal of K^+ , and, later, renal excretion (22). However, oral K^+ loads exceeding 160 mEq in adults can cause fatal increases in plasma K^+ concentrations to above 8 mEq/L, even in patients with normal renal function (374). Severe hyperkalemia is more likely to occur with a rapid intravenous infusion or in infants, because of their small size (373). Infants, as well as adults, have become hyperkalemic after the administration of potassium penicillin in an intravenous bolus (1.7 mEq K^+ per 1 million U) (375,376) or after the use of stored blood (more than 5 days old) in exchange transfusions (377).

Most salt substitutes contain significant amounts of K^+ (10 to 13 mEq/g or 50 to 65 mEq per level teaspoon) (378) and can cause severe hyperkalemia in infants (379) or those who concurrently use ACE inhibitors. Many enteral nutrition products, including Boost and Ultracal (Mead Johnson), Ensure Plus (Nestle), Promote (Ross) and Scandishake (Scandipharm) contain K^+ in concentrations exceeding 40 mEq/L. Intravenous KCl preparations added to parenteral fluid bags without adequate mixing may layer out at the injection port, so that the initial solution administered to the patient has a markedly elevated K^+ concentration (380,381).

Endogenous K^+ Load. Massive cellular breakdown with endogenous K^+ release after intravascular coagulation, sickle cell hemolytic crisis, rhabdomyolysis, trauma, burns, massive gastrointestinal bleeding, tumor lysis syndromes associated

with chemotherapeutic destruction of lymphoproliferative malignancies (e.g., lymphoma), and, less frequently, solid tumors (e.g., neuroblastoma), as well as severe starvation, can rapidly induce hyperkalemia (62,353).

Decreased Renal Excretory Capacity

Potassium excretion is normally so efficient that even a massive long-term increase in K^+ intake will not produce hyperkalemia in healthy subjects (382). Thus, for hyperkalemia to persist, urinary K^+ excretory capacity must be reduced. Three major causes of reduced urinary K^+ excretion include renal failure, decreased effective circulating volume, and hypoaldosteronism.

Renal Failure. Hyperkalemia is a routine complication of acute renal failure. Not only does an acute decrease in glomerular filtration rate limit net urinary K^+ losses, but also the diminished urinary flow rate in the distal nephron, where K^+ secretion is flow dependent, markedly impairs further K^+ excretion (383,384). Hyperkalemia may develop in nonoliguric patients because of an acute increase in K^+ load requiring excretion, resulting from enhanced tissue breakdown, increased K^+ intake (see Table 8.5 for K^+ content of various foods), hypoaldosteronism, or therapeutic maneuvers such as blood transfusion. Although the rate at which endogenous hyperkalemia develops is variable, patients with uncomplicated abrupt cessation of renal function are expected to demonstrate a rise in plasma K^+ concentration at a rate of approximately 0.5 mEq/L/day (357,385).

In addition to decreased kaliuresis, K^+ uptake by cells is impaired in chronic renal failure (386,387). Cells have reduced K^+ concentrations in the basal state as well as after K^+ loading (22,388). Total body K^+ stores are normal or slightly reduced in stable chronic renal insufficiency (389–391). The reduction in K^+ content in leukocytes and muscle cells in uremic patients can be normalized by hemodialysis, which suggests that accumulation of a uremic toxin inhibits cellular Na^+ - K^+ -ATPase activity and results in impaired K^+ uptake into cells (392–394).

Plasma K^+ concentration in chronic renal failure may be maintained within normal limits by both renal and extrarenal adaptive mechanisms (170,395,396). Despite a marked decrease in glomerular filtration rate, renal adaptation provides for a rapid increase in K^+ excretion per surviving nephron to the extent that K^+ excretion may exceed filtered load in patients with a significant reduction in functional renal mass (101,170,391). However, the capacity of the surviving nephrons to excrete an additional acute K^+ load is generally impaired (391). Extrarenal adaptive mechanisms include increased excretion of K^+ by the colonic mucosa and increased cellular uptake due to high circulating levels of insulin and catecholamines. The finding of hyperkalemia in a stable

patient with chronic renal failure suggests the presence of an increased excretory burden, possibly due to ingestion of K^+ -rich foods and medications.

Acute renal failure is often accompanied by metabolic acidosis secondary to accumulation of organic acids, concomitant lactic acidosis, or ketoacidosis, factors that reduce cellular uptake of K^+ and exacerbate hyperkalemia (53,397). Although most patients with nonoliguric renal failure who maintain a reasonable urine output do not develop hyperkalemia, plasma K^+ concentrations exceeding 7 mEq/L have been observed in very-low-birth-weight neonates with nonoliguric renal failure (398). The hyperkalemia that develops in these infants, provided no exogenous K^+ source exists, likely reflects a shift of K^+ from the intracellular to the extracellular space during the transition from fetal to postnatal life, as well as a limited urinary K^+ excretory capacity (399).

Effective Circulating Volume Depletion. The ability to handle an acute K^+ load is diminished in hypovolemia, in which there is usually a low glomerular filtration rate and increased proximal Na^+ and fluid reabsorption; this results in decreased distal fluid delivery and impaired K^+ secretion, despite secondary hyperaldosteronism (86,400). Volume depletion from salt-losing nephropathy can also result in poor renal K^+ excretion and hyperkalemia (401).

Hypoaldosteronism. Mineralocorticoids stimulate K^+ secretion in both the colon and the kidney and so are of primary importance in maintaining K^+ homeostasis. Deficiencies in mineralocorticoid production or end-organ responsiveness can thus result in hyperkalemia. The most common causes are hyporeninemic hypoaldosteronism and the use of K^+ -sparing diuretics in adults and adrenal enzyme deficiencies in children (298,373). In addition to hyperkalemia, varying degrees of Na^+ wasting and metabolic acidosis are present in hypoaldosteronism (because aldosterone normally stimulates Na^+ reabsorption and H^+ and K^+ secretion; see earlier). The metabolic acidosis is a type IV RTA.

Hyporeninemic hypoaldosteronism may account for more than half the cases of initially unexplained hyperkalemia in adults (402,403), after elimination of obvious causes. Most patients are adults who have a mild to moderate impairment of renal function that complicates diabetic glomerulosclerosis, or other chronic renal disease such as obstructive uropathy, sickle cell disease, tubulointerstitial nephritis, or even glomerulonephritis (298,404). Typically, the hyperkalemia and hyperchloremic metabolic acidosis found in these patients is disproportionate to the degree of renal insufficiency (353,402). A similar clinical picture has been observed in hyporeninemic children, who often have primary renal interstitial disease (405). Because angiotensin II and K^+ are the main physiologic stimuli to aldosterone secretion, hyporeninemia is

clearly an important cause of the hyperkalemia. The mechanisms responsible may include a primary renal defect leading to decreased renin secretion, a primary adrenal defect in aldosterone biosynthesis or release, or a mixed disturbance (402,404).

Congenital adrenal enzymatic defects in mineralocorticoid production lead to depressed aldosterone synthesis. Whereas certain of these disorders are accompanied by an increased synthesis of other compounds with mineralocorticoid-like properties, such as DOC, other enzyme deficiencies may not allow production of alternate mineralocorticoid-like hormones. The most common of the latter disorders is *21-hydroxylase* deficiency, characterized by diminished mineralocorticoid and glucocorticoid production with consequent salt wasting, hyperkalemia, virilization, and failure to thrive (278, 406,407). Children with a defect in *aldosterone synthase* have isolated hypoaldosteronism (408–410). Infants affected by this rare autosomal recessive disorder have salt wasting, recurrent dehydration, hyperkalemia and failure to thrive (278,411).

Treatment varies with the type of enzyme deficiency. Mineralocorticoid replacement with fludrocortisone is sufficient in patients with isolated hypoaldosteronism, whereas those with 21-hydroxylase deficiency require replacement of both mineralocorticoid and glucocorticoid (as hydrocortisone or dexamethasone) (373).

In *primary adrenal insufficiency* there is diminished glucocorticoid as well as mineralocorticoid secretion, but the clinical picture is dominated by the complications of salt wasting, even though there may also be symptoms and signs of hyperkalemia (412). Severe hyperkalemia is more likely to occur in patients receiving inadequate mineralocorticoid replacement or in those with significant intravascular volume depletion and reduced glomerular filtration rate in whom low distal urinary flows further limit renal K^+ excretion (413).

Impaired Tubular Secretion without Abnormalities in Mineralocorticoid Production. *Pseudohypoaldosteronism type I* is an autosomal recessive disorder of end-organ resistance to aldosterone associated with renal salt wasting; elevated NaCl concentrations in sweat, stool, and saliva; hyperkalemia; and markedly elevated plasma renin activity and aldosterone concentrations (414,415). These findings resemble the aldosterone resistance caused by K^+ -sparing diuretics, except that all aldosterone target organs are involved, including colon and sweat and salivary glands. The disorder is especially marked in the neonatal period, with vomiting, hyponatremia, failure to thrive, and occasionally respiratory distress syndrome. These infants do not respond to exogenous mineralocorticoids, but with vigorous salt replacement and control of hyperkalemia, they can survive. The severity of the disorder appears to lessen with maturation, and most patients ultimately out-

grow the need for therapy (414–417). The defect appears to be a mutation in any one of the three ENaC subunits leading to a loss of function (418,419). Although many patients outgrow the need for therapy by age 4 years (298), the disorder has been reported in children as old as 7 years of age (420).

Low-birth-weight infants may demonstrate a similar transient disorder with salt wasting and hyperkalemia, abnormalities that usually resolve spontaneously by approximately 6 weeks of age (421,422). The underlying disorder appears to be a hyporesponsiveness of the immature distal tubule and cortical collecting duct to aldosterone (421). Unlike those with the ENaC mutations, these affected patients do not have pulmonary or other organ system involvement. In keeping with the hyporesponsiveness to aldosterone, studies have identified in affected patients and kindreds mutations in the mineralocorticoid receptor gene (MLR) (423).

Carbenoxolone, which inhibits 11β -HSD type II (the enzyme that converts cortisol to cortisone), can partially correct the apparent mineralocorticoid resistance in these patients (424). By slowing the conversion of cortisol to cortisone, carbenoxolone raises the intracellular cortisol concentration sufficiently to maintain high activation of the wild-type mineralocorticoid receptor and thus overcome the functional defect in the mutant receptor in this autosomal dominant disorder (284).

All index cases had presented with neonatal salt wasting with hyperkalemic acidosis despite high aldosterone levels, and all improved with age, so that none was symptomatic by 10 years of age. This mild disease contrasts with the more severe form of pseudohypoaldosteronism type I, which is mediated by mutations in ENaC genes, and might be considered as a new class of *pseudohypoaldosteronism type II* (284). A suggested nomenclature for these genetic disorders in which blood pressure and aldosterone secretion are inversely related is shown in Table 8.8. Similar improvement with age is seen in patients with congenital hypoaldosteronism due to aldosterone synthase deficiency, which probably reflects a reduced dependence on aldosterone action with increasing age (425). Therapy with Na^+ supplementation has been shown usually to correct the biochemical and clinical abnormalities, although plasma aldosterone levels remain elevated. High-dose fludrocortisone may be beneficial if a high-salt diet is ineffective or not tolerated (426).

Patients with sickle cell disease, renal transplants, systemic lupus erythematosus, lead nephropathy, papillary necrosis, or reflux or obstructive uropathy may present with a similar clinical picture that resembles hyporeninemic hypoaldosteronism but is characterized by normal levels of aldosterone in the plasma (435,437,438).

Familial hyperkalemia with hypertension (formerly pseudohypoaldosteronism type II) is manifest by a primary defect in renal distal nephron K^+ secretion. Rather

TABLE 8.8. SUGGESTED NOMENCLATURE FOR DISORDERS OF POTASSIUM HOMEOSTASIS IN WHICH BLOOD PRESSURE IS INVERSELY PROPORTIONAL TO ALDOSTERONE SECRETION

Descriptor	Inheritance	Mutations	Phenotype	OMIM
Pseudoaldosteronism				
PA1	AD	γ and β ENaC subunits	\uparrow BP, \downarrow K, \downarrow pH	177200
PA2	AD	S801L MR	\uparrow BP, \downarrow K, \downarrow pH	605115
Pseudohypoaldosteronism				
PHA1	AR	α , β , γ ENaC subunits	\uparrow K, \uparrow pH, \downarrow BP (neonatal)	264350
PHA2	AD	MR	\uparrow K, \uparrow pH, \downarrow BP (mild)	177735

\uparrow , increased; \downarrow , decreased; AD, autosomal dominant; AR, autosomal recessive; BP, blood pressure; ENaC, epithelial sodium channel; K, plasma potassium concentration; MR, mineralocorticoid receptor; OMIM, Online Mendelian Inheritance in Man; PA, pseudoaldosteronism; pH, plasma pH; PHA, pseudohypoaldosteronism; S801L, serine to leucine mutation at position 801 of the MR.

From Warnock DG. Renal genetic disorders related to K⁺ and Mg²⁺. *Annu Rev Physiol* 2002;64:845, with permission.

than being volume depleted due to salt wasting, these patients present with hyperkalemia, volume expansion-mediated hypertension, normal glomerular filtration rate, low or low-normal plasma renin activity and aldosterone concentrations, metabolic acidosis, and short stature; all have normal dietary K⁺ intake and Na⁺ handling (Spitzer-Weinstein syndrome) (427–430). This syndrome is probably similar to Gordon's syndrome and the chloride shunt syndrome (431,432).

Despite the hyperkalemia, the fractional excretion of K⁺ (2.8%) is an order of magnitude less than in controls studied similarly (427). Low-renin hypertension appears to become more severe with aging in this autosomal dominant disorder (433). The lack of Na⁺ wasting and a normal antinatriuretic response to exogenous mineralocorticoids indicate that the underlying abnormality is not simply resistance to aldosterone. Enhanced NaCl reabsorption by the distal tubule leads to both volume expansion and decreased distal Na⁺ and fluid delivery to the K⁺-secreting cells of the cortical collecting duct, which thereby reduces K⁺ secretion and causes hyperkalemia. Administration of a mineralocorticoid leads to an appropriate reduction in Na⁺ excretion but does not appreciably affect that of K⁺. On the other hand, urinary K⁺ excretion increases dramatically after the infusion of Na⁺ with a nonchloride anion, such as sulfate or bicarbonate (431).

Therapy consists of a high-Na⁺, low-K⁺ diet and usually a thiazide diuretic; the latter suggests that the primary defect in this disorder may be increased activity of the thiazide-sensitive NaCl co-transporter in the luminal membrane of cells of the distal tubule and adjacent connecting segment (432,434,435).

Genetic studies of patients with this disorder (Online Mendelian Inheritance in Man No. 145260) have identified probable gain-of-function missense mutations in members of the WNK family of serine-threonine kinases that are expressed in the distal nephron (436). These

kinases may serve to increase transcellular or paracellular Cl⁻ conductance in the collecting duct, thereby increasing salt reabsorption and intravascular volume, while concomitantly dissipating the electrical gradient and dissipating K⁺ secretion. Another possibility is that the mutant kinases stimulate constitutive activity of the Na-Cl co-transporter in the cortical collecting duct or a marked increase in the activity of this transporter in the distal tubule (436).

Distal Renal Tubular Acidosis—Hyperkalemic Form. Hypokalemia is generally observed with distal RTA, in part because the decrease in H⁺ secretion requires that Na⁺ reabsorption occur in exchange for K⁺ secretion. However, hyperkalemia may result when the underlying mechanism is a decrease in distal Na⁺ reabsorption (439); this is the voltage-dependent defect. Hyperkalemic RTA most often occurs in patients with obstructive uropathy (440) and sickle cell disease (441). Unlike in hyporeninemic hypoaldosteronism, which is also observed in these disorders, in RTA the plasma aldosterone level is normal.

Drug Effects. Distal nephron K⁺ secretion is inhibited by the *K⁺-sparing diuretics*, which are used primarily to mitigate diuretic-induced K⁺ depletion but are also administered to patients with cirrhosis. Spironolactone acts as a competitive inhibitor of aldosterone. Triamterene and amiloride diminish K⁺ secretion independently of mineralocorticoids by directly closing the luminal Na⁺ channel in cells of the distal nephron and thereby decreasing the negative luminal voltage. Severe hyperkalemia can develop in patients with compromised renal function and occasionally in patients with diabetes in whom cellular K⁺ uptake is impaired in the absence of insulin (442).

Inhibitors of prostaglandin synthesis such as nonsteroidal antiinflammatory drugs also cause hyperkalemia. Inhibition of prostaglandin synthesis produces iatrogenic hyporeninemic hypoaldosteronism (443). Prostaglandins

also inhibit NaCl reabsorption in the loop of Henle, thereby augmenting distal tubular delivery of Na⁺.

ACE inhibitors such as captopril or enalapril increase plasma K⁺ levels by blocking the conversion of angiotensin I to angiotensin II, the latter of which is a potent vasoconstrictor and stimulator of aldosterone release. Patients on long-term ACE inhibitor therapy do not routinely develop clinically significant hyperkalemia unless their course is complicated by renal or adrenal insufficiency, congestive heart failure with decreased renal perfusion, or administration of nonsteroidal antiinflammatory drugs.

Other drugs that are associated with hyperkalemia include trimethoprim-sulfamethoxazole, pentamidine, heparin, and calcineurin inhibitors (cyclosporin A, tacrolimus). High-dose trimethoprim therapy, commonly used for the treatment of *Pneumocystis carinii* infection, frequently causes a significant increase in plasma K⁺ levels (by approximately 1 mEq/L). Like amiloride, trimethoprim and pentamidine cause hyperkalemia by blocking the luminal Na⁺ channel, which decreases luminal electronegativity and thereby reduces K⁺ secretion (444–446). Heparin reversibly suppresses adrenal aldosterone production and can thus be associated with a natriuresis and reduced urinary excretion of K⁺ (447). Therefore, plasma K⁺ concentration should be monitored in patients taking heparin for 3 or more days, particularly if these patients are at risk for development of hyperkalemia due to complicating renal insufficiency, diabetes, or use of other K⁺-retaining drugs. Cyclosporine A (448) and tacrolimus (449), immunosuppressive drugs routinely used by transplant recipients, have been associated with hyperkalemia, even in patients with normal renal function and no evidence of transplant rejection.

Clinical Manifestations of Hyperkalemia

The clinical consequences of hyperkalemia are related to the adverse electrophysiologic effects of an altered transmembrane K⁺ gradient on excitable tissues. Specifically, an increased extracellular K⁺ concentration reduces the resting membrane potential, initially enhancing but ultimately suppressing tissue excitability (“depolarizing block”).

Cardiac

Cardiac toxicity generally develops when the plasma K⁺ concentration rises above 7 mEq/L, a concentration that should immediately signal the need for initiation of specific treatment for hyperkalemia (450,451). Regardless of the degree of hyperkalemia, however, treatment should be initiated in any patient with suspected hyperkalemia if electrocardiographic abnormalities characteristic of hyperkalemia are noted. It is important to remember that the extracellular K⁺ concentration demonstrates at best a rough correlation with the onset and degree of cardiotoxicity. For example, adverse effects may be seen with a plasma K⁺ concentration of less than 7 mEq/L if hyperkalemia has devel-

oped acutely or is accompanied by other metabolic derangements such as acidosis or hypocalcemia (373). The characteristic electrocardiographic changes accompanying hyperkalemia are depicted in Figure 8.10. The first and most specific abnormality seen is development of tall, peaked T waves, which usually become apparent with plasma K⁺ levels above 6 mEq/L. The PR interval lengthens and the QRS complex then widens. At K⁺ concentrations above 8 mEq/L, the P-wave amplitude decreases and may in fact disappear with atrial standstill. As ventricular conduction time continues to lengthen, the QRS complex merges with the peaked T wave, producing a “sine-wave” pattern. Finally, ventricular fibrillation or asystole may occur with K⁺ levels above 10 mEq/L.

Neuromuscular

Hyperkalemia is clinically associated with changes in neuromuscular conduction. Persistent depolarization inactivates Na⁺ channels in the cell membrane, thereby producing a net decrease in membrane excitability (373). This is manifested clinically by skeletal muscle weakness, paresthesias, and ascending flaccid paralysis. Such muscle weakness does not usually develop until the plasma K⁺ concentration exceeds 8 mEq/L (452). Generally, the trunk and head muscles as well as muscles of respiration are spared.

Approach to the Patient with Hyperkalemia

Diagnosis

The diagnostic workup of a patient with hyperkalemia should begin with a complete history taking similar to that described earlier for hypokalemia. The physical examination must include measurement of growth indices and blood pressure, assessment of volume status, and evaluation for signs of chronic illness.

An electrocardiogram must be obtained promptly for any patient with hyperkalemia. Because renal failure is a common cause of hyperkalemia, additional laboratory evaluation should include a repeat set of plasma, not serum, electrolyte levels including glucose, calcium, blood urea nitrogen, and creatinine. Note that sequential measurements of plasma K⁺ concentrations are expected to vary little from day to day. Increased K⁺ load due to increased tissue breakdown can be assessed from the complete blood count and levels of uric acid, lactate dehydrogenase, and creatine phosphokinase enzymes. Renal function can be further assessed with a urinalysis. An abnormal urinary specific gravity or pH may suggest a renal tubular defect, such as obstructive uropathy or RTA, whereas the presence of casts or large amounts of protein or red blood cells is consistent with glomerular disease. Information regarding renal K⁺ conservation can be obtained from a timed collection on a constant Na⁺ and K⁺ intake (2 to 3 mEq/kg/day), which will allow the calculation of creatinine clearance, absolute K⁺ excretion

TABLE 8.9. PHARMACOLOGIC TREATMENT OF ACUTE HYPERKALEMIA^a

Mechanism of action	Drug	Dosage	Route of administration	Onset of action	Duration of action
Antagonism Redistribution	Calcium gluconate (10%)	100 mg/kg/dose (= 1 mL/kg/dose)	i.v. over 3–5 min	1–3 min	30 min
	Glucose (25%) (insulin)	0.5 g/kg (= 2 mL/kg) (regular insulin, 0.1 U/kg)	i.v. over 15–30 min	30 min	2–4 h
Removal	Albuterol (0.5%)	0.1–0.3 mg/kg for <12 yr 2.5–5.0 mg for >12 yr	Nebulized over 10 min	Within 30 min	4–6 h
	Sodium bicarbonate	1–2 mEq/kg	i.v. over 5–10 min	10–30 min	2 h
	Furosemide	1–2 mg/kg	i.v. or i.m.	15–30 min	4–6 h
	Sodium polystyrene sulfonate resin	0.5–1.0 g/kg	Orally or rectally	60–120 min	4–6 h

^aIn the setting of acute or chronic renal failure or failure to remove adequate amount of potassium, dialytic removal may be necessary.

rate, fractional excretion of K⁺, urinary Na⁺/K⁺ ratio, and transtubular K⁺ gradient (TTKG) (see later).

Hyperkalemia is frequently due to a condition that causes impairment of urinary K⁺ excretion. The most common conditions are advanced renal failure, severely reduced effective volume depletion, and hypoaldosteronism (because aldosterone is the primary hormone mediating urinary K⁺ excretion). If renal function is normal or only modestly impaired and no other causes are obvious, the patient should be evaluated for hypoaldosteronism. In infants and children, enzyme deficiencies and type I pseudohypoaldosteronism are most common. Salt wasting may be very severe in infants with hypoaldosteronism, who typically present with volume depletion, hyperkalemia, hyponatremia, metabolic acidosis, and an elevated urinary Na⁺ concentration. Ultimately, measurement of morning plasma renin activity and aldosterone and cortisol levels should be performed. The patient should be given 0.5 to 1 mg/kg of furosemide the night before the blood specimens are obtained. This regimen enhances aldosterone secretion (via stimulation of renin) in healthy subjects, but not in patients with hypoaldosteronism (402).

In addition to measuring plasma aldosterone level, one can estimate the degree of aldosterone activity by measuring the tubular fluid K⁺ concentration at the end of the cortical collecting duct. In humans, this determination can be estimated clinically from the calculation of the TTKG, on the assumption that (a) urine osmolality at the end of the cortical collecting duct is comparable to that in plasma and (b) little or no K⁺ is transported in the medullary collecting duct. The calculation is relatively accurate as long as the urine is not dilute and urine [Na⁺] is above 25 mEq/L (453,454). Thus,

$$\text{TTKG} = \frac{\{\text{urine } [\text{K}^+]/(\text{urine osmolality}/\text{plasma osmolality})\}}{\text{plasma } [\text{K}^+]}$$

Normally, TTKG is 8 to 9 on a regular diet and rises to above 11 with a K⁺ load, which indicates increased K⁺ secretion by the cortical collecting duct (454). Hypokalemia with a TTKG higher than 4 suggests renal K⁺ loss due to increased distal K⁺ secretion. A value below 7, and

particularly below 5, in a hyperkalemic patient is highly suggestive of hypoaldosteronism. Limited urine flow (and distal Na⁺ delivery), rather than a limitation in the secretion of K⁺, may be seen in advanced congestive heart failure resulting in insufficient urinary K⁺ excretion.

The TTKG is normally higher in infants (median 7.8) than in children (median 6.3) and correlates directly with the fractional excretion of K⁺ and urine K⁺/Na⁺ ratios (455). In patients with hypoaldosteronism and pseudohypoaldosteronism, TTKG values varied between 1.6 and 4.1, and all were below the third percentile established for the age of the subject (455). The TTKG level is lower in preterm neonates than in term infants (456), which probably reflects the immaturity of renal tubular K⁺ secretion or hyporesponsiveness to aldosterone.

Therapy

The presence of severe hyperkalemia (plasma K⁺ concentration above 8 mEq/L) with electrocardiographic abnormalities or severe muscle weakness is a potentially life-threatening event that requires immediate therapeutic intervention with almost all of the measures listed in Table 8.9. Such treatment can prevent fatal cardiac arrhythmias. Treatment measures used in this medical emergency can be divided into three general categories: (a) those that rapidly antagonize the membrane effects of hyperkalemia, (b) those that rapidly enhance the transfer of extracellular K⁺ into cells, and (c) those that remove K⁺ from the body. Because the onset and duration of action of each of these maneuvers differ, and because the first two measures are only temporizing, several treatment methods, including at least one for inducing K⁺ removal from the body, should be instituted simultaneously for symptomatic hyperkalemia (373). For asymptomatic hyperkalemia, treatment can be solely with a cation exchange resin, because rapid therapy is not necessary.

The effect of hyperkalemia on the cardiac cell membrane can be rapidly reversed with calcium. A rise in ionized calcium makes less negative the threshold potential at

which excitation occurs and thereby mitigates the depolarizing blockade resulting from hyperkalemia. Calcium gluconate (10%) is the preparation most often used; it is infused slowly intravenously with continuous electrocardiographic monitoring. The duration of action is transient, and cardiotoxicity will reappear once the infused calcium is sequestered in bone or is excreted.

Somewhat more long-lasting effects (several hours) can be obtained by transferring extracellular K^+ into cells and thereby reestablishing a more physiologic transmembrane potential gradient. This can be well accomplished by inducing endogenous insulin release through infusion of glucose. It has been customary to give insulin as well, although this may not be necessary in the absence of diabetes. The dose of glucose with or without insulin may be repeated as needed, with monitoring for the complications of hyperglycemia or hypoglycemia.

Administration via nebulizer of β_2 -agonists (albuterol, salbutamol), which promote K^+ uptake by cells, has been widely used in adults for the treatment of hyperkalemia in chronic renal failure (457) and has been shown to be safe and efficacious in children as well (458). A single dose of nebulized albuterol can lower plasma K^+ concentration by as much as 0.5 mEq/L (457,458); the more potent parenteral preparation is not available in the United States. Transient side effects associated with this class of drug include elevation of heart rate, tremor, and mild vasomotor flushing.

Although alkalization of the ECF with sodium bicarbonate to promote the rapid cellular uptake of K^+ was formerly recommended as a mainstay of therapy, it is no longer considered to be useful. However, this maneuver remains valuable if metabolic acidosis is at all responsible for the hyperkalemia.

The treatment options discussed thus far are only temporizing. To remove K^+ from the body, renal K^+ excretion must be enhanced, for example, by stimulating flow-dependent K^+ secretion in the distal nephron through administration of loop or thiazide diuretics, a response that requires the presence of good renal function. Diuretics are useful in chronic hyperkalemia due to hypoaldosteronism, heart failure, or a selective K^+ secretory defect (373).

In patients with renal insufficiency, a cation exchange resin may be administered to promote gastrointestinal elimination. Sodium polystyrene sulfonate (Kayexalate) is the resin used most commonly. Within the intestinal lumen the resin binds 1 mEq of K^+ in exchange for 1 mEq of Na^+ ; 1 g/kg of resin is expected to reduce plasma K^+ concentration by 1 mEq/L. When given orally, each gram of resin is suspended in 3 to 4 mL water and mixed with 70% sorbitol or a 10% aqueous dextrose solution to reduce constipation. The resin is most often provided as a retention enema in sorbitol, to be retained for at least 15 to 30 minutes. Because the efficacy of K^+

removal by the resin is variable and the cation exchange is not entirely specific for K^+ , plasma concentrations of K^+ , Ca^{2+} , and Mg^{2+} as well as the electrocardiogram must be monitored frequently. Administration can be repeated at least six times in 24 hours.

Addition of sodium polystyrene sulfonate directly to infant formulas and nutritional supplements (1 g/mEq K^+ in the formula) effectively lowers the K^+ content by approximately 50% (459). However, caution should be exercised in routinely prescribing this mode of therapy, because pretreatment of the formulas is associated with a 200% increase in Na^+ concentration, a problem that may be avoided by using calcium polystyrene sulfonate (459). Failure of the resin to control hyperkalemia should prompt the clinician to evaluate whether K^+ is being continuously delivered to the ECF, possibly from extensive ongoing tissue damage or continued absorption of K^+ -containing gastrointestinal contents.

If the amount of K^+ to be removed is of such magnitude that the administration of cation exchange resins does not suffice, dialysis may be necessary. Hemodialysis can remove up to 1 mEq/kg of body weight per hour in children and adults (460). Plasma K^+ concentration can be lowered by using a low dialysate K^+ concentration. Dialysis against a low- K^+ bath must be performed cautiously, however, because rapid fluctuations in plasma K^+ concentration can induce cardiac rhythm disturbances (461). One approach that is especially useful if frequent measurements of plasma K^+ concentration are not possible is to lower the K^+ concentration of the dialysate in gradual decrements over the course of the dialysis treatment (461). Continuous venovenous hemofiltration is also effective in removing total body K^+ from hemodynamically compromised patients. Peritoneal dialysis is less efficient in removing K^+ (462).

Patients with disease characterized by chronic hyperkalemia, such as chronic renal insufficiency (glomerular filtration rate less than 10% of normal), require indefinite dietary K^+ restriction and frequent monitoring of the plasma K^+ concentration. Because patients differ in their dietary intake, extrarenal handling of K^+ , and rates of glomerular filtration and urinary flow, the regimen for K^+ restriction must be tailored to the individual. Occasionally, these patients require the use of supplemental oral cation exchange resins (0.1 g/kg three times a day) to maintain normokalemia.

Children with hypoaldosteronism often respond to the oral mineralocorticoid fludrocortisone acetate (0.1 to 1 mg/day). Fludrocortisone may exacerbate preexisting hypertension or edema, however, so that better control of the hyperkalemia is achieved using a low- K^+ diet and a loop or thiazide-type diuretic. Persistent hyperkalemia associated with K^+ secretory abnormalities in the absence of diminished renal function or hypoaldosteronism often improves with a thiazide diuretic.

ACKNOWLEDGMENTS

The studies in the author's laboratory have been supported by National Institutes of Health grants HD13232 and DK50603 and grants-in-aid from the New York Heart Association and American Heart Association. The author was an Established Investigator of the American Heart Association (1984–1989). Thanks to Ms. W. Lepsch for assistance in preparing the manuscript.

ACID-BASE HOMEOSTASIS

JAMES C. M. CHAN
ROBERT H. K. MAK

The importance of acid-base homeostasis is underscored by Hastings (1):

To Faraday, we are indebted for naming the products of dissociation, ions—and thus we came by hydrogen ion, a term now synonymous with proton. . . . Tiny though it is, I suppose no constituent of living matter has so much power to influence biological behavior . . .

Endogenous cellular metabolism produces two kinds of hydrogen ion or acid (2). The first class of acid is the volatile, metabolizable acid that on complete oxidation is converted to carbon dioxide (CO₂) and water, with the CO₂ rapidly excreted by the lungs (3). The second category of acid is the nonvolatile, nonmetabolizable net acid, with the kidneys as its sole route of elimination (4). With the lungs and kidneys working in concert to maintain acid-base homeostasis, the normal blood pH can be maintained close to 7.40 despite challenges to acid-base homeostasis. This complex subject may seem difficult. A historical prospective on how the field developed may assist in this understanding (5).

HISTORICAL PERSPECTIVE

The first clinical account of severe disturbances in acid-base homeostasis was O'Shaughnessy's delineation of the massive loss of carbonate of soda in the watery diarrhea of cholera victims during the 1831 epidemic in London (6). No distinction was made between carbonate and bicarbonate at the time. Physiologic acid-base disturbances were next noted in 1877 when Walter (7) found that administration of hydrochloric acid by stomach tube to rabbits caused a virtual depletion of the CO₂ in blood. In 1909, Henderson's renowned monograph illustrated the interrelationships between the metabolic and respiratory components of acid-base equilibrium by an equation that subsequently became known as the *Henderson-Hasselbalch equation* (8). In the same year, Sorensen (9) perfected the first electrode to measure hydrogen ion concentration in the blood and coined the term *pH* to stand for the negative logarithm of

the hydrogen ion concentration. In 1923, Bronsted and Lowry (10) set forth the modern definition of an *acid* as a substance that donates hydrogen ion and a *base* as a substance that accepts hydrogen ion. At the same time, Van Slyke (11), in collaboration with Wu and McLean in the Beijing Union Medical College and Hastings in the Rockefeller University, perfected the acid-base measuring equipment that has since come to be known as the *Van Slyke apparatus*. In the preinsulin era, these advances had major clinical implications in the early detection and treatment of diabetic ketoacidosis by averting diabetic coma and markedly improving the survival rate of patients (12,13).

PHYSICAL CHEMISTRY OF ACIDS AND BASES

In accordance with the universally accepted Bronsted and Lowry definition (10), an *acid* is a donor of proton or hydrogen ion, and a *base* is an acceptor of proton or hydrogen ion.

As visualized in the above equation, HA is an acid able to donate a hydrogen ion, and A⁻ is a base able to accept a hydrogen ion. The acid-base pair is intimately linked, with HA being the conjugate acid of A⁻, and A⁻ being the conjugate base of HA. Acids and bases differ in "strength" contingent on their readiness to donate or accept a hydrogen ion. A strong acid yields its hydrogen ion promptly; a weak acid tends not to (e.g., hydrochloric acid is a strong acid because it dissociates almost completely into its hydrogen ion and chloride ion; in contrast, a weak organic acid does not readily dissociate into hydrogen ion and its conjugate base).

The blood pH of 7.40 is normally maintained within the range of 7.35 to 7.45, despite continuous dietary metabolic and endogenous production of acids and bases. Prevention of excess fluctuations of blood pH beyond these ranges is necessary for optimal cellular enzyme activity and membrane integrity. Substantial pH fluctuations can precipitate severe glycolysis and brain dysfunction (14,15).

In view of the fact that the term *pH* stands for the negative logarithm of hydrogen ion concentration, it is inappropriate to present calculated mean values of *pH* or to take percentage changes in *pH* values. The change in *pH* and the corresponding hydrogen ion concentration are shown below:

<i>pH</i>	H ⁺ (nEq/L)
7.35	44.7
7.40	39.8
7.45	35.5

BICARBONATE AND NONBICARBONATE BUFFERING SYSTEMS

The first line of defense against acid-base disturbances resides in the blood bicarbonate and nonbicarbonate buffering systems. In the plasma, the buffers consist of bicarbonate, inorganic phosphate, and protein. In the erythrocytes, the buffers consist of hemoglobin, oxyhemoglobin, inorganic and organic phosphate, and bicarbonate. At a normal blood *pH* of 7.40, 40% of the total buffering capacity of the blood resides in the plasma and erythrocyte bicarbonate buffering system. As metabolic acidosis develops and the blood *pH* falls to, for example, 7.30, more and more bicarbonate is used up. Thus, determination of the total blood bicarbonate concentration is a reliable indicator of the degree of metabolic acidosis.

In addition to the blood buffering system, two additional systems defend the acid-base homeostasis: the respiratory system and the renal system.

The respiratory compensation to any acid-base disturbance is prompt. In contrast, the renal response to acid-

base disturbance is gradual, with stepwise increments of net acid excretion to a hydrogen ion load over 3 or 4 days until maximum renal acidification occurs and the excretion of hydrogen ion reaches a plateau (Fig. 9.1). Closer examinations of the normal responses show that the titratable acidity component of the renal net acid excretion rises abruptly, primarily with the phosphate buffering of the hydrogen ion in the urine. The ammonium component of the net acid excretion rises more gradually in a stepwise fashion until glutaminase-dependent ammonium formation reaches a plateau.

INTERRELATIONSHIP BETWEEN METABOLIC AND RESPIRATORY COMPONENTS

Changes of serum bicarbonate concentration correlate closely with changes in blood *pH*. Carbonic acid (H₂CO₃) concentration stays in balance with the CO₂ content of the blood because the lungs provide an open system of exchange. These relationships between the metabolic component (as represented by the plasma bicarbonate in mEq/L) and the respiratory component [as represented by the plasma partial pressure of CO₂ (PCO₂) in mm Hg] are governed by the Henderson-Hasselbalch equation:

$$pH = pK + \log \frac{HCO_3^-}{S \times PCO_2}$$

where HCO₃⁻ is the bicarbonate concentration (24.0 mEq/L); S is the solubility constant of H₂CO₃ (S = 0.03 at 37°C); PCO₂ is the partial pressure of CO₂ in blood (PCO₂ = 40 mm Hg); and pK is the dissociation constant for both CO₂ and H₂CO₃. With pK of 6.1 and the log of

FIGURE 9.1. Net acid excretion of urinary titratable acid (TA) and ammonium (NH₄⁺). With any acid load, the renal acidification rises in stepwise fashion until a maximum level is achieved in 3 or 4 days, after which a plateau is reached. In chronic renal failure, the urinary acidification is inadequate.

FIGURE 9.2. Relationship between the metabolic component (plasma bicarbonate) and the respiratory component [plasma partial pressure of carbon dioxide (PCO_2)] in clinical acid-base disturbances. The diagrams represent 95% confidence limits between changes in plasma bicarbonate (mEq/L) in relationship with a predictable increase or fall in PCO_2 .

$\text{HCO}_3^-/\text{S} \times \text{PCO}_2 = 1.3$, the normal pH is 7.4.

In the clinical setting, the pH of blood is determined by the interrelationship between the metabolic component and the respiratory component. The metabolic component in blood and the respiratory component are shown in Figure 9.2 (2,16–18). There is a narrow confidence limit for the respiratory compensation to acid-base disturbance. The ninety-fifth percentile confidence limits for respiratory acidosis and metabolic acidosis are wide and are less useful clinically (Fig. 9.2).

Let us use the example of a child with severe metabolic acidosis secondary to diarrhea dehydration to illustrate the respiratory compensation to metabolic acidosis. The plasma bicarbonate has fallen to 10 mEq/L due to bicarbonate loss in the diarrhea. In this case, in the absence of any secondary process, the respiratory response (hyperventilation) brings the PCO_2 down to approximately 20 mm Hg, within the ninety-fifth percentile confidence limits for metabolic acidosis (Fig. 9.2). However, if the plasma PCO_2 should stay above the ninety-fifth percentile confidence limits, an independent secondary process interfering with CO_2 exchange (e.g., a pneumonitis or airway obstruction) would have to be considered. On the other hand, if the PCO_2 were to fall below the fifth percentile confidence limits, an independent secondary process stimulating the respiratory center (e.g., salicylate intoxication) would have to be

postulated. Thus, any PCO_2 value outside of the ninety-fifth percentile confidence limits for metabolic acidosis would indicate a secondary process other than a normal respiratory compensation.

NUTRITION AND ACID-BASE HOMEOSTASIS

Hydrogen ion production from metabolism of dietary intake or endogenous production is eliminated by excretion in the urine. The impact of dietary intakes on the urinary acidity was first described by Claude Bernard (19):

One day, rabbits from the market were brought into my laboratory. . . . I happened to observe that their urine was clear and acid. This fact struck me because rabbits, which are herbivore, generally have turbid and alkaline urine; while on the other hand carnivore, as we know, have clear and acid urine. . . . So I had rabbits fed on cold, boiled beef (which they eat very nicely when given nothing else). My expectation was again verified, and as long as the animal diet was continued, the rabbits kept their clear and acid urine.

As a result of Bernard's observation, the acidity of a carnivorous diet influencing the urinary pH and net acid excretion has become widely accepted (13,20). The urine of vegetarians has an average pH of 6.6 (21). However, some confusion remains because of the ambiguity of what consti-

TABLE 9.1. INFLUENCE OF DIETARY ALKALINE ASH AND METABOLISM OF SULFUR-CONTAINING AMINO ACIDS ON RENAL ACID EXCRETION

Diet	N	Alkaline ash (mEq/d)	Urinary sulfate (mEq/d)	Net acid excretion (mEq/d)	Urine pH
Milk	4	131.3	71.4	66.7	<7.00
Lettuces	2	40.1	56.7	60.4	<7.00
Vegan	2	58.8	23.5	29.2	>7.10
DL-methionine	1	—	92.1	92.9	5.10
Beef fillet	1	—	124.5	137.5	5.60

N, number of subjects studied.

Note: Calculated mean values from the original data of Hunt (21) in normal medical students and in vegan subjects.

tutes a typical vegetarian diet. In some cases, a vegetarian may simply eschew red meat while continuing to consume eggs, dairy products, and fish as well as vegetables and fruit. Those whose alkaline ash diets do have a small effect on urine pH are the vegans who consume only food of vegetable origin and exclude dairy products, eggs, and fish.

ALKALINE ASH IN FOOD

The acidity-alkalinity of dietary ash has been calculated by McCance and Widdowson (22) to be the cation content of sodium, potassium, calcium, and magnesium, minus the anion content of chloride and phosphorus. If the cations are in excess, as is the case in most vegetables, the foodstuff is considered to provide an alkaline ash.

Such excess of cation implies that the foods with an alkaline residue must contain a surplus of organic anions (e.g., citrate and bicarbonate). Therefore, it has been assumed that the ingestion of a high alkaline ash diet should result in an alkaline urine. Consistent with that assumption is the fact that ingestion of large amounts of sodium bicarbonate indeed alkalinizes the urine, the bicarbonate being recovered more or less quantitatively from the urine. The reasonableness of such an assumption may account for the scarcity of published experiments testing it. Until recently, the dietary and metabolic sources of acid in the urine do not appear to have been thoroughly investigated since the work of Sherman and Gettler (23). Subsequently, Sherman (24) came to the conclusion that most of the acid in the urine had its origin in the oxidation of sulfur from dietary sulfur-containing amino acids. However, confirmatory data were not available until the work of Hunt (21). To test the relationship between an alkaline ash diet and urinary output of acid, Hunt placed four students on a diet limited to 3 to 5 liters of milk per day for 4 days, supplying a caloric intake of 2100 to 3400 calories a day. Milk was chosen both because it is a “highly standardized food” with an alkaline ash and because it is a “complete food for infants” and,

therefore, cannot be criticized as being “unnatural.” The pH of the daily outputs of urine showed no increase, although the diet certainly had an alkaline ash. The total net acid excretion was confirmed to be more closely correlated with the urinary sulfate excretion (Table 9.1).

However, interpretation of Hunt’s experimental results was clouded by the fact that the protein content of the diet was high and protein metabolism was known to promote acid urine. Therefore, another source of alkaline ash was used in a second experiment. Hunt (21) persuaded two volunteers to eat 4 kg of lettuce each day for 4 days, supplying an alkaline ash content of approximately 40 mEq/day. However, even such large amounts of alkaline ash did not neutralize the acid excreted through the kidney, whereas the sulfate output approximately matched the output of acid. Hunt (21) also collected data on two subjects who had lived on a vegan diet for several years, showing that their urinary output of acid was lower but well balanced by the urinary output of sulfate. Their urinary pH was greater than 7.

CONCEPT OF HYDROGEN ION BALANCE

To determine the influence of diets with a high content of sulfur, Hunt (21) supplemented the diet of one subject with 583 mEq of sulfur as DL-methionine. The mean urinary output of acid immediately increased to 92.9 mEq/day, and the urinary output of sulfur rose to 92.1 mEq/day—results clearly demonstrating that the sulfur of methionine is oxidized in the body to sulfate, which is then excreted in the urine together with a corresponding amount of net acid. In further studies, Hunt (21) provided another volunteer with 7 pounds of beef fillet only, most of which he ate in 2 days. His urinary net acid excretion, however, did not match his urinary sulfate excretion.

To reconcile these discrepancies, Lemann and Relman (25) conducted additional studies that confirmed Hunt’s work by showing that sulfur-containing amino acids are oxidized to urea plus CO_2 , water, sulfate, and hydrogen ion. From the amount of urinary sulfate excreted, the

amount of hydrogen ion produced in this step of intermediary metabolism could be extrapolated. In view of the fact that the total net acid excretion was not fully accounted for, Relman et al. (26) searched for a second component of endogenous acid production, discovering that incompletely oxidized organic acid dissociates in the renal tubule to organic anion and hydrogen ion. By measurement of organic anions, the obligatory renal excretion of fixed, "nonmetabolizable" hydrogen ion produced by dissociation of organic acid could be extrapolated. Furthermore, because the hydrogen ion produced by dissociation of organic acid could be extrapolated from the two metabolic sources combined and approximated the net acid excretion measured, Relman et al. (26) proposed that endogenous acid production from intermediary metabolism can be estimated by summing urinary sulfate and organic anion. A typical daily acid production of 70 mEq was thus established.

In a later study (27), Lennon, Lemann, and Litzow found that the correlation between net acid excretion and endogenous acid production as computed by the sum of the sulfate and organic anions could be improved by subtracting the quantity of "undetermined anion" in the diet. As defined by McCance and Widdowson (22), the "undetermined anion" in foodstuff is the difference between the cations and the predominant anions, calculated as the sum of sodium, potassium, calcium, and magnesium minus the sum of chloride and phosphorus. Lennon et al. (27) further refined the correlation by taking the undetermined anion in the stool into consideration. The difference between undetermined dietary anion and undetermined stool anion constitutes the amount of undetermined anion absorbed.

Despite these refinements, the endogenous acid production continues to be estimated as the sum of sulfate and organic anions (27–29). Finally, in view of the fact that phosphorus is present in food as phosphates, phosphorus oxidation is negligible (21), and phosphoric acid production, once proposed as a third component of endogenous acid production (30), is consequently ignored in the computation of endogenous acid production (27–29). Rather, phosphate intake is accounted for in the dietary undetermined anion computations (27–29).

ACID-BASE BALANCES IN INFANTS AND CHILDREN

Chan (31) carried out metabolic balance studies in ten healthy, normal, 1-week-old infants receiving the milk formula Similac as their sole dietary intake. The sum of cations minus the sum of anions in the milk left a value of 8 mEq/kg body weight per day as the undetermined dietary anion fraction. Similarly computed, the undetermined stool anion fraction was 5 mEq/kg body weight per day. Thus, the undetermined anion fraction absorbed was an

insignificant portion of the total dietary anions. Similar studies in ten adult volunteers who agreed to consume only milk for 14 days also revealed insignificant undetermined anion absorption (31).

Goodman, Lemann, and Lennon (32) demonstrated that, despite minor daily fluctuations, the cumulative acid balance in normal individuals is approximately zero. Typical acid production in adults is estimated at 70 mEq/day by extrapolating from urinary sulfate and organic anion. The urinary acid output is also estimated to be 70 mEq/day (32). Goodman et al. (32) demonstrated that with chronic renal insufficiency, serum CO_2 content reaches the acidotic level over a period of 6 days after withdrawal of bicarbonate therapy. The patient's net acid production is not matched by the compromised net acid excretion; therefore, a positive balance of 21 to 30 mEq of acid per day can be demonstrated (32). In other words, withdrawing the alkaline therapy of a patient with chronic renal disease led to a metabolic acidosis resulting primarily from hydrogen ion retention.

In view of the fact that acid retention may continue for months or years in patients with chronic renal acidosis, the base-donating tissue must have a large alkaline pool that can be expended very slowly. Evidence points toward bone as the source of the endogenous base.

The acidosis of chronic renal failure is accompanied by retention of such metabolic wastes as urea and creatinine. Moreover, in renal insufficiency, vitamin D metabolism is defective (33–35). Thus, the effects of metabolic acidosis on calcium metabolism are more appropriately examined in the "pure" state, namely in children with renal tubular acidosis (RTA) but normal renal function. Most adults with RTA have some renal impairment resulting from nephrocalcinosis and nephrolithiasis; for example, of adult patients with RTA studied by Goodman et al. (32), few had a normal glomerular filtration rate.

The acid balance data of two young brothers with distal type I RTA, studied by Chan, are shown in Figure 9.3A,B. Over a 6-day period, the patient in Figure 9.3B maintained a mean net acid balance of 22 mEq/M²/day and manifested persistent metabolic acidosis. In contrast, with the alkaline therapy increased to over 100 mEq/M²/day, the patient in Figure 9.3A regained a normal serum CO_2 concentration and a zero acid balance by the end of the study period (41).

The major effects of alkaline therapy on mean daily calcium balances are shown in Figure 9.4. During the patient's acidotic period, his mean calcium intake was 44 mEq/day, and the stool and urinary calcium outputs were 25 and 8 mEq/day, respectively, leaving a mean calcium balance of 11 mEq/day. The dramatic threefold increase in his mean calcium balance to 32 mEq/day ($p < .05$) on correction of acidosis by alkaline therapy is clearly shown. Most of the improvement occurred through reduction of calcium losses in the stool; a lesser

FIGURE 9.3. A: Serum CO₂ content and acid balance in a 4-year-old boy with type I renal tubular acidosis (RTA) who received alkaline therapy that increased to more than 100 mEq/M²/day. B: Serum CO₂ content and acid-base balance in a 6-year-old boy with RTA-I. C: Fifty-nine-year-old woman with distal RTA and normal kidney functions.

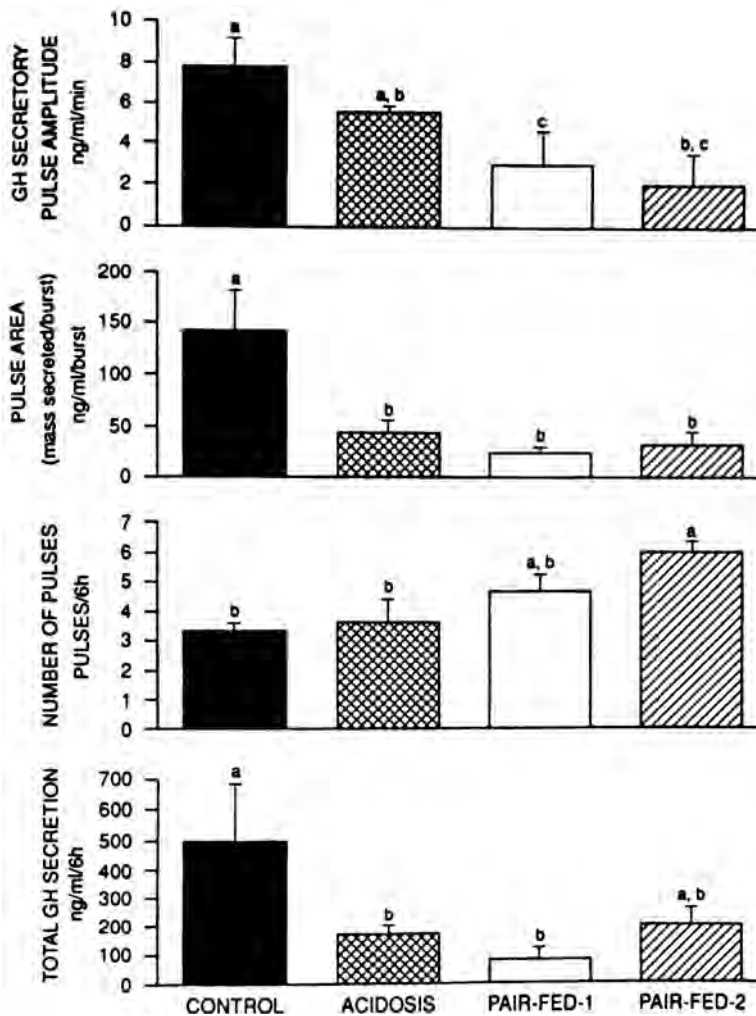

FIGURE 9.5. Data from deconvolution analysis of pulsatile growth hormone (GH) secretion in control (N = 9), acidotic (N = 9), pair-fed-1 (N = 8), and pair-fed-2 (N = 6) groups. Values for mean GH secretory pulse amplitude (height), pulse area (mass), pulse number, and total GH secreted as pulses are shown. Data are expressed as means \pm standard error of means. *Pair-fed-1* indicates animals pair-fed in the morning, and *pair-fed-2* indicates pair-fed in the afternoon. In each panel, values with *a*, *b*, or *c* are significantly different ($p = .05$). (From Challa A, Krieg RJ, Thabet MA, et al. Metabolic acidosis inhibits growth hormone secretion in rats: mechanism of growth retardation. *Am J Physiol* 1993;265:E547-E553, with permission.)

effect was attributable to reduction of urinary calcium losses.

The data of Greenberg et al. (36,37) and of Cooke et al. (38) for children with RTA also show that their patients' calcium balances underwent improvement with correction of metabolic acidosis.

The underlying mechanism of the growth failure of children with RTA has remained unclear. It is commonly assumed that because negative calcium balances have been found to accompany positive acid balances and hypercalciuria in adults with renal acidosis secondary to renal parenchymal diseases, then negative calcium balances must also occur in children with RTA. The foregoing calcium balance data therefore contain some interesting information. First, in contrast to the persistent negative calcium in adults with stable metabolic acidosis secondary to parenchymal renal diseases, the children studied clearly maintained positive calcium balances in both the acidotic and the corrected states. The manifold augmentation of their calcium balances through reduction of fecal and urinary calcium losses as a consequence of aci-

dosis correction amply demonstrates that metabolic acidosis diminishes intestinal calcium absorption in children with classic type I RTA.

In a recent study, Lee et al. (39) showed that the enzymatic hydroxylation of 25-hydroxyvitamin-D to 1,25-dihydroxyvitamin-D was impaired in rats made acutely acidotic by ammonium chloride ingestion. Despite some contrary evidence (40), the data of Lee et al. (39) reinforce the hypothesis, based on observations of children with classic RTA (12), that interference with vitamin D metabolism is the mechanism by which systemic metabolic acidosis provokes malabsorption of calcium through the intestinal tract.

MECHANISMS OF GROWTH RETARDATION IN CHRONIC ACIDOSIS

Growth retardation is a frequent, long-recognized complication of chronic metabolic acidosis (41). Preliminary studies in acidotic children with classic RTA have shown a

blunted release of growth hormone (GH) in response to provocative stimuli (42). The growth retardation associated with acidosis can be reversed by systemic bicarbonate therapy (43). The release of GH under acidotic conditions has recently been revisited (44). Exploration in rats with normal anion gap acidosis from ingestion of ammonium chloride demonstrated aberrant GH secretion. Significant inhibition of pulsatile GH secretion was present in the acidotic rats such that both the amplitude of the GH secretory pulse and the area under the curve were significantly smaller than in controls (Fig. 9.5). These reductions in pulse amplitude and area were correlated to decreased growth (weight) in the acidotic rats (44). Using *in situ* hybridization histochemistry in combination with immunocytochemistry, the expression of GH/insulin-like growth factor (IGF)-1 in the tibial epiphyseal growth plate has been examined (45). Evaluation of tibial epiphyseal growth plate (IGF-1) gene expression in acidotic and control rats revealed that IGF-1 messenger RNA abundance was lower in the acidotic growth plates (45). IGF-1 peptide was predominantly localized to the hypertrophic zone of chondrocytes and was weakly detectable in the proliferative zone in both the acidotic and control rats' growth plates (45). Anthropomorphic measurements demonstrated that acidotic rats grew less than did control rats in both length and weight, and these physical measurements were reflected in the size of the tibial epiphyseal growth plates being significantly smaller in the acidotic rats compared with the control group. Taken together, these observations suggest that metabolic acidosis reduces IGF-1 message abundance and induces resistance to IGF-1 peptide action within the tibial epiphyseal growth plate. As demonstrated in two independent laboratories (46,47), the use of GH to stimulate growth in normal anion gap acidosis has been ineffective, despite enhancement of IGF-1 and IGF binding protein immunoreactivity within the stem-cell chondrocyte zone of the tibial epiphyseal growth plate.

CONCEPT OF UNDETERMINED ANION GAP

The serum undetermined anion gap is usually approximated by the difference between the measured cation, sodium (140 mEq/L), minus the measured anions, chloride (105 mEq/L), and bicarbonate (25 mEq/L). This typically gives a normal anion gap of 10 mEq/L. This anion gap is made up of the undetermined variables consisting of sulfate, phosphates, and others. In view of the variability in measurements of serum sodium, chloride, and bicarbonate, the normal anion gap varies between 8 and 15 mEq/L.

Significantly elevated anion gap, not related to laboratory errors in measurements of the cation and anions, can be found when there is accumulation of endogenous lactic acid and keto acids or in uremic acidosis related to accumulation of sulfate and phosphates. Intoxications with salicylate,

paraldehyde, methanol, or ethylene glycol ("antifreeze") may give rise to acidosis with large anion gaps. Elevated anion gaps, in the absence of intoxication or uremia, are usually encountered in alcoholic ketoacidosis and diabetic ketoacidosis, with lactic acid, β -hydroxybutyric acid, and acetoacetic acid accumulation. The differential diagnosis of normal anion gap associated with acidosis, especially in the neonate, is presented in Table 9.2.

FIGURE 9.6. Acid-base nomogram. Shown are the 95% confidence limits of the normal respiratory (RESP) and metabolic compensations for primary acid-base disturbances. (From Dubose TD Jr, Cogan MG, Rector FC. Acid-base disorder. In: Brenner BM, Rector FC, ed. *Brenner and Rector's the kidney*, 5th ed. Philadelphia: WB Saunders, 1996:929-998, with permission.)

Abnormally depressed anion gap may be related to a reduction in serum albumin or secondary to overhydration. In addition, intoxications (e.g., lithium or polymyxin B) may give rise to significantly reduced anion gap due to increased undetermined cations. Increased serum cationic proteins in multiple myeloma should be in the differential diagnosis of a decreased anion gap.

RENAL REGULATION

The average American diet generates 1 to 3 mEq/kg/day of net acid in healthy infants and children (48,49) and 50 to 80 mEq/day in healthy adults (50). In addition, HCO_3^- may be lost in urine or stool. The kidney maintains acid-base homeostasis by reabsorption of HCO_3^- from the glomerular filtrate as well as hydrogen ion secretion into the urine. The balance of HCO_3^- , pH, and PCO_2 in acute and chronic abnormal acid-base states is shown in Figure 9.6. Most of the known transporters and exchangers involved have now been cloned and characterized. Mutations in the genes encoding these proteins form the molecular basis of the known inherited disorders of acid-base balance.

Proximal Mechanisms

The proximal tubule reabsorbs 80 to 90% of the filtered HCO_3^- and lowers luminal pH by only 0.5 to 0.7 pH units (50). HCO_3^- reabsorption in the proximal tubule is mediated primarily by H^+ ion secretion by a Na^+ - H^+ exchanger (NHE)-3 at the luminal membrane (51,52) and HCO_3^- transport via a Na^+ - HCO_3^- cotransporter (NBC)-1 (53). H_2CO_3 is formed within proximal tubular cells by hydration of CO_2 , a reaction catalyzed by cytoplasmic carbonic anhydrase (CA) II (54). H_2CO_3 ionizes and H^+ ion is secreted in exchange for luminal Na^+ . This mechanism is electron neutral and is driven by the lumen-to-cell Na^+ gradient, which is generated by the basolateral membrane Na^+ - K^+ -adenosine triphosphatase (ATPase). HCO_3^- exits across the basolateral membrane by mass action as well as by carrier-mediated cotransport by the Na^+ - HCO_3^- exchanger (NBC-1). The secreted H^+ combines with filtered HCO_3^- to form luminal H_2CO_3 , which is dehydrated by luminal CA IV to form H_2O and CO_2 . Luminal CO_2 can freely diffuse back into the cell to complete the reabsorption cycle. These processes are described in Figure 9.7 (49). Approximately 20% of the filtered HCO_3^- is reabsorbed by passive back-diffusion along the paracellular pathway. Major factors that regulate the proximal acid-base processes include the filtered load, peritubular HCO_3^- , pH, PCO_2 , and angiotensin (AT) II. Other less important or less well-defined factors include extracellular volume, peritubular protein concentration, NaCl reabsorption, K^+ depletion, parathyroid hormone (PTH), Ca^{2+} , and adrenergic nerve activity (49,50).

FIGURE 9.7. Schematic model of HCO_3^- reabsorption in proximal convoluted tubule. The processes occurring are H^+ secretion at the luminal membrane via a specific Na^+ - H^+ exchanger (NHE) and HCO_3^- transport at the basolateral membrane via a 1 Na^+ -3 HCO_3^- cotransporter. Cytoplasmic carbonic anhydrase (CA II) and membrane-bound carbonic anhydrase IV (CA IV) are necessary to reabsorb HCO_3^- . ATP, adenosine triphosphate. (From Rodriguez-Soriano J. Renal tubular acidosis: the clinical entity. *J Am Soc Nephrol* 2002;13:2160–2170, with permission.)

NHEs extrude protons from cells and take up sodium ions into cells. Six isoforms (NHE-1 to NHE-6) have been cloned. The housekeeping NHE-1 is located at the basolateral membrane of most renal tubular cells. NHE-2 is located apically in selected nephron segments. Both isoforms have minor roles in renal salt and water handling. NHE-3 is the predominant apical isoform in the proximal tubule and loop of Henle, whereas NHE-2 is the predominant isoform in the distal tubule (51,52). Fourteen isoforms of CA have been identified. Cytosolic CA II comprises approximately 95% of renal CA. CA II is expressed in the proximal convoluted and straight tubules, thin ascending and thick ascending limbs of the loop of Henle, and intercalated cells of the cortical and medullary cortical collecting duct; it is weakly expressed in principal cells and the inner medullary collecting duct. Membrane-associated CA is mostly CA IV, which is linked to the apical membrane via a glycosylphosphatidylinositol anchor. CA IV is also localized on the basolateral membranes of proximal tubules (54). There are four NBC isoforms and two NBC-related proteins. NBC-1 is expressed on the basolateral membrane of the proximal tubule, is electrogenic, and is directly stimulated by CA II, which binds to the carboxy terminal of NBC-1. NBC-2 has two variants—NBCn1 and mNBC3—both of which are electroneutral transporters. NBCn1 is expressed on the basolateral membrane of the thick ascending limb of Henle, whereas mNBC3 is expressed on the apical membrane of intercalated cells (53). Furthermore, an apical proton-translocating vacuolar ATPase (H^+ -ATPase) is also present and contributes significantly to proximal HCO_3^- reabsorption. This is a multisubunit enzyme with a membrane-bound component (V_0 domain) and an intracellular catalytic component (V_1 domain) (55).

Distal Mechanisms

Urine acidification occurs in the distal tubule by three processes: (a) reabsorption of the remainder of the filtered HCO_3^- , which is left over from the proximal tubule (approximately 20%); (b) titration of divalent basic phosphate (HPO_4^-), which is converted to the monovalent acid form (H_2PO_4^-) or titratable acid; and (c) accumulation of ammonia intraluminally, which buffers H^+ to form nondiffusible ammonium (NH_4^+). These processes are described in Figure 9.8.

The thick ascending limb of the loop of Henle reabsorbs approximately 15% of the filtered HCO_3^- load through the apical NHE-3. It also participates in NH_3 transport. NH_4^+ absorption occurs in the apical membrane of the loop of Henle by both the $\text{Na}^+\text{K}^+-2\text{Cl}^-$ cotransport as well as K^+-H^+ antiport systems. The medullary thick ascending limb has low permeability to NH_3 , which limits back-diffusion. A medullary NH_4^+ concentration gradient is generated and amplified by countercurrent multiplication through NH_4^+ secretion into the proximal tubule and possibly into the thin descending limb of the loop of Henle. The accumulation of NH_3 in the medullary interstitium increases the driving force for diffusion of NH_3 into the collecting tubule.

Distal urinary acidification occurs mainly in the collecting duct. In the cortical collecting tubule, the principal cells are in charge of Na^+ reabsorption and K^+ secretion, whereas the intercalated cells are involved in HCO_3^- absorption and H^+ secretion. There are two types of intercalated cells. The α cell is responsible for H^+ secretion, and the β cell is responsible for HCO_3^- absorption. There is a lack of consensus as to whether α and β intercalated cells are molecular images of each other or separate cell types. The cellular

FIGURE 9.8. Schematic model of H^+ secretion in cortical collecting tubule. The main pump for luminal H^+ secretion in the α -type intercalated cell is a vacuolar H^+ -adenosine triphosphatase (ATPase). An H^+, K^+ -ATPase is also involved in H^+ secretion. Intracellularly formed HCO_3^- leaves the cell via Cl^- - HCO_3^- exchange, facilitated by an anion exchanger (AE1). Cytoplasmic carbonic anhydrase II (CA II) is necessary to secrete H^+ . ATP, adenosine triphosphate. (From Rodriguez-Soriano J. Renal tubular acidosis: the clinical entity. *J Am Soc Nephrol* 2002;13:2160–2170, with permission.)

processes involved in distal acidification are described in Figure 9.8. H^+ is secreted by vacuolar H^+ -ATPase on the luminal surface of α intercalated cells in the cortical collecting tubule and outer medullary collecting duct. The secreted H^+ is generated by intracellular CA on H_2CO_3 . Basolateral Cl^- - HCO_3^- exchanger facilitates exchange of Cl^- for HCO_3^- . A gastric-type H^+, K^+ -ATPase is also present on the luminal surface of intercalated cells in the same regions and contributes to H^+ secretion and K^+ absorption. Buffer systems are present to prevent extreme luminal acidity. NH_3 is produced from glutamine and enters the lumen by nonionic diffusion. NH_3 captures H^+ to form NH_4^+ . Filtered phosphate provides another buffer (Fig. 9.8). These acid salts comprise titratable acidity and enable urine acidification. NH_3 also stimulates the cortical collecting duct net HCO_3^- reabsorption by activating an apical H^+, K^+ -ATPase independent of NH_3 's known effects on intracellular pH. This mechanism is dependent on intracellular calcium and a zinc endopeptidase specific for vesicle-associated SNARE protein and appears to involve insertion of cytoplasmic vesicles into the apical plasma membrane of cortical collecting duct intercalated cells (56).

Mineralocorticoids, Na transport, buffer delivery, changes in systemic pH and PCO_2 , luminal pH, and potassium status are important factors in the regulation of distal acidification. Aldosterone stimulates H^+ -ATPase in the intercalated cells and sodium reabsorption by the principal cells. Distal acidification is subject to different regulatory factors along different segments. Acidification in the cortical collecting tubule is regulated by Na^+ transport-dependent changes in potential difference as well as chronic systemic acid-base status. The outer medullary cortical tubule has a high capacity for H^+ secretion but is not affected by systemic acid-base status or by sodium transport. The inner medullary duct is regulated by systemic acid-base status and K^+ balance (49,50).

H^+, K^+ -ATPases belong to the X^+K^+ -ATPase subfamily of P-type cation-transporting ATPase. H^+, K^+ -ATPases are composed of at least 13 different subunits, organized into a membrane-anchored V_0 (stalk) domain through which protons are moved and a V_1 head that hydrolyzes ATP. At least two of the α intercalated cell apical pump's subunits, the β subunit in the V_1 domain and the α subunit in the V_0 domain, have been found to be different tissue-specific isoforms. Several isoforms of H^+, K^+ -ATPase have been identified in the kidney. Renal tubular apical pumps contain β_1 rather than β_2 subunits and α_4 instead of α_1 subunits. Being ubiquitously expressed, β_2 and α_1 are regarded as the housekeeping isoforms. The colonic isoform, $\text{H}^+, \text{K}^+\alpha_2$, has been localized to the outer and inner renal medulla and appears to be site-specifically upregulated in response to chronic hypokalemia. $\text{H}^+, \text{K}^+\alpha_2$ assembles stably with β_1 - Na^+K^+ -ATPase in the renal medulla and in the distal colon (57–59). Apical tubular H^+, K^+ -ATPase is functionally coupled to basolateral HCO_3^- exit (in exchange for Cl^-) via the

anion exchanger (AE) AE1. Na⁺-independent AEs—AE1, AE2, and AE3—are expressed in the kidney. The AE1 gene encodes erythrocyte eAE1 (band 3), the major intrinsic protein of the erythrocyte as well as kidney kAE1, the basolateral Cl⁻-HCO₃⁻ exchanger of the acid-secreting type A intercalated cell. Mutations in AE1 are responsible for distal tubular acidosis. The widely expressed AE2 participates in recovery from alkaline load and in regulatory cell volume increase after shrinkage. AE2 is regulated by NH₄⁺. These properties are not shared by AE1. Less is known about AE3 in the kidney (60). Two other potential Cl⁻-HCO₃⁻ exchangers, pendrin and AE4, have been reported and may reside apically in the β intercalated cell (61–63).

RESPIRATORY REGULATION

The CO₂-HCO₃⁻ system in the respiratory tract provides the most important open buffer system for acid-base homeostasis in the body. Its significance can be appreciated if one considers the rate of development of acidosis during an acute respiratory tract obstruction versus that during an acute urinary tract obstruction. H⁺ ions from the addition of acid combine with HCO₃⁻ to form H₂CO₃, which dissociates in the presence of CA into H₂O and CO₂. CO₂ is freely diffusible across alveolar barriers and cell membranes. The efficacy and potency of this system are due to the large buffer capacity in an open system, as CO₂ can rapidly escape from the fluid and be excreted in the lung. A constant PCO₂ is maintained by rapid adjustments in alveolar ventilation (50).

GASTROINTESTINAL REGULATION

Gastrointestinal disorders are common causes of acid-base imbalance in the pediatric age group. Diarrhea is the most common cause of metabolic acidosis in children and results from loss of large quantities of HCO₃⁻. Compared with plasma, diarrheal stools contain a higher concentration of HCO₃⁻ as well as higher amounts of HCO₃⁻ decomposed by reactions with organic acids. Large quantities of K⁺ are also lost in the stools and from the urine as high levels of renin and aldosterone result from hypovolemia. Urine pH may not be less than 5.5 because metabolic acidosis and hypokalemia enhance renal NH₄⁺ synthesis and excretion. Thus, high urinary NH₄⁺ may be the differentiating clinical feature for diarrhea-associated metabolic acidosis from RTA, which typically presents with low urinary NH₄⁺. The urinary anion gap is a useful clinical tool for estimation of urinary NH₄⁺. Gastrointestinal HCO₃⁻ loss can also result from external loss of pancreatic and biliary secretions. Coexistent lactic acidosis is also common in severe diarrheal diseases. On the other hand, H⁺ loss through gastric secretions can be caused by vomiting, gastric aspiration, or

presence of a gastric fistula and result in HCO₃⁻ retention and metabolic alkalosis. Hypovolemia from extracellular volume contraction also results in increased levels of renin and aldosterone, which enhance renal HCO₃⁻ reabsorption in exchange for Cl⁻, which further potentiates the metabolic alkalosis (50).

MINERALOCORTICOID AND OTHER HORMONAL ACID-BASE REGULATION

Mineralocorticoids increase net acid excretion and result in hypokalemic metabolic alkalosis which is only sustained by sufficient distal Na⁺ delivery and, therefore, dependent on adequate salt intake. The normal feedback is extracellular volume expansion and hypertension. There are several congenital forms of metabolic alkalosis with low-renin hypertension from conditions of mineralocorticoid excess or pseudoaldosteronism: Liddle's syndrome, glucocorticoid remediable alkalosis, and apparent mineralocorticoid excess. Congenital hyperkalemic metabolic acidosis may be caused by different forms of pseudohypoaldosteronism. These congenital disorders are now known to result from genetic mutations, and the underlying molecular pathophysiology is now well understood (see the section Molecular Genetics of Acid-Base Homeostasis). Renin generates AT II, which stimulates aldosterone. Renin is increased by diminished effective circulating volume, which is sensed by the kidney. AT stimulates H⁺ transport by both Na⁺-H⁺ exchange and vacuolar H⁺-ATPase in the late distal tubule and only in the early distal segments. This mechanism is mediated through the AT1 receptor (64). AT II, on the other hand, plays an important role in the adaptive enhancement of NH₄⁺ secretion in the proximal tubule (65). Deficiency of 11α- or 17α-hydroxylase gives rise to hypokalemic metabolic alkalosis related to excess mineralocorticoids (e.g., deoxycorticosterone and corticosterone). Glucocorticoids stimulate renal tubule acidification both in proximal and distal nephrons by enhancing NH₄ production and net acid secretion. Excess glucocorticoids cause metabolic alkalosis.

Hypercalcemia and vitamin D excess may increase renal HCO₃⁻ reabsorption. Vitamin D poisoning and excessive ingestion of milk and antacids as in the milk alkali syndrome lead to metabolic alkalosis, nephrocalcinosis, and renal insufficiency (50). The effects of PTH on acid-base homeostasis is controversial. Hyperchloremic metabolic acidosis has been reported in both primary and secondary hyperparathyroid states, and PTH inhibits tubular reabsorption of HCO₃⁻ in rats under conditions of chronic hyperparathyroidism (66). PTH infusion in normal human subjects causes a biphasic response. An initial transient renal acidosis develops on the first day of PTH infusion, followed by a prompt increase in net acid excretion and an increase in plasma HCO₃⁻ to result in a steady state of mild

metabolic alkalosis for up to 13 days (67). PTH is a potent inhibitor of renal proximal tubular NHE-3 (68). GH and IGF-I increase plasma HCO_3^- concentration by increasing renal NH_3 production and NH_4^+ net acid excretion (69).

PHYSIOLOGIC RESPONSES TO METABOLIC ACIDOSIS AND ALKALOSIS

An acute, nonvolatile acid load is distributed rapidly and attenuated by extracellular buffers within 20 to 30 min-

utes. A second phase of buffering by intracellular processes then occurs. Approximately two-thirds of this intracellular buffering is through $\text{Na}^+\text{-H}^+$ exchange and one-third through either $\text{K}^+\text{-H}^+$ or $\text{Cl}^-\text{-HCO}_3^-$ exchanges (70). Intracellular processes function as H^+ storage and restore normal arterial pH within 24 hours of an acute acid load. Renal mechanisms then increase net acid excretion by efficiently retaining all filtered HCO_3^- and increasing both titratable acid and NH_4^+ excretion. With chronic metabolic acidosis, renal acid excretion increases over the course of 3 to 5 days. Proximal conservation of

TABLE 9.4. CAUSES OF METABOLIC ALKALOSIS

Mechanism	Class of agents	Clinical conditions
Excessive loss of acid with volume contraction	Chloride deficiency syndromes	Normal blood pressure, high renin and aldosterone, low potassium: vomiting of gastric juices, gastric drainage fistula; diuretic and laxative abuse; Bartter's syndrome; chloride-deficient infant formula Cystic fibrosis; villous adenoma of the colon; congenital alkalosis with chloride diarrhea (Darrow)
Excessive gain of base	Base overload	Iatrogenic, especially in the context of renal insufficiency; milk alkali syndrome
	Conversion of lactate, acetate to base	Iatrogenic; dialysis excess
	Nonmetabolizable acid into cells	Glucose-induced alkalosis in fasting
Increased (distal) bicarbonate reabsorption	Excess proximal tubular bicarbonate reabsorption	Posthypercapnic state Phosphate excess Hypoparathyroidism
	Volume expansion, mineralocorticoid excess	Hypertension, high renin and aldosterone: secondary nonedematous aldosteronism (e.g., renal artery stenosis, intrarenal vascular disease, accelerated hypertension) Renin-secreting tumors Hypertension, low renin, high aldosterone: primary hyperaldosteronism; dexamethasone-suppressible hyperaldosteronism; adrenal carcinoma Hypertension, low renin, low aldosterone: adrenocorticosteroid excess; deficiency of 11-hydroxylation/17-hydroxylation; adrenal carcinoma; Liddle syndrome; licorice (glycyrrhizic acid) excess

HCO_3^- is achieved by low filtered load of HCO_3^- and enhanced proximal acid excretion. However, the secondary hypocapnia induced by metabolic acidosis may counteract proximal HCO_3^- conservation. The greatly reduced HCO_3^- delivery to the distal tubule plus stimulation of collecting duct H^+ secretion and NH_4^+ excretion result in urine with low pH, almost no HCO_3^- , and high levels of titratable acid and NH_4^+ . Acidosis increases NH_4^+ production through stimulation of glutaminase and phosphoenolpyruvate carboxykinase in the proximal tubule. The increased distal delivery enhances NH_4^+ reabsorption by the thick ascending limb of the loop of Henle, thus increasing the inner medullary NH_3 concentration. This, in turn, increases NH_4^+ excretion in the medullary collecting duct. The net effect is an increase in both renal NH_4^+ production and excretion. Urinary NH_4^+ can increase up to approximately fivefold. The nature of the anion accompanying H^+ affects renal acid excretion. The nonreabsorbable anions enhance the ability to generate a distal tubule potential difference and augment H^+ excretion. Titratable acid excretion can increase by two- or threefold with an absorbable anion but by five- to tenfold with a nonabsorbable anion (e.g., organic anions during ketoacidosis). In severe cases, renal mechanisms may not account for total acid excretion. Bone may represent a major site of acute and chronic intracellular acid buffering. Calcium, phosphorus, and hydroxyproline excretion are increased during metabolic acidosis (50). Conditions that cause metabolic acidosis are described in Table 9.3,

and conditions that cause metabolic alkalosis are described in Table 9.4.

An acute base load is rapidly distributed in the extracellular fluid within 25 minutes (71) followed by cellular buffering of the HCO_3^- load with a half-life of 3 hours. Only one-third of the base load is buffered cellularly, principally by H^+ - Na^+ exchange and to a lesser extent by Cl^- - HCO_3^- exchange. Modest hypokalemia also results. There is poorer stabilization of intracellular pH in the alkaline range than in the acid range. Neutralization of HCO_3^- by buffers results in an increase in PCO_2 , which stimulates ventilation acutely. However, if the respiratory system is compromised, dangerous hypercapnia may ensue. The increase in PCO_2 is approximately 0.75 mm Hg/mEq/L in plasma HCO_3^- . The kidney excretes HCO_3^- more rapidly than acid. The proximal tubule is principally responsible for HCO_3^- excretion. Glomerular ultrafiltrate HCO_3^- rises in conjunction with plasma HCO_3^- , but absolute proximal HCO_3^- reabsorption does not increase because of suppression of proximal acidification processes by alkalemia. The most sensitive response to alkali input is a decline in the excretion of NH_4^+ . The next level of response is to increase the excretion of unmeasured anions. This latter rise is quantitatively the most important process in eliminating alkali. The maximum excretion of citrate is approximately 70% of its filtered load. An even higher alkali load augments the excretion of 2-oxoglutarate to more than 400% of its filtered load. Only with the largest alkali load does bicarbonaturia become quantitatively important. Thus, renal

mechanisms eliminate alkali while minimizing bicarbonaturia. This process of limiting changes in urine pH without sacrificing acid-base balance lessens the risk of kidney stone formation (72).

The physiologic adaptation to metabolic acidosis and alkalosis has also been studied at the molecular level. Chronic acid loading (7-day) is associated with an increase in apical NHE-3 in the renal proximal tubule. Because NHE-3 mediates both proton secretion and Na reabsorption, compensatory changes in Na handling develop, involving decreases in the abundance of the thiazide-sensitive $\text{Na}^+\text{-Cl}^-$ cotransporter of the distal convoluted tubule and both the β and γ subunits of the amiloride-sensitive epithelial Na channel of the collecting duct. In addition, the renal cortical abundance of the proximal type 2 Na-dependent phosphate transporter was markedly decreased. In contrast, abundance of the bumetanide-sensitive Na-K-2 Cl cotransporter of the thick ascending limb and the α subunit of the epithelial Na channels were unchanged. A similar profile of changes is seen with short-term (16-hour) acid loading. Long-term (7-day) base loading with NaHCO_3 results in the opposite pattern of response, with marked increases in the abundance of the β and γ subunits of epithelial Na channel and type 2 Na-dependent phosphate. These adaptations may play critical roles in the maintenance of Na balance when changes in acid-base balance occur (73). Several targets have also been identified at the gene expression level to account for the adaptation of renal NH_4^+ synthesis and transport in response to an acid load. These are key enzymes of ammoniogenesis (mitochondrial glutaminase and glutamine dehydrogenase) and gluconeogenesis (phosphoenolpyruvate carboxykinase) in the proximal tubule, the apical $\text{Na}^+\text{-K}^+(\text{NH}_4^+)\text{-2 Cl}^-$ cotransporter of medullary collecting ducts. Two major factors control the expression of these genes during metabolic acidosis, an acid pH and glucocorticoids, which appear to act in concert to coordinate the adaptation of various tubular cell types (74).

PHYSIOLOGIC RESPONSES TO RESPIRATORY ACIDOSIS AND ALKALOSIS

Respiratory acidosis (Tables 9.5 and 9.6), which follows hypercapnia, is initiated by an increase in arterial partial pressure of CO_2 (PaCO_2) and elicits acidification of body fluids. An acute increase in plasma HCO_3^- occurs and is complete within 5 to 10 minutes. This results from acidic titration of nonbicarbonate buffers, such as phosphates, hemoglobin, and intracellular proteins. When respiratory acidosis is chronic, renal adjustments worsen the acidemia by a further increase in plasma HCO_3^- . This chronic adjustment phase takes 3 to 5 days to complete and involves upregulation of the renal acidification mechanisms. Ninety-five percent confidence limits for graded degrees of acute and chronic respiratory acidosis are shown in Figure 9.6.

TABLE 9.5. CAUSES OF ACUTE RESPIRATORY ACIDOSIS

Mechanism	Conditions
Airway obstruction	Aspiration of vomitus or foreign body Laryngospasm and edema Bronchospasm Obstructive sleep apnea
Neuromuscular impairment	Injury of brain stem and high cord Botulism Tetanus Guillain-Barré syndrome Myasthenia gravis crisis Overdose of narcotic, sedatives Toxic agents (curare, succinylcholine) Aminoglycosids, organophosphate Hypokalemic myopathy Familial hypokalemic periodic paralysis
Thorax or pulmonary disorders	Respiratory distress syndrome Pneumothorax Hemothorax Smoke inhalation Severe pneumonitis
Inadequate ventilation	Large dead space mechanical ventilation Erroneous settings for tidal volume
Vascular accidents	Massive pulmonary embolism and edema Cardiac arrests
Central nervous system depression	General anesthesia Tranquilizer overdose Cerebral trauma or infarction Central sleep apnea

Respiratory alkalosis is initiated by a decrease in PaCO_2 from different causes (Table 9.7). Respiratory alkalosis causes alkalization of body fluids. The acute response consists of a decrease in plasma and is complete within 5 to 10 minutes from the onset of hypocapnia. It occurs by alkaline titration of nonbicarbonate buffers of the body as well as increased production of organic acids. When respiratory alkalosis is chronic, renal adjustments worsen the alkalemia by an additional decrease in plasma HCO_3^- . This adaptation takes 2 to 3 days to complete and involves downregulation of renal acidification mechanisms. Ninety-five percent confidence limits for graded degrees of acute and chronic respiratory alkalosis are also shown in Figure 9.6. For the same PaCO_2 , the degree of alkalemia is lower in chronic than in acute respiratory alkalosis (75). Conditions that cause respiratory acidosis are described in Tables 9.5 and 9.6, and conditions that cause respiratory alkalosis are described in Table 9.7.

Chronic but not acute respiratory acidosis stimulates activity of $\text{H}^+\text{-ATPase}$ and $\text{H}^+\text{,K}^+\text{-ATPase}$ in the proximal tubule, medullary thick ascending limb, and collecting tubule. By contrast, both acute and chronic respiratory alkalosis decrease both renal proton pumps. The stimulatory effect of respiratory acidosis and inhibitory effect of

Arterial hypoxemia		
Multiple mechanisms	Hepatic failure	
	Gram negative sepsis	
	Shock	

PHYSIOLOGIC RESPONSES TO MIXED ACID-BASE DISORDERS

Metabolic acidosis and alkalosis primarily involve plasma HCO_3^- disturbances, whereas respiratory acidosis and alkalosis primarily involve PCO_2 disturbances. Figure 9.2 shows the 95% confidence limits of these simple acid-base disorders. Values that fall outside these limits imply that a mixed disorder may exist. Table 9.8 shows the possible combinations of mixed acid-base disturbances. Primary metabolic disturbances invoke secondary respiratory responses, whereas primary respiratory disturbances invoke secondary metabolic responses. Metabolic acidosis resulting from the addition of nonvolatile acids lowers the extracellular fluid HCO_3^- concentration and, hence, extracellular pH. Medullary chemoreceptors are stimulated by the low pH and invoke an increase in ventilation. The ratio of HCO_3^- to PCO_2 and subsequent pH are returned toward but not entirely to normal. Compensation is a physiologic consequence of the primary disturbance and does not represent a secondary alkalosis or acidosis. However, by definition, mixed acid-base disturbances exceed physiologic limits of compensation.

MOLECULAR GENETICS OF ACID-BASE HOMEOSTASIS

The advent of molecular biology and molecular genetics has advanced our understanding of the *in vivo* functions of acid-base transport proteins and the clinical syndromes caused by their genetic mutations. A gene family of $\text{Na}^+\text{-H}^+$ exchanger has been identified. One of its members, NHE-3, is identified as the $\text{Na}^+\text{-H}^+$ exchanger isoform responsible for transepithelial electroneutral Na^+ absorption in intestine and renal epithelial cells. The NHE-3 gene has been localized to 5p15.3 (77). The transient neonatal form of distal RTA may be caused by immaturity of the NHE-3 $\text{Na}^+\text{-H}^+$ exchanger isoform, which is known to undergo postnatal development (78). No human mutations of the NHE-3 exchange have been identified as yet. The human gene for NBC-1 has been cloned and maps to 4p21. A nonsense mutation in the kidney NBC-1 gene (SLC4A4) has been identified. It predicts a truncated NBC-1 protein with loss of function, compatible with the phenotype of isolated proximal RTA. Other features of the syndrome include ocular abnormalities, mental retardation, and short stature (79).

Inherited defects in two of the key acid-base transporters involved in distal acidification, as well as mutations in cytosolic CA gene, can cause distal RTA. Both autosomal-dominant and autosomal-recessive patterns have been described. Recessive distal RTA present with either acute

TABLE 9.8. MIXED ACID-BASE DISORDERS

Mechanism	Disorders	Adaptation	Blood pH
Inadequate response	Mixed metabolic acidosis and respiratory acidosis	Paco ₂ ↑↑ HCO ₃ ↓↓	Depressed
	Mixed metabolic alkalosis and respiratory alkalosis	Paco ₂ ↓↓ HCO ₃ ↑↑	Elevated
Excessive response	Mixed metabolic acidosis and respiratory alkalosis	Paco ₂ ↓↓ HCO ₃ ↓↓	Normal or decreased or increased
	Mixed metabolic alkalosis and respiratory acidosis	Paco ₂ ↑↑ HCO ₃ ↑↑	Normal or increased or decreased
Triple acid-base disorders	Mixed metabolic alkalosis (diuretics or Cl-deficient intake), metabolic acidosis (lactic acids of sepsis to hypoxemia, hypotension), and respiratory acidosis or alkalosis	Paco ₂ inappropriate HCO ₃ inappropriate Anion gap exceeds 20 mEq/L	Variable
	Chronic respiratory acidosis, obstructive lung disease, superimposed acute respiratory acidosis from pneumonitis or congestive heart failure, acute respiratory alkalosis (intubation) mechanical ventilation	Paco ₂ inappropriate HCO ₃ inappropriate	Variable

↑↑, increased; ↓↓, decreased; Paco₂, partial pressure of CO₂.

illness or growth failure at a young age, sometimes accompanied by deafness, whereas dominant distal RTA is usually a milder disease and involves no hearing loss (80). The AE1 gene encodes band 3 Cl⁻-HCO₃⁻ exchangers that are expressed in the basolateral membranes of the intercalated cells in the distal tubule as well as erythrocytes. Several mutations of the AE1 gene cosegregate with dominant nonsyndromal distal RTA (81). However, the modest degree of loss of function exhibited *in vitro* by these mutations does not explain the abnormal distal acidification phenotype. Other AE1 mutations have been linked to the recessive syndrome of distal RTA without hemolytic anemia, in which loss of function can be demonstrated by *in vitro* studies of the mutations (82). Several mutations in the CA II gene are associated with the autosomal-recessive syndrome of RTA, osteopetrosis, and cerebral dysfunction (83). Mutations in ATP6B1, encoding the B subtype unit of the apical H⁺-ATPase, are responsible for a group of patients with autosomal-recessive distal RTA associated with sensorineural deafness (84). Another gene, ATP6N1B, which encodes a noncatalytic accessory of the proton pump, is exclusively expressed on the luminal surface of the intercalated cells in the collecting duct and maps to chromosome 7. Nonsense, deletion, and splice-site mutations of this gene truncate the protein and result in the phenotype of distal tubular acidosis with preserved hearing (85).

Syndromes of aldosterone resistance [pseudohypoaldosteronism (PHA)] leading to hyperkalemic or type 4 RTA have also been characterized at the molecular level. PHA type I has a characteristic phenotype of neonatal

salt wasting with dehydration, metabolic acidosis, hyperkalemia, and hypotension. Two forms of PHA-I exist. An autosomal-recessive form features severe disease with manifestations persisting into adulthood. This form is caused by loss-of-function mutations in genes encoding subunits of the amiloride-sensitive epithelial sodium channels (86–88). Autosomal-dominant or sporadic PHA-I is a milder disease that remits with age. Mineralocorticoid receptor gene mutations, including frameshifts, premature terminations codons, and splice donor mutations, have been identified with the autosomal-dominant or sporadic form of PHA-I (89). PHA type II, otherwise known as *Gordon's syndrome*, is an autosomal-dominant disorder with a phenotype of hyperkalemic hyperchloremic acidosis with normal renal function and volume-dependent, low-renin hypertension, which is responsive to thiazide diuretics. Recently, two genes causing PHA-II have been identified. Both genes encode members of the WNK (with no kinase) family of serine-threonine kinases and are on chromosomes 1 and 17. Disease-causing mutations in WNK1 are large intronic deletions that increase WNK1 expression. The mutations in WNK4 are missense, which cluster in a short, highly conserved segment of the encoded protein. Both proteins localize to the distal nephron. WNK1 is cytoplasmic, whereas WNK4 localizes to tight junctions (90).

Bartter's syndrome is an autosomal-recessive disease characterized by diverse abnormalities in electrolyte homeostasis including hypokalemic metabolic alkalosis. Mutations in the Na-K-2 Cl cotransporter (NKCC2) cause Bartter's syndrome with the phenotype of hypokale-

mic alkalosis, salt-wasting, hypercalciuria, and low blood pressure (91). NKCC2 mutations can be excluded in some Bartter's syndrome kindreds, prompting examinations of regulators of cotransporter activity. One such regulator is ROMK, an ATP-sensitive K⁺ channel that recycles reabsorbed K⁺ back to the tubule lumen. Examination of the ROMK gene reveals mutations that cosegregate with the disease and disrupt ROMK function in Bartter's kindreds. These findings establish the genetic heterogeneity of Bartter's syndrome and demonstrate the physiologic role of ROMK *in vivo* (92). The antenatal variant of Bartter's syndrome is also caused by mutations in ROMK (93). Bartter's syndrome type III phenotype is characterized by hypokalemic alkalosis with salt-wasting, low blood pressure, normal magnesium, and hyper- or normocalciuria with notable absence of nephrocalcinosis. Linkage of this phenotype has also been demonstrated to a segment of chromosome 1 containing the gene encoding the chloride channel CLCNKB. Loss-of-function mutations, including large deletions and nonsense and missense mutations of this gene, impair chloride reabsorption in the thick ascending limb of the loop of Henle (94). A variant of Bartter's syndrome, associated with sensorineural deafness and renal failure, has recently been mapped to chromosome 1 (95). A novel gene that encodes Barttin is expressed in the thin limb and the thick ascending limb of the loop of Henle in the kidney and in the dark cells of the inner ear (96). Barttin acts as an essential β subunit for basolateral CLC chloride channels, with which it colocalizes in basolateral membranes of renal tubules and of potassium-secreting epithelia of the inner ear (96). Gitelman's syndrome represents the predominant subset of Bartter's patients having hypomagnesemia and hypocalciuria. Complete linkage of Gitelman's syndrome has been demonstrated to the locus encoding the renal thiazide-sensitive Na-Cl cotransporter. A wide variety of nonconservative mutations has been identified, consistent with loss of function alleles, in affected subjects (97).

Mutations have also been identified in a number of mendelian disorders resulting in hypokalemic metabolic alkalosis as well as low-renin hypertension from conditions of mineralocorticoid excess or pseudoaldosteronism. Premature termination, frameshift (98), or missense (99) mutations in the gene encoding the β subunit of the amiloride-sensitive epithelial sodium channel cause constitutive activation of this channel leading to pseudoaldosteronism or Liddle's syndrome. Furthermore, mutations truncating the carboxy-terminus of the γ subunit of this channel also cause Liddle's syndrome (100). Chimeric gene duplications causing ectopic expression of aldosterone synthase enzymatic activity result in glucocorticoid-remediable aldosteronism (101). Point mutations in the HSD11B2 gene cause deficiency of 11 β -hydroxysteroid dehydrogenase type 2, which is responsible for the conver-

sion of cortisol to inactive metabolites, and result in the phenotype of apparent mineralocorticoid excess (102).

ACID-BASE CHANGES RELATED TO GROWTH AND DEVELOPMENT

Children with chronic metabolic alkalosis (e.g., Bartter's syndrome) do not grow well. However, the mechanism of this growth failure has not been well studied. Preliminary data have suggested the growth failure of Bartter's syndrome may be related to a primary effect of metabolic alkalosis or suppressing the IGF-GH axis (41). The effects of chronic hypokalemia in Bartter's syndrome on the growth axis have not been examined.

Children with chronic metabolic acidosis from RTA also suffer from failure to thrive and growth retardation (20). In an abstract presented in 1979, McSherry et al. (42) reported the blunting of GH release in children who have RTA. To determine how metabolic acidosis affects GH secretion and expression, Challa et al. (44) demonstrated that acidosis inhibits the GH pulse amplitude, pulse area, and total GH secretion in acidotic animals compared with that of control and pair-fed animals. They also demonstrated that serum IGF, hepatic IGF-1 mRNA, hepatic GH receptor mRNA, and gene expression of IGF at the growth plate of the long bone all are suppressed in the presence of metabolic acidosis (45,47,103). Thus, it appears that acidosis interferes with major aspects of the IGF-GH axis, although reduced nutrition from acidosis may contribute to decreased GH secretion. However, metabolic acidosis inhibits IGF-1 mRNA expression in the growth plate of the long bone and in the hepatic GH receptor mRNA specifically. These animal experiments showed that metabolic acidosis directly inhibited GH secretion and gene expression at target sites—anomalies that contribute to the growth failure of metabolic acidosis.

CALCIUM AND PHOSPHORUS

ANTHONY A. PORTALE

CALCIUM

Body Composition

Calcium is the most abundant electrolyte in the human body, and in healthy adults, accounts for approximately 2%, or 1300 g, of body weight. Approximately 99% of body calcium is in the skeleton, mainly in the form of hydroxyapatite crystals ($[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$); the remainder is in teeth, soft tissue, and extracellular fluid. By contrast, at birth, calcium accounts for only approximately 0.9% of body weight (1). From birth to approximately 20 years of age, when the skeleton reaches its full size and density, calcium content increases by some 40-fold (2). During this period, the increase in skeletal weight and calcium content requires the net retention of 150 to 200 mg of calcium per day. Thus, in growing individuals, calcium balance must be positive to meet the needs of skeletal growth and consolidation. In adults, calcium balance is zero after peak bone mass is attained and becomes slightly negative as bone is slowly lost with aging.

Extracellular Metabolism of Calcium

Calcium in plasma exists in three fractions: protein-bound calcium (40%), which is not filtered by the renal glomerulus, and ionized calcium (48%) and complexed calcium (12%), which are filtered (3). Complexed calcium is that bound to various anions such as phosphate, citrate, and bicarbonate. Albumin accounts for 90% of the protein binding of calcium in plasma, and globulins for the remainder. Conditions that affect the concentration of albumin in plasma, such as nephrotic syndrome or hepatic cirrhosis, affect the measurement of total serum calcium concentration. A decrease in albumin concentration of 1 g/dL results in a decrease in protein-bound and hence total calcium concentration of approximately 0.8 mg/dL. Binding of calcium to albumin is strongly pH dependent between pH 7 and pH 8; an acute increase or decrease in pH of 0.1 pH units will increase or decrease protein-bound calcium, respectively, by approximately 0.12 mg/dL. Thus, in hypocalcemic patients with metabolic acidosis, rapid correc-

tion of acidemia with sodium bicarbonate can precipitate tetany, due to increased binding of calcium to albumin and a consequent decrease in the ionized calcium concentration.

The total serum calcium concentration exhibits a circadian rhythm characterized by a nadir at 1 to 3 a.m. and a peak at 12 to 1 p.m., with amplitude (nadir to peak) of approximately 0.5 mg/dL (4–6). This rhythm is thought to reflect hemodynamic changes in serum albumin concentration that result from changes in body posture (7). Prolonged upright posture or venostasis can cause hemoconcentration and thus increases of approximately 0.5 mg/dL in serum calcium concentration. There is little difference between values taken in fasting and nonfasting states.

Normal values of serum total calcium concentration differ among clinical laboratories and in general range from 9.0 to 10.6 mg/dL. The calcium concentration is higher in children than in adult subjects. It is highest at 6 to 24 months of age (mean of approximately 10.2 mg/dL), decreases to a plateau of approximately 9.8 mg/dL at 6 to 8 years, and decreases further to adult values at 16 to 20 years (8). In men, the calcium concentration decreases from a mean of approximately 9.6 mg/dL at age 20 to approximately 9.2 mg/dL at age 80 years; the decrease can be accounted for by a decrease in serum albumin concentration (9). In women, no change is observed with age.

Ionized calcium is the fraction of plasma calcium that is important for physiologic processes such as muscle contraction, blood coagulation, nerve conduction, hormone secretion and action (parathyroid hormone [PTH] and 1,25-dihydroxyvitamin D [$1,25(\text{OH})_2\text{D}$]), ion transport, and bone mineralization. Measurement of the blood ionized calcium concentration is most useful in critically ill patients, particularly those in whom serum protein levels are decreased or acid-base disturbances are present, or to whom large amounts of citrated blood products are given, such as with cardiac surgery or hepatic transplantation. A decrease in the blood ionized calcium concentration can occur not only due to increased binding of calcium to albumin, such as in metabolic alkalosis, but also due to increased complexing with other anions. For example, in severe uremia, the ionized fraction of calcium can decrease

due to increased complexing with phosphate, sulfate, and citrate (10). Based on *in vitro* studies of human serum (11), an increase in serum phosphorus concentration of 3.7 mg/dL was required to induce a decrease in ionized calcium of 0.1 mg/dL, the smallest decrease thought necessary to stimulate release of PTH (12,13).

Determinations of the concentration of ionized calcium in healthy individuals vary somewhat among laboratories depending on which technique is used and whether the measurement is made on serum, plasma, or heparinized whole blood. In healthy infants, ionized calcium levels decrease from approximately 5.8 mg/dL (1.4 mmol/L) at birth to a nadir of 4.9 mg/dL (1.2 mmol/L) at 24 hours of life (14), and increase slightly during the first week of life (15). Values in young children are slightly higher (by approximately 0.2 mg/dL) than those in adults until after puberty. In adult men and women, normal serum ionized calcium concentrations range from 4.6 to 5.3 mg/dL (1.0 to 1.3 mmol/L); there are no significant sex differences (16,17). The blood ionized calcium concentration exhibits a circadian rhythm characterized by a peak at 10 a.m. and a nadir at 6 to 8 p.m., with an amplitude of 0.3 mg/dL (4). Specimens must be obtained anaerobically to avoid spurious results due to *ex vivo* changes in pH.

Extracellular Calcium Homeostasis

Calcium homeostasis is maintained by the interaction between three major organ systems, bone, intestine, and kidney. It is regulated principally by PTH and 1,25(OH)₂D and, to a lesser extent, by calcitonin. In healthy adults, net intestinal absorption of calcium is 20 to 25% of dietary intake. To meet the demands of rapid skeletal growth, fractional calcium absorption in infants is higher, 40 to 45%, reaching values as high as 80% in low-birth-weight, breast-fed infants (18,19). The efficiency of calcium absorption also is increased during adolescence, during pregnancy, and with administration of vitamin D metabolites, and is decreased in vitamin D deficiency and in the elderly. Calcium is absorbed principally in the duodenum and proximal jejunum, both by a saturable, active transport mechanism that requires stimulation by 1,25(OH)₂D and by a nonsaturable, passive diffusion mechanism. A small amount of calcium is secreted into the intestinal lumen, presumably by paracellular diffusion. An overall schema of calcium metabolism is depicted in Figure 10.1.

Absorbed calcium enters the extracellular calcium pool, which is in equilibrium with the bone calcium pool; the latter includes a rapidly exchangeable pool, which plays an important role in maintaining extracellular calcium concentration, and a more stable bone mineral pool. Calcium is filtered by the renal glomerulus and is nearly completely reabsorbed by the renal tubule. In individuals in zero calcium balance, the amount of calcium excreted by the kidney is equal to the net amount absorbed by the intestine,

FIGURE 10.1. Calcium fluxes between body pools in the normal adult human in zero calcium balance. ECF, extracellular fluid.

and in growing children is less than the net amount absorbed due to deposition of calcium in bone. In response to a decrease in extracellular concentration of ionized calcium, secretion of PTH from the parathyroid gland is increased (Fig. 10.2). PTH acts on the kidney to decrease excretion of calcium, to increase excretion of phosphorus, and to stimulate the production of 1,25(OH)₂D. The 1,25(OH)₂D acts on the intestine to stimulate active absorption of calcium and phosphorus, and, together with PTH, acts on bone to stimulate release of calcium and phosphorus into the extracellular fluid. PTH action on bone is thought to occur in two phases: an initial rapid mobilization of bone mineral that occurs within hours, is associated with increased metabolic activity of osteoclasts, and does not require protein synthesis, and a later phase that occurs after 12 to 24 hours of exposure to PTH, is associated with an increase in both the activity and num-

FIGURE 10.2. The homeostatic response to hypocalcemia. 1,25(OH)₂D, 1,25-dihydroxyvitamin D; Pi, inorganic phosphate; PTH, parathyroid hormone.

bers of osteoclasts, and does require protein synthesis (20). The combined effects of PTH and $1,25(\text{OH})_2\text{D}$ on their target tissues results in an increase in extracellular calcium concentration toward normal values, with the serum phosphorus concentration being little changed.

Conversely, in response to an increase in blood ionized calcium concentration, secretion of PTH and production of $1,25(\text{OH})_2\text{D}$ are decreased, and release of calcitonin is stimulated. The combined effects of these hormonal changes on bone, kidney, and intestine are opposite to those occurring with hypocalcemia and result in a decrease in calcium concentration toward normal values.

Calcium Receptor

Changes in the extracellular calcium concentration are detected by the extracellular calcium-sensing receptor (CaR) located on the plasma membrane of parathyroid cells. The CaR has been cloned from bovine, human, and rat parathyroid tissue (21–23) and from rat kidney (24). The receptor has a predicted molecular weight of approximately 120 kDa and is a member of the superfamily of receptors that couple with guanine-nucleotide-regulatory (G) proteins. Activation of the CaR results in increased activity of the enzyme phospholipase-C, which catalyzes the hydrolysis of the membrane-bound phospholipid inositol 4,5-bisphosphate to two second messengers, inositol 1,4,5-triphosphate (IP3) and diacylglycerol. Intracellular accumulation of IP3 induces release of calcium from storage pools and thereby a rapid increase in cytosolic calcium concentration, and possibly an increase in movement of calcium from the extracellular to the cellular compartment. In parathyroid cells, the increase in cytosolic calcium concentration is associated with a decrease in secretion of PTH.

Vitamin D

Vitamin D exists as either ergocalciferol (vitamin D_2) produced by plants, or cholecalciferol (vitamin D_3) produced by animal tissues and by the action of near-ultraviolet radiation (290 to 320 nm) on 7-dehydrocholesterol in human skin. Both forms of vitamin D are biologically inactive prohormones that must undergo successive hydroxylations at carbons 25 and 1 before they can bind to and activate the vitamin D receptor. The 25-hydroxylation of vitamin D occurs in the liver, catalyzed by one or more enzymes, including the mitochondrial enzyme vitamin D 25-hydroxylase. The activity of hepatic 25-hydroxylation is not under tight physiologic regulation, and thus circulating concentrations of 25OHD are determined primarily by dietary intake of vitamin D and exposure to sunlight. Although 25OHD is the most abundant form of vitamin D in the blood, it has minimal capacity to bind to the vitamin D receptor and elicit a biologic response.

The active form of vitamin D, $1,25(\text{OH})_2\text{D}$, is produced by the 1α -hydroxylation of 25OHD by the mitochondrial

enzyme 25-hydroxyvitamin D- 1α -hydroxylase (1α -hydroxylase or P450c1 α). The circulating concentration of $1,25(\text{OH})_2\text{D}$ primarily reflects its synthesis in the kidney; however, 1α -hydroxylase activity also is found in keratinocytes, macrophages, and osteoblasts (25–27). The 1α -hydroxylation is the rate-limiting step in the bioactivation of vitamin D, and enzyme activity in the kidney is tightly regulated. The steroid $1,25(\text{OH})_2\text{D}$ is one of the principal hormonal regulators of calcium and phosphorus metabolism and thus is critically important for normal growth and mineralization of bone. The classical actions of $1,25(\text{OH})_2\text{D}$ are to stimulate calcium and phosphorus absorption from the intestine and thereby maintain plasma concentrations of these ions at levels sufficient for normal growth and mineralization of bone. The hormone $1,25(\text{OH})_2\text{D}$ also has direct actions on bone, kidney, parathyroid gland, and many other tissues unrelated to mineral metabolism (reviewed in 28).

The other important vitamin D-metabolizing enzyme, 25-hydroxyvitamin D-24-hydroxylase (24-hydroxylase), is found in kidney, intestine, lymphocytes, fibroblasts, bone, skin, macrophages, and possibly other tissues (29). The enzyme can catalyze the 24-hydroxylation of 25OHD to $24,25(\text{OH})_2\text{D}$ and of $1,25(\text{OH})_2\text{D}$ to $1,24,25(\text{OH})_3\text{D}$; both reactions are thought to initiate the metabolic inactivation of vitamin D via the C24-oxidation pathway. The kidney and intestine are major sites of hormonal inactivation of vitamin D by virtue of their abundant 24-hydroxylase activity.

The synthesis of $1,25(\text{OH})_2\text{D}$ in the kidney is subject to complex regulation by PTH, calcium, phosphorus, and $1,25(\text{OH})_2\text{D}$ (28,30,31). Synthesis of $1,25(\text{OH})_2\text{D}$ can be stimulated by PTH, insulin-like growth factor-1, and phosphorus deficiency, and can be suppressed by plasma ionized calcium and $1,25(\text{OH})_2\text{D}$ itself. The renal 1α -hydroxylase enzyme is a mitochondrial cytochrome P450 mixed-function oxidase that requires the presence of two electron transport intermediates for catalytic activity, a flavoprotein termed *ferredoxin reductase* and an iron-sulfur protein termed ferredoxin (32). These two proteins mediate the transfer of electrons from the reduced form of nicotinamide adenine dinucleotide phosphate to the 1α -hydroxylase. The complementary DNA (cDNA) for the 1α -hydroxylase, designated P450c1 α , has been cloned from human, rat, mouse, and pig (33–38). The human P450c1 α cDNA is 2.4 kilobases (kb) in length and encodes a protein of 508 amino acids with a predicted molecular mass of 56 kDa (33). The human gene for 1α -hydroxylase (officially termed CYP27B1) is single copy, comprises nine exons and eight introns, and is located on chromosome 12 (Fig. 10.3) (34,39). Although, at 5 kb, it is a substantially smaller gene than those for other mitochondrial P450 enzymes (39), its intron-exon organization is very similar, especially to that of P450scc (39,40). This strongly suggests that, although the mitochondrial P450 enzymes retain only 30 to 40% amino acid sequence identity with each other, they all belong to a single evolutionary lineage. The mouse P450c1 α gene also has been cloned (41,42).

FIGURE 10.3. Scale diagram of the human P450c1 α gene showing the intron-exon organization and principal restriction endonuclease cleavage sites. The lesser-thickness bars at the beginning and end of the first and last exons represent the 5' and 3' untranslated regions, respectively. (From Fu GK, Portale AA, Miller WL. Complete structure of the human gene for the vitamin D 1 α -hydroxylase, P450c1 α . *DNA Cell Biol* 1997;16:1499–1507, with permission.)

Loss-of-function mutations in the human P450c1 α gene result in the autosomal recessive disease vitamin D 1 α -hydroxylase deficiency (33,43–49), also known as *hereditary pseudo-vitamin D deficiency rickets* (50), *vitamin D dependency* (51), or *vitamin D-dependent rickets type I*. As of mid-2003 a total of 31 different mutations have been found on 88 distinct chromosomes since the first description of gene mutations in 1997 (33,48).

Cellular Metabolism of Calcium

A detailed discussion of intracellular calcium metabolism is found in comprehensive reviews (52–54). Most of the total amount of calcium in the cell, estimated at approximately 10⁻³ mol/L, is sequestered in intracellular storage compartments, principally the endoplasmic reticulum and mitochondria, or bound to specific cytoplasmic proteins such as calmodulin and calbindin-D. The cytosolic concentration of free ionized calcium is approximately 10⁻⁷ mol/L, 10,000-fold lower than that in extracellular fluid. Thus, a steep gradient exists that favors movement of calcium into the cell. Cytosolic calcium serves as an intracellular second messenger and plays a critical role in regulating physiologic functions, including muscle contraction, neurosecretion, hormone secretion and action, cell division and aggregation, membrane permeability, enzyme activity, and gene transcription. The cytosolic calcium concentration is tightly regulated by interplay between specific mechanisms of calcium entry into and exit from the cell, movement of calcium into and from intracellular storage compartments, and reversible complexing of calcium by high-affinity cytosolic calcium-binding proteins. Binding of calcium to such proteins provides for rapid and precise buffering of cytosolic calcium concentration. Long-term maintenance of the calcium gradient between the cytosol and extracellular environment is provided by calcium pumps and exchangers, which are intrinsic to the plasma membrane and the membranes of intracellular organelles. Mitochondria can buffer large amounts of ionized calcium when its cytosolic concentration increases to levels sufficient to activate the low-affinity mitochondrial transport systems.

Transepithelial Transport of Calcium

Transport of calcium across the plasma membrane of calcium-absorbing epithelia such as the intestine and renal

tubule occurs via either the paracellular (between cells) or the transcellular (across cells) pathway, or via both pathways (Fig. 10.4). Paracellular transport is passive, linked to the net paracellular absorption (lumen-to-interstitium) of water, a process termed *solvent drag* or *convection*. Paracellular transport of calcium also can occur by passive diffusion driven by a chemical gradient, as occurs in the proximal convoluted tubule (PCT), or a lumen-positive transepithelial potential difference that results from sodium chloride reabsorption, as occurs in the thick ascending limb of the loop of Henle (TALH).

Transcellular transport of calcium is a three-step process consisting of passive entry across the apical membrane, diffusion through the cytosol facilitated by 1,25(OH)₂D-dependent calcium-binding proteins (calbindins), and active extrusion across the basolateral membrane mediated by a high-affinity Ca²⁺-adenosine triphosphatase (ATPase) and Na⁺-Ca²⁺ exchanger (55).

Calcium Entry

Although calcium entry across the luminal membrane is favored by both electrical and chemical gradients (56,57), the physical and chemical properties of lipid bilayer membranes prevent passive diffusion of the positively charged Ca²⁺ ion across cell membranes. Thus, calcium entry across the luminal membranes of the kidney and intestine is thought to occur through Ca²⁺ channels. Studies using a variety of approaches, including Ca²⁺ channel agonists and antagonists, patch-clamp analysis, and cell-attached electrophysiologic techniques, have shown the presence of calcium channels in proximal and distal nephron segments and in cultured distal renal tubule cells (58). Using an expression cloning strategy, Hoenderop et al. (59) cloned and characterized the cDNA encoding a new epithelial Ca²⁺ influx channel, which is named ECaC by analogy with the amiloride-sensitive, aldosterone-dependent epithelial sodium channel, ENaC (60,61). ECaC is expressed exclusively in the distal renal tubule, proximal small intestine, and placenta. The rabbit ECaC cDNA encodes a protein of 730 amino acids with a predicted molecular mass of 83 kDa (59). In rabbit kidney, ECaC is present along the apical membranes of the distal convoluted tubule (DCT), connecting tubule (CNT), and cor-

FIGURE 10.4. Possible cellular mechanisms involved in calcium transport in the proximal S1 and S2 tubule segments (**A**) and the distal convoluted tubule (**B**). Major transport systems are (a) $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase; (b) adenosine triphosphate-dependent $\text{Ca}^{2+}\text{-H}^+$ exchanger; (c) $\text{Na}^+\text{-Ca}^{2+}$ exchanger; and (d) Mg^{2+} -dependent Ca^{2+} -adenosine triphosphatase. For the distal tubule, calcium and chloride channels are depicted by “=” (From Suki WN, Rouse D. Renal transport of calcium, magnesium, and phosphate. In: Suki WN, Rouse D, eds. *Brenner and Rector's the kidney*. Philadelphia: WB Saunders, 1996:472–509, with permission.)

tical collecting duct, where it co-localizes with calbindin- $\text{D}_{28\text{K}}$ (59,62). This part of the nephron is the major site of regulation of Ca^{2+} reabsorption by PTH and $1,25(\text{OH})_2\text{D}$, and ECaC is thought to play a major role in such regulation. ECaC has been identified in several species, including rabbit, rat, mouse, and human (58,63).

Transcytoplasmic Calcium Movement

It is proposed that calcium diffusion through the cytoplasm is facilitated by the calcium-binding protein calbindin-D, whose synthesis is dependent on $1,25(\text{OH})_2\text{D}$. Calbindins also are proposed to act as an intracellular Ca^{2+} buffer to keep the otherwise tightly regulated cytosolic calcium concentration within physiologic levels during periods of stimulated transcellular Ca^{2+} transport (64–68). Two forms of calbindin-D have been described: a 28-kDa protein (calbindin- $\text{D}_{28\text{K}}$) found in highest concentration in avian intestine and avian and mammalian kidney, brain, and pancreas, and a 9-kDa protein (calbindin- $\text{D}_{9\text{K}}$) found in highest concentration in mammalian intestine, placenta, and uterus but also present in kidney,

lung, and bone (69,70). Much is now known about the amino acid sequence, x-ray crystal structure, and biophysical and calcium-binding properties of the calbindins. Calbindin- $\text{D}_{28\text{K}}$ is highly conserved in evolution, with a high degree of sequence homology observed among the various mammalian and avian $\text{D}_{28\text{K}}$ calbindins (71). By contrast, calbindin- $\text{D}_{9\text{K}}$ is not highly conserved, and there is no amino acid sequence similarity between calbindin- $\text{D}_{28\text{K}}$ and calbindin- $\text{D}_{9\text{K}}$. The genes for both rat calbindin species and chicken calbindin- $\text{D}_{28\text{K}}$ have been cloned and sequenced, and their transcriptional regulation by $1,25(\text{OH})_2\text{D}$, glucocorticoids, and other factors has been investigated (reviewed in 69 and 70).

The calbindins belong to the superfamily of EF-hand helix-loop-helix, high-affinity calcium-binding proteins (dissociation constant of 10^{-8} to 10^{-6} mol/L), which contains more than 250 proteins. Calbindin- $\text{D}_{28\text{K}}$ binds 4 mol of calcium per mole of protein and calbindin- $\text{D}_{9\text{K}}$ binds 2 mol of calcium per mole of protein. In the intestine, $1,25(\text{OH})_2\text{D}$ stimulates both the synthesis of calbindin and the transfer of calcium across the luminal brush-border membrane (BBM). The rate and time course of

active calcium absorption correlate well with the amount of calbindin-D over a wide variety of physiologic conditions (72,73), which provides strong support for the role of calbindin-D_{28K} and calbindin-D_{9K} in vitamin D-dependent active calcium transport. Calbindin-D may play a similar role in mediating active renal tubular reabsorption of calcium (74,75). In several mammalian species, both calbindin-D_{28K} and ECaC have been localized in the DCT and CNT (59,62,76,77), which are the major sites of active calcium reabsorption. Calbindin-D_{9K} also has been localized to the distal nephron in the rat and mouse (78,79).

Calcium Exit

At the basolateral membrane, calcium is actively extruded from the cell against its electrochemical gradient, a process mediated via a high-affinity, magnesium-dependent Ca²⁺-ATPase or an electrogenic 3Na⁺-1Ca²⁺ exchanger.

Ca²⁺-Adenosine Triphosphatase

The plasma membrane Ca²⁺-ATPase (Ca²⁺ pump) is an obligatory component of eukaryotic plasma membranes that mediates efflux of calcium from the cell. It is thought to play the most important role in maintaining the cytosolic calcium concentration within the normal range. The Ca²⁺ pump belongs to the family of P-type ATPases in that it forms a phosphorylated intermediate (an aspartylphosphate) during the reaction cycle. The pump has a high affinity for calcium, with an estimated Michaelis-Menton constant of 0.2 mmol/L and an apparent molecular weight of 120 to 140 kDa (reviewed in 80–84). The pump is activated by direct interaction with calmodulin, a specific calcium receptor protein present in the cytosol, which results in an increase in both the pump's affinity for calcium and its maximum transport velocity (V_{max}). The pump also is activated by cyclic adenosine monophosphate (cAMP)-dependent and protein kinase C-dependent phosphorylation of the pump protein, by limited proteolysis, and by exposure to acidic phospholipids. Transport of calcium from the cell is balanced by countertransport of hydrogen ion (H⁺), and thus the activity of the Ca²⁺ pump can be either electroneutral (Ca²⁺-2H⁺) or electrogenic (Ca²⁺-H⁺).

The Ca²⁺ pump is located exclusively in the basolateral portion of the plasma membrane of renal tubule cells (85,86). In earlier studies, activity of the Ca²⁺ pump was found along the entire length of the rabbit nephron, with the activity highest in the distal tubule where the majority of active calcium reabsorption occurs (87). In later studies using monoclonal antibodies against the erythrocyte plasma membrane Ca²⁺ pump, an epitope of this enzyme was identified in human and rat kidneys in the basolateral portion of only the DCT (85,88). The purified Ca²⁺ pump protein co-localizes with calbindin-D_{28K} in this nephron segment (85,88).

Analysis of different nephron segments of rat kidney using reverse transcription polymerase chain reaction revealed that the Ca²⁺ pump is expressed in both the distal and proximal nephron (89). In the intestine, the Ca²⁺ pump is stimulated by calmodulin and by 1,25(OH)₂D, which acts to increase pump activity by increasing its V_{max} (90).

Four isoforms of the plasma membrane Ca²⁺ pump have been identified and their cDNAs cloned (91–95). In humans and rats, the isoforms are encoded by a family of four genes that have been mapped to chromosomes 12, 1, 3, and X. Additional isoforms of the enzyme are created by alternative RNA splicing of the primary gene transcript. The isoforms exhibit 81 to 85% amino acid homology among themselves, and a single isoform exhibits approximately 99% homology among different species (96,97). The deduced amino acid sequences of rat and human isoforms of the plasma membrane Ca²⁺ pump predict a secondary structure that contains 10 transmembrane domains, with four main units accounting for most of the pump mass protruding into the cytoplasm (80,81,97). The predicted secondary structure of the human plasma membrane Ca²⁺ pump is depicted in Figure 10.5.

Na⁺-Ca²⁺ Exchanger

The Na⁺-Ca²⁺ exchanger is an integral membrane protein that normally exports calcium from the cell, although under some circumstances it mediates calcium influx. The exchanger is a low-affinity, high-capacity transport system for calcium, which is driven by the inwardly directed transcellular electrochemical Na⁺ gradient that is normally maintained by the basolateral Na⁺-K⁺-ATPase. In excitable tissue such as heart and neurons, the exchanger is electrogenic, mediating the export of one intracellular calcium ion for the import of three extracellular sodium ions. Activity of the exchanger is regulated by intracellular calcium, by changes in the transmembrane voltage; it is inhibited by sodium ionophores and ouabain, which reduce the transmembrane sodium gradient, and is increased by ATP (reviewed in 98–100).

Complementary DNAs encoding functional Na⁺-Ca²⁺ exchangers have been isolated from heart, kidney, and brain in a variety of species (101–107), which suggests that the protein plays an important role in different physiologic processes in various cell types. Three mammalian isoforms of the Na⁺-Ca²⁺ exchanger (NCX), designated NCX1, NCX2, and NCX3, have been cloned and are the products of separate genes (108–111). NCX1 is expressed most abundantly in heart but is found in most tissues, including kidney, whereas expression of NCX2 and NCX3 is restricted to brain and skeletal muscle (111,112). A number of alternative splicing variants of NCX1 are expressed in a tissue-specific fashion, which is a common feature of a variety of transmembrane proteins (112). The three NCX proteins share 68 to 75% amino acid sequence identity, and all are predicted to share the same topology of 11 membrane-spanning segments with

FIGURE 10.5. Sequence, predicted secondary structure, and topology of the plasma membrane Ca^{2+} pump showing ten membrane-spanning domains and four large cytoplasmic regions. CaM is the calmodulin-binding domain. PL is a sequence that interacts with acidic phospholipids. The shaded region (ATP) is the domain where adenosine triphosphate becomes bound. (From Carafoli E, Garcia-Martin E, Guerini D. The plasma membrane calcium pump: recent developments and future perspectives. *Experientia* 1996;52:1091–1100, with permission.)

a large hydrophilic cytoplasmic loop located between membrane-spanning segments 5 and 6. In NCX1, the cytoplasmic loop is thought to be a regulatory region and contains the binding site for Ca^{2+} and the location of the exchanger inhibitory peptide (XIP) sequence (Fig. 10.6).

Activity of the $\text{Na}^{+}\text{-Ca}^{2+}$ exchanger is found only in basolateral membrane preparations of renal tubules (113) and is

localized exclusively to the distal tubule in the rabbit and rat (114). Using antibodies that recognize the $\text{Na}^{+}\text{-Ca}^{2+}$ exchanger in rabbit kidney, immunolocalization was detected predominantly along the basolateral plasma membrane of cortical CNTs, with weak staining of principal cells of the collecting duct; no staining was detected in other cell types in either the cortex or medulla (115). When polymerase chain

FIGURE 10.6. Topology of the Na⁺-Ca²⁺ exchanger isoform NCX1 showing putative transmembrane-spanning domains 1 to 11 and a long intracellular loop, f. Loop f contains regions important in calcium regulation of exchanger activity (Ca²⁺ binding site) and in sodium-dependent inactivation (endogenous XIP region). The α-repeats in the transmembrane domains appear to be important in ion translocation. XIP, exchanger inhibitory peptide. (From Doering AE, Nicoll DA, Lu Y, et al. Topology of a functionally important region of the cardiac Na⁺/Ca²⁺ exchanger. *J Biol Chem* 1998;273:778–783, with permission.)

reaction was used to localize the exchanger in microdissected segments of rat nephron, NCX1 expression was observed in the DCT but little or no expression was seen in other segments (116). Thus, the distal nephron exhibits Ca²⁺ pump and Na⁺-Ca²⁺ exchanger activity, messenger RNA (mRNA) expression, and protein expression, which is consistent with the important role of this nephron segment in hormone-regulated calcium reabsorption.

Calcium Transport by the Nephron

Approximately 60% of plasma calcium is freely filtered by the glomerulus, as shown by a glomerular filtrate to plasma ratio for calcium that ranges between 0.63 and 0.70 (117,118). The fraction of plasma calcium that is filterable represents ionized calcium and complexed calcium. To maintain zero calcium balance, 98 to 99% of the filtered load of calcium, estimated at approximately 8 g/day in the adult, must be reabsorbed by the renal tubules. Clearance studies in humans and experimental animals show that an increase in the filtered load of calcium, as occurs with calcium infusion, results in an increase in both urine excretion and absolute tubular reabsorption of calcium (119–123). Thus it is thought that no maximum tubular reab-

sorptive rate exists for calcium within the normal physiologic range (124).

Approximately 70% of filtered calcium is reabsorbed in the proximal tubule; approximately 20% is reabsorbed between the late proximal and early distal tubule, primarily in the TALH; 5 to 10% is reabsorbed in the distal tubule; and less than 5% is reabsorbed in the collecting duct (Fig. 10.7) (117,125–127). Thus, 1 to 3% of filtered calcium is excreted in the urine. As discussed later, physiologic regulation of renal calcium reabsorption occurs in the distal nephron.

Proximal Nephron

The majority of filtered calcium is reabsorbed in the proximal tubule, with approximately 60% being reabsorbed by the end of the accessible portion of the superficial proximal tubule and an additional 10% reabsorbed in the proximal straight tubule. In the early PCT (S1 and S2 segments), calcium is reabsorbed passively in parallel with the reabsorption of sodium and water principally via the paracellular pathway, mediated by convection (solvent drag) across the tight junctions. Evidence for passive reabsorption of calcium is the finding that, in several species studied by micropuncture, the ratio of calcium concentration in tubular

FIGURE 10.7. Profile of calcium reabsorption along the nephron, as derived from micropuncture data. CCD, cortical collecting duct; CNT, connecting tubule; DCT, distal convoluted tubule; IMCD, inner medullary collecting duct; PCT, proximal convoluted tubule; PST, proximal straight tubule; TALH, thick ascending limb of the loop of Henle. fluid to that in glomerular ultrafiltrate is approximately 1.0 in the early PCT (127). In the late S1 segment, reabsorption of calcium lags slightly behind that of sodium, which thus creates a favorable chemical gradient for reabsorption downstream. In the S2 segment of the PCT, the transepithelial voltage is lumen positive; thus, the electrical gradient is favorable for passive calcium reabsorption. In rabbit early S2 segments, net flux of calcium was zero in the absence of both water transport and an electrochemical gradient (128), which provides further evidence for passive calcium reabsorption. There also is evidence that calcium reabsorption is active in the proximal nephron, particularly in the earliest segments of the PCT where the transepithelial voltage is lumen negative (127). Calcium reabsorption also appears to be active in the S3 segment of the proximal tubule, because it is not dependent on sodium, occurs against an electrochemical gradient, and is not inhibited by ouabain (129).

Loop of Henle

In the thin descending and ascending limbs of the loop of Henle, calcium transport is negligible (129,130). In the TALH, however, approximately 20% of the filtered calcium load is reabsorbed (127). In isolated, perfused segments of TALH, calcium reabsorption is passive, driven by the large

lumen-positive transepithelial voltage difference in this segment (131–133) that results from the secondary active transport of sodium chloride out of tubular fluid. Inhibition of sodium chloride transport with furosemide reduces the transepithelial voltage and thus increases calcium excretion. In some studies, however, calcium transport in the TALH is found to be active (130,134,135). It has been proposed that axial heterogeneity may account for some of the differences observed in the studies reported (136). Calcium transport in the cortical TALH can be increased by addition of PTH to the bath (137) and, in medullary segments, by addition of calcitonin or cAMP (138).

Distal Convoluted Tubule and Connecting Tubule

Physiologic regulation of calcium excretion occurs in the DCT, which reabsorbs up to 10% of the filtered calcium load. The capacity for calcium transport in this segment appears to be high and to be limited mainly by the availability of transportable ions. Although calcium transport in the DCT normally occurs in parallel with that of sodium, it is not dependent on either sodium or the transepithelial voltage and occurs against an electrochemical gradient; thus, it is active and presumably transcellular. Reabsorption of calcium in the DCT can be dissociated from that of sodium by administration of thiazide diuretics, which increase reabsorption of calcium and decrease that of sodium. As discussed earlier, luminal calcium entry is thought to be mediated via the apical ECaC. Both vitamin D-dependent calbindin-D and the Ca^{2+} -ATPase co-localize in the DCT and are thought to facilitate transcellular movement and basolateral extrusion of calcium, respectively. The Na^+ - Ca^{2+} exchanger also is localized, perhaps exclusively, to the basolateral membrane of the DCT and CNT (79,114–116), although its physiologic role in these segments remains to be defined.

Collecting Tubule

Net reabsorption in the collecting tubule accounts for less than 5% of filtered calcium (127). In the cortical collecting tubule, calcium transport probably is active, because both calbindin-D (77,79) and Ca^{2+} -ATPase activity (87) are found in this nephron segment. In the medullary collecting tubule, approximately 1% of the filtered load may be reabsorbed (139).

Determinants of Renal Handling of Calcium

Diet

A number of factors can influence renal tubular reabsorption and urine excretion of calcium (Table 10.1) (124,127). Expansion and contraction of the extracellular fluid volume induce an increase and decrease, respectively, in excretion of both calcium and sodium. Acute infusion of sodium chloride increases urine calcium excretion, an effect attributed to inhibition of calcium reabsorption in both the proximal and late distal tubule

TABLE 10.1. FACTORS AFFECTING RENAL CALCIUM EXCRETION

Factor	Ca excretion	Mechanism/nephron site
Diet		
Volume expansion	↑	↓ Distal reabsorption
Sodium chloride	↑	Undefined
Protein	↑	↑ Net acid and sulfate excretion
Phosphorus	↓	↓ Production of 1,25(OH) ₂ D ↓ Intestinal absorption of Ca ↑ Reabsorption distal nephron
Metabolism		
Acidosis	↑	↓ Proximal and distal reabsorption
Alkalosis	↓	↑ Proximal and distal reabsorption
Hypercalcemia	↑	↑ Filtered load of Ca ↓ Proximal and distal reabsorption (PTH)
Hormones		
PTH	↓	↑ Reabsorption TALH, DCT, and CNT
Vitamin D	↓	↑ Distal reabsorption, ? other sites
Insulin	↑	↓ Proximal and distal reabsorption
Glucagon	↑	? ↑ RBF and GFR
Growth hormone	↑	Undefined
Thyroid hormone	↑	↑ Filtered load of Ca, ↓ PTH
Calcitonin	↓	↑ Reabsorption TALH
Diuretics		
Mannitol	↑	↓ Proximal reabsorption
Furosemide	↑	↓ Reabsorption TALH
Thiazides, amiloride	↓	↑ Reabsorption DCT

Glucose	↑	↓ Proximal and distal reabsorption
Glucocorticoids	↑	? ↓ Bone resorption, volume expansion
Estrogens	↓	? ↓ Bone resorption

↑, increased; ↓, decreased; 1,25(OH)₂D, 1,25 dihydroxyvitamin D; CNT, connecting tubule; DCT, distal convoluted tubule; GFR, glomerular filtration rate; PTH, parathyroid hormone; RBF, renal blood flow; TALH; thick ascending limb of loop of Henle.

(140). An increase in dietary sodium chloride induces an increase in urine calcium, although the intrarenal mechanisms responsible have not been defined.

Changes in dietary calcium within the normal range have only a modest effect on urine calcium excretion. A linear relationship exists between dietary protein intake and urine calcium excretion (141), an effect that is exaggerated in patients with recurrent nephrolithiasis. An increase in either oral or parenteral intake of phosphorus is associated with a decrease in urine calcium excretion, an effect mediated in part by increased calcium reabsorption in the distal

nephron (142). Phosphorus loading can reduce intestinal calcium absorption and stimulate PTH secretion, both in part by decreasing the renal production and serum concentration of 1,25(OH)₂D (6,143). Conversely, phosphorus restriction increases urine calcium excretion (124,127). This effect is independent of vitamin D and is attributed to a reduction in tubular calcium reabsorption, principally in distal nephron segments, that is independent of PTH.

Hormones

PTH stimulates renal calcium reabsorption and is thought to be the principal hormonal determinant of urine calcium excretion. PTH acts to reduce calcium excretion in part by decreasing glomerular filtration rate (GFR) via a reduction in the glomerular capillary ultrafiltration coefficient K_f (144), and thus decreasing the filtered load of calcium. PTH also increases tubular calcium reabsorption in the cortical TALH, DCT, and CNT of the rabbit, with the principal effect being on the DCT (131,138,145–149). PTH action is attributed to activation of both the cAMP–protein kinase A and phospholipase-C–protein kinase C signaling pathways (126). The PTH-induced increase in calcium reabsorption is associated with an increase in the cytosolic calcium concentrations in cortical TALH, DCT, and CNT, which is mediated by an increase in the rate of calcium entry through dihydropyridine-sensitive channels (149–151). The role of ECaC in PTH-mediated stimulation of calcium reabsorption remains to be determined.

The effect of vitamin D on renal calcium reabsorption is variable, depending on vitamin D status, the activity of PTH, and the species studied (55). Although vitamin D has no detectable effect on calcium transport by the proximal tubule (152), 1,25(OH)₂D stimulates Ca²⁺ transport in distal nephron segments, including DCT of the dog and CNT and cortical collecting duct of the rabbit (55,153). The effect of 1,25(OH)₂D on expression of ECaC was studied in vitamin D–deficient rats. Administration of 1,25(OH)₂D induced an increase in the abundance of ECaC mRNA and protein in the distal part of the DCT and in CNT (154). The human ECaC promoter contains several putative vitamin D–responsive elements, which suggests that 1,25(OH)₂D stimulates ECaC expression at least in part at the transcriptional level (154). Thus, it is thought that 1,25(OH)₂D acts on the distal nephron to increase calcium reabsorption by increasing the expression of ECaC in this nephron segment.

Urine calcium excretion is increased by exposure to the following: insulin, glucose, glucagon, growth hormone, thyroid hormone, and corticosteroids; urine calcium is decreased by calcitonin and estrogens (127).

Metabolism

Both acute and chronic metabolic acidosis, as induced by ammonium chloride loading in humans and experimental animals, is attended by an increase in urine calcium excre-

tion (155–157). This increase is irrespective of a change in filtered load of calcium or in circulating PTH and is attributed to a decrease in calcium reabsorption in the distal nephron (155). Hypercalciuria is reversed when the acidosis is corrected with administration of alkali (155,158,159). Conversely, metabolic alkalosis is associated with a decrease in calcium excretion (160,161). The effects of respiratory acid-base changes are similar to those of metabolically induced changes (162,163). Hypercalcemia, by increasing the filtered load of calcium, is associated with an increase in its excretion. This effect is mitigated to some extent by hypercalcemia-induced reduction in the ultrafilterability of calcium and phosphorus (164) and in GFR (165); the reduction in GFR is attributed to a PTH-dependent decrease in K_f . Hypercalcemia can decrease calcium reabsorption in the PCT, TALH, and distal nephron (124); the effect on this latter segment requires the presence of parathyroid glands (166).

Diuretics

Diuretic agents such as mannitol, which act on the proximal nephron, and furosemide or ethacrynic acid, which act on the TALH, induce an increase in both calcium and sodium excretion, because calcium reabsorption is passive and linked to that of sodium in these nephron segments. By contrast, thiazide diuretics and amiloride, which act on the DCT, decrease the excretion of calcium but increase that of sodium (127). The hypocalciuric effect of thiazide diuretics is due in part to increased calcium reabsorption by the DCT; the blockade of sodium chloride entry may reduce the cell sodium concentration sufficiently to enhance basolateral $\text{Na}^+\text{-Ca}^{2+}$ exchange (167). The hypocalciuria induced by chronic administration of thiazide diuretics is thought to reflect enhanced calcium reabsorption by the proximal tubule (127); this effect can be reversed by increased salt intake.

PHOSPHORUS

Body Composition

In the adult, phosphorus accounts for approximately 1% of body weight, or 600 to 700 g (1). Approximately 85% of body phosphorus is in the skeleton and teeth, approximately 15% is in soft tissue, and the remainder is in extracellular fluid. At birth, phosphorus accounts for only approximately 0.6% of body weight (1). In growing individuals, the balance of phosphorus must be positive to meet the needs of skeletal growth and consolidation; in the adult, phosphorus balance is zero. Phosphorus not only is an important constituent of bone mineral but also plays a critical role in many metabolic processes within the cell, including those involved in energy metabolism, protein phosphorylation, nucleotide metabolism, and phospholipid metabolism.

Extracellular Metabolism of Phosphorus

Phosphorus exists in plasma in two forms, an organic form consisting principally of phospholipids and phosphate esters, and an inorganic form (168). Of the total plasma phosphorus concentration of approximately 14 mg/dL, approximately 4 mg/dL is in the inorganic form. In clinical settings, only the inorganic orthophosphate form is routinely measured. Approximately 10 to 15% of total plasma inorganic phosphorus is protein bound; the remainder, which is filtered by the renal glomerulus, exists principally either as the undissociated or “free” phosphate ions HPO_4^{2-} and H_2PO_4^- , which are present in serum in a ratio of 4:1 at pH 7.4, or as phosphate complexed with sodium, calcium, or magnesium.

The terms *phosphorus concentration* and *phosphate concentration* are often used interchangeably, and for clinical purposes the choice matters little. Phosphorus in the form of the phosphate ion circulates in blood, is filtered by the renal glomerulus, and is transported across plasma membranes. The content of “phosphate” in plasma, urine, tissue, or foodstuffs, however, is measured and expressed in terms of the amount of elemental phosphorus contained in the specimen, hence use of the term *phosphorus concentration*.

In healthy subjects ingesting typical diets, the serum phosphorus concentration exhibits a circadian rhythm, characterized by a rapid decrease in early morning to a nadir shortly before noon, a subsequent increase to a plateau in late afternoon, and a small further increase to a peak shortly after midnight (Fig. 10.8) (4,6). The normal circadian rhythm in serum phosphorus concentration can be described as the sum of sinusoidal functions with periodicities of 24 and 12 hours (6). The amplitude of the rhythm (nadir to peak) is approximately 1.2 mg/dL, or 30% of the 24-hour mean level. Restriction or supplementation of dietary phosphorus induces a substantial decrease or increase, respectively, in serum concentrations of phosphorus during the late morning, afternoon, and evening, but induces less or no change in the morning fasting phosphorus concentration (Fig. 10.8) (6). To minimize the impact of changes in dietary phosphorus on the serum phosphorus concentration, one should obtain specimens for analysis in the morning fasting state. Specimens obtained in the afternoon are more likely to be affected by diet and thus may be more useful to monitor the effect of dietary phosphorus on serum phosphorus concentrations, as in patients with renal insufficiency receiving phosphorus-binding agents to treat hyperphosphatemia.

Factors other than time of day and diet can affect the serum phosphorus concentration. Presumably because of movement of phosphorus into cells, the serum phosphorus concentration can be decreased acutely by intravenous infusion of glucose or insulin, ingestion of carbohydrate-rich meals, acute respiratory alkalosis, or infusion or endogenous release of epinephrine. The decrease in phosphorus concentration induced by acute respiratory alkalosis can be

FIGURE 10.8. Effect of dietary phosphorus on the circadian rhythm of serum phosphorus concentration in healthy men. Blood was drawn from an indwelling venous needle at hourly intervals for 24 hours after subjects had received a normal intake (\bullet) (1500 mg/day) of phosphorus for 9 days and after phosphorus was restricted for 1 day (---) and 10 days (\circ) (<500 mg/day), and then supplemented (\blacktriangle) (3000 mg/day) for 10 days. Spectral analysis of the variations in serum phosphorus concentration over time (time series) revealed significant periodicities of 24 hours, 12 hours, or both in each of the subject studies. Depicted are mean values plus and/or minus the standard error of the mean. (From Portale AA, Halloran BP, Morris RC Jr. Dietary intake of phosphorus modulates the circadian rhythm in serum concentration of phosphorus: implications for the renal production of 1,25-dihydroxyvitamin D. *J Clin Invest* 1987;80:1147–1154, with permission.)

as much as 2.0 mg/dL (169). Serum phosphorus concentration can be increased acutely by metabolic acidosis and by intravenous infusion of calcium (127).

There are substantial effects of age on the fasting serum phosphorus concentration. Phosphorus levels are highest in infants, ranging from 4.8 to 7.4 mg/dL (mean, 6.2 mg/dL) in the first 3 months of life and decreasing to 4.5 to 5.8 mg/dL (mean, 5.0 mg/dL) at age 1 to 2 years (170). In mid-childhood, values range from 3.5 to 5.5 mg/dL (mean, 4.4 mg/dL) and decrease to adult values by late adolescence (8,171). In adult men, serum phosphorus levels decrease with age from approximately 3.5 mg/dL at age 20 years to 3.0 mg/dL at age 70 (9,171). In women, the values are similar to those of men until after menopause, when they increase slightly from approximately 3.4 mg/dL at age 50 years to 3.7 mg/dL at age 70. Because plasma phosphate is composed of divalent (HPO_4^{2-}) and monovalent (H_2PO_4^-) ions in a ratio of 4:1, the composite valence of phosphorus in serum (or intravenous solutions) at pH 7.4 is 1.8. At this pH, 1 mmol phosphorus is equal to 1.8 mEq.

Extracellular Phosphorus Homeostasis

In the adult in zero phosphorus balance, net intestinal absorption of phosphate (dietary phosphorus minus fecal phosphorus) is 60 to 65% of dietary intake. To satisfy the demands of rapid growth of bone and soft tissue, net intestinal absorption of phosphate is higher in infants than in adults and can exceed

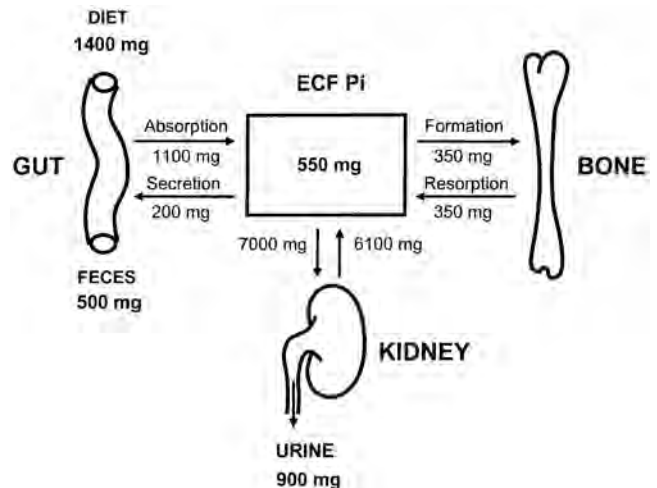

FIGURE 10.9. Phosphorus fluxes between body pools in the normal human adult in zero phosphorus balance. ECF, extracellular fluid; Pi, inorganic phosphate.

90% of dietary intake (172,173). Metabolic balance studies in normal adult humans reveal that over the customary range of dietary phosphorus, net absorption is a linear function of intake (174). Phosphate is absorbed primarily in the duodenum and jejunum and to a lesser extent in the ileum and colon. Intestinal phosphate absorption occurs via two mechanisms: an active, sodium-dependent transcellular process that has been localized to the mucosal surface, and passive diffusion through the paracellular pathway. Under usual dietary circumstances, the bulk of phosphate absorption is thought to occur via passive diffusion, with active transport playing an important role when luminal phosphorus concentration is low, as when dietary phosphorus is restricted (175,176). The active absorption of phosphate across the luminal membrane involves a sodium-dependent high-affinity transport system that is simulated by $1,25(\text{OH})_2\text{D}$ (177–180). This process is mediated by the now cloned intestinal sodium-phosphate cotransporter (type IIb), which is expressed in small intestine and other epithelial cells but not in kidney and plays a role in the physiologic regulation of intestinal phosphate absorption (181,182). A small amount of phosphate is secreted into the intestinal lumen in digestive fluids. An overall schema of phosphorus metabolism is depicted in Figure 10.9.

Absorbed phosphate enters the extracellular phosphate pool, which is in equilibrium with the bone and soft tissue phosphate pools. Phosphate is filtered at the glomerulus and is reabsorbed to a large extent by the renal tubule. In adults in neutral phosphorus balance, the amount of phosphorus excreted by the kidney is equal to the net amount absorbed by the intestine; in growing children it is less than the net amount absorbed due to deposition of phosphorus in bone.

The tubular reabsorption of phosphate plays a central role in the regulation of plasma phosphorus concentration and phosphate homeostasis. In response to a decrease in the extracellular phosphorus concentration, urine excretion of phosphorus

FIGURE 10.10. The homeostatic response to hypophosphatemia. 1,25(OH)₂D, 1,25-dihydroxyvitamin D; Pi, inorganic phosphate; PTH, parathyroid hormone.

phorus decreases promptly due to an increase in phosphate reabsorption by the proximal tubule (Fig. 10.10). This acute response reflects both a decrease in the filtered load of phosphate and an adaptive response of the nephron to increase phosphate reabsorption in response to a decrease in plasma concentration and dietary intake of phosphorus (see later). Hypophosphatemia is a potent stimulus for the renal production of 1,25(OH)₂D (183–185). In normal humans, moderate as well as severe restriction of dietary phosphorus can induce within 48 hours a substantial increase in the serum concentration of 1,25(OH)₂D (143,186,187); the increase is mediated by an increase in renal production of this hormone (143). In healthy humans in whom dietary phosphorus was manipulated throughout its normal range and beyond, the 24-hour mean serum phosphorus concentration varied inversely and significantly with the serum concentration of 1,25(OH)₂D (187). The increased serum 1,25(OH)₂D induced by hypophosphatemia acts to stimulate absorption of phosphorus and calcium by the intestine and mobilization of these minerals from bone. Hypophosphatemia also can directly promote mobilization of bone phosphate and calcium. The resulting increase in plasma calcium concentration induces suppression of PTH release, which leads to a further decrease in urine phosphorus excretion and an increase in calcium excretion. These homeostatic adjustments result in an increase in extracellular phosphorus concentration toward normal values, with little change in the serum calcium concentration. Conversely, in response to an increase in plasma phosphorus concentration, production of 1,25(OH)₂D is decreased and release of PTH is increased. The net effects of hyperphosphatemia on bone, kidney, and intestine are opposite to those occurring with hypophosphatemia, the net result being a decrease in phosphorus concentration toward normal values.

Renal Tubular Transport of Phosphate

In the proximal renal tubule, phosphate is transported across the luminal membrane against its electrochemical

gradient by a unidirectional, transcellular, secondary active process, driven by the inwardly directed electrochemical sodium gradient that is maintained by the basolateral Na⁺-K⁺-ATPase. The transport of phosphate is dependent on the presence of luminal sodium and is coupled to that of sodium. Based on electrophysiologic and tracer studies of phosphate transport, it is proposed that three sodium ions and one phosphate ion are transported together via a transporter protein that spans the lipid bilayer of the BBM; both monovalent and divalent phosphate can interact with the transporter (188).

Factors Affecting Sodium-Phosphate Co-Transport by the Renal Tubule

The rate of phosphate reabsorption by the proximal tubule can be modulated by several factors, and this modulation reflects changes in sodium–inorganic phosphate (Na–Pi) co-transport by the BBM (124,189,190). Indeed, the BBM entry step is thought to be the final target of physiologic and pathophysiologic regulation of proximal tubular phosphate reabsorption (190–193). The rate of phosphate reabsorption by the proximal tubule decreases with decreasing pH of tubular fluid (194). In BBM vesicles isolated from rat kidney cortex, the rate of phosphate uptake decreased severalfold when extravesicular (luminal) pH was decreased from 8.0 to 6.0 or when extravesicular sodium was decreased from 175 to 10 mmol/L (195). The effect of luminal pH on phosphate reabsorption is sodium dependent; it is greater at lower luminal sodium concentrations. The decrease in phosphate reabsorption observed with acidic luminal pH is thought to be due to competition between protons and sodium ions for a common binding site on the phosphate transporter, which results in decreased affinity of the transporter for luminal sodium and thereby for luminal phosphate (196). Phosphate uptake by BBM vesicles is increased when intravesicular (cytosolic) pH is lowered (197,198); this finding is also consistent with an effect of hydrogen ion to decrease the transporter's affinity for sodium and hence for phosphate at the cytosolic side of the plasma membrane, which thus accelerates the transport cycle.

Changes in the lipid composition or fluidity state of the BBM are associated with changes in BBM Na–Pi co-transport (199–201). However, short-term (hours-long) restriction of dietary phosphorus induces an increase in phosphate uptake before changes in either BBM fluidity or cholesterol content are detectable, which suggests that neither fluidity nor cholesterol content is critical to the early adaptive response of the BBM to phosphorus restriction (202).

Cellular and Molecular Mechanisms

Attention has focused on the molecular events involved in regulation of renal tubular phosphate reabsorption. Using an expression cloning strategy, the laboratory of Murer cloned two different Na–Pi co-transporters, designated type I and

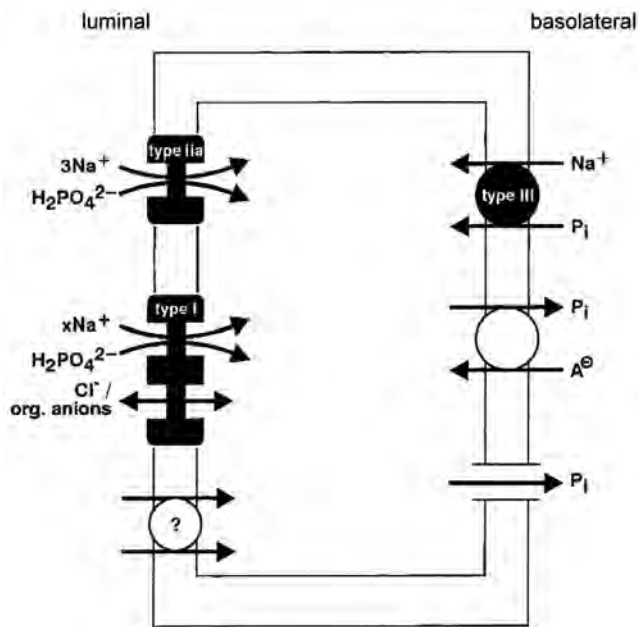

FIGURE 10.11. Location of identified and postulated Na-dependent and Na-independent phosphate transporters in the proximal tubule cell. Available data indicate that most proximal phosphate reabsorption occurs via the type IIa co-transporter, which is the major target of physiologic regulation of renal phosphate reabsorption. Org., organic; Pi, inorganic phosphate. (From Murer H, Forster I, Hernando N, et al. Posttranscriptional regulation of the proximal tubule NaPi-II transporter in response to PTH and dietary P_i. *Am J Physiol* 1999;277:F676–F684, with permission.)

type II (203,204). Currently, three types of Na-Pi co-transporters that mediate transport of phosphate from the extracellular to the intracellular compartment are identified: type I, type II, and type III (Fig. 10.11) (reviewed in 205).

The type I Na-Pi co-transporter is expressed primarily in apical BBMs of the proximal renal tubule, as determined by immunohistochemical analysis in rabbits and mice (206). Conditions that physiologically regulate proximal tubule phosphate transport such as dietary phosphorus or PTH do not alter type I Na-Pi co-transporter protein or mRNA expression. Thus, the type I co-transporter is not thought to be a major determinant of proximal tubule phosphate handling. The cDNA for the type I Na-Pi co-transporter was initially cloned from rabbit kidney, and its phosphate transport activity was expressed in *Xenopus laevis* oocytes (203); homologous cDNA has now been isolated from human, mouse, and rat kidney cortex and human brain (207–215). The rabbit cDNA encodes a protein of 465 amino acids with a predicted molecular mass of approximately 52 kDa and a secondary structure that contains six to eight transmembrane regions. The human gene encoding the type I Na-Pi co-transporter (*NPT1*) is located on chromosome 6 p21.3-p23.

The type IIa transporter is highly expressed in the apical region of the proximal tubule BBM and in subapical vesicular structures. The type IIa Na-Pi transporter is the principal determinant of overall Na-dependent phosphate reabsorption

by the proximal tubule under physiologic and pathologic conditions, and the rate of transport is principally regulated by altering the abundance of type IIa protein in the BBM (188,193,205,216,217). Genetic disruption of the *NPT2* gene, which encodes the type IIa transporter, results in hypophosphatemia due to severe renal phosphate wasting (218). A related Na-Pi transporter, type IIb, is expressed in the BBM of the small intestine but not in kidney, and plays a role in the physiologic regulation of intestinal reabsorption of phosphate (181,182). A type IIa transporter appears to be expressed also in osteoclasts and may play a role in bone resorption (219). The type IIa Na-Pi co-transporter cDNA, initially cloned from rat and human kidney cortex libraries (204), encodes a protein of 637 amino acids with a predicted secondary structure containing eight transmembrane regions. Type II-related transporters have now been identified in renal cortex from rabbit (220), mouse (211,221), flounder (222), and opossum kidney cells (OK cells) (223), and from bovine renal NBL-1 cells (224). The human *NPT2* gene is located on chromosome region 5q35, and the corresponding mouse gene is located on chromosome region 13B (225–227). The structures of the *NPT2* genes are similar in both species; they are approximately 16 kb in length and consist of 13 exons and 12 introns. A high degree of homology is found within the promoter regions of the human, mouse, rat, and opossum genes. A model of the secondary structure of the rat type IIa Na-Pi co-transporter is depicted in Figure 10.12.

The viral receptors for gibbon ape leukemia virus (Glv-1) and for mouse amphotropic retrovirus (Ram-1) exhibit Na-Pi co-transport activity when expressed in *X. laevis* oocytes (228–230). These receptors have been named PiT-1 and PiT-2, respectively, and are classified as type III Na-Pi co-transporters. Type III transporter mRNA is expressed in many tissues, including kidney, parathyroid glands, bone, liver, lung, striated muscle, heart, and brain (205); in mouse kidney, mRNA abundance of the type III transporter is two orders of magnitude less than that of the type IIa transporter (231). Type III transporter protein is localized to the basolateral region of the proximal tubule. The role of the type III transporter is thought to be that of “housekeeping” Na-Pi transport; that is, mediating phosphate flux into cells if luminal phosphate entry is not sufficient for metabolic processes.

The mechanisms of phosphate efflux at the basolateral membrane are not well defined. Current evidence suggests that phosphate can exit the cell down its electrochemical gradient via (a) a low-capacity Na-Pi co-transport system that couples flux of one sodium ion with that of one divalent phosphate ion, and (b) a high-capacity phosphate-anion exchange mechanism (124).

Overall Phosphate Transport by the Nephron

Under normal physiologic conditions, 80 to 97% of the filtered load of phosphate is reabsorbed by the renal tubule

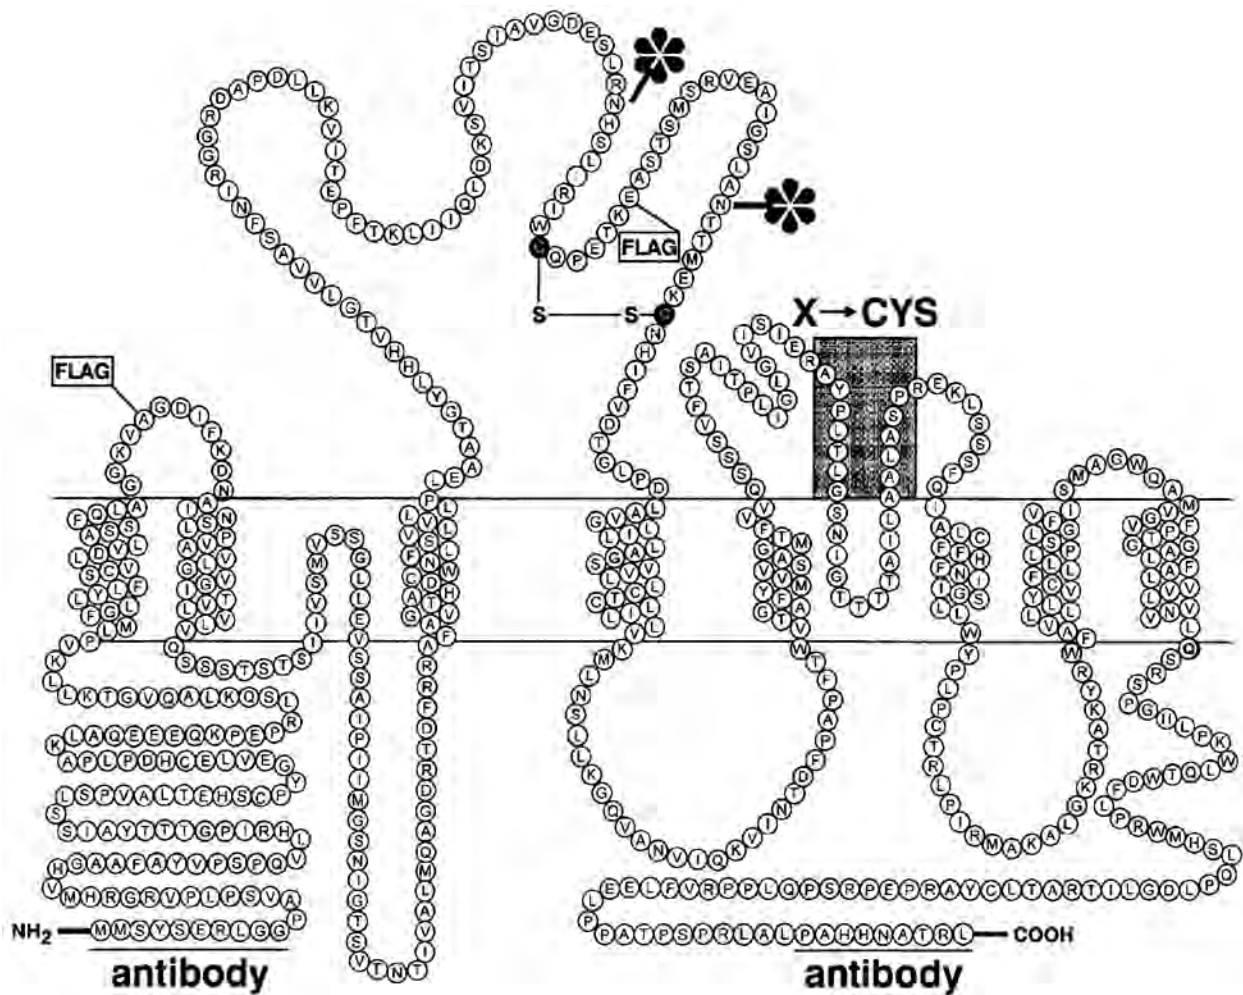

FIGURE 10.12. Model of the secondary structure of the rat type IIa Na-Pi co-transporter, derived from hydropathy predictions and experimentally supported (see reference 205). The two *N*-glycosylation sites in the secondary extracellular loop are indicated by asterisks. Cysteine residues likely to form a disulfide bridge and possibly important for function are shown in black. (From Murer H, Hernando N, Forster I, et al. Proximal tubular phosphate reabsorption: molecular mechanisms. *Physiol Rev* 2000;80:1373–1409, with permission.)

(124,127). Clearance studies in humans and experimental animals show that, when the filtered load of phosphate is progressively increased, phosphate reabsorption rises until a maximum tubular reabsorptive rate for phosphate, or TmP , is reached, after which phosphorus excretion increases in proportion to its filtered load. The measurement of TmP varies among individuals and within the same individual, due in part to variation in GFR. Thus, the ratio TmP/GFR , or the maximum tubular reabsorption of phosphate per unit volume of GFR, is the most reliable quantitative estimate of the overall tubular phosphate reabsorptive capacity and can be considered to reflect the quantity of Na-Pi co-transporters available per unit of kidney mass (175). The serum phosphorus concentration at which phosphate reabsorption is maximal is called the *theoretical renal phosphate threshold*; this value is equal to the ratio TmP/GFR and closely approximates the normal fasting serum phosphorus concentration. Thus, the renal reabsorptive

capacity for phosphate is the principal determinant of the serum phosphorus concentration. Approximately 80% of filtered phosphate is reabsorbed in the proximal tubule, 5 to 10% is reabsorbed in the distal tubule, and 2 to 3% is reabsorbed in the collecting tubules (Fig. 10.13).

Proximal Tubule

Approximately 70% of the filtered load of phosphate is reabsorbed by the PCT. Under normal physiologic conditions, reabsorption rates in early convolutions (S1 segment) are as much as four times higher than those in late convolutions (S2 segment) and the pars recta (S3 segment) (232–234). Due to this axial heterogeneity in phosphate transport, most of the phosphate reabsorption in the PCT occurs within the first 25% of PCT length. Internephron heterogeneity is also seen in phosphate reabsorption in the proximal tubule; proximal

FIGURE 10.13. Profile of phosphate reabsorption along the mammalian nephron, as derived from micropuncture data. CCD, cortical collecting duct; DCT, distal convoluted tubule; IMCD, inner medullary collecting duct; PCT, proximal convoluted tubule; Pi, inorganic phosphate; PST, proximal straight tubule; PTH, parathyroid hormone; TALH, thick ascending limb of the loop of Henle. (Data from Suki WN, Rouse D. Renal transport of calcium, magnesium, and phosphate. In: Suki WN, Rouse D, eds. *Brenner and Rector's the kidney*. Philadelphia: WB Saunders, 1996:472–509.)

tubules of juxtamedullary nephrons have a greater capacity both to reabsorb phosphate (235–238) and to adapt to changes in its filtered load (239,240) than do proximal tubules of superficial nephrons. In the absence of PTH, up to an additional 10% of filtered phosphate can be reabsorbed in the proximal straight tubule.

Loop of Henle, Distal Convoluted Tubule, and Collecting Tubule

Little or no transport of phosphate is thought to occur in the loop of Henle except for the proximal straight tubule segment (127). Up to 10% of the filtered load of phosphate is reabsorbed by the DCT in the absence of PTH; an additional 3 to 7% may be reabsorbed beyond the accessible late DCT, presumably by the CNT (127).

Collecting Tubule

Although some investigators have failed to demonstrate phosphate reabsorption in isolated perfused cortical collecting tubules (241), others have shown a small but significant net efflux of phosphate in this portion of the nephron (242,243).

Physiologic Regulation of Renal Phosphate Transport

Dietary Phosphorus and Plasma Phosphorus

Dietary intake of phosphorus is one of the most important physiologic regulators of renal Na-Pi co-transport. An increase

or decrease in dietary phosphorus predictably induces an increase or decrease, respectively, in urine excretion of phosphorus; with severe phosphorus restriction, urine phosphorus excretion is negligible. This adaptation is independent of changes in the filtered load of phosphate; does not depend on changes in extracellular fluid volume, plasma calcium level, growth hormone level, vitamin D status, or parathyroid activity; and appears to reflect changes in the rate of phosphate reabsorption by the proximal tubule, specifically, an increase or decrease in the V_{max} of Na-Pi co-transport activity. In addition, phosphorus restriction in animals can severely blunt the phosphaturic response to administration of PTH (196). The adaptation can be demonstrated both *in vivo* and in isolated perfused PCT segments and BBM vesicles taken from animals maintained on differing dietary intakes of phosphorus (244–249).

Renal tubule adaptation to changes in either dietary intake or plasma concentration of phosphorus can occur rapidly; an increase in BBM vesicle Na-Pi co-transport was observed after 2 to 4 hours of phosphorus restriction in the rat (250–252); conversely, a decrease in phosphate transport was induced after 1 hour of phosphorus infusion (253). The adaptation induced by short-term (hours-long) phosphorus restriction was preceded by a decrease in serum phosphorus concentration and was not inhibited by cycloheximide or actinomycin D, which suggests that protein synthesis is not required for the adaptation to occur (251). By contrast, the adaptation induced after long-term (3 days) phosphorus restriction was inhibited by cycloheximide and actinomycin D, which suggests that new protein synthesis is required (254). Similarly, exposure of cultured renal epithelial cells (LLC-PK1) to a low-medium phosphorus concentration induced both short-term (minutes-long) and long-term (hours-long) adaptations in Na-Pi co-transport (255–257). Thus, adaptation to changes in both dietary intake and plasma concentration of phosphorus involves two phases with different time courses: a rapid phase that is independent of protein synthesis and appears to involve activation or recruitment of preexisting transporter units, and a long-term phase that requires protein synthesis and permits a large increase (>100%) in phosphate transport rate (190,196,256).

Physiologic and pathologic changes in the renal handling of phosphate can be accounted for by changes in the abundance of type IIa Na-Pi co-transporter protein in the renal BBM. Short-term (hours-long) exposure of rats to a low-phosphorus diet induced an increase in both BBM Na-Pi co-transport activity and protein abundance but no change in Na-Pi-specific mRNA (258). The changes in transporter activity and protein abundance were blocked by prior treatment of the animals with colchicine, a microtubule-disrupting agent, but were not blocked by treatment with actinomycin D or cycloheximide (258). In opossum kidney (OK) cells, exposure to a low-phosphate medium induced within hours an increase in type IIa protein abundance in parallel with an increase in Na-Pi co-

transport activity but no change in type II co-transporter mRNA abundance (259,260). Thus, acute regulation of Na-Pi co-transport activity appears to be independent of transcription and translation and is thought to result from retrieval (decrease) or insertion (increase) of preexisting transporters from or into the BBM (reviewed in 182, 193, 205, 261, and 262). An intact microtubular network is required for the acute adaptation to phosphorus restriction (258). In contrast, long-term (days-long) restriction of dietary phosphorus in mice, rats, and rabbits leads to an adaptive increase in BBM Na-Pi co-transport and in the abundance of type II Na-Pi co-transporter protein and mRNA (220,263–268); no change was observed in the abundance of type I transporter mRNA or protein (220). The increase in *Npt2* gene expression induced by a long-term (4 days) low-phosphorus diet was attributed to transcriptional mechanisms (269).

Hormones

Parathyroid Hormone

PTH is the principal hormonal regulator of renal phosphate reabsorption (124,270). PTH inhibits renal phosphate reabsorption in the convoluted and straight segments of the proximal tubule, where the majority of filtered phosphate is reabsorbed. Although PTH also inhibits proximal tubule reabsorption of bicarbonate, sodium, and fluid, the suppressive effect of PTH on phosphate reabsorption can be dissociated from that of sodium and fluid and thus is specific for phosphate (270). As further evidence of such specificity, in renal BBM vesicles isolated from animals treated with PTH *in vivo*, Na-Pi co-transport was reduced, whereas sodium-dependent transport of D-glucose and other solutes was unchanged (271,272). PTH-sensitive phosphate transport also is observed in the DCT and in the cortical collecting duct (135,243,273); however, the localization of PTH action along the nephron differs greatly in the various species studied (270).

PTH binds to its specific receptors on the apical and basolateral membranes of proximal tubule cells and activates adenylate cyclase, which results in an increase in intracellular cAMP and subsequent activation of protein kinase A. The phosphaturic effect of PTH can be mimicked by exogenous cAMP in intact animals, isolated perfused tubules, and BBM vesicles. PTH binding also activates the phosphoinositide-cytosolic calcium-dependent signaling pathway. In proximal tubule cells, PTH activates phospholipase C, which stimulates the production of diacylglycerol and IP₃ (274); the latter induces an increase in the cytosolic calcium concentration (275,276). The formation of diacylglycerol and increase in cytosolic calcium result in activation of protein kinase C. In OK cells, exposure to PTH activates phospholipase C, stimulates production of IP₃, and inhibits Na-Pi co-transport (274,277); activation of protein kinase C by phorbol esters also is associated with inhibition of phosphate trans-

port (278,279). Based on findings in isolated perfused mouse tubules, binding of PTH to its receptor located on the apical surface primarily activates the phospholipase C–protein kinase C pathway, whereas binding to the receptor on the basolateral surface primarily activates the adenylate cyclase–protein kinase A pathway (280). Studies indicate that activation of the extracellular signal-related peptide/mitogen-activated protein kinase (ERK/MAPK) pathway also plays a central role in the regulation by PTH of renal phosphate transport (281).

The phosphaturic action of PTH is attributed to inhibition of phosphate transport by the BBM (205) and is associated with a reduction in the abundance of type IIa Na-Pi co-transporter protein, as determined by Western blot analysis of isolated proximal tubule BBMs and Na-Pi-IIa-specific immunofluorescence in convoluted and straight segments of proximal tubules (280,282). A prolonged increase in PTH also can induce a decrease in type II Na-Pi co-transporter mRNA abundance (282). The reduced abundance of type IIa Na-Pi co-transporter protein, induced acutely by infusion of PTH or feeding of a high-phosphorus diet, is attributed to endocytic internalization of phosphate transporters from the plasma membrane (205). The type IIa Na-Pi co-transporters are thought to be internalized via the same endocytic pathway as are soluble proteins (205,283) and, after internalization, are directed to the lysosomes for degradation. Studies in OK cells suggest that Na-Pi co-transporters, once internalized, are not immediately available for recycling back to the plasma membrane (284,285).

Vitamin D

Chronic administration of vitamin D or its metabolites is associated with a decrease in renal phosphate reabsorption. This effect is thought to be mediated by a vitamin D–induced increase in intestinal phosphate absorption and thus in phosphate balance, which induces an adaptive decrease in phosphate reabsorption by the proximal tubule (124,127). The effects of acute administration of vitamin D on phosphate transport appear to depend on the experimental conditions of study, including the dose of vitamin D administered and the prior vitamin D, PTH, and phosphorus status of the organism. In the rat, vitamin D depletion is associated with a decrease in renal phosphate reabsorption, which is rapidly corrected by physiologic amounts of 1,25-dihydroxyvitamin D₃. This effect is mediated by an increase in BBM Na-Pi co-transport (286) and is associated with a change in the lipid composition of the membrane (287,288). Vitamin D metabolites also stimulate renal phosphate reabsorption in hypophosphatemic or phosphorus-deprived states, or when basal phosphorus excretion is increased, as occurs with volume expansion or administration of PTH. By contrast, vitamin D induces phosphaturia in hyperphosphatemic or phosphorus-replete states (124).

Growth Hormone

Growth hormone acts to increase renal phosphate reabsorption, independently of PTH (191,289). In growth hormone-deficient subjects, the serum phosphorus concentration and the TmP/GFR ratio are reduced; both increase with administration of growth hormone (290,291). In patients with acromegaly, serum phosphorus concentrations are increased (292). Growth hormone also increases GFR, renal plasma flow, and renal gluconeogenesis (289). Growth hormone stimulates proximal tubular Na-Pi co-transport (293–296) and is mediated, at least in part, by increased production and release of insulin-like growth factor-1 (289,297). Receptors for growth hormone have been identified on the basolateral membrane of proximal tubule cells and appear to activate the phospholipase C pathway. Receptors for insulin-like growth factor-I also have been identified in proximal tubule membranes, and their effects may involve tyrosine kinase activity (289).

Phosphatonin

Attention has focused on the role of a circulating humoral factor(s), originally named phosphatonin (298), in the regulation of serum concentration and renal handling of phosphorus. Three disorders, autosomal dominant hypophosphatemic rickets (ADHR) (299–301), oncogenic hypophosphatemic osteomalacia (OHO) (also known as *tumor-induced osteomalacia*) (302–304), and X-linked hypophosphatemia (XLH) (305), each are characterized by hypophosphatemia due to renal phosphate wasting, inappropriately low or normal serum concentrations of 1,25(OH)₂D, and rickets or osteomalacia (305). ADHR is caused by mutations in the *FGF23* gene, which encodes a novel secreted peptide that is processed to aminoterminal and carboxyterminal peptides. Affected individuals harbor mutations in the peptide's furin cleavage site, which prevent the processing of mutant fibroblast growth factor-23 (FGF-23) (306), presumably resulting in its accumulation in the plasma. FGF-23 is abundantly expressed in tumors that cause OHO (307,308), and serum concentrations of FGF-23 are greatly increased in patients with this disorder and also in patients with XLH (309,310). With surgical removal of the tumor, FGF-23 concentrations can decrease to normal values and the disorder resolves. Because extracts from these tumors inhibit phosphate transport in renal proximal tubule cells *in vitro* (298,311), it has been suggested that FGF-23 is responsible for this inhibition. In support of this hypothesis are the findings that recombinant FGF-23 inhibits phosphate transport in renal proximal tubule cells *in vitro* (312) and that administration of recombinant FGF-23 to mice induces hypophosphatemia and increased renal phosphate clearance (308). FGF-23-treated mice also exhibit decreased serum concentrations of 1,25(OH)₂D (308,313,314) due to reduced renal 1 α -hydroxylase mRNA expression (308,314) and increased 24-hydroxylase mRNA expression (314). Taken together, these findings suggest that a common circulating factor, perhaps FGF-23, plays a central pathogenetic role in ADHR, OHO, and XLH. Further study is required, however, to determine

the mechanisms by which FGF-23 or other peptide factor(s) regulates renal phosphate handling or vitamin D metabolism, and whether such factors play a role in the physiologic regulation of phosphorus or vitamin D metabolism.

Urine phosphorus excretion can be increased by exposure to the following: calcitonin, atrial natriuretic peptide, glucose, glucagon, and glucocorticoids; urine phosphorus excretion can be decreased by thyroid hormone and insulin (reviewed in 127, 205, and 315). The mechanism of action of such lipophilic substances as thyroid hormone, vitamin D, and glucocorticoids is unclear, although it is assumed that genomic mechanisms are involved (316).

Volume Status

Expansion of the extracellular fluid volume results in an increase, and volume contraction in a decrease, in urine excretion of phosphorus (Table 10.2) (124,127). The effect can be attributed in part to changes in the filtered load of phosphate and rate of phosphate reabsorption by the proximal tubule as well as to changes in plasma ionized calcium, the latter affecting secretion of PTH. A direct effect of volume expansion on tubular phosphate reabsorption also has been reported.

TABLE 10.2. FACTORS AFFECTING RENAL PHOSPHORUS EXCRETION

Factor	Pi excretion	Mechanism/nephron site
Diet		
Volume expansion	↑	↑ Filtered load of Pi, ↓ proximal and distal reabsorption
Phosphorus restriction	↓	↑ Proximal reabsorption
Metabolism		
Acidosis	↑	↓ Tubular reabsorption
Alkalosis	↓	↑ Tubular reabsorption
Hormones		
PTH	↑	↓ Proximal and distal reabsorption
Vitamin D (long term)	↑	↓ Proximal reabsorption
Growth hormone	↓	↑ Proximal reabsorption, ↑ GFR
Calcitonin	↑	↓ Tubular reabsorption
Thyroid hormone	↓	↑ Tubular reabsorption
Insulin	↓	↑ Proximal reabsorption
Phosphatonin	↑	↓ Proximal reabsorption
Diuretics		
Mannitol, loop diuretics, thiazides	↑	↑ Tubular reabsorption, site varies
Other		
Growth and development	↓	↓ Proximal and distal reabsorption
Glucose	↑	Osmotic diuresis, ↓ reabsorption PCT
Glucocorticoids	↑	↓ Proximal reabsorption

↑, increased; ↓, decreased; GFR, glomerular filtration rate; PCT, proximal convoluted tubule; Pi, inorganic phosphate.

Acid-Base Status

Changes in acid-base status can significantly effect the renal handling of phosphate (124,270). Acute respiratory acidosis results in a decrease in renal phosphate reabsorption; this effect may depend on an increase in $p\text{CO}_2$ tension, but it does not depend on an increase in filtered load of phosphate, expansion of the extracellular fluid volume, or change in PTH or blood bicarbonate concentration (317). Conversely, acute respiratory alkalosis induces an increase in renal phosphate reabsorption and resistance to the phosphaturic action of both PTH and cAMP; these effects may depend on changes in $p\text{CO}_2$ tension but are independent of changes in plasma phosphorus concentration (318).

Although acute metabolic acidosis has minimal effects on urine phosphorus excretion (319), chronic metabolic acidosis can impair renal phosphate reabsorption independently of PTH and even when dietary phosphorus is severely restricted (320,321). The suppressive effect of metabolic acidosis on Na-Pi co-transport is demonstrable in BBM vesicles and is attributed to a decrease in the V_{max} of the transporter (321). The suppression of phosphate reabsorption might be mediated, in part, by changes in luminal and intracellular pH. Acute metabolic alkalosis induced by infusion of sodium bicarbonate reduces phosphate reabsorption when the prior dietary intake of phosphorus is high, but increases phosphate reabsorption when dietary phosphorus is normal (124,322–325). Chronic metabolic alkalosis predictably increases renal phosphate reabsorption (270).

Changes in the pH of luminal fluid can affect tubular reabsorption of phosphate. In rat proximal tubules, phosphate reabsorption was stimulated by increasing luminal pH when luminal phosphorus concentration was low (326). However, the effect of luminal pH on phosphate reabsorption was reduced or abolished when luminal phosphorus concentration was high (326), as occurs with intravenous infusion of phosphorus (327) or high dietary phosphorus (328). These findings suggest that the sensitivity of phosphate reabsorption to luminal pH depends on both luminal and peritubular and/or intracellular phosphorus concentration (196). The effects of luminal pH on phosphate transport observed *in vivo* are in good agreement with those observed in isolated BBM vesicles.

Growth and Development

As noted earlier, the serum phosphorus concentration is considerably higher in newborn infants and young children than in older children and adults. This finding is not due to a limitation of the immature kidney's ability to excrete phosphorus but rather reflects a higher rate of tubular phosphate reabsorption in infants and immature animals, as demonstrated by their higher values for the TmP/GFR ratio compared with values in adults (329). In newborn animals, as compared with adult animals, reabsorption of

phosphate is greater, both in the early PCT and in more distal nephron segments, presumably the pars recta and segments beyond the DCT. In BBM vesicles, the V_{max} for Na-Pi co-transport is higher in newborn than in adult guinea pigs, a finding that cannot be accounted for by differences in plasma concentrations of phosphorus, ionized calcium, PTH, thyroxine, or calcitonin. The higher capacity for phosphate reabsorption by the immature kidney also may reflect its relatively greater number of juxtamedullary nephrons, which have a higher capacity to reabsorb phosphate. Newborn animals demonstrate a blunted phosphaturic response both to phosphorus loading and to administration of PTH, the latter despite a normal increase in urine cAMP. In phosphorus-restricted rats, the adaptive increase in phosphate reabsorption is much greater in immature animals than in adults. Growth hormone may play an important role in mediating the increased renal reabsorption of phosphate during development. The intracellular free phosphate concentration, as determined by phosphorus-31 nuclear magnetic resonance spectroscopy, is lower in the kidneys of growing rats than in those of adult rats; it has been suggested that this finding is due to age-related differences in cellular phosphate metabolism and results in part in an adaptive increase in tubular phosphate transport (330,331). It has also been suggested that most of the age-related changes in phosphate reabsorption can be explained by differences in BBM expression of the type II Na-Pi co-transporter (188). Thus, through a variety of mechanisms (329), phosphate handling by the immature kidney is regulated so that phosphate retention is promoted, presumably to meet the increased needs for phosphorus of the growing organism (329,332).

Diuretics

Although their mechanisms and sites of action differ, the following diuretic agents predictably induce phosphaturia: mannitol, acetazolamide, thiazide diuretics, and loop diuretics. Urine phosphorus excretion is little affected by amiloride, spironolactone, and triamterene (127).

DISORDERS OF PHOSPHORUS, CALCIUM, AND VITAMIN D

CRAIG B. LANGMAN

Patients who have disturbances in mineral homeostasis exhibit several different clinical pictures: a predominance of bone disease (rickets or hyperparathyroidism), the metabolic effects of disturbances in calcium (neurologic, musculoskeletal disorders) or phosphorus (cardiovascular, hematologic disorders), or evidence of phenotypic syndromes. Many of these disturbances result from or produce abnormalities in renal tubular divalent mineral handling.

In the evaluation of such patients, the clinician is expected to perform serum and urine biochemical analyses that involve phosphorus, calcium, and vitamin D. Such blood measurements include levels of ionized calcium, serum total calcium, serum phosphorus, intact parathyroid hormone (PTH), and 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D [1,25(OH)₂D]. Urinary studies may include quantitative determinations of excretion of calcium, phosphorus, and other ions of interest (oxalate, citrate). The results of such biochemical evaluations lend themselves to diagnostic schemes that involve the kidney in a primary or secondary manner. In what follows, these diagnostic schemes are arranged by primary abnormality in serum calcium or phosphorus and are then further organized by pattern of urinary biochemical findings. Because the changes in one component of mineral homeostasis often produce abnormalities in the other components of the system, the biochemical findings of any given disorder can be approached in a number of different ways that are discussed later.

The reader is referred to Chapter 10 for a discussion of the normal physiology and renal handling of calcium and phosphorus and to a published review of the physiology of vitamin D (1).

DISORDERS OF PHOSPHORUS HOMEOSTASIS

Hyperphosphatemia Associated with Reduced Urine Phosphorus Excretion

Tumoral Calcinosis

Tumoral calcinosis (2–10) is a rare but disabling disorder of mineral metabolism in which two pathophysiologic abnormal-

ities occur: (a) an inability to excrete phosphorus and (b) the resultant hyperphosphatemia. Furthermore, the consequent hyperphosphatemia does not lead to an appropriate suppression of the production of 1,25(OH)₂D, the active vitamin D metabolite, and thus normal serum levels of the hormone are present. The pathophysiologic basis of this disorder is unknown but presumably involves abnormalities of tubular phosphorus handling as well as of vitamin D metabolism. Thus, affected patients have hyperphosphatemia, a normal blood calcium level, and a reduction in urinary phosphorus excretion. This is the mirror image of the serum and urine profile of a patient with hypophosphatemic rickets. In tumoral calcinosis, serum levels of intact PTH are suppressed to low normal or frankly low values, as is nephrogenous cyclic adenosine monophosphate (cAMP) excretion. The physical-chemical product of calcium × phosphorus is greater than 70, and soft tissue calcifications occur. Of importance, a systemic osteopenia is seen in such patients, despite the elevation of the product of blood phosphorus × calcium.

The calcifications are commonly located along the extensor surfaces of major joints. Relief of symptoms often requires surgical removal of the calcifications. Without adequate control of the underlying disease, recurrence is universal. Neural compression is common. The tumors can ulcerate the overlying skin, leading to draining sinus tracts and chronic infections. Associated findings include anemia, splenomegaly, low-grade fevers, and regional lymphadenopathy. In some patients, a characteristic dental abnormality may occur. Although the disease is worldwide in distribution, in North America there is an ethnic bias toward African Americans; there is no gender bias.

The treatment of patients with tumoral calcinosis has been uniformly unrewarding. Simple surgical removal of calcifications provides temporary relief of painful symptoms. Radiation therapy and corticosteroid therapy have not been successful. The use of phosphate-binding antacids and a low dietary intake of phosphate and calcium has met with some success, but this regimen is generally difficult for patients to follow.

In an effort directly to promote phosphaturia and indirectly to increase suppressed levels of PTH with consequent

phosphaturia, we have used long-term calcitonin administration (5 U/kg subcutaneously initially, and then repetitively but with increasing intervals between administrations) in these patients. Using calcitonin therapy in this manner, combined with dietary phosphate restriction and/or administration of oral phosphate binders, we have prevented the recurrence of the tumors in six such patients over the past several years. In addition, we have seen an increased bone density in nonaffected skeletal sites of such individuals.

Hypoparathyroidism

Absence of PTH biologic action is associated with significant hyperphosphatemia, hypocalcemia, and inappropriate renal tubular retention of phosphorus. It may occur as an inherited abnormality or be acquired through surgical removal of parathyroid gland tissue (for a general review, see reference 11).

Idiopathic hypoparathyroidism begins in early childhood and is part of the differential diagnosis of prolonged neonatal hypocalcemia. In the neonate, hypoparathyroidism is associated with aplasia of the glands, but beyond the neonatal age range, glandular hypoplasia is found instead. Idiopathic hypoparathyroidism may be X-linked, especially when it occurs in the neonate. The DiGeorge anomaly, a migrational disturbance in neural crest cells that results in abnormal development of the structures arising from the third and fourth branchial pouches, including anatomic cardiac defects and thymic dysplasia or absence, also is associated with a spectrum of abnormalities of the parathyroid gland ranging from frank hypoparathyroidism to a normocalcemic disorder termed *latent hypoparathyroidism*. Both normocalcemic children and adults with the DiGeorge anomaly may be unable to secrete PTH when faced with a hypocalcemic stimulus such as an infusion of ethylenediaminetetra-acetic acid (EDTA), which suggests that maximal secretion of serum PTH is occurring from hypoplastic parathyroid tissue (12). Furthermore, children with isolated conotruncal cardiac defects have a high frequency of latent hypoparathyroidism (13) associated with a 22q11 gene deletion commonly seen in DiGeorge anomaly (see reference 14 for general review). Evolution of the latent hypoparathyroidism associated with the 22q11 deletion into frank hypoparathyroidism (hypocalcemia, hyperphosphatemia) has been demonstrated across generations and over time within a generation (15).

Hypoparathyroidism (autosomal dominant, occasionally sporadic) may result from heterozygous mutations (16) in now-cloned extracellular calcium receptor, which sets a stable level of hypocalcemia (for a general review, see reference 17). Such patients appear to be uniquely sensitive to therapy with calcium and vitamin D analogues and must be closely monitored for the complications of nephrocalcinosis, nephrolithiasis, and renal insufficiency.

Hypoparathyroidism diagnosed in the latter part of the first decade of life may be associated with *autoimmune*

TABLE 11.1. FEATURES OF THE AUTOIMMUNE POLYGLANDULAR SYNDROME ASSOCIATED WITH HYPOPARATHYROIDISM

Feature	Frequency (%)
Addison disease (adrenal failure)	—
Chronic mucocutaneous candidiasis	—
Alopecia totalis	38
Steatorrhea	30
Primary hypogonadism	20
Pernicious anemia	15
Primary hypothyroidism	15
Chronic active hepatitis	12
Vitiligo	—

polyglandular disease (Table 11.1). The disease is inherited in an autosomal recessive manner, and the other organ dysfunctions may occur years after the diagnosis of one component of the syndrome. PTH antibodies occur in 30 to 40% of cases. Associated clinical findings include the development of cataracts, basal ganglion calcifications, and steatorrhea in more than 25% of cases. Repetitive diagnostic testing for the diseases associated with this syndrome is suggested once the diagnosis of autoimmune hypoparathyroidism is made.

Other rare causes of isolated hypoparathyroidism in children and adults may also be inherited, with patterns varying from autosomal recessive to autosomal dominant (see earlier), with incomplete penetrances. Hypoparathyroidism is a commonly encountered component of mitochondrial myopathies and associated renal (tubular and glomerular) dysfunction, which are now understood to result from either deletions or mutations of mitochondrial, maternally inherited genes related to electron transport (18,19). Such diseases include complete or partial absence of *cytochrome c oxidase*, *Kearns-Sayre syndrome* (ophthalmoplegia, retinitis pigmentosa, and heart block), *MELAS* (mitochondrial encephalopathy, lactic acidosis, and stroke), and *MERRF* (mitochondrial encephalopathy with ragged red fiber myopathy). Hypoparathyroidism, transient or permanent, is also an integral part of *Kenny-Caffey syndrome*, which is marked by both growth retardation and tubular long bones with medullary stenosis (some children with this disorder have been noted to have pseudohypoparathyroidism; see below).

Pseudohypoparathyroidism

Pseudohypoparathyroidism is characterized by peripheral resistance to endogenously secreted PTH (for a general review, see reference 11). It may be inherited in an autosomal recessive, autosomal dominant, or X-linked manner. In addition to the lack of appropriate phosphaturia to endogenously secreted PTH, patients have hypercalciuria, reduced bony mobilization of calcium, and reduced renal production and subsequent serum levels of 1,25(OH)₂D. Systemic

osteopenia is present, and despite the lack of classic renal responses to endogenous PTH levels, excess bony resorption does occur.

Patients with pseudohypoparathyroidism may be classified by their response to exogenous administration of synthetic PTH. Most have an absence of urinary excretion of cAMP (*type I pseudohypoparathyroidism*) with administration of PTH; a few (fewer than 10%) have an intact generation of cAMP (*type II pseudohypoparathyroidism*).

Type I pseudohypoparathyroidism is associated with a characteristic clinical phenotype called *Albright hereditary osteodystrophy*, composed of facial dysmorphism, shortened metacarpals and metatarsals, short stature, mild mental retardation, thickened cranium, and abnormal carrying angles at the elbow, knee, and hip. Subcutaneous ossification may occur (and is seen with higher frequency in a disorder that resembles Albright osteodystrophy phenotypically but has normal serum phosphorus, calcium, and PTH levels and is termed *pseudopseudohypoparathyroidism*; frank hypoparathyroidism may develop later in life in this rare disorder). The disturbance in Albright osteodystrophy is a generalized decrease in the function of the stimulatory guanine nucleotide-binding protein (G_s) present in all cells (20,21). The decrease in function may be secondary to a point mutation in the α subunit of G_s (22). Because the G-protein signaling system mediates the response of other hormones, it is not unexpected that associated hormonal disturbances are seen in patients with Albright osteodystrophy, including hypergonadotropic hypogonadism and hypothyroidism (23).

Acute Tubular Necrosis

The abrupt cessation of effective glomerular filtration is associated with many pathophysiologic changes, including hyperphosphatemia and, usually, hypocalcemia. Levels of $1,25(\text{OH})_2\text{D}$ are often reduced and, with the relief of oliguria, may increase above normal (24). Nonoliguric acute tubular necrosis is also associated with hyperphosphatemia from insufficient urinary phosphorus excretion.

Chronic Renal Insufficiency

Hyperphosphatemia occurs late in the course of chronic renal insufficiency, usually when the glomerular filtration rate (GFR) is less than 20% of normal. Functional nephrons filter more of the filtered phosphorus load, and thus phosphaturia is common in early chronic renal insufficiency. However, as the GFR declines to less than 20%, despite a low fractional reabsorption of filtered phosphorus, quantitative phosphorus excretion falls dramatically.

Hyperostosis

Closely linked but pathogenetically distinct from tumoral calcinosis is endosteal hyperostosis (25), which has also

been associated with hyperphosphatemia. The disorder is inherited as either an autosomal recessive or autosomal dominant trait and has its onset in late childhood, often with asymmetric mandibular enlargement. Nasal bridge enlargement and mild frontal bossing are common accompanying signs; facial nerve palsies or neural deafness are seen occasionally from nerve entrapment.

Hyperphosphatemia Associated with Increased Urine Phosphorus Excretion

Disorders of Phosphorus Distribution and Systemic pH

Hyperphosphatemia with resultant phosphaturia may occur because phosphorus is released from intracellular stores into the extracellular fluid (ECF). This occurs commonly during *acute respiratory acidosis*. Aggressive treatment of the elevation in serum phosphorus is best approached by recognition of the systemic acid-base disturbance.

During the generation of *acute metabolic acidosis*, phosphorus is released into the ECF from intracellular stores, and phosphaturia results. However, during the maintenance phase of metabolic acidosis, ECF phosphorus levels are often reduced, but phosphaturia continues.

Disorders of Phosphorus Distribution

Cell Breakdown

Hyperphosphatemia and phosphaturia occur commonly in clinical diseases in which there is rapid cell lysis or turnover, including *tumor lysis syndrome* (most commonly seen with hematologic malignancies, Burkitt lymphoma, and metastatic breast or small cell lung carcinomas), *rhabdomyolysis* (of traumatic and nontraumatic causes, Table 11.2), and severe *hemolytic anemias*. The pathophysiology of the resultant abnormality in these diverse groups of diseases is the same: excessive egress of intracellular phosphate stores into the ECF compartment from cellular destruction exceeds the kidney's ability to excrete the released phosphorus load. Commonly associated findings with either tumor lysis or rhabdomyolysis are severe hypocalcemia and hyperkalemia. The latter results from the fact that potassium is the major intracellular cation released with cell breakdown.

The increased cell metabolic and turnover rates that occur in *thyrotoxicosis* or *Addison disease* are rare causes of hyperphosphatemia.

Increased Phosphorus Absorption

Long-term use of the *bisphosphonate* etidronate for the treatment of osteopenias of varying causes has been associated with mild hyperphosphatemia and phosphaturia. This first-generational bisphosphonate can now be replaced with more potent ones (amino-bisphosphonates) that have not been associated with such biochemical findings.

TABLE 11.2. CAUSES OF RHABDOMYOLYSIS ASSOCIATED WITH HYPERPHOSPHATEMIA AND PHOSPHATURIA

Hereditary	Exertional	Metabolic	Toxic
Phosphorylase deficiency	Anterior tibial syndrome	Carbon monoxide poisoning	Haff disease
Phosphofructokinase deficiency	Status epilepticus	Barbiturate, narcotic use	Chronic alcoholism
Muscle carnitine palmitoyltransferase deficiency	High-voltage electrical shock	Hypothermia	Heroin use
Malignant hyperthermia	Agitated delirium	Diabetic ketoacidosis, nonketotic hyperglycemic coma	Malayan snakebite poison
Defect unknown, familial distribution	Overexercise, often in excessively hot environment Crush injury Coma (crush by own body mass)	Systemic infection with fever Idiopathic paroxysmal paralytic myoglobinuria (Mayer-Batz disease)	K ⁺ loss: glycyrrhizate, carbenoxolone, amphotericin B associated

Infusion of inappropriate amounts of *sodium or potassium phosphate salts* during parenteral alimentation or intravenous fluid therapies may result in hyperphosphatemia and phosphaturia. More common is the severe hyperphosphatemia and phosphaturia caused by the use of sodium phosphate enema preparations (26). Tremendous quantities of phosphate can be absorbed by the dilated colon, and the use of such enemas in small children has been associated with renal failure and death.

As part of the syndrome of *vitamin D intoxication*, whether from the use of the parent compound or one of the available vitamin D metabolites, hyperphosphatemia and phosphaturia result. Such disturbances commonly have associated hypercalcemia. The disturbance in phosphate appears to result in part from increased vitamin D–driven dietary phosphate absorption.

Hypophosphatemia Associated with Reduced Urine Phosphorus Excretion

Phosphorus Deprivation

Dietary restriction of phosphorus, if severe, can lead to phosphorus deprivation and elimination of urine phosphorus excretion. Severe decreases in phosphorus intake may be simulated by the excessive use of *phosphate-binding antacids* or by the rare occurrence of an *enteroenteric fistula* that leads to excessive stool phosphorus losses. The clinical picture may be dominated by the accompanying caloric or protein deprivations. An elevated serum calcium level is common, and PTH levels are suppressed as a result. Acutely, increased serum 1,25(OH)₂D levels are present, but levels subside to subnormal after 10 to 14 days of dietary deprivation.

Disorders of Phosphorus Distribution and Systemic pH

Disorders associated with *respiratory alkalosis* cause an acute shift of extracellular phosphorus into the intracellular space because alkalosis stimulates production of the enzyme phosphofructokinase and increases formation of

sugar phosphate moieties. Such disorders include acute hyperventilation (such as with temper tantrums), sepsis, heat stroke, or salicylate intoxication. In addition, patients with chronic bronchospastic pulmonary disorders can demonstrate hypophosphatemia and reduced urine phosphorus excretion during acute exacerbations.

Disorders of Phosphorus Distribution: Hormonal and Food-Fuel Effect

The following hormones promote a primary transport of phosphorus from the ECF into the intracellular fluid compartment: insulin, glucagon, androgens of adrenal or testicular origin, and β-adrenergic agonists. Endogenous physiologic overproduction or pharmacologic administration may produce the hypophosphatemia and associated reduction in urine phosphorus excretion. Insulin augments renal tubular reabsorption of phosphorus in addition to directing extracellular phosphorus to move to the intracellular compartment.

In addition, infusions of specific food-fuel nutrients promote the same translocation of phosphorus into the intracellular compartment. Such agents include glucose, fructose, lactate, and amino acid salts. Two other agents closely related to the food-fuels, glycerol and xylitol, also promote such phosphorus movement.

Increased Phosphorus Uptake into Bone

Two additional situations are associated with the production of hypophosphatemia and a reduced urine phosphorus excretion. After long-standing primary or secondary hyperparathyroidism is relieved, increased avidity of bone for calcium and phosphorus accumulation is seen. This has been termed the *hungry bone syndrome* and is commonly manifest with both hypophosphatemia and hypocalcemia, which may be symptomatic. Circumstances in which the hungry bone syndrome occurs include the immediately postoperative period after parathyroidectomy or after successful renal transplantation in cases of previous long-standing secondary hyperparathyroidism. However, the latter condition

may also be associated with a phosphorus-losing tubulopathy as noted later.

The hungry bone syndrome has been observed also with vitamin D treatment of long-standing vitamin D deficiency. In this setting, long-standing secondary hyperparathyroidism produces hypophosphatemia with phosphaturia. Over a short time after reintroduction of vitamin D, the biochemical picture worsens with respect to the serum level of phosphorus, whereas the excessive urine phosphorus excretion ceases.

Miscellaneous Conditions

Chronic myelogenous leukemia in a proliferative *blast crisis* has been associated with hypophosphatemia and decreased phosphorus excretion. In this condition, the increased anabolic state of white blood cells necessitates a large amount of intracellular phosphorus transport.

Refeeding of a starved infant or child may promote increased phosphate transport into the intracellular compartment and a reduction in phosphaturia. The hypophosphatemia is rarely severe, unlike in the disorders mentioned earlier.

Hypophosphatemia Associated with Increased Urine Phosphorus Excretion

Fanconi Syndrome

For information regarding hypophosphatemia and Fanconi syndrome, see Chapter 41.

X-linked Hypophosphatemic (Vitamin D-Resistant) Rickets

Disorders of vitamin D metabolism and resultant rickets occur commonly in children and are most often related to a simple deficiency of the parent vitamin. Lack of subsequent hepatic production of the 25-hydroxyvitamin D substrate leads to insufficient amounts of the active, renally produced vitamin D metabolite 1,25(OH)₂D. This results in profound hypocalcemia, secondary hyperparathyroidism, hypophosphatemia, and rachitic bone disease. Provision of modest amounts of the parent compound, vitamin D, cures the disorder.

The most commonly inherited form of rickets is X-linked hypophosphatemic rickets. Hypophosphatemic rickets in children is a systemic disorder in which renal phosphate wasting produces hypophosphatemia (27). Normocalcemia and normal levels of PTH are demonstrated. The circulating levels of the active vitamin D metabolite 1,25(OH)₂D also are often normal (28,29). The “defect” in vitamin D metabolism in this disorder is the inappropriately normal levels of 1,25(OH)₂D, because reduced serum phosphorus levels represent a potent stimulus for increased renal production of the active metabolite of the vitamin D endocrine system (1,30,31). The gene for X-linked hypophosphatemic rickets has been cloned and is

termed the *PHEX* gene for phosphate-regulating with homology to endopeptidase on the X chromosome (32). The disorder is now viewed as involving an abnormality of the phosphaturic factor fibroblast growth factor-23 (FGF-23). If *PHEX* is mutated, its natural substrate, FGF-23, is not inactivated by proteolysis and can exert its phosphaturic action (33). A study has documented the excessive levels of FGF-23 in this, and several other, rachitic hypophosphatemic disorders discussed later (34). It is not yet understood why there is a lack of appropriately increased synthetic ability of the renal 1 α -hydroxylase enzyme that produces 1,25(OH)₂D in the face of such profound hypophosphatemia. Phenotypically normal family members of affected children with rickets have normal serum phosphorus levels, but serum levels of 1,25(OH)₂D have not been systematically studied.

The untreated disorder in children results in generalized rickets and often linear growth failure (35); other features appear in adults (36,37). Although there is controversy surrounding the efficacy of treatment, most clinicians believe that frequent phosphate supplementation and pharmacologic dosing with 1,25(OH)₂D are indicated (38). Despite the large doses of phosphate used, hypophosphatemia remains, and secondary hyperparathyroidism may be induced with long-term phosphate salt administration (39,40). Thus, a better understanding of the need for phosphate is required. The addition of 1,25(OH)₂D has improved the healing of the rickets (41,42). Recommendations for both phosphate therapy and 1,25(OH)₂D therapy are based on clinical experience. Neither the initial dosing nor subsequent modifications are based solely on measured serum levels of either phosphorus or the hormone, but rather on the clinical course of the child with respect to rickets, linear growth, or both. A recommendation for the starting dosage for toddler-aged children is elemental phosphorus 1 to 3 g/day in four to five divided doses and calcitriol 30 to 70 ng/kg/day in two or three divided doses (43).

Two different murine models of the human disease exist. In the affected *Hyp* mouse (44), the renal 25-hydroxyvitamin D-1 α -hydroxylase defect is pervasive; it does not respond to PTH or phosphorus by increasing the production of 1,25(OH)₂D. Calcitonin does stimulate hormonal synthesis, which suggests that the enzyme is capable of being upregulated in this animal model (45). Hormone catabolism also is increased in the *Hyp* mouse (46,47). In the *Gy* mouse, however, only the PTH-independent arm, the response to hypophosphatemia, is blunted (48). Thus, in response to dietary calcium restriction and subsequent secondary hyperparathyroidism, the renal production of 1,25(OH)₂D increases in the affected *Gy* mouse (49). Which murine model most resembles children with hypophosphatemic rickets with respect to renal 1 α -hydroxylase is untested. Evidence from experimental animals suggests that the renal 1 α -hydroxylase is regulated inversely by phosphorus during chronic metabolic acidosis, a disorder characterized by phosphaturia, mild hypophosphatemia,

“normal” basal levels of $1,25(\text{OH})_2\text{D}$, and insufficient synthetic capacity in response to PTH-stimulation but intact response to phosphate restriction (50). Increasing the phosphate concentration of the bathing medium increases the *in vitro* production of $1,25(\text{OH})_2\text{D}$ in kidney tubules from rats with chronic metabolic acidosis; tubules from nonacidemic controls show the expected decline in production. Similarly, tubules from control animals increase production of $1,25(\text{OH})_2\text{D}$ during depletion of extracellular phosphorus, whereas tubules from the acidotic rats show only basal production. The data for humans with metabolic acidosis are controversial (51,52). Interestingly, administration of phosphate to the *Hyp* mouse increases peripheral receptors for $1,25(\text{OH})_2\text{D}$ (53) and stimulates uptake of the hormone by target cells in the intestine (54).

Other Causes of Hypophosphatemic Rickets

Several other disorders of renal tubular phosphorus transport are associated with rickets similar to X-linked hypophosphatemic rickets. *Hereditary hypophosphatemic rickets with hypercalciuria* (55,56) is a rare disorder in which the hypophosphatemia is associated with increased levels of $1,25(\text{OH})_2\text{D}$. In turn, PTH secretion is suppressed, both from an increase in calcium consequent to the elevated levels of $1,25(\text{OH})_2\text{D}$ and from direct inhibition of preproparathyroid hormone gene transcription by $1,25(\text{OH})_2\text{D}$. It is presumed that the inhibition of PTH leads to the hypercalciuria. The genetic transmission of the disorder remains unknown at present. In the few reports of this disease, children first manifest rickets from the first year of life through the end of the first decade of life (55). There are also unaffected relatives, children or adults, who manifest only the hypercalciuria portion of the disorder (56). Although clinically well, these unaffected relatives may have some or all of the biochemical abnormalities of their affected relatives, but with values closer to the normal values for age. Treatment consists of a high intake of phosphorus supplements alone. Unlike the disturbances in X-linked hypophosphatemic rickets, the rickets in this disorder is often healed by 6 to 9 months of therapy. Serum phosphorus levels increase and $1,25(\text{OH})_2\text{D}$ levels decrease to normal. A study has documented that the kidney proximal tubular sodium–inorganic phosphate co-transporter is not mutated in this condition (57).

Some adolescents and young adults develop hypophosphatemic rickets at an advanced age, compared with the classic X-linked disturbance. There do not appear to be any specific differences in the pathophysiology or clinical consequences of this disease, termed *adolescent hypophosphatemic osteomalacia*, and the X-linked disorder discussed earlier. The treatment is the same and includes both phosphorus supplementation and administration of calcitriol. There is, in addition, an *autosomal dominant* variety of hypophosphatemic rickets. In general, final height is not as

severely affected nor are levels of $1,25(\text{OH})_2\text{D}$ as low as in patients with X-linked hypophosphatemic rickets. FGF-23 abnormalities have been implicated in each.

Frymoyer and Hodgkin described a large kindred with X-linked renal phosphate wasting in whom bone disease did not manifest as rickets but as osteomalacia (58). Adults showed progressive lower extremity bowing but were otherwise indistinguishable biochemically and clinically from patients with X-linked hypophosphatemic rickets. Scriver et al. described autosomal dominant transmission of a similar disorder in a different kindred (59,60). Both disorders have been called *nonrachitic hypophosphatemic osteomalacia*.

Phosphaturia, hypophosphatemia, and rickets or osteomalacia have been described in a handful of patients with *fibrous dysplasia* (monostotic or polyostotic, the latter in McCune-Albright syndrome), *epidermal nevus syndrome*, or other soft tissue *tumors of mesenchymal origin* (61) and has been termed *tumor-induced osteomalacia*. This is likely a heterogeneous disorder at the level of renal 1α -hydroxylase, because levels of $1,25(\text{OH})_2\text{D}$ have been reported to be normal, elevated, or reduced; a minority of patients also have elevated serum PTH levels. Therapy with $1,25(\text{OH})_2\text{D}$ may heal or worsen the underlying bone disease, but it generally improves the hypophosphatemia. Excision of the offending tumor, if possible, is curative. Again, FGF-23 has been implicated in the pathogenesis (53,54).

Vitamin D–Dependent Rickets

Children with the rare autosomal recessive disorder *vitamin D–dependent rickets, type 1* present with classic vitamin D–deficiency rickets but do not respond to replacement dosages of the parent vitamin D compound that are used to treat the deficient state. Rather, such children remain hypophosphatemic and severely hypocalcemic. The disease arises from a primary deficiency in the renal 1α -hydroxylase enzyme that produces the active vitamin D metabolite $1,25(\text{OH})_2\text{D}$ (62). This is borne out by the lack of change of serum $1,25(\text{OH})_2\text{D}$ levels when vitamin D or PTH is administered to such patients (63). Children with the disorder have elevated levels of the substrate of that reaction, 25-hydroxyvitamin D; children with deprivational rickets have reduced levels of 25-hydroxyvitamin D, or it is absent. Lifelong administration of the active hormone calcitriol is curative for the disorder. The gene for renal 25-hydroxyvitamin D– 1α -hydroxylase has been cloned (64,65) and localized to 12q13.3. In patients with this disorder, inactivating mutations have been described in the gene, which lead to absence of enzyme activity in experimental systems (64,66) and explain the virtual absence of circulating $1,25(\text{OH})_2\text{D}$.

Since the original description in 1978 by Brooks et al. (67), fewer than four dozen patients have been reported with the classic clinical and radiographic findings of deprivational rickets but significantly increased serum levels of $1,25(\text{OH})_2\text{D}$

and an associated resistance to the healing effect of $1,25(\text{OH})_2\text{D}$. Some patients also have alopecia (areata or universalis) or other ectodermal defects (oligodontia, milia, or epidermal cysts). This disease, *vitamin D-dependent rickets, type 2*, represents a disorder in which some aspect of the function of the vitamin D receptor is abnormal. The pathogenesis of the disturbance has been shown to involve one of a number of identified point mutations in the vitamin D receptor gene (68). Treatment consists of maintaining suprapharmacologic levels of $1,25(\text{OH})_2\text{D}$ for prolonged periods (6 to 12 months minimum), which often requires parenteral therapy with the hormone and administration of oral or parenteral calcium. The response of the rachitic disorder to therapy probably depends on the exact defect in vitamin D receptor function (69).

Idiopathic (Genetic) Hypercalciuria

A minority of children with idiopathic (genetic) hypercalciuria (see later) have a primary renal phosphorus leak that leads to hypophosphatemia and phosphaturia in association with a frank elevation in serum $1,25(\text{OH})_2\text{D}$ levels. In such children the response to phosphorus supplementation is reduced hypercalciuria, normalized serum phosphorus levels, and further exaggeration of urine phosphorus excretion.

Renal Transplantation

Several disturbances in phosphorus homeostasis may result after renal allograft transplantation (70–83). Hypophosphatemia and phosphaturia occur in 70% of all patients with successful renal allografts within the first year after transplantation, sometimes without distinct elevation in serum PTH levels. A distinct phosphorus-losing tubulopathy is less common and leads to a more pronounced hypophosphatemia indistinguishable from that of Fanconi syndrome. It is not associated with an elevation of serum $1,25(\text{OH})_2\text{D}$ levels. Most often, the serum PTH level is in the upper range of normal to frankly elevated levels in this situation. Phosphorus supplementation may exaggerate the mild hyperparathyroidism, if present; if hyperparathyroidism is absent, it is the treatment of choice.

Primary Hyperparathyroidism

Primary hyperparathyroidism (see reference 84 and later in this chapter) is uncommon in the first decade of life but increases in incidence thereafter. It may occur as an isolated finding and most commonly presents with nephrolithiasis in the first several decades of life. Primary hyperparathyroidism may be associated with polyglandular endocrinopathy type II, which is characterized by medullary carcinoma of the thyroid, hypercalcitoninemia, and hypercalcemia. There is an adenomatous transformation of one of the four primary glands in more than 85% of children and young

adults with primary hyperparathyroidism; infants and toddlers with primary hyperparathyroidism show diffuse glandular hyperplasia.

Severe neonatal hyperparathyroidism may result from homozygous inactivating mutations of the extracellular calcium receptor (85,86) or even from the presence of only one abnormal allele of the gene (87). In both cases, severe hypophosphatemia and phosphaturia are present. Total surgical parathyroidectomy is curative, and, interestingly, patients are often normocalcemic thereafter. (See Familial Hypocalciuric Hypocalcemia.)

Miscellaneous Disorders

Many clinical situations have been associated with hypophosphatemia and phosphaturia, although the exact relationship between the agents implicated and the biochemical findings is less certain than in the disorders described earlier. These situations include chronic *corticosteroid usage*, the *diuretic phase of acute tubular necrosis* or a “*postobstructive diuresis*,” chronic *glycosuria* (but not the entities of renal glycosuria), *hypokalemic disturbances* with a normal GFR, and chronic *alcohol abuse*.

DISORDERS OF CALCIUM HOMEOSTASIS

Hypercalcemia Associated with Hypocalciuria: Familial Hypocalciuric Hypercalcemia

The autosomal dominant condition familial hypocalciuric hypercalcemia (85,86,88,89), best characterized as an abnormality in the physiologic set point for serum calcium concentration, may begin in infancy or childhood with the development of hypercalcemia. The infant or child is generally asymptomatic, and the elevated blood calcium level is unexpected for the clinical disease being evaluated. The exception is the homozygous infant in whom life-threatening hypercalcemia and hyperparathyroidism have been reported (see reference 90 and earlier discussion).

The disease results most often from an inherited abnormality of the extracellular calcium receptor, an inactivating mutation of one of the two alleles of the gene (see earlier and reference 91). The gene defect changes the relationship between PTH release and serum calcium level; the sigmoid curve describing that relationship is shifted to the right. Thus, the calcium set point (i.e., the serum calcium level that suppresses maximal PTH release by 50%) is increased. Apparently, a similar set point for renal tubular calcium reabsorption is increased as well, which accounts for the relative hypocalciuria in the face of an elevated serum calcium level. However, there may be additional abnormalities in the disorder. PTH levels remain inappropriately normal despite the elevated serum calcium levels, and histopathologic abnormalities in the gland itself have been

seen in up to 20% of patients who have frank hyperparathyroidism (92).

The treatment of the disorder is one of recognition and no specific therapy. Subtotal parathyroidectomies produce persistent hypercalcemia, and the production of hypoparathyroidism by total parathyroidectomy is of no benefit to the patient who is largely asymptomatic. Diagnostic clues include a family history, absence of the autoimmune polyglandular syndromes, a ratio of urinary calcium to creatinine (both values in milligrams) of 0.03 or less with elevated serum calcium levels and serum magnesium levels elevated between 3 and 4 mg/dL.

Hypercalcemia Associated with Hypercalciuria

Primary Hyperparathyroidism

Although primary hyperparathyroidism (84) is common in adult patients with *de novo* hypercalcemia, it is unusual in the first decade of life and occurs most commonly in neonates. In neonates and infants in the first 6 months of life, primary hyperparathyroidism has been reported approximately 100 times, always associated with extreme elevations in serum calcium levels (often greater than 14 mg/dL) and marked symptoms related to that elevation (93). The pathology in neonatal hyperparathyroidism is diffuse glandular hyperplasia in more than 90% of reported cases; adenomatous changes in one or more glands are responsible for the additional 10% of cases.

When primary hyperparathyroidism occurs in children younger than 10 years of age, a search for an associated endocrinopathy syndrome should be made (see later). In the second decade of life, the incidence of primary hyperparathyroidism increases dramatically (compared with younger ages) and may approach 1 in 1000 population. There does not seem to be a gender predilection among children and adolescents with primary hyperparathyroidism, which contrasts sharply with the female predominance of the disease in adults.

In addition to hypercalcemia and hypophosphatemia, the disease has other major features that result from the effects of elevated PTH levels on the skeleton and the kidney. The skeleton shows classically subperiosteal resorption in the distal phalanges, a "salt-and-pepper" appearance of the cranium, resorption and tapering of the clavicles, brown tumor formation in the long bones, and bone cysts as a result of chronic stimulation from PTH excess. In addition, severe osteopenia, especially in cortical bone, is demonstrated by determination of bone mineral density.

In the kidney, primary hyperparathyroidism is associated with calcium nephrolithiasis in up to 25% of patients in several series, a reduction in GFR, polyuria from an antidiuretic hormone-resistant concentrating defect, nephrocalcinosis, and systemic hypertension, especially with an acute onset of the disease. Other systemic manifestations may include a myopathy, now shown to be due to type II muscle

fiber atrophy; peptic ulcer disease; pancreatitis; anemia; alteration in consciousness from lethargy through coma; nausea and vomiting; constipation; and clinical depression.

Primary hyperparathyroidism may occur as part of the multiple endocrine syndromes. In type 1 disease (hyperfunction of the parathyroid, pancreatic, and anterior hypophysis cells), 95% of patients develop hyperparathyroidism, whereas fewer than 30% develop the associated prolactinoma or gastrinoma. In type 2A disease (hyperfunction of the cells of the adrenal glands, parathyroid glands, and C cells of the thyroid glands), hyperparathyroidism occurs in only one-third of cases, whereas the development of C-cell cancer of the thyroid is more common. In the latter group of patients, the occurrence of a pheochromocytoma is associated with hypercalcemia in 15 to 20% of patients, independent of parathyroid gland pathology.

In addition to the isolated disease and the disease associated with multiple endocrine syndromes 1 and 2, another variant of primary hyperparathyroidism has been described, termed *cystic parathyroid adenomatosis*, which also indicates its pathology (94). The disorder is one of recurrent adenomatous change over time, but usually only in one gland at the time of hypercalcemia. To date, there have been no reports of children with the disorder. Associated fibrous tumors of the cheekbones are present in the patients described.

Diagnostically, primary hyperparathyroidism is characterized by an elevation in the level of circulating intact PTH in almost all patients, and an inappropriately high level of PTH for the degree of hypercalcemia in all patients. Corroborative findings include elevated nephrogenous cAMP levels, mildly elevated 1,25(OH)₂D levels, hypophosphatemia with phosphaturia, and mild renal tubular acidosis.

The treatment of symptomatic primary hyperparathyroidism in children is surgical with exploration of all four neck glands strongly recommended. Although "asymptomatic" primary hyperparathyroidism exists as an entity in adults, it is not clear that this occurs in children. Therefore, medical treatment of that disorder (phosphorus supplementation, the use of bisphosphonates, and provision of sex steroids) is probably inappropriate for most children with primary hyperparathyroidism.

A new class of drugs, called calcimimetics (95), has been designed to interact within the transmembrane-spanning domains of the extracellular calcium receptor and act allosterically to reduce the activation of the receptor by calcium levels in the ECF. Such agents may have great promise in the treatment of primary hyperparathyroidism, hyperparathyroidism that occurs in the course of chronic renal insufficiency and end-stage renal disease or after renal transplantation, and, perhaps, in severe neonatal hyperparathyroidism. Treatment with calcimimetic agents is also without study in children.

Syndromic Hypercalcemia

Two important syndromes in infants and children produce hypercalcemia: Williams syndrome and idiopathic infantile

hypercalcemia. Williams described infants with supraaortic stenosis, peculiar facies (“elfinlike”), and hypercalcemia during the first year of life (96,97). Currently, it is thought that the disorder represents a spectrum of abnormalities from the facial dysmorphism alone through all of the described abnormalities. A scoring system has been developed to categorize the suspected disease in infants as lying within or outside the syndrome itself (98). Two-thirds of infants with the disorder have been small for gestational age and many are born past their expected date of birth. Facial abnormalities include structural asymmetry, temporal depression, flat malae with full cheeks, microcephaly, epicanthal folds, lacy or stellate irises, a short nose with a long philtrum, an arched upper lip with a fuller lower lip, and small, maloccluded teeth. The vocal tone is hoarse. The children are affable and have been described as “cocktail party-like” with unusual friendliness to strangers. Additional cardiovascular abnormalities include other congenital heart defects and peripheral organ arterial stenoses of the renal, mesenteric, and celiac vessels. Hypercalcemia, if initially present, rarely remains by the end of the first year of life, but hypercalciuria persists throughout childhood and adolescence.

Several reports (99,100) have emphasized the renal abnormalities demonstrated by patients with Williams syndrome, including urinary frequency, daytime urinary incontinence, and some structural abnormalities, including hypoplasia or dysplasia.

The genetic defect for Williams syndrome is a heterozygous microdeletion of 7q11.23 and encompasses the elastin gene (101). Rarely, it may involve a defect of chromosome 11 [del(11)(q13.5q14.2)] or even chromosome 22 [r(22)(p11→q13)] (102).

The pathogenesis of the disturbance in calcium is unknown. Studies have largely focused on abnormalities of vitamin D metabolism (103–106). Previous studies of affected children have demonstrated increased circulating levels of 25-hydroxyvitamin D after vitamin D administration, increased levels of 1,25(OH)₂D during periods of hypercalcemia but not normocalcemia, and diminished levels of calcitonin during calcium infusions (107).

The treatment is directed toward the associated abnormalities, especially hypertension and cardiovascular anomalies. There are no data on the clinical effect of normalizing mildly elevated serum calcium levels, but the author has anecdotal evidence that normalization of persistent, mild hypercalcemia may improve the final neurologic outcome of children with Williams syndrome.

Idiopathic infantile hypercalcemia was reported by Lightwood (108) in the early 1950s in England and was ascribed to vitamin D intoxication. Other cases have been described subsequently in which maternal exposure to vitamin D was not an issue, which thus led to the designation of the disorder as “idiopathic” (109,110). Affected infants generally have much higher serum calcium levels than those

with Williams syndrome, increased thirst, and the associated problems of symptomatic hypercalcemia. The distinction between this disorder and Williams syndrome remains a bit problematic because some infants have cardiovascular anomalies similar to those seen in the Williams disorder. Other clinical manifestations of idiopathic infantile hypercalcemia include hypertension, strabismus, inguinal hernias, disordered posture, kyphosis, radioulnar synostosis, and dislocated patellae. Hyperacusis is seen commonly, may be persistent, and is problematic.

We have identified (111) more than a dozen infants and young children with this disorder in whom an elevated level of N-terminal PTH-related protein (PTH-rp) was demonstrated at the time of hypercalcemia. Furthermore, in seven of those children who achieved normocalcemia, the levels of PTH-rp were normal or unmeasurably low, and in two children with persistent hypercalcemia, the levels of PTH-rp remained elevated. No other nonmalignant, hypercalcemic disorder that we have investigated, including Williams syndrome, includes elevated levels of the peptide.

The therapy for this disorder is normalization of the extremely high serum calcium level. We have not seen a recurrence of the disorder once the calcium level is normalized, although the systemic manifestations noted earlier are not changed.

Hypercalcemia with Malignancy

There are three general mechanisms whereby patients with malignancy develop hypercalcemia: lytic bone metastases, the ectopic production of PTH-rp, and the ectopic production of 1,25(OH)₂D. Because most children with cancer develop hematologic malignancies, few of which metastasize to bone with enough tumor burden to produce hypercalcemia, and few children develop the solid organ malignancies associated with tumoral production of PTH-rp, the ectopic production of 1,25(OH)₂D is most often responsible for the hypercalcemia seen with leukemias and lymphomas in infants and children. Occasionally, primordial mesenchymal tumors produce an osteoclast-activating factor that may lead to local, osteolytic hypercalcemia. Such factors include interleukin-1 and tumor necrosis factor- α , which are potent promoters of bone resorption. Treatment of the malignancies eliminates the hypercalcemia from the ectopic production of hormones and cytokines (112).

Miscellaneous Disorders

Subcutaneous Fat Necrosis

Michael et al. (113) reported on the association of significant birth trauma with fat necrosis in two infants who were small for gestational age and who subsequently developed severe, symptomatic hypercalcemia. Histologic examinations of the violaceous pressure sites that developed revealed an inflammatory, mononuclear cell infiltrate and calcium-

containing crystals. The author has noted such hypercalcemia in patients with subcutaneous fat necrosis associated with major trauma or disseminated varicella. The mechanism of the disorder is unknown but may be related to minimally elevated levels of $1,25(\text{OH})_2\text{D}$ or excessive prostaglandin production from the tissue trauma site.

Granulomatous Disorders

Of children with sarcoidosis, an autoimmune disorder, 30 to 50% manifest hypercalcemia, and an additional 20 to 30% demonstrate isolated hypercalciuria (114). Some of the presenting signs and symptoms of children with sarcoid are related to hypercalcemia. Twins with cat-scratch disease were reported to develop symptomatic hypercalcemia associated with that granulomatous disorder (115). In such disorders, it is believed that expression of 25-hydroxyvitamin D-1 α -hydroxylase, or another mixed-function microsomal oxidase capable of transforming 25-hydroxyvitamin D, is expressed and leads to unregulated production of $1,25(\text{OH})_2\text{D}$ and consequent hypercalcemia. Treatment of the underlying disorder abolishes the supraphysiologic levels of $1,25(\text{OH})_2\text{D}$ and the associated hypercalcemia.

Limb Fracture

Isolated fracture of a weight-bearing limb that requires immobilization for even a few days may be associated with hypercalcemia and hypercalciuria in young children or adolescents (116). Their occurrence probably reflects the more rapid skeletal turnover in this age group than in adults.

Vitamin D Metabolite Therapy

Children with renal osteodystrophy are commonly treated with calcitriol and develop hypercalcemia as a result once every 12 to 15 treatment-months per patient. Newer therapies of pulse oral or intravenous $1,25(\text{OH})_2\text{D}$ may produce hypercalcemia every 6 to 9 treatment-months per patient. The use of calcitriol to treat other mineral disorders is associated with hypercalcemia only one-third as often as is the use of calcitriol or any other vitamin D metabolite to treat renal osteodystrophy. Treatment with the parent compound, vitamin D, may produce long-lasting hypercalcemia if used in excess, because of lipid storage (117).

Jansen Syndrome

Jansen syndrome presents in neonates with rickets and hypercalcemia and is a form of metaphyseal dysplasia. After infancy, the radiographic picture becomes one of mottled calcifications in the long bones, which represent partially calcified cartilage protruding into the diaphysis. The skull and spine may be affected in the neonate as well (118).

The biochemical picture of the affected infant or child with this disorder resembles that of those with primary hyperparathyroidism, but with some important exceptions: hypercalcemia, hypophosphatemia, and hypercalciuria are present but in the virtual absence of calciotropic hormones, including

PTH, PTH-related peptide, and calcitriol. However, reports of patients with Jansen syndrome have demonstrated that, secondary to one of several point mutations in the structure of the PTH/PTH-rp receptor, ligand-independent activation of the receptor and consequent biologic action occur in such individuals (119–121).

Hypophosphatasia

Infantile hypophosphatasia, a disorder in which serum alkaline phosphatase activity is absent or significantly diminished, is associated with hypercalcemia, hypercalciuria, and radiological signs of rickets. The diagnosis is confirmed with demonstration of an increase in urinary phosphoethanolamine excretion. See Whyte (122) for a comprehensive review of this disorder.

Other Causes of Hypercalcemia

Additional causes of hypercalcemia are uncommon in infants and children. For the sake of completeness, one can list the following: thyrotoxicosis, adrenal insufficiency, VIPoma, leprosy, use of thiazide diuretics, lithium therapy, vitamin A toxicity, and milk-alkali syndrome. Aggressive treatment with calcitonin, and later with thiazide diuretics, has been shown to ameliorate the hypercalcemia often seen in the infantile forms (123).

Normocalcemic Hypercalciuria

Normal Levels of Calcium Excretion

Studies of several populations of children of diverse ethnicity have revealed a rather uniform degree of calcium excretion. On a daily basis, calcium excretion above 3.5 mg/kg is considered excessive (hypercalciuria) (124–127), although some normative data showing higher excretion rates may reflect the effect of a high dietary intake of sodium on calcium excretion dynamics (128). Data from multiple studies of adults and children with hypercalciuria have demonstrated that hypercalciuria is likely present when a randomly voided urine sample shows a calcium to creatinine ratio (both values in milligrams) exceeding 0.2 (or exceeding 0.5 for values in millimoles). Values of the ratio for randomly collected specimens of 0.15 to 0.2 (for measurements in milligrams) are highly suspicious for frank hypercalciuria and, in the author's experience, signal quantitative hypercalciuria in more than 65% of children. However, the clinician is encouraged to perform complete 24-hour urine collections to determine if hypercalciuria is indeed present, because there is a significant incidence of false-positive results when ratios are used (129).

Urinary calcium to creatinine ratios in neonates and infants younger than 3 months of age should be interpreted with caution, because such ratios have been shown to depend on both gestational age and source of milk protein (commercial formula vs. human milk) (130,131). In practice, the author does not use ratios for screening for hyper-

TABLE 11.3. DIFFERENTIAL DIAGNOSIS OF NORMOCALCEMIC HYPERCALCAEMIA

Genetic (idiopathic) hypercalcaemia
Furosemide therapy
Corticosteroid therapy
Sarcoidosis
Immobilization
Hereditary hypercalcaemia with hypophosphatemic rickets
CLCN5 chloride-channel mutation
Bartter's syndrome
Seyberth syndrome
Prostaglandin E infusion
Vitamin D toxicity (early)
Limb fracture
Thyrotoxicosis
Distal renal tubular acidosis

calcaemia in this population but proceeds to a formal collection. On formal collection, daily calcium excretion of more than 5 mg/kg is viewed as hypercalcaemia.

Genetic Hypercalcaemias

Hypercalcaemia may result from an X-linked, recessively inherited disorder associated with one of several mutational defects in a renal chloride channel (132) or may be familial without a gene abnormality that has yet been described. The latter entity has been called idiopathic hypercalcaemia. Chloride-channel defects in the kidney have a wide phenotypic expression, ranging from complete Fanconi syndrome with rickets, termed Dent's disease (133), to a disorder that is mild in childhood and is characterized by nephrolithiasis or nephrocalcinosis but that in adulthood appears to be progressive to chronic renal failure (134,135).

The differential diagnosis of normocalcaemic hypercalcaemia is shown in Table 11.3. Normocalcaemic hypercalcaemia that has been termed *idiopathic* is more prevalent than the chloride-channel defect (for a general review, see references 136–138). It may occur in 7 to 10% of all children. The inheritance of this disorder appears to be autosomal dominant with incomplete penetrance (139). The disorder is associated with nephrolithiasis, recurrent gross and microscopic hematuria, or otherwise unexplained pyuria, or solely with recurrent abdominal pain, and has been implicated in the frequency-dysuria syndrome (140–142).

Hypercalcaemia may be seen in patients who ingest an excessive amount of dietary sodium, and the physician is encouraged to define the level of salt excretion in the assessment of urine calcium excretion. Especially in the small group of children with genetic hypercalcaemia who form kidney stones (perhaps 2 to 3% of this group), other urine abnormalities may occur, including hypocitraturia in 25%, dietary hyperoxaluria in 30 to 40%, and hyperuricosuria in 20%.

The mechanisms of genetic hypercalcaemia have been debated intensely in the literature, with evidence for primary overabsorption of calcium from intestinal sources vying with

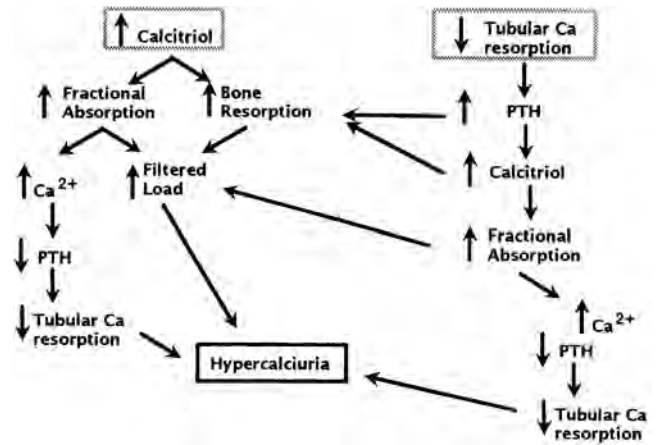

FIGURE 11.1. Pathophysiologic schemes for the production of normocalcaemic hypercalcaemia. The postulated "primary" defects in genetic hypercalcaemia are depicted in the lightly shaded boxes. It can be seen that the two defects merge in the production of hypercalcaemia (solid box). Up-pointing arrows represent increases in the associated physiologic process, and down-pointing arrows represent decreases in the associated physiologic process. Ca²⁺, blood ionized calcium level; Ca, calcium; PTH, parathyroid hormone.

a primary renal calcium leak as a single pathophysiologic mechanism for the disorder. The current view is that both of these disease mechanisms occur in a child with genetic hypercalcaemia. The pathophysiologic mechanism that dominates the clinical picture is wholly dependent on the dietary intake of calcium during the time diagnostic studies are performed. On a calcium-rich or calcium-sufficient diet, the gastrointestinal disorder manifests easily, whereas at very low levels of dietary calcium intake, "renal" hypercalcaemia pertains. Alternatively, gastrointestinal absorption of calcium may contribute little to the final urinary calcium levels (143). Habitual dietary calcium intake determines the level of 1,25(OH)₂D found: normal with elevated calcium intake and elevated during dietary calcium restriction (144). Similarly, secondary hyperparathyroidism may be seen during dietary calcium restriction when the renal excretion of calcium is manifest (145) but may be absent during dietary calcium sufficiency (146). The two predominant mechanisms of genetic hypercalcaemia are summarized Figure 11.1.

Thus, it remains unknown whether the primary disturbance in genetic hypercalcaemia is at the level of the intestine or the kidney. Experimentally, the intestine may have an abnormal sensitivity to 1,25(OH)₂D, perhaps because of the presence of a vitamin D receptor with a higher maximum transport velocity than that in normocalcaemic experimental animals (147). Alternatively, the renal 1 α -hydroxylase may produce more of 1,25(OH)₂D than is needed for systemic calcium homeostasis. Lastly, perhaps the abnormality in genetic hypercalcaemia results from a disorder in the metabolic clearance of 1,25(OH)₂D.

Until recently, it was not thought that bone calcium contributed to the urinary excess of calcium in patients

with genetic hypercalciuria. Studies in adults with the disease and in children with genetic hypercalciuria have now convincingly shown that excessive bone resorption occurs (148–153). The bone loss is from both cortical and trabecular bone and is associated with serum markers that indicate increased bone resorption (C. B. Langman, *unpublished data*, 2002). Frank osteoporosis with fracturing bone disease has been seen in adults and children, especially when the latter group is placed on a calcium-restricted diet.

Treatment of genetic hypercalciuria is directed toward normalization of calcium excretion. In view of the tendency for bone disease to be part of the disorder, dietary calcium restriction seems contraindicated for most infants, children, and adolescents. Whether treatment of any sort need be given is dictated by the clinical picture and local customs. In the author's view, indications for therapy include stone formation, documentation of severe osteopenia without other cause, and symptomatic urinary findings. Treatment for gross hematuria alone in the absence of stone formation does not seem warranted, although in follow-up studies, it appears that children with gross hematuria from hypercalciuria had associated nephrolithiasis more often than did a control population of hypercalciuric children without gross hematuria (154).

If dietary sodium restriction does not ameliorate the hypercalciuria, an increase in dietary potassium may be initiated (155) in the absence of stone disease. If stone disease is present, the next therapy to institute is administration of thiazide diuretics in dosages used to treat mild primary hypertension. Such agents directly inhibit tubular calcium secretion in the cortical thick ascending limb (156,157) and promote whole-body calcium retention as well (158). Thiazides may have direct effects on bone mineralization, and these effects are currently being studied in children and adults in several centers. Some concern has been raised about long-term use because thiazides alter lipid metabolism in a proatherogenic manner (159).

Other treatments for hypercalciuria unresponsive to thiazide therapy alone may include the administration of supplemental alkali, usually in the form of citrate salts, and/or the provision of neutral phosphate salts to limit dietary calcium absorption. Careful attention to all components of the urine related to nephrolithiasis is mandatory when multiple therapies for genetic hypercalciuria are undertaken.

Bartter's Syndrome

See Chapter 38 for a discussion of Bartter's syndrome, a metabolic disorder. The overwhelming majority of infants and children with Bartter's syndrome are hypercalciuric (160), and occasionally hypercalciuria is the presenting sign of the disease. Hypercalciuria may be associated with the development of nephrolithiasis, but it is commonly associated with nephrocalcinosis.

Hyperprostaglandin Syndromes

Several disorders of prostaglandin metabolism in infants and children are associated with hypercalciuria, although the urinary finding rarely dominates the clinical picture. These include Seyberth (hyper-prostaglandin E) syndrome (161,162) and the use of prostaglandin infusions in neonates with congenital heart disease. Some data implicate excess urinary prostaglandin excretion in genetic (idiopathic) hypercalciuria (163,164).

Distal Renal Tubular Acidosis

An important feature of distal renal tubular acidosis is the attendant hypercalciuria that arises in part from an acquired defect in citrate metabolism secondary to the acidosis (165,166). Correction of the hypercalciuria with adequate alkali supplementation is critical to achieve normal growth in children with the disorder (167).

Juvenile Rheumatoid Arthritis

Children with clinically active juvenile rheumatoid arthritis have hypercalciuria and osteopenia (168,169). A reduction in disease activity improves both the osteopenia and the hypercalciuria (170).

Normocalcemic Hypocalciuria

Magnesium-Losing Tubulopathy (Gitelman's Syndrome)

Gitelman's syndrome may result in a frank hypokalemic metabolic alkalosis or have a more limited clinical expression in which renal magnesium wasting with hypomagnesemia occurs as an isolated entity (171) (see Chapter 38). Urine calcium excretion is generally under 0.5 mg/kg body mass per day. The lack of even normal levels of urine calcium excretion is unexpected, because severe hypomagnesemia inhibits the release or action of PTH. The disorder has an autosomal dominant inheritance, although incomplete phenotypic expression occurs commonly. Children manifest severe hypokalemia but grow and develop normally, unlike children affected with Bartter's syndrome

TABLE 11.4. CLINICAL FEATURES OF HYPOPHOSPHATEMIA

Acute hypophosphatemia	Chronic hypophosphatemia
Muscle weakness	Musculoskeletal complaints
Paresthesias	Paresthesias
Hyporeflexia	Depressed reflexes
Cranial nerve palsies	Tremor
Tremor	Seizures
Confusion → coma	Cardiac failure
	Respiratory failure
	Hemolytic anemia
	Rhabdomyolysis

TABLE 11.5. CLINICAL FEATURES OF HYPERCALCEMIA

Lethargy → confusion → coma	Hyporeflexia
Depression, paranoia	Abnormal electroencephalographic pattern
Muscle weakness	Nausea with or without emesis
Constipation	Bradycardia
Reduced QT _c interval on electrocardiogram	Polyuria with concentrating and diluting defects
Systemic hypertension	Nephrolithiasis
Nephrocalcinosis	Malignant venous thrombosis
Extraneous calcifications	
Headache	

(172–174). Nephrocalcinosis is uncommon, and nephrolithiasis is slightly more common than in the general population; stones formed are composed of oxalate. When the disorder presents in infancy or early childhood, it may be associated with symptomatic hypocalcemia. In late adolescence and adulthood, chondrocalcinosis may develop whether the biochemical abnormalities have been effectively treated or not.

Cisplatinum Nephrotoxicity

Chronic cisplatinum nephrotoxicity is associated with a magnesium-losing tubulopathy that has a pronounced hypocalciuric component. Calcium excretion is often below 0.5 mg/kg body mass per day. The low urinary calcium excretion is unexpected, and its mechanism is unknown.

CLINICAL FEATURES OF MINERAL DISORDERS

Tables 11.4 to 11.6 list the most common manifestations of the disturbances discussed in this chapter. Whether or not an isolated blood mineral disturbance produces clinical features depends on the acuteness of the change and on the depth and chronicity of the directional changes.

TABLE 11.6. CLINICAL FEATURES OF HYPOCALCEMIA

Paresthesias	Muscle cramps
Seizures	Laryngospasm
Carpal pedal spasms	Tetany
Electroencephalographic changes	Irritability, depression, psychosis
Papilledema	Increased cerebrospinal fluid pressure
Intracranial calcification	Cataracts (hypoparathyroidism and pseudohypoparathyroidism)
Prolonged QT _c interval on electrocardiogram	Dental abnormalities

NUTRITION AND METABOLISM

FREDERICK J. KASKEL**

NUTRITION AND METABOLISM IN CHRONIC KIDNEY DISEASE

Influences of Chronic Kidney Disease on Nutrition and Metabolism

Poor nutrition adversely affects weight gain, growth, and, likely, development of children with chronic kidney disease (CKD). The etiology of poor weight gain in CKD is thought to be multifactorial. There is evidence that most infants and young children with CKD have subnormal caloric intake (1). Foreman et al. found that mean caloric intake was $80 \pm 23\%$ [mean \pm standard deviation (SD)], of the recommended dietary allowance (RDA) for age in these children (1). There was no correlation between caloric intake and height velocity. Calcium, vitamin B₆, zinc, and folate intakes were also low. The mean protein intake in these children was $153 \pm 53\%$ of the RDA. The same study suggested that the amount of energy per unit body weight (kcal/kg/day) consumed by children with CKD is comparable to that of age-matched healthy children, but because of their small size, children with CKD consume fewer total calories and have a lower %RDA. Despite the general use of supplemental feedings in children with CKD, it is still not known whether these supplements consistently improve height or weight gain (2). This review suggests that additional mechanisms may be responsible for the growth deficits in CKD.

CKD creates a state of glucose intolerance (3). The anabolic effect of insulin is blunted, including the glucose metabolism, as are amino acid uptake into cells and the lipoprotein lipase (LPL) activity. Clinically, this state usually consists of fasting euglycemia but abnormal glucose tolerance with a delayed decrease in blood glucose in response to insulin and hyperinsulinemia. The mechanisms responsible seem to be multiple, but the most prominent metabolic disturbance in uremic patients is insulin resistance, mainly due to a postreceptor defect (4,5). Chronic metabolic acidosis (CMA), frequently associated with CKD, contributes to insulin resistance, and its treatment increases insulin sensitivity (6). In addition to the insulin

resistance, there is abnormal insulin release attributable to reduced adenosine triphosphate content in the pancreatic islets, induced partially by high intracellular calcium, secondary to augmented parathyroid hormone (PTH)-induced calcium entry into cells (4,5).

Regarding protein metabolism, abundant evidence from cross-sectional analyses indicates that low values of serum proteins and loss of muscle mass are commonly found in patients with CKD (7). In addition to an inadequate diet, CMA, inflammation, and resistance to anabolic hormones, especially to insulin, contribute to abnormalities in protein turnover and ultimately result in low-serum proteins (8). Each of these factors stimulates protein breakdown in muscle and activates a common proteolytic pathway, the *ubiquitin-proteasome pathway* (9–12). CMA stimulates amino acid and protein catabolism in children with CKD by either a primary effect of acidification or secondary effects due to changes in hormonal responses induced by acidification (13). For example, CMA causes resistance to insulin and impaired function of growth hormone (GH), thyroid hormone, and the conversion of vitamin D to its most active form, 1,25(OH)₂-cholecalciferol (14–16). Inflammatory proteins, such as acute-phase reactant proteins, tumor necrosis factor, and interleukins (IL), have been found in excess in serum from adult hemodialysis (HD) patients (17,18). These inflammatory factors could cause excessive protein catabolism and suppression of hepatic synthesis of albumin. Insulin deficiency causes loss of muscle mass and activates the ubiquitin-proteasome pathway to degrade muscle protein (19). Further characterization of the biochemical mechanisms that regulate the ubiquitin-proteasome and other catabolic pathways will be necessary to identify new strategies for preventing protein deficits in CKD.

Dyslipidemia increases the risk of cardiovascular events among individuals with CKD and contributes to the progression of renal disease itself (20). The characteristics of dyslipidemia are different in non-nephrotic patients compared with the nephrotic ones. Hyperlipidemias can occur in as many as 70% of the non-nephrotic patients with

CKD, as opposed to 100% in the nephrotics (21). The characteristic abnormality in plasma lipids in non-nephrotic patients with CKD includes elevated triglycerides (TG) accompanied by an increased concentration of very-low-density lipoproteins (VLDL), decreased high-density lipoproteins (HDL), and normal to below normal levels of low-density lipoproteins (LDL), which represents a type IV hyperlipoproteinemic pattern. In the nephrotic patients, serum lipoprotein patterns are nearly equally distributed among types IIa, IIb, and V. The finding of low total cholesterol (TC) level should not necessarily be reassuring, because it could be a marker of malnutrition associated with increased mortality risk in HD patients (22). The mechanism of this low cholesterol involves a defective catabolism of TG-rich lipoproteins and decreased activity of both LPL and hepatic TG-lipase (23). In addition, CMA and hyperinsulinemia depress LPL activity (24). Disordered lipoprotein metabolism results from complex interactions among many factors, including the primary disease process, use of medications such as corticosteroids, the presence of malnutrition or obesity, and diet.

The most recent data regarding growth in children with CKD is provided by the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS, 2001). Patients with CKD are 1.4 SD below age- and gender-adjusted norms for height. Adolescents (older than 12 years) have less severe height deficits (-1.01 ± 0.04) at baseline, relative to infants (-1.81 ± 0.07 ; younger than 24 months) and toddlers (-1.77 ± 0.05 ; age, 2 to 5 years). The height deficit for females is marginally worse than for males, and patients with baseline glomerular filtration rate (GFR) less than the median of $36.5 \text{ mL/min/1.73 m}^2$ have more severe growth retardation than the patients with higher GFR. Children with end-stage renal disease (ESRD) are, overall, approximately 1.6 SD below the appropriate age- and gender-adjusted height levels at the time of dialysis initiation, and younger patients, in particular, have more severe growth retardation. Although the weight deficits of dialysis patients are not as severe as height, patients are, on average, more than 1 SD below normal for weight.

The GH/insulin-like growth factor-1 (IGF-1) axis plays a fundamental role in the growth process during childhood. Although serum GH and IGF-1 levels are usually normal or high in growth-retarded CKD children (25), it was recognized long ago that uremic serum has a high IGF-1 binding capacity, resulting in low IGF-1 bioactivity (26,27). The mechanisms for this increased IGF-1 binding capacity seem to be related to decreased renal clearance of IGFBP (IGF binding proteins), because serum levels of IGFBP-1, -2, -4, and -6 were shown to correlate inversely with GFR (28,29). In addition, uremia raises hepatic mRNA levels for IGFBP-1 and -2 by an unknown mechanism (30).

Secondary hyperparathyroidism has significant effects on longitudinal growth. High PTH levels are associated with mobilization of calcium from bone. PTH also causes

proliferation of the fetal growth plate chondrocytes, inhibits the differentiation of these cells into hypertrophic chondrocytes, and stimulates accumulation of cartilage-specific proteoglycans that are thought to act as inhibitors of mineralization (31). However, despite the high serum PTH levels, there is "PTH resistance" at the level of growth plates, owing to intertwined factors affecting the PTH/PTH-related peptide receptors. This receptor's mRNA expression was found to be downregulated in the kidney and growth plate of uremic rats, in the osteoblasts of patients with ESRD (32), and as a result of high-dose intermittent calcitriol therapy (33,34). On the other hand, PTH/PTH-related peptide expression is upregulated by GH and physiologic doses of calcitriol (33).

CMA may affect growth independently of uremia, because diseases such as renal tubular acidosis are associated with growth defects, and catch-up growth can be achieved when patients are given alkali therapy. When the blood pH is less than 7.25, length gain is diminished earlier than weight gain. A reduction of weight gain is observed only for more severe acidosis with pH less than 7.20 (35). This finding suggests that the longitudinal growth of bone is more sensitive to acidosis than are such factors as protein synthesis, which influences body weight. The mechanisms appear to be a profound *in vitro*-negative effect of CMA on the GH/IGF-1 axis, mainly through a downregulation of the receptors for both hormones (36) plus a stimulation of osteoclastic and a suppression of osteoblastic activity (37).

Nutritional Support for the Predialysis Child

Nutritional guidelines for children with chronic renal insufficiency (CRI) before dialysis are not as well established as those for children on dialysis. However, recent studies show that disturbances in nutritional intakes, bone biochemistry, and growth occur early in CRI and suggest the need for joint medical and dietary intervention in children even with mild and moderate CRI (38).

Children who are not yet on dialysis need nutritional intake to provide calories for both maintenance and catch-up growth. The protein requirements are slightly greater than for the normal healthy controls (39) (Table 12.1).

Vitamin and trace element supplementation may be indicated during the predialysis period if their estimated intake is considerably less than the RDA. Iron supplementation is usually required in the predialysis period when depletion of iron stores is documented by laboratory studies. Patients receiving erythropoietin generally require iron supplementation owing to increased turnover of red blood cells, and require regular checking of serum iron levels. Zinc supplementation is not routinely administered to children during the predialysis phase, but because foods rich in zinc are often limited owing to poor appetite, supplementation by pharmacologic means on the basis of RDA stan-

TABLE 12.1. PREDIALYSIS: FLUID AND NUTRIENT RECOMMENDATIONS FOR CHILDREN

	Infant (0–1 yr)	Toddler (1–3 yr)	Child (4–10 yr)	Adolescent (11–18 yr)
Energy	0–0.5 yr: ≥108 kcal/kg 0.5–1 yr: ≥98 kcal/kg	102 kcal/kg	4–6 yr: 90 kcal/kg 7–10 yr: 70 kcal/kg	Girls 11–14 yr: 47 kcal/kg Girls 15–18 yr: 40 kcal/kg Boys 11–14 yr: 55 kcal/kg Boys 15–18 yr: 45 kcal/kg
Protein	0–0.5 yr: 2.2 g/kg 0.5–1.0 yr: 1.6 g/kg	1.2 g/kg	4–6 yr: 1.2 g/kg 7–10 yr: 1 g/kg	11–14 yr: 1.0 g/kg 15–18 yr: 0.9 g/kg
Sodium	Generally unrestricted; 1–3 mEq/kg if edema or HTN present	Generally unrestricted; 1–3 mEq/kg if edema or HTN present	Generally unrestricted; 1–3 mEq/kg if edema or HTN present	Generally unrestricted; 1–3 mEq/kg if edema or HTN present
Calcium	0–0.05 yr: 400 mg/d 0.5–1.0 yr: 600 mg/day (provided hypercalcemia does not occur and calcium-phosphorus product does not exceed 70)	800 mg/d (provided hypercalcemia does not occur and calcium-phosphorus product does not exceed 70)	800 mg/d (provided hypercalcemia does not occur and calcium-phosphorus product does not exceed 70)	1200 mg/d (provided hypercalcemia does not occur and calcium-phosphorus product does not exceed 70)
Potassium	1–3 mEq/kg, if needed (usually not until GFR is <10% normal)	1–3 mEq/kg, if needed (usually not until GFR is <10% normal)	1–3 mEq/kg, if needed (usually not until GFR is <10% normal)	1–3 mEq/kg, if needed (usually not until GFR is <10% normal)
Phosphorus	Use low-content formula if serum levels of phosphate are elevated; restrict high-content foods	Usually 600–800 mg/d when serum levels are elevated	Usually 600–800 mg/d when serum levels are elevated	Usually 600–800 mg/d when serum levels are elevated
Vitamins	1 mL multivitamin drops; vitamin D metabolites if needed, based on serum calcium, PTH, and alkaline phosphatase levels	Multivitamin, if needed; vitamin D metabolites, if needed, based on serum calcium, PTH, and alkaline phosphatase levels	Multivitamin, if needed; vitamin D metabolite, if needed, based on serum calcium, PTH, and alkaline phosphatase levels	Multivitamin if needed; vitamin D metabolite if needed, based on serum calcium, PTH, and alkaline phosphatase levels
Trace minerals	Supplement zinc, iron, or copper, if needed	Supplement zinc, iron, or copper, if needed	Supplement zinc, iron, or copper, if needed	Supplement zinc, iron, or copper, if needed
Fluid	Unrestricted unless needed; then replace insensible + urinary output	Unrestricted unless needed; then replace insensible + urinary output	Unrestricted unless needed; then replace insensible + urinary output	Unrestricted unless needed; then replace insensible + urinary output

GFR, glomerular filtration rate; HTN, hypertension; PTH, parathyroid gland.

dards may be recommended if there is reason to suspect zinc deficiency. Fluoride supplementation is provided only when the water supply is not satisfactory (40).

Monitoring Energy and Protein Intake for the Child on Dialysis

The outcome measures chosen for adult studies, mainly mortality rates, are not appropriate for children, who generally have low mortality rates while being treated for ESRD. Alternatively, complications unique to younger patients, such as impaired growth, puberty, or school performance, are better end points for evaluation of

treatment strategies in these children (41). An initial evaluation and ongoing monitoring of nutritional and growth status is a major component of providing optimal care to children with ESRD. For children on chronic renal replacement therapy, it is essential that the evaluations are done by experienced pediatric renal nutritionists with skills in age-appropriate data collection, interpretation, and counseling.

A thorough nutritional assessment should include observation of physical signs and symptoms, dietary intake assessment using the 24-hour or 3-day dietary history, biochemical values, anthropometric measurements, body composition data, and assessments of protein catabolic rate if

available. The physical exam may lead to clues suggestive of deficiencies of proteins and vitamins (42).

The protein-caloric status in children with CKD is usually indirectly assessed by measuring albumin and transferrin, both of which are affected by inflammation, infection, malnutrition, acidosis, hormonal influences, liver disease, dialysis, and blood loss. More sophisticated measurements of protein stores involve protein turnover studies and biochemical analysis of skeletal muscle and the nitrogen balance (43).

Growth parameters in a pediatric patient on dialysis must be measured according to standardized protocols with consistent equipment and preferably performed by the same person. The most used parameters are weight, height, head circumference (in those less than 3 years of age), body mass index (BMI), mid-arm circumference, and skinfold thickness, for which nomograms are available depending on age and gender. Anthropometric measurements in relation to nutritional status can be thought of predominantly as methods of assessment of protein-calorie malnutrition (44).

Body composition data are generally used for research purposes only, owing to the difficulty of standardization (45). For determination of fat-free mass, the following methods can be used: total body water, total body potassium, total body nitrogen and calcium, bioelectrical impedance, and electromagnetic scanning. Determination of body fatness can be done by densitometry, inert gas absorption, or near-infrared interactance. Neutron activation or dual-energy x-ray absorptiometry can be used to determine the bone mineral content (46).

Nutrition evaluation and counseling are recommended at the initiation of dialysis, ideally within the first week, and after that, on an ongoing basis because of the dynamic nature of the child's medical condition and food preferences. The maximum time between such updates should be 3 to 4 months. Conditions that could dictate a more frequent evaluation of the nutrition plan of care include decreasing dry weight, ongoing decrease in oral intake, change in gastrointestinal function, significant change in SD scores (SDS), elevated or suboptimal laboratory values related to nutrients, ongoing excess interdialytic weight gain, concern for appropriate compliance with recommendations, change in psychosocial situation, or when placement of a tube for feeding is under consideration (42).

Compliance with the nutrition prescription and recommendations from other team members are important at any age, especially in adolescents. Integrating the treatment goals of the dietitian, social worker, child development specialist, nurse, and physician helps to maximize patient and family adherence to the overall plan of care.

Nutritional Support for the Child on Maintenance Hemodialysis

Chronic HD results in dialysate loss of amino acids and water-soluble vitamins. In addition, the HD procedure itself has catabolic effects (47). In adult studies, up to 8 g of free

amino acids lost per HD session have been reported. This loss is further influenced by the choice of membrane: Newer synthetic polyacrylonitrile membranes have decreased losses relative to cellulose membranes (48).

In adults, multiple studies have reported that a good nutritional status predicts a better outcome in terms of mortality, morbidity, and rehabilitation (49,50). In pediatrics, similar studies have not been done owing to the small number of patients treated and the relatively short period of treatment before transplantation. Recently, data from the United States Renal Data System (USRDS) were used to identify all patients under the age of 18 years who initiated dialysis between 1995 and 1998. This multivariate analysis performed on almost 2000 pediatric patients demonstrated that each decrease in serum albumin of ~ 1 g/dL was associated with a 54% higher risk of death. This finding was independent of glomerular causes of their CKD and other potential confounding variables (51).

Good dialysis adequacy is a prerequisite for good nutritional status in adult dialysis patients. Observations made on pediatric patients undergoing dialysis in 13 units throughout the six-state New England region over a period of 18 months showed that vigorous dialysis, evidenced by a high Kt/V (urea amount cleared from plasma divided by distribution volume), did not appear to improve serum albumin concentrations in younger HD patients (52). However, most of these patients were well dialyzed, and thus this finding is likely consistent with the adult studies. Thus, there appears to be little additional benefit in nutritional status once a given level of clearance is attained. In a recent report of a combination of enhanced HD clearance and nutritional supplementation, this regimen was associated with improved growth in prepubertal to early-pubertal HD children monitored for more than 2 years while receiving an average of 90.6% and 155.9% of their recommended energy and protein intake, respectively. Average weekly treatment time was 14.8 hours, with a urea reduction ratio of 85% and Kt/V of 2.0 per treatment, all well above current guidelines (53). On this regimen, the patients gained, on average, more than 0.3 SD in height without GH and normal pubertal development was also described (53).

Children on maintenance HD require an adequate caloric intake not only for weight gain and growth, but also to avoid the use of proteins as an energy source. Current recommendations are that children treated with maintenance HD should receive caloric intake according to the RDA for chronological age at the time of the initial evaluation. Furthermore, ongoing adjustments should be made, depending on the child's clinical and biochemical response (42).

Current recommendations regarding the dietary protein intake (DPI) in patients on maintenance HD are that, initially, DPI should be based on the RDA for chronological age plus an additional increment of 0.4 g/kg/day to achieve a positive nitrogen balance (42) (Table 12.2).

Children on maintenance HD often have an insufficient intake of oral nutrients because of anorexia and dietary

restrictions. The first step to provide nutritional support is by oral supplementation (54) (Table 12.3). This issue is most important during periods of very high-energy requirements during the first 2 years of life and the adolescent years (55). When oral supplementation fails, enteral feeding through a nasogastric or gastrostomy tube is commonly used and is successful in opposing growth retardation and achieving catchup growth in infants and young children (56,57).

Intradialytic parenteral nutrition (IDPN) can be initiated if enteral feeding has failed (58). Morbidity and mortality were lower in adult HD patients who received IDPN (59,60), and criteria exist for IDPN in this population (61). However, one study failed to demonstrate a beneficial effect of IDPN (62). One study evaluating the use of IDPN in the pediatric population demonstrated a dramatic increase in oral caloric intake and eventual weight gain after 3 months, secondary to the improved dietary status (63).

Possible side effects of IDPN are hyperglycemia associated with glucose infusion or rebound hypoglycemia when the infusion is suddenly terminated. A frequent complaint in patients receiving IDPN is painful cramps in the arm containing the fistula, an effect thought to be due to the rapid

infusion of the hyperosmolar solution causing rapid fluid shifts from muscle cell to interstitium. A long-term complication of IDPN is the possible development of abnormal liver function tests due to fatty deposition in the liver and cholestasis. Therefore, the patients on IDPN require close monitoring in terms of glucose control, hepatic function, and lipid profile (58).

Pediatric IDPN indications and appropriate compositions are not well defined but involve the infusion of 5 to 6 mg/kg/min of glucose, 1.2 to 1.4 g/kg/day of protein, and possibly the addition of intralipids (63).

IDPN provides minimal supplementation, usually between 500 and 1500 kcal and is administered only three times per week. In addition, only approximately 70% of the infused amino acids are retained owing to rapid clearance by HD (58). Thus, in patients who are severely malnourished, IDPN could not provide sufficient nutrients, and total parenteral nutrition (TPN) is indicated. However, in patients with moderate malnutrition who are intolerant to further oral supplementation secondary to anorexia, a short course of IDPN may improve nutritional status sufficient to permit more physiologic oral supplementation (63).

TABLE 12.3. FORMULAS FOR CHILDREN WITH RENAL DISEASE

	Manufacturer	kcal/ mL	Protein [g/L (sources)]	Fat [g/L (sources)]	Carbohydrate [g/L (sources)]	Na/K (mEq/L)	Ca/P (mg/ L)	mOsm/kg water

In conclusion, short-term IDPN is a promising safe and effective nutritional intervention in children on HD who are not receiving sufficient nutrition from enteral feedings. However, IDPN is quite expensive, and generally restrictive criteria prevent reimbursement. As soon as the patient can tolerate an increase in oral intake or becomes a candidate for tube feedings, enteral supplementation should be undertaken.

The practice of prescribing water-soluble vitamins for HD patients has not been rigorously tested but probably does little harm. There are losses of water-soluble vitamins in the dialysate fluid, particularly ascorbic acid (64). Vitamin B₆ and folate are important supplements, especially because they are useful in reducing the homocysteine levels (65). In view of the reports of peripheral neuropathy and hyperoxalemia with high-dose vitamin B₆ and vitamin C supplementation, megavitamin therapy with water-soluble vitamins should be avoided (66). Fat-soluble vitamins should be given only when there is a clear indication because of the risk of toxicity. Vitamin A levels are invariably increased in the plasma of CRI patients, because retinol-binding protein is increased in uremia (67).

Trace elements are indispensable components of many enzymes, and abnormalities are primarily the result of uremia and the dialysis procedure. Plasma trace element concentrations in adult HD patients are distinctly different compared to those of healthy controls. Elements such as cesium, magnesium, molybdenum, and rubidium are reduced, and cadmium, cobalt, and lead are accumulated

in HD patients (68). Adequate water treatment, including reverse osmosis, prevents the accumulation of the majority of trace elements in HD patients. Zinc supplementation may be recommended for patients with proven zinc deficiency, but its use in all HD patients is questionable (69,70). Selenium deficiency is to be suspected in dialyzed patients, and supplementation may be beneficial by increasing glutathione peroxidase activity, cardioprotective effect, and immunostimulatory properties (71).

Nutritional Support for the Child on Chronic Peritoneal Dialysis

Malnutrition in children receiving chronic peritoneal dialysis (PD) has specific etiologies and treatments (72). Benefits of this modality, such as a more constant control of uremia, a liberalization of dietary restrictions, and an additional source of calories from the dialysate glucose absorption, are counter balanced by losses of proteins, amino acids, vitamins and trace elements in the dialysate, anorexia possibly related to the pressure effect of dialysate in the abdomen, and to the hyperglycemia effects of absorption of glucose from dialysate (73). Finally, there is a catabolic effect induced by episodes of peritonitis (74,75).

As with HD, good nutritional status in PD is associated with a better clinical outcome. Studies done in adults showed that markers of nutritional status, mainly albumin, correlate well with morbidity and mortality in patients on PD (76). In children, it was shown that better nutrition correlates with a reduced rate of infections, particularly peritonitis (77). Inter-

TABLE 12.4. PERITONEAL DIALYSIS: FLUID AND NUTRIENT RECOMMENDATIONS FOR CHILDREN

Data from Nelson P, Stover J. Nutrition recommendations for infants, children and adolescents with end-stage renal disease. In: Gillitt D, Stover J, eds. *A clinical guide to nutrition care in end-stage renal disease*, 2nd ed. Chicago, IL: American Dietetic Association, 1994:79–97; and K/DOQI Nutrition in chronic renal failure. *Am J Kidney Dis* 2000;35:S112–S115.

estingly, cardiovascular disease is also a surprisingly common cause of death in children on PD, and low serum albumin levels in children on dialysis have recently been shown to be associated with an increased risk of patient death (51,78).

Adequate dialysis may be an important factor for obtaining and maintaining adequate nutritional status and growth (79,80). The delta height velocity of children with a mean age at initiation of dialysis of 28.5 months was found to be significantly correlated with total creatinine clearance, residual GFR, and residual Kt/V_{urea} (81). On the other hand, on a cautionary note, Schaefer et al. have also described an important inverse correlation between growth rates and creatinine clearance in children on PD, perhaps attributable to dialytic losses of an essential factor (82). The change in height SDS over 18 months in children on PD revealed that high-transporter state and total dialysate volume had a negative effect, whereas higher dialytic creatinine clearance had a positive effect (83). Alternatively, Kt/V greater than 2.75 in PD patients had no effect on nutrition but resulted in increased albumin losses (52).

Malnutrition in PD patients is multifactorial. Increased losses of amino acids, water-soluble vitamins and trace ele-

ments occur, whereas protein losses are inversely related to the patient's weight and peritoneal membrane total area (73). During peritonitis, the permeability of the peritoneum for proteins and amino acids increases significantly by 50 to 100%. Between 100 and 300 mg of proteins/kg/day are lost in the drained peritoneal dialysate, which translates to up to 10% of the total protein intake (73,75). The main protein lost is albumin, but there are also losses of immunoglobulins, transferrin, opsonins (84), and water-soluble vitamins, such as vitamin B₆, vitamin C, and folic acid (84,85).

In addition to the nonspecific factors contributing to decreased caloric intake in CKD, there are specific factors related to PD, such as the abdominal fullness from the dialysate and the absorption of the glucose from dialysate. Whereas the glucose absorbed from the dialysate provides calories, it also contributes to the anorexia seen in PD patients (54,86). The number of calories provided by dialysate glucose absorption may be predicted by an equation applied in adults (87). Pediatric studies reported dialysate glucose absorption ranging from 9 to 18 kcal/kg/day, representing 7 to 15% of the total daily caloric intake, respectively (39).

Current recommendations for energy intake in children treated on PD should follow the RDA for chronologic age, including calories derived from the dialysate glucose, and adjusted accordingly (42). Malnourished children, however, will require “catchup” energy supplementation detailed by the American Academy of Pediatrics (88). Supplemental g-tube feeding facilitates weight gain in infants and older children receiving PD and arrests the decline in height SDS traditionally observed in infants with CRI total protein and albumin (89,90). Gastrostomy feedings via a button in children on PD significantly improved BMI (91).

Current recommendations regarding DPI in patients on PD are also based on the RDA for chronologic age, to which a supplement based on anticipated peritoneal losses should be added (42,73) (Table 12.4). Dietary recommendations for children on PD could be further defined using a series of nitrogen balance studies. The correlation between estimated DPI and nitrogen balance indicates that a DPI of more than 140% RDA and a total energy intake of more than 85% RDA are required to obtain an estimated nitrogen balance of at least 50 mg/kg/day, which is considered adequate for metabolic needs in children (92). High biologic value protein (e.g., meat, milk, eggs) should constitute 60 to 70% of the DPI (39).

The use of special amino acid–based dialysis solutions in children on PD may compensate for losses into the dialysate (93). Furthermore, the potential complications related to the

dialysate glucose load, such as hyperlipidemia, excessive weight gain, and glucose intolerance, could be ameliorated (94,95). Usually, one exchange per day is replaced with the amino acid solution consisting of both essential and nonessential amino acids with electrolyte composition similar to that of standard dialysis solutions (96) (Table 12.5).

Between 50 and 90% of the amino acids are absorbed without any changes in ultrafiltration compared with standard dialysate (97). Side effects include a rise in blood urea nitrogen, metabolic acidosis, anorexia, and nausea (98,99). This promising nutritional intervention is still rather expensive and should be reserved for malnourished patients who fail more conservative nutritional support.

Dietary intake of water-soluble vitamins is lower than the RDA in the majority of children on PD and supplementation results in intakes that exceed the RDA (44,100,101). *Hyperhomocysteinemia*, an independent risk factor for cardiovascular disease in adults (102), is associated with deficiencies of folate, vitamin B₆, and vitamin B₁₂ (103). Elevated plasma homocysteine levels in pediatric patients on PD were significantly reduced after administration of 2.5-mg folic acid daily for 4 weeks (104). Supplementation of trace elements is reserved for specific deficiencies such as zinc (72,105).

NUTRITION AND METABOLISM OF THE ACUTELY ILL CHILD

There is no conclusive evidence that acute renal failure (ARF) per se increases energy expenditure (EE). However, ARF is often associated with other organ system failures that increase energy demands (106). Metabolic changes occurring in such situations are different from the mechanisms associated with starvation alone. The optimal intake of nutrients in children with ARF is therefore influenced more by the nature of the disease causing ARF, the extent of catabolism, and the modality and frequency of renal replacement therapy, rather than by renal dysfunction itself.

The stress response is characterized by increased catabolism with subsequent release of large amounts of glucose, amino acids, and fatty acids from the body's stores. These metabolic changes are mediated by proinflammatory cytokines such as tumor necrosis factor- α and the ILs IL-1 α , IL-1 β , and IL-6. These changes have consistently been viewed as adaptive or beneficial, as they may reduce and redirect energy consumption, postpone anabolism, and at the same time activate the immunologic reaction (107). However, a prolonged stress response can trigger a sustained and irreversible catabolic state mediated by release of cytokines and by activation of the hypothalamic-pituitary axis (108,109).

The mortality rate remains very high in patients with ARF, reaching between 40 and 80% in adults (110,111) and between 30 and 80% in children (112,113). In adult

populations, a correlation between energy balance and survival has been established (114). Although studies suggesting that nutrition improves outcome of ARF in children have not been documented, it is reasonable to suggest that the complication rate is reduced, and recovery is enhanced by adequate nutrition.

Assessment of the general nutritional status before the acute episode becomes very important. Studies performed in adults report that a poor prior nutritional status places the patient at risk in terms of morbidity and mortality: Malnourished patients have longer hospitalizations and increased morbidity and mortality (115). Unfortunately, surveys of hospitalized pediatric patients indicate a 20 to 40% prevalence of protein-energy malnutrition (116).

There are four primary goals in managing the nutritional needs of children in ARF: maintaining adequate caloric intake, avoiding excessive protein intake to control the rise in blood urea nitrogen, minimizing potassium and phosphate intake, and reducing fluid intake (117). Enteral nutrition should be considered first, whenever possible, because it also supports maintenance of the gut barrier and may prevent bacterial invasion (106). If the patient is not able to ingest adequate intake, tube feeding can be introduced. When this is not possible, TPN becomes necessary. If the child is oligo-anuric and sufficient calories cannot be achieved while maintaining appropriate fluid balance, an earlier initiation of dialysis should be instituted.

A hypermetabolic state occurs during critical illness in adults, characterized by an EE significantly greater than that in the normal resting state (118,119). Recent studies suggest the same EE state exists in pediatric patients with critical illnesses (120). In an effort to estimate the EE in stress situations, including ARF, one needs to determine the resting EE (REE) and the 24-hour EE (24h EE) for healthy children first. There are traditionally several methods for estimating REE in children, the most commonly used being the World Health Organization and the Schofield weight and weight-height equations (121,122). Recently, a study using the enhanced metabolic testing activity chamber, a new indirect calorimetry technology, was able to propose new equations to estimate the REE and 24h EE in infants 0 to 7 months of age (123). According to this study, both the World Health Organization and the Schofield equations underestimated REE by greater than 15 kcal/kg/day. The new proposed equations were within 4% of the REE obtained by using the enhanced metabolic testing activity chamber.

Extrapolating from adult studies, the energy requirements in critically ill children might be estimated by adding a stress-related correction to the REE (124,125). A recent prospective study using indirect calorimetry on children admitted to an intensive care unit (postcardiac surgery, sepsis, systemic inflammatory response syndrome) showed that EE predicted by the specific formulas grossly overestimates the actual EE, which means that 24h EE was closer

TABLE 12.6. EQUATIONS FOR PREDICTING BASAL METABOLIC RATE AND ENERGY REQUIREMENTS

Age range (yr)	Basal metabolic rate (kcal/d)
Males	
0–3	60.9 • weight – 54
3–10	22.7 • weight + 495
10–18	17.5 • weight + 651
Females	
0–3	61.0 • weight – 51
3–10	22.5 • weight + 499
10–18	12.2 • weight + 746
Level of activity	Activity factor
Confined to bed	1.2
Sedentary	1.5
Normal	1.7
Athlete	2.0

Note: Energy requirement = basal metabolic rate × activity factor. Adapted from WHO. Energy and protein requirements: report of a joint FAO/WHO/UNU expert consultation. WHO Technical Report Series No. 724. Geneva: World Health Organization, 1985.

to REE than predicted by the formulas (126). Therefore, direct measurement of EE is the only means currently available for accurate determination of caloric requirements.

For practical purposes, where indirect calorimetry is not available, one must rely on one of numerous methods that attempt to predict EE and, therefore, nutritional requirements, based on age, weight, and/or height. Caloric requirements are a summation of basal metabolic needs, activity, and growth (Table 12.6). In healthy children, REE accounts for approximately 50% of total EE, whereas activity and growth account for the remaining 50% of total EE (127). To predict energy requirements for critically ill children, one must first determine basal energy requirements and adjust for hypermetabolism (128) (Table 12.7).

Patients with ARF have high protein catabolic rates. Several studies done in adult populations reported between 1.4 and 1.8 g/kg/day protein catabolic rates (129,114). Another parameter that is used to measure the protein catabolic state, urea nitrogen appearance (UNA), has been found to be significantly elevated in children with ARF, with levels more than 180 mg/kg/day (130). A recent study of critically ill children demonstrated that protein turnover but not lipolysis correlated with the severity of the critically ill condition (131).

In addition to the catabolic effect of the illness, there are amino acid losses through dialysate solutions. Although the amino acid losses in conventional HD and PD were discussed earlier, it is worthwhile discussing the case of continuous renal replacement therapy–related amino acid losses. Amino acid clearances and calculated losses in adults on continuous venovenous hemofiltration have been reported between 2 and 11% of the dietary intake, whereas studies done for continuous venovenous HD found 8 to 22% dietary loss (132,133). The ultrafiltrate volumes, as well as blood flow rates, have varied widely between these individ-

TABLE 12.7. METHOD TO PREDICT METABOLIC RATES DURING CRITICAL ILLNESS

Average hospital energy requirements			
Body weight (kg)	kcal/kg/day	Increases in energy with stress	
0–10	100	Fever	12% per degree Celsius >37°C
10–20	1000 + 50/kg	Cardiac failure	15–25%
>20	1500 + 20/kg	Major surgery	20–30%
		Burns	Up to 100%
		Severe sepsis	40–50%

Adapted from Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics* 1957;19:823–832; and Wesley JR, et al., eds. *Parenteral and enteral nutrition manual*. Chicago: Abbot Laboratories, 1980:17.

ual studies, making direct comparison among the treatments difficult. The only study performed in children reported amino acid losses of 11 to 12% of dietary intake. The patients had similar blood and dialysate/filtered replacement fluid flow rates, and there were equivalent amino acid losses and urea clearances with no significant difference in regard to modality, continuous venovenous hemofiltration, or continuous venovenous HD (134). A negative nitrogen balance occurred in those children despite the delivery of standard TPN containing 1.5 g/kg/day of proteins and caloric intake of 20 to 30% above REE.

It is possible to estimate the protein requirements by measuring the protein equivalent of total nitrogen appearance (PNA), which is an estimate of the protein losses (135). When the patient is in nitrogen balance, PNA should be equal to the protein intake. The PNA can be derived from the UNA by using the Bergström formula:

$$\text{PNA [g/day]} = 20.1 + 7.5 \text{ UNA [g/day]}$$

The UNA results from measuring the urea nitrogen content of all measurable outputs (urine, dialysate or ultrafiltrate, fistula drainage) plus the change in body urea nitrogen:

$$\text{UNA [g/day]} = \text{output urea nitrogen} + \text{change in body urea nitrogen}$$

Where change in body urea nitrogen [g/day] is given by:

$$(\text{SUN}_f - \text{SUN}_i) [\text{g/L/day}] \times \text{BW}_i [\text{kg}] \times 0.6 [\text{L/kg}] + (\text{BW}_f - \text{BW}_i) [\text{kg/day}] \times \text{SUN}_f [\text{g/L}] \times (1 \text{ L/kg})$$

where *i* and *f* are the pre- and postdialysis moments in time, SUN is serum urea nitrogen, BW is the body weight, 0.6 is an estimate of the total body water and 1 L/kg is the volume of distribution of urea in the weight that is gained or lost.

The PNA is normalized to body weight to obtain the nPNA, which is expressed as g/kg/day.

In addition to the previously described particularities of ARF in regard to the energy intake and protein metabolism, such children also need daily intake of lipids, minerals, and vitamins, according to the normal daily requirements for age.

NUTRITIONAL AND METABOLIC CHANGES AFTER RENAL TRANSPLANTATION

Metabolic disorders post-renal transplantation result from a complex interaction of factors such as genetic susceptibility; medications; and physiologic changes related to ischemic, immunologic, vascular, and mechanical injury. Although other chapters discuss the electrolyte imbalances that frequently occur after renal transplantation, this subchapter focuses on common derangements pertinent to lipid and carbohydrate metabolism.

Posttransplant Hyperlipidemia

Hyperlipidemia is a risk factor for cardiovascular disease in adult transplant patients (136–139) and may also cause chronic allograft nephropathy (140), whereas no data exist in the pediatric transplant population.

The prevalence of hyperlipidemia is highest immediately posttransplant, declining to 30% after 5 years (139). A longitudinal evaluation of pediatric renal transplant recipients showed that the prevalence of elevated TC and TG declined from 70 to 35% and 46 to 15%, respectively, between 1 and 10 years posttransplant, most likely as the doses of immunosuppressive agents were decreased (141).

Causes of post-renal transplant hyperlipidemia include preexisting hyperlipidemia, especially with a familial history; medications (immunosuppressives, diuretics, and beta blockers); graft dysfunction; older age; male gender; obesity; and hypoalbuminemia secondary to nephrotic syndrome (142). Risk factors for high TC in transplanted children on cyclosporine A (CsA) include preexisting hyperlipidemia plus a family history and, unlike the adult studies, worsen with time (143). In the same study, elevated TG was associated with reduced GFR.

The specific lipid profile abnormalities posttransplant include increased TC, LDL, VLDL, and apolipoprotein B levels. HDL levels can be low, normal, or slightly elevated.

The chronic use of immunosuppressive medications is an important determinant of hyperlipidemia in posttransplant children. The most commonly used medications, cor-

ticosteroids and CsA, were clearly reported to produce hyperlipidemia. Tacrolimus seems to have a less prominent effect, whereas sirolimus has a more pronounced effect.

Corticosteroids were shown to be associated with increased TC and TG levels (144). They enhance lipogenesis by increasing the activity of acetyl-coenzyme A carboxylase and free fatty acid synthetase, thus increasing hepatic synthesis of VLDL, downregulating LDL receptor activity, and increasing the activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase. Concurrently, they induce insulin resistance resulting in decreased activity of LPL, thus raising TG. Finally, the corticosteroid-induced decrease in adrenocorticotrophic hormone release may contribute to the lipid abnormalities, because adrenocorticotrophic hormone upregulates LDL receptor activity (142). Withdrawal of steroids posttransplantation significantly reduces TC and LDL levels (145). However, there is a simultaneous decrease in HDL levels, which may decrease the HDL:cholesterol ratio. Replacement of low-dose oral methylprednisone with deflazacort resulted in decreased TC and LDL and increased HDL in pediatric patients (146).

CsA is associated with increased TC and increased LDL, whereas HDL and TGs are not strongly affected (147). CsA is highly lipophilic, and up to 80% is transported in the blood mostly in the core of LDL particles (148). Its hyperlipidemic effect is due to several known mechanisms. It binds to the LDL receptor and raises LDL levels (149). In addition, CsA increases hepatic lipase activity and decreases LPL activity, resulting in impaired clearance of VLDL and LDL (142). On the other hand, like the corticosteroids, part of the hyperlipidemic effect seems to be secondary to the insulin resistance. Tacrolimus has an effect on lipid metabolism similar to that of CsA, but it seems to be less prominent (150,151). Sirolimus is associated mainly with high TG and, to a lesser extent, elevated TC. The mechanisms of sirolimus-induced hyperlipidemia have not been completely elucidated, and the effect is dose dependent and reversible (152).

Lipid-lowering agents, such as fluvastatin, are effective in adult transplant recipients (153–155). A prospective 12-week intensive dietary intervention study (American Heart Association step 2 diet) was effective in reducing hyperlipidemia in postrenal transplant children (156). Among pediatric cardiac transplant recipients, pravastatin was effective and well tolerated (157), whereas atorvastatin also effectively lowered lipids but was associated with rhabdomyolysis and asymptomatic creatine kinase elevation (158).

Posttransplant Glucose Intolerance

Hyperglycemia and posttransplant diabetes mellitus (PTDM) are well-known complications of organ transplantation, which worsen graft outcome and increase patient mortality. PTDM in adult liver transplant recipients results in an increase in the number of rejection episodes in the first

posttransplant year and an increase in mortality in the second year (159). PTDM in adult post-renal transplant patients worsened mortality (160).

The incidence of PTDM in adult kidney transplant recipients ranges from 4 to 41% (161,162). The very wide range may be due to the lack of a standard definition of PTDM, as some patients have transient hyperglycemia after transplant, and other patients have persistent DM. In pediatric populations, the prevalence of PTDM parallels that of type 2 DM (163,164). A comprehensive study of pediatric renal transplant recipients reported a 7% prevalence of PTDM (serum glucose >200 mg/dL) (165).

In adults with PTDM, risk factors include the type of immunosuppressive regimen, ethnicity, age, BMI, family history of DM, episodes of rejection, and HLA type (166,167). PTDM in pediatric renal recipients occurred within 1.2 years posttransplant (range, 1 day to 6.2 years), especially with a family history of type 2 DM, tacrolimus use versus CsA (odds ratio, 9.1), and hyperglycemia in the immediate posttransplant period (165).

Corticosteroids increase insulin resistance in peripheral tissues by decreasing insulin receptor number and function, increasing hepatic glucose output, decreasing glucose uptake in muscle, and increasing lipolysis and free fatty acid release from adipose tissue (161). In addition, corticosteroids may inhibit insulin secretion by the pancreatic beta cells (168).

Tacrolimus has been clearly associated with PTDM in children (169). It may affect beta-cell function and peripheral insulin resistance and diminishes insulin secretion (170,171). Tacrolimus reversibly suppressed insulin gene transcription in normal rats (172). Furthermore, tacrolimus damages beta cells directly and possibly irreversibly (173). Beta-cell antibodies were transiently found in the setting of PTDM during tacrolimus use (174). Thus, in patients with a strong family history of type 2 DM or hyperglycemia in the immediate posttransplantation period, tacrolimus should be used cautiously (165). CsA also inhibits insulin secretion from beta cells and decreases glucose disposal by similar mechanisms.

INFLUENCES OF NUTRITION DISORDERS ON RENAL FUNCTION

Influences of Obesity on Renal Function

Obesity was found to be an important risk factor for a certain number of diseases, including cardiovascular diseases, hypertension, lipid and lipoprotein abnormalities, type 2 DM, nonalcoholic steato-hepatitis, pseudotumor cerebri, obstructive sleep apnea, and orthopedic problems such as Blount disease (175–177).

It is a problem of major concern that the prevalence and severity of obesity is increasing in the pediatric popu-

lation. As a consequence, the prevalence of the sequelae of obesity is expected to be increasing as well. The last large investigation done by the National Health and Nutrition Examination Survey (NHANES III) reported a prevalence of childhood obesity of 25% in the United States, defined by a BMI of more than 95% for age and gender (178). This prevalence represented a 30% increase comparative to a previous similar investigation, NHANES II. The same trend has been observed in Western Europe in the past 30 years.

The association of obesity with proteinuria has been well described in adults (179–181). Despite the prevalence of childhood obesity, an association between obesity and renal abnormalities such as proteinuria has not been clearly reported until very recently (182). Obesity-associated proteinuria in adults is associated with focal segmental glomerulosclerosis (FSGS). However, the FSGS diagnosed in these patients shares clinical features distinctive from those usually seen with primary FSGS: Albumin levels tend to be higher, often above 3 g/dL; TC levels are only mildly elevated, often <300 mg/dL; proteinuria is moderate; blood pressure tends to be normal or only mildly elevated; and edema may be minimal to absent (183). Patients who lost weight successfully showed marked decreases in proteinuria. Histologic features of obesity-associated proteinuria in adults include focal segmental sclerotic changes often in a hilar location, mesangial proliferation and hypertrophy, foci of hyalinosis, and glomerulomegaly (184,185). In obesity-associated FSGS, on electron microscopy, the foot process fusion is often minimal and focal rather than diffuse, as opposed to idiopathic FSGS.

FSGS is the histologic expression of a variety of conditions that differ in cause, pathogenesis, clinical course, and response to therapy (186–189). Although the pathophysiology of obesity-related FSGS is unclear, potential etiologic factors seem to be hyperfiltration, hyperlipidemia, renal venous hypertension, and glomerular hypertrophy.

Based on the above clinical and pathologic characteristics, the patients with obesity-related FSGS seem to share features with a very diverse group of patients whose initiating factor is a reduction in renal mass. The reduction in renal mass can be due to reflux nephropathy (190), nephrectomy for Wilms' tumor (191), unilateral renal agenesis (192), or unilateral nephrectomy (193). These reduced numbers of glomeruli may be subjected to hemodynamic stress by taking on the filtration of a constant volume of plasma. This sets up a cascade of proteinuria, mesangial cell gene expression, and focal scarring. Similarly, in case of obesity, there is increased plasma volume and cardiac output that translates into a relative deficit in the number of glomeruli (194). In addition, obesity is associated with hypertension. Significant weight gain is accompanied by excess renal sodium resorption, leading to increased systemic arterial pressure and glomerular hyperfiltration (195). These changes result in glomerular capillary wall

stress, leading to glomerular cell proliferation, matrix accumulation, and glomerular sclerosis.

Hyperlipidemia is another potential contributing factor, because the Zucker obese rat, a model in which FSGS develops, is hyperlipidemic, and reduction in serum lipids appears to decrease or prevent development of FSGS (196). A study of autopsies in obese adults noted that those with FSGS had higher lipid levels and showed lipid deposits in renal tubular epithelial cells (185).

Renal venous hypertension has been incriminated as another contributing factor to obesity-related FSGS. One study demonstrated that adult obese patients had increased plasma volume and increased right atrial pressure, which decreased with weight reduction along with parallel decreases in urinary protein losses (179). Other conditions also associated with increased right atrial pressure and presumed renal venous hypertension, such as tricuspid atresia, constrictive pericarditis, and pulmonary hypertension, have been associated with proteinuria and nephrotic syndrome (197,198).

The glomerular hypertrophy theory postulated a sequence of changes that may occur in the genesis of obesity-related FSGS from glomerular hypertrophy, stimulated in part by angiotensin II and other growth factors, leading to production of excess amounts of extracellular matrix in mesangial areas and the development of obesity-related FSGS (199).

Very recent studies showed the connection between adipose tissue and kidney at molecular level mediated by leptin, a small peptide mainly produced in adipose tissue, therefore directly reflecting the amount of body fat. In glomerular endothelial cells, leptin stimulates cellular proliferation, transforming growth factor β_1 (TGF- β_1) synthesis, and type IV collagen production. Conversely, in mesangial cells, leptin upregulates synthesis of the TGF β type II receptor but not TGF- β_1 and stimulates glucose transport and type I collagen production through signal transduction pathways involving phosphatidylinositol-3-kinase. These data suggest that leptin triggers a paracrine interaction in which glomerular endothelial cells secrete TGF- β , to which sensitized mesangial cells may respond. Both cell types increase their expression of extracellular matrix in response to leptin. Infusion of leptin into normal rats produces the development of FSGS and proteinuria (200).

An association between obesity and renal abnormalities, such as proteinuria, has not been reported until very recently. In one study, seven obese black adolescent patients had FSGS and significant proteinuria but no edema; serum albumin levels were slightly low and TC was normal or mildly elevated. The histologic features included glomerular hypertrophy, FSGS, increased mesangial matrix and cellularity, relative preservation of foot process morphology, and absence of evidence of inflammatory or immune-mediated processes (182). These clinical and histologic characteristics resemble the descriptions of obesity-related FSGS found in the adult studies. Obesity-related FSGS may lead to ESRD (182). Children with FSGS in hilar areas, as commonly

seen in obesity-associated FSGS, have a much higher likelihood of developing CKD than patients with peripherally located focal segmental lesions (201).

There is clearly a predisposition of the black children to develop obesity-related FSGS (182). Idiopathic primary FSGS is also much more common in adult black individuals (202). Epidemiologic data also suggest that there is a racial genetic component to susceptibility to renal injury as a complication of both type 2 DM and chronic hypertension in blacks compared with whites (203,204).

The treatment of obesity-related FSGS should include weight reduction. Obese Zucker rats showed a reduction in FSGS lesions with reduced dietary intake and subsequent reduced weight (196). Several studies reported that extensive reduction of body weight without use of any therapy markedly reduced or eliminated proteinuria in obese adult patients (205). In the pediatric study, one patient showed a dramatic reduction in proteinuria in response to weight reduction (182). The other treatment modality is the use of angiotensin-converting enzyme inhibitors. One study done in obese adults reported that patients with proteinuria who were given captopril had reductions in proteinuria similar to those seen with weight reduction alone. It is not clear whether the action of angiotensin-converting enzyme inhibitors in such cases is related to hemodynamic changes in efferent arteriolar resistance or to nonhemodynamic factors (205). In the pediatric study, three out of seven patients with obesity-related FSGS who were given angiotensin-converting enzyme inhibitors had significant reduction of proteinuria (182).

Influences of Malnutrition on Renal Function

Extensive data already showed in the sixties and seventies that renal development is influenced by many factors, including nutrition. Maternal diet may influence nephrogenesis, with the result that individuals whose mothers have low protein intake during gestation may have a relatively lower total number of nephrons at birth (206,207). After birth, the nutritional intake of an infant is a major stimulus to both renal growth and functional maturation. In early infancy, protein and amino acid intake can influence renal growth. GFR increases more rapidly in premature infants receiving a relatively high-protein diet than in those who do not (208). However, a high-protein diet has been reported to be associated with metabolic acidosis, failure to thrive, and even evidence of renal injury (209).

Later in life, renal function alterations are similar with diverse forms of malnutrition such as primary protein-calorie malnutrition, iatrogenic malnutrition, or anorexia nervosa. These changes include decrease in GFR, decrease in renal plasma flow, poor urinary concentrating ability, decreased ability to excrete sodium, and impaired acid excretion. In cases of malnutrition, GFR can be as low as 50%. A low-

calorie diet and also a low-protein diet can independently produce a fall in GFR or renal plasma flow (210). These changes are usually reversible, not associated by renal structural damage, and are not explained by hypoproteinemia or edema, which can occur in these states (211).

FLUID AND ELECTROLYTE THERAPY IN CHILDREN

MICHAEL J. G. SOMERS

The importance of fluid and electrolyte therapy in clinical pediatrics cannot be underestimated. In ambulatory practice, given the frequency with which children develop dehydrating illnesses, the clinician is often called on to formulate approaches to rehydration. In hospitalized children, myriad clinical and practice parameters impact fluid and electrolyte therapy and frequently go beyond merely providing adequate water and electrolytes to replace losses.

Over the last several years, the role of fluid and electrolyte therapy in clinical medicine has been subject to reinterpretation as a better understanding of the physiologic principles of fluid and electrolyte homeostasis has evolved and as common clinical practices have been critically reevaluated. Historically, it was two centuries ago that the first attempts to replace enteral losses from cholera led to an initial understanding of the profound morbidity and mortality that can accompany significant losses of salt and water (1). The recognition that affected patients improved simply by providing repeated intravenous infusions of a saline solution served as an impetus to define and develop parameters for fluid and electrolyte therapy. This understanding was later generalized to other illnesses in which there was an element of dehydration and ultimately helped to define the threshold for the minimum daily provision of fluid and electrolytes—so-called maintenance requirements—as well as a threshold of maximal tolerance.

In the first decades of the twentieth century, the work of Gamble and colleagues was especially significant to the development of fluid therapy in pediatrics (2). The concepts of extracellular and intracellular fluid compartments in the body helped to underscore the important role that renal mechanisms play in maintaining normal fluid and electrolyte balance. In turn, this enhanced knowledge of body fluid physiology spawned a tradition of clinical therapy grounded on rather elaborate guidelines for intravenous fluid and electrolyte replacement in the ill child based on continuing (maintenance) needs and past and current losses (deficits).

This so-called deficit therapy approach to fluid therapy in children, cogently outlined by Holliday and Segar in

1957 (3), has subsequently been taught as the gold standard to minimize complications and improve clinical outcomes. Recent reassessment of this traditional approach, again spawned in large measure by Holliday's work, has come to appreciate that such elaborate maneuvers are often unnecessary and may be counter-therapeutic (4). Rather, the use of standard oral rehydration and maintenance hydration fluids is a simple, safe, and efficacious alternative for most children in need of fluid and electrolyte therapy to restore intravascular volume in the setting of a dehydrating gastroenteritis (5).

Nonetheless, there continues to be a place for the more precise traditional assessment and prescription of fluid and electrolyte therapy, especially in children with nondiarrheal illness (6). In more complex disorders of fluid and electrolyte pathophysiology (e.g., frequently seen postoperatively or in critically ill children with sepsis, burns, or trauma), an understanding of the distribution of body fluids, usual fluid and electrolyte requirements, and the effect of perturbations in normal homeostatic balance remains vital to the correct prescription of initial therapy and the proper assessment of clinical response.

Such an understanding becomes more crucial when approaching the care of a child with renal disease. Frequently, the presence of a preexisting renal condition or the development of an acute renal dysfunction can complicate the fluid and electrolyte management of the child. Standard approaches to such therapy assume that normal renal homeostatic mechanisms come into play with the provision of adequate fluid and electrolytes. These approaches are ill advised for the child with renal disease in whom volume and electrolyte regulation may be deranged. Similarly, these approaches may have limited value with the critically ill child in whom normal fluid and electrolyte homeostasis may also be altered. In these circumstances, the clinician needs to approach fluid and electrolyte therapy systematically and with attention to individual clinical circumstance. Otherwise, in the absence of such a customized fluid and electrolyte prescription, the possibility arises that a thera-

peutic intervention may be deleterious, given preexisting reduced tolerance to alterations in body fluid volume, composition, or distribution.

DISTRIBUTION OF BODY FLUIDS

Total Body Water: Extracellular and Intracellular Fluid Compartments

Water makes up a large proportion of body weight, varying with age, body size, and body composition. In early gestation, 90% of the weight of the developing fetus may be water. In premature infants born early in the third trimester, total body water (TBW) approximates 80% of body weight. This falls to 70 to 75% in term infants, 65 to 70% in toddlers and young children, and eventually to 60% in older children and adolescents. Lean individuals have more body water than obese individuals, and pubertal adolescent boys with increasing muscle mass tend to have more TBW than adolescent girls. Although 60% is often the benchmark for estimating TBW in older children and adults, the actual percentage may be lower, especially in less well-conditioned individuals or the elderly (7).

Body water is distributed into intracellular and extracellular compartments. The intracellular compartment consists of water found within the cells of the body and comprises approximately two-thirds of TBW or 40% of body weight. The extracellular compartment comprises one-third of TBW or 20% of body weight and is divided into the interstitial fluid that bathes all cells and the plasma water that is carried intravascularly. The increased TBW seen in young children is due to an increased extracellular compartment, the result of a relatively increased surface area as compared to body weight (8).

The boundary between the intracellular and extracellular compartments is the cell membrane. Input or output from the body generally proceeds via some interface with the extracellular compartment. For instance, provision of intravenous fluid and electrolyte therapy is into the intravascular space, and subsequent delivery intracellularly depends on a host of factors.

Because most cell membranes are readily permeable to water, the distribution of water between the intracellular and extracellular spaces largely reflects osmotic forces. Each body space has a solute that is primarily sequestered within that compartment and that maintains its osmotic gradient (9,10). For instance, activity of the sodium-potassium pump found in cell membranes leads to an increased concentration of potassium intracellularly and an increased concentration of sodium in the interstitium. Thus, sodium serves as the effective osmole interstitially and potassium intracellularly. Similarly, plasma proteins, most notably albumin, exert an osmotic force to maintain water intravascularly. Osmotic force is counterbalanced by hydrostatic

pressure pushing water across the capillary from the lumen to the interstitium. Perturbations in the distribution of effective osmoles can result in redistribution of water between the intracellular and extracellular spaces.

There is an ongoing dynamic equilibrium between the intracellular and extracellular spaces. Diffusional gradients, osmotic forces, and the activity of cellular pumps or transporters all combine to establish the differences in the composition of the body compartments. The intracellular space cannot be directly accessed. As a result, access to the intracellular space is achieved via its communication with the extracellular space. Thus, any intake by ingestion or infusion into the extracellular space results in a new equilibrium being established with the intracellular space as solute and fluid come to be exchanged. Ultimately, the final equilibrium is a result of complex biochemical, electrical, and physical interactions.

The communication between the cellular spaces can be bidirectional. In other words, there can be exchange from the intracellular space to the extracellular space allowing, for instance, for transfer or release of cell metabolites. In addition, because the extracellular space can communicate with the external milieu, any output from the extracellular space to the external milieu results in effective excretion from the body. There is, however, no direct communication between the intracellular space and the external milieu, and any output from the cells themselves is mediated via the cell's direct ability to interface with the interstitial fluid or the plasma water.

For the clinician, it is always important to remember that any impairment in the patient's normal homeostatic mechanisms regulating fluid and electrolyte balance has a striking impact on the patient's TBW and its extracellular and intracellular constituents. Clinically, a common example of this disruption of normal balance is the hypertension frequently exhibited by the renal patient with progressive renal dysfunction. As renal function declines, the ability of the kidney to excrete free water (CH_2O) also declines. Frequently, this is in the setting of decreased effective nephron number with concomitant impairment of overall tubular solute excretion, most notably salt. Often superimposed on this baseline tendency for dysregulation of solute and water balance are clinical factors (e.g., circulatory failure and decreased effective arterial volume) leading to further renal salt and water retention. This salt and water overload can lead to chronic expansion of the TBW and resulting systemic hypertension with expansion of the extracellular volume compartment. Appropriate therapy in this instance includes the judicious use of diuretics to reduce the total body burden of salt and water and to restore the TBW to a more physiologic state. In this instance, a clinician's failure to appreciate the preexisting expansion of the TBW because of chronic salt and water overload could prove deleterious to the patient if management did not include some measure to reduce the salt and water overload. This example also

underscores the concept that fluid and electrolyte therapy may involve the removal of solute and water as well as the more usual notion that it is solely concerned with the correction of deficits of electrolytes and volume.

Effective Circulating Volume

The concept of effective circulating volume is somewhat more abstract than the division of body water into intracellular and extracellular fluid compartments. Through the circulation of the vascular volume, oxygen and nutrients are delivered to the intracellular space, and cellular metabolites are cleared from the intracellular space. The *effective circulating volume* refers to that portion of the extracellular vascular space that is actually perfusing the tissues and accomplishing such an exchange.

Any compromise in this exchange can prove deleterious to usual cell homeostasis; as a result, the body constantly senses and regulates effective perfusion of fluid through the intravascular space. Homeostatic feedback mechanisms include baroreceptors that respond to the stretch of specialized areas of the carotid arteries and the atrium. Hypoperfusion of these areas results in decreased stimulation of these stretch receptors, triggering the secretion of vasopressin and eventually leading to increased water reabsorption in the most distal nephron and expansion of the vascular volume. Similarly, in response to glomerular hypoperfusion, there is not only decreased afferent arteriolar stretch but also decreased glomerular filtration and delivery of sodium to the macula densa. Both of these stimuli can lead to the secretion of renin from the juxtaglomerular cells of the afferent arteriole. Renin release initiates a cascade of events resulting ultimately in increased aldosterone-mediated sodium reabsorption from the kidney as well as increased angiotensin-mediated vasoconstriction and sodium and water uptake.

Thus, the effective circulating volume is a product of multiple factors, not the least of which includes the size of the vascular space and the influence of various regulatory hormones. As a component of the extracellular body water, the size of the vascular space often parallels the size of the extracellular space. However, the size of the vascular space and the adequacy of the effective circulating volume do not necessarily vary coordinately. It is possible for the extracellular space to be replete or expanded and the actual effective circulating volume to be decreased. For instance, children with significant liver disease are often edematous, a sign of sodium retention and expansion of the interstitial component of the extracellular space. The intravascular component of their extracellular space may also be expanded due to factors resulting in avid salt and water reabsorption by the kidney. However, because of portal hypertension, splanchnic vessel congestion, and multiple arteriovenous spider angiomas generally seen with this condition, much of the expanded intravascular volume is ineffective—it does not serve to perfuse

the tissues and accomplish effective cellular exchange. Thus, these children act as if they are volume depleted: They excrete little sodium in their urine, and they vigorously continue to expand their already overexpanded extracellular space by reabsorbing even more salt and water in response to the effects of aldosterone and antidiuretic hormone (ADH). Similarly, this paradoxical state of sodium avidity and ADH-mediated water reabsorption can be seen frequently in children with nephrotic syndrome or with cardiac failure despite their preexisting expansion of the extracellular space.

In managing all aspects of a patient's fluid and electrolyte therapy, the clinician must accurately assess both the patient's current extracellular volume status and effective circulating volume and reconcile these with potential causes of volume loss. At all times, it is most important to maintain an effective circulating volume and to make therapeutic decisions based on each patient's unique clinical circumstances at that time. This may require rather disparate therapeutic interventions. For instance, expansion of the extracellular volume with vigorous rehydration therapy may be called for in a child with poor perfusion secondary to gastroenteritis-induced dehydration, whereas another child with equally poor perfusion due to cardiodynamic compromise may be intravascularly replete and require the initiation of pressor therapy, and another child with edema from relapsed nephrotic syndrome may actually require fluid restriction. These examples underscore that loss of effective circulating volume generally arises as a result of one or more broad perturbations in the extracellular fluid compartment that impacts effective perfusion (Table 13.1).

Clinical signs and symptoms of effective circulating volume loss may be subtle. At times, there may be preservation of effective circulating volume in the face of an overall depleted extracellular fluid compartment. Failure to initiate appropriate fluid and electrolyte therapy in such a circumstance may result in eventual compromise of the effective circulating volume. Important initial clinical signs to assess in any patient being evaluated for fluid therapy include pulse rate and capillary refill. Tachycardia and sluggish refill generally precede more obvious signs of ineffective circula-

TABLE 13.1. ALTERATIONS IN EFFECTIVE CIRCULATING VOLUME

Cause	Mechanism
Contracted extracellular fluid space	Water or sodium chloride deficit
Massive vasodilatation	Loss of vascular tone sustaining perfusion pressure
Loss of intravascular osmotic pressure	Osmotic fluid losses into interstitium
Overfill of the intravascular space	Hydrostatic fluid losses into interstitium
Hemorrhage	Direct loss of blood and plasma water

tion (e.g., hypotension and oliguria). Clinical symptoms may also be nonspecific and include fatigue and lethargy that are often attributed to an underlying illness rather than to volume depletion. Proper restoration of effective circulating volume or extracellular fluid compartment depletion requires an understanding of baseline fluid and electrolyte needs as well as consideration of any extenuating clinical circumstances unique to the patient in question.

FLUID AND ELECTROLYTE REQUIREMENTS

Maintenance Water Therapy

The fluid and electrolytes required to replace daily losses and to maintain an overall net balance of zero fluid or electrolytes gained or lost are often termed *maintenance needs*. Such needs are a function of individual homeostatic and environmental factors and, thus, vary from day to day and from individual to individual. In the average child with adequate access to sources of fluid and nutrition, these maintenance needs are generally readily met (3,11). In the ill or hospitalized child who requires therapeutic intervention, these needs must be considered in the choice of fluid therapy provided.

To assist in estimating these needs, fluid and electrolyte requirements are generally calculated on the basis of weight or surface area, but individual clinical circumstance must be considered when making such calculations (12). For instance, the 20-kg child who is well requires a far different maintenance quantity of fluid and electrolytes than the 20-kg child who is tachypneic and febrile or the 20-kg child who is anuric and on

a ventilator in the intensive care unit. Careful repeated assessment of the patient's volume status and close attention to a balance of overall daily input and output proves more useful at arriving at a correct estimate of daily fluid and electrolyte needs than reliance on mathematic formulas alone. With these caveats in mind, it is nonetheless a common clinical practice to make certain empirical assumptions regarding daily needs for water and the major electrolytes.

Historically, daily maintenance water needs have been estimated based on energy expenditure (Fig. 13.1) (3,11). Thus, for every kilocalorie (kcal) of energy used per day, 1 mL of water must be provided. Based on the computed energy expenditure of the average hospitalized patient, for the first 10 kg of body weight, 100 mL of water per kg is provided daily. For the next 10 kg of body weight, 50 mL of water per kg is provided daily, and for every kilogram of body weight in excess of 20 kg, 20 mL of water per kg is provided daily. In addition, in the process of oxidation of carbohydrate and fat, approximately 15 mL of water is generated for every 100 kcal of energy produced. This water of oxidation contributes significantly to overall water balance.

Maintenance water losses occur from insensible sources (almost exclusively evaporative and respiratory losses) and from urine output. In the child with average metabolic demands, for every 100 kcal of energy expended, 100 mL of water must be taken in. Of this 100 mL of water, 40 mL is lost insensibly, and 75 mL is lost as urine output. There is, however, 15 mL of water generated from the water of oxidation rendering net water balance equilibrated.

Clinical factors can have a striking impact on water losses (Table 13.2). Fever increases insensible losses by

FIGURE 13.1. A comparison of the relation of estimated energy expenditure to weights over the range of 3 to 70 kg. (Courtesy of Malcolm Holliday.)

TABLE 13.2. FACTORS AFFECTING INSENSIBLE WATER LOSSES

Increased losses	Change (%)	Decreased losses	Change (%)
Prematurity	100–300	Enclosed incubator	25–50
Radiant warmer	50–100	Humidified air	15–30
Phototherapy	25–50	Sedation	5–25
Hyperventilation	20–30	Decreased activity	5–25
Increased activity	5–25	Hypothermia	5–15
Hyperthermia	12°C		

nearly 10% per degree Celsius. Premature infants with relatively increased surface areas for size can have insensible losses two- to threefold higher than baseline, especially if they are on open warmers or under phototherapy. On the other hand, children on ventilators being provided humidified oxygen may have only half of the insensible losses of a nonventilated child. Similarly, urinary output can vary tremendously. A child with a concentrating defect or ADH unresponsiveness may have urinary water losses of several liters per day, whereas an anuric child has no urinary losses. In any child with normal renal function, even in the setting of maximal ADH stimulation, there is a minimal volume of urinary water losses that is obligatory to excrete the osmotic load ingested by the diet and generated by basal metabolism. Thus, even the child concentrating urine at 1200 to 1400 mOsm/L loses approximately 25 mL of water as urine for every 100 kcal of energy expended (3).

Water Homeostasis and Serum Osmolality

Water homeostasis is crucial to maintaining a stable serum osmolality. The major factors contributing to serum osmolality are the serum concentrations of sodium, glucose, and blood urea nitrogen (BUN) (13). Serum osmolality is estimated by the following equation:

$$(2 \times \text{serum Na}) + (\text{serum glucose}/18) + (\text{BUN}/2.8)$$

where the serum sodium is measured in mEq/L and the glucose and BUN in mg/dL. Normally, the contributions of glucose and BUN to the effective osmolality are small, and the serum osmolality can be estimated by doubling the serum sodium concentration (14,15). Thus, most children have a serum osmolality between 270 and 290 mOsm/L, corresponding to serum sodium values of 135 to 145 mEq/L. Chemoreceptors in the hypothalamus constantly sense serum osmolality and respond to even small variations toward either limit of normal by adjusting ADH release from the posterior pituitary. Changes in osmolality in the setting of hypovolemia augment ADH release further. ADH effect on water permeability of the collecting tubule is a principal influence on the regulation of water balance.

Alterations in water intake or excretion result in the development of hypo- or hyperosmolality as the usual ratio of extracellular solute to water is perturbed. Because sodium is the largest component of extracellular osmolality,

its concentration can be influenced profoundly by changes in water metabolism. An understanding of this link between water regulation and serum sodium values is crucial when prescribing fluid and electrolyte therapy. Most important, the clinician must recognize that hypo- or hypernatremia is usually a manifestation of impaired water regulation and that therapy must address regulation of water balance rather than alterations in body sodium stores.

Factors Contributing to Altered Water Homeostasis in Ill Children

In children with acute illness, vasoactive hormone levels appear to be increased, predisposing them to altered water homeostasis and changes in measured serum sodium levels. In one study of 103 acutely ill children, plasma vasopressin and renin levels were significantly elevated when compared to 31 control children awaiting elective surgery (16). These elevations were independent of the child's underlying illness and resulted in the ill children as a group having a lower measured serum osmolality than the control group.

In ill children, there are multiple causes of both physiologic and aberrant vasopressin effect (Table 13.3). As a result, in such at-risk children who receive hypotonic intravenous fluids for prolonged periods of time or in volumes exceeding those generally recommended, there is the risk of acute hyponatremia. After volume resuscitation with isotonic fluids, most hospitalized children are provided hypo-

TABLE 13.3. COMMON CAUSES OF VASOPRESSIN EFFECT IN HOSPITALIZED CHILDREN

Category	Specific etiology
Physiologic	Hyperosmolar state, hypovolemia
Pulmonary	Pneumonitis, pneumothorax, asthma, bronchiolitis, cystic fibrosis
Drug effect	Narcotics, barbiturates, carbamazepine, vincristine, cyclophosphamide
Metabolic	Hypothyroidism, hypoadrenalism, porphyria
Central nervous system	Infection (meningitis or encephalitis), tumor, trauma, hypoxia, shunt malfunction, nausea, pain, anxiety

tonic fluids for their maintenance therapy. Given the tendency for ill children to have vasopressin effect independent of the usual osmotic and volume-related stimuli, some investigators have suggested that isotonic fluids may be safer alternatives and should be continued as the source of maintenance fluid even after acute volume repletion (17).

Maintenance Electrolyte Therapy

Estimates for the maintenance requirements of the major electrolytes sodium, potassium, and chloride can also be made based on metabolic demands or, by extension, on daily water needs (3). For sodium and chloride, approximately 2 to 3 mEq/100 mL of water per day is required. For potassium, 1 to 2 mEq/100 mL of water per day is needed. Again, these estimates may require adjustment based on clinical circumstance, but the daily intake of most healthy individuals contains more than adequate electrolytes for maintenance needs. Although there can be significant electrolyte losses at times through the skin or the gastrointestinal tract, most electrolyte losses are urinary (12,18). Thus, in the setting of anuric renal failure, in the absence of concomitant electrolyte losses from other sources, a much lower level of maintenance electrolyte supplementation is needed, and often patients maintain adequate electrolyte balance with water supplementation alone to provide insensible fluid losses.

As with provision of water, it is vital in children who require electrolyte therapy to tailor their electrolyte prescription to their individual needs. For the provision of sodium and chloride, this requires careful assessment of the extracellular fluid space, especially the effective circulating volume. Providing too little sodium chloride results in volume contraction and circulatory compromise; providing too much causes volume overload and sequelae (e.g., hypertension and edema). Similarly, inappropriate potassium supplementation may have significant clinical ramifications. In children with diminished renal function or who are at risk of hyperkalemia for other reasons, it is usually appropriate to forego any maintenance potassium supplementation. When supplementation is given acutely, it is important to monitor serum potassium values closely. When chronic potassium supplementation is needed, there should continue to be periodic assessments. A course of supplemental potassium administered orally is safer than a bolus intravenous injection; intravenous potassium supplements rarely need to exceed 0.5 mEq/kg/hr (13).

PERTURBATIONS IN FLUID AND ELECTROLYTE HOMEOSTASIS

Alterations in Water Balance, Serum Sodium, and Cell Volume

As discussed earlier, the regulation of osmolality is achieved by alterations in water intake and excretion. Serum sodium

levels often vary with these alterations in water balance. Generally, serum sodium is kept regulated at levels between 135 and 145 mEq/L. Serum sodium below 130 mEq/L or above 150 mEq/L is out of the range of normal homeostasis and is often indicative of some problem with water balance.

Because sodium is the major extracellular osmole, alterations in serum sodium can result in water flux between the intracellular and extracellular spaces. Because significant water flux into or out of cells could prove deleterious to cell function, cell volume is closely regulated to minimize such shifts (19). For instance, with hyponatremia, there is decreased effective osmolality in the extracellular space. As a result, water can shift from the plasma into the intracellular space, and cell swelling occurs acutely. To counterbalance such swelling, the cell acutely attempts to regulate its volume by transporting electrolytes, especially potassium, from the intracellular space into the extracellular space, thereby decreasing the osmotic gradient for water transfer. Over several days, when faced with chronic hyponatremia or chronic hypo-osmolality, the cells also achieve effective volume regulation by losing organic osmolytes (e.g., as taurine and inositol), thereby further diminishing the osmotic gradient for water transfer into the cell (20).

With hypernatremia, the osmotic gradient favors water flux out of the cells into the extracellular space. Without protective mechanisms, cell volume shrinks. Again, there are both acute and chronic mechanisms that attempt to minimize changes in cell volume. Acutely, there is transport of electrolytes intracellularly. Over time, there is stimulation of the production of organic idiogenic osmoles (20,21). Together, these act to ameliorate the loss of intracellular volume that would otherwise occur.

Thus, alterations in serum sodium values that arise slowly or are more chronic in nature tend to be better tolerated clinically than acute alterations. Chronic or slow changes allow for maximal counterregulation and fewer clinical sequelae. On the other hand, profound sudden alterations—serum sodium values falling to approximately 120 mEq or below or 160 mEq or above—are often accompanied by dramatic neurologic complications directly related to the acute changes in cell volume in the central nervous system (CNS).

These regulatory mechanisms must also be kept in mind when formulating specific therapeutic intervention. Acute perturbations can be corrected more rapidly than chronic conditions because the full gamut of responses to the imbalance has yet to come into play.

Hyponatremia: Initial Approach

Hyponatremia is usually defined as a serum sodium value less than 130 mEq/L. As noted earlier, low serum sodium values are less likely to arise secondary to depleted salt stores and more likely to be the result of persistent ADH effect and a relative surfeit of water for solute in the extracellular space.

TABLE 13.4. ETIOLOGY OF HYPONATREMIA

Circulating volume	Urinary Na (mEq/L)	
	<20	>20
Decreased	Burns Cystic fibrosis Diuretics—late Gastroenteritis	Adrenal insufficiency Diuretics—early Salt wasting
Normal or increased	Cardiac failure Hepatic cirrhosis Nephrotic syndrome	Renal failure Syndrome of inappropriate secretion of antidiuretic hormone Water intoxication

Infrequently, pseudohyponatremia may be seen. This is a result not of depletion of sodium stores but of an alteration in the usual makeup of the extracellular space such that the relative concentration of sodium is now depressed. Common etiologies of pseudohyponatremia include hyperglycemia, hyperlipidemia, and hyperproteinemia. In these clinical conditions, it is not uncommon for serum sodium values to be only modestly depressed. Because there is no underlying true anomaly in sodium or water stores in these conditions, the serum sodium need not be addressed with any therapeutic maneuvers. With the introduction of ion-sensitive electrodes for the measurement of plasma sodium concentration, pseudohyponatremia related to the presence of confounding factors in the laboratory assay is much less commonly encountered.

In attempting to clarify the etiology of the hyponatremia, it is often useful initially to assess the patient's extracellular volume status and determine if it is decreased, normal, or increased. Then, by quantitating urine sodium excretion and determining the renal response to the hyponatremia, it becomes easier to determine if the patient should receive sodium and water or if a sodium and water restriction is the appropriate therapy (Table 13.4).

Hyponatremia: Decreased Volume Status and Urine Sodium Less Than 20 mEq/L

Decreased circulating volume is usually seen with states of significant sodium loss. The most common site of this loss is the gastrointestinal tract as a result of vomiting, diarrhea, or tube drainage. The renal response to the decreased effective circulating volume includes increased activity of the renin-angiotensin axis and relatively high levels of aldosterone and angiotensin. As a result, urine sodium values are generally low (less than 20 mEq/L), and water reabsorption in the distal nephron is augmented by high levels of ADH. In the face of continuing sodium losses exceeding intake, this state of vigorous ADH effect leads to a relative excess of water and concomitant hyponatremia.

Such findings can also be seen in cystic fibrosis in which there are increased skin losses of sodium and chloride, with bleeding, with burns, with certain losses of fluid from the

intravascular space of the extracellular fluid into the interstitial space ("third-spacing") as can occur postoperatively in conditions of vascular leak, or with peritonitis. Such hyponatremia can also be seen after a period of diuretic therapy. In response to chronic diuretic-mediated volume contraction, the mechanisms outlined above come into play. Thiazide diuretics, especially in combination with a loop diuretic (e.g., furosemide), are particularly prone to inducing such hyponatremia.

The appropriate therapeutic response to these conditions is the provision of sodium and water either by use of intravenous saline solutions or oral electrolyte solutions. This results in restoration of sodium balance and volume expansion.

Hyponatremia: Decreased Volume Status and Urine Sodium Greater Than 20 mEq/L

Decreased circulating volume and urinary sodium excretion greater than 20 mEq/L are indicative of renal salt wasting, either from an intrinsic tubulopathy or from early diuretic effect. Less commonly, adrenal insufficiency can cause sodium wasting from the principal cell of the distal nephron. Such cortisol deficiency can arise from an intrinsic endocrine defect (e.g., congenital adrenal hyperplasia related to 21-hydroxylase deficiency); from some secondary impairment of adrenal function caused by infection, bleeding, or malignancy; or from pharmacologic adrenal suppression without adequate replacement therapy. In the setting of adrenal insufficiency, replacement of appropriate adrenal hormones and provision of adequate sodium and water prove therapeutic. With renal salt wasting, supplementation with sodium and any other electrolytes exhibiting impaired renal reabsorption is useful.

Hyponatremia: Normal or Expanded Volume and Urine Sodium Less Than 20 mEq/L

Normal or increased circulating volume and urine sodium excretion less than 20 mEq/L can be seen in conditions in which there is an excess of both TBW and total body sodium. The three major disorders that cause this type of

hyponatremia are the nephrotic syndrome, hepatic failure related to cirrhosis, and cardiac failure. In all these conditions, there is a state of sodium and water avidity related to high levels of ADH and aldosterone. Most commonly, this is in the setting of preexisting total body sodium overload as evidenced by edema. In all of these conditions, despite the increased extracellular or circulating volume, the effective circulating volume is often depressed. As a result of this ineffective perfusion of the tissues, sodium and water avidity is only heightened by stimulation of the renin-aldosterone-angiotensin axis, further exacerbating the total body excess of salt and water. Appropriate therapy includes striking a balance between interventions promoting the maintenance of effective circulating volume and restricting the provision of excess water and sodium that only contributes to further TBW and sodium overload.

Hyponatremia: Normal or Expanded Volume and Urine Sodium Greater Than 20 mEq/L

Hyponatremia in the setting of normal or increased effective circulating volume is always related to persistent ADH effect (10). If the urine sodium value is greater than 20 mEq/L, the most common clinical scenario is the syndrome of inappropriate secretion of ADH (SIADH). SIADH can arise from disparate clinical conditions, including in the postoperative child, the child with significant pain, or the child with pulmonary disease; as alluded to earlier, ill children are at risk for both SIADH and inappropriate ADH effect (22). In SIADH, despite a state of hypo-osmolality, the urine is inappropriately concentrated as a result of an inability to suppress ADH secretion and block ADH-mediated water reabsorption from the distal nephron. Appropriate therapy for SIADH includes restricting water intake and attending to any underlying clinical factors predisposing to this syndrome.

Normal or increased extracellular volume and high urine sodium concentration can also be seen in the setting of renal failure as glomerular filtration and water clearance fall and the fractional excretion of sodium rises. A more unusual cause of this form of hyponatremia is polydipsia, usually psychogenic in nature. Such water intoxication is rare in children but can occasionally be seen in emotionally disturbed older children or infants inappropriately provided large volumes of water or very hypotonic fluid. In both of these circumstances, restriction of the volume of CH_2O ingested on a daily basis may be beneficial.

Hypernatremia

Hypernatremia is defined as a serum sodium value greater than 150 mEq/L. Generally, higher serum sodium values can be tolerated, and significant clinical and neurologic effects of hypernatremia do not occur until sodium values exceed 160 mEq/L. As with hyponatremia, hypernatremia

is more commonly a reflection of a problem with water balance rather than a sodium imbalance (23). In most instances, the patient has a relative deficiency of water for normal extracellular solute content.

Because sodium is the major determinant of plasma osmolality, as serum sodium levels rise, serum osmolality concomitantly increases. Increases in serum osmolality are sensed by hypothalamic osmoreceptors, triggering ADH release from the posterior pituitary once serum osmolality begins to increase over 280 mOsm (24). Increased serum osmolality also causes a sensation of thirst. Thus, in the normal state, as serum osmolality increases, there is increased fluid intake in the setting of high ADH levels. This results in increased reabsorption of CH_2O from the cortical collecting and reequilibration of serum sodium levels and serum osmolality before clinically significant hypernatremia or hyperosmolality occurs.

Outside infancy, hypernatremia as a result of sodium excess or salt poisoning is infrequently seen in pediatrics. Its major cause is improper preparation of powdered or liquid concentrated formula resulting in a hypertonic, hypernatremic solution. Because infants do not have free access to water, they cannot respond to their increasing sense of thirst as they develop hypernatremia. Exacerbating the whole situation are the facts that, most typically, caregivers continue to provide the same incorrectly prepared formula for further feedings and that young infants are unable to excrete sodium loads as efficiently as older children. Iatrogenic sodium loading can also be seen in children who have received large doses of sodium bicarbonate because of persistent acidosis or during a resuscitation or in children who have been given inappropriate amounts of sodium in peripheral nutrition. Iatrogenic sodium loading can also be seen in the child who has received repeated large volumes of blood products, generally isotonic or sodium-rich solutions.

Children who have hypernatremia from sodium excess should exhibit physical signs and symptoms compatible with extracellular space expansion. Thus, they frequently have peripheral edema and may have hypertension or symptoms of pulmonary edema. These children can respond to therapy aimed at augmenting the elimination of excess sodium. The use of diuretics and the provision of adequate CH_2O serve to decrease the total body sodium burden. Rarely, dialysis may need to be considered in cases in which it is clinically indicated to ameliorate the hypernatremia rapidly (25,26).

More commonly, hypernatremia is the result of a CH_2O deficit or a combined water and sodium deficit in which the water losses exceed the sodium losses. Hypernatremia secondary to a water deficit arises in the setting of inadequate access to water or an impairment in ADH release or response. It is uncommon to see hypernatremia secondary to poor water intake except in infants or young children who cannot get water for themselves in response to their

sense of thirst (27). As for ADH-related anomalies, there are many causes of central or nephrogenic diabetes insipidus (28). Again, given normal access to water, it is rare for the older child to develop hypernatremia even with an impairment in the ADH axis because of the strong drive to drink in response to thirst (29). In very young children with diabetes insipidus, however, the issue of access to water arises, and hypernatremia may be a concern.

The most common etiology of hypernatremia in children is the loss of hypotonic fluid (i.e., fluid with a relative excess of water for its sodium content). In these situations, the TBW is decreased more than the total body sodium. The usual clinical scenario leading to such a condition is viral diarrheal illness in the setting of poor water intake or persistent vomiting. In this condition, there is loss of stool with a sodium content generally less than 60 mEq/L. These children tend to excrete small volumes of concentrated urine with urine sodium content less than 20 mEq/L, underscoring the fact that they are conserving both water and sodium. Their hypernatremia is not a manifestation of a total body excess of sodium but a depletion of sodium that is overshadowed by a larger relative depletion of body water. Therapy is aimed at restoring water and sodium balance by providing back the hypotonic fluid that was initially lost either by the use of intravenous saline solutions or with oral electrolyte therapy.

FLUID REPLACEMENT THERAPY

Most commonly, the importance of fluid replacement therapy lies with restoration of an adequate effective circulating volume. In its absence, significant metabolic derangements can occur, which only serve to exacerbate perturbations in fluid and electrolyte homeostasis. The volume of fluid replacement required varies with the extent and etiology of the compromised circulation. Children with mild dehydra-

tion, manifesting with less than 5% weight loss, usually respond to 30 to 50 mL/kg of fluid. In the setting of more significant dehydration or loss of vascular tone, more than 200 mL/kg may be needed. The clinician can approach such fluid resuscitation with either intravenous or oral rehydration therapy.

Clinical and Laboratory Assessment of Volume Depletion

In estimating the severity of dehydration, the most objective measure is usually the change in weight from baseline (30). As rehydration proceeds, following weights on a serial basis becomes an important adjunct in assessing the efficacy of fluid repletion. Frequently, the clinician is faced with the situation in which no baseline weight is known, and various parameters based on history and physical examination need to be used to judge the severity of dehydration (Table 13.5). Children with mild dehydration have minimal clinical signs and only a modest decline in urine output. As dehydration becomes more significant, more classical findings (e.g., dry mucous membranes, tenting skin, sunken eyes, and lethargy) become prominent. With profound dehydration, there is anuria, marked alterations in consciousness, and hemodynamic instability.

A capillary refill time greater than 2 seconds is a useful physical finding in effective volume depletion (31). However, delayed capillary refill is neither a sensitive nor specific marker of dehydration (32,33) and may be most useful if normal, as this does seem to exclude reliably severe dehydration. In a prospective cohort study of dehydrated Egyptian children between 3 and 18 months of age, the best correlation between clinical assessment of degree of dehydration and actual volume depletion came in children who had such clinical parameters of significant dehydration as prolonged skinfold tenting, a dry mouth, sunken eyes, and altered sensorium—findings generally associated with more substantial

TABLE 13.5. CLINICAL ASSESSMENT OF DEHYDRATION

Physical sign	Degree of dehydration		
	Mild	Moderate	Severe
Vital sounds			
Pulse	Normal	Rapid	Rapid and weak
Blood pressure	Normal	Normal to slightly low	Shock
Weight loss			
Infant	<5%	10%	>15%
Older child	<3%	6%	>9%
Mucous membranes	Tacky	Dry	Parched
Skin turgor	Slightly decreased	Decreased	Tenting
Eye appearance	Normal tears	Decreased tears ± sunken	No tears + very sunken
Capillary refill	Normal	Delayed (>3 s)	Very delayed (>5 s)
Urine output	Decreased	Minimal	Anuric

dehydration (34). Similarly, in a review of preschool children with dehydration, the best clinical indicators of volume depletion—decreased skin turgor, poor peripheral perfusion, and Kussmaul breathing—accompanied more significant dehydration (35), underscoring the difficulty with which more subtle degrees of dehydration may be estimated by the clinician without access to prior weights.

A study of 97 American children who needed intravenous fluids in an emergency department for rehydration underscored the difficulty in assessing accurately even severe dehydration by standard clinical estimates (36). Physicians' initial estimate of dehydration compared to the actual percent loss of body weight varied dramatically, with a sensitivity of 70% for severe dehydration (greater than 10% loss) but only 33% for moderate dehydration (6 to 10% loss). This study suggested that adding a serum bicarbonate level to the assessment may be useful, increasing the sensitivity of the clinical scales to 100% in severe dehydration and 90% in moderate dehydration if standard clinical features and a serum bicarbonate less than 17 mEq/L were found.

Other studies have found that laboratory studies by themselves are poor indicators of the degree of dehydration. In 40 children receiving intravenous fluids for dehydration, prehydration assessment of serum BUN, creatinine, uric acid, anion gap, venous pH, and venous base deficit were made, as well as assessment of urinary specific gravity, urinary anion gap, and fractional excretion of sodium. Only the serum BUN/creatinine ratio and serum uric acid significantly correlated with increasing levels of dehydration, but both lacked sensitivity or specificity for detecting more than 5% dehydration (37). Similarly, in a retrospective review of 168 dehydrated children, elevated serum urea levels and depressed serum bicarbonate levels were found to be useful adjuncts to clinical evaluation in accurately assessing the degree of dehydration but were not by themselves predictive (38).

In fact, with the most common clinical scenario (i.e., viral gastroenteritis) leading to dehydration in children, there rarely is a significant laboratory anomaly despite clinical volume depletion. In a cohort of children from the United Kingdom admitted for rehydration due to viral gastroenteritis, only 1% of admitted children had an electrolyte derangement (39–41).

In children with volume depletion accompanying trauma, sepsis, surgery, or underlying renal dysfunction, it is more likely to find perturbations in electrolyte and acid-base status. Thus, in the absence of a straightforward case of mild to moderate diarrheal dehydration, the general consensus is that blood should be obtained for assessments of electrolytes, bicarbonate, and renal function to help guide fluid and electrolyte therapy (42,43).

As the child is volume resuscitated, it is important to assess the child's response. Initial estimates as to the degree of dehydration may need to be adjusted if the

child is not showing progressive improvement. Clinical parameters to follow include monitoring the child's general appearance and sensorium, the change in weight from initiation of rehydration, as well as urine output and urine osmolality. In children with some types of underlying renal dysfunction, there may often be a chronic urinary concentrating defect. In these children, relatively dilute urine flow may be maintained even in the face of clinical dehydration. In these children, markers other than urine output and osmolality should be followed.

Oral Rehydration Therapy

Parenteral fluid and electrolyte therapy have been the mainstays of medical treatment for most children presenting with fluid and electrolyte imbalances even though oral rehydration with electrolyte solutions is actually a safe, efficacious, and convenient alternative that can treat mild to severe volume depletion (44–47). Although this approach has been especially underused in North America, oral therapy has proved successful in clinical settings worldwide in resuscitating children of all ages with profound fluid and electrolyte anomalies; short of significant circulatory compromise, it can be used as first-line therapy in all fluid and electrolyte aberrations (48,49). An example of a situation in which oral hydration therapy is indicated is presented in the following case study:

A healthy 5-year-old boy with no significant medical history presents to his pediatrician's office after 2 days of a febrile illness. For most of this time, his appetite has been severely depressed, and his parents estimate that he has only had a few cups of fluid in the last 8 to 12 hours. Today, he vomited once, prompting the office visit. He has continued to urinate, although urine volume is less than usual. On physical examination, the boy is nontoxic and alert. Initially, his pulse is 120 beats per minute; however, after acclimation to the examination, it has decreased to 100 beats per minute. His sitting blood pressure is 90/50 mm Hg, and he is not compliant with attempts at orthostatic vital signs. His mucous membranes are dry, and his weight today is 20 kg, exactly the same as his weight at a well-child examination 6 months previously. His parents are concerned that he is becoming dehydrated.

Pediatricians, family practitioners, and emergency room physicians face such clinical scenarios regularly. The otherwise well child with an apparent viral illness causing mild to moderate dehydration is frequently treated by intravenous therapy under the oftentimes misguided assumption that oral rehydration rarely succeeds, is too labor intensive, or takes too much time. In fact, such children are excellent candidates for oral rehydration. In most developed countries where a viral disease is believed to be

TABLE 13.6. ORAL REHYDRATION THERAPY (ORT) FOR PREVIOUSLY HEALTHY, WELL-NOURISHED CHILDREN

Type of dehydration	Rehydration prescription	Rehydration duration
Mild (<5%)	30–50 mL/kg ORT	3–4 h
Moderate (5–10%)	50–100 mL/kg ORT	3–4 h

^aWith fluid containing 45 to 90 mmol/L Na, 90 mmol/L glucose, 20 mmol/L K, and 10 to 30 mmol/L citrate.

the etiology of the dehydration and there is little concern about a cholera-like enteritis, oral rehydration solutions with sodium contents from 30 to 90 mEq/L (54,55,57,59) can be chosen as oral therapy with expectation of success.

With this child, given his history and physical examination, it is unlikely that any electrolyte perturbations would be found; hence, there is little indication for assaying electrolytes or renal function before starting oral rehydration (39–41). The family is given a commercially available oral rehydration solution containing 75 mEq/L sodium, 20 mEq/L potassium, 30 mEq/L citrate, and 2.5% glucose. They are asked to provide 1 L of fluid (50 mL/kg) to the child over the next 4 hours. The child should be offered small aliquots of fluid very often—5 mL every 1 to 2 minutes at initiation. If this regimen is tolerated with no vomiting, the aliquots may be gradually increased in volume and the frequency reduced, aiming to deliver at least the prescribed total volume over approximately 4 hours.

A common cause of failure with oral rehydration is not recognizing that the initial provision of fluid given “little and often” is far more likely to be well tolerated than larger aliquots. If families are unwilling to provide the fluid in this manner, a nasogastric tube may be placed for continuous infusion.

Although some children may not respond to this approach and require intravenous rehydration, most children with mild to moderate rehydration can be rehydrated orally without a great deal of trouble. A guide for the volumes of fluid to provide and the duration of rehydration can be found in Table 13.6.

The first oral rehydration solutions were developed in the 1940s at academic medical centers. Within 10 years, a commercial preparation was available, but its use was associated with an increased incidence of hypernatremia (50). Several factors contributed to the development of this problem: The preparation was a powder meant to be reconstituted with water and was sometimes incorrectly administered as the powder itself or improperly diluted with too little water. When correctly reconstituted, the solution had a final carbohydrate concentration of 8% leading to an

osmotic diarrhea in some children; it was a common practice at that time for parents to use high-solute fluids (e.g., boiled skim milk) as an adjunctive home remedy. Taken together, these early experiences contributed to a reluctance by many clinicians to use oral rehydration solutions.

Over time, there came to be a better understanding of the physiology of water and solute absorption from the gut. Of prime importance was the recognition that many substances actively transported across intestinal epithelium had an absolute or partial dependence on sodium for absorption and that sodium itself was actually better absorbed in their presence (51–53). This led to the routine introduction of glucose into oral rehydration solutions in a fixed molar ratio of no more than 2:1 with sodium. Moreover, it became clear that the sodium/glucose cotransporter remained intact not only in the face of enterotoxic gastroenteritis (e.g., as seen with cholera or *Escherichia coli*) but also in more common viral and bacterial enteritides (48,49).

The World Health Organization (WHO) and the United Nations Children’s Fund have championed the use of a rehydrating solution that includes Na 90, Cl 80, K 20, base 30, and glucose 111 (2%) mmol/L. This WHO solution has proved useful in many clinical trials in children with dehydration from various causes, including secretory and nonsecretory diarrhea, and has been shown to reduce the morbidity and mortality associated with diarrheal illness regardless of its etiology (54,55). Most commercially available oral rehydration solutions differ from WHO solution in that they have a somewhat higher carbohydrate content, a lower sodium content, and a higher carbohydrate to sodium ratio (Table 13.7).

These formulation changes arose from concerns that using an oral rehydrating solution with a sodium content greater than 60 mmol/L may prove problematic in developed countries where most gastroenteritis is viral in nature and has a lower sodium content than the secretory diarrheas commonly seen in less developed areas. It was feared that if minimally dehydrated children losing small amounts of sodium in their stools were exclusively provided WHO solution without provision of some excess CH₂O, hyper-

TABLE 13.7. ORAL REHYDRATION SOLUTIONS

natremia might ensue. A few studies did indeed document iatrogenic hypernatremia related to such rehydration techniques (56). In cases of mild dehydration stemming from causes other than secretory diarrhea, solutions with lower sodium contents may be useful; in fact, solutions with sodium content ranging from 30 to 90 mmol have proved quite effective in this setting (57–59). A more recent metaanalysis of studies focused on the safety and efficacy of oral rehydration solution in well-nourished children living in developed countries documented little evidence that WHO solution was more likely to cause aberrations in serum sodium than oral rehydration solutions with lower sodium content.

Oral Rehydration with Fluids Other Than Oral Rehydration Solution

Despite the proven efficacy and fairly widespread availability of commercial oral rehydration solutions and the ease with which other electrolyte solutions can be mixed at home with recipes requiring few ingredients other than water, sugar, and salt, there are, nonetheless, many children who are given common household beverages in attempts at oral rehydration. In children with dehydration accompanied by electrolyte losses from vomiting or diarrhea, most common household beverages do not contain adequate

sodium or potassium supplementation. Moreover, the base composition and the carbohydrate source are often suboptimal for the dehydrated child, especially in the setting of diarrheal illness (Table 13.8). Similarly, most beverages marketed as sports drinks for “rehydration” after exercise are also deplete of sufficient electrolytes given that the electrolyte composition of sweat is many times lower than the composition of gastrointestinal fluid. In prescribing oral rehydration to children in an ambulatory setting, the clinician should clarify for the family the appropriate fluid and volume for the child to ingest, emphasizing the need to use a fluid with appropriate electrolyte content if there is concern about evolving imbalances in sodium, potassium, or bicarbonate homeostasis.

Oral Rehydration and Significant Sodium Alterations

Although oral rehydration is often associated with the child with modest dehydration and no presumed electrolyte anomalies, it has also been used in cases of dehydration accompanied by hyponatremia or hypernatremia (60,61). It has met with overall success when a WHO-like solution has been used. In children with severe hypernatremia (greater than 160 mEq/L), although most can be successfully rehydrated orally, there have been reports of seizures, generally as a result of too rapid correction of serum sodium stemming from the provision of supplemental water in addition to the glucose-electrolyte solution (60–62). In those cases, the average serum sodium fell by 10 to 15 mEq/L over 6 hours rather than over 24 hours as advised. In follow-up studies, no seizure activity was seen in a similar cohort of hypernatremic children who received 90 mmol Na rehydration solution alone at a rate calculated to replace the infant’s deficit over 24 hours (60). It is important for the practitioner to remember that once peripheral perfusion has been stabilized with initial volume expansion, there is no benefit to correcting any deficit rapidly, and tak-

ing 24 to 48 hours may be a more prudent course in the face of significant electrolyte anomalies.

Oral Rehydration Schemes

Several oral rehydration schemes have been shown to be quite effective and well tolerated. In one approach used extensively in developing countries, the patient's volume deficit is calculated on the basis of weight loss and clinical appearance (63). The volume deficit is doubled; this is the target rehydration volume to be given over 6 to 12 hours. Two-thirds of this volume is given as a glucose-electrolyte solution containing 90 mmol Na over 4 to 8 hours; once this has been ingested, the remaining volume is provided as water alone over 2 to 4 hours. In cases of suspected or confirmed hypernatremia with serum sodium exceeding 160 mEq/L, the volume deficit is not doubled and is administered as 90 mmol Na glucose-electrolyte solution alone over 12 to 24 hours. Patients who refuse to take fluids by mouth have nasogastric tubes placed. With this approach, successful oral rehydration is the rule; 95% of children are fully rehydrated without the need for intravenous therapy.

An alternative approach has been to have the child begin by taking 15 mL/kg/hr of a 60- to 90-mmol Na rehydration solution by mouth or nasogastric tube (64). The solution is given in small, frequent quantities and increased up to 25 mL/kg/hr until hydration has improved, at which point solid feedings are reintroduced and volumes of 5 to 15 mL/kg of rehydration solution offered after feeds until the volume deficit has been delivered.

The American Academy of Pediatrics has issued guidelines for the treatment of fluid and electrolyte deficits with oral rehydration solutions (48). Children with acute dehydration and extracellular volume contraction should be provided 40 to 50 mL/kg of a glucose-electrolyte solution containing 75 to 90 mmol/L Na, 110 to 140 mmol/L glucose (2.0 to 2.5%), 20 mmol/L potassium, and 20 to 30 mmol/L base. This volume should be administered over 3 to 4 hours; once there has been amelioration of the extracellular volume contraction, the patient should be changed to a maintenance solution with 40 to 60 mmol Na at half the rate. If the child is still thirsty on this regimen, there should be free access to supplemental water or low-solute fluid (e.g., breast milk).

In a recent evidence-based guideline for treating dehydration in children from industrialized European countries, oral rehydrating solution containing 60 mmol/L of sodium, 90 mmol/L of glucose, 20 mmol/L of potassium, and 10 mmol/L of citrate was recommended, with rehydration occurring over 3 to 12 hours using from 30 to 150 mL/kg of fluid depending on the degree and type of dehydration (30). This rehydration scheme is summarized in Table 13.6.

Limited Use of Oral Rehydration Solutions

Despite the promulgation of guidelines for oral rehydration in a variety of clinical situations, less than 30% of a mixed

group of American academic pediatricians, private practitioners, and pediatric house staff actually acknowledged using such therapy (57). Oral rehydration schemes have been shown to be used significantly more frequently by emergency room physicians who were familiar with the American Academy of Pediatrics' oral rehydration recommendations (65). Yet, even in these more knowledgeable emergency physicians, oral therapy was underused in children with all degrees of dehydration. Worldwide, WHO estimates that less than 25% of patients who could benefit from oral rehydration are actually treated with an appropriate oral therapy (66). Moreover, even in areas of the world, such as Bangladesh, where oral rehydration has been championed by both local and international medical agencies for decades, its use is still suboptimal (67,68).

When used, oral rehydration has been demonstrated to be quite successful, with more than 95% of children in a meta-analysis of oral rehydration studies achieving some degree of volume repletion (69). Other advantages to oral therapy include its ability to be administered readily anywhere by the child's usual caretaker, the safety and stability of the product despite its lengthy shelf-life, and avoidance of the discomfort and potential complications associated with intravenous catheter placement (70). In developed countries, there has been concern that the WHO solution may not be looked on by parents as a convenient hydration solution because it involves preparation from a powdered packet. In fact, in a randomized controlled trial of an urban pediatric clinic and a suburban medical practice in the United States, parents were equally as satisfied with the ease of administration and effectiveness of the WHO solution as compared to a commercially prepared oral rehydration solution (71).

Oral rehydration is somewhat less successful in hospitalized children than in children treated in an ambulatory setting (69). This difference may be directly related to the degree of dehydration or other complicating clinical issues leading to hospital admission. Moreover, the relatively labor-intensive, slower approach to oral rehydration may be problematic in medical facilities with time constraints or space limitations (70,72).

There are recent reports that frozen flavored oral rehydration solution may be more readily accepted than conventional oral solution. Its use resulted in higher rates of successful rehydration in children with mild to moderate dehydration, even if these children initially did not respond to conventional oral rehydration (70). Frozen flavored rehydration solution is now commercially available in some parts of the world, as is a variety of flavored rehydration solutions.

Another potential issue with oral rehydration is that its use does not alter the natural course of the child's illness. Thus, in gastroenteritis with dehydration, by far the most common illness requiring rehydration in children, oral rehydration does not lower stool output or change the duration of diarrheal illness (73). As a result, caretakers may abandon oral rehydration because the child is not getting

TABLE 13.9. COMPOSITION OF COMMON INTRAVENOUS FLUIDS

better and is not appreciating the benefits of ongoing hydration. Oral rehydrating solutions have been formulated with lower electrolyte composition and different carbohydrate moieties with the goal to reduce the osmolarity of solutions and theoretically augment fluid absorption from the small intestine (74). The rice-based oral solutions have been studied most extensively. In these solutions, glucose is substituted with 50 to 80 g/L of rice powder. In a metaanalysis of 22 randomized clinical trials comparing rice-based solutions to conventional glucose-containing solutions, stool output dramatically decreased in children with cholera given rice-based hydration but did not change in children with other bacterial or viral enteritides (75).

There are some reports that suggest that providing children with noncholera enteritis with reduced osmolarity rehydration solution may be beneficial. In one study, 447 boys younger than 2 years of age admitted for oral rehydration were assigned to receive either the WHO solution (osmolarity, 311 mmol/L) or a solution containing less sodium and chloride (osmolarity, 224 mmol/L). Children who received the lower-osmolarity solution had reduced stool output, reduced duration of diarrhea, reduced rehydration needs, and reduced risk of requiring intravenous fluid infusion after completion of oral hydration (76). A metaanalysis of nine trials comparing WHO solution to reduced-osmolarity rehydration solution concluded that children admitted for dehydration had reduced needs for intravenous fluid infusion, lower stool volumes, and less vomiting when receiving the reduced-osmolarity solution (77).

Intravenous Therapy

Although absolute indications for parenteral intravenous therapy are limited, they do include any condition of impaired peripheral circulation or overt shock. In addition,

there are occasional children who are truly unable to sustain an adequate rate of oral fluid intake despite concerted efforts or have such persistent losses that parenteral therapy comes to be necessary. The mainstays of fluid therapy in children are saline or buffered saline crystalloid solutions. Isotonic versions of these crystalloids are used for volume resuscitation, and hypotonic saline solutions may be used in addition to provide supplemental maintenance hydration. In addition to crystalloid solutions, there are several colloid fluids that are used by many clinicians. Table 13.9 lists the electrolyte content of some of the more common intravenous solutions used for pediatric fluid therapy.

Choice and Volume of Parenteral Fluid

Children with significant extracellular volume contraction (greater than 10% acute weight loss in an infant or 6% weight loss in an older child) should receive an isotonic crystalloid solution [e.g., 0.9% saline (154 mEq/L NaCl) or Ringer's lactate (130 mEq/L NaCl)] at a rate of 20 mL/kg over 30 to 60 minutes. Children with a more moderate degree of dehydration may not exhibit signs or symptoms of volume contraction. In certain situations, however, it may be clinically warranted to provide them with an initial rapid intravenous bolus to initiate rehydration therapy.

Concomitant with the placement of intravenous access, blood should be obtained for determination of serum electrolytes, osmolality, and renal function. Given that dehydrated children often have high levels of vasoactive hormones and high vasopressin levels, it is most circumspect to establish baseline electrolyte levels, as it is possible to alter electrolyte balance rapidly with intravenous therapy. In the face of inadequate tissue perfusion, a parenteral fluid infusion should begin immediately before the return

of any pertinent laboratory results. If hemorrhagic shock is suspected, resuscitation with packed red blood cells is optimal. In cases of severe volume depletion, if the child does not improve with the initial 20-mL/kg crystalloid bolus, this should be repeated up to two additional times. In children who have not improved despite administration of 60 mL/kg of total volume over 1 hour or in children in whom underlying cardiac, pulmonary, or renal disease may make empiric aggressive rehydration more problematic, consideration should be given to placement of a central monitoring catheter to more accurately assess intravascular volume and cardiac dynamics (78). In some instances of profound ineffective circulating volume (e.g., those that might accompany certain cases of sepsis), initial volume resuscitation may require sequential infusions of fluid ultimately exceeding 100 mL/kg.

Within minutes of infusion of a crystalloid fluid, it becomes distributed throughout the extracellular space. Because this involves equilibration of the fluid between the two components of the extracellular space—the intravascular and interstitial spaces—actually only one-third to one-fourth of infused crystalloid stays in the blood vessels (78). This accounts for the need to give large volumes of crystalloid in the setting of circulatory collapse and leads some to suggest that colloid solutions (e.g., 5 or 10% albumin) should play a role in resuscitation (79,80).

Colloid Solutions for Volume Resuscitation

The use of colloid solutions for volume resuscitation is controversial. In the 1990s, colloids were included in a number of widely promulgated guidelines for the care of patients in emergency facilities and intensive care units both for hemorrhagic shock before the availability of blood and for non-hemorrhagic shock as an adjunct to crystalloid use (81). Types of colloids used included 5% albumin, fresh frozen plasma, modified starches, dextrans, and gelatins. These guidelines, generally aimed toward the fluid resuscitation of adults, were composed despite the prior publication of a systematic review of randomized controlled trials that demonstrated no effect on mortality rates when colloids were used in preference to crystalloids (82). Moreover, there is a distinct cost disadvantage to using colloid solutions.

Two subsequent systematic reviews have looked at this issue anew. In one meta-analysis of 38 trials comparing colloid to crystalloid for volume expansion, there was no decrease in the risk of death for patients receiving colloid (81). In the other review, albumin administration was actually shown to increase mortality by 6% compared to crystalloid (83). Proposed mechanisms contributing to this worse outcome include anticoagulant properties of albumin (84) and accelerated capillary leak (85).

A drawback of all these systematic reviews, however, has been the limited number of studies that included children other than ill premature neonates. As a result, generaliza-

tion of these results from ill adults may not be germane to all critically ill, volume-depleted children. For instance, a report of 410 children with meningococcal disease suggests that albumin infusion in this population may not have been harmful, as case fatality rates were lower than predicted (86). Overall, however, there seem to be no substantive data to support the routine use of colloid to complement or replace crystalloid in fluid resuscitation. Rather, repetitive infusions of large volumes of crystalloid seem to be well tolerated in volume-depleted children; do not seem to predispose to excessive rates of acute respiratory distress syndrome or cerebral edema; and in some conditions (e.g., sepsis), play an important role in improved survival (87). A recent survey of pediatric anesthesiologists in western Europe reported that colloid solutions are being used less frequently in infants and older children and suggested that familiarity with some of the issues raised in these systematic reviews is affecting practice patterns (88).

Repetitive infusions of crystalloid may also prove problematic in some children. Most notably, if very large volumes of 0.9% saline are used acutely for volume resuscitation, it is not unusual for children to develop a hyperchloremic metabolic acidosis. This occurs as acidotic peripheral tissues begin to reperfuse and already depleted extracellular bicarbonate stores are diluted by a solution with an isotonic concentration of chloride (78,89). This acidosis can be ameliorated by supplemental doses of bicarbonate as well as the addition of supplemental potassium as needed. There is sometimes a tendency for clinicians to react to the hyperchloremic metabolic acidosis with further saline bolus infusions. In the face of corrected hypoxia or hypovolemia, however, such maneuvers may only exacerbate the chloride-driven acidosis (90). This hyperchloremic acidosis is seen less frequently when Ringer's lactate solution is used as the resuscitation fluid because of the metabolic conversion of lactate to bicarbonate. In the setting of significant preexisting acidosis or underlying hepatic dysfunction preventing the metabolism of lactate, infusion of Ringer's lactate solution may, however, exacerbate an acidosis.

Large-volume infusion of blood may predispose to electrolyte anomalies as well as manifestations of citrate toxicity. If aged whole blood is infused, there is the possibility that a large potassium load is delivered to the patient, as potassium, over time, migrates down its concentration gradient from less viable erythrocytes into plasma. Because most patients receive packed red blood cells instead of whole blood, this potential problem is minimized, as little plasma is infused; thus, the relatively small amount of infused potassium can be accommodated by movement intracellularly.

Citrate is used as the anticoagulant in stored blood. Because citrate complexes with calcium, there can be a fall in ionized calcium levels if large volumes of blood are infused rapidly or if there are concomitant perturbations in calcium homeostasis. Similarly, citrate may complex with magne-

sium, and magnesium depletion may occur. The liver usually metabolizes infused citrate into bicarbonate. Alkalosis may, therefore, occur if large volumes of citrate are metabolized. In the setting of hepatic dysfunction, however, citrate is not metabolized, serves as an acid load, and helps to create an acidosis or exacerbate any underlying acidosis.

Regardless of the initial infusion with either colloid or crystalloid, once sufficient volume to restore circulatory integrity has been infused, less rapid volume expansion is necessary. During this phase, the rapidity of fluid repletion is most probably not a concern unless there are severe underlying aberrations in the serum sodium or serum osmolality. In the absence of these derangements or profound volume deficit, if the child has improved significantly with the initial parenteral volume expansion, attempts should be made to reinstate oral rehydration. Prolonged intravenous therapy should rarely be needed.

Rapid Rehydration

Over the last decade, a scheme of rapid intravenous resuscitation and follow-up oral rehydration has been adopted by many pediatric emergency departments to successfully treat children with up to 10% dehydration secondary to vomiting and gastroenteritis (91). After infusion of 20 to 30 mL/kg on intravenous crystalloid, the child is allowed to take up to several ounces of a standard oral rehydration fluid; if this intake is tolerated without vomiting for 30 to 60 minutes, then the child is discharged home to continue rehydration, initially with a prescribed volume of standard rehydration solution.

If the child does not tolerate oral rehydration or if there are such significant electrolyte anomalies that there are concerns regarding potential adverse CNS sequelae of too rapid rehydration, then intravenous rehydration may be the best route for continued hydration. It is rare for children to become symptomatic from serum sodium aberrations until levels less than 120 mEq/L or greater than 160 mEq/L are reached. Children who have had very sudden fluxes in electrolytes may become symptomatic earlier. On the other hand, children whose severe sodium abnormalities are believed to be more chronic in nature must be treated in a more controlled fashion, as they are at higher risk for developing CNS symptoms during treatment.

The vast majority of children treated in emergency facilities for volume repletion do well with such rapid rehydration. These children are generally healthy with normal cardiac and renal function and have developed extracellular volume depletion relatively rapidly. As a result, they experience no ill effects from rapid rehydration. In fact, the clinical success of this aggressive restoration of extracellular volume underlies the calls to reexamine the traditional deficit therapy approach to rehydration with its tedious calculations of fluid and electrolytes losses and requirements (4,92).

Symptomatic Hyponatremia

In the setting of symptomatic hyponatremia, especially if the child has seizures, it is important to raise the serum sodium approximately 5 mEq/L acutely. Generally, this results in stabilization of the clinical situation and allows for further evaluation and treatment of the child to proceed in a nonurgent fashion. This is one of the few situations in which hypertonic saline (3% saline) should be used.

To calculate the proper volume of 3% saline to infuse, the child's TBW must be multiplied by the 5-mEq/L desired increase in serum sodium to determine the amount of sodium (in milliequivalents) to infuse. Because every milliliter of 3% saline contains 0.5 mEq of sodium, doubling the number of milliequivalents of sodium needed results in the proper volume in milliliters of 3% saline to infuse. Thus, in the 20-kg child, the TBW is approximately 12 L ($0.6 \text{ L/kg} \times 20 \text{ kg}$), and the desired sodium dose is 60 mEq ($12 \text{ L} \times 5 \text{ mEq/L}$). If 120 mL of 3% saline were infused, the serum sodium would be expected to rise by approximately 5 mEq/L. The infusion should be given at a rate to increase the serum sodium by no more than 3 mEq/L/hr and is often given more slowly over the course of 3 to 4 hours (93). If the child continues to be symptomatic from hyponatremia after this infusion, additional 3% saline may be given until the symptoms improve or the serum sodium is in the 120 to 125 mEq/L range. At that point, further correction of the hyponatremia should consist of a slower infusion of more dilute saline to cover the sodium deficit, the sodium maintenance needs, and any volume deficit.

Asymptomatic Hyponatremia

If a child has severe hyponatremia but is not symptomatic, there is no need to administer hypertonic saline based solely on a laboratory anomaly. With or without symptoms, in cases of severe hyponatremia, the child should be carefully evaluated as to the etiology of the hyponatremia, keeping in mind that hyponatremia may be the result of an imbalance of water regulation. If this is the case, CH_2O should be restricted and appropriate supplementation with intravenous saline solutions begun to provide maintenance sodium requirements of approximately 2 to 3 mEq/kg/day and any ongoing losses of sodium.

Besides these maintenance sodium needs, if the child has an element of dehydration, every kilogram of body weight lost from baseline represents a 1-L deficit of normal saline from the TBW as well. These losses are often referred to as *isotonic losses*. These account for a sodium deficit of 154 mEq/L that also must be included in the calculations for sodium replacement.

In the setting of hyponatremic dehydration, there have been additional sodium losses as well. Generally, this sodium deficit occurs because stool losses are replaced with fluids with a sodium content less than 60 mEq/L. To esti-

mate these sodium losses, the difference between the child's desired serum sodium and current serum sodium is multiplied by the child's estimated TBW. This product represents the hyponatremic sodium losses that must be added to the maintenance sodium needs, any ongoing losses, and the sodium losses that accompanied weight loss. An example of the calculations and therapeutic maneuvers that need to be considered with significant hyponatremia is presented in the following case study:

A girl who normally weighs 10 kg presents having generalized seizures. She has had 1 week of gastroenteritis with intermittent fever and has been drinking water only, refusing any other feeds for several days. Emergency intravenous access is obtained. Lorazepam is administered, and the seizure activity stops. Blood work is obtained, and the child is weighed and found to be 8.8 kg. A bolus infusion of 200 mL of 0.9% NaCl is administered, after which the girl appears adequately perfused but still lethargic. She no longer has diarrhea but vomits any small volumes of oral rehydration solution offered. The serum sodium is then reported to be 112 mEq/L. While further evaluation of the child's overall status is ongoing, it is important to begin correcting the apparent symptomatic hyponatremia.

The child has actually already received approximately 30 mEq of sodium in the 0.9% NaCl bolus given because of her dehydration and poor perfusion. Given her TBW of roughly 5.4 L (weight in kg \times 0.6 L/kg), this should result in her serum sodium having already increased by approximately 5 mEq/L. Because the child has had hyponatremic seizures and is still exhibiting some CNS effect with her lethargy, it is probably prudent to raise the serum sodium by approximately 5 mEq/L so that it is in the 120- to 125-mEq/L range. Because she is hemodynamically stable, it is probably best not to provide an excess of further volume until the child's brain is imaged to assess for cerebral edema, especially given the history of seizures, lethargy, and hyponatremia. By using a small volume of hypertonic saline, the serum sodium could begin to be raised in a controlled manner while further evaluation of the child continues. It would take approximately 22 mEq of sodium (TBW \times desired increase in serum sodium = 5.4 L \times 5 mEq/L) to accomplish the desired elevation. Because each milliliter of 3% saline contains approximately 0.5 mEq of sodium, a total of 44 mL of 3% saline could be infused over approximately 3 to 4 hours.

In addition to this acute management to restore circulation and perfusion and to raise the serum sodium to a safer level, plans must be formulated to attend to the patient's overall volume and sodium deficit. To prescribe the proper follow-up intravenous fluid, the patient's initial water and electrolyte deficits must be reconciled with her therapy thus far.

The child's water deficit is 1.2 L, reflecting the 1.2-kg weight loss. She has normal maintenance water needs of an additional 1 L/day based on her normal weight of 10 kg. She is having no other ongoing water losses and has already received nearly 250 mL in intravenous fluid in the form of 0.9% NaCl and 3% NaCl. Thus, her current water needs are 1950 mL.

The child's normal maintenance sodium needs are 30 mEq/day (3 mEq/kg/day). She has lost 1.2 kg in body weight that represents 185 mEq of sodium. In addition, she has hyponatremic sodium losses that have arisen as her diarrheal stool was replaced with water alone. To calculate these needs, her normal TBW needs to be multiplied by the difference in her serum sodium from a normal value of 135 mEq/L. Her TBW is 6 L (TBW = 0.6 L/kg \times 10 kg), and the difference in serum sodium is 23 mEq/L (135 mEq/L to 112 mEq/L); her hyponatremic losses are, therefore, 138 mEq (6 L \times 23 mEq/L). Thus, total sodium needs are 30 mEq of maintenance, 185 mEq of isotonic losses, and 138 mEq of hyponatremic losses, or a total of 353 mEq. She has already received 52 mEq of sodium from the 400 mL of 0.9% NaCl given in the emergency department. Her current sodium needs are, thus, approximately 300 mEq.

To choose the proper solution for this child, the deficit of 1950 mL of water should contain 300 mEq of sodium. This is best approximated by 0.9% NaCl with its NaCl content of 154 mEq/L NaCl. In the past, it has been suggested that half of the fluid and sodium deficit be replaced over 8 hours and the remainder over the ensuing 16 hours. Although such a plan can be followed, there is little evidence that more rapid correction of the hyponatremia is harmful except if the patient has been symptomatic with hyponatremia or has profound asymptomatic hyponatremia of chronic duration. In these cases, it is safest to plan to correct the serum sodium by no more than 12 to 15 mEq/L over 24 hours. More rapid correction has resulted in osmotic demyelination injury to the brain with devastating long-term neurologic outcomes (93,96,97).

Severe Hypernatremia

With hypernatremia, intravenous therapy is again guided by the clinical situation and is usually reserved for those children with very elevated serum sodium values. In cases of hypernatremia due to salt poisoning, there should be signs of overhydration and volume expansion. Excretion of sodium should be enhanced by using a loop diuretic to augment urine sodium losses and by replacing urine output with CH_2O . If the patient has significant renal or cardiac compromise because of the electrolyte imbalance, dialysis and ultrafiltration may be necessary (25,26). With hypernatremia and volume expansion, however, it is detrimental to provide further intravenous saline.

In hypernatremia accompanied by volume loss, any significant alterations in effective circulation should be addressed with 20-mL/kg bolus infusions of an isotonic crystalloid solution until effective peripheral perfusion is restored. Then, further provision of water and sodium should be provided based on calculated water and sodium needs. In the majority of cases, however, with mild elevations in serum sodium and minimal degrees of dehydration, the actual calculation of deficits is probably unnecessary, as the child is hemodynamically stable initially and a candidate for exclusive oral rehydration. In situations in which there is profound hypernatremia or circulatory compromise, it remains necessary, however, to be able to calculate a CH_2O deficit to tailor intravenous rehydration therapy. An example of such a situation is outlined in the following case study:

After 2 days of refusing any fluid intake, a 5-kg infant with a viral syndrome presents in shock and is 15% dehydrated with a weight of 4.25 kg and a serum sodium of 170 mEq/L. She receives 300 mL of 0.9% NaCl in the emergency department and is now admitted for further therapy.

The child has lost 750 g of weight. Because this is hypernatremic dehydration, there has been loss of water in excess to salt. Thus, part of the weight loss represents isotonic losses, but a larger proportion represents CH_2O loss. The child's CH_2O deficit can be calculated by the following equation:

$$[(\text{serum Na actual})/(\text{serum Na desired}) \times \text{TBW}] - \text{TBW}$$

Substituting the appropriate data for this baby:

$$[(170/145) \times (0.6 \times 4.25)] - (0.6 \times 4.25) =$$

$$(1.2 \times 2.55) - 2.55 = 0.51 \text{ L}$$

Therefore, of this baby's 750-mL fluid deficit due to dehydration, 510 mL is CH_2O and 240 mL is normal saline.

Too rapid correction of the child's serum sodium with CH_2O could result in cerebral edema as the water infused into the extracellular space follows osmotic forces and moves into the intracellular space. In cases of hypernatremia in which the serum sodium exceeds 160 mEq/L, it is considered safest to correct the serum sodium by no more than 15 mEq/day. In this baby's case, this means that correction to a serum sodium in the normal range would take approximately 2 days.

If the fluid and electrolyte therapy must be given intravenously, the appropriate prescription again depends on calculation of water and sodium requirements and deficits. Her original fluid deficit was 750 mL, and her maintenance water needs are estimated at 500 mL/day. Thus, over the next 2 days, the fluid needs to replace her deficit and to provide maintenance are 1750 mL. Of this, she has already received 300 mL of fluid in the emergency department, so she has a net deficit of 1450 mL.

The baby has maintenance sodium needs of 15 mEq/day (3 mEq/kg/day). Her sodium deficit reflects only her isotonic fluid losses that have been estimated above at 240 mL of normal saline or 37 mEq of sodium. Thus, over the next 2 days, her sodium needs are 67 mEq, of which she has already received the vast majority in the emergency department due to her need for initial volume expansion.

Initiating an infusion of 30 mL/hr of CH_2O should result in the slow and steady correction of the hypernatremia over 2 days. The serum sodium should be monitored every 4 hours initially; if it is falling faster than desired (approximately 0.5 mEq/hr), then sodium should be added to the rehydration fluid.

FLUID AND ELECTROLYTE THERAPY WITH RENAL DYSFUNCTION

Impact of Renal Disease on Fluid and Electrolyte Therapy

Compromised renal function reduces the tolerance for changes in TBW as well as changes in the composition or distribution of volume between the intracellular and extracellular body spaces. Similarly, alterations in electrolyte balance are less readily tolerated because the normal homeostatic mechanisms are frequently perturbed. Thus, in the child with certain renal disorders (e.g., marked nephrosis or significant impairment in renal clearance), it becomes vital to approach the provision of fluids and electrolytes with great care.

As far as fluid therapy is concerned, it is important to recognize that any scheme to provide maintenance fluids or electrolytes presupposes normal renal function. Roughly two-thirds of any daily maintenance fluid prescription is to replace urinary water losses. Similarly, urinary electrolyte losses figure prominently in daily electrolyte balance. In the setting of oliguria or anuria, provision of maintenance fluids could contribute to and potentially exacerbate volume overload, and maintenance electrolyte therapy could result in electrolyte anomalies.

It is better to approach the fluid and electrolyte needs of the child with renal dysfunction in the context of his or her current volume status and electrolyte needs. The patient who is symptomatic due to volume depletion benefits from volume expansion regardless of urine output. Once volume is replete, the child's needs can be reassessed along with his or her current renal function. The child who is volume overloaded is best managed by volume restriction and provision of only insensible fluid losses of approximately 300 mL/m². Insensible fluid losses should be considered essentially CH_2O . The child who is volume replete should be kept volume replete. This is most readily accomplished by providing a combination of insensible losses as CH_2O and any other volume losses (urine output, diarrheal stool, surgical drain output, vomitus) on an addi-

tional milliliter-for-milliliter basis. If there are significant ongoing losses from a single source, the electrolyte composition of this fluid can be assayed so that the replacement fluid may more accurately reflect the electrolyte losses. Otherwise, a solution of 0.45% NaCl can be used initially and altered as the clinical situation continues to develop and further electrolyte determinations are made.

If the child's volume status or the adequacy of renal function is difficult to discern initially, it is probably best to provide the child with replacement of both insensible and ongoing losses. This should maintain the child's current volume status and allow for further determination of the appropriateness of more vigorous hydration or, conversely, fluid restriction as the clinical situation clarifies. Monitoring the child's weight on at least a daily basis and documenting the child's total fluid intake and output also assists in arriving at a proper hydration regimen.

Assessing the child's current electrolyte status and monitoring the loss of electrolytes in the urine or in any other source of significant electrolyte losses assist in tailoring the daily electrolyte prescription. An understanding of the pathophysiology underlying the child's renal dysfunction is also useful. The child who has profound tubular electrolyte losses requires more sodium on a daily basis than the child who is edematous and has total body salt overloaded from his or her nephrotic syndrome. The child with chronic renal insufficiency and hypertension mediated by long-standing salt and water overload may actually benefit from diuretic therapy to remove salt and water rather than any further volume expansion with saline.

Certainly, the provision of supplemental potassium to the child with renal dysfunction must be done judiciously. The oliguric or anuric child should receive no potassium until it is well documented that serum potassium levels are low or that there are extrarenal potassium losses (e.g., gut losses from diarrheal stool). The child with marginal renal function should receive small amounts of potassium (approximately 1 mEq/kg/day) with at least daily assessment of electrolyte balance to reassess the adequacy and appropriateness of continued potassium supplementation.

Fluid and Electrolyte Therapy in the Intensive Care Unit

Many children who are critically ill present a challenge to the clinician attempting to prescribe appropriate fluid and electrolyte therapy. Oftentimes, there may be renal dysfunction, and frequently there may be multiorgan failure complicating management decisions. What frequently creates significant fluid and electrolyte anomalies is rather rote reliance on standard formulas to prescribe fluid and electrolyte therapy. Rather than relying exclusively on a set maintenance requirement of fluid or electrolytes, it is almost always best to assess the patient's individual fluid and electrolyte needs in the context of the underlying pathophysiology, volume status, the

efficacy of tissue perfusion, current ventilatory requirements, and current renal function. Whenever there is concern about incipient or exacerbating volume overload, it is important to review the volume and types of fluids being provided. Increasing the concentration of continuous medication drips and assessing medication compatibility for simultaneous infusion are important steps in limiting total daily fluid input. Initially, it is often appropriate in these critically ill children to ascertain that their intravascular space is replete to help maintain hemodynamic stability. Once the patient is believed to be intravascularly replete, maintaining euvolemia by providing insensible water losses as well as replacing any ongoing fluid and electrolyte losses should maintain the patient in fluid and electrolyte balance.

Oftentimes, despite a desire to limit fluids in the critically ill child, medication requirements, nutritional needs, and hemodynamic insufficiency may result in the development of significant volume overload. There may also be situations in which due to the "vascular leak" phenomenon, the critically ill child becomes massively volume overloaded but has a decreased effective circulating volume. In other words, renal and tissue perfusion may be a sluggish because fluid has leaked from the intravascular space into the interstitial space. In this setting, there may be a need to continue to administer large volumes of fluid to maintain circulatory integrity with the knowledge that such infusions only exacerbate the total body fluid overload. Aggressive diuretic therapy may prove useful especially if renal function is not compromised. Combination diuretic therapy using agents that work at separate sites along the renal tubule may be necessary. Ultimately, the use of either periodic or continuous ultrafiltration may be beneficial to these patients by allowing ongoing fluid administration but limiting the daily imbalance between fluid intake and output. Ultrafiltration may be accomplished via peritoneal dialysis, by intermittent hemodialysis with ultrafiltration, or by using one of the slow continuous ultrafiltration techniques now known as *continuous renal replacement therapy*.

If ultrafiltration is initiated, extreme vigilance is necessary to prevent exacerbation of intravascular depletion and the development of prerenal azotemia or frank renal failure. Special care must be taken with the continuous modalities to insure that ultrafiltration rates are periodically reassessed and readjusted. Furthermore, because the electrolyte losses that accompany the ultrafiltration of fluid are isotonic, the electrolyte content of infused fluids must be adjusted to match the composition of the ultrafiltrate. Serum electrolyte values need to be followed in a serial fashion with periodic review and readjustment of the composition of supplemental intravenous fluids.

Alterations in Serum Sodium Complicated by Renal Failure

Because of the important contribution of serum sodium to serum osmolality, alterations in serum sodium, especially

coupled with alterations in BUN related to renal failure, can complicate the usual approach to a child with fluid and electrolyte anomalies. Generally, there are greater concerns with hypernatremia and renal failure, as the need to correct the sodium in a slow fashion can be problematic when renal replacement therapy needs to be initiated for clearance of urea. Balancing the correction of sodium and the hyperosmolar state with the clearance of urea requires a carefully considered plan that is grounded in a firm understanding of fluid and electrolyte homeostasis.

In most cases of hypernatremia related to severe dehydration, some degree of acute renal insufficiency is present. This renal failure is usually prerenal in nature, a result of a decreased effective circulating volume rather than an intrinsic glomerular or tubular disorder. Most often, in the course of rapid restoration of perfusion and early rehydration, the urine output increases, and the azotemia begins to resolve.

Alternatively, there are occasional cases in which, due to intrinsic renal dysfunction or acute tubular necrosis, the renal insufficiency does not respond to volume infusion; in fact, the provision of excess volume may contribute to significant volume overload. In these cases, there may be need to consider some form of renal replacement therapy to assist in the controlled correction of fluid and electrolyte derangements, especially if the renal failure is oliguric or anuric in nature. Such an example is detailed in the following case study:

A 15-year-old boy presents with a several-week history of polyuria, severe weight loss, fatigue, and poor oral intake. He is diagnosed by his pediatrician as having diabetes mellitus with ketoacidosis and is referred to an emergency department for management. At this point, his serum sodium is 154 mEq/L, his creatinine is 3.0 mg/dL, and his BUN is 30 mg/dL. In the emergency department, the child receives several bolus infusions of normal saline supplemented with sodium bicarbonate and is started on an insulin drip. He is admitted and continues to receive brisk intravenous hydration with normal saline with bicarbonate supplementation. He is noted to be oliguric, and this does not improve with several more hours of hydration with normal saline. The next morning, laboratory values reveal a serum sodium of 165 mEq/L, a creatinine of 4.5 mg/dL, and a BUN of 50 mg/dL. He has made only 75 mL of urine in the last 8 hours and is developing some mild peripheral edema.

In this case, the renal insufficiency and poor urine output have complicated the usual management of diabetic ketoacidosis and have exacerbated an underlying hypernatremia. Given the patient's evolving renal failure, it is not feasible to provide the necessary volume of CH₂O to correct the hypernatremia without contributing to further volume overload. Because of the apparent progressive renal failure, it is also useful to correct the hypernatremia in case dialysis becomes nec-

essary for urea clearance. By performing controlled ultrafiltration on the patient and replacing back with CH₂O the volume ultrafiltered, the serum sodium could be corrected without exacerbating the volume status.

With a serum sodium of 165 mEq/L and an estimated TBW of 42 L (70 kg × 0.6 L/kg), this patient has CH₂O needs of 7.5 L to lower his serum sodium to the 140-mEq/L range [(165/140 × 42) - 42]. Because the patient is now significantly hypernatremic and has been subject to various fluid and electrolyte shifts as his diabetic ketoacidosis has been treated, it is prudent to correct his serum sodium by no more than 10 to 12 mEq/day over the course of 3 days. Thus, if the patient is ultrafiltered for 2.5 L/day, and the ultrafiltration volume each day is replaced back as CH₂O, the serum sodium should be in the normal range in 3 days' time. The ultrafiltration goal could be achieved over the course of a few hours each day if the patient were hemodynamically stable or over a more prolonged period of time each day if there were concerns regarding hypotension. Thus, a conventional hemodialysis setup could be used for relatively rapid ultrafiltration only or a continuous filtration circuit for either rapid or slow filtration.

Because the fluid removed in ultrafiltration is isonatremic to the serum sodium, the sodium concentration of each liter of ultrafiltrate should mirror the serum sodium concentration at the time of ultrafiltration. Thus, on the initial day of ultrafiltration, each liter of ultrafiltrate should contain a sodium content of 165 mEq/L. By providing back the volume ultrafiltered each day as CH₂O, the serum sodium content is expected to fall, in this case, by approximately 8 to 10 mEq/L/day.

It is important to recognize that CH₂O must be provided back to the patient to make up for the ultrafiltration losses. Otherwise, because the ultrafiltrate is isotonic, there is no change in the serum sodium concentration, and the ultrafiltration may potentially exacerbate the renal failure by depleting the intravascular space and the effective circulating volume.

Moreover, it is also important to recognize that the patient's overall daily fluid needs are greater than the daily ultrafiltration volume alone, as maintenance fluid requirements and any ongoing fluid losses must also be considered. Because the patient is in renal failure, his maintenance fluid needs are scaled back to insensible losses of 300 mL/M²/day; in this case, there are no ongoing losses. Thus, each day for the next 3 days, this 70-kg patient needs to receive approximately 500 mL/day of insensible losses and 2500 mL/day of ultrafiltration replacement, or a total of 3000 mL/day. His maintenance sodium requirements are 3 mEq/kg/day. Although it may seem counterintuitive to provide a hypernatremic

patient with maintenance sodium, disregarding these requirements results in a more rapid correction of the hypernatremia than desired. If the child were to receive a saline infusion of 0.45% NaCl at a rate of 125 mL/hr, this would provide just over 3 mEq/kg/day of sodium in a total volume of 3 L/day.

If the child with hypernatremia has profound renal failure and requires dialysis for urea clearance, the dialysis prescription must take into account the need to slowly correct the serum sodium. Normally, regardless of the modality of renal replacement therapy, most dialysate contains sodium isotonic to the normal serum sodium range. It may prove detrimental, however, to dialyze a patient who is very hypernatremic against a dialysate with a sodium concentration at least 30 mEq/L less than the patient's serum sodium concentration. The diffusional gradient during dialysis leads to more rapid correction of the serum sodium than the desired drop of approximately 1 mEq every 2 hours.

Although most hemodialysis machines can be readjusted so that the dialysate produced has a sodium content as high as the low to mid-150s, this still may not reduce the gradient sufficiently in cases of severe hypernatremia. In those situations, by maximizing the sodium concentration of the dialysate and by performing dialysis for limited amounts of time, one can minimize the drop in serum sodium. Still, there need to be frequent assessments of the serum sodium concentration, and overall clearance may need to be sacrificed to prevent too rapid correction of the serum sodium and a rapid concomitant decrease in the serum urea that may increase the chances for dialysis disequilibrium.

Alternatively, a continuous hemodiafiltration technique such as continuous venovenous hemodiafiltration can be performed. By asking the hospital pharmacy to increase the sodium content of the dialysate fluid to within 10 to 12 mEq/L of the serum sodium concentration, the diffusional gradient for sodium clearance can be minimized. Then, by making appropriate adjustments in the sodium content of the dialysate as the serum sodium falls, the serum sodium levels can be reduced gradually by 10 to 12 mEq/L/day while adequate urea clearance and ultrafiltration for most situations are achieved.

Peritoneal dialysis has also been used in cases of severe hypernatremia (94,95). Again, the concentration of sodium in the dialysate may need to be adjusted upward in severe hypernatremia to prevent too rapid clearance of sodium. In addition, because the degree of clearance and ultrafiltration may not be as precisely controlled as with hemodialysis or hemodiafiltration, frequent assessment of electrolyte values is necessary. Manipulation of dwell volumes and dwell times also influences overall clearance, and the use of smaller dwell volumes for longer periods of time helps to minimize sodium clearance.

In contradistinction to hypernatremia, because hyperosmolality is less common with hyponatremia, in some ways

it is easier to use renal replacement therapy in the setting of severe hyponatremia and concomitant renal insufficiency. Again, the focus needs to be on the rapidity of the correction of the serum sodium. In conditions of chronic severe but asymptomatic hyponatremia, the rate of correction of serum sodium should parallel the rate of correction recommended in hypernatremia—approximately 10 to 12 mEq/L/day. Correction of chronic hyponatremia at a more rapid rate has been associated with the development of central pontine demyelination.

All of the manipulations described above for hypernatremia and renal failure can be used with hyponatremia and renal failure with the understanding that the dialysate sodium concentration should now not exceed the serum sodium value by 10 to 12 mEq/L. Conventional hemodialysis machines can be adjusted to produce dialysate with a sodium concentration as low as the mid-120s. In the very rare situation in which a child with profound hypernatremia (less than 110 mEq/L) was being hemodialyzed, brief hemodialysis runs may be necessary initially to prevent too rapid correction of the serum sodium level and the attendant risk of central pontine demyelination. If dialysate is being custom prepared for peritoneal dialysis or hemodiafiltration, precise alterations in the electrolyte content can be made more readily to reduce the sodium gradient.

The local resources, the training of ancillary staff, the unique circumstances of each patient, and the comfort of the clinician with different modalities of renal replacement therapy guide the choice of therapy when faced with renal failure and significant serum sodium anomalies. The actual modality of renal replacement therapy used is less important than careful attention to the rate of correction of the electrolyte anomaly, to the rate of urea clearance being achieved, and to the clinical response of the patient to ongoing therapy.

RESEARCH METHODS

MOLECULAR BIOLOGY

FRANCESCO EMMA
GIAN MARCO GHIGGERI

OVERVIEW OF MOLECULAR CELL BIOLOGY

The discipline of molecular biology began in the mid-1940s through an effort by scientists to discover the universal laws that govern the process of self-replication in living organisms (1). Earlier efforts by Mendel, Wilson, Morgan, and Garrod to study genetic inheritance used organisms with complex genomes. These studies were based entirely on the natural breeding systems of the organisms that were analyzed. As a result, a factor that determined a phenotypic future (i.e., a gene) could be shown to reside at a specific location, or locus. Until the advent of molecular biology, the concept of genes and loci remained intangible. Chromosomal loci were merely the sites determining differences, usually between “normal” and “mutant,” and genes remained detectable only if mutated (2).

From the 1940s through the 1960s, these concepts were revolutionized. After Beadle and Tatum had established for the first time a link between genes and proteins, Griffith and Avery proposed that DNA was the molecule containing genetic information. Soon after, work by Wilkins, Franklin, Watson, and Crick described the structure of DNA as a double helix. The discovery of the genetic code and the establishment of the role of RNA in the synthesis of proteins laid the foundations for the development of modern-day molecular biology (3).

Efforts by many scientists have provided key technological innovations since the 1960s, allowing recombinant DNA technology to be applied to a wide variety of biologic problems. Major milestones include the discovery of restriction nucleases and DNA ligases; the development of DNA libraries (4), DNA cloning procedures, nucleic acid hybridization techniques, rapid sequencing techniques (5), and the polymerase chain reaction (PCR) (6); and the production of transgenic animals (7). These advances permit detection, amplification, and engineering of DNA sequences and delineation of the role of genes in cellular physiology and pathophysiology (2).

The molecular revolution has affected all of the sciences, including medical and clinical research, and has culminated

in the completion of the human genome project (8). It has provided new insight into the complexity of living organisms that can only be partially studied with commonly available techniques.

The complexity of biologic systems presents new challenges for molecular biology in the post-genomic era. Recent progress in microengineering, computer technology, and bioinformatics has led to the development of nanotechnologies and to the emergence of new fields of investigation, including functional genomics and proteomics.

Basic Concepts

Central Dogma

The research efforts described led to the formulation of the so-called central dogma of molecular biology soon after the discovery of DNA structure in 1953. According to the central dogma, DNA sequences are transcribed into RNA molecules that carry the flow of genetic information out of the nucleus to be translated into proteins (1,3). These processes have been well defined and are detailed in most introductory cell biology texts (3,9). The simple concept of a one-way flow of information from DNA to RNA to protein has been thoroughly revised. Genetic information is conveyed in both directions through a complex series of feedback loops.

Proteins and Nucleic Acids: Different Molecules with Common Features Linked by a Genetic Code

Both DNA and proteins are composed of a limited number of units that are assembled sequentially in a step-by-step process that always proceeds in one unique direction (9). The link between nucleic acids and proteins is provided by the genetic code. To translate four nucleotides into 20 different amino acids, groups of at least three nucleotides (codons) yielding 64 possibilities are required. Of these, 61 correspond to specific amino acids, whereas three correspond to termination codons. The code is said to be degen-

erate, as it contains redundancies. Codons corresponding to the same amino acid generally differ by the nucleotide in the third position (3,9).

As a consequence of the degeneracy of the genetic code, nucleotide substitutions (point mutations) in the third nucleotide of a given codon may not change the primary sequence of a protein and are frequently found in nature, as they are not subject to natural selection. Point mutations in the first and second position result in an amino acid substitution or in a termination codon, either of which can dramatically alter protein structure and function.

In principle, each messenger RNA (mRNA) can be translated in any of the three possible reading frames determined by overlapping triplet codes. With few exceptions, only one reading frame produces a functional protein because stop codons encountered in the other two reading frames terminate translation. As the only punctuation signal is located at the start codon (ATG), the reading frame is set at the beginning of the translation and proceeds until a termination codon is reached. Thus, finding the correct reading frame and locating the start codon are essential steps in the process of cloning genes and defining their protein products. Mutations causing the deletion or insertion of one or two nucleotides result in a shift of the reading frame (frame-shift mutations) and cause the production of aberrant protein products.

Gene Structure

The complementary strands of chromosomal DNA are arranged in an antiparallel fashion as dictated by hydrogen bond pairing of nucleotide bases. It is estimated that the human genome is composed of approximately 3 billion base pairs of DNA containing 30,000 to 100,000 genes arrayed on 23 pairs of chromosomes (10). Overall, the amount of DNA containing genes comprises a minority of nuclear DNA.

Traditionally, a gene is depicted as a “transcriptional unit” as illustrated in Figure 14.1. The DNA double helix is represented as a line interrupted by rectangular boxes corresponding to exons, with its 5' end on the left and its 3' end on the right. Each gene is divided into two major regions, namely the promoter and the coding regions.

Typically, the promoter region is located upstream near the 5' boundary of the coding region and contains clusters of short sequences (fewer than ten base pairs) spread over a few hundred bases that bind transcription factors. These regulatory proteins mediate the attachment and activation of type II RNA polymerase, which mediates the transcription along the DNA while unwinding the duplex and adding nucleotides to the growing RNA molecule. DNA sequences in the promoter region that bind to transcription factors are referred to as *cis-acting* elements. In some cases, transcription factors also interact with other *cis-acting* elements (termed *enhancers*) that are located at a greater distance (up to a few thousand bases) from the promoter.

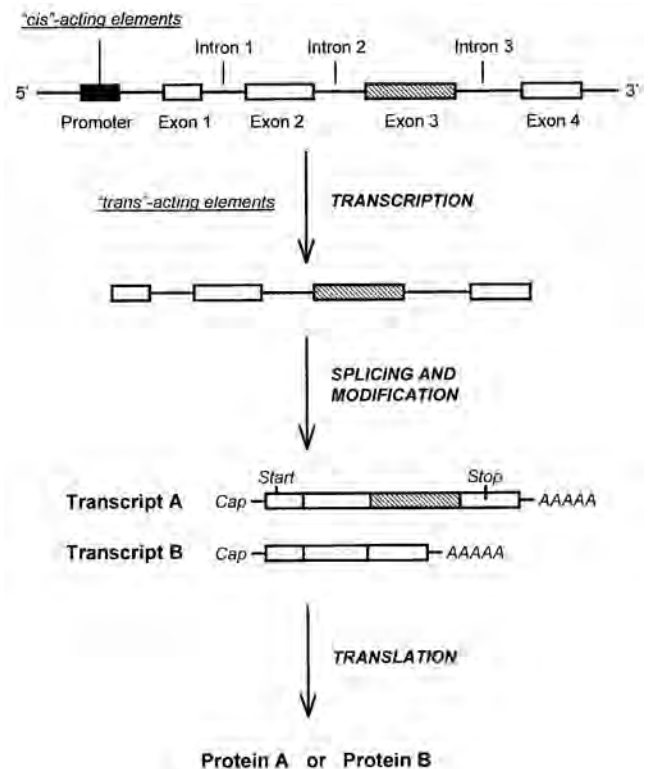

FIGURE 14.1. General organization and processing of a eukaryotic gene. A gene consisting of four exons and three introns is shown. The promoter region (black box) is located near the 5' end of the gene. Transcription of the gene yields a primary messenger RNA (mRNA) transcript that contains both exon and intron sequences. Differential splicing of this mRNA transcript yields two mature mRNA species by inclusion or exclusion of exon 3 (hashed box). To be exported into the cytosol and translated, mRNAs need to be modified by polyadenylation of their 3' end and capping of their 5' end with methylated guanines. Differential splicing results in two different protein isoforms that are encoded by a single gene.

The physical gap between the enhancer and the promoter explains the need for accessory factors that convey transcriptional signals to the RNA-polymerase through protein-protein interactions (Fig. 14.2). All molecules, generally proteins, which are physically involved in the regulation of transcription are referred to as *trans-acting* elements, because their DNA sequence resides in a different location of the genome (3,9).

The coding region contains the information for protein synthesis. In this region, most genes are composed of a succession of exons and introns. Exons are coding sequences that ultimately transfer into mature mRNA, whereas introns are edited out of the newly synthesized transcript by a process called *splicing*.

Control of Gene Expression

As only a fraction of the available genes are expressed in a given cell at a given developmental stage, differential trans-

FIGURE 14.2. Transcriptional regulation in prokaryotes and eukaryotes. **A:** In prokaryotes, genes are organized in a cluster of related genes under the control of a single promoter, forming an operon. The RNA polymerase complex is constituted by a core enzyme that is activated on binding of a σ factor. **B:** This modular system is much more complex and sophisticated in eukaryotes. Different transcription factors bind to the promoter and enhancer regions and position type II RNA polymerase at the starting point of transcription. General transcription factors shown in black interact with the TATA box and hold together the enhancer-promoter-RNA polymerase complex. When not activated, eukaryotic genes are hidden in nucleosomes that are composed of a central core formed by histones. Activation of eukaryotic genes requires remodeling of the chromatin to allow the transcriptional apparatus to interact with the regulatory sequences.

cription and processing of genes provides for enormous diversity between cells within the same organism. Although gene expression can be controlled at different levels, transcriptional regulation generally predominates.

The information that governs transcription is located in DNA sequences that correspond to *cis*-acting elements or that encode for transcription factors. These sequences occupy a minimal portion of the entire genome but are the key determinants of cell organization by ensuring a balanced expression of different genes that preserves phenotypic stability. They also provide for differences among cell types within the same organisms and are at the core of the evolutionary process.

Gene Expression in Prokaryotes: A Simple Model of Regulation

The prokaryotic RNA polymerase has a simple structure formed by a core enzyme that mediates RNA transcription

and a factor σ that recognizes the promoter region located 10 to 35 bases upstream to a transcription starting point (11) (Fig. 14.2). Thus, σ factors are the simplest examples of *trans*-acting elements. Once transcription begins, σ factors separate from the core enzyme. Sequential expression of different σ factors promotes the activation of different genes in a cascade of events that modifies the phenotype. During sporulation, for example, σ factor 43 promotes the transcription of specific genes involved in sporulation and the transcription of σ factors E and K that regulate and terminate this process (12). Conversely, intrinsic palindromic regions forming DNA hairpins or other *trans*-acting elements termed *p factors* that bind to the core enzyme can terminate transcription by the RNA polymerase. In addition, natural σ factor competitors, such as pN, NusH, or NuH6, can maintain RNA polymerase in an inactive state (13).

Therefore, gene expression in prokaryotes is controlled by balanced initiation and termination of transcriptional signals and by the specificity of different σ factors. However, this simple organization cannot provide for highly coordinated profiles of gene expression. This is achieved by physical alignment of clusters of genes termed *operons* behind the same promoter that enables sequential synthesis of proteins that are functionally related (14). The *lacZYA*, for example, is a classic operon that codes for proteins involved in the β -galactose metabolism (breaking, transport, and acetylation of galactose) and is under the negative control of the *lacI* gene that encodes for the *lac* repressor (15). The repressor maintains the operon in the inactive state until it is inactivated by end-products of galactose metabolism (16). In this way, transcription of enzymes responsible for galactose metabolism is activated only in the presence of galactose in a highly efficient and ergonomic manner. The *lacZ* gene is frequently inserted in recombinant bacterial plasmids, allowing colorimetric detection of colonies containing exogenous DNA material (Fig. 14.3).

Transcriptional Regulation in Eukaryotes

Three general principles govern the control of gene transcription in eukaryotes:

1. Unlike prokaryotes, genes operating within the same metabolic pathway are not usually physically aligned along genomic DNA and are often located on different chromosomes.
2. Recurrent structural motifs in DNA-binding domains (enhancers and promoters) indicate that the expression of functionally related genes is achieved by the activation of shared classes of transcription factors rather than by unique, gene-specific regulatory proteins.
3. Transcription factors are often involved in developmental regulation.

The eukaryotic type II RNA polymerase differs from its prokaryotic ancestor by the complexity of transcription fac-

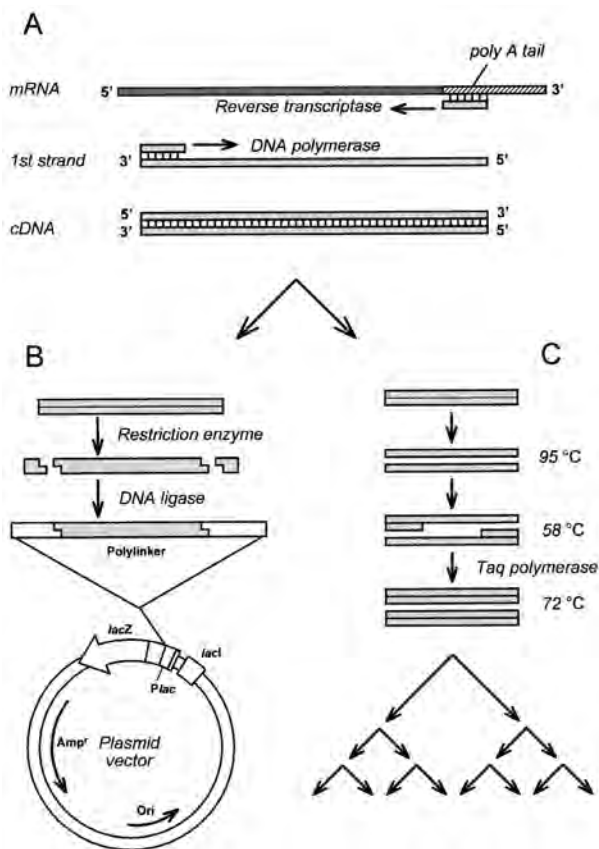

FIGURE 14.3. Basic enzymes and techniques in recombinant DNA technology. The figure summarizes basic procedures used in routine laboratory experiments. **A:** Messenger RNA (mRNA) molecules are reverse-transcribed into complementary DNA (cDNA) using the enzyme reverse transcriptase to synthesize the first cDNA strand, which is then used to generate double-stranded cDNA using a DNA polymerase. Both enzymes require priming with complementary oligonucleotides. **B:** cDNA and other DNA molecules can be amplified in bacteria after insertion into plasmids using restriction enzymes and DNA ligase. Recombinant plasmids generally contain a polylinker that offers different restriction sites to facilitate the insertion of exogenous DNA. In addition, they are engineered to contain antibiotic resistance genes (Amp^r) for selection of transformed bacteria and often contain other useful genes, such as the *lacZ* in this example, which allows color detection of colonies transformed with "empty" plasmids. **C:** Alternatively, DNA can be amplified by polymerase chain reaction (PCR) with the *Taq* polymerase. Repeated cycles of DNA denaturation (95°C), primer annealing (58°C in this example), and DNA synthesis (72°C) allow for exponential replication of DNA strands encompassed by the two primers. When reverse-transcription and PCR are combined, the procedure is referred to as *RT-PCR*.

tors that are required for its activation (17) (Fig. 14.2). This elaborate modular system allows for flexible and highly coordinated regulation of gene transcription.

On transcription, DNA rearranges to allow interaction between transcription factors located at the promoter and at the enhancer site. The TATA box, which contains consensus sequences recognized by general transcription factors (TFIID, TBP, and TAF), is usually located approximately 24 bases upstream from the promoter and acts as a bridge

that holds together the enhancer-promoter-RNA polymerase complex and positions the enzyme at the starting point of transcription (18). Although enhancers are not essential, they increase promoter efficiency.

A second major characteristic of transcription in eukaryotic cells is related to the association of nuclear DNA with histones, forming nucleosomes. This particular organization prevents interaction between regulatory sequences and transcription factors unless conformational changes of the chromatin permit gene activation (Fig. 14.2).

It is suggested that chromatin remodeling is achieved by specific energy-dependent reactions that displace nucleosomes along the DNA strand. Alternatively, histone acetylation is thought to inactivate the natural binding of histones to DNA, allowing nucleosome remodeling, binding of transcription factors, and functional interactions between enhancers and promoters (18,19). This view is supported by the fact that histone acetylation correlates with the state of activation of gene expression.

Finally, gene transcription can also be chemically blocked in eukaryotic cells by methylation of specific DNA regions located near the promoter. Experimentally, the state of DNA methylation can be determined by inhibition of the nuclease activity of restriction enzymes, such as *HpaII*, that recognize non-methylated GC doublets.

Transcription Factors

The major characteristic of transcription factors is to contain specialized domains that allow for DNA interaction. Zinc-fingers, helix-turn-helix (HTH) domains, helix-loop-helix domains, and leucine zippers are examples of DNA-binding domains that are encountered in more than 80% of transcriptional factors (20).

Zinc-finger motifs are composed of a Zn ion holding together a peptide loop (the finger) through interaction with two histidines and two or four cysteines. The functional DNA binding domain is located in the amino acid residues at the base of the finger and recognizes specific consensus sequences that are generally located in the enhancer region. Steroid receptors are the most popular examples of this class of transcription factor, including glucocorticoid, mineralocorticoid, androgen, progesterone, thyroid hormone, and vitamin D receptors (21). Increasing evidence implicates the involvement of steroid receptors, such as the proto-oncogene *bcl-6* or *WT1*, in cancer (22).

Similar DNA binding activity characterizes other classes of transcription factors. HTH domains are often found in proteins that have key roles during morphogenesis such as the homeobox group of transcription factors (23). Members of the helix-loop-helix class include proteins that control myogenesis, such as *MyoD*, that have been implicated in the *trans*-differentiation of myofibroblasts, which promote renal fibrosis (24). Leucine-zipper motifs are used by the Jun and Fos proteins. Both are members of the AP-1 heteromeric

transcription complex that is involved in cell proliferation and regulation of cell matrix during fibrogenesis (25). An important transcription factor that is often implicated in renal diseases is nuclear factor- κ B, which regulates many proinflammatory pathways and is itself under the control of other proteins, such as angiotensin II, known to promote inflammatory reactions in the renal parenchyma (26).

Transcriptional Control during Development

As discussed above, transcriptional regulation plays a central role during development by governing complex sequences of events that transform undifferentiated embryonic cells into highly specialized mature cells (3,9).

Three major classes of developmental regulatory genes have been identified. These include maternal genes, segmentation genes, and homeotic (Hox) genes. Each is expressed at different stages of cell maturation following complex sequences of activation in which gene products that are expressed at a given stage activate genes at a following stage. This highly sophisticated sequence of events creates a hierarchy according to which maternal, segmentation, and homeotic genes are expressed sequentially.

Four maternal systems activate the expression of specific transcription factors, termed *morphogens*, that are responsible for the initial patterning of the embryo. Segmentation genes are zinc-finger proteins that control the boundaries of compartments, whereas Hox genes control the differentiation steps of each segment. Hox genes are characterized by a common HTH-type DNA-binding motif at their carboxy-terminus termed *homeobox* and are organized in the human genome in four different clusters (A,B,C,D) containing up to ten genes each.

As the number of identified developmental transcription factors is rapidly increasing, their impact on renal development and involvement in congenital renal anomalies is a field of active research, as detailed in Chapter 1. Moreover, during the recovery phase of renal cell injury, cells reactivate several developmental genes in repair and restoration of function (27). Strategies to stimulate these patterns of expression are being investigated to promote early recovery from acute injury (28,29).

Messenger RNA Modification and Splicing

During cleavage and processing of primary RNA transcripts, the RNA molecules are capped at their 5' origin by the addition of methylated G nucleotides, and a segment of poly-A residues is attached near their 3' end (Fig. 14.1). These modifications are necessary to allow the export of the transcript from the nucleus, to stabilize mRNA molecules, and to allow interaction with ribosomes. The presence of a poly-A tail is a major characteristic of mRNAs and constitutes a key tool to isolate mRNAs from other RNA molecules, mostly ribosomal, using complementary oligo-dT primers.

Before RNA is exported into the cytosol, splicing of intron segments should be performed. The exact function of introns remains unclear. Because they facilitate recombination events, they have played a major role in the evolution of species and are often targeted in the process of generating knockout animals. Their physical structure may be more important than their actual nucleotide sequence, as these diverge more rapidly between species than exons (30).

Introns can range in size from 80 to several thousand nucleotides. They contain specific sequences at their extremities referred to as the 5' *splice site* (always ending with 5'-GU-3') and the 3' *splice site* (always ending with 5'-AG-3') that come together in the process of splicing. During splicing, a large catalytic heteromeric complex, termed *spliceosome*, is formed by the assembly of different ribonucleoproteins (31). After RNA binding, spliceosomes bridge together two exons and excise their intron segment.

In the majority of genes, each 5' splice site pairs with the closest 3' splice site in the spliceosome, producing only one form of mRNA. In some cases, however, splicing of RNA enables a single gene to produce different mRNA transcripts by jumping from a given 5' splice site to a more distant 3' splice site (Fig. 14.1). Each of these mRNAs yields different isoforms of the same protein that can be alternatively produced in different types of cells.

Recent genome-wide analysis of alternative splicing indicates that 40 to 60% of human genes have alternative splice isoforms (32), including molecules involved in kidney diseases such as angiotensin-converting enzyme and nephrin. Splicing of mRNA is an important regulatory step in the production of cell proteins that requires a high degree of accuracy. One pressing and still inadequately answered question is the functional meaning of these alternative transcripts. In general, DNA mutations that involve splice sites (splice site mutations) do not prevent splicing but instead cause the normal partner to seek alternative splice sites, producing the synthesis of various abnormal proteins lacking one or more exons, as, for example, in Frasier syndrome (33).

Translation of Messenger RNA into Proteins

Mammalian ribosomes are the site of mRNA translation and are composed of two asymmetric subunits, the 40S that binds mRNAs and the 60s that interacts with transfer RNAs. The genetic code is housed in the transfer RNA molecules that associate specific codons with the corresponding amino acid.

Eukaryotic cells can decrease their rate of protein synthesis in various conditions such as infections or heat shock. One important mechanism that mediates these types of nonselective responses involves phosphorylation of a repressor protein termed *eIF-2* that interacts with target regions containing the AUG start codon preventing ribosomal binding.

A second gene-specific mechanism of translational regulation is termed *attenuation* and involves the formation of mRNA hairpins that block the translation. Similar mechanisms also regulate mRNA stability and degradation by RNases. Given the fact that each molecule of mRNA can serve as a template for multiple copies of proteins, the rate of mRNA degradation is a major determinant of protein abundance and is often the site of complex regulatory processes. In general, these processes operate primarily on unstable mRNAs (such as cytokines) that are stabilized under specific conditions by their interaction with *trans*-acting elements (34). The stability of transferrin mRNA, for example, increases during iron deprivation, triggering the synthesis of more transferrin molecules (35).

Protein Sorting and Degradation

Newly synthesized polypeptides are processed by a complex network of cellular enzymes and other binding proteins that are arranged in a highly organized fashion in various organelles in the cell. Information resident in the primary amino acid sequence as well as the folded structure of the proteins allow each to be recognized and targeted to its ultimate destination (3,9). Proteins that are synthesized in free cytosolic ribosomes are normally directed to the nucleus or to the mitochondria, whereas membranous ribosomes are the site of synthesis for proteins that enter the reticuloendothelial system (cotranslational transport) to be redirected to their final destination after being processed in the Golgi apparatus. An excellent example of this process is highly polarized epithelial cells in renal tubules. In these cells, transport proteins are located specifically on the apical or basolateral plasma membranes. This arrangement enables epithelial cells to perform net transport of solutes and water to either secrete or reabsorb fluid.

Some proteins are able to self-assemble by spontaneous interaction among reactive amino acid groups, whereas other proteins require the assistance of chaperon molecules such as the Hsp70 system and chaperonins. These molecules control the accessibility of reactive groups and maintain the peptide in a relatively flexible state until it reaches its final conformation.

The final fate of most cell proteins is degradation into proteosomes. A process called *ubiquitination* that involves covalent linkage of small peptides called *ubiquitins* to target proteins precedes this step. Ubiquitination is also involved in important signal-transduction pathways, such as the nuclear factor- κ B pathway, in which inhibitory subunits are degraded after stimulatory signals and activate various signaling cascades (36).

RECOMBINANT DNA TECHNOLOGIES AND PROTEIN ANALYSIS

When reduced to its basics, molecular biology has until recently addressed two major objectives; namely, to identify genes and to analyze their function. With the completion of

the human genome project, focus is gradually shifting from the first to the second goal and the more complex task of delineating complex patterns of gene expression. In the following sections, several recombinant DNA technologies are described to illustrate common experimental procedures that are routinely used in molecular diagnostics as well as basic research. A few examples of new, promising approaches are also provided.

Basic Recombinant DNA Technology

Hybridization and Detection of Nucleic Acids

The pairing of nucleotide bases in DNA and RNA allows a wide variety of specific recognition processes both *in vivo* and *in vitro*. These not only form the basis of many critical cellular functions but also provide the molecular biologist with tools to detect and study single genes. Based on specific hydrogen bonding arrangements, G pairs with C and A with T or U.

The extraordinary specificity of nucleic acid-base recognition has been exploited in the process of hybridization of complementary DNA or RNA *in vitro*. Under appropriate conditions, a unique nucleotide sequence present within a complex mixture of nucleic acids can be identified with a resolution of greater than one part per million (37). Using standard techniques, DNA or RNA is isolated from cells or tissues, stripped of proteins, and denatured into single strands. When incubated under conditions favoring renaturation, complementary sequences again reassociate. The experimental conditions (commonly temperature and salt concentration) can be altered to allow for only perfect or nearly perfect sequence matches. This is called *stringency*. Lowering stringency conditions is sometimes desirable to identify close relatives of particular nucleotide sequences. Thus, one can search for a gene or mRNA in kidney that is a close relative of a transcript expressed in other tissues as well as species (38,39).

Nucleic acids are commonly fractionated by agarose gel electrophoresis. Under these conditions, the agarose acts as a molecular sieve, retarding larger strands while allowing smaller strands to migrate in the electric field placed across the gel. Fractionated DNA or RNA is then eluted from the gel or transferred to a filter and exposed to a labeled DNA probe. When the filter contains DNA, this process is called a Southern blot (40), whereas it is called Northern blot if it contains RNA (41).

This same procedure has also been adapted to tissue sections to localize the expression of mRNA transcripts by specific cell types within a complex organ such as the kidney. This technique is called *in situ hybridization* (42).

Binding of specific DNA sequences to DNA or RNA species can also occur in solution. One example is protection of specific mRNA transcripts from digestion by S1 nuclease via hybridization (43). This technique, referred to as *S1 nuclease protection assay*, is more sensitive than standard Northern blotting.

Restriction Endonucleases

In eukaryotic chromosomes, strings of DNA are several million bases long. The discovery by Arber in 1962 of bacterial nucleases that cut DNA molecules at specific locations constitutes one of the cornerstone steps in the development of recombinant DNA techniques (44).

Most restriction enzymes recognize palindromic DNA sequences, meaning that the 5' to 3' sequence in the upper strand is identical to the 5' to 3' sequence in the lower strand. To date, nearly 1000 different restriction enzymes have been purified. Each enzyme can produce defined DNA restriction fragments possessing specific nucleotide sequences at each end from any given DNA sample.

With these enzymes, strings of DNA can be isolated, ligated into plasmid or phage genomes, and amplified (Fig. 14.3). Restriction nucleases have also allowed construction of the first detailed maps of various genomes (restriction maps) and are used for allelic discrimination by restriction fragment length polymorphism. In this technique, DNA mutations that modify the recognition sequence for specific restriction enzymes can be identified by the length of the restriction reaction product.

DNA Amplification Using Prokaryotic Systems

The possibility of replicating specific strings of DNA to obtain quantities sufficient for analysis and further manipulation is central to all recombinant DNA technologies. In the early 1970s, work by Boyer and by Cohen provided the first fundamental tools for DNA cloning with the discovery of DNA ligases and the characterization of bacterial plasmids. Plasmids are circular molecules of DNA that replicate in the cytoplasm of bacterial cells (Fig. 14.3).

Specific regions of plasmids not vital for vegetative growth under laboratory conditions can be engineered using restriction nucleases for the insertion of exogenous DNA fragments. When inserted into *Escherichia coli* cells, plasmid genes encoding for antibiotic resistance are expressed, allowing selection of bacteria that have been transformed. During this process, the inserted DNA is replicated along with the rest of the bacterial genome. This technology enables the amplification and characterization of virtually any DNA string of appropriate size. Because bacteria have a mean generation time of approximately 20 minutes during exponential growth and contain often as many as 500 copies of plasmids per bacterium, virtually limitless amounts of DNA can be grown and harvested routinely. Most available plasmids are engineered to incorporate a polylinker corresponding to a portion of DNA that contains multiple restriction sites that facilitate cloning of DNA fragments generated by various restriction enzymes.

Because of their simplicity, DNA is generally cloned into plasmids. The relatively low efficiency of bacteria transformation with plasmids limits their use, however, when generating DNA libraries. In this case, bacterial viruses, such as the *bacte-*

riophage λ , are more advantageously used. The λ phages are composed of a head that contains the viral genome and a tail that infects bacterial cells with high efficiency. Phages can be packaged *in vitro* after insertion of exogenous DNA and are replicated in bacteria.

Both λ phages and plasmids can amplify DNA fragments up to 20 kilobases (kb). They are ideal for cDNA and other relatively small DNA molecules, but are insufficient for large strings of genomic DNA. In these cases, other vectors can be used. These include cosmid vectors, containing elements of both plasmids and λ phages that can accommodate up to 45-kb fragments or bacteriophage P1 housing up to 100 kb of exogenous DNA. If even larger fragments need to be replicated, bacterial artificial chromosomes or yeast artificial chromosomes can incorporate up to 300 or 1000 kb of DNA, respectively (9).

DNA Amplification with Polymerase Chain Reaction

The second breakthrough in DNA amplification was achieved in 1985 by Mullis and coworkers who developed PCR (6). PCR relies on the binding of two priming oligonucleotides that flank a region of DNA to amplify the region located in between (Fig. 14.3). These two oligonucleotides are complementary to the opposite DNA strands. Addition of DNA polymerase results in the synthesis of new DNA. Repeated cycles of denaturation, annealing, and DNA synthesis are performed in a chain reaction such that the newly synthesized strands become templates for further DNA synthesis. This process exponentially increases the number of DNA copies containing the sequence of interest. Modern PCR uses thermostable DNA polymerase species derived from the thermophilic bacterium *Thermus aquaticus* (*Taq* polymerase), which retain activity after being heated to 95°C and obviate the need for addition of fresh enzyme after each round of DNA synthesis and denaturation (45). Several modified enzymes that guarantee more reliable DNA duplication or allow for the amplification of longer strings are also available.

PCR permits selective amplification of minute quantities of DNA, facilitating every aspect of molecular biology research and diagnostics (including forensic pathology), including site-directed mutagenesis, labeling, and sequencing of DNA. Even fixed tissues on slides or small tissue fragments, such as renal biopsy specimens, can provide sufficient material for PCR amplification.

Amplification of Messenger RNA with Reverse Transcription

Many experimental circumstances require direct amplification of mRNAs. Indeed, mRNA transcripts reflect the actual genes that are activated in a cell system and contain nucleotide sequences that can be directly translated into proteins, obviating the tedious task of sorting exon seg-

ments from introns when working with genomic DNA. This process is achieved with a reverse transcriptase derived from retroviruses, which are one major exception to the central dogma, as they harbor their genetic information in RNA molecules that are copied into DNA on infection of host cells. The DNA obtained by reverse-transcription is called *cDNA*, as it reflects the nucleotide sequences of mRNAs (Fig. 14.3). Similar to DNA polymerases, reverse transcriptase requires complementary oligonucleotide priming to begin transcription. Oligo-dT hybridizing to poly-A tails can be used to reverse-transcribe in a nonselective manner mRNA molecules (3,9). In other circumstances, gene-specific primers are designed to amplify selected mRNA molecules. Once converted into cDNA, nucleic acids are often ligated into plasmids or phages or directly amplified by the PCR reaction, a process that is referred as reverse transcription polymerase chain reaction (RT-PCR) (Fig. 14.3).

Sequencing Nucleic Acids

The highly specific binding of small oligonucleotides to DNA also lies at the heart of the dideoxy chain termination sequencing of DNA. DNA sequences are obtained from a uniform population of DNA, generally synthesized in large amounts by expansion in a bacterial plasmid or by PCR. After DNA is denatured, a complementary primer is added. In the traditional manual sequencing, synthesis of complementary radioactive DNA strands is initiated by DNA polymerase after addition of all four deoxynucleotides (dATP labeled with ³⁵S, dGTP, dCTP, and dTTP) in four different reaction tubes containing one of the four dideoxynucleotide analogs of G, A, T, or C. In each reaction, chain termination can occur whenever a dideoxy analog is inserted in the newly formed DNA strand, preventing further extension. After resolution of each mixture of nested DNA fragments by gel electrophoresis, the nucleotide sequence is determined by reading the order of bands in the four lanes of the corresponding autoradiogram. Practically, 300 to 400 nucleotides can be determined with a single manual gel run. This sequence can be extended by construction of other oligonucleotides complementary to a short portion of the nucleotide sequence determined previously (46).

These procedures have been improved and automated. The basic principles behind automated sequencing remain similar to the manual technique. The major difference resides in the fluorescence labeling of one deoxynucleotide in each reaction tube using different dyes. The reaction mixtures are then pooled and separated in a single lane on a sequencing gel or electrophoresis capillary. As the bands advance along the electric gradient, they pass under a laser beam that excites their fluorescence, which is read and analyzed by a computer. Reliable DNA sequences can often be obtained for more than 500 nucleotides per run, and multiple lanes can be read simultaneously by the machine (46).

Analysis of Gene Expression

A critical issue in normal physiology and renal pathophysiology is the determination of the expression of given genes under different cellular and environmental conditions. Classically, gene expression analysis is performed by protein detection with specific antibodies in Western blotting or, when antibodies are not available, by measuring the amount of mRNA transcripts by Northern blotting or with the more sensitive S1 nuclease assay. Densitometric methods have been developed to compare the amount of expressed protein or mRNA with respect to a control preparation. These semiquantitative techniques, however, have severe limitations. They require relatively large amounts of starting material, can only study a limited numbers of genes simultaneously, and require development of specific probes such as antisera. To overcome some of these limitations, other techniques have recently been developed and are briefly reviewed.

Quantitative Reverse Transcription Polymerase Chain Reaction

RT-PCR is more sensitive than traditional Northern blot analysis and requires less RNA. The major difficulty in quantifying mRNA by RT-PCR is related to the exponential nature of the method.

In competitive RT-PCR, an internal standard sharing the same priming sequences as the transcript of interest is added to the mixture and acts as a competitor during the reaction (47,48). The abundance of mRNA is determined by comparing the signal obtained from the target signal with the internal standard. As this method is time consuming and often difficult to set up, it is increasingly replaced by real-time RT-PCR.

Real-time RT-PCR allows detection of products of the PCR reaction as they are being formed (Fig. 14.4). In the modern version of this technique, quenched fluorescent dyes linked to the 5' end of one primer are released by the 5' nuclease activity of the *Taq* DNA polymerase and become fluorescent (49). The emitted light is measured in real time during the PCR reaction and is proportional to the amount of PCR product. The number of cycles required to cross a given fluorescence threshold is inversely proportional to the amount of mRNA present in the original reaction mixture.

Multiplex real-time RT-PCR represents an extension of this technique and is based on differential fluorescent labeling of primers that amplify for different genes. This permits comparison within the same PCR reaction of the relative amount of different transcripts (50). By this method, housekeeping genes that are presumed to be stably expressed serve as internal controls, allowing correction of the results for the amount of RNA that was loaded in the initial sample reaction. Multiplex real-time RT-PCR allows

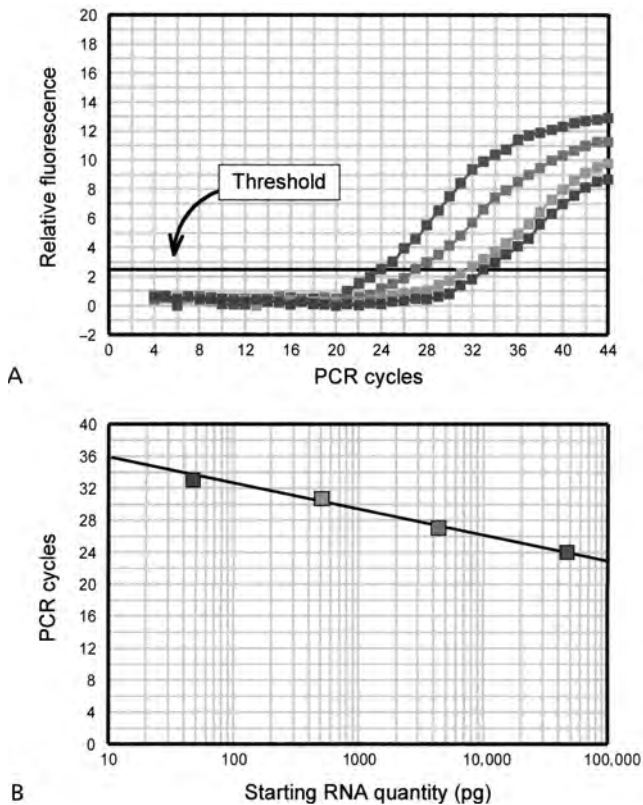

FIGURE 14.4. Real-time reverse transcription polymerase chain reaction (PCR). The figure illustrates an actin calibration curve. Total RNA was extracted from HK2 cells and loaded in increasing concentrations in the sample reaction. Fluorescence was measured in real time as primers were incorporated in newly synthesized PCR fragments with an ABI Prism 7700. The number of cycles required to cross a given fluorescence threshold (**A**) is proportional to the initial amount of loaded messenger RNA (**B**). (See Color Plate 14.4.)

determination of gene expression even from extremely small samples, such as renal biopsies, and has been developed, for example, to detect gene expression in human renal specimens (51).

Differential Messenger RNA Display Using DNA Microarrays

With the identification of increasing numbers of genes, DNA microarray technology has rapidly developed as a valuable technique for comparative gene expression analysis.

DNA chips are composed of thousands of known expressed sequence tags (see Gene Cloning and Analysis of Cloned Sequences) or synthetic oligonucleotides that are deposited in gridded arrays by a robotic spotting device on a solid support such as a glass microscope slide or a membrane matrix. Oligonucleotide sequences are usually directly selected from databases such as GenBank, dbEST, or UniGene (52). As many as 10,000 genes can be spotted on a single microscope slide.

FIGURE 14.5. Differential display on DNA microarrays. Messenger RNA (mRNA) obtained from two different samples are labeled with two fluorescent cyanine dyes with one round of reverse transcription. The fluorescent targets are then pooled and hybridized under stringent conditions to the clones on the microarray chip. The emission light is measured with a scanning confocal laser microscope at two different wavelengths that are specific for each dye. Monochrome images are then pseudocolored, combined, and analyzed with suitable computer software. (See Color Plate 14.5.)

For differential display, two populations of mRNA are labeled with different fluorophores, hybridized to the chip and analyzed with a laser scanning device (Fig. 14.5). The intensity of fluorescence emitted by each dye is proportional to the amount of RNA that has hybridized at a given location, reflecting the level of a gene expression represented by that spot. The enormous quantity of information generated by expression data from thousands of genes

requires sophisticated computer analysis to generate meaningful results (53).

Currently, DNA microarray technology is rapidly evolving. Despite increasing miniaturization and the development of more flexible techniques to generate “custom made” chips, it still has technical limitations, particularly in terms of chip reproducibility and variability in the efficiency of labeling and hybridization. New protocols and technical improvements are solving many of these limitations (52).

The major challenge of this technology is the development of computer-based inferential analysis strategies that recognize patterns of gene expression within complex genetic networks such as the human genome. The so-called cluster analysis is emerging as a powerful statistical tool, permitting the grouping of genes in hierarchical clusters that follow similar patterns of expression. This information can then be used as a molecular fingerprint in diagnosis or in monitoring response to therapy.

Gene Cloning and Analysis of Cloned Sequences

Cloning of genes responsible for genetic disorders can be achieved without prior knowledge of the molecular nature of the disease by a strategy termed *positional cloning*, which is based on the genomic localization of the locus of interest using genetic markers present at a known chromosomal location (54). (See Chapter 19.)

Alternatively, gene cloning is performed by screening tissue-specific collections of recombinant vectors containing sequences of foreign cDNA, called *cDNA libraries* (4). This basic approach can also be refined. Subtractive libraries, for example, are obtained by subtracting unwanted mRNA species from the library before screening (55).

Altogether, the success of any cDNA cloning strategy is related to the quality of the library to be screened and to the efficiency of the probing system that is used.

Since the 1990s, the process of cloning genes has been revolutionized by the creation of electronic databases. More than 53,000 partial sequences of cDNA called *expressed sequence tags* that cover most human genes have been collected (56). In addition, computer programs have been developed to identify putative genes within genomic databases by sorting out and mending together potential exon regions. All of these sequences and sequences from already cloned genes have been collected in databases that can be accessed online (www.ensembl.org and www.celera.com). Taken together, these databases constitute virtual DNA libraries that can be screened electronically using partial DNA or protein sequences. By this method, entire genes can sometimes be identified.

Screening Libraries by Nucleic Acid Hybridization

The object of screening a DNA library is to identify single plasmids or phages containing the nucleotide sequences of

interest. Routinely, 50,000 phages (each containing a unique inserted DNA sequence) are plated on a lawn of bacteria in an agar plate. Phage DNA can be transferred in replicate fashion to a nylon filter and probed with a labeled DNA of interest to identify clones that hybridize with the probe. Individual plaques are picked from the plate, and the cloned DNA insert is characterized. When partial transcripts are obtained, these can be used to further screen libraries in search of overlapping sequences. Alternative procedures, termed *rapid amplification of cDNA ends*, allow the amplification of the missing 5' or 3' ends by RT-PCR (57).

This approach has tremendous flexibility and power. Knowledge of only a partial mRNA or protein sequence allows synthesis of oligonucleotides that can be used as probes. Because of the degeneracy of the genetic code (3,9), it is impossible to specify the exact nucleotide sequence corresponding to a specific peptide fragment. In these cases, mixtures of degenerate oligonucleotides containing several possible sequence combinations are used (58). Cloning strategies can also aim at identifying genes based on their homology with other proteins expressed in other tissues or species. By computer alignment of related sequences, constant regions that have been preserved throughout evolution within the same family of proteins can be identified and used to design degenerate oligonucleotides. By a similar approach, cDNA clones from related genes can serve directly as probes. By lowering the stringency of the hybridization conditions, homologous clones that contain high percentages of sequence identity with the probing DNA can be identified.

Library Screening with Antibodies, with Functional Assays, or by Protein-Protein Interaction

In addition to the use of DNA fragments or oligonucleotides as probes, phage plaques can be screened with antisera raised against purified proteins. Using expression plasmids, peptides encoded by exogenous cDNAs can be directly translated in the bacterial lawn and identified with specific antisera (59).

With a similar approach, phage epitope libraries expressing randomly generated oligopeptides can be screened to find domains recognized by antibodies or by other proteins (60). The recognized epitope sequence generally corresponds to a partial amino acid sequence contained in the natural antigen or binding protein. From this sequence, the protein can be identified or cloned. This technique is particularly powerful for identifying autoantibodies or to clone proteins by their reciprocal interactions such as in receptor-ligand association. The two-hybrid system is an alternative strategy that permits investigators to fish for clones that code for peptide that interact with other proteins offered as bait in the screening process (see Protein-Protein Interaction) (48).

Another powerful approach relies on screening cDNA clones that produce functionally active proteins when expressed in a suitable system. *Xenopus* oocytes have emerged as a favorite system to clone membrane transport proteins. Assays using oocytes have used electrode impalements, patch clamping, and optical or isotope flux techniques. Large quantities of RNA (cRNA) can be synthesized *in vitro* from cDNA libraries, fractionated, and used for injection into oocytes. When the oocyte demonstrates the expected physiologic response, smaller fractions of the original cRNA pool are injected until the process is narrowed down to a single clone (61).

Initial Analysis of Cloned Complementary DNAs

DNA sequences are generally read and entered into a suitable computer program for analysis and storage. Computer programs provide important clues as to the nature of newly cloned proteins, such as structural aspects, including membrane-spanning domains, antigenicity, and the presence of specialized amino acid sequences coding for phosphorylation or glycosylation. Sequence alignment in databases helps define the relationships with other genes and identify functional motifs, such as DNA-binding and protein-binding domains, that can give important clues to the biologic function of the newly cloned sequence (62).

Expression of Specific Genes in Various Experimental Systems

An important aspect of recombinant DNA technology is the demonstration that a clone selected from a library codes for a gene of interest. In cases in which structural analysis of the clone demonstrates a high degree of conservation with another homologous gene or cDNA, expression studies can compare these structural and functional differences. Site-directed mutagenesis studies can further refine knowledge of the function of various portions of a single protein (63).

Bacteria infected with recombinant phage can express polypeptides coded by cDNAs as fusion proteins. These fusion proteins can be purified in large quantities and used for functional studies or as immunogens to raise antisera.

Mammalian proteins expressed in bacteria, however, are not posttranslationally modified. This limitation has been circumvented by use of the baculovirus expression system, in which recombinant proteins are produced by viral infection of cultured insect cells (64). These proteins are then properly processed, glycosylated, and phosphorylated. Yeast has also been used extensively as an expression system (65). Detailed knowledge of yeast physiology and genetics coupled with the ability to mutagenize this organism has enabled detailed dissection of genomic control mechanisms as well as identification of proteins that regulate endocytosis and membrane fusion (66).

A variety of mammalian cells in culture, including green monkey kidney or COS cells, have been used to express vari-

ous cDNAs using retroviral vectors. In these systems, viral promoters initiate and produce high levels of expression of the desired protein. However, such studies are often hampered by the transient nature of the expression of transfected genes. Using the same system, regulatory regions of genes may be transfected into cells and their effects on a neighboring gene determined using a gene product that is easily assayed, such as chloramphenicol acetyltransferase (67).

Sorting and trafficking of proteins within highly polarized epithelial cells of the kidney has been addressed using recombinant DNA technology and cultured epithelial cells such as the MDCK cell line. These cells maintain a polarized morphology and possess distinct apical and basolateral plasma membrane domains. Selective budding of viruses, such as vesicular stomatitis virus exclusively from the apical or basolateral membranes of MDCK cells, has permitted detailed study of the fundamental determinants of epithelial cell polarity (68).

Xenopus oocytes are a popular system to express membrane transport proteins. The cystic fibrosis gene was among the first gene to be isolated without knowledge of its actual function. Oocytes were used to demonstrate its function as an epithelial cell chloride channel (69). Other fundamental membrane transport proteins cloned using *Xenopus* oocytes include Na-H exchangers (70), bumetanide-sensitive Na-K-2Cl and thiazide-sensitive NaCl cotransporters (71), the renal outer medullary adenosine triphosphate-regulated potassium channel (72), multiple aquaporin water channels (73), and the amiloride-inhibitable epithelial Na⁺ channel, or ENaC (74). These data provide molecular links between epithelial cell transport data and the expression of specific genes within individual kidney epithelial cells. In turn, detailed knowledge of these transporter proteins has allowed the identification of specific gene abnormalities in humans that cause inherited disorders of renal tubular function, including nephrogenic diabetes insipidus (75) and Bartter's (76,77), Gitelman's (78), and Liddle's (79) syndromes.

Expression and Suppression of Specific Genes in Animal Models

Single cell expression systems cannot be used to study expression in multicellular organisms in which a gene's expression or lack thereof has complex effects on an animal's development and physiology. For these studies, the introduction and disruption of specific genes into amphibian, insect, and mammalian embryos have permitted studies of gene expression in the resultant offspring.

Xenopus and *Drosophila* embryos have been used to characterize various developmentally specific transcripts governing tissue-specific differentiation (3,9). This research is greatly facilitated by the ability to manipulate various cells of the earliest embryo stages, then transplant them to other embryos and allow them to develop. This research has pro-

duced a fundamental understanding of pattern formation in these animals. Homologs of these pattern genes have been characterized in mammals.

In a similar fashion, transgenic mice have been used extensively to produce a stable transfer of new or altered genes into the germ line of rodents (7). Both the homozygous and heterozygous offspring of transgenic animals can then be studied extensively. Production of transgenic animals involves injection of a new gene (transgene) into the pronucleus of a one-cell stage embryo so that it can integrate into the genome. This embryo is then implanted into a foster mother and allowed to develop. Transgenes are usually passed from parent to offspring. This permits propagation of the new trait. Inclusion of the appropriate regulatory elements of a gene allows study of gene expression in its various target tissues at precise times during the life span of the transgenic animal. This technology has been used on a large scale to determine not only gene functions that are critical to embryo development and survival but also genes that produce specific phenotypes that mimic human abnormalities (80).

Moreover, this technology has been carried one step further through development of gene targeting. Instead of introducing genes into cells, special vectors are designed to disrupt or knock out specific genes in mice. The offspring of these mice possess various copy numbers of the disrupted gene and can be examined using a wide array of anatomic, physiologic, and cellular methods (81).

Protein Analysis and Proteomics

Protein analysis involves protein detection, protein separation and purification, characterization of peptide sequences, and identification of interactive partners. Direct recognition of proteins is usually achieved with specific antibodies after protein separation in polyacrylamide gels (Western blotting) or can be directly performed *in situ* on biologic samples by immunocytochemistry. Antibodies can also be used to pull down or blot specific proteins from solutions, which are then used for further manipulations or are quantified (i.e., by enzyme-linked immunoassays).

Protein-Protein Interaction

One important question in protein analysis is to identify interactions between proteins, which regulate most intracellular signaling and are critical to the assembly of functional peptides. Protein-protein interaction assays have been developed in which labeled proteins are extracted from a crude mixture as they bind to target proteins linked to solid supports. These approaches can be further refined with recombinant DNA techniques, allowing for bacterial synthesis of partial protein fragments that are used as targets to identify specific domains that mediate protein-protein interaction.

The yeast two-hybrid system is also an attractive method based on the modular structure of gene activation, which complements or is used as an alternative to pull-down experiments. In the yeast two-hybrid system, the GAL4 transcriptional activator is often exploited (59). This transcription factor has a DNA-binding domain and an activation domain, both of which must be in close association to activate transcription. By DNA recombinant techniques, two protein sequences acting as bait and target are fused with sequences encoding with one of the GAL4 domains. When expressed in yeast cells, the activation domain and the DNA-binding domain are bridged together if the two proteins interact, thus promoting transcription of a reporter gene. These systems can be used to study interactions between known molecules or to clone new proteins using cDNAs libraries, as mentioned before.

Similar prokaryotic systems have been developed based on the modular structure of bacterial RNA polymerases, in which target and bait cDNAs are fused to either the core enzyme or a σ factor.

Protein-DNA Interaction

Techniques for protein separation also offer an important tool to study protein-DNA interactions. This permits analysis of regulation of DNA expression by transcriptional factors. Such experiments are essential to identify DNA binding sites and have been successfully used to purify and identify a number of regulatory proteins.

The basic principles behind these studies rely on the fact that protein-DNA interaction forms high molecular weight complexes that are retarded during polyacrylamide gel electrophoresis or protected from digestion with DNase (82). In the example shown in Figure 14.6, a nuclear protein extract from cells stimulated with angiotensin II was coincubated with DNA strings containing the promoter sequences of collagen III. As shown, angiotensin II promotes the synthesis of a protein that binds to the ^{32}P -labeled DNA target, forming a macromolecular complex that is retarded in the gel (83).

Protein Separation and Purification

Separation of proteins is another important aspect of protein analysis required as a preliminary step for peptide sequencing or to perform other tasks such as functional assays. These complex sets of experimental procedures need high levels of expertise in protein biochemistry and are generally based on prior knowledge of the physical characteristics of the protein of interest, including size, isoelectric point, and hydrophobicity. The availability of antibodies or specific ligands greatly simplifies the experimental procedures by allowing detection of the final products or the use of alternative strategies such as the above-mentioned pull-down assay.

FIGURE 14.6. Gel retardation assay. The figure demonstrates binding of regulatory nuclear proteins to *cis*-elements in the COL3A1 promoter after angiotensin II (Ang II) stimulation. Nuclear extracts were obtained from Ang II-stimulated cells (Ang II+) and incubated with a ³²P-labelled oligonucleotide (414) that contains sequences +3 to +20 of the COL3A1 promoter. Ang II stimulates the synthesis of a peptide that binds to the target DNA and retards its migration in the gel (lane 2). This reaction can be competed with increasing amounts of nonlabeled, wild-type oligonucleotide (lanes 3 to 5) but not with a cold mutated analogue sequence (414m) (lanes 6 to 8). In the absence of Ang II stimulation (Ang II-), no DNA-protein complex generating gel retardation is observed (lane 1).

In general, protein separation involves prepurification chromatographic steps that are performed with ion exchange, size exclusion, hydrophobic interaction, or affinity chromatography, followed by gel electrophoresis. Since the 1990s, two-dimensional electrophoresis has gained considerable favor. This powerful technique has been the object of major developments and permits fine resolution of proteins. Recent advances based on the use of new sol-

FIGURE 14.7. Two-dimensional electrophoresis analysis. The figure shows platelet proteins resolved in a low polyacrylamide-concentration, macroporous, two-dimensional gel. The initial protein mixture was solubilized with a tri-*n*-butyl phosphate:acetone:methanol solution according to an optimization protocol for high molecular weight proteins (85). Proteins were separated according to their isoelectric points using an immobilized pH gradient (IPG) in the first dimension (*horizontal*) and by their molecular weight (M.W.) in the second dimension (*vertical*). Single spots on the gel represent individual protein species.

vents and macroporous gels also allow for the detection of poorly soluble high molecular weight peptides (more than 150,000 kDa) that cannot be resolved by traditional gels (Fig. 14.7) (84). Moreover, new staining procedures based on silver stains or negative dyes offer increased sensitivity, with detection limits in the nanograms range (85).

Proteomics

One of the challenges of the post-genomic area is the characterization of global patterns of gene expression directly at the protein level. This new field of investigation has come to light in recent years with the combined developments of mass spectrometry techniques, nanotechnologies, and bioinformatics, and is generally referred to as *proteomics* (86). With a similar approach to differential transcription analysis, techniques permitting analysis of patterns of protein expression have been developed.

Although antibodies can only measure the expression of few proteins simultaneously, two-dimensional gels combined with chromatography techniques considerably increase the number of gene products that can be studied simultaneously. The complexity of peptide expression patterns represents, however, a major obstacle in proteomics. In general, the abundance of proteins in biologic samples is

in the range of 10^6 whereas no more than 10^3 different proteins can be visualized even with high-quality two-dimensional gels. For these reasons, the initial step of any proteomic approach requires reduction of sample complexity by preliminary removal of uninteresting components using various affinity strategies.

In two-dimension differential protein display, proteins from different sources are labeled with different fluorescent cyanine dyes and run contemporaneously in the same gel. Similarly to differential display with DNA microarray techniques, the gel is analyzed with a laser beam scanner that measures the emitted fluorescence from each dye after excitation at different wavelengths. Computer analysis determines the relative contribution of the original protein mixtures to every spot on the gel, which correspond to unique protein species. These can then be recognized by their gel migration profile or with antibodies. If unknown, they can be analyzed by mass spectrometry (87).

Alternative new tools for protein expression analysis are also in the process of being developed, based on nanotechnologies. Similarly to DNA chips, recombinant proteins or small peptides containing protein binding domains or specific antibodies can be arrayed on miniaturized protein chips and used as probes to bind other proteins. At the moment, however, a number of technical problems still need to be resolved before protein chips become a reality in biomedical research.

Unlike DNA, peptide sequencing requires highly sophisticated techniques. Currently, mass spectrometry has replaced the classic Edman degradation technique. Femtomoles of proteins extracted from two-dimensional gel or protein chips can be analyzed by mass spectrometry, and different peptides can be detected within the same sample. Protein identification with mass spectrometry is performed with two possible strategies. In the first approach, matrix-assisted laser desorption/ionization (MALDI) provides a peptide mass fingerprint of the eluted peptide mixture under study. The protein composition of the mixture is then derived from the analysis of the mass spectrum. In the second approach, referred to as *tandem mass spectrometry*, the MALDI step is followed by fragmentation of individual peptides into amino acids with a tandem mass spectrometer. Despite being more complex and time consuming, if coupled with electronic databases this approach permits identification of peptides directly from amino acid sequences, which produces more reliable results than peptide mass analysis (86).

IN VITRO METHODS IN RENAL RESEARCH

PATRICIA D. WILSON

Significant advances in the understanding of renal cell function, epithelial cell biology, and morphogenesis have been made in recent years by the application of *in vitro* techniques. The researcher today is presented with a wide choice of *in vitro* models, and the aim of this chapter is to provide not only an overview of techniques available but also sufficient information to allow insight into the advantages and limitations of each system. This provides the experimental pediatric nephrologist with an appreciation of the range of renal *in vitro* methods currently available and allows selection of the most appropriate *in vitro* system to adequately answer the questions posed. For a more complete methodologic review of isolation and culture techniques, the reader is referred to standard tissue culture texts (1–3).

RENAL CELL TYPES AND ISOLATION TECHNIQUES

The kidneys are extremely heterogeneous, predominantly epithelial organs, each containing 1 million nephrons that are highly segmented and composed of many different cell types (Fig. 15.1). Detailed studies of the properties of these individual cell types are needed for the fundamental understanding of normal function and development of the kidney, and progress toward achievement of this goal has accelerated dramatically since 1990.

The initial requirement for the establishment of renal cell culture was the development of reproducible and reliable isolation techniques for individual cell types. The most successful of these are summarized in Table 15.1 and include physical microdissection, size discrimination by graded sieving or centrifugation over a Percoll or other similar gradients, and removal of specific components by immunoabsorption (4–11). Certain fundamental differences between these starting isolates should be stressed. Most of these techniques use an initial period of tissue disaggregation by incubation in collagenase, pronase, or other dissociative enzyme solutions. The length of time and conditions of this incubation determine whether tubule fragments or single cells are obtained. However, enzyme

pretreatment is now considered undesirable because of the resultant damage to cell membrane proteins, such as receptors, and the deleterious effects on cell adhesion properties, which limit viability. For these reasons, physical microdissection of tubules without enzyme pretreatment is often the preferred choice. Many segments of the nephron can be isolated with precision by microdissection, and the ease of dissection is increased by using pathogen-free animals or salt solution-perfused human kidneys. Although physical microdissection of tubules provides the most accuracy, only relatively small numbers of tubules can be obtained from a single isolate because of the limited period of tissue viability. This limitation can be alleviated to some extent by freezing tissue slices in 5% dimethyl sulfoxide-containing medium for subsequent use, but the technique remains time consuming and labor intensive.

If purity is less important than large quantities of cells, the isolation technique of choice is gentle enzymatic digestion and/or calcium chelation (by ethylenediaminetetraacetic acid) of thin tissue slices followed by differential sieving or Percoll centrifugation. These techniques are widely used for the derivation of highly enriched proximal tubule preparations from cortical slices, but no discrimination between S1, S2, and S3 segments is possible in these types of isolates. Similar techniques have been applied to isolate thick ascending limbs of Henle and collecting tubules using cortical, outer, or inner medullary slices. The limitation of compromised cell type purity of this technique can be addressed by the application of a subsequent immunoabsorption step using cell type-specific antibodies. In this case, the quality of the preparation is a function of the specificity of the antibodies used. In addition to tubule epithelial cells, it is also possible to isolate glomerular epithelia by trypsinization and two rounds of sieving to produce pure podocytes (12–14).

There are many obvious advantages to long-term study of defined cell populations *in vitro*. The ability to adapt conditions to allow the proliferation of isolated renal cells *in vitro* has led to a dramatic increase in our understanding of renal cell biology and provides a powerful tool for study of renal tubule function, development, and disease. Most

FIGURE 15.1. Schematic representation of distribution of cell types in the mammalian nephron. All tubule cell types can be isolated by microdissection techniques, and those shaded can be grown as primary culture monolayers in serum-free defined media. Glomeruli can be isolated by sieving and individual cell types grown in culture. Additional cells (not shown) include juxtaglomerular, vascular endothelia and smooth muscle cells, and interstitial fibroblasts of the cortical and medullary zones. tubule isolation techniques have used adult kidneys as starting material, but it has been easy to adapt these basic techniques to the isolation and proliferation of fetal tubules (2).

CELL AND TISSUE CULTURE

Cell and tissue culture techniques have been developed for the *in vitro* proliferation of many of the defined cell types in the kidney. These are summarized in Table 15.2, but for a more detailed survey, the reader is referred to several reviews (3,13,15).

Primary Cell Cultures

Traditional explant techniques, in which small pieces of the whole kidney (separated into cortex or medulla) are chopped and placed into tissue culture media containing serum and cell monolayer outgrowths studied in primary culture, are of little use in kidney research because of the extreme heterogeneity of cell types and the nonselective nature of serum stimulation of growth. These problems stimulated the development of cell type-specific isolation techniques. Significant advances in renal cell biology have been made by the application of

these pure or highly enriched cell populations to defined culture media conditions. This has allowed the production of primary cultures of homogeneous populations of several renal cell types (Table 15.2).

Glomeruli can be readily isolated from mammalian kidney cortex by graded sieving (14), and the differential supplementation of culture media and extracellular matrix to the collagenase digests favors the primary outgrowth of epithelial, endothelial, or mesangial cells. Mesangial cells are the easiest to obtain because they grow on uncoated plastic in Roswell Park Medical Institute (RPMI) medium containing high levels (20%) of serum (16). Endothelial cells require gelatin for attachment and endothelial cell growth factor supplementation in the medium (17), whereas epithelial cells require collagen as matrix and supplementation of the medium with transferrin, insulin, dexamethasone, triiodothyronine, and prostaglandin E2 (18). These cells undergo few passages, and cloning is recommended for purity. Epithelial cells are usually considered to be visceral (podocyte) in origin because Bowman's capsules containing parietal epithelia are removed by the collagenase treatment. However, definitive marker analysis is required to substantiate this assertion (Table 15.3).

Primary cultures of defined renal tubule epithelia have been derived from several species, using a wide variety of techniques. As discussed earlier, microdissected tubules pro-

vide maximum purity and allow discrimination between the S1, S2, and S3 portions of the proximal tubule (19–21). Commonly used and reliable techniques are available for the culture of proximal tubules, thick ascending limbs of Henle's loop, and collecting tubules of cortical and medullary origin, and these are used for the primary monolayer culture of cells of adult and fetal origin. In addition to epithelial cells, renal interstitial fibroblasts can also be cultured with ease from the cortical or medullary explants (22). These are fairly easy to generate because fibroblasts proliferate rapidly in response to 10% serum stimulation, whereas renal epithelial proliferation is inhibited under these conditions. This means that the renal fibroblasts initially present in mixed cell populations from explants eventually overgrow the cultures because of their selective growth in response to 10% serum in simple Dulbecco modified Eagle medium. Subculture with trypsin results in the acquisition of pure preparations of fibroblasts by the third passage, because renal epithelia are more sensitive to the destructive effects of trypsin than fibroblasts (22). Additional cell types, including juxtaglomerular and renal vascular smooth muscle cells, have also been grown in primary culture (34,39).

To assess the validity of any primary culture technique, marker analysis (Table 15.3) is essential because each cell type contains some specific protein(s) *in vivo*. This allows the analysis of both the purity of preparation and the maintenance of the differentiated state *in vitro*. If these criteria are fulfilled, primary cultures are particularly useful for the study of normal cell function. Most cell cultures derived from isolated glomerular or tubule preparations survive a few (three to five) passages but then die out. This is consistent with normal cell properties and is thought to represent the maximal repair capacity of renal cells *in vivo*. This contrasts with neoplastically transformed cells, which possess unlimited proliferative potential and produce tumors *in vivo* and immortal cell lines *in vitro*.

Permanent Cell Lines of Renal Origin

Several permanently growing cell lines of renal epithelia are in current use and can provide a convenient supply of large numbers of cells for the study of polarity, ion transport, and hormone receptor interactions. However, their limitations should be appreciated. Although LLC-PK1, OK, and JTC-

TABLE 15.3. MARKERS OF DIFFERENTIATED CELL TYPES: ADULT

Glomerulus	
Visceral epithelium	Podocalyxin, synaptopodin, podocin, laminin α_5 , integrin α_3 , C3B receptor, angiopoietin, VEGF
Parietal epithelium	Cytokeratin, VCAM1
Endothelial cells	Factor VIII, angiotensin-converting enzyme, Weibel-Palade bodies, acetylated low-density lipoprotein uptake, PDGFB, Tie 2
Mesangial cells	Actomyosin, contractility, angiotensin receptors, kinin receptors, protein kinase C, desmin, PDGFR β
Tubules	
Proximal	Abundant brush border, alkaline phosphatase, γ -glutamyl transpeptidase, isomaltase, leucine aminopeptidase, meprin, aminopeptidase N, dipeptidylpeptidase Na-glucose transporter, Na-amino acid transporter, Na-amino acid transporter, parathyroid hormone receptors, aquaporin-1, midkine, NHE3; CIC5, rBAT, PEX, NBC, hUAT, GLUT-2, villin, 1,25-hydroxy 2D ₃
Thin descending limb of Henle	Aquaporin 1
Thick ascending limb of Henle	No brush border, abundant mitochondria, highest Na-K-ATPase activity, preproepidermal growth factor, ROMK channel, CaSR, Tamm-Horsfall protein, glucocorticoid receptor, osteopontin, NKCC2 (BSC1)
Juxtaglomerular apparatus	Renin
Distal convoluted tubule	Epidermal growth factor, osteopontin, Ca-ATPase, NCCT, claudin 16
Connecting tubule	Kallikrein, calbindin
Collecting tubule:	
Principal cells	Light cytoplasm, few organelles, calcium-binding protein, vasopressin, receptor V2 aquaporin 2, ENaC 11-hydroxysteroid dehydrogenase, mineralocorticoid receptor, AE1, aquaporin 4
Intercalated cells	Dense cytoplasm, many organelles, band 3, carbonic anhydrase II, H ⁺ ATPase, mineralocorticoid receptor
Fibroblasts	
Cortical	Vimentin I; CAM-1; α_1 , α_4 , $\alpha_5\beta$, integrins
Medullary	Vimentin, tenascin

CaSR, calcium sensing receptor; CIC5, chloride channel; ENaC, epithelial sodium channel; GLUT-2, Na⁺/glucose cotransporter; hUAT, urate transporter; PDGF, platelet-derived growth factor; PEX, Na/phosphate transporter; NBC, Na⁺/HCO₃⁻ transporter; NCCT, Na⁺/Cl⁻ transporter; NHE3, Na⁺/H⁺ exchanger; NKCC2 (BSC1), Na⁺K⁺Cl⁻ transporter; rBAT, cystine and dibasic amino acid transporter; ROMK, renal outer medullary potassium clearance; VCAM1, V-cell adhesion molecule 1; VEGF, vascular endothelial growth factor.

12 cells have properties suggesting proximal tubule origin, and Madin-Darby canine kidney (MDCK) cells have some properties of distal tubules, the precise cells of origin of these spontaneously immortal lines is unknown. In addition, like all immortal cell lines, they have undergone genetic drift because of numerous passages, which has led to the loss of some properties and acquisition of other anomalous properties. Therefore, spontaneously immortal renal cell lines (40–46) may not be the system of choice for the study of normal epithelial function, although they have proved invaluable for the study of certain specific proteins, notably transporters, and for analysis of mechanisms controlling epithelial cell polarity. However, their value for studies of renal development is limited.

Immortalized Cell Lines

An important advance in the generation of cell lines for renal research has been the successful application of immortalization techniques using recombinant viral vectors introduced into cells by infection or transfection. Initial studies used oncogenic viruses such as adenovirus or papilloma virus to generate cell lines (47–57) (Table 15.2) such as HEK 293, HKC-8, mIMCD, and HK-2, which have proved to be very useful for several types of studies, not least because they are permissive to transfection. However,

these types of cells also suffer from the limitation that they are permanently transformed with an abnormal proliferative phenotype conferred by the expression of the introduced oncogene.

Conditionally Immortalized Cell Lines

By far the most successful advance made toward the goal of production of large numbers of permanently proliferating but normally differentiated renal cell cultures has been the introduction of a temperature-sensitive (tsA58) allele-containing Simian virus (SV-40) T antigen into defined renal cell types (50,55,57–60). This has allowed for the immortalization by virtue of expression of the integrated SV-40 T antigen at the permissive temperature of 33°C but the differentiation and loss of T antigen expression after 7 to 10 days at nonpermissive, normal temperature (37°C). This technique has been successfully applied either by making cultures from renal tissues from the SV-40tsA58 transgenic mouse (58,61) or by transfection of human renal epithelial cells in culture (50). The latter technique has proved to have a wide use and has been used to conditionally immortalize renal epithelial cells of normal and diseased origin, including human normal fetal and normal adult proximal tubules, thick ascending limbs and collecting tubules, and epithelia from patients with cystinosis and

autosomal dominant and autosomal recessive polycystic kidney disease. By using actively proliferating microdissected renal tubule segments as starting material—6 weeks of neomycin selection and dilution analysis—clones have been isolated with the marker characteristics of their normal renal epithelia of origin (Table 15.4).

Role of Matrix

Studies in several *in vitro* systems have elucidated a major role for the extracellular matrix in the regulation of epithelial proliferation, differentiation, and gene expression (62). *In vivo*, the renal extracellular matrix is made up of the mesenchymal layer of interstitial fibroblasts that secrete types I and III collagen and the thin basement membrane on which epithelial cells rest, composed of type IV collagen, laminin, fibronectin, entactin, and heparan sulfate proteoglycans. Confluent renal tubule epithelial cells *in vitro* also secrete a basement membrane with normal structural and biochemical characteristics (19,63,64). Several of the techniques for primary cultures of renal tubule epithelia include precoating tissue culture dishes with type I (rat-tail) collagen or growth on collagen gels, EHS sarcoma matrix

(matrigel), or amnion. This not only provides adhesion but also produces epithelial cultures with more differentiated characteristics. In addition, cultures of microdissected tubules and glomerular epithelia have an absolute requirement for extracellular matrix. By contrast, cells of mesenchymal origin in the adult kidney (i.e., mesangial and interstitial cells) have no matrix requirement and grow on uncoated plastic.

Role of Growth Factors

Soluble growth factors have long been known to play a major role in the control of cell proliferation. *In vitro*, serum was first used to induce cell growth. However, serum is a complex mixture of proteins, and detailed composition has not been fully elucidated. The value of serum in renal cell culture is that it favors the growth of fibroblasts at the expense of epithelia. In mixed epithelial and fibroblast cell populations, this enables the differential survival of fibroblasts because *in vitro*, after approximately three passages, the epithelial cells have disappeared and fibroblasts continue to proliferate. A significant advance for renal epithelial cell culture was the definition of serum-free growth

factor-supplemented culture media that support the proliferation of renal epithelial cells (65). Modifications of the original formulation have led to the ability to culture most renal tubule epithelia in serum-free media. All epithelia have an absolute requirement for transferrin and proximal tubules are stimulated to proliferate by combinations of dexamethasone (or hydrocortisone) and insulin, although this requirement can be substituted by epidermal growth factor (EGF). Optimal proliferation of thick ascending limb epithelia requires additional supplementation with triiodothyronine, whereas collecting tubules require only dexamethasone and transferrin (19–21). Although it is not surprising that different renal epithelial cell segments with their individual complements of membrane proteins, including receptors, should require distinct hormone supplementation, the precise mechanisms regulating renal cell-type specific proliferation are not fully understood. Because normal renal epithelial cell division is complete before birth in humans, it is thought that the limited ability to proliferate *in vitro* represents a repair response.

ORGAN CULTURE TECHNIQUES

It is often desirable to study tissue and cell interactions, and although this can be accomplished by co-cultures of primary monolayers or cell lines, an alternative is to use an organ culture technique. Such techniques maintain the three-dimensional organization of the tissue of origin, including interactions with endogenous matrix proteins and intercalated growth factors. The emphasis in such systems is to retain viability of tissues rather than to encourage monolayer outgrowth of new cells.

These techniques have proved particularly useful for the study of renal development, because the embryonic organ can be removed and placed in organ culture in which the influence of a variety of inductive factors can be studied in detail. Most studies of this type have used mouse metanephric blastema (66–68), although rat and human renal organ culture have been reported (69,70). Small pieces of tissue or whole embryonic kidneys are dissected and placed on a stainless steel raft or membrane filter apparatus that has been placed in a tissue culture dish. Sufficient tissue culture medium is added to the dish to bathe the tissue from below and form a thin film of media above but not to submerge it. Organ culture techniques have also been used to study mechanisms of cyst formation and regression in normal mouse kidneys and in those cultured from mice with congenital recessive polycystic kidney disease (71,72). This technique is also now being used to microinject recombinant viral reporter-DNA constructs into either the blastema or the ureteric bud to analyze lineage tracing of progenitor cells or the effects of specific gene expression in the developing ureteric bud, respectively.

MORPHOGENESIS AND DIFFERENTIATION: APPLICATION OF *IN VITRO* TECHNIQUES TO RENAL DEVELOPMENT

Mammalian renal development is a complex process that involves the induction of undifferentiated mesoderm to form epithelia (73,74). As described in detail in Chapter 1, the ureteric bud (a branch of the mesonephric duct) invades and is induced to branch by the mesenchyme of the metanephric blastema and in return the ureteric bud induces the undifferentiated blastemal cells to proliferate, condense, and differentiate into primitive renal vesicles, comma bodies, and S-shaped bodies. The exquisite regulation of gene expression necessary to complete this elaborate set of reciprocal interactions is beginning to be understood (75).

Transfilter Techniques

For studies of renal development and nephrogenesis, the most important modification of organ culture, the *transfilter technique*, was first introduced by Grobstein (67) and continues to be used extensively. Metanephric blastemas are attached to a filter suspended above a tissue culture dish or well. To induce nephrogenesis, tissue fragments of ureter or spinal cord can be applied to the undersurface of the filter. Alternatively, the natural inducer, the ureteric bud is left in the blastema of a day 11 to 12 embryonic kidney, and culture on the membrane is carried out in optimized serum-free, supplemented media that can support the normal three-dimensional development of organogenesis in culture for up to 2 weeks.

Progressively refined analysis of the transfilter organ culture system has provided the basis for much of our present understanding of the cellular and molecular events associated with nephrogenesis and has led to an understanding of the complex temporally and spatially coordinated interactions involved. These include cell-cell contact and cell-matrix attachment, allowing regulated migration and cell shape changes as well as appropriate growth factor-receptor interactions regulating proliferation and apoptosis as well as epithelial polarization events associated with renal tubule maturation.

Proliferation and Differentiation of Primary Cultures

Cell culture techniques have been used to study renal development and epithelial differentiation and have included the isolation and culture of S-shaped bodies from newborn rabbit kidneys that give rise to the outgrowth of collecting duct principal cell monolayers (31). More recently, several primary and conditionally immortalized cell lines of normal human fetal proximal and collecting tubule epithelia have been generated from microdissected nephron segments providing a readily manipulatable system for the analysis of epi-

FIGURE 15.2. Phase-contrast light micrographs of confluent primary cultures. **A:** Epithelial monolayer grown from individually microdissected human fetal proximal tubule explanted onto type I collagen-coated plastic plates in Click–Roswell Park Medical Institute medium supplemented with human transferrin, dexamethasone, insulin, and fetal bovine serum (1%). Note elongated spindle morphology.

thelial differentiation, polarization, and transport events (Fig. 15.2). These processes can be particularly well studied when cells are grown on filters suspended in a tissue culture well because there is individual access to the separate culture medium compartments bathing the apical and basal surfaces of the cell monolayer. For instance, the polarized fate of a radioactive tracer added to one compartment can easily be traced by scintillation techniques (Fig. 15.3). These types of studies have been widely applied in functional analysis of normal fetal, adult, and diseased (e.g., polycystic kidney disease) epithelia (76–78). An additional advantage of these membrane-grown cultures is that the differentiated and polarized characteristics of the cells are maximized under these conditions of nutrient access to both basal and apical cell surfaces.

Although much has been learned about induction and differentiation associated with nephrogenesis using the transfilter organ culture system, recent important technical advances provide the potential for more detailed molecular analyses of the underlying processes

of induction and differentiation. Major advances have been made in the development of renal progenitor and ureteric bud cell culture systems. The isolation of normal human renal progenitor cells from 12- to 16-week human fetal kidneys and their dependence on conditioned media from a Wilms' tumor cell line (WT-CM) has led to the identification of a new soluble growth factor activity (midkine) involved in the control of renal progenitor proliferation (79–81). Human renal progenitor cells *in vitro* not only retain the distinctive morphology of renal cortical progenitors but also retain the capability to convert into epithelial phenotypes with appropriate switches in gene transcription and protein expression after withdrawal of WT-CM and addition of serum and/or collagen matrix (82) (Fig. 15.4). Most recently, similar studies have resulted in the isolation and characterization of renal progenitor cells from mouse kidneys and progress is being made in isolating subpopulations of epithelial, and stromal/fibroblast progenitors (D. Hyink, *personal communication*, 2002).

FIGURE 15.3. Schematic representation of *in vitro* system for study of transport and differentiation properties of epithelial monolayers. Cells (C) are seeded at high density on permeable, translucent membranes (M) mounted on a plastic ring and suspended in a tissue culture well. In this way, the medium overlying the apical surface of the cell monolayer (AM) is in a separate compartment from the medium bathing the basal surface of the cell monolayer (BM), which allows addition of radioactive tracer to either the basal or the apical compartment. Loss from that compartment or appearance in the contralateral compartment can be measured by scintillation counting of media aliquots.

FIGURE 15.4. A: Outer cortical region of human fetal kidney of 14 weeks' gestation showing small, round undifferentiated mesenchymal blastemal cells. B: Phase-contrast light micrograph of human fetal nephroblasts *in vitro*, plated on gelatin and grown in serum-free medium containing Midkine from G401 conditioned media (CM). Cells show small round morphology, small overall diameter (4 μ m), large nuclei, and thin rim of cytoplasm with few organelles. C: Light micrograph of differentiated focus of cultured renal epithelial progenitor cells after removal of G401 CM and addition of 10% fetal bovine serum. Note polygonal cells with large overall diameter and extensive cytoplasm. D: Electron micrograph of outer cortical region of kidney in A. E: Electron micrograph of cultured nephroblasts in B. F: Electron micrograph of epithelial focus in C.

TABLE 15.5. MARKERS OF RENAL DEVELOPMENT

Cell type or structure	Markers
Metanephric blastema (undifferentiated mesenchyme)	Vimentin; syndecan; integrins α_1 , α_9 ; collagen I, III; laminin β_1 , γ_1 ; fibronectin; N-CAM; IGF-II; GDNF HGF; c-Met; NGFR; midkine; CRABP; BF2; tenascin; WT1 cadherin-11; Hox All; Hox DII; Six-2; Sca-1; P75NGFR; FGF2; BMP4; PNA+; apoptosis

S-shaped bodies	Laminin α_1 integrin, E-cadherin, syndecan, tenascin, N-myc, NGFR, wnt4, Notch-1
Glomerular pole	Vimentin, WT1, α_3 integrin, podocalyxin, C3b receptor, IGF-II, nephrin B ₂
Tubular pole	γ GT, MDR, α_6 integrin, α_1 -dystroglycan
Fetal tubule epithelia	Cytokeratin, laminin α_1 , collagen IV, α_6 integrin, E-cadherin, desmoplakin, HGF, c-Met, LIM-1, α_1 -dystroglycan
Proximal	Alkaline phosphatase, leucine aminopeptidase, renal peptidase, meprin, MDR, midkine, aquaporin 1, CFTR, cadherin 6
Thin descending limb	Aquaporin 1
Thick ascending limb	Na-K-ATPase $\alpha_1\beta_2$, Tamm-Horsfall protein, osteopontin, L-myc, integrin β_4 , integrin α_2 , calcium-binding protein, E-cadherin, Brn 4/1
Collecting tubule/ureteric bud	Midkine, Wnt7b, PKD-1, polycystin-1, CFTR, Pax-2, carbonic anhydrase, H-ATPase, aquaporin 2, Hox B7, c-ret, calbindin, Pax-2, E-cadherin and DBA+
Fetal glomeruli	Vimentin; integrin α_3 , β_1 ; podocalyxin; C3bR; WT1; ACE
Fetal interstitium/stroma	Vimentin, tenascin, GD-3, ganglioside, IGF-II, FGFa, NGFR, RAR α , RAR β , BF-2

ACE, angiotensin-converting enzyme; ATPase, adenosine triphosphatase; BMP, bone morphogenetic protein; CAM, cell adhesion molecule; CFTR, cystic fibrosis transmembrane regulator; FGF, fibroblast growth factor; GDNF, glial derived factor; γ GT, γ -glutamyl transpeptidase; HGF, hepatocyte growth factor; IGF, insulin-like growth factor; MDR, multidrug resistance; NGFR, nerve growth factor receptor; RAR, retinoic acid receptor; WT1, Wilms' tumor 1.

Differentiation of Immortalized Cell Lines

Mouse metanephric renal progenitor cells have also been transfected with SV-40 T antigen (83,84) and provide a useful system for the analysis of growth factor interactions. Together with immortalized cells derived from the ureteric bud (85), these cellular approaches promise to increase our molecular understanding of proliferation, induction, and differentiation in nephrogenesis.

Marker Analysis

The differentiation process involved in conversion of undifferentiated, nonadhesive, nonpolarized mesenchymal cells into polarized, adhesive, highly specialized renal tubule (and glomerular) epithelia involves several stages of modification under strict temporal control. These include specific matrix (laminin) and receptor (integrin) expression, intercellular tight-junction formation and E-cadherin expression, and segregation of membrane proteins to apical and basolateral domains. This is followed by elaboration of specialized membrane and cytoplasmic proteins, including enzymes, transporters, receptors, and structural components of the brush border and cytoskeleton (86–89). To study such a complex array of events in cell or organ cultures, a series of developmental cell- and stage-specific markers are necessary. Known markers derived from tissue localization studies are summarized in Table 15.5. These markers can be used to characterize a culture system and evaluate its relevance for further study. For instance, in cultures of undifferentiated human and mouse renal progenitors, vimentin and syndecan expression is strong. After differentiation into cells with epithelial characteristics, however, the former are lost, and E-cadherin, alkaline phosphatase, and cytokeratin are highly expressed (79,82), whereas Pax-2 and N-CAM are appropriately, transiently expressed. The use of the renal progenitor cell system for study rests on the fidelity of expression of these markers before and after induction *in vitro*.

Regulation of Differentiation by Matrix and Soluble Factors

The interactions of extracellular matrix (e.g., collagens I, III, IV, and V; laminin; and proteoglycans) with specific matrix receptors such as syndecan and integrins are critically important in nephrogenesis (74,86,87,90). These interactions appear to be of particular importance in establishing cell polarity, a prerequisite for epithelial differentiation, in which laminin α_1 -chain expression and interaction with an epithelial integrin α_6 subunit is required (86,87). An important role for the adhesion protein E-cadherin (uvomorulin) has also been proposed (88). *In vitro* techniques allow the analysis of the influence of matrix proteins on proliferation (64), but few studies have been carried out

in fetal cells. An absolute requirement for collagen has been demonstrated for the attachment and growth of human fetal proximal and collecting tubules, whereas undifferentiated renal progenitor cells not only grow in suspension in the absence of matrix but also require its absence to retain their undifferentiated state.

The action of soluble factors via specific receptors plays an important role in proliferation and nephrogenesis, but studies in transfilter organ cultures were unable to identify a role for many candidate growth factors (90). More recently, however, the combination of embryonic kidney organ culture and cell culture studies has begun to identify important roles for a variety of growth factor ligands, including midkine, neuregulin, fibroblast growth factor, and leukemia inhibitory factor (81,85,91,92).

Establishment of Epithelial Cell Polarity

Reabsorption and secretion in the kidney are the byproducts of vectorial transport—the physiologic hallmark of renal epithelia. This is possible because renal tubule epithelial cells are polarized with asymmetric distributions of membrane proteins on their apical and basolateral membranes. This polar distribution of transporters, channels, and other proteins is a characteristic of fully differentiated functionally competent adult renal epithelia. Polarity is not only a functional characteristic but also reflects structural differences of apical and basolateral membranes. Typically, the apical (luminal) membrane is elaborated into a brush border, although the degree of specialization of microvilli depends on the tubule cell type. The basal membrane is characterized by its close proximity to the secreted basement membrane, which is composed of a thin electron-dense layer and separated from the epithelial cell by a thin electron-lucent zone. Proteins of the apical and basolateral domains are prevented from intermixing by the occluding tight junctional complexes that form a continuous belt between epithelial cells at the apical pole of the cell and serve to prevent intercellular leakage. When renal tubule epithelia are grown in culture, they also establish polarity characterized by formation of tight junctions and segregation of membrane proteins to appropriate apical or basolateral domains. This results in the vectorial transport of ions characteristic of those epithelia *in vivo*. The degree of polarization achieved *in vitro* is dependent on the cell type and the culture conditions. Polarization begins when cells attach to a substrate, which can be glass or plastic but is induced by collagen. Maximal polarization of epithelia is seen when cells are grown to confluence on collagen-coated filter membrane (transwell) inserts in which feeding is from the basal as well as the apical surface.

During renal development, a key feature of nephrogenesis is the conversion of undifferentiated, nonpolarized mesenchymal cells of the metanephric blastema through several stages into polarized, highly specialized tubule and glomerular epithelia. After induction by reciprocal interaction with the ureteric bud, mesenchymal cells first adhere to one

TABLE 15.6. MARKERS OF POLARITY: NORMAL ADULT

Apical	Basal and lateral
Influenza hemagglutinin	VSV G
Alkaline phosphatase	Na-K-ATPase
γ -Glutamyl transpeptidase	Ankyrin
5'-Nucleotidase	Fodrin
Meprin	E-cadherin
Diaminopeptidase IV, meprin	V ₂ receptors
Amino peptidases M, N, P	Epidermal growth factor receptors
Maltase	Insulin-like growth factor-1 receptors
H ⁺ -ATPase	Laminin receptors
Trehalase	Type IV collagen receptors
Carcinoembryonic antigen	HSPG receptors
Na-glucose transporter GLUT2	Integrin α_6
Na-amino acid transporter	Integrin α_2
Na-H exchanger NHE3	Integrin β_1
Aquaporin 2	Integrin β_4
Na ⁺ K ⁺ 2Cl ⁻ symporter	Cl/HCO ₃ transporter, AE1
Urate transporter	AQP 4

AQP, aquaporin; ATPase, adenosine triphosphatase; HSPG, heparin sulfate proteoglycan.

another in the condensate stage and then begin to establish polarity in the vesicle and S-body stages. An important role for the adhesion protein E-cadherin has been suggested (88), and inhibitory antibody studies suggest a critical role for laminin α_1 chain and its receptor $\alpha_6\beta_1$ integrin because these are expressed concomitantly with onset of epithelial polarization (86,87). The formation of occluding tight junctions between cells has also been correlated with the expression of adherens junction and desmosomal plaque proteins, including ZO-1, catenins, and desmoglein (93, 94). Subsequent differentiation into tubule cell types is a result of further insertion of polarized tubule cell-specific membrane proteins. This is particularly marked on the apical surface, which is elaborated into a brush border to provide increased surface area to accommodate an array of enzymes, transporters, and receptors. Table 15.6 shows some typical markers of apical and basolateral membranes in renal tubular epithelia, which might be used to analyze differentiation processes. The analysis of cell polarization events in monolayer primary cultures derived from differentiated renal progenitors will in the future provide a temporal and spatial map of sequential events involved in tubule maturation during nephrogenesis.

EPITHELIAL-MESENCHYMAL INTERACTIONS

The regulation of ordered growth in the developing kidney and the subsequent maintenance of differentiation is a function of reciprocal interactions between the epithelial and mesenchymal components of the organ (95,96). In the embryonic kidney, the mesenchyme provides a pool of progenitor cells that differentiate along epithelial (glomerular and tubule), vascular, and fibroblast lineages, and morpho-

genesis can be studied by embryonic organ culture techniques. Co-culture techniques of epithelial and fibroblast components have also shown the importance of these interactions in the adult kidney (97).

Morphogenesis Assays

Three-Dimensional Gels

Experimental confirmation of the role of mesenchymal and extracellular matrix induction on normal renal epithelia has also been shown by the ability of collagen or reconstituted basement membrane gels to promote the development of three-dimensional tubule-like structures from mouse (inner medullary collecting duct) and bovine (MDCK) collecting tubules (98,99) as well as human, dog, and rabbit proximal tubules (3). When initially seeded into type I collagen gels, MDCK and LLC-PK1 cells form cysts (100,101), the specific polarity of which is a reflection of the responsiveness of the epithelium to inductive signals from the collagen matrix (95,96). Landmark studies showed that co-cultures of MDCK cysts in type I collagen gels with fibroblasts or the addition of fibroblast-conditioned media elicits a tubulogenic effect on MDCK cells in collagen gels that is mediated by hepatocyte growth factor (102,103). These studies have led to the wide use of this technique to further dissect the mechanisms of hepatocyte growth factor regulation (104,105) as well as to elucidate the role of cyclic adenosine monophosphate, protein kinase A, and protein kinase X (106,107). The use of this system is that it provides a robust three-dimensional assay system to analyze the roles of cell-cell, cell-matrix, and cell-soluble factor interactions. The concentration on MDCK cells will most likely in the future give way to the use of more normal cell lines derived from conditionally immortalized mouse and human nephron segments from adult and fetal kidneys.

Embryonic Organ Culture

An increased level of three-dimensional organization and normal cell-cell, cell-matrix, and cell-soluble factor interactions can be achieved by organ culture. Because fetal mouse kidneys can now be encouraged to grow and differentiate relatively normally for periods up to and exceeding 14 days, this system can be used very successfully for analysis by adding growth factors, antibodies, or even antisense to the media or by introducing genes into the organ rudiments. Studies of this type have been instrumental in identifying important matrix and growth factors in the regulation of ureteric bud branching and progenitor cell production including laminin, $\alpha_6\beta_1$ -integrin, sulfated proteoglycans, galectin-3, ganglioside D3, retinoic acid, midkine, EGF, and neuregulin (75,91,108–113).

TABLE 15.7. IN VITRO TECHNIQUES FOR THE STUDY OF CELL INJURY AND DISEASES

Insult or abnormality	Cell type	Species	References
Ischemia (anoxia)	PT, PCT, PST	Human, rat	117
	cTAL, mTAL, CCT	Rabbit	118
Gentamicin	LLC-PK1, PT PCT, PST, CCT	Human, dog, rabbit	119–122
Cyclosporine	LLC-PK1, PCT, PST, TAL, CCT, mesangial, endothelia, vas- cular smooth muscle	Human, dog, rabbit	123–126
Nephropathic cystinosis	T	Human	50
ADPKD	Primary monolayer: epithelia fibroblasts	Human	22,63
	Conditionally immortalized: epithelia	Human	50,55
	Primary monolayer epithelia	Human, mouse	127–130
ARPKD	Conditionally immortalized epithelia	Human, mouse	50,55,131
	Organ culture	Mouse	72
Nephronophthisis	Primary monolayer	Human	132
Wilms' tumor	G401, 5K-NEP, WIT 13, GOS-4	Human	44,133
Renal adenocarcinoma	A704, AHCN RAG	Human, mouse	44
Renal carcinoma	CAKI-1, 2: A-498; RC-1; RCC; CCF-RC1, -2	Human	44,123, 134–136

ADPKD, autosomal dominant polycystic kidney disease; ARPKD, autosomal recessive polycystic kidney disease; CCT, cortical collecting tubule; cTAL, cortical thick ascending limb of Henle; mTAL, medullary thick ascending limb of Henle; PCT, proximal convoluted tubule; PST, proximal straight tubule; PT, proximal tubule.

IN VITRO TECHNIQUES FOR ANALYSIS OF RENAL CELL INJURY AND DISEASE

Renal tubule cell injury *in vivo* can be induced by ischemia, nephrotoxins, genetic abnormalities, or cancer. An understanding of some of the cellular and molecular mechanisms involved is beginning to emerge, in large part because of the use of *in vitro* techniques, as summarized in Table 15.7.

Glomerular Disease

The availability of pure glomerular cell types *in vitro* has led to their use in elucidating cellular mechanisms of disease. For example, glomerular epithelial cells in culture have been exposed to Heymann nephritis antigen and provided experimental evidence for binding in coated pits, patching, capping, and final shedding from the cell surface (114). More recently, the advent of well-differentiated, conditionally immortalized podocyte cell systems from normal mice and their genetically manipulated diseased counterparts has significantly contributed to the understanding of the roles of collagen 4 α 4 in Alport's syndrome, nephrin in Finnish-type nephropathy, and podocin in immunoglobulin A nephropathies (61,115). Glomerular epithelial cell cultures have also been used to demonstrate a role for loss of negative charge and adhesive properties in puromycin aminonucleoside nephrosis. Mesangial cell cultures have also been used as a model system to study diabetes by their isolation

from diabetic kidneys and/or by addition of glucose, transforming growth factor β , interleukin-1 β , or galectin-3 to their tissue culture media *in vitro* (110,116).

Ischemic Injury

Isolated tubules were the first preparations used to study anoxic and ischemic injury *in vitro*. These studies identified a role for increased calcium in postischemic cell death (117). Subsequent studies also showed protective effects of extracellular acidosis and glycine. Molecular mechanisms of cell injury can be studied easily in long-term cultures, but permanent cell lines including MDCK and LLC-PK1 are not well suited for the study of ischemic damage because they have adapted to the relatively hypoxic conditions of tissue culture and are abnormally resistant to ischemic damage. However, primary cultures of rat, rabbit, and human renal tubule epithelial cells retain their sensitivity to hypoxic and postischemic reperfusion injury. They have been used successfully to demonstrate differential tubule cell sensitivity and attenuation of cell death by polyethylene glycol, extracellular calcium restriction, calcium channel blockers, and inhibitors of calmodulin and cysteine protease activities (117,118).

Nephrotoxic Injury

LLC-PK1 and primary cultures of rabbit and human proximal tubules and conditionally immortalized human proximal

mal, thick ascending limb, and collecting tubules have been used to reproduce the characteristics of gentamicin and aminoglycoside antibiotic toxicity *in vivo*. They have demonstrated a major role for lipid changes, including decreased turnover and degradation caused by reductions in sphingomyelinase activity in cellular injury primarily in the proximal tubule (50,119–122).

Cyclosporine toxicity can also be studied in LLC-PK1 rabbit proximal tubule and human proximal, thick ascending limb, and collecting tubule cultures and has been shown to exert differential toxic effects on proximal tubule cells. These toxic effects can be attenuated by extracellular calcium restriction, calcium channel blockers, and cysteine protease inhibition. The mechanism of action may be through intracellular binding to cyclophilin and increased intracellular calcium-dependent protease activity (123,124). Renal vascular effects have also been demonstrated by observation of increased proliferation of endothelial and vascular smooth muscle cells in culture as well as increases in intracellular free calcium in mesangial cells (125,126) that are inhibited by cyclosporine.

Genetic Renal Tubular and Cystic Diseases

The first cell culture system devised for the study of genetic cystic disease was for human autosomal dominant polycystic kidney disease (ADPKD) in which individual cysts were microdissected and grown in primary culture (63). Subsequently, several primary, immortalized, and conditionally immortalized monolayer systems for human ADPKD, human and mouse autosomal recessive polycystic kidney diseases (ARPKD), and nephronophthisis (132) have been established (Table 15.7). Monolayer primary cultures were particularly instrumental in delineating the excessive tubule epithelial cell proliferation, matrix adhesion, and polarity and fluid secretion defects in cystic epithelia (137) (Chapter 35). The advantages of these *in vitro* monolayer culture techniques are the capacity to carry out strict comparisons of normal and abnormal cells, which have allowed structural and functional characterization of the modified phenotype in ADPKD epithelia, compared with similarly cultured normal tubule epithelia of proximal, thick ascending limb or collecting tubule origin. Use of these techniques in combination with *in vivo* studies has identified several abnormalities and determined their functional consequences. Mislocalization of Na-K-ATPase to the apical membranes of ADPKD epithelia is associated with similarly mislocated ankyrin, fodrin, and E-cadherin and a basal-to-apical vectorial transport of sodium, suggesting a mechanism for the secretion of ions and fluids into cysts (138). A mechanism for increased proliferation in ADPKD cyst epithelia is suggested by detection of hypersensitivity of ADPKD epithelia *in vitro* to the mitogenic effects of EGF, apical secretion of EGF into cyst fluids, and mislocalization of EGF receptors to apical cell membranes of

ADPKD epithelia. Similar abnormalities in Na-K-ATPase and EGF receptor proteins have been found in human ARPKD, in *cpk/cpk*, and PKD1 and PKD2 knock-out mice, which is consistent with their fundamental roles in cyst formation in genetically determined polycystic kidney disease. However, ADPKD differs from ARPKD in that cysts are derived from all segments of the nephron, and there are additional interstitial abnormalities, including increased extracellular matrix (heparan sulfate proteoglycan) turnover and overproliferation of fibroblasts (22,64). The identification of the PKD-1–encoded protein polycystin-1 and its localization to cell membranes of normal fetal collecting duct and ADPKD epithelia *in vivo* and *in vitro* correlates with demonstrated abnormal fetal patterns of gene transcription in adult epithelia from ADPKD kidneys. Primary and conditionally immortalized cell lines derived from these cell types provide an essential tool to analyze the precise function of polycystin-1 and to determine the primary effects of PKD-1 mutations (Table 15.4).

In addition to monolayer cultures, organ cultures of embryonic and postembryonic kidneys from cystic and other disease states have provided invaluable information (72). As more mouse models of genetic disease become available and developmental defects suspected, these types of techniques are likely to be used increasingly. Not only will the results from the mutant phenotype be analyzed but also the effects of addition of exogenous compounds or introduction of DNA constructs will allow for *in vitro* testing of potential therapeutic agents.

Culture techniques are also being used increasingly to study mechanisms of disease from genetically engineered mice such as the *orpk* model of ARPKD and the *gy* model of X-linked hypophosphatemia (139). It is to be anticipated that further crosses with the immortomouse (58) will lead to isolation of cells from a variety of mouse models of disease. To advance the study of human disease, the same temperature-sensitive conditionally immortalizing construct was first used to generate a unique model for analysis of nephropathic cystinosis (50), as well as human ADPKD and ARPKD (55). The success of generating immortal cell lines from these human disease states that retain their unique characteristics suggests the general use of this approach for the future. In addition, the ability to generate identical clonal cells will facilitate the detailed analysis of the functional effects of mutations.

Cancer: Wilms' Tumor

Although it has been surprisingly difficult to culture cells from primary Wilms' tumors, some permanently growing cell lines are available for study, the most widely used of which are G401 and SK-NEP. The Wilms' tumor suppressor gene, WT1, localized on chromosome 11p13, is a zinc-finger DNA-binding protein involved in normal renal development, and the deletion of this gene *in vivo* results in

Wilms' tumor formation, and, therefore, cell lines that fail to express WT1 should provide a suitable model system for the study of Wilms' tumor. Four candidates have been described: WIT 13, GOS-4, G401, and SKNEP (Table 15.7). Each has limitations, however. WIT 13 has two different 11p13 deletions (both lacking the WT1 locus), grows slowly, and has fibroblast morphology because it was derived from the stromal component of a Wilms' tumor. GOS-4 and G401 have intact 11p13 regions but fail to transcribe WT1 mRNA, suggesting that the primary disturbance in growth control is related to a mutation in an unlinked gene. It is a consistent finding that primary cultures of Wilms' tumors rarely produce immortal cell lines. Typically, they have been subcultured but could be maintained only for 15 to 25 passages, did not produce tumors in nude mice, and did not demonstrate WT1 deletions.

Renal Cell Carcinoma

Renal cell carcinoma is associated with deletions on chromosome 3p at 14.2. Several permanent cell lines have been derived (Table 15.7), representing adenocarcinoma and clear cell carcinoma with metastatic and nonmetastatic phenotypes. Surprisingly, few studies of cellular abnormalities have been carried out using these lines, which therefore provide an underused source of material for experimental analysis of the tumorigenic renal epithelial cell phenotype.

Interstitial Fibrosis

Interstitial fibrosis is an important manifestation of renal disease and cause of renal functional decline. Experimental analyses of rat cortical fibroblasts implicate increases in α_5 , β_1 , and α_v integrins, as well as nonintegrin matrix receptors and discoidin domain receptors in fibrotic responses (35,140). Using renal biopsy specimens, fibroblasts cultured from interstitial fibrosis and from ADPKD end-stage kidneys have been used to analyze matrix protein synthesis and growth characteristics, providing a new tool for the analysis of inappropriate fibroblast proliferation in response to disease (22).

CONCLUSION AND PERSPECTIVES

The ability to culture pure populations of renal cells has increased dramatically in the last decade, which has led to a concomitant increase in our understanding of renal cell biology. Recent additional progress in conditional immortalization by transfection techniques, the sequencing of the human genome, the generation of genetically engineered mouse models, and improvements in embryonic organ culture technology sets the stage for a new explosion in the application of renal *in vitro* analysis.

ACKNOWLEDGMENTS

I am indebted to Drs. Christopher Burrow, Deborah Hyink, Katalin Polgar, and Jill Norman for continued stimulating discussion concerning the application of renal *in vitro* techniques for studies of normal and abnormal renal development.

ANIMAL MODELS

JORDAN A. KREIDBERG

The use of animal models has been an essential aspect of nearly all areas of nephrologic research since its earliest days. Research on kidney formation and malformation, physiology and pathophysiology, immunologic injury, and tolerance or transplant rejection all depend on the use of animal experimentation. This chapter emphasizes genetic approaches that use animals, as this area has shown the most progress in the development of novel technologies since the previous edition of this book.

INSTITUTIONAL OVERSIGHT

There is increasing public awareness of the use of animals in research and with this comes increasing concern about the appropriateness of the use of animals and whether much of the research that does involve animal models could be accomplished using nonanimal models. Therefore, it is important to note that all animal research in the United States must be evaluated by institutional committees before any experimentation may commence. Furthermore, the U. S. Department of Agriculture provides constant oversight through the use of frequent and usually unannounced visits to animal facilities of research institutions. These regulatory committees and agencies are charged with evaluating animal protocols to make certain that animals are used in an ethical manner, with proper use of anesthetics or analgesics to minimize or eliminate any source of pain during experimentation. They are also charged with verifying that animals are indeed required for the specific research in question, that large animals are not used when smaller ones would suffice, and that the investigators are trained and knowledgeable about proper use of animals. Despite these several layers of oversight, in the end, it is up to the principal investigator to be thoughtful about whether the intended experimental approach will yield sufficiently important and worthwhile results to justify the use of laboratory animals.

GENETIC MODELS

The early 1990s to the present have witnessed an explosion in the use of genetic approaches to understand development and

physiology, and, thus, they receive appropriate emphasis in this chapter. Several genetic approaches are available for use with animal model systems. There are *reverse* genetic systems, in which a gene of interest is mutated using gene targeting or expressed in transgenic mice in such a way to interfere with its normal function. Using *forward* genetic approaches, one starts with a phenotype of interest, which could either be obtained as a spontaneous mutation or from mice treated with a mutagen, and an effort is made to identify the mutated gene responsible for the phenotype. Reverse genetic approaches using gene-targeted or transgenic mice are useful for a wide variety of developmental and physiologic studies in which there is a need to study the function of a known gene. Forward genetic approaches, on the other hand, are mainly used in projects in which the goal is the identification of novel genes.

Gene Targeting

Gene targeting was originally used to introduce a deletion or interruption into a gene of interest, using the scheme shown in Figure 16.1, such that it could be determined whether mice would be able to develop in the absence of that gene's function. In cases in which a gene was shown not to be essential for development, the homozygous mutant mouse might serve as a useful model in which to study the role of a specific gene in a physiologic or disease process. For example, targeted deletions of the *Wt1* (1), *Pax2* (2), *GDNF* (3–5), *Wnt4* (6), and *BMP7* (7,8), among others, showed these genes to be essential for various aspects of early kidney development. On the other hand, the absence of many immunology-related genes does not result in any developmental impairment, but these mice have served as useful models to study the role of the immune system in transplant rejection.

The advent of gene targeting was made possible through the use of two technologies developed mainly in the 1980s. The first was the development of tissue culture conditions that allowed embryonic stem (ES) cell lines to be grown indefinitely in culture while retaining their totipotency (9). ES cells grown in culture could then be introduced into mouse preimplantation embryos or blastocysts and become fully integrated into those embryos such that their descendant cells would give

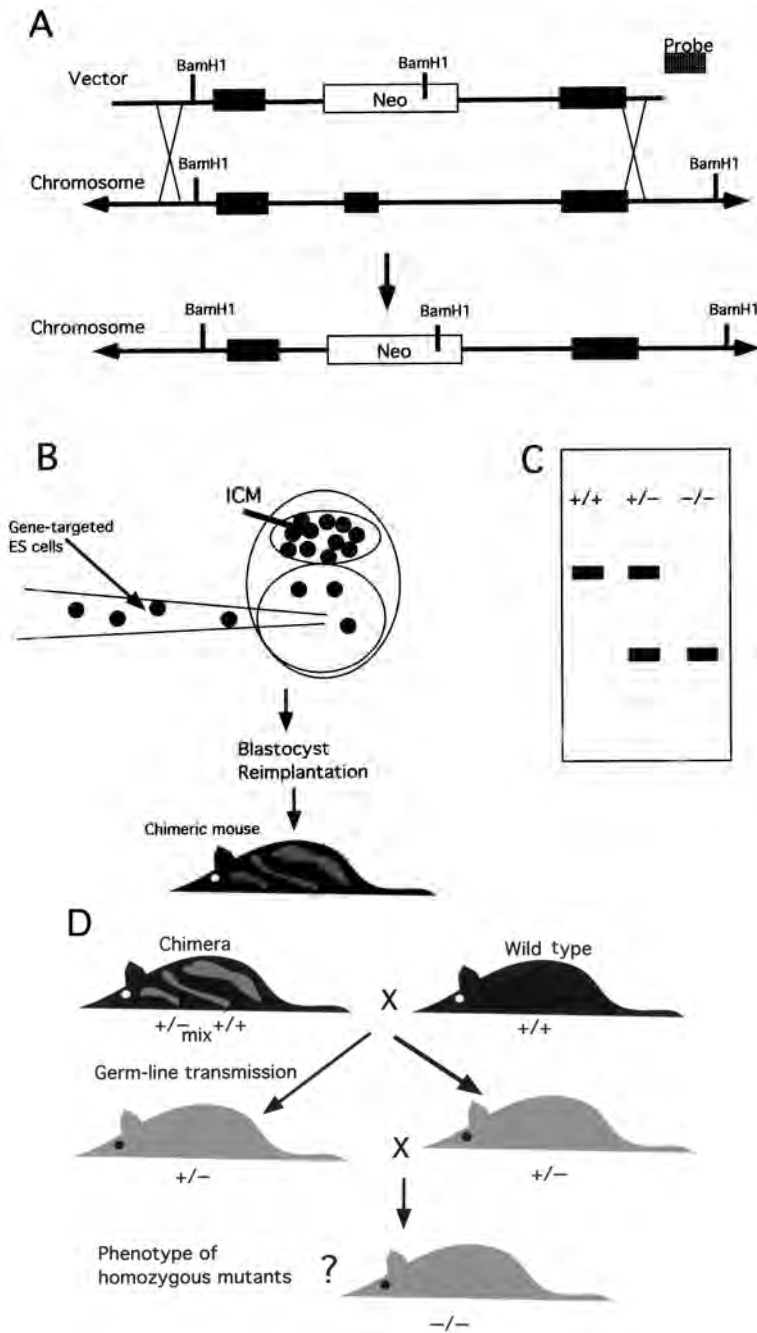

FIGURE 16.1. Gene targeting in mice. **A:** The scheme for targeting a deletion of an exon in embryonic stem (ES) cells. Exons are shown as black boxes along a chromosome. Restriction sites for restriction enzyme BamH1A are shown. The replacement vector is constructed such that the neomycin resistance gene (*neo*) is shown as an open box, in place of one of the exons. An external probe specifically does not overlap with the replacement vector. A double homologous recombination results in the integration of the vector into the chromosome, thus replacing the exon with the Neo gene. The BamH1 site within the neo gene results in a shorter BamH1 restriction fragment detected by probe after homologous recombination. **B:** ES cells can be injected through a micropipette into a blastocyst, in which they become part of the inner cell mass. The injected blastocyst is introduced into the uterus of a hormonally primed mouse and gives rise to a chimeric mouse, partially derived from the ES cells and partially from the original inner cell mass (ICM) cells. If the ES cells and blastocysts are derived from strains with different coat colors, then the chimeric mouse will have a variegated coat color pattern on its fur, providing an indication of its overall extent of chimerism. In the best cases, the resultant mouse is nearly entirely derived from ES cells. **C:** Shows a possible pattern obtained in a Southern blot, based on the scheme shown in A, using the external probe. A wild-type mouse shows only the longer band. A heterozygous mouse shows both the wild-type and gene-targeted band, and the homozygous mutant shows only the shorter band, due to the presence of the BamH1 site in the neo gene. **D:** The mating involved in obtaining germ-line transmission of the mutation and subsequently obtaining homozygous mutant mice.

rise to all developmental lineages that are found in adult mice (10). The second technology involved is the use of homologous recombination to introduce mutations into mammalian genes (11–13). As shown in Figure 16.1, when long stretches of genomic DNA in recombinant DNA constructs are introduced into cells in culture, this DNA will, at variable and often quite low frequency, recombine into the locus from which the genomic DNA was originally derived. Therefore, homologous recombination of the correctly designed genomic fragment can be used to introduce a deletion or insertion into a genomic locus that renders the gene unable to be expressed. This ES cell

would in essence be heterozygous for a mutation in the targeted gene, and heterozygous ES cells can be isolated and expanded to provide a population for injection into blastocysts. Therefore, by combining the ES cell technology and homologous recombination, it became possible to target mutations into genes in ES cells and then introduce ES cells carrying these mutations into blastocysts, finally obtaining a mutant adult mouse.

In a typical experiment, gene-targeted ES cells would contain one mutated allele and one normal or wild-type allele for the gene under study. The targeted ES cells would be injected

into preimplantation blastocysts, and groups of these blastocysts would be introduced into female mice that were previously hormonally primed to allow implantation of the injected blastocysts into their uteri to begin a pregnancy. The resultant mice from these injections are termed *chimeras*, because any specific cell is either derived from an ES cell or the original injected embryo (i.e., the chimeric mouse essentially has four parents, the male and female that provided the blastocyst and the male and female that provided the embryo from which the ES cell line in use was originally derived). In the best cases, a chimera might be nearly entirely derived from the ES cells. Among the tissues that ES cells contribute to are the germ cells: spermatocytes or oocytes. When ES cells heterozygous for a mutation are used to make a chimera, germ cells derived from the ES cells have a 50% chance of carrying the mutant rather than the wild-type allele. Therefore, mating a chimeric and wild-type mice can result in some of the offspring being true heterozygotes for the mutated gene. After obtaining both male and female heterozygotes, they can be mated to obtain homozygous mutant embryos or mice, depending on whether or not the gene is essential for development.

Conditional Gene Targeting

The process described in the preceding section results in the inactivation of a target gene from the beginning of

embryogenesis. In this situation, an embryo will become nonviable at the first point at which expression of the inactivated gene becomes essential for survival. However, it may be highly desirable to study the function of a gene product in many later events during development or adult life. Conditional gene targeting allows the inactivation of a gene in particular tissues or at particular times during development or adult life (14–16). This technology has been developed more recently, and has proved more difficult to use on a widespread basis thus far, for reasons that are discussed next.

The general approach to conditional gene targeting is shown in Figure 16.2. This is a variation on traditional gene targeting, in that it also relies on homologous recombination to introduce a segment of recombinant DNA into the locus of a gene in ES cells. However, whereas traditional gene targeting inactivates the gene, conditional gene targeting must modify the gene such that it can be expressed until such time as its inactivation is desired. The most commonly used approach involved the insertion of LOX sites, which are 34 base pair sites involved in site-specific recombination by Cre recombinase, an enzyme originally derived from a bacteriophage (15). Because LOX sites are rather small, it is usually possible to insert them in introns in which they have no effect on gene expression. By placing two LOX sites in a gene to flank an exon, Cre can be used to inactivate a gene by recombining out the DNA seg-

FIGURE 16.2. Conditional gene targeting. The targeting vector is different from the previous figure in that LOX sites flank the exon that will eventually be deleted, and the Neo gene is flanked by FRT sites. The vector is incorporated into the chromosome through homologous recombination, and embryonic stem (ES) cells with this knock-in are used to make chimeric mice, and germline transmission is obtained. Although the LOX sites should not interfere with expression of the gene, the Neo gene is likely to interfere with normal gene expression. However, in most cases, mice will tolerate one inactive gene, as long as the other allele is functional. After obtaining heterozygous mice, they are mated with Flp-deleter mice, that express Flp recombinase in germ cells. Flp will recombine the FRT sites and eliminate the neo gene. Mice without the neo gene, but still containing the exon flanked by LOX sites, are mated with mice expressing Cre in a particular tissue or cell type, or expressing an inducible Cre, to obtain the conditional knock-out. The breeding scheme shown in the figure is oversimplified. In the actual experiment, a more complicated breeding scheme is required to obtain a mouse that is homozygous for alleles with LOX sites and that also has the Cre-expressing transgene. An alternative is to breed mice with the conditional allele with mice carrying a traditional knock-out. This has the advantage that to obtain the conditional knock-out, Cre must only recombine one, and not two, pairs of LOX sites in each cell.

ment containing the exon that was situated between the two LOX sites, thus inactivating the gene. There are experimental approaches for expressing Cre in temporally or spatially specific manners or both. Spatial- or lineage-specific expression of Cre is most often obtained by placing the Cre cDNA downstream of a known tissue-specific promoter. Sometimes this is achieved by using homologous recombination to insert the Cre gene into the genomic locus of a gene with known tissue-specific expression, such that Cre replaces the first exon of that gene. Temporally, specific expression of Cre has proved more difficult to obtain. One approach is to regulate Cre using the tetracycline system for inducible gene expression (17). The other approach makes use of a fusion protein consisting of Cre and a portion of the estrogen receptor that confers steroid-mediated nuclear localization (18,19). The latter is modified to bind tamoxifen or tamoxifen derivatives instead of estrogen. The Cre-modified estrogen receptor fusion protein will remain in the cytoplasm and therefore not be able to mediate site-specific recombination of LOX sites until tamoxifen is administered to the mouse to induce nuclear translocation of the Cre fusion protein. This system can be used to induce recombination in embryos when tamoxifen is administered to pregnant mice. The major obstacle to using conditional gene targeting on a widespread basis is the availability of promoter/enhancer elements that are able to confer robust tissue or cell-lineage-specific expression of Cre recombinase. For example, in the kidney, there are not promoters available that are able to direct expression of a transgene in every distinct cell lineage or groups of lineages. However, this situation is gradually improving. For example, the nephrin and podocin promoters have recently been shown to confer podocyte-specific expression (20–22), and the upstream region of the aquaporin-2 promoter confers expression in collecting ducts (23).

As more tissue-promoter elements become available, conditional gene targeting promises to have a large impact on genetic approaches to kidney disease. As noted earlier, there are many genes expressed both in the developing and adult kidney, in which the knock-out of the gene results in embryonic lethality. This precludes study of how the product of that gene might function in postnatal kidneys or why a mutation in that gene leads to kidney disease in humans. It also raises the question of why humans carrying such mutations are able survive, albeit with a genetic disease, when mice carrying mutations in the same gene do not survive embryogenesis. Sometimes this is simply because mice and humans differ in their respective requirements for specific genes, but more often, it is because humans with genetic disease often have point mutations that lead to partial loss of function, whereas mouse knock-outs often involve complete loss of function mutations. Conditional gene targeting can sometimes offer a solution to this problem by allowing normal gene expression during embryogenesis and then inactivating a gene in adult mice. Alternatively, there are variations on the Cre-LOX approach that allow the introduction of point mutations into mice. The introduction of point mutations into mice has been greatly facilitated

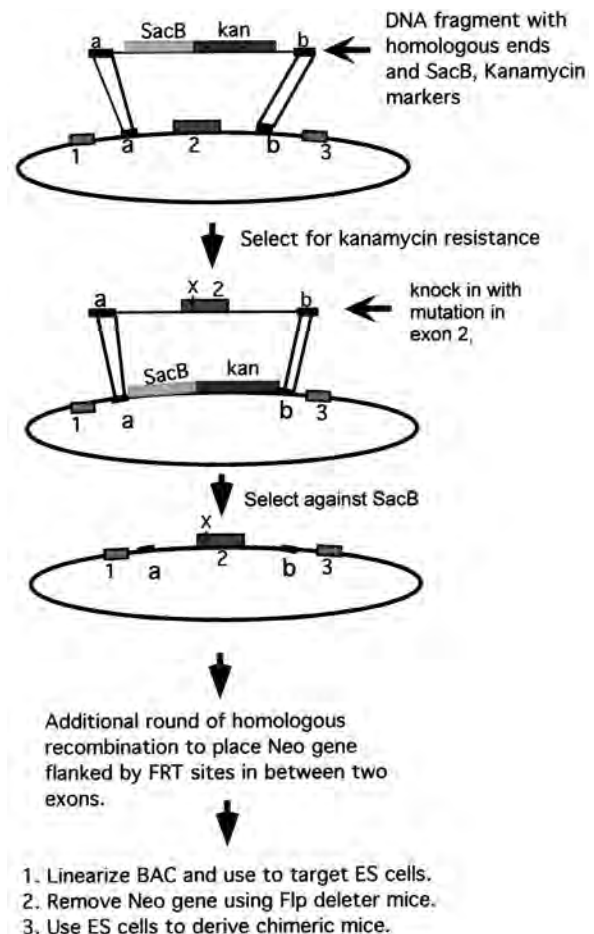

FIGURE 16.3. Gene targeting using bacterial artificial chromosome (BAC) clones. Homologous recombination is done in *Escherichia coli* instead of in embryonic stem (ES) cells. In the first step, a DNA fragment is prepared that contains the kanamycin resistance-positive selectable marker, and the SacB-negative selectable marker, which also contains homologous ends (a and b, each approximately 50–60 bp), is introduced into *E. coli*. This fragment can usually be prepared by polymerase chain reaction, using primers that contain the homologies to the genomic region and also to a vector containing the selectable markers. Usually, a strain of *E. coli* is used that allows transient activation of the enzymes required for homologous recombination. Selection for kanamycin resistance obtains BAC clones where the selectable markers have recombined into the BAC. In a second round of homologous recombination, a DNA fragment with the same homologous ends but containing a mutated exon 2, denoted by the “X,” is introduced into the *E. coli* containing the BAC. Selection against SacB obtains BACs in which the mutated exon 2 has replaced the selectable markers. A third round of homologous recombination is used to insert the Neo gene, flanked by FRT sites, so that the BAC can be used for homologous recombination in ES cells. As shown, this scheme is used to introduce point mutations or small deletions into a gene. It can also be used to construct conditional knock-out vectors, similar to those shown in Figure 16.2. An additional use is to knock-in a green fluorescent protein or β -galactosidase (LacZ) reporter gene into a locus to obtain information about patterns of gene expression.

by recent advancements that facilitate homologous recombination into BACs (bacterial artificial chromosomes) in *Escherichia coli* (Fig. 16.3). BACs are used because they contain large amounts of genomic DNA and, thus, are ideal for use as gene-

targeting vectors. The longer length of BACs compared with shorter genomic clones should improve the frequency of homologous recombination in ES cells.

TRANSGENIC MICE

As mentioned earlier, many mutations that result in human disease are point mutations that result in *hypomorphic*, or partial, loss of function alleles of a gene. In this case, a disease state may result from decreased activity of a gene product. In other cases, a point mutation or deletion mutation may produce a protein that interferes with the function of the normal gene; this is referred to as a dominant negative effect. This could occur in instances in which a protein requires homodimerization for activity, and dimerization of a wild-type and a mutant form of a protein leads to an inactive complex. Dominant-negative effects can also be found in cases in which two proteins heterodimerize, and an inactive mutant protein is able to complex with its partner protein, but the complex is inactive. Dominant-negative effects can be studied in animal models using transgenic mice. Although gene-targeted mice discussed in the previous sections can also be considered to be transgenic because foreign DNA is used to disrupt the endogenous gene, here the term *transgenic* is reserved for those mice in which foreign DNA has been inserted into the murine genome through pronuclear injection. In contrast to gene-targeting schemes in which genes are modified in ES cells and ES cells are then used to derive chimeric mice, in transgenic strategies, DNA is directly microinjected into the pronucleus of a fertilized egg or zygote, and the injected zygotes are then reimplanted into the oviduct of a hormonally primed female mouse. The injected DNA is able to recombine by nonhomologous or illegitimate recombination into random locations within the genome and in variable amounts from zygote to zygote. Once mice are derived from the injected zygotes, they are tested to determine whether they carry the injected DNA within their genomes as a transgene, and if they do, whether the transgene is expressed. By injecting DNA constructs that contain a tissue-specific promoter and a mutated gene of interest, it is possible to study whether expression of the mutant gene leads to an observable phenotype. In other instances, the gene to be expressed is not mutated, and the experiment is designed to determine whether overexpression or *de novo* expression of the gene results in an observable phenotype or disease model.

FORWARD AND REVERSE GENETICS

Forward genetic approaches begin with a phenotype and attempt to identify the gene. These phenotypes may be obtained through mutagenesis screens or from spontaneous mutations identified within a population. In contrast,

reverse genetic approaches start with a known gene and attempt to characterize the phenotype resulting from mutation of that gene. Knock-out mice described earlier are one type of reverse genetic approach; ENU mutagenesis described later is an example of a forward genetic approach. This approach would also be used with spontaneous mutations that affect renal function. In either case, whether or not a mutagen is applied, these projects are designed to lead to the identification of the gene whose mutation is causing the phenotype. Now that the human and mouse genomes have been sequenced, forward genetic approaches may tend more often to assign diseases to previously identified genes than identify the gene outright.

Animal models of disease that have a genetic basis may either result from spontaneous or induced mutations. Spontaneous mutations or phenotypes are those noticed either by chance or through the directed observation of large numbers of mice that were not otherwise treated to induce a mutation. In contrast, induced mutations are those resulting from the treatment of mice with irradiation or mutagenic agents known to introduce point mutations or deletions into the genome. At present, several major efforts in several countries involve the use of *N*-ethyl-*N*-nitrosourea (ENU) to introduce small mutations throughout the mouse genome (24–31). These large genome-scale approaches, which can involve very large mouse colonies, are justified by the following arguments:

1. Most disease-related human mutations are caused by point mutations; therefore, an ENU-mutagenic approach may have a greater chance of producing a phenotype resembling a human disease than will gene-targeted mutations that usually completely inactivate a gene.
2. An ENU-based approach does not rely on previous identification or cloning of the gene (i.e., any gene is a theoretical target and can be studied) to the extent that some degree of compromise in the gene product's activity will result in an observable phenotype. The obvious disadvantage in comparison with gene targeting is that a large amount of work lies between the observation of a phenotype and the final identification of the mutated gene.
3. Given a large enough effort, it should be possible to eventually "saturate" the genome with mutations—that is, examination of several hundred thousand mutagen-treated mice is likely to provide the opportunity to observe the effects of placing a mutation in every gene capable of causing an observable phenotype.

However, one important point remains to be mentioned that dramatically increases the labor and expense of an ENU-based effort. Most observable phenotypes tend to be genetically recessive instead of dominant, meaning that they are not apparent in the first-generation offspring of mutagen-treated mice. Instead, it is necessary to breed a

FIGURE 16.4. *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis. A scheme is depicted for finding recessive phenotypes through ENU mutagenesis. Dominant phenotypes require a less complicated approach, as phenotypes will be apparent in the first generation derived from crossing founders with wild-type mice. In this scheme, a mutagenized male founder that probably carries many mutations after mutagenesis is mated with a wild-type mouse to produce heterozygote offspring that carry a subset of these mutations. These heterozygotes are mated with wild-type mice to produce a second generation, which will carry a smaller subset of the original mutations. These are then mated to the original heterozygous offspring of the founders, and 25% of the offspring of this cross will be homozygous for any particular mutation that was present in the second heterozygous generation.

second generation and then backcross it to the first-generation mice, resulting in a third generation (Figure 16.4). Doing this on a large scale will result in many third-generation mice that are now homozygous for mutations resulting from the original mutagenic treatment, and some will have observable phenotypes that can be studied for biologic interest and to map the responsible gene.

Mapping sites of induced or spontaneous mutations in mice has been greatly aided by the development of sets of microsatellite repeat markers. Microsatellite repeats used in mapping are stretches of CA dinucleotide repeats that are found interspersed throughout mammalian genomes (32,33). Typically, these CA repeats contain 10 to 20 CA dinucleotides. These CA repeats are flanked by unique sequences, and thus it is possible to design pairs of polymerase chain reaction primers that correspond to these flanking

sequences that will amplify the $(CA)_n$ sequence between the two primers. Within a genetically inbred strain of mice, each individual mouse will contain the same number of CA dinucleotides at each repeat. However, similar to the variation observed between human individuals, different inbred strains may differ in the number of CA dinucleotides at any particular repeat. In addition, there are species of mice closely related to *Mus musculus*, such as *Mus spretus*, that provide even greater differences in the number of CA dinucleotides at many repeats than are found between the inbred strains of *M. musculus*. As depicted in Figure 16.5, genetic mapping using microsatellite markers takes the following approach: A mouse (or mice) with a phenotype produced by induced or spontaneous mutagenesis is mated with a mouse from a different inbred strain or from a different species, such as *M. spretus*, to produce F1 mice that are now heterozygous at all loci, containing one allele from each of the two parental strains and one mutant allele. In the case of a recessive phenotype, these F1 mice are now either backcrossed to the original mutant strain or intercrossed among themselves to produce approximately 100 progeny mice, approximately 25% of which can be expected to show the mutant phenotype. For dominant phenotypes, the backcross can be to a wild-type mouse of either parental strain, and 50% will display the phenotype. Importantly, during this back- or intercross, there is independent segregation of chromosomes, such that each individual of the 100 mice is genetically unique, in that at any given locus it may be homozygous for alleles from a parental strain or heterozygous, containing an allele from each strain. A set of polymerase chain reaction primers corresponding to approximately 40 to 50 microsatellite repeats (about two to three per mouse chromosome) are used in the first round of analysis. These are chosen such that the two parental strains are known to differ in the length of the CA repeat between each primer pair. DNA samples are now obtained from all the progeny and are tested for the length of the CA sequence at each of the microsatellites, and these results are correlated with the observed phenotypes (in practice, a computational result, called a lod score is produced). Most of the microsatellites will not be genetically linked to the locus containing the mutation, and there will be no observable correlation between the strain genotype at a particular microsatellite and the presence or absence of the phenotype. In contrast, if a microsatellite marker is sufficiently closely linked to the site of a mutation causing a recessive phenotype, both alleles of the microsatellite marker are more likely to be derived from the parental strain originally containing the mutation. Thus, the goal of the first round of screening is to identify at least one marker that is linked to the mutation. Thereafter, subsequent rounds will use sets of markers linked to the original positive marker, with the expectation that it will be possible to identify a marker or pair of markers very closely linked to the mutation that will delimit the region of a single chromosome on which the mutation is

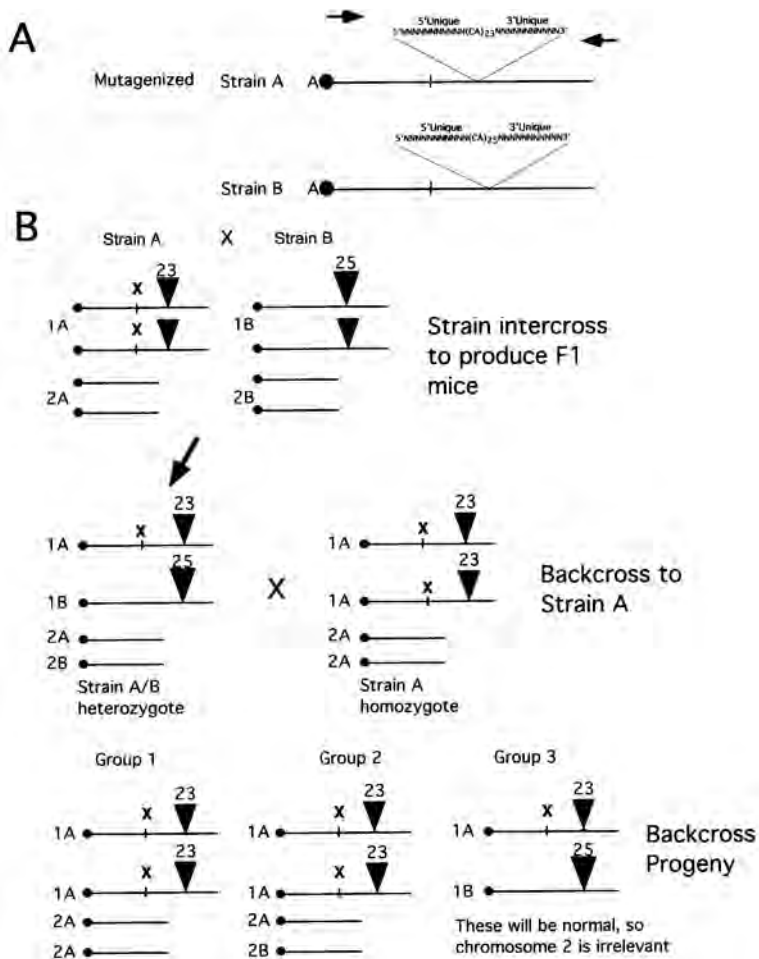

FIGURE 16.5. A scheme for mapping a mutation to a genetic locus. **A:** Depicts the use of microsatellite CA repeats. Strains A and B are two inbred strains of mice that differ in the length of many CA repeats, including the one shown here. Strain A has 23 CA dinucleotide repeats, whereas strain B has 25. They have the same unique 5' and 3' sequences flanking the CA repeats; thus, the same polymerase chain reaction primers can be used for both strains, but amplification will yield a longer product from strain B than A. **B:** The mating scheme to begin mapping the mutation. Only chromosomes 1 and 2 are shown. Strain A has a homozygous mutation on chromosome 1, marked as an "X" that is linked to the CA repeat, here designated by the black inverted triangle. This recessive mutation yields an observable phenotype. Strains A and B are mated to produce an F1 progeny, which will be heterozygous at all loci, including the one mutated in strain A. They will also be heterozygous for all CA repeats, including those on chromosome 2. Thus, any CA repeats that differ between the two strains will yield two bands on a polymerase chain reaction using the flanking unique primers for that CA repeat. F1 mice are backcrossed to strain A homozygotes, and many offspring are examined. Fifty percent of these offspring should be homozygous for X and have the observable phenotype. When these mice are analyzed for the CA repeat close to the locus for X, most mice with the phenotype will show only the strain A amplification product, whereas most of those without the phenotype will show both the strain A and strain B bands. In contrast, amplification of any CA repeats from chromosome 2 or any other chromosome will not show any correlation of strain A homozygosity with the observed phenotype.

located. This can then be used to initiate either a candidate gene approach or a chromosome walking approach to eventually identify the mutated gene. Newer sets of markers include single nucleotide repeats and improved radiation hybrid maps that will also aid in the mapping and identification of mutated genes (34,35).

These forward genetic approaches are not only suited to study developmental anomalies. Some of the large-scale efforts on mouse mutagenesis ongoing around the world involve performing basic blood work, urinalyses, and renal structural studies on each mouse from the group being screened for new phenotypes. Thus, this approach has the potential to identify genes involved in disease progression, as well as those responsible for morphogenetic processes.

GENETIC MODELS IN OTHER SPECIES

The previous discussion focuses on mice as the obvious model for genetic approaches to kidney development or disease. Mice are the most popular model system for genetic approaches, given their long history of study, the availability of many inbred lines, and that they are the most

inexpensively maintained mammal. However, it should be mentioned that other animals may provide advantages that suggest them as an alternative to mice. Zebrafish are much less expensive to maintain than mice, and genetic tools to map zebrafish mutations will soon equal those available for mice (36–38). The zebrafish excretory system involves a pronephric duct and glomus that bears important similarity to mammalian nephrons and has already been the subject of many research studies (39–46). Alternatively, there is often a desire to use genetic approaches in animals that allow more complex physiologic studies than are usually done with mice. Rats provide an alternative, although the availability of genetic markers has not progressed as far as for murine systems (33,47), and they are more expensive than mice to maintain.

ANIMAL MODELS OF KIDNEY DISEASE

The selection of an animal model for some aspect or type of kidney disease takes several factors into consideration. Most important, the similarity to human disease that can be observed in a particular model is taken into account. Other

important factors include the cost of the animals involved: The cost of maintaining animals larger than rodents increases dramatically with size, and the numbers of animals that can be studied consequently decreases. For this reason, some studies may begin with a rodent model, and then progress to a larger model once the rodent model establishes the feasibility of the hypothesis under study. The size of an animal may be important to the extent that it affects the ability to perform surgical manipulations or physiologic measurements. However, because it has become increasingly desirable to obtain physiologic measurements on various strains of knock-out mice, the equipment available to perform these measurements has improved and become commercially available.

MODELS OF RENAL FAILURE

Approaches to the study of renal failure include acute and chronic models. Acute renal failure has been induced using pharmacologic agents, antisera against kidney tissue or other antigens in which immune complex formation leads to glomerular disease (48–54). Ischemia-reperfusion models of acute renal failure, achieved by temporarily ligating a renal artery, allow study of the pathologic processes involved in tubular damage, as well as the effect of various pharmacologic treatments on the pathologic process (55–75).

There is often considerable variability in the response to a treatment among animals of a particular species. For example, different species of rats or mice may respond differently to different treatments. This difference in response is presumably due in a large part to genetic differences between different strains of rats or mice. The identification of so-called modifier genes that are responsible for these interstrain differences may contribute importantly to the understanding of human disease (76–82). Differences among humans in the sensitivity to nephrotoxic agents or differences in the severity of a disease process among different individuals may be due to polymorphisms in these same modifier genes.

MODELS OF IMMUNOLOGIC INJURY

There are many models of autoimmune injury to the kidney. The traditional model for a lupus-like autoimmune disease is the New Zealand black mouse, which has been studied for many years (83–87). These mice develop autoantibodies similar to those observed in humans with systemic lupus erythematosus and other related autoimmune disorders. More recently, many strains of mice carrying mutations in genes involved in the regulation of the immune response have been used to increase our understanding of the role the immune system plays in the onset and progression of kidney disease (88–98). These knock-out strains have allowed investigators to begin a genetic dissection of genes involved in autoimmune and other disorders.

TRANSPLANT MODELS

Animal models have been used extensively to study transplant rejection and in efforts to understand how tolerance to transplanted tissue may be improved. Over the past 20 years, there has been an extraordinary advancement in our mechanistic understanding of the immune function, and this has been brought to bear on the study of transplant rejection and tolerance (99–105). Important models under study include skin and heart transplants in mice and kidney transplants in rats (106–113). In addition, it is possible to produce “humanized” mice by transplanting human tissue into immunodeficient or irradiated mice whose immune system has been reconstituted with human lymphocytes, thus allowing the study of human immune function in an animal model (114–117). One area of research that remains controversial is involving xenografts (118,119). Because the supply of human kidneys and other organs for transplants continues to fall far short of the demand, there is a desirability of determining whether nonhuman animals provide an alternative source of organs for transplantation. The major concerns here include the strong immunologic rejection to a xenograft that must be overcome and the danger that xenografts might serve as vectors for the introduction of novel infectious agents into the human population.

ANIMAL MODELS FOR THE STUDY OF RENAL PHYSIOLOGY

Historically, several animal models have been used to study renal physiology, including swine, sheep, guinea pigs, rabbits, rats, and mice. Fetal lambs have been a particularly important model in which developmental aspects of physiology have been studied, particularly relating to obstructive uropathy (120–132). As alluded to earlier, when genes encoding proteins involved in the regulation of physiologic processes are knocked out, there is a desirability to perform physiologic studies in murine systems to determine how physiologic responses are altered in the absence of a particular protein (133–140). Although gene knock-outs are not yet done in rats, the availability of genetic models and gene mapping of physiologic traits has yielded important information (141–145). The ability to perform sophisticated physiologic experiments in mice has improved dramatically over the past several years, as new equipment has become available (139). As in other situations, there is a constant need to balance the advantages of a large animal model with the lower costs of smaller animal models.

SUMMARY

Animal models are of increasing importance in the study of kidney disease. An important shift since the early 1990s is the use of rodent models and the use of genetic models.

Large animal use remains an important aspect of these studies. The use of large versus small animals must take into account cost and ethical considerations.

CLINICAL INVESTIGATION

SUSAN L. FURTH
JEFFREY FADROWSKI

CLINICAL RESEARCH QUESTION

How can we best evaluate, treat, and assess long-term risks for children with kidney disease? Who is at risk of developing end-stage renal disease (ESRD) in childhood or young adulthood? Clinicians are often faced with questions such as these with uncertain answers in the practice of pediatric nephrology. Parents ask, “Why did my child get this disease?” “What is the most effective method to treat this condition?” “What’s the prognosis of this condition in my child?” Frequently, these answers are not known, and these questions are the inspiration for high-quality clinical research. The first step in developing a valuable clinical study is determining whether the initial query can be translated into a good research question.

Hallmarks of a Good Research Question

A good research question gives *useful* information, is interesting to the researcher, builds on what is known, and can be answered with available resources. Research is a labor of love, demanding attention to detail, perseverance, honesty, and imagination. Developing a good research question is an iterative process. One needs input from knowledgeable colleagues and collaborators. The researcher must become thoroughly familiar with what is already known about the topic by reviewing the literature and consulting with experts in the area. Investigating what is already known has several benefits. First, it can reveal that the candidate research question has already been answered adequately. Second, learning what is already known provides insight into potentially useful methods for addressing a research question. For example, previous studies may demonstrate good ways to measure a variable of interest or provide background information for determining sample size. Third, a literature review may suggest ways to frame the research question at hand. For example, a literature review may reveal that particular modifiable risk factors are consistently associated with a disease process, and an intervention to modify these risk factors may form a sound basis for a clinical trial.

Finally, a good research question needs to be answerable with available resources. These include subjects available for

study, technical expertise of the research staff, and the time and money that can be devoted to the project. Once a question is framed, the researcher needs to outline the study protocol or methods, which include specifying the recruitment method, number of subjects and how they will be recruited, how each variable will be operationally defined, and the plan for data analysis. A poorly designed study is worse than no study at all because, like imprecise measurements and an improper analytic plan, it can also lead to false conclusions.

Steps in Refining a Good Research Question

A good research question usually begins with a broadly stated concept. The initial question is then made more specific by identifying independent and dependent variables. Often, research questions are concerned with causal relationships. *Independent variables* are those conceptualized to be causes; *dependent variables* are those conceptualized to be effects. The research question can be modified to ask about the role of multiple potential causes in leading to the specific outcome. A simple research question asks whether x (independent variable) causes y (dependent variable). More complex research questions could assess the relative importance of x and other variables (e.g., a and b) as causes of y . A different research question might ask how strongly x predicts y in one population versus another.

The next step is to translate a research question into a hypothesis. In our simple example, the researcher may hypothesize that x causes y . In the actual research project, the information collected is examined to determine whether it is reasonable to conclude that x does cause y . In examining the data, the investigator tests the *null hypothesis* that x does not cause y versus the *alternative hypothesis* that it does.

SCIENTIFIC METHOD

A study’s potential value is determined by the relevance of the research question. Its ultimate worth is determined by the study methods. Methodologic issues concern the **study**

design, subject selection, data collection techniques, and the **analytic plan.** Subsequent sections in this chapter discuss each of these aspects. As a foundation, this section describes the concepts of inference, generalizability, and validity.

Inference

As Figure 17.1 shows, scientific research begins with the research question. It then moves (clockwise in the figure) to the controlled arena of the study design and then through the implementation of the actual study and findings. Inferences from the findings in the study approximate the “truth in the study.” From these “truths” we attempt to infer the applicability of the findings to general clinical practice. Researchers describe and explain reality by sampling a portion of it, measuring characteristics of the sample, analyzing the measurements, and interpreting the results. Researchers make inferences from the sample measures of operationally defined variables to the hypothesized relationships of the theoretical constructs in the larger population of interest. Errors in the design or implementation of the study can lead to false conclusions. The strength of inference depends largely on the research methods used in the recruitment of study subjects (sampling) and in the choice and integrity of the study design.

Statistical inference depends on the methods used to define and sample the population. The researcher uses inferential statistics to *extrapolate* the sample findings to the larger population of children from which the sample was drawn. Inferential statistics assume that the studied sample is drawn by probability methods and can be used to make inferences about the larger population. The size of a probability sample determines the certainty of inferences from it. All other things being equal, the larger the sample size, the greater the certainty of inferences to the population.

The researcher’s ability to make a *causal inference* from study results depends largely on issues of study design. Study designs are *observational* when the investigator does

FIGURE 17.1. The role of inference in drawing conclusions from clinical research studies.

not manipulate the risk factor but merely selects children with and without disease and compares them in terms of the risk factor(s). Study designs are experimental when the investigator not only observes but actually manipulates the relationship between two variables. Observational designs provide somewhat weaker evidence of causation, because they fail to rule out explanations other than association between the variables studied. Experimental designs can provide much stronger evidence for causation. In an experimental study, the investigator controls the independent variable, which is the factor hypothesized to produce change in a dependent variable. In an experimental study, subjects are randomized to receive or not receive the independent variable. The goal of the process of randomization is to produce study groups that are “balanced” in terms of other factors that could influence the dependent variable. Unfortunately, experimental designs often are not feasible, ethical, or desirable. Epidemiologic studies of disease preclude manipulation of risk factors in humans. Health services researchers studying the public health impact of changes in health policy rarely can control these changes.

Within the broad categories of observational and experimental designs, there are many variations. These variations, distinguishing characteristics, primary uses, strengths, and weaknesses are discussed in the section Study Design. Study design also influences the validity of study results.

Validity

Validity is the extent to which study findings correctly reflect and explain reality. The concepts of internal and external validity are illustrated in Figure 17.2. As a research question’s relevance increases, so does the need for validity. To some extent, every research question worth answering is controversial because of its implications for policy and practice and because it addresses areas in which existing evidence is scant or contradictory. If a question is not contro-

FIGURE 17.2. External and internal validity in experimental designs. (From Fletcher RH, Fletcher SW, Wagner EH. *Clinical epidemiology: the essentials*, 3rd ed. Baltimore: Williams & Wilkins, 1996:12, with permission.)

versial, there is little need for a scientifically rigorous search for its answer. The clarity and rigor of study design as well as the careful implementation of the research plan increase the likelihood that inferences from the study are valid.

Cook and Campbell (1) define several aspects of validity. *Statistical validity* is the correctness of study conclusions regarding the existence of a relationship between two variables. A study lacks statistical validity when it concludes there is no relationship between variables when in fact there is one or when it concludes there is a relationship when in fact there is none. Statistical validity is jeopardized most often by inadequate sample size and by improper use of statistical tests.

If there is a relationship between two variables, *internal validity* (Fig. 17.2) is the correctness of conclusions about whether the relationship between the operationally defined independent and dependent variables is causal. Internal validity is jeopardized when a study design fails to control for factors that could confound the hypothesized causal relationship.

Finally, given a causal relationship between the independent and dependent variables, *external validity* (Fig. 17.2) is the correctness of generalizing to other persons, settings, and times. Poor choice of a study population and inadequate research procedures are common challenges to external validity.

In summary, the scientific method involves extrapolating inferences from a study situation to the larger world. The value of research depends on the validity of such inferences, which in turn is determined by the researcher's choice of methods. The following sections explain the strengths and weaknesses of the methodologic choices available.

STUDY DESIGN

Observational Studies

There are four major types of observational studies: case series, cross-sectional, case-control, and cohort. Observational designs are weaker than interventional designs in establishing causation, but they are useful when it is not feasible to manipulate the independent variable. Studies of disease etiology usually are observational. In these types of observational studies, risk factors or exposures are the independent variables, and disease is the dependent variable.

Case Series

In a *case series* study, a sample of cases is chosen, and the presence of the risk factor is measured. A case series study is easy to conduct and is useful as a preliminary study to reinforce anecdotal evidence, to generate hypotheses, or to establish variable distributions in planning future research. Case series can sometimes identify previously unrecognized constellations of symptoms or morbidities attributed to exposures to

drugs or toxins. An example of a case series is the report by Furth et al. on diabetes associated with the use of tacrolimus in pediatric renal transplant recipients (2). The authors identified a number of pediatric transplant recipients treated with tacrolimus who developed diabetes. The authors summarized the case histories and reviewed existing literature regarding diabetes associated with immunosuppressive therapy in adult transplant recipients. A case series such as this can provide useful information for the clinician. However, as a method to determine the risk associated with a particular factor, this design is extremely weak because there is no means of comparison. Even if a risk factor is highly prevalent among the cases (in this example, all the cases of diabetes posttransplant had been treated with tacrolimus), there is no way of knowing whether the risk of the disease is greater with exposure to tacrolimus than with exposure to other immunosuppressive medications—for example, cyclosporine or steroids. The case series design cannot provide an estimate of risk.

Cross-Sectional Design

A *cross-sectional study* is one in which the disease and risk factors are measured at the same time in a sample of subjects. Subjects can be categorized as either having or not having the risk factor. Within each group, the presence of the disease can be determined. Analytically, the association between a particular risk factor and the disease is measured as the relative prevalence of the disease among those with, versus those without, the risk factor.

The cross-sectional study design is superior to the case series in that it provides a means for comparison. Cross-sectional studies are relatively economic, easy to conduct, and allow simultaneous examination of multiple risk factors. An example of a cross-sectional study is the analysis of demographic factors associated with rates of hospital admissions for infection in pediatric ESRD patients in the U.S. Renal Data System (USRDS). In this analysis, presented in Figure 17.3, admissions for infection from 1997–1999 for incident and prevalent pediatric ESRD patients were described according to age, race, gender, and ESRD treatment modality (3). In this analysis, the youngest patients were at highest risk for hospital admission because of infection, and dialysis patients were at greater risk than transplant patients.

Cross-sectional studies have a number of limitations. For example, in the analysis of risk factors for hospitalization for infection in the USRDS, patients studied are those with hospitalization data in the USRDS database. These are patients that have survived ESRD long enough to be counted in the database. If they died early after developing ESRD, they may not be included. In addition, because of varying Medicare eligibility criteria (which influences the data available in this particular database), patients who have gone on to have long-term successful kidney transplants may not be included. Therefore, the characteristics increasing risk for hospitalizations for infection in this study may not be generalized to all pediatric

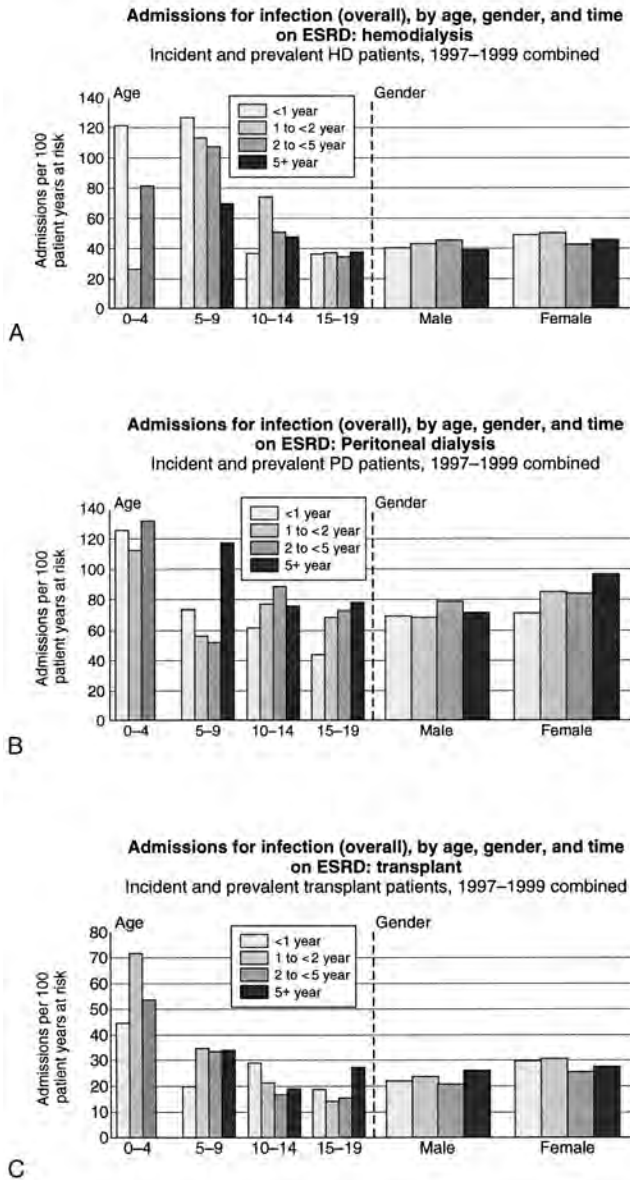

FIGURE 17.3. Cross-sectional study of risk factors for infection in pediatric end-stage renal disease (ESRD). HD, hemodialysis; PD, peritoneal dialysis. (From U.S. Renal Data System. USRDS 2001 Annual Data Report: atlas of end-stage renal disease in the United States. Bethesda, MD: National Institute of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2001:114, with permission.)

patients with ESRD. Studying prevalent patients runs the risk of missing those patients who were “cured” or who died soon after developing the disease. Also, because in cross-sectional analyses the presence or absence of two factors is assessed at the same time, it is not possible to attribute causality.

Case-Control Studies

Case-control studies are also known as case-referent, compeer, retrospective, case history, and cohort studies. A case-

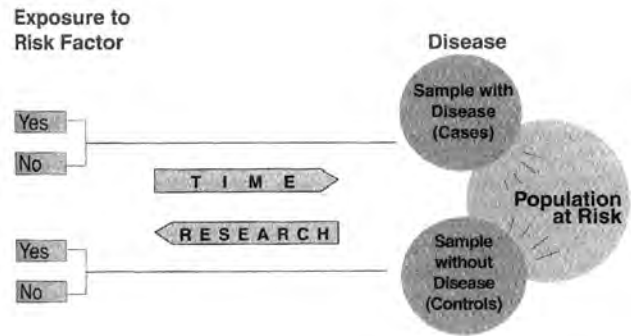

FIGURE 17.4. Design of a case-control study. (From Fletcher RH, Fletcher SW, Wagner EH. *Clinical epidemiology: the essentials*, 3rd ed. Baltimore: Williams & Wilkins, 1996:213, with permission.)

control study starts with the identification of persons with the disease or other outcome variables of interest in the population at risk (Fig. 17.4). A suitable control group of persons without the disease or outcome is also selected from the population at risk. This is pictured on the right side of Figure 17.4. To examine the possible relation of one or more exposures to the given disease or outcome, the researcher then looks back in time to compare the proportions of the cases and controls exposed and not exposed to the risk factor in question.

The case-control design has several advantages. It provides stronger evidence of causation than the cross-sectional design. In a cross-sectional study, outcomes and exposures are assessed simultaneously, and the investigator must infer cause and effect relationships because the temporal sequence cannot be established. In a case-control design, an attempt to establish a temporal relationship between the outcome and exposure is made by starting with a population of persons with and without the outcome and then working backwards to examine suspected exposures. Thus, compared to the cross-sectional design, the investigator is more confident that the exposure of interest came before the outcome, not as a result of the outcome. As compared to other study designs, case-control studies are efficient in the study of rare diseases or those with long latent periods between exposure and outcome. Whereas cross-sectional or cohort designs would require a large number of subjects and time to identify risk factors for a rare disease, a well-designed case-control study can identify similar risk factors with comparatively fewer subjects and much less time and expense. Also adding to the efficiency of the case-control design, several potential risk factors for a disease or outcome can be examined simultaneously.

A recent case-control study by Foreed et al. confirmed the association of acetaminophen and aspirin with chronic renal failure (4). Adult Swedish patients with early-stage chronic renal failure were identified as cases (N = 918) from monthly reports of serum creatinine measurements from medical laboratories. Controls were randomly selected

throughout the ascertainment period from the Swedish Population Register (N = 980). Aspirin and acetaminophen were used regularly by 37 and 25%, respectively, of the patients with renal failure and by 19 and 12%, respectively, of the controls. Regular use of either drug in the absence of the other was associated with an increase by a factor of 2.5 (odds ratio via logistic regression) in the risk of chronic renal failure from any cause.

Case-control studies yield an odds ratio as an estimate of relative risk. This measure is calculated by dividing the odds that a patient was exposed to a given risk factor by the odds that a control was exposed to the risk factor. It can also be obtained from logistic regression analysis. Logistic regression allows the investigator to obtain the odds ratio for a given risk factor independent of other potential risk factors or confounders using the technique of adjustment. Odds ratios are generally a good approximation of relative risk if the outcome is rare.

As with any study design, the case-control method has limitations. Case-control studies allow for the study of only one disease at a time, as opposed to cross-sectional or cohort studies. This design does not allow for the measurement of incidence, prevalence, or excess risk. Case-control studies are also subject to error, or bias, which can threaten the validity of the study. Selection and information biases, the two major categories of bias, are possible in the case-control design. Selection bias arises if the manner in which cases and controls were selected yields an apparent association when, in reality, exposure and disease are not associated. For example, cases, by definition, include only individuals who have been identified as having the disease and who are available for study. Those who have not been diagnosed, have been misdiagnosed, or have died are excluded. If diagnosis or availability is related to the exposure being studied, the sample of cases will be biased.

Avoiding selection bias can be even more challenging in the selection of controls. The control group must be comparable to the cases. They should not be chosen in such a way that important differences between cases and controls exist that might influence exposure history and thus limit the inferences derived from the study. A number of strategies exist to select a control group that is at risk for the disease and otherwise representative of the same population as the cases. These include sampling cases and controls in the same way (e.g., from the same clinical setting), matching controls to cases on key variables related to the disease (e.g., age), using multiple control groups, and using population-based samples of both cases and controls (e.g., using disease registries).

Information bias occurs when the case and control groups differ in terms of the quality of the data collected to measure risk factors. The retrospective approach to measuring an exposure in the case-control design introduces the possibility of differential recall between the cases and controls. Cases may have been asked more often about the presence of a given exposure and/or may be more circum-

spect in their recall of such exposures. This introduces *recall bias*, a form of information bias because of better, and sometimes exaggerated, recollection of exposures by cases as compared to controls.

It can be difficult for an investigator to remain objective in collecting exposure information. In interviewing subjects and in reviewing records, there may be a tendency to look more carefully or evaluate evidence differently for cases than for controls. Strategies for dealing with this problem include the use of objective measures and to ensure that the individuals collecting data are unaware of the subject's group status (*blinding/masking*). The more subjective the method for measuring the exposure, the more important it is to mask the observer. Blinding as to the specific exposure being studied or study hypothesis is useful and also can be used to attempt to control recall bias.

Nested case-control studies and nested case-cohort studies are alternative case-based hybrid designs that have many advantages. A nested case-control study involves selecting all cases and control subjects from a known cohort. In this design, the controls are free of the outcome or disease. Nested case-control studies eliminate the problem of recall bias, because the exposure information is obtained before the outcome has developed (cohort design). Also, the temporal sequence between exposure and outcome is defined. This design is also much more economical and efficient; the entire cohort need not be analyzed for a given exposure (e.g., via a laboratory specimen). Nested case-cohort studies also use the selection of cases and controls from a known cohort. However, in this design, controls are randomly selected from the initial cohort irrespective of outcome. This design permits the delineation of *relative risk* for an exposure.

Cohort Design

Various names, including prospective, follow-up, and longitudinal, have been used to label cohort studies in the past, reflecting the temporal sequence of exposure and disease in this category of observational studies (Fig. 17.5). The word *cohort* originated from the Latin word *cohors*, describing a group of warriors that marched together. Clinical investigators have adapted this term to a

FIGURE 17.5. Design of a cohort study. (From Fletcher RH, Fletcher SW, Wagner EH. *Clinical epidemiology: the essentials*, 3rd ed. Baltimore: Williams & Wilkins, 1996:102, with permission.)

specific type of research study: a group of individuals free of the disease(s) of interest is assembled, their risk status is determined, and the group is followed over time to measure the incidence of disease. Comparison of the incidence of disease (or rate of death from disease) between those with and without the exposure of interest permits measurement of the association between the risk factor and the disease.

The significance of the cohort design has been emphasized by the wealth of scientific data obtained from famous cohorts such as the Framingham Study or the Physicians Health Study. Pediatric nephrology has also benefited from studies using the cohort design. For example, Wong et al. used the cohort design to demonstrate a 17-fold increase in the risk of hemolytic uremic syndrome (HUS) associated with antibiotic use in children with *Escherichia coli* O:157 diarrheal infections (5). In this study, children with *E. coli* O:157 were followed to assess risk factors for the development of HUS.

The cohort design has an obvious niche in clinical research. Ethical and practical considerations often do not allow for randomization of individuals to an exposure of interest. Cohort designs allow for the examination of exposure and disease associations under such circumstances.

Cohort studies can be classified as concurrent or nonconcurrent. In a concurrent cohort study (also referred to as a prospective or longitudinal study), the clinical investigator identifies the population and collects extant exposure information and then follows the cohort to a designated point in the future. Nonconcurrent cohort studies (i.e., retrospective, historical, and nonconcurrent prospective) require the investigator to identify a cohort that has been delineated in the past, along with information regarding the exposure(s) of interest. This population can then be followed for the development of a given disease in the more recent past, the present, or into the future.

Traditionally, the outcome of interest in cohort studies is the ratio of the incidence of disease in those with the exposure divided by the incidence of disease in those without the exposure. This can be interpreted as the *relative risk* for disease in many cases. When calculating and interpreting risks in the cohort design, the absence of randomization must be taken into account. Because the investigator is merely observing the exposure and not controlling for it via randomization, subjects with and without the risk factor might differ in terms of other characteristics that are related to the disease. If the characteristic is related to both the exposure being evaluated and the disease, it can lead to a misleading association between the exposure and the disease. Such a characteristic would be a *confounder*.

To avoid misinterpreting such an association, the investigator must measure potential confounders and adjust for

them in the analysis. Multivariable analyses are examples of statistical tools used to adjust for confounders. However, unsuspected confounders might still jeopardize the validity of conclusions.

For example, Wong et al. (5) used a multivariate logistic-regression analysis to account for potential confounders in the association of antibiotic use for *E. coli* O:157-associated diarrhea and HUS. Adjustments were made for the initial white blood cell count and the day of illness on which the initial stool culture was obtained for analysis. These factors had been previously associated with increased risk of HUS. A higher initial white blood cell count could be a potential confounder, for example, because it is associated with an increased risk of HUS (the outcome) and might make the physician more likely to prescribe antibiotics (the exposure), thus potentially falsely linking antibiotic usage with HUS. After adjustment for these factors, the multivariate analysis revealed a persistent association, reassuring the discerning reader.

Cohort studies have several advantages. Because risk factors are measured before disease, the temporal sequence of risk and disease is established, and the potential for biased risk measurement is avoided. Several diseases or outcomes can be measured, and disease occurrence can be measured in terms of incidence, not just prevalence. Cohort studies often require large sample sizes and are unsuitable for studying rare diseases. Large sample size and long follow-up periods can make cohort studies costly. A nonconcurrent cohort design can reduce cost, but it decreases the investigator's control over subject selection and risk factor measurement.

Experimental Design

In an experimental design, the investigator controls the independent variable or intervention and uses randomization to determine which subjects will receive the intervention (the intervention, study, or experimental group) and which subjects will not (the control or placebo group) (Fig. 17.6).

FIGURE 17.6. Design of a randomized trial. (From Fletcher RH, Fletcher SW, Wagner EH. *Clinical epidemiology: the essentials*, 3rd ed. Baltimore: Williams & Wilkins, 1996:139, with permission.)

The North American IgA Nephropathy Study is an example of a randomized controlled clinical trial. In this study, eligible patients younger than 40 years with immunoglobulin A (IgA) nephropathy on kidney biopsy, glomerular filtration rate >50 mL/min/1.73 m², and evidence of proteinuria are randomly assigned to receive alternate day prednisone, fish oil, or placebo (6). The goal of this study is to determine the relative benefits of fish oil or alternate day prednisone on the progression of IgA nephropathy. In this and other controlled clinical trials, randomization is the key feature of its experimental nature. Through randomization, all potential confounders, both those recognized by the investigator and those that are not suspected, are likely to be balanced between the study groups. In other words, the three groups in this study are considered to be the same except for the treatment they receive. Differences in rates of progression of kidney disease in the three groups are attributable to the intervention, because the effect of confounders has been ruled out by the balance achieved by randomization. Therefore, experimental designs offer stronger evidence of causality than do observational designs.

In an experimental study, it is important to ensure that subject assignment is truly random. This can be achieved by using random numbers, either through computer-assisted assignment or manually, with a table of random numbers. Sometimes *blocking* is used in conjunction with random assignment. A block of subjects is simply a set number of consecutive study enrollees. Within each block, a predetermined number of subjects is randomly assigned to each study group. For example, if the block size is set at six and two study groups of equal size are desired, then three subjects in each block of six are randomly assigned to one group and three to the other. Blocking is useful when study enrollment is expected to be prolonged. Over extended periods, both study procedures and outside conditions can change. Blocking ensures that the study groups will be balanced with regard to such changes.

Experimental studies, like observational studies, are subject to measurement bias. Research staff should be masked or blinded to the subject's group assignment during data collection, especially if any outcome measures are not strictly objective. In the IgA study, for example, both the research staff and the study subjects are unaware of which treatment they receive. In one arm of the study, placebo capsules are made to look exactly like fish oil capsules. In another arm, placebo tablets are distributed that are identical to prednisone. If outcomes are measured without subject or staff knowledge of the subject's group status, they are less likely to be influenced by expectations about potential differences between treatment and control group outcomes.

Quasi-Experimental Designs

In a quasi-experimental study, the investigator maintains control over the intervention but cannot use randomiza-

tion to assign subjects to study groups. Such designs are useful in evaluating programs that are targeted to groups of individuals (e.g., a community-based health education program). In this case, the investigator might control the program's design but cannot randomly assign community residents to be exposed to it.

Quasi-experimental designs fall into two broad categories: nonequivalent control group designs and time series designs. In the former, two or more study groups are compared. The investigator tries to assemble groups that are comparable but cannot be assured of their comparability. In time series designs, the investigator measures the outcome of interest at several points in time before and after the intervention. Agreement between hypothesized and observed patterns of outcome measures supports a causal relationship between intervention and outcome. There are many variations on these two broad types of quasi-experimental designs. Some variations incorporate both types. For example, studies of community health programs often involve time series analysis of two or more communities, some with the health program and some without.

In summary, many research designs are available to the investigator. No single design is best for all research questions. Although experimental designs are superior to observational designs in addressing threats to internal validity, they are not always feasible or ethical. The most appropriate design for a given research question is the design that maximizes internal validity within the constraints of the research environment.

IMPORTANT ISSUES IN CARRYING OUT A RESEARCH PLAN

Selection of Subjects

In any research study, one would like to extrapolate the findings to all patients with the condition of interest (Fig. 17.2). The study population is the group that is meant to represent the target population from which a sample is drawn. Sampling decisions involve defining the study population and sample.

Defining the Target Population

Although there is no one single ideal target population, the investigator needs to consider the ramifications of one definition versus another. If the investigator were interested in studying risk factors for a specific disease, the target population could be defined as all children with this disease or a subset of them (e.g., children of a certain age). The broader the target population, the greater the generalizability of the study findings. On the other hand, the increased heterogeneity of a broadly defined target population could introduce variability

among subgroups in terms of the importance of risk factors. For example, a particular characteristic could be a major risk factor in some population subgroups but not in others. Assessing the importance of risk factors within subgroups requires a larger study sample and perhaps a more complex sampling design.

Defining the Study Population

A practical consideration in defining the target population is availability of the population for study. The investigator could have all children available seen in a particular clinical setting. Insofar as children seen in this setting are representative of the target population, the clinical site would be a good choice for study; the experience of its enrollees could be considered *generalizable* to the target population. If children enrolled in the clinical setting differ systematically from the target population, *sampling bias* is introduced. For example, tertiary care pediatric nephrology centers might be more likely to serve children with advanced stages of the kidney disease or more severe or complicated cases. Studying only these cases may introduce bias toward only studying the most complex forms of a particular disease. Sampling bias impairs the generalizability of study findings. Representativeness, therefore, is a prime consideration in defining a study population. Investigators should evaluate the representativeness of candidate settings and the likely implications of potential biases. One possible approach to this in studies of patients with kidney disease is to compare the characteristics of participants in a study to known characteristics of the larger population to whom one would like to generalize the results.

Defining the Sampling Scheme

Just as we generalize from the study population to the target population, we generalize from the study sample to the study population. *Sample statistics* are measures that pertain to the samples that are studied. A sample mean, for example, is the sample's average score on a particular measure, and a sample standard deviation expresses the variability of the sample scores. The sample statistics are the investigator's best estimates of the *population parameters*. The sample mean is the best estimate of the population mean; the sample standard deviation is the best estimate of the population standard deviation.

Extending beyond inference to hypothesis testing, sample statistics of the association between variables are the best estimates of these associations in the target population. The association between a hypothesized risk factor and the occurrence of disease in the study sample (perhaps measured by odds ratios or relative risks) is the investigator's best estimate of the association between the risk factor and disease in the target population.

Probability theory is the rationale for extrapolating inferences from a study sample to the reference population. A *probability sample* is one in which every subject, or element, in the study population has a known probability of being selected. A *nonprobability sample* is one in which the probabilities of selection are unknown. It is legitimate to extrapolate from a sample to its population only if probability sampling has been used.

There are several types of probability sampling. In *simple random sampling*, each element has an equal chance of being selected. In *systematic sampling*, each element in the population is assigned a consecutive number, and every *n*th element is sampled. Systematic sampling is easy to use, but it will generate a biased sample if the sampling fraction (e.g., every tenth case) is the same as some periodicity in the ordering of cases in the population. For example, if every tenth patient is sampled in a clinic where ten patients are seen each session and the most complex cases are scheduled first, then the sample will contain either all complex cases or no complex cases, depending on the first element drawn. *Stratified random sampling* is useful when one believes that population subgroups differ in important ways. The population is divided into the subgroups, or *strata*, of interest. Simple or systematic random samples are then drawn from each stratum. *Cluster sampling* is useful when it is difficult or costly to sample elements in a population individually. Instead of elements, groups of elements are sampled. For example, in a study of school children, the investigator could take a probability sample of classrooms and then study all the students within each selected classroom. The selected classrooms, in combination, must be representative of the overall population. As with stratified sampling, formulas for calculating variance must be modified, and consultation with a statistician is recommended.

Nonprobability sampling techniques include *convenience sampling*, *quota sampling*, and *purposive sampling*. A convenience sample is one that is most readily obtained without the use of random sampling. A quota sample is a convenience sample drawn to assure specified numbers of subjects in specified strata, without the use of random sampling. A purposive

TABLE 17.1. EXAMPLE ILLUSTRATING HOW α , β , AND EFFECT SIZE AFFECT SAMPLE SIZE

Confidence 1 - α (%)	Power 1 - β (%)	Effect size (%)	Total sample No.
95	80	10 → 40	76
95	90	10 → 40	96
95	90	10 → 20	572
95	99	10 → 40	156

Adapted from Sample size calculator (Statcalc) in Epi-info Stat Calc. Available at: <http://www.cdc.gov/epiinfo/>. Accessed April 11, 2003.

sample is one in which subjects are selected because they are judged to be representative of the population of interest.

Probability sampling is preferred but not always possible. In clinical research, the investigator is often limited to a particular clinic population. If a clinic population is believed to be representative and if it is larger than the number of subjects needed for study, the investigator should use a probability sampling technique to draw the study sample.

An example of probability sampling using stratified sampling techniques can be seen in a recent survey study of adult and pediatric nephrologists (7). The authors created a survey containing ten case vignettes to assess whether increased experience with pediatric patients influenced nephrologists' recommendations for peritoneal or hemodialysis in otherwise identical patients with ESRD described in the vignettes. Because the authors wanted the survey respondents to represent the population of U.S. adult and pediatric nephrologists, they randomly selected a representative sample of nephrologists in five geographic regions of the United States. Each randomly selected nephrologist was mailed a survey containing ten case vignettes to assess what factors affected the nephrologists' dialysis recommendations.

Determining Sample Size

In any study, several factors determine the required sample size. This section describes those that come into play in several common types of investigations. Detailed sample-size formulas and tables are beyond the scope of this chapter, but several excellent references are listed in Suggested Reading. Briefly, to estimate sample size, the researcher needs to set the acceptable level of α (probability of type I error), β (probability of type II error), and determine the effect size that one is likely to see. In determining sample size, the probability of making a type I error, α , is usually set at 0.05. This is the probability of concluding that an association between two variables exists when it does not. β error is the probability of concluding that no association exists, when in fact it does. The reader will be more familiar with β error in terms of its relationship to "power." The power of a study is equal to $1-\beta$. In many studies, β is customarily set at 0.2 for a power of 80%. If β is set to 0.1, the power of the study is 90%.

In addition to specifying α and β , the researcher must also determine an estimate of the response to treatment in one of the groups (in a clinical trial) or the rate of occurrence of disease (in a cohort study). The effect size is an estimate of how much better than the comparison group you expect a treatment group to be in a clinical trial or how increased the risk of a particular disease is in the setting of a particular risk factor (in a cohort study). An illustration of estimated sample sizes for given α , β , and effect sizes is shown in Table 17.1 for a study comparing differences in proportions in two groups (8).

Table 17.1 illustrates how varying the acceptable levels of α , β , and effect size influences sample size. For example, if we designed a study to determine whether a new drug could "cure" 40% of patients compared to an old drug that "cured" 10% of patients, we would have 90% power to see such an effect with 95% confidence in a total sample of 96 patients (see row 2 in Table 17.1). In contrast, to obtain a significant result documenting a smaller effect size from the old drug cure rate of 10% to a new drug cure rate of 20% with the same $\alpha = 0.05$ and 90% power, we would need to study 572 patients.

Attrition of Study Subjects

Sample size calculations determine the number of subjects needed at the study's conclusion. In determining the number of subjects to enroll, the investigator must estimate attrition rates and enroll a sufficiently large sample to compensate for study dropout.

Even if probability sampling is used to define the study, subject attrition could produce a biased sample at the study's conclusion. An attrition rate of more than 25% is cause for concern. In data analysis, subjects completing the study should be compared with those who drop out to determine whether the two groups differ in a clinically significant way. Such differences must be considered in interpreting the study findings.

DATA COLLECTION: MEASUREMENT

Decisions on what data to collect and how to do so begin with specifying the variables that need to be measured and operationally defining each. The investigator will need to evaluate the suitability of existing measures and determine whether to use an existing measure or develop a new one. The data sources for each variable must also be identified. Finally, the investigator should specify the level of measurement of each variable. An efficient way to document the data collection plan is to make a table with columns listing the variables to be measured, their operational definitions, the data source(s) for each variable, and level of measurement for each. This section describes issues pertaining to each of these tasks.

Identifying the Variables to Be Measured

Researchers are often tempted to collect as much information as possible. This can be costly, in terms of time, money, and data quality. The investigator should be able to justify each variable to be measured. Most important are the hypothesized independent and dependent variables. In addition, identified potential confounders should be measured. Finally, data characterizing the study population and sample will be needed to describe the study's generalizability.

Sources of Data

Study data can be collected from existing sources or can be generated specifically for the specific research hypothesis being tested, using surveys, interviews, or observations. Most studies combine both strategies.

An enormous variety of existing data sources is available, including medical records, vital records, national and local health surveys, and census data. Health programs often keep records of services provided, and billing records can be especially helpful. Examples of existing data sources in pediatric kidney disease include the USRDS (3) and data collected by the North American Pediatric Renal Transplant Case Study (NAPRTCS) (9). Existing sources can provide data for time periods and individuals otherwise unavailable to the investigator. The number of studies published by the NAPRTCS and their tremendous contribution to our understanding of clinical outcomes in pediatric kidney transplantation and dialysis illustrate this point. The chief disadvantage of existing sources gleaned from registry data is that the data are often not collected as systematically as in a prospective research study. Important data elements are sometimes missing. Incomplete data and inaccuracies are also possible with registry data.

Primary data collection is expensive and is limited to subjects available to the investigator. On the other hand, the investigator's control over data collection makes data quality more certain. Many primary data collection strategies are available, including mail surveys, mass-administered questionnaires, telephone and in-person structured and unstructured interviews, direct observation, and videotaping and audiotaping. Choosing a strategy should be based on the research question, the sensitivity of the data to be collected, the literacy of the population to be studied, and the resources available for the study. The key factor should be data quality—that is, which method will provide the most complete and accurate information within budgetary constraints.

Assessing Data Quality

One strategy to enhance data quality is to train research staff thoroughly. Often, data-collection staff work independently. To ensure that they follow study procedures, the protocol for data collection should be detailed in a study manual. Training sessions should be held to explain the study's aim to staff, as well as how each one's role fits into the big picture. Staff should be given ample time to practice their data-collection skills. Once the fieldwork of the main study begins, staff should be encouraged to bring problems to the attention of supervisory staff. Such problems should be resolved in a timely fashion, and the resolution should be documented and added to the study manual. In this way, research staff are kept apprised of changes in the study protocol and are impressed with the importance of adhering to it.

After the instrument pretesting and staff training, the investigator should pilot test the data-collection activities.

A pilot test is a dress rehearsal of the activities for selecting study subjects, contacting them, securing informed consent, and collecting and processing data. Activities that do not work as planned should be modified and the pilot testing continued until the fieldwork procedures run smoothly.

Data quality should be monitored during the main study. Interviews and questionnaires should be reviewed as they are completed to allow recontacting subjects to correct errors. The reliability of subjective measures and those requiring special technical skill should be assessed. For studies with unsupervised interviewing of subjects, it is wise to validate a portion of the completed interviews handed in by fieldworkers. This can be done by recontacting a random sample of subjects and then asking them to verify their responses to a sub-sample of the interview questions.

ANALYTIC PLAN

Data Analysis

Investigators often defer considering data analysis until the data have been collected. This is a serious mistake. Study planning should include an analytic plan of the steps needed to answer the study questions once the fieldwork is completed.

Use of Statistical Tests

As noted earlier, statistical validity is the correctness of study conclusions regarding group differences and variable relationships. A key threat to statistical validity is the use of inappropriate statistical tests. *Parametric statistical tests* are based on assumptions about parameters of the population and are the most powerful tests available in situations in which these assumptions are met. *Nonparametric statistical tests* are based on fewer assumptions about the population, so they are appropriate in situations in which the assumptions underlying parametric statistics are not met.

Assumptions vary by statistical test. If a test is used in a situation that violates its assumptions, it will be inaccurate, leading to a misleading measure of statistical significance. This, in turn, will lead to an incorrect estimate of the likelihood of a type I error.

In developing the analytic plan, the investigator should consider the assumptions of candidate tests in determining which ones to use. A discussion of specific statistical tests is beyond the scope of this chapter, but a framework for deciding which tests to use can be given. In this framework, three factors determine the type of test to use: the major analytic question to be answered, the levels of measurement used, and the number and independence of comparison groups.

In preparing the analytic plan, the investigator needs to translate the research question into analytic terms. Three major analytic approaches are to describe characteristics of the sampled population, to compare groups of subjects,

TABLE 17.2. BIVARIATE STATISTICAL TESTS

Level of measurement	Two groups		Three or more groups	
	Independent (unpaired groups)	Paired groups	Independent (unmatched groups)	Matched groups
Nominal dichotomy	Chi-square or Fisher's exact test	McNemar's test	Chi-square	Cochran's test
More than two categories	Chi-square	McNemar's test	Chi-square	Cochran's test
Ordinal	Mann-Whitney test	Sign test	Kruskal-Wallis one-way analysis of variance (ANOVA)	Friedman two-way ANOVA
Interval	<i>t</i> Test for groups	Wilcoxon matched-pairs signed-ranks test <i>t</i> Test for pairs	One-way ANOVA	ANOVA for repeated measures

and to measure associations among variables. In addition, the appropriate analytic test is determined by the level of measurement of the variables of interest. Measurements can be normal, ordinal, or interval.

Where group comparisons are to be made, the appropriate statistical test is also determined by the number of groups to be compared (two vs. three or more) and by whether comparison groups are independent or matched. Thus, in a study of cases matched with sibling controls, it would be inappropriate to use a statistical test for independent groups.

As decisions about level of measurement and the selection of study groups are part of study planning, it is easy to see how these decisions are better informed if their ramifications for data analysis are considered. Level of measurement, study group formation, and data analysis are all interrelated, and all should be considered part of study planning.

When the study's purpose is to describe a population, the investigator makes inferences from sample statistics to population parameters. Sample proportions and measures of central tendency (mean, median, and mode) and dispersion (standard deviation, range) are used to estimate these parameters in the population. Confidence intervals can be constructed around proportions and means to express the certainty of the sample-based population estimates. When the study's objective is to compare two or more groups, sample group differences in proportions and means are used to estimate such differences in the population. Statistical tests of significance can be used to assess the certainty of sample-based inferences about group differences in the population. The appropriate statistical test depends on the number of groups compared, whether subjects in the groups are matched, and the level of measurement of the variable on which the groups are being compared. Table 17.2 displays bivariate statistical tests commonly used in assessing the significance of group differences.

When the research aim is to measure the association between variables, sample statistics again are used to estimate population parameters. The variables' levels of measurement determine the appropriate statistical measure of the strength

of their association, the appropriate test of the statistical significance of the association, and the certainty of estimates of its strength. For dichotomous variables, the odds ratio and relative risk are measures of the degree of association. For continuous data, Pearson's correlation coefficient is used to measure association.

Studies of the combined and relative impacts of multiple independent variables, or the effect of an independent variable after controlling for other factors, will require multivariable analytic tests. The appropriateness of a multivariable technique is determined by the levels of measurement of the independent and dependent variables. The references cited at the end of this chapter describe the applicability and interpretation of the most commonly used multivariable statistical tests.

Statistical Significance and Confidence Intervals

Most readers of the medical literature will be familiar with the term *statistical significance*, which is most often referred to in clinical reports as a "*p* value <.05." This highly sought after result of a statistical test refers to the probability of α , or a type I error. A *p* value of .05 in a study means that there is a 5% chance that the results seen in the study could have occurred by chance. However, the authors have concluded that this probability is low enough for them to accept the alternative hypothesis (that there is a real difference between groups) and to reject the null hypothesis (there is no difference between groups). It is important to note that the *p* value in a study result depends on the size of the observed difference between the groups in question and the size of the sample of patients studied. Standing alone, the *p* value does not convey any sense of the magnitude of the treatment effect seen in the study or the precision of the estimate of the size of the treatment effect. Confidence intervals, in contrast to *p* values, can convey this information in a more meaningful way.

For any estimated value, it is useful to have an idea of the uncertainty of the estimate in relation to the true value it is trying to approximate. For example, if we designed a study to estimate the beneficial effect of a new lipid-lowering medication in

chronic renal failure in adolescents, we would try to recruit a large representative sample of hyperlipidemic adolescents and randomize them to treatment with a new lipid-lowering medication. From our study, we might want to estimate the magnitude of lipid level reduction associated with the new medicine. We might also want to use this estimate as an approximation for the “true” reduction in lipid levels that would be seen in the “universe” of pediatric patients with hyperlipidemia and chronic renal failure. To estimate the “true” reduction in lipid levels (which can never be directly measured), we can generate a confidence interval around our estimate.

In any study, construction of a *confidence interval* around the point estimate gives us a range of values in which we can be confident that the true value resides. A confidence interval gives a sense of the estimate’s precision; it extends evenly on either side of the estimate by a multiple of the standard error (SE) of the estimate. In our example, our study might yield an estimate of the drop in serum low-density lipoprotein cholesterol levels of the treatment group of 30% with a standard deviation of that estimate of 20%. One could then use this estimate to generate a confidence interval around this estimate. In the medical literature, one will most often see references to 95% confidence intervals. The general equation for a 95% confidence interval is equal to the estimate ± 1.96 times the SE of the estimate. The factor 1.96 comes from the standard normal distribution, in which 95% of estimates would fall within ± 1.96 SEs of the mean. If one wanted to increase the probability of including the true estimate in the confidence interval, one could generate a 99% confidence interval, which would equal the estimate ± 2.56 times the SE of the estimate. Because the SE of an estimate is equal to the standard deviation of the population divided by the square root of the sample size, N , one can see that a larger sample size is needed in a study to generate a precise estimate of a treatment’s effect. Given the same standard deviation, the SE in our study would be smaller if we studied 100 children compared to 20 children. The larger study would generate a narrower 95% confidence interval. The strict interpretation of a 95% confidence interval is that this is the range of values for the true population estimate that is consistent with the data observed in the study. In our hypothetical example, the smaller study might give us the opportunity to conclude that the new lipid lowering is associated with a 30% reduction in low-density lipoprotein cholesterol with a relatively broad 95% confidence interval of 21 to 39%, whereas the larger study yields a more precise estimate. The 95% confidence interval around the same point estimate of a 30% reduction is 26 to 34% in the study with the larger sample size.

EVALUATING THE LITERATURE: RATING THE STRENGTH OF SCIENTIFIC EVIDENCE

Health care decisions should be based on research-based evidence. Whether the individual nephrologist is making a clinical

decision or a national organization is developing clinical practice guidelines, efforts should be made to systematically assess the strengths of scientific evidence related to a particular clinical diagnostic or treatment plan. Guidelines first developed more than 20 years ago at the Department of Clinical Epidemiology and Biostatistics at McMaster University first introduced tools to allow clinicians to critically review original articles on etiology, diagnosis, prognosis, and therapy (10). In the following decade, the series was widely read and cited, was modified for use by the general public, and was published in clinical epidemiology texts (11). At the same time, clinicians at McMaster University and across North America continued to expand and improve the guidelines. Their focus has expanded to include clinicians’ ability to access, summarize, and apply information from the literature to everyday clinical problems, transforming the Readers’ Guides to Users’ Guides (12–35).

Such systematic approaches have also been adapted to assess entire bodies of research on particular subjects. In 1999, the U.S. Congress directed the Agency for Health Care Policy Research and Quality to identify methods to assess health care research results. The results of that effort were published in a report entitled “Systems to rate the strength of scientific evidence” (36). Key features of this report and the users’ guides are summarized in Randomized Controlled Trials.

Randomized Controlled Trials

If a clinician or researcher is interested in evaluating the evidence that a cause-effect relationship exists between a treatment and a result, a randomized experiment is the design of choice. In evaluating the quality of the randomized clinical trial, one must assess whether a number of important elements are addressed in the clinical trial. These are outlined in Table 17.3. The study population should be clearly defined. Randomization should have resulted in study groups that are balanced at the start of the study in terms of potential confounders. The reader should be wary of two threats to this balance. The first is differential group attrition during the course of the study, resulting in groups that are no longer balanced with respect to confounders by the study’s end. To guard against this, the investigator should provide evidence of low attrition rates or should analyze treatment effectiveness on the basis of “intent to treat,” including in the analysis of all study subjects both those who completed the study and those dropping out. An intent-to-treat analysis maintains individuals and their outcomes in the treatment group to which they were assigned. This maintains the balance achieved by randomization and is the most conservative analysis plan. The second threat to validity is biased outcome measurement. The reader should look for evidence that outcome measurement was objective and not biased by observer knowledge of subject group status. Finally, in determining treatment impact, the investigator should provide evidence that both statistical and clinical

TABLE 17.3. IMPORTANT DOMAINS AND ELEMENTS FOR ASSESSING STRENGTH OF EVIDENCE IN RANDOMIZED CONTROLLED TRIALS

Domain	Element
Study question	Clearly focused and appropriate question
Study population	Description of study population Specific inclusion and exclusion criteria Sample size justification
Randomization	Adequate approach to sequence generation Adequate concealment method used Similarity of groups at baseline
Blinding	Double-blinding (e.g., of investigators, caregivers, subjects, assessors, and other key study personnel as appropriate) to treatment allocation
Interventions	Intervention(s) clearly detailed for all study groups (e.g., dose, route, and timing for drugs and details sufficient for assessment and reproducibility for other types of interventions) Compliance with intervention Equal treatment of groups except for intervention
Outcomes	Primary and secondary outcome measures specified Assessment method standard, valid, and reliable
Statistical analysis	Appropriate analytic techniques that address study withdrawals, loss to follow-up, missing data, and intention to treat Power calculation Assessment of confounding Assessment of heterogeneity, if applicable
Results	Measure of effect for outcomes and appropriate measure of precision Proportion of eligible subjects recruited into study and followed up at each assessment
Discussion	Conclusions supported by results with possible biases and limitations taken into consideration
Funding or sponsorship	Type and sources of support for study

From Agency for Healthcare Research and Quality. Systems to rate the strength of scientific evidence. AHRQ Publication No. 02-E016, April 2002. Rockville, MD: Agency for Healthcare Research and Quality. Available at: <http://www.ahrq.gov/clinic/streinv.htm>. Accessed May 2003, with permission.

relevance were considered in establishing sample size and in drawing conclusions.

Observational Studies

In a study of disease etiology, a randomized experiment is seldom possible. When a randomized trial is not feasible, the reader should determine whether the investigator has used the strongest alternative observational design possible. Important domains and elements to assess for the quality of observational

TABLE 17.4. IMPORTANT DOMAINS AND ELEMENTS FOR ASSESSING STRENGTH OF EVIDENCE IN OBSERVATIONAL STUDIES

Domain	Element
Study question	Clearly focused and appropriate question
Study population	Description of study populations Sample size justification For all observational studies Specific inclusion/exclusion criteria for all groups Criteria applied equally to all groups Comparability of groups at baseline with regard to disease status and prognostic factors Study groups comparable to nonparticipants with regard to confounding factors
	Use of concurrent controls Comparability of follow-up among groups at each assessment Additional criteria for case-control studies Explicit case definition Case ascertainment not influenced by exposure status Controls similar to cases except without condition of interest and with equal opportunity for exposure
Exposure or intervention	Clear definition of exposure Measurement method standard valid and reliable Exposure measured equally in all study groups
Outcome measurement	Primary/secondary outcomes clearly defined Outcomes assess blind exposure or intervention status Method of outcome assessment standard valid and reliable Length of follow-up adequate for question
Statistical analysis	Statistical tests appropriate Multiple comparisons taken into consideration Modeling and multivariate techniques appropriate Power calculation provided Assessment of confounding Dose-response assessment, if appropriate
Results	Measure of effect for outcomes and appropriate measure of precision Adequacy of follow-up for each study group
Discussion	Conclusions supported by results with biases and limitations taken into consideration
Funding or sponsorship	Type and sources of support for study

From Agency for Healthcare Research and Quality. Systems to rate the strength of scientific evidence. AHRQ Publication No. 02-E016, April 2002. Rockville, MD: Agency for Healthcare Research and Quality. Available at: <http://www.ahrq.gov/clinic/streinv.htm>. Accessed May 2003, with permission.

studies are outlined in Table 17.4. The reader should look for additional evidence of a causal relationship as well, such as the consistency of findings across studies, confirmation that the cause preceded the effect temporally, and the presence of a dose-response effect. As with an experimental study, measurements of cause and outcome should be objective and unbiased, and both clinical and statistical relevance should be considered in the analysis. Finally, because available designs do not achieve balance between study groups with respect to confounders, it is important that the investigators identify and control for potential confounders in the analysis.

In evaluating an observational study of the prognosis of disease, the reader should focus on subject selection, measurement, and analysis. The primary purpose of this type of study is to describe the clinical course of patients with a particular disease. As in studies of etiology, the investigator might also seek to identify factors influencing outcome. It is essential that those studied be representative of such patients, including both those who will eventually recover and those who will die. The reader's first task, therefore, is to seek evidence that the study sample was selected early in their disease. The next task is to determine the adequacy of subject follow-up. As the number of subjects lost to follow-up increases, the representativeness of the sample becomes suspect. Assuming a representative sample and adequate follow-up, the reader should then determine whether patient outcomes were measured reliably in ways that can be related to the reader's own practice. Finally, the reader should determine whether the investigator controlled for potential confounders in assessing the role of prognostic factors. As in studies of etiology, it is impossible to

TABLE 17.5. IMPORTANT DOMAINS AND ELEMENTS FOR ASSESSING STRENGTH OF EVIDENCE IN DIAGNOSTIC STUDIES

Domain	Element
Study population	Subjects similar to populations in which the test would be used and with a similar spectrum of disease
Adequate description of test	Details of test and its administration sufficient to allow for replication of study
Appropriate reference standard	Appropriate reference standard ("gold standard") used for comparison
Blinded comparison of test and reference	Reference standard reproducible Evaluation of test without knowledge of disease status, if possible Independent, blind interpretation of test and reference
Avoidance of verification bias	Decision to perform reference standard not dependent on results of test under study

From Agency for Healthcare Research and Quality. Systems to rate the strength of scientific evidence. AHRQ Publication No. 02-E016, April 2002. Rockville, MD: Agency for Healthcare Research and Quality. Available at: <http://www.ahrq.gov/clinic/strevinv.htm>. Accessed May 2003, with permission.

randomly assign patients to groups with and without a prognostic factor. Therefore, it is essential that potential confounders be controlled for in the analysis.

Studies Evaluating Diagnostic Tests

In reviewing a study evaluating a diagnostic test, the reader's chief concerns are subject selection and measurement (Table 17.5). The study sample should be representative of the population of interest in terms of spectrum of disease. Regarding measurement, it is essential that the can-

TABLE 17.6. IMPORTANT DOMAINS AND ELEMENTS FOR ASSESSING STRENGTH OF EVIDENCE IN SYSTEMATIC REVIEWS

Domain	Element
Study questions	Question clearly specified and appropriate
Search strategy	Sufficiently comprehensive and rigorous with attention to possible publication biases Search restrictions justified (e.g., language or county of origin) Documentation of search terms and databases used Sufficiently detailed to reproduce study
Inclusion and exclusion criteria	Selection methods specified and appropriate, with a priori criteria specified if possible
Interventions	Intervention(s) clearly detailed for all study groups
Outcomes	All potentially important harms and benefits considered
Data extraction	Rigor and consistency of process Number and types of reviewers Blinding of reviewers Measure of agreement of reproducibility Extraction of clearly defined interventions/exposures and outcomes for all relevant subjects and subgroups
Study quality and validity	Assessment method specified and appropriate Method of incorporation specified and appropriate
Data synthesis and analysis	Appropriate use of qualitative and/or quantitative synthesis, with consideration of the robustness of results and heterogeneity issues
Results	Narrative summary and/or quantitative summary statistic and measure of precision, as appropriate
Discussion	Conclusion supported by results with possible biases and limitations taken into consideration
Funding or sponsorship	Types and sources of support for study

From Agency for Healthcare Research and Quality. Systems to rate the strength of scientific evidence. AHRQ Publication No. 02-E016, April 2002. Rockville, MD: Agency for Healthcare Research and Quality. Available at: <http://www.ahrq.gov/clinic/strevinv.htm>. Accessed May 2003, with permission.

didate test be compared with a “gold standard,” that the comparison is unbiased, and that the reliability of the test is established. From a practical standpoint, it is important that the diagnostic test procedures, as evaluated in the research, can be used in clinical practice.

Systematic Reviews

As opposed to a traditional invited review, a systematic review is an organized method of locating, assembling, and evaluating a body of literature on a particular topic using a set of specific predefined criteria. If the systematic review includes a quantitative pooling of data, then it is referred to as a metaanalysis. As systematic reviews have been more frequently used in recent years as part of the development of practice guidelines, criteria for evaluating the quality of systematic reviews have also been developed (Table 17.6). An example of a systematic review in pediatric nephrology is the evidence-based assessment of treatment options for children with IgA nephropathy by Hogg and Wyatt (37).

In summary, the busy clinician can afford to be selective in reviewing the literature. In rating the strength of scientific evidence in evaluating a specific clinical problem or treatment, one needs to be selective. The simplest criteria for choosing which studies to read in detail or which to weigh heavily in evidence are clinical relevance and methodologic soundness. This chapter has introduced a simple framework for evaluating such features in the context of sound clinical research methodology and has outlined the most recent guidelines for assessing the strength of scientific evidence for making decisions in clinical care. These tools for systematic assessment of existing research can also guide the clinical investigator toward areas that require further study in which current evidence for treatment or outcomes is scant.

GENETICS

LISA M. GUAY-WOODFORD

The principles of classic genetics were established by Gregor Mendel in 1865. Based on controlled breeding experiments with the garden pea, Mendel determined that physical characteristics (phenotypes) were transmitted by “hereditary units” from one generation to the next in a predictable fashion. These hereditary units (genes) exist in alternate forms (alleles) that determine the expression of a particular phenotype. Mendel’s first law of heredity describes the segregation of alleles: *Alleles have no permanent effect on one another when present in the same organism, but they segregate unchanged by passing into different gametes.* An organism is homozygous if both alleles of a given gene are identical, and it is heterozygous if the alleles are different. Alleles typically have dominance properties. For example, one dominant allele determines the phenotype regardless of the dominance characteristics of the other allele. The recessive phenotype only appears when the organism is homozygous for the recessive allele. Mendel also determined that alleles of one gene and alleles of another gene are transmitted independently to gametes; thus he formulated his second law of heredity: *The assortment (transmission) of one gene does not influence the assortment of another* (1).

Mendel’s laws were first applied to human disease by Sir Archibald Garrod in 1909. Based on his clinical observations, Garrod reasoned that alkaptonuria, albinism, cystinuria, and pentosuria were transmitted as mendelian recessive traits. With alkaptonuria, he postulated that an essential enzyme was defective, a so-called inborn error of metabolism (2). The one gene–one enzyme concept later postulated by George Beadle and Edward Tatum had immediate implications for the inborn errors of metabolism described by Garrod. Indeed, shortly thereafter, the era of biochemical genetics began with the identification of specific enzyme defects as the genetic basis of recessive methemoglobinemia, von Gierke disease, and phenylketonuria (2). Subsequent studies in the 1940s and early 1950s determined that the genetic information in each cell is encoded in double-stranded DNA molecules. These findings set the stage for the modern era of molecular genetics.

PATTERNS OF INHERITANCE

Pedigree Analysis

The family history is a critical tool for assessing inherited disorders and determining inheritance patterns. The key issues to investigate are (a) whether anyone in the family has had a condition similar to the patient and, if so, whether this condition “runs in the family”; and (b) whether the family has suffered fetal losses late in gestation or whether there have been unexplained infant deaths. In the case of rare disorders, the possibility of consanguinity should be explored by inquiring whether the parents are related, whether their grandparents or great-grandparents may have intermarried, or whether the parental families originate from the same village or small community.

With the details obtained from a careful family history, the disease distribution within the family or kindred can be evaluated. The pattern of inheritance is documented by constructing a pedigree (Fig. 18.1) in which the first identified patient is designated as the proband or index case. Pedigree analysis indicates whether the disease behaves as a single mendelian trait (i.e., whether it is transmitted according to Mendel’s principles of segregation and independent assortment). Alternatively, if the inheritance pattern does not conform to mendelian principles, the genetic trait may arise from (a) polygenic inheritance, (b) genomic imprinting, (c) uniparental disomy, or (d) mitochondrial inheritance.

Mendelian Inheritance

Single-gene disorders that follow a mendelian pattern of inheritance are manifested as (a) autosomal-dominant traits, (b) autosomal-recessive traits, (c) X-linked dominant traits, or (d) X-linked recessive traits. Genes involved in human autosomal disorders are carried on any one of the 22 pairs of nonsex chromosomes (autosomes). The terms *X-linked dominant* and *X-linked recessive* refer to trait expression in females. In comparison, males carry only one X chromosome and, therefore, are hemizygous for X-linked traits.

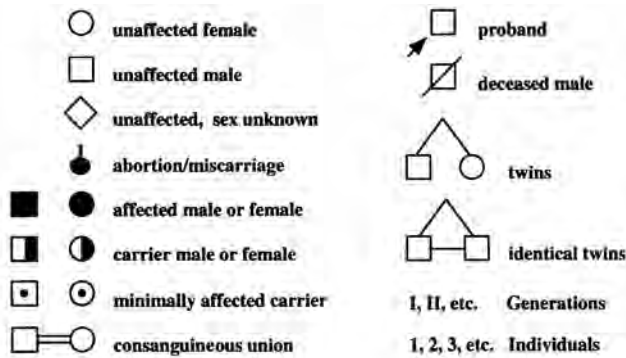

FIGURE 18.1. Standard pedigree symbols.

Dominant disorders are expressed in heterozygotes, hemizygotes, as well as homozygotes, whereas recessive disorders are only expressed in homozygotes and hemizygotes. It is important to note that the terms *dominant* and *recessive* refer to the inheritance of the disease phenotype rather than to the expression of the mutant gene. For example, in the case of autosomal-dominant polycystic kidney disease (ADPKD), the disease phenotype is inherited as an autosomal-dominant trait. However, in cystic epithelia of *PKD1* and *PKD2* patients, there appears to be a “second hit,” which results in the somatic cell loss of the normal allele. These data therefore suggest that *PKD1*- and *PKD2*-associated diseases behave in a recessive fashion at the molecular level (3).

Autosomal-Dominant Traits

Dominant traits are expressed when only one mutant allele is inherited. The characteristic pattern of autosomal-dominant inheritance is shown in Figure 18.2. When large numbers of patients are evaluated, an equal number of males and females are affected. An affected child typically has an affected parent, and vertical transmission of the trait occurs

FIGURE 18.2. Pedigree illustrating an autosomal-dominant pattern of inheritance. Note the male-to-male transmission (individual II:4 to individual III:6) and nonpenetrance (individual IV:8).

through successive generations. Each child of an affected individual has a 50% risk of inheriting the mutant allele. The *sine qua non* of autosomal-dominant inheritance is father-to-son transmission.

Many autosomal-dominant disorders are characterized by delayed clinical onset as well as variability in the disease phenotype between families and even within families. These issues are important (e.g., when evaluating fetuses and neonates with presumed polycystic kidney disease). In ADPKD, clinical disease is typically manifested after the third decade of life. Given this delayed clinical presentation, individuals who carry a mutant ADPKD allele may be clinically asymptomatic throughout their child-bearing years. However, ADPKD can be diagnosed *in utero*; for approximately 30% of these fetuses, parental sonographs can identify the previously unaware, transmitting parent (4).

Occasionally, the expression of the dominant trait is so minimal that clinical disease appears to have “skipped” a generation. Individuals who carry a mutant allele for an autosomal-dominant trait but who have little evidence of clinical disease are said to demonstrate decreased or incomplete penetrance (Fig. 18.2). In contrast, when an individual inherits a mutant allele for an autosomal-dominant trait from each parent, the clinical phenotype can be very severe. For example, clinical disease in individuals with the dominant disorder familial hypocalciuric hypercalcemia may proceed undetected. However, the union of two such heterozygotes can produce a child with two mutant alleles who then manifests the often fatal disorder neonatal severe hyperparathyroidism (5).

Although each child of an individual with a specific autosomal-dominant disorder has a 50% risk of inheriting the disease trait, not every affected child necessarily has an affected parent. This is because in every autosomal-dominant disorder, affected individuals can develop the disease phenotype as the result of a new (spontaneous) mutation rather than through inheritance of a mutant allele. A reasonable estimate of the frequency of mutation is on the order of 10^{-6} mutations per allele per generation (1). Many new mendelian mutations occur in the gametes of fathers who are of relatively advanced age, the so-called paternal age effect (2). Most of these mutations either do not impair the function of the gene product or behave as recessive alleles. However, others cause a defective gene product that gives rise to a dominant trait. In these situations, the parent in whose gametes the mutation arose remains clinically unaffected. Similarly, the siblings of the affected individual are also clinically unaffected because spontaneous mutations typically affect only one or a few germ cells.

Before concluding that a dominant trait in a given individual is the result of a spontaneous mutation, two other possibilities must be considered. First, the disease gene may be carried by one parent in whom the disease phenotype is either nonpenetrant or incompletely penetrant. Second, the father may be someone other than the designated man.

Studies in various cultures around the world have detected nonpaternity in approximately 3 to 5% of children (2).

A number of different molecular mechanisms may cause the disease phenotype associated with dominant traits. One mechanism involves haploinsufficiency, in which 50% of the normal gene product is insufficient to maintain a normal phenotype. This mechanism may be operative in disorders involving cellular receptors (e.g., familial hypercholesterolemia) and key regulatory enzymes (e.g., porphyrias). A second mechanism involves a dominant-negative effect in which the incorporation of an abnormal subunit disrupts the function of a multimeric protein (e.g., enzyme pumps, transport proteins, and complex ion channels). This mechanism may be operative in autosomal-dominant forms of nephrogenic diabetes insipidus (6). A third mutational mechanism involves a gain of function in which the mutation causes overexpression of the protein product or results in a new, aberrant function of the protein. This mechanism may be responsible for one form of autosomal-dominant hypocalcemia, in which a mutation in the gene encoding the calcium-sensing receptor causes expression of an overactivated receptor (7). A fourth mechanism for a dominant phenotypic effect results when a heterozygous mutation becomes homozygous at the cellular level due to a second somatic mutation or a “second hit.” This mechanism appears to underlie the molecular pathogenesis of ADPKD (3) and tuberous sclerosis (8).

Autosomal-Recessive Disorders

Autosomal-recessive conditions are clinically apparent only in the homozygous state (i.e., when both alleles of a particular gene carry mutations). In most autosomal-recessive disorders, the clinical presentation tends to be more uniform than in dominant diseases, and the onset is often early in life. In recessive pedigrees, the parents are clinically unaffected; on average, one-fourth (25%) of the children are affected, with an equal gender distribution. Given the small family sizes typical in many societies, pediatricians usually see isolated or sporadic cases of a recessive disorder. A typical simplex pedigree is shown in Figure 18.3A. In these situations, a high index of suspicion is required to make the correct genetic diagnosis.

Multiply affected families do occur, particularly in the context of parental consanguinity (Fig. 18.3B). In general, the less frequent the disease phenotype, the more likely it is that an affected child resulted from a consanguineous union. On the other hand, certain recessive disorders have a relatively high carrier frequency in specific populations (e.g., cystic fibrosis in whites and hemoglobin S in blacks). In these populations, recessive diseases usually do not involve consanguinity in the parents.

New mutations for recessive diseases occur, but because they generate an asymptomatic heterozygote, these mutations are not clinically detectable. In the homozygous state,

FIGURE 18.3. Pedigrees illustrating autosomal-recessive patterns of inheritance. **A:** A simplex family. **B:** A consanguineous family.

recessive alleles generally cause a complete or nearly complete loss of protein function. For example, a specific monomeric enzyme is rendered nonfunctional in the majority of inborn errors of metabolism. Affected individuals may be homozygous for the same mutant allele, as in the case of parental consanguinity, or they may have inherited a different mutant allele from each parent. In the latter case, the affected individual is referred to as a *compound heterozygote*.

X-Linked Inheritance

Diseases or traits that result from genes located on the X chromosome are termed *X-linked*. Because the female has two X chromosomes, the terms *X-linked dominant* and *X-linked recessive* refer only to expression of the trait in females. Affected males transmit their X chromosome to all of their daughters, rendering them all obligate carriers of an X-linked disease trait. Affected males do not transmit an X chromosome to their sons. Thus, an important feature of X-linked inheritance is the absence of father-to-son transmission.

The female carries two X chromosomes in each cell, but only one is expressed per cell. Both X chromosomes are apparently active early in development. However, through the process of lyonization, one of the X chromosomes is randomly inactivated in each cell during differentiation (9). Once inactivated, the cell's X chromosome is permanently nonfunctional such that all of its daughter cells inherit the same inactivated X chromosome. Therefore, depending on the proportion of mutant and normal X chromosomes in key tissues, a genetically heterozygous female may be clinically normal, may have mild disease, or, in rare cases, may have even severe disease manifestations.

Recognizing new mutations can be more complicated in X-linked disorders than in autosomal disorders. A new mutation may arise in one of the mother's two X chromosomes, and a single affected male may be born to a woman who is not a known carrier. Alternatively, the new mutation may arise in the maternal grandfather's X chromosome. In this scenario, a woman without a known family history of an X-linked disease may have one or more affected sons.

FIGURE 18.4. Pedigree illustrating an X-linked dominant pattern of inheritance. Note lethality in hemizygous males.

X-Linked Dominant Traits

The X-linked dominant pattern is a rare mode of inheritance characterized by a disease frequency in females that is often twice that evident in males. Vitamin D-resistant rickets is an example of an X-linked dominant trait (10). Heterozygous females transmit the trait to offspring of both genders, whereas hemizygous males transmit the trait to all of their daughters and none of their sons. The disease expression is more variable and generally less severe in heterozygous females than in hemizygous males. In other rarer X-linked dominant disorders (e.g., oral-facial-digital syndrome type I) (11), the phenotype may be expressed only in the heterozygous female because the condition is lethal in the hemizygous male (Fig. 18.4).

X-Linked Recessive Traits

In comparison to X-linked dominant inheritance, X-linked recessive inheritance is relatively common. These disorders are fully expressed in the hemizygous affected male. The pedigree pattern tends to be oblique in that affected males have affected uncles and nephews (Fig. 18.5). This oblique pattern is readily distinguished from the vertical transmis-

FIGURE 18.5. Pedigree illustrating an X-linked recessive pattern of inheritance.

sion in autosomal-dominant inheritance and the horizontal pattern of autosomal-recessive inheritance. Heterozygous females are usually phenotypically normal. Depending on the pattern of lyonization in key tissues, these females may occasionally exhibit mild features of the disease and may rarely be severely affected.

Nonmendelian Inheritance

Polygenic Inheritance

In general, most phenotypic traits are determined by the interaction of several genes rather than by single gene effects. In terms of genetic disease, polygenic inheritance provides the basis for understanding many diseases that have a genetic component but lack a clear-cut pattern of mendelian inheritance. These disorders include congenital malformations (e.g., most forms of congenital heart disease), meningomyelocele and other neural tube defects, and vesicoureteral reflux, as well as many familial adult-onset diseases (e.g., essential hypertension, type II diabetes, and coronary artery disease) (2).

In multifactorial genetic diseases, multiple different genes interact with one another and with certain environmental factors to cause disease. An individual who inherits a particular combination of interacting genes has a relative risk of developing disease. When this genetic component interacts with a set of environmental factors, a biologic threshold is crossed and disease expression occurs (2). For example, maternal folate deficiency is an important environmental contributor to defective neural tube development in the fetus. Population studies have demonstrated that folic acid treatment in women before and during pregnancy reduces the incidence of neural tube defects by nearly half. These observations prompted efforts to identify variations in genes encoding enzymes of the folic acid metabolic pathway. Recent studies have determined that women carrying specific variants in several of these genes have an increased risk of bearing a child with neural tube defects (12).

Genomic Imprinting

Genomic imprinting refers to the phenomenon in which the phenotypic abnormalities of a given disorder differ depending on the sex of the transmitting parent. Genomic imprinting reflects a functional modification in which there is a temporary change in the function or expression of a gene depending on whether it is maternally or paternally derived (9).

Strong evidence for genomic imprinting in humans has resulted from molecular studies of two chromosomal deletion syndromes, Prader-Willi syndrome and Angelman syndrome. Although clinically quite distinct, both syndromes share similar cytogenetic deletions involving chromosome

15q11-13. The key factor that determines the specific phenotype is not the size of the deletion but the parental origin of the deleted chromosome. Prader-Willi syndrome occurs when the deletion is on the paternally derived chromosome 15, and Angelman syndrome occurs when the deletion is on the maternally derived chromosome 15. These parent-of-origin differences are believed to occur through methylation or other modifications of DNA, which differentially modify the expression of a small number of genes. Therefore, instead of the typical situation in which both maternal and paternal alleles of a gene are expressed, genomic imprinting acts by silencing the expression of one of the parental alleles. This differential expression of certain genes depending on the parent of origin appears to be effaced and reestablished during gametogenesis at each generation (13).

Uniparental Disomy

Uniparental disomy refers to the phenomenon in which both chromosomes of a given pair are inherited from only one parent. This phenomenon appears to result from errors in chromosome segregation during gamete formation. Uniparental isodisomy occurs when both chromosomes in the pair are completely identical, and uniparental heterodisomy results when the two chromosomes come from one parent but are different (14). Uniparental disomy can cause genetic disease either by rendering a mutant allele from the transmitting parent homozygous in the child or by unmasking an imprinted gene.

Mitochondrial Inheritance

The inheritance of nuclear chromosomes forms the basis for mendelian inheritance. In contrast, mitochondrial genes are inherited only from the mother. Mitochondria are passed from generation to generation via the cytoplasm of the oocyte. Because sperm do not contribute mitochondria to the zygote, mitochondrial genes have a strictly maternal pattern of inheritance (15). In theory, if penetrance were complete, then all of the sons and daughters of an affected female would be affected. In reality, penetrance is rarely complete; thus, confusing inheritance patterns can result.

Most cells contain hundreds or thousands of mitochondria, and each mitochondrion contains two to ten mitochondrial DNA (mtDNA) molecules (15). The mitochondrial genome is a small, circular, 16.6-kilobase, double-stranded DNA molecule that contains no introns. In the normal situation, each mtDNA molecule in a given individual is identical. However, the mutation rate in mtDNA is five to ten times greater than in nuclear DNA (16). Cells that contain a mixture of wild-type and mutant mtDNA are termed *heteroplasmic*, whereas cells with a single identical mtDNA are termed *homoplasmic*. Because mitochondria partition to daughter cells in an entirely random fashion, the cellular phenotype depends on the relative proportions of mutant

and wild-type mtDNAs within a given cell and the degree to which that cell depends on oxidative phosphorylation. The central nervous system is most dependent on mitochondrial energy, followed by the heart, skeletal muscle, liver, and kidney. Therefore, defects in the mitochondrial genome and the associated impairment of oxidative phosphorylation typically manifest as neuromuscular disease but may also cause renal tubular dysfunction or glomerular disease (16).

MEDICAL GENETICS

Genomic Organization and the Transmission of Genetic Information

The genetic complement of each individual is arrayed in 23 pairs of chromosomes (the diploid genome). One-half of each individual's chromosomes, or one haploid genome, is maternally derived, and the other half is of paternal origin. Each diploid genome is composed of 22 pairs of autosomes, numbered in order of descending size, and one pair of sex chromosomes (females, XX; males, XY). Chromosomes are stored in the cell nucleus and distributed to daughter cells by either mitotic or meiotic cell division. In both processes, the chromosomes are unwound and the two DNA strands are copied. The replicated strands, called *chromatids*, remain joined at the centromere. The chromatids, which can be visualized at this stage by light microscopy, are composed of two asymmetric arms. The shorter of the two is termed the *p arm*, whereas the longer of the two is called the *q arm*. When chromosomes are arranged systematically in pairs 1 to 23, they comprise the karyotype.

During somatic cell division, the process of mitosis distributes one chromatid of each chromosome pair to the daughter cells; thus, the full diploid complement of 23 chromosome pairs is transmitted. In contrast, germ cells undergo a reduction division called *meiosis*, in which only one chromatid is transmitted to each gamete. The diploid germ cell therefore generates haploid oocytes or sperm that contain 23 individual chromosomes. During fertilization, the union of the oocyte and sperm constitutes a diploid zygote with 23 pairs of chromosomes.

Recombination and Genetic Mapping

Meiosis is the process by which the chromosome number of diploid germ cells ($N = 46$) is reduced to the haploid number ($N = 23$) in the gametes. The independent assortment of chromosomes into gametes during meiosis produces a remarkable variety of possible genotypes in the progeny. For a given set of parents, there are 2^{23} different chromosome combinations possible in their offspring; thus, the likelihood that this set of parents will produce two independent offspring with an identical complement of chromosomes is 1 in 84 million (1 in 2^{23}) (2). The phenomenon of genetic

recombination during meiosis adds further to the enormous genetic diversity in humans and provides the basis for genetic mapping.

During the first meiotic division, chromatids pair with their homologues (e.g., the maternally derived chromosome 1 chromatids pair with the paternally derived chromosome 1 chromatids). This close proximity allows the exchange of segments between maternal and paternal homologues, a process termed *crossing over*. These exchanges, which result in genetic recombination, occur on average approximately 50 times during meiosis, with a slightly higher frequency in female germ cells than male germ cells. With the completion of this first meiotic division, each daughter cell has 46 chromosomes but only one copy of each chromatid pair. This separation of maternal and paternal chromosome homologues is referred to as a *reduction division*. The second meiotic division proceeds without further chromosome replication. The resulting gametes have a haploid chromosome complement.

Due to genetic recombination, two genes that are located on opposite ends of a given chromosome typically behave as if they are on different chromosomes (i.e., they segregate in an entirely random fashion). In comparison, recombination events are less likely between genes that are located close to one another. The distance between two such genes can be quantitated either in terms of genetic distance (i.e., the probability of recombination events per generation) or physical distance [i.e., millions of base pairs (megabases)]. Genetic distance is measured in centimorgans (cM). For two genes that are 1 cM apart, there is a 1% chance of a recombination event occurring between them in a given meiotic division. Although on average in the human genome, 1 cM corresponds to approximately 1 megabase of DNA, the frequency of recombination may vary in specific chromosomal regions and between female and male germ cells (2).

Mutations

A *mutation* is a stable alteration of the DNA sequence that can be passed from a parent cell to daughter cells. Alterations of DNA sequences in cells other than germ cells are termed *somatic mutations*. Although these alterations are not transmitted to the next generation, the mutations are passed on to the progeny of those mutated cells. When a somatic mutation occurs early in development, the resulting individual may be a mosaic or a combination of normal cells and mutant cells. Once development is complete, somatic mutations can be silent (i.e., they may not be associated with a specific phenotype). Alternatively, somatic mutations (e.g., those involved in ADPKD) play a central role in disease pathogenesis.

In comparison, germ-line mutations are transmitted from one generation to the next. On average, the rate of mutation is approximately 10^{-6} per locus per generation

(1). Most of these mutations occur in noncoding sequences and typically are detected as variations or polymorphisms in the population. In comparison, mutations in coding sequences often cause disease. From an evolutionary perspective, these coding sequence mutations appear to play an important role in generating genetic diversity and thereby permit environmental adaptation of the species through the process of natural selection.

Single base changes that occur in coding regions cause three types of mutations: (a) a silent mutation, in which the base change results in a different three-base code (codon) for the same amino acid; (b) a missense mutation, in which the base change results in a new codon (i.e., the wild-type amino acid is replaced by a new amino acid); and (c) a nonsense mutation, in which the base substitution changes the amino acid codon to a termination (stop) codon. The deletion or insertion of a single base or a few bases within the coding region can cause a frame shift mutation in which the reading frame of the genetic code is altered. Frame shift mutations alter the amino acid sequence and often lead to premature truncation of the peptide by generating a new stop codon.

Germ-line mutations can also involve millions of base pairs and cause gross chromosomal alterations, including duplications, insertions, deletions, or translocations. Such alterations may disrupt the coding sequence and cause either an absence of the protein product, as in juvenile nephronophthisis (NPH1) (17), or the fusion of two closely related protein products, as in glucocorticoid-remediable aldosteronism (18). Finally, sequence alterations in the DNA flanking the coding regions may lead to changes in RNA splicing, transcriptional efficiency, or regulated tissue expression.

STRATEGIES FOR GENE IDENTIFICATION

After the seminal report by Watson and Crick in 1953 describing the structure of DNA, identification of disease-causing genes was predicated on first identifying the defective protein (functional cloning). Perhaps the best known successes of the functional cloning approach involve disease gene identification in phenylketonuria and sickle cell disease. However, for most human diseases, our level of insight into the fundamental pathogenic mechanisms remains rather limited; thus, functional cloning has not been a broadly applicable approach.

To a certain extent, the candidate gene approach also depends on functional insight into disease pathogenesis. By itself, this knowledge is not sufficient to precisely pinpoint the gene; rather, it provides a framework to form a series of educated guesses. For example, clinical studies of Bartter syndrome patients indicated a primary defect in transepithelial sodium chloride transport in the thick ascending limb of the loop of Henle. With the cloning of genes

encoding the key transport proteins in the thick ascending limb [e.g., the bumetanide-sensitive sodium-potassium-chloride cotransporter (*NKCC2*), the apical adenosine triphosphate-regulated potassium channel (*ROMK*), and the kidney-specific basolateral chloride channel (*ClC-Kb*)], direct molecular studies became possible. Loss-of-function mutations in the genes for each of these transport proteins have been demonstrated in patients with either antenatal Bartter syndrome or the more classic phenotype (19).

Beginning in 1986, positional cloning or map-based gene discovery became the leading method for identifying disease susceptibility genes in inherited disorders. With the availability of the human genome sequence, the positional candidate approach has rapidly emerged as the preferred method for elucidating the molecular basis of genetic disease. This strategy combines genetic mapping, usually by linkage analysis, with information from databases that catalogue the human genomic sequence and its transcripts [e.g., those maintained by the National Center for Biotechnology Information (<http://www.ncbi.nlm.nih.gov>)]. Once a candidate disease-susceptibility gene is mapped to a chromosomal subregion, the databases can then be surveyed to identify attractive candidate genes within the interval.

To date, the successes in gene discovery have primarily involved single-gene disorders. Investigators have determined that the phenotypic expression of these disorders is due to different mutations within the disease-susceptibility gene. In addition, disease expression appears to be influenced by the modifying effects of other genes (modifying genes) that are involved in the same molecular pathway(s) (20). In comparison to single-gene disorders, multifactorial genetic diseases involve genetic susceptibility and environmental factors. In these disorders, the expression of the disease phenotype depends on the complement of risk genes that is inherited and the interaction of these risk genes with certain environmental factors. The major challenge facing molecular geneticists is to elucidate and characterize the molecular components involved in both single-gene and multifactorial disorders and to determine how these molecular factors influence the disease phenotype.

GENETIC TESTING

The immediate clinical impact of gene mapping and identification is the potential for gene-based diagnostic testing. DNA-based diagnosis of single-gene disorders is well established in prenatal, pretransplant, and presymptomatic contexts. For mendelian traits, such genetic testing can be performed in one of two ways: (a) indirect testing, which usually involves linkage analysis, or (b) direct gene-based testing.

Before genetic testing can be offered, the molecular “specifics” for a given disorder must be evaluated. The practicality of genetic testing depends on a number of factors, including (a) the number of genes/loci involved; (b) the genetic map

for those disease genes that have yet to be cloned; (c) the size and the complexity of the disease genes; and (d) the number and distribution of different mutations within the disease genes. In addition to the technical challenges of genetic testing, issues such as phenotype-genotype correlation, sensitivity and specificity, proper informed consent, and access to genetic counseling must be addressed before a test is ready for clinical use (21).

It is important to stress that genetic tests differ from other medical tests. They have direct implications for family members and for reproductive decision making. They often raise issues of privacy, independence, insurability, and discrimination, and the test results may have dire emotional consequences (21). Therefore, genetic counseling should precede genetic testing to allow informed decision making.

Linkage Analysis

Linkage analysis is an indirect method for diagnostic genetic testing. It is useful in mendelian disorders in several contexts: (a) when the disease gene has not yet been identified; (b) when the disease gene is very large or complex; and (c) or when the mutations are too heterogeneous to be readily identified. In linkage-based testing, the disease gene is not directly analyzed. Rather, its presence is inferred by family studies that track the cosegregation of flanking polymorphic markers and a specific disease phenotype.

The principal advantage of linkage-based testing is that it can be applied to any mapped mendelian trait. The disadvantages of linkage analysis include (a) the absolute dependence of the test on correct phenotypic diagnosis; (b) the requirement for DNA typing of an affected proband as well as other affected and unaffected family members; and (c) the limitation of the maximum confidence level to 95 to 99%. Such confidence limits are inherent to linkage analyses because of the possibility that recombination events could occur between the marker and the mutant gene, with the probability directly related to the genetic distance between them. The risk of possible error can be minimized when intragenic and multiple flanking markers are used for testing. Although linkage-based testing is a powerful diagnostic tool in many disorders, diagnoses based on such an indirect methodology are estimates and should be treated as such.

Direct Mutation Analysis

Once a disease gene is cloned, direct mutation detection strategies can be designed to identify the genetic defect that is causally responsible for the disease phenotype. Direct mutation analysis can be performed by several methods. The details of these testing modalities are beyond the scope of this chapter and the reader is referred to several excellent reviews (22–25). In general, the choice of method depends on the types and numbers of mutations that cause the disorder.

TABLE 18.1. GLOSSARY OF TERMS

Term	Definition
Allele	An alternative form of a gene. Humans carry two sets of alleles for every gene or genetic marker, one from each parent.
Alternative splicing	A regulatory mechanism by which exons are variably incorporated into the mRNA, leading to the production of more than one related protein or isoform.
Autosomes	All of the chromosomes except for the sex chromosomes and the mitochondrial chromosome.
cDNA	A DNA sequence made from an mRNA molecule. cDNAs contain only exonic sequences.
Cloning	The process of generating multiple copies of a particular piece of DNA.
Codon	A three-base sequence of DNA or RNA that specifies a single amino acid.
Conservation	Sequence similarity for genes that are present in two distinct organisms. Conservation can be detected by measuring the sequence similarity at the nucleotide (DNA or RNA) or the amino acid level.
Epigenetic	A term describing nonmutational phenomena (e.g., methylation and histone modification) that modify the expression of a gene.
Euchromatin	The gene-rich regions of the genome.
Exon	A region of a gene that encodes a portion of its protein product.
Genomics	The study of the functions and interactions of all the genes in the genome, including their interactions with environmental factors.
Genotype	The set of genes that an individual carries; usually refers to the particular pairs of alleles that the individual has at a given region of the genome.
Haplotype	A group of nearby alleles that are closely linked (i.e., likely to be inherited together).
Heterochromatin	Compact gene-poor regions of the genome that are difficult to clone and thus are usually ignored in genome sequencing.
Intron	A region of a gene that does not code for a protein.
mRNA	The template for protein synthesis. A precursor RNA is constructed from the gene sequence and then processed with removal of the introns by splicing. Spliced RNAs contain only exonic sequences from which proteins are synthesized.
Microarray	High-dimensional tool that allows expression analysis of thousands of genes (or proteins) in a single hybridization experiment.
Monogenic disease	Caused by mutations in a single gene.
Multifactorial disease	Caused by the interaction of multiple genetic and environmental factors.
Mutation	An alteration in an individual's genomic sequence compared to a reference sequence. These sequence variants can have harmful effects (pathogenic mutations) or no harmful effects (silent mutations or polymorphisms).
Penetrance	The likelihood that a person carrying a particular mutant gene will have an altered phenotype.
Phenotype	The observable properties and physical characteristics of an individual.
Polymorphism	A region of the genomic sequence that varies between individual members of a population.
Proteomics	The study of the functions and interactions of all the proteins encoded in the genome.
SNP	A polymorphism caused by the change of a single nucleotide. The human genome is estimated to contain approximately 10 million SNPs.
Transcription	The process of copying a gene into RNA.
Transcriptosome	The complete set of RNAs transcribed from the genome.
Translation	The process of using an mRNA sequence to build a protein.

cDNA, complimentary DNA; mRNA, messenger DNA; SNP, single-nucleotide polymorphism.

Modified from Venter J, Adams M, Myers E, et al. The sequence of the human genome. *Science* 2001;291:1304–1351; and Guttmacher A, Collins F. Genomic medicine—a primer. *N Engl J Med* 2002;347:1512–1520.

When compared with linkage-based testing, direct mutation analysis has several advantages. Most notable among these are (a) a previously affected sibling is not essential, and (b) studies on other family members are not typically required. The pitfalls can include (a) locus heterogeneity, in which the same phenotype can be caused by mutations in more than one gene; (b) no *a priori* knowledge of the specific mutation segregating in a family or present in a given individual; and (c) the inability of a given technique to detect all mutations.

With current technologies, detection of mutations can be time-consuming and expensive. In the postgenomic era, the search for clinically useful assays will emphasize the use of

newer DNA sequencing technologies as well as the development of microarray-based genomic and proteomic screening.

INSIGHTS FROM THE HUMAN GENOME PROJECT

In February 2001, the draft sequence of the human genome was published by two groups, the International Human Genome Sequencing Consortium (26) and Celera Genomics (27). The estimated size of the human genome is 3.2×10^9 base pairs or gigabases. The sequence is approximately 90% complete for the 2.95 gigabases of euchro-

FIGURE 18.6. Schema of a typical eukaryotic gene and RNA splicing. The nontranslated portion of the gene contains DNA control regions that specify the RNA transcription start site and define the specificity of tissue expression. The sequences that encode the polypeptide product are organized into discrete units (exons) and specific sequences within the exons determine the translation start site (ATG) and stop site (TGA). The exons are interrupted by noncoding sequences (introns). The DNA sequence is transcribed in the nucleus into an RNA product, and the intervening introns are removed or “spliced out.” By alternative splicing, a single gene can produce multiple related proteins. mRNA, messenger RNA. 1–5, exons.

matic or weakly staining gene-rich regions of the human genome (Table 18.1). Based on initial analyses, investigators predict that the human genome contains 30,000 to 35,000 protein-encoding genes (Fig. 18.6), which comprise 1.1 to 1.4% of the total sequence (28). The number of coding genes in the human sequence compares with 6000 for the yeast *Saccharomyces cerevisiae*; 13,000 for *Drosophila*; 18,000 for the roundworm *Caenorhabditis elegans*; and 26,000 for the mustard weed *Arabidopsis* (29). Therefore, our complexity as a species derives from more than just our complement of genes. Factors such as variations in gene regulation, gene expression, the splicing of gene transcripts, and modifications of proteins after translation probably all contribute to our complexity.

The human genome sequence is providing new tools and new challenges for genetic investigators (29). This information has already begun to revolutionize biologic investigation by allowing researchers to examine global gene expression in different cells, tissues, and disease states using high dimensional tools, such as microarrays. The power of these genomic tools will be enhanced as the genomic sequence is annotated so that the full complement of genes as well as their regulatory regions is defined. By extension, the genomic sequence will inform our understanding of the full complement of human proteins, the proteome. Ultimately, this information will permit detailed characterization of the cellular pathways and networks in which these proteins interact.

In addition, the human genome sequencing effort has demonstrated that individual humans differ from one another by approximately one base pair per thousand. By examining the patterns of these single-nucleotide polymorphisms in patients and controls, researchers can evaluate the contribution of individual genes to relative susceptibility or resistance to disease. This genetic variation may also provide insights into individual responses to pharmaceutical treatment (30).

FUTURE CONSIDERATIONS

To date, genetic discoveries have largely focused on identifying the genes involved in rare mendelian disorders. In the

postgenomic era, methods for automated mutation detection, array-based systems for gene and protein expression, and polymorphism profiles of disease susceptibility will all become feasible. These advances will facilitate both the diagnosis of mendelian disorders (e.g., autosomal-recessive polycystic kidney disease) and the evaluation of genetic susceptibility to more common, multifactorial disorders (e.g., vesicoureteral reflux).

Detailed understanding of the molecular pathophysiology of human disease will provide new opportunities for diagnosis and treatment of both rare and common disorders (Fig. 18.7). Some of these treatments may entail

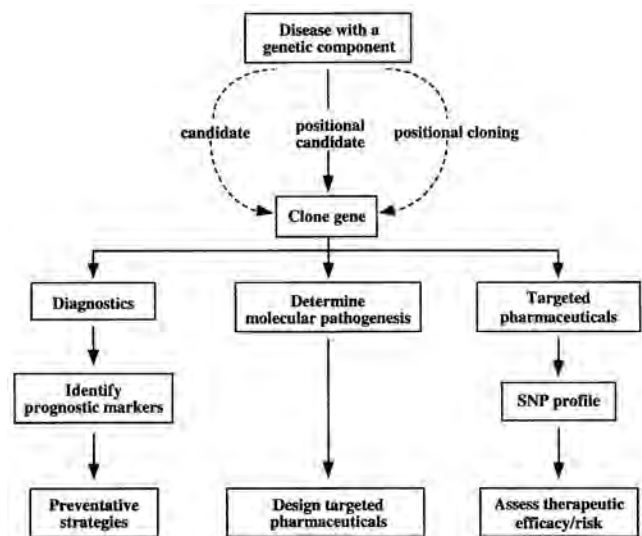

FIGURE 18.7. Advances in molecular genetics and the clinical implications. In the postgenomic era, positional candidate approaches can be applied to identify disease-susceptibility genes for mendelian and, eventually, polygenic disorders. Gene discovery can be translated into DNA-based diagnostic tests. In a growing number of instances, improved diagnostic specificity can lead to the identification of specific genetic risk factors and ultimately facilitate the development of preventative medicine strategies. In addition, gene discovery will open up new treatment options involving pharmaceuticals that target specific aspects of the molecular pathogenesis. Increasingly, the efficacy and risk of these new pharmaceuticals for a given individual will be assayed using single-nucleotide polymorphism (SNP)-based profiles. (Modified from Collins F. Positional cloning moves from perditoal to traditional. *Nat Genet* 1995;9:347–350.)

sophisticated gene therapy techniques, but others will involve the development of targeted pharmaceuticals based on more precise understanding of molecular physiology. Single-nucleotide polymorphism profiling will afford risk assessment for an individual's genetic susceptibility to certain illnesses (e.g., type II diabetes), and specific preventative medicine programs will be developed to target this risk. In addition, it will become standard practice to use single-nucleotide polymorphism-based profiles to predict drug responses in individual patients (31). Pediatricians and pediatric subspecialists must become familiar with the advances in the postgenomic era to incorporate these changes into their practices.

TISSUE ENGINEERING

ANTHONY ATALA

Regenerative medicine, a recently defined field, involves the diverse areas of tissue engineering, stem cells, and cloning toward the common goal of developing biologic substitutes that would restore and maintain normal tissue and organ function.

Tissue engineering follows the principles of cell transplantation, materials science, and engineering toward the development of biologic substitutes that restore and maintain normal function. Tissue engineering may involve matrices alone, wherein the body's natural ability to regenerate is used to orient or direct new tissue growth, or the use of matrices with cells.

When cells are used for tissue engineering, donor tissue is dissociated into individual cells that are either implanted directly into the host or expanded in culture, attached to a support matrix, and reimplanted after expansion. The implanted tissue can be heterologous, allogeneic, or autologous. Ideally, this approach might allow lost tissue function to be restored or replaced *in toto* and with limited complications (2). The use of autologous cells avoids rejection, wherein a biopsy of tissue is obtained from the host, the cells are dissociated and expanded *in vitro*, reattached to a matrix, and implanted into the same host.

One of the initial limitations of applying cell-based tissue-engineering techniques to urologic organs had been the previously encountered inherent difficulty of growing genitourinary-associated cells in large quantities. In the past, it was believed that urothelial cells had a natural senescence that was hard to overcome. Normal urothelial cells could be grown in the laboratory setting but with limited expansion. Several protocols were developed over the last two decades that improved urothelial growth and expansion (3–6). Using these methods of cell culture, it is possible to expand a urothelial strain from a single specimen that initially covers a surface area of 1 cm² to one covering a surface area of 4202 m² (the equivalent area of one football field) within 8 weeks (3).

Biomaterials in genitourinary tissue engineering may function as an artificial extracellular matrix and elicit biologic and mechanical functions of native extracellular matrix found in tissues in the body. The design and selec-

tion of the biomaterial is critical in the development of engineered genitourinary tissues. The biomaterial must be capable of controlling the structure and function of the engineered tissue in a predesigned manner by interacting with transplanted cells and/or the host cells. Generally, the ideal biomaterial should be biocompatible, promote cellular interaction and tissue development, and possess proper mechanical and physical properties.

In general, three classes of biomaterials have been used for engineering genitourinary tissues: naturally derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa), and synthetic polymers [e.g., polyglycolic acid (PGA), polylactic acid, and poly(lactic-co-glycolic acid)]. These classes of biomaterials have been tested in respect to their biocompatibility with primary human urothelial and bladder muscle cells (7,8). Naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition. Synthetic polymers can be produced reproducibly on a large scale with controlled properties of their strength, degradation rate, and microstructure.

TISSUE ENGINEERING OF GENITOURINARY STRUCTURES

Urethra

Various strategies have been proposed over the years for the regeneration of urethral tissue. Woven meshes of PGA have been used to reconstruct urethras in animals (9,10). PGA has been also used as a cell transplantation vehicle to engineer tubular urothelium *in vivo* (11). When using cells for transplantation, it has been shown that cells from an abnormal environment, if genetically stable, are able to be engineered into normal tissues (12). A homologous free graft of acellular urethral matrix was used in a rabbit model (13). All tissue components were seen in the grafted matrix after 3 months, with further improvement over time; however, the smooth muscle in the matrix was less than in normal rabbit urethra and was not well oriented.

FIGURE 19.1. Urethrogram 6 months postoperatively of a patient who had a portion of his urethra replaced using tissue-engineering techniques.

Acellular collagen matrices obtained from donor bladder submucosa have proven to be suitable grafts for repairing urethral defects both experimentally and clinically at our institution. Rabbit neourethras reconstructed with acellular matrices demonstrated a normal urothelial luminal lining and organized muscle bundles without any signs of strictures or complications (14). These results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction, wherein the urethral defects were repaired with human bladder acellular collagen matrices in an onlay fashion, with the size of the created neourethras ranging from 5 to 15 cm (Fig. 19.1) (15). The same technique was used to repair urethral strictures on more than 40 adult patients (16). One of the advantages over nongenital tissue grafts used for urethroplasty is that the collagen-based acellular material is “off the shelf.” This eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease operative time as well as the potential morbidity due to the harvest procedure.

It has also been noted that although acellular collagen-based grafts may be suitable for partial onlay urethral replacement, they are not effective for the replacement of tubularized segments, as this results in the collapse of the grafts, with subsequent stricture formation (17). Tubularized urethral repairs require the application of collagen-based grafts seeded with both urothelial and muscle cells

(17). Total urethral replacement is possible with the use of tissue-engineered constructs composed of urothelial and muscle cell seeded matrices.

Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb specific solutes, whereas bladder tissue is designed for the excretion of solutes. When gastrointestinal tissue is in contact with the urinary tract, multiple complications may ensue, such as infection, metabolic disturbances, urolithiasis, perforation, increased mucous production, and malignancy (18). Owing to the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative methods, materials, and tissues for bladder replacement or repair.

Seromuscular grafts and deepithelialized bowel segments, either alone or over a native urothelium, have been attempted (19–26). The concept of demucosalizing organs is not new to urologists. More than four decades ago, in 1961, Blandy proposed the removal of submucosa from intestinal segments used for augmentation cystoplasty to insure that mucosal regrowth would not occur (19). Hypothetically, this would avoid the complications associated with using bowel in continuity with the urinary tract (20,21). Since Blandy’s initial report, 25 years transpired before there was a renewed interest in demucosalizing intestinal segments for urinary reconstruction (22). Since 1988, several other investigators have pursued this line of research (23–26). These investigative efforts have emphasized the complexity of both the anatomic and cellular interactions present when combining tissues with different functional parameters. The complexity of these interactions is emphasized by the observation that the use of demucosalized intestinal segments for augmentation cystoplasty is limited by either mucosal regrowth or contraction of the intestinal patch (23,24). It has been noted that removal of only the mucosa may lead to mucosal regrowth, whereas removal of the mucosa and submucosa may lead to retraction of the intestinal patch (27,28).

Some researchers have combined the techniques of autoaugmentation with enterocystoplasty. An autoaugmentation is performed, and the diverticulum is covered with a demucosalized gastric or intestinal segment. In a series of autoaugmentation (25) enterocystoplasty, patients with a neurogenic bladder had either incorporation of stomach or colon. In both groups of patients, the mucosa of the enteric segment was dissected away from the underlying muscle, and the resulting mucosa-free graft was used to cover a newly created bladder diverticulum. A satisfactory increase in bladder capacity and compliance was achieved in most patients. In another series of patients who underwent seromuscular colocolocystoplasty,

FIGURE 19.2. Bladders augmented with a collagen matrix derived from bladder submucosa seeded with urothelial and smooth muscle cells [allogenic bladder submucosa (ABS) + cells] showed a 100% increase in capacity compared to bladders augmented with the cell-free ABS, which showed only a 30% increase in capacity within 3 months after implantation. (See Color Plate 19.2.)

the bladder capacity increased an average of 2.4-fold in 14 patients (26). Ten patients had a postoperative bladder biopsy. Seven patients demonstrated urothelium covering the augmented portion of the bladder, two had regrowth of colonic mucosa, and one showed a mixture of colonic mucosa and urothelium. Although colonic mucosal regrowth is seen, there is a subset of patients who may benefit from these procedures, wherein mucous secretion may be reduced or eliminated (26).

Bladder grafts, initially used experimentally in 1961, have been used recently by various investigators (29–32). The allogenic acellular bladder matrix has served as a scaffold for the ingrowth of host bladder wall components. The matrix is prepared by mechanically and/or chemically removing the cellular components.

Allogenic bladder submucosa was used as a biomaterial for bladder augmentation in dogs (31). Biomaterials preloaded with cells before their implantation showed better tissue regeneration compared to biomaterials implanted with no cells in which the tissue regeneration depended on the ingrowth of the surrounding tissue. The bladders showed a significant increase in capacity of 100% when augmented with scaffolds seeded with cells, compared to a capacity of 30% for scaffolds without cells (Fig. 19.2).

Small-intestinal submucosa derived from pig small intestine has been used for augmentation cystoplasty in dogs (33). Preoperative mean bladder capacity was 51 mL compared to a postoperative mean capacity of 55

mL. Histologically, the muscle layer was not fully developed. A large amount of collagen was interspersed between a smaller number of muscle bundles. A computerized assisted image analysis demonstrated a decreased muscle-to-collagen ratio with a loss of the normal architecture in the small-intestinal submucosa-regenerated bladders. *In vitro* contractility studies performed on the small-intestinal submucosa-regenerated dog bladders showed a decrease in maximal contractile response by 50% from those of normal bladder tissues. Cholinergic and purinergic innervation was present (34).

In multiple studies using different materials as an acellular graft for cystoplasty, the urothelial layer was able to regenerate normally, but the muscle layer, although present, was not fully developed (30–33). Engineering tissue using selective cell transplantation may provide a means to create functional new bladder segments (11). The success of using cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth.

Urothelial and muscle cells can be expanded *in vitro*, seeded onto the polymer scaffold, and allowed to attach and form sheets of cells. The cell-polymer scaffold can then be implanted *in vivo*. A series of *in vivo* urologic-associated cell-polymer experiments were performed in mice, rabbits, and dogs (3,11,31,35).

To better address the functional parameters of tissue-engineered bladders, an animal model was designed that required a subtotal cystectomy with subsequent replacement with a tissue-engineered organ (36). Dogs underwent a trigone-sparing cystectomy. The animals were randomly assigned to one of three groups. Animals underwent closure of the trigone without a reconstructive procedure, underwent reconstruction with a cell-free bladder-shaped biodegradable matrix, or underwent reconstruction using a bladder-shaped biodegradable matrix that delivered autologous urothelial and smooth muscle cells. The cell populations had been separately expanded from a previously harvested autologous bladder biopsy. Preoperative and postoperative urodynamic, radiographic, gross, histologic, and immunocytochemical analyses were performed serially, at 1, 2, 3, 4, 6, and 11 months postoperatively (36).

The cystectomy only controls and polymer-only grafts maintained average capacities of 22% and 46% of preoperative values, respectively. An average bladder capacity of 95% of the original precystectomy volume was achieved in the tissue-engineered bladder replacements. These findings were confirmed radiographically. The subtotal cystectomy reservoirs, which were not reconstructed, and polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42%). The compliance of the tissue-engineered bladders showed almost no difference from preoperative values that were measured when the native

FIGURE 19.3. Hematoxylin and eosin histologic results 6 months after surgery (original magnification: $\times 250$). **A:** Normal canine bladder. **B:** The bladder dome of the cell-free polymer reconstructed bladder consists of normal urothelium over a thickened layer of collagen and fibrotic tissue. Only scarce muscle fibers are apparent. **C:** The tissue-engineered neo-organ shows a histomorphologically normal appearance. A tri-layered architecture consisting of urothelium, submucosa, and smooth muscle is evident.

bladder was present (106%). Histologically, the polymer-only bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle (Fig. 19.3). Immunocytochemical analyses for desmin, α -actin, cytokeratin 7, pancytokeratins AE1/AE3, and uroplakin III confirmed the muscle and urothelial phenotype. S-100 staining indicated the presence of neural structures. The results from this study showed that it is possible to tissue engineer bladders that are anatomically and functionally normal (36). Human bladders have been created using the same techniques.

Clinically, cells used for tissue engineering may be harvested from abnormal bladders. We investigated the contractility of tissue-engineered bladder smooth muscle derived from patients with functionally normal bladders and functionally abnormal neuropathic and exstrophic bladders (12). The tissue-engineered cells showed similar expression of smooth muscle marker proteins (α -actin and myosin) regardless of their origin. All scaffolds showed similar muscle formation and were α -actin positive. At retrieval, the muscle cell-seeded scaffolds exhibited contractile activity to electrical field stimulation and carbachol. There was no statistical difference between the three different types of muscle cells seeded (normal,

neurogenic, exstrophic). The results of this study were also consistent with prior findings that, in diseased bladders, a large portion of the pathologic effects seen are due to increased fibrosis, whereas the cells retain their genetic stability.

Genital Tissues

Reconstructive surgery is required for a wide variety of pathologic penile conditions, such as penile carcinoma, trauma, severe erectile dysfunction, and congenital conditions like ambiguous genitalia, hypospadias, and epispadias. The creation of autologous functional and structural corporal tissue *de novo* would be beneficial clinically. Studies conducted in our laboratory showed that cultured human corporal smooth muscle cells may be used in conjunction with biodegradable polymers to create corpus cavernosum tissue *de novo*. The formation of normal corporal cavernosa tissue is enhanced with the addition of corporal endothelial cells (37,38).

Further studies show that it is possible to replace entire cross-sectional segments of both corporal bodies in the protruding penis *in vivo* by interposing autologous engineered tissue (39). Rabbits had a small corporal biopsy. Cavernosal smooth muscle and endothelial cells were harvested and expanded. Matrices were obtained using cell lysis techniques from donor penile tissues. Cav-

ernosal smooth muscle and endothelial cells were seeded on the matrices. The entire cross section of the protruding rabbit phallus was excised, leaving the urethra intact. The experimental corporal bodies demonstrated intact structural integrity by cavernosography and only a slight decrease in pressure by cavernosometry when compared to the controls. Mating activity in the animals with the engineered corpora normalized by 3 months. Mating activity in the animals with the matrix alone was low throughout the study. The presence of sperm was confirmed during mating, and was present in all the rabbits with the engineered corpora but in only two with the matrix alone. Gross examination of the corporal implants with cells showed continuous integration of the graft into native tissue. The acellular matrices demonstrated the presence of fibrosis. Histologically, sinusoidal spaces and walls lined with endothelium and smooth muscle were observed in the engineered grafts. However, grafts without cells contained fibrotic tissue and calcifications with sparse corporal elements. Each cell type was identified immunocytochemically using antibodies to smooth muscle and endothelium. These studies demonstrate the possibility of engineering autologous penile corpora cavernosa tissue. The engineered tissue is able to achieve adequate structural and functional parameters. This technology may be potentially applicable to patients who require additional tissues for phallic reconstruction; however, additional studies involving larger phallic structures need to be completed. These studies are currently being performed in our laboratory.

Other alternative tissues are also being studied as possible replacements for silicone penile prostheses. Although silicone is an accepted biomaterial for penile prostheses, biocompatibility is a concern (40). The use of a natural prosthesis composed of autologous cells may be advantageous. A feasibility study for creating natural penile prostheses made of cartilage was performed (41). Cartilage, harvested from the articular surface of calf shoulders, was isolated, grown, and expanded in culture. The cells were seeded onto preformed cylindrical PGA polymer rods. The cell-polymer scaffolds were implanted in the subcutaneous space of athymic mice and retrieved up to 6 months postimplantation. At retrieval, the polymer scaffolds seeded with cells formed milky-white, rod-shaped, solid cartilaginous structures, maintaining their preimplantation size and shape. Biomechanical analyses showed that the engineered cartilage rods possessed the mechanical properties required to maintain penile rigidity. Histologic examination showed the presence of mature and well-formed cartilage.

In a subsequent study using an autologous system, the feasibility of applying the engineered cartilage rods *in situ* was investigated (42). Autologous chondrocytes harvested from rabbit ears were grown, expanded in culture, and seeded onto biodegradable polymer rods. The cell-polymer

rods were implanted into the corporal spaces of rabbits. All animals tolerated the implants for the duration of the study (6 months) without any complications. Gross examination at retrieval showed the presence of well-formed milky-white cartilage structures within the corpora at 1 month. All polymers were fully degraded by 2 months. There was no evidence of erosion or infection in any of the implant sites. The animals could copulate and impregnate their female partners without problems.

We further investigated the feasibility of engineering biomechanically adequate large autologous human cartilage rods that could be used clinically as penile prostheses (43). Chondrocytes were isolated from human auricular cartilage and expanded *in vitro*. The chondrocytes were seeded onto preformed rod-shaped biodegradable polymer scaffolds (1.2 cm in diameter, 6.0 cm in length) and maintained in a cell culture bioreactor for 1 month. Subsequently, the cell-seeded scaffolds were implanted into the subcutaneous space of athymic rats. The cell-seeded scaffolds formed milky-white cartilaginous rods that maintained the same size and shape as the initial implants. Histologic analyses using hematoxylin and eosin, toluidine blue, and Alcian blue demonstrated mature and well-formed chondrocytes. Tensile tests showed that the engineered cartilaginous rods were readily elastic and could withstand high degrees of tensile force (1.78 ± 0.29 kg), which was not significantly different from the Jonas (2.64 ± 0.24 kg) or AMS 700 inflatable prostheses (2.35 ± 0.21 kg). Dynamic bending tests demonstrated that the cartilaginous rods were flexible and durable. None of the cartilage rods ruptured during the continuous strenuous mechanical tests. The results from the above studies demonstrate that autologous human auricular cartilage tissue can serve as a cell source for engineering cartilaginous penile prostheses. Clinically, a cartilage biopsy would be obtained from the patient's ear, and the cells would be expanded and seeded onto biodegradable rod-shaped scaffolds sized for the patient. One month after being in a bioreactor, the engineered cartilage rods could be implanted surgically into the patient. Further long-term functional studies are currently being performed to apply this technology to the clinical setting.

Kidney

Although the kidney was the first organ to be substituted by an artificial device and was the first successfully transplanted organ (1), current modalities of treatment are far from satisfactory. In addition to the inherent shortage of transplant organs, complications associated with renal transplantation are yet to be resolved. The kidney is probably the most challenging organ to reconstruct using tissue-engineering techniques in the genitourinary system owing to its complex structure and function. Extracorpo-

renal assist devices may be improved by implanting isolated renal cell lines on bioartificial hemofilters (44). This may aid in the replacement of specific aspects of renal function, such as improved selected metabolic and endocrinologic parameters. Eventually, reconstruction of a tissue-engineered kidney by renal cell expansion *in vitro* and subsequent transplantation *in vivo* may be possible. To achieve this prospect, there are still many technical challenges to be solved.

The feasibility of achieving renal cell growth, expansion, and *in vivo* reconstitution using tissue-engineering techniques was explored in our laboratory. In one set of experiments, distal tubules, glomeruli, and proximal tubules from donor rabbit kidneys were plated separately *in vitro*, seeded onto biodegradable PGA polymer scaffolds, and implanted subcutaneously into host athymic mice. At retrieval, the scaffolds histologically showed progressive formation and organization of the nephron segments within the polymer fibers over time (45). To examine the tubular reconstitution process, nephron elements from animal kidneys were harvested and the cells were expanded *in vitro*, seeded on biodegradable polymers with a single-cell suspension, and reimplanted into syngeneic hosts (46). Sequential retrieval of the seeded polymers over time revealed that the renal epithelial cells first organized into a cord-like structure with a solid center. Subsequent canalization into a hollow tube could be seen by 2 weeks. Histologic examination with nephron segment-specific lectins showed successful reconstitution of proximal tubules, distal tubules, loops of Henle, collecting tubules, and collecting ducts.

In a third set of experiments, an attempt was made to harness the reconstitution of renal epithelial cells for the

generation of functional nephron units. Renal cells were harvested and expanded in culture. The cells were seeded onto a tubular device constructed from a polycarbonate membrane, connected at one end with a silastic catheter, which terminated into a reservoir. The device was implanted in the subcutaneous space of athymic mice (47). Histologic examination of the implanted device revealed extensive vascularization, formation of glomeruli, and highly organized tubule-like structures. Immunocytochemical staining with anti-osteopontin antibody, which is secreted by proximal and distal tubular cells and the cells of the thin ascending loop of Henle, stained the tubular sections. Immunohistochemical staining for alkaline phosphatase stained proximal tubule-like structures. Uniform staining for fibronectin in the extracellular matrix of newly formed tubes was observed. Yellow fluid was collected from inside the implant, and uric acid and creatinine levels were determined. The fluid collected from the reservoir contained 66 mg/dL uric acid (as compared to 2 mg/dL in plasma). The creatinine assay performed on the collected fluid showed an 8.2-fold increase in concentration (27.91 ± 7.56 mg/dL), as compared to serum (4.49 ± 0.08 mg/dL). These results suggested that the reconstituted tubules are capable of unidirectional secretion and concentration of solutes. The fluid retrieved was consistent with the make-up of dilute urine, as evidenced by its creatinine and uric acid concentrations. Similar studies were performed with renal cells obtained through nuclear transfer (48). The renal cells were expanded, seeded onto polycarbonate membrane devices, and implanted into steers. The seeded constructs were able to form well-defined renal structures that secreted dilute urine. The retrieved structures demonstrated the presence of nephron units (Fig. 19.4).

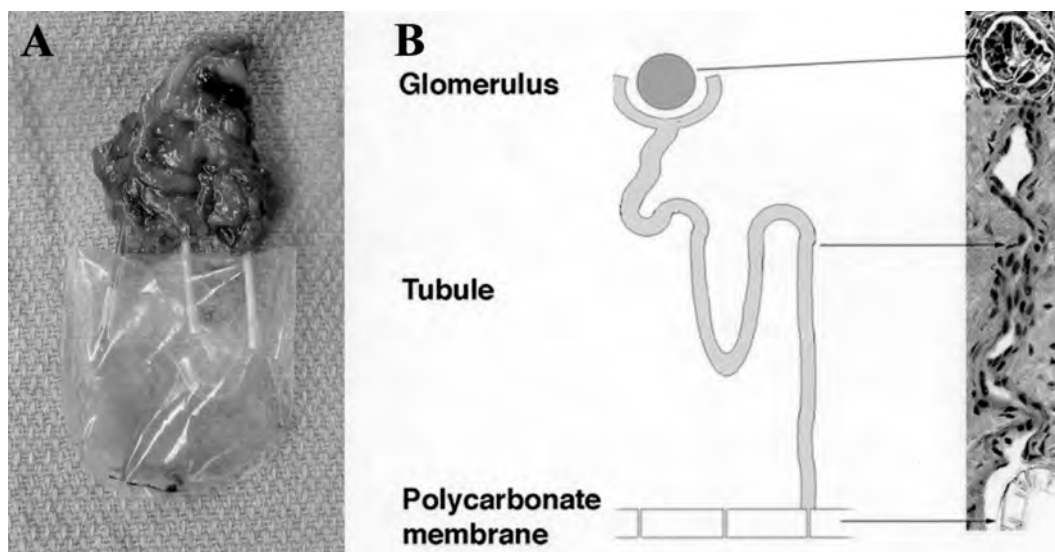

FIGURE 19.4. Tissue-engineered renal units. **A:** Retrieved tissue-engineered renal unit shows the excretion of yellow fluid in the reservoir. **B:** The engineered tissue showed a clear unidirectional continuity between the mature glomeruli, their tubules, and the reservoir. (See Color Plate 19.4.)

The results of these studies demonstrate that renal cells can be successfully harvested, expanded in culture, and implanted *in vivo*. The single cells form multicellular structures and become organized into functional renal units that are able to excrete high levels of solutes through a urine-like fluid. Further challenges await this technology, including the expansion of this system to larger three-dimensional structures.

Fetal Tissue Engineering

There are several strategies that may be pursued using today's technologic and scientific advances that may facilitate the future prenatal management of patients with urologic disease. Having a ready supply of urologic-associated tissue for surgical reconstruction at birth may be advantageous. Theoretically, once the diagnosis of the pathologic condition is confirmed prenatally, a small tissue biopsy could be obtained via ultrasound guidance. These biopsy materials could then be processed and the different cell types expanded *in vitro*. Using tissue-engineering techniques, reconstituted structures *in vitro* could then be readily available at the time of birth for reconstruction. Toward this end, a series of experiments were conducted using fetal lambs. Bladder exstrophy was created surgically in 90- to 95-day gestation fetal lambs. A small fetal bladder specimen was harvested via fetoscopy. The bladder specimen was separated, and muscle and urothelial cells were harvested and expanded separately. Seven to 10 days before delivery, the expanded bladder muscle cells were seeded on one side and the urothelial cells on the opposite side of a biodegradable polymer scaffold. After delivery, one-half of the lambs had surgical closure of their bladder using the tissue-engineered bladder tissue. No fetal bladder harvest was performed in the other lambs, and bladder exstrophy closure was performed using only the native bladder. Cystograms were performed 3 and 8 weeks after surgery. The engineered bladders were more compliant ($p = .01$) and had a higher capacity ($p = .02$) than the native bladder closure group (49). Similar prenatal studies were performed in lambs, engineering skin for reconstruction at birth. In addition to being able to manage the bladder exstrophy complex in utero with tissue-engineering techniques, one could also manage patients after birth in a similar manner whenever a prenatal diagnosis is not assured. In these instances, bladder tissue biopsies could be obtained at the time of the initial surgery. Different tissues could be harvested and stored for future reconstruction, if necessary.

Injectable Therapies

Both urinary incontinence and vesicoureteral reflux are common conditions affecting the genitourinary system, wherein injectable bulking agents can be used for treatment. The goal of several investigators has been to find alternate implant materials that would be safe for human

use (50). Long-term studies were conducted to determine the effect of injectable chondrocytes *in vivo* (51). It was initially determined that alginate, a liquid solution of glucuronic and mannuronic acid, embedded with chondrocytes, could serve as a synthetic substrate for the injectable delivery and maintenance of cartilage architecture *in vivo*. A biopsy of the ear could be easily and quickly performed, followed by chondrocyte processing and endoscopic injection of the autologous chondrocyte suspension for therapy.

Chondrocytes can be readily grown and expanded in culture. Neocartilage formation can be achieved *in vitro* and *in vivo* using chondrocytes cultured on synthetic biodegradable polymers (51). This system was adapted for the treatment of vesicoureteral reflux in a porcine model (52). Chondrocytes were harvested from the left auricular surface of surgically created refluxing mini-swine and expanded. The animals underwent endoscopic repair of reflux with the injectable autologous chondrocyte solution on the right side only. Serial cystograms showed no evidence of reflux on the treated side and persistent reflux in the uncorrected control ureter in all animals. The harvested ears had evidence of cartilage regrowth within 1 month of chondrocyte retrieval.

At the time of sacrifice, gross examination of the bladder injection site showed a well-defined rubbery to hard cartilage structure in the subureteral region. Histologic examination of these specimens showed evidence of normal cartilage formation. The polymer gels were progressively replaced by cartilage with increasing time. Aldehyde fuchsin–Alcian blue staining suggested the presence of chondroitin sulfate.

Using the same line of reasoning as with the chondrocyte technology, the possibility of using autologous muscle cells was also investigated (53). *In vivo* experiments were conducted in mini-pigs, and reflux was successfully corrected. In addition to its use for the endoscopic treatment of reflux and urinary incontinence, the system of injectable autologous cells may also be applicable for the treatment of other medical conditions, such as rectal incontinence, dysphonia, plastic reconstruction, and wherever an injectable permanent biocompatible material is needed.

Recently, the first human application of cell-based tissue-engineering technology for urologic applications has occurred with the injection of chondrocytes for the correction of vesicoureteral reflux in children (Fig. 19.5) and for urinary incontinence in adults. The clinical trials are currently ongoing (50,54–56).

The potential use of injectable, cultured myoblasts for the treatment of stress urinary incontinence has recently been investigated in preliminary experiments (57). Primary myoblasts obtained from mouse skeletal muscle were transduced *in vitro* to carry the β -galactosidase reporter gene and were then incubated with fluorescent microspheres that serve as markers for the original cell population. Cells were then directly injected into the proximal urethra and lateral bladder walls of nude mice with a microsyringe in an open

FIGURE 19.5. A: Preoperative voiding cystourethrogram of a patient showing bilateral reflux. B: Postoperative radionuclide cystogram of the same patient 6 months after the injection of autologous chondrocytes.

surgical procedure. Tissue was harvested up to 35 days postinjection, analyzed histologically, and assayed for β -galactosidase expression. Myoblasts expressing β -galactosidase and containing fluorescent microspheres were found at each of the retrieved time points. In addition, regenerative myofibers expressing β -galactosidase were identified within the bladder wall. By 35 days postinjection, some of the injected cells expressed the contractile filament α -smooth muscle actin, suggesting the possibility of myoblastic differentiation into smooth muscle. The authors reported that a significant portion of the injected myoblast population persisted *in vivo*. The fact that myoblasts can be transfected, survive after injection, and begin the process of myogenic differentiation further supports the feasibility of using cultured cells of muscular origin as an injectable bioimplant.

Testicular Hormonal Replacement

Leydig cells are the major source of testosterone production in males. Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment for testicular dysfunction consists of periodic intramuscular injections of chemically modified testosterone or, more recently, of skin patch applications. However, long-term nonpulsatile testosterone therapy is not optimal and can cause multiple problems, including erythropoiesis and bone density changes.

A system was designed wherein Leydig cells were microencapsulated for controlled testosterone replacement. Microencapsulated Leydig cells offer several advantages, such as serving as a semipermeable barrier between the transplanted cells and the host's immune system, as

well as allowing for the long-term physiologic release of testosterone.

Purified Leydig cells were isolated, characterized, suspended in an alginate solution, and extruded through an air jet nozzle into a 1.5% CaCl_2 solution in which they gelled and were further coated with 0.1% poly-L-lysine. The encapsulated cells were pulsed with human chorionic gonadotropin every 24 hours. The medium was sampled at different time points after human chorionic gonadotropin stimulation and analyzed for testosterone production. Cell viability was confirmed daily. The encapsulated Leydig cells were injected into castrated animals, and serum testosterone was measured serially. The castrated animals receiving the microencapsulated cells were able to maintain testosterone levels long term (58). These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone into situations in which anorchia or testicular failure is present. A similar system is currently being applied for estrogen.

Gene Therapy and Tissue Engineering

Genetically Engineered Cells

Cells can be engineered to secrete growth factors for various applications, such as for promoting angiogenesis for tissue regeneration. *Angiogenesis*, the process of new blood vessel formation, is regulated by different growth factors. These growth factors stimulate endothelial cells that are already present in the patient's body to migrate to the implanted area of need, where they proliferate and differentiate into blood vessels (59). One of the major molecules that pro-

mote and regulate angiogenesis is vascular endothelial growth factor (VEGF) (60). Several methods have been used experimentally to deliver VEGF *in vivo*. The growth factor protein can be directly injected into tissues (61); however, the rapid clearance of VEGF proteins from the vascular system limits its effect to only minutes. The VEGF gene could be delivered to tissues using various techniques; however, the transfection efficiency is low, the onset of action is delayed for up to 48 to 72 hours after the VEGF cDNA is incorporated, and the effect is transient, lasting only several days (61,62).

An approach that has been pursued in our laboratory to increase and stimulate rapid vascularization *in vivo* was to engineer a cell line to secrete high levels of VEGF proteins by gene transfecting the cells with the VEGF cDNA. The VEGF-secreting cells were encapsulated in polymeric microspheres. The microspheres would allow nutrients to reach the cells, while the VEGF proteins secreted from the cells diffused into the surrounding tissues. The microspheres protect the coated cells from the host immune environment. This novel system of neovascularization was tested *in vitro* and *in vivo* in an animal model. The degree of VEGF secretion and the period of delivery can be regulated by modulating the number of engineered cells that are encapsulated per microsphere, as well as the number of microspheres injected. A similar strategy has also been pursued for the genetic engineering of antiangiogenic factor-secreting cells (63). These strategies could be useful for antitumor therapy in urology.

Gene Therapy for Tissue-Engineered Constructs

Based on the feasibility of tissue-engineering techniques in which cells seeded on biodegradable polymer scaffolds form tissue when implanted *in vivo*, the possibility was explored of developing a neo-organ system for *in vivo* gene therapy (64). In a series of studies conducted in our laboratory, human urothelial cells were harvested, expanded *in vitro*, and seeded on biodegradable polymer scaffolds. The cell-polymer complex was then transfected with PGL3-luc, pCMV-luc, and pCMV β -gal promoter-reporter gene constructs. The transfected cell-polymer scaffolds were then implanted *in vivo*, and the engineered tissues were retrieved at different time points after implantation. Results indicate that successful gene transfer may be achieved using biodegradable polymer scaffolds as a urothelial cell delivery vehicle. The transfected cell/polymer scaffold formed organ-like structures with functional expression of the transfected genes (64). This technology is applicable throughout the spectrum of diseases, which may be manageable with tissue engineering. For example, one can envision the use of effecting *in vivo* gene delivery through the *ex vivo* transfection of tissue-engineered cell/polymer scaffolds for the genetic modification of diseased corporal smooth muscle cells harvested from impotent patients. Theoretically, the *in*

vitro genetic modification of corporal smooth muscle cells harvested from an impotent patient, resulting in either a reduction in the expression of the transforming growth factor-1 gene or the overexpression of genes responsible for prostaglandin E1 production, could lead to the resumption of erectile functionality once these cells were used to repopulate the diseased corporal bodies.

Stem Cells for Tissue Engineering

Most current strategies for engineering urologic tissues involve harvesting of autologous cells from the host diseased organ. However, in situations in which extensive end-stage organ failure is present, a tissue biopsy may not yield enough normal cells for expansion. Under these circumstances, the availability of pluripotent stem cells may be beneficial. Pluripotent embryonic stem cells are known to form teratomas *in vivo*, which are composed of a variety of differentiated cells. However, these cells may be immunocompetent and may require immunosuppression if used clinically.

The possibility of deriving pluripotent cells from postnatal mesenchymal tissue from the same host and inducing their differentiation *in vitro* and *in vivo* was investigated. Pluripotent cells were isolated from human foreskin-derived fibroblasts. Adipogenic, myogenic, and osteoblastic lineages were obtained from these progenitor cells. The cells were grown, expanded, seeded onto biodegradable scaffolds, and implanted *in vivo*, where they formed mature tissue structures. This was the first demonstration that stem cells can be derived from postnatal connective tissue and can be used for engineering tissues *in vivo ex situ* (65).

Therapeutic Cloning for Tissue Engineering

Recent advances with the cloning of embryos and newborn animals have expanded the possibilities of this technology for tissue engineering and organ transplantation. There are many ethical concerns with cloning in terms of creating humans for the sole purpose of obtaining organs. However, the potential for retrieving cells from early-stage cloned embryos for subsequent regeneration is being proposed as an ethically viable benefit of therapeutic cloning (Fig. 19.6). The feasibility of engineering syngeneic tissues *in vivo* using cloned cells was investigated.

Unfertilized donor bovine eggs were retrieved, and the nuclear material was removed. Bovine fibroblasts from the skin of a steer were obtained. The nuclear material was removed from the fibroblast and microinjected into the donor eggshell (nuclear transfer). A short burst of energy was delivered, initiating neo-embryogenesis. These techniques replicate what was performed to clone the first mammal—Dolly the sheep. However, instead of implanting the embryo into a uterus, the goal would be to harvest stem cells from the embryo, which was created not from the union of a sperm and an egg but rather

FIGURE 19.6. Schematic diagram of therapeutic cloning approach for the isolation of genetically matched tissues. (See Color Plate 19.6.)

from a skin cell and an eggshell, devoid of any genetic material. To achieve a proof of principle, bypassing the *in vitro* differentiation, the embryos were placed in the same steer uterus from which the fibroblasts had been obtained. The cloned embryo, with identical genetic material as the steer, was retrieved for tissue harvest. Various cell types were harvested, expanded *in vitro*, and seeded on biodegradable scaffolds. The cell-polymer scaffolds were implanted into the back of the same steer from which the cells were cloned. The implants were retrieved at various time points for analyses. Renal tissue, cardiac, and skeletal muscle were engineered successfully using therapeutic cloning.

These studies demonstrated that cells obtained through nuclear transfer can be successfully harvested, expanded in culture, and transplanted *in vivo* with biodegradable scaffolds in which the single suspended cells form and organize into tissue structures, which are the same genetically as the host. These studies were the first demonstration of the use of therapeutic cloning for the regeneration of tissues *in vivo* (48). One could envision taking one skin cell from a patient and having the ability to generate most types of tissues for replacement or transplantation, which would be genetically identical and fully biocompatible. Thus, each patient could conceivably have a ready-made supply of his or her own tissues available on demand.

CONCLUSION

Tissue-engineering efforts are currently being undertaken for every type of tissue and organ within the urinary system. Primary autologous cells, stem cells, and therapeutic cloning are being applied for the creation of tissues and organs. Tissue-engineering techniques require expertise in growth factor biology, a cell culture facility designed for human application, and personnel who have mastered the

techniques of cell harvest, culture, and expansion. Polymer scaffold design and manufacturing resources are essential for the successful application of this technology.

The first human application of cell-based tissue engineering for urologic applications occurred at our institution with the injection of autologous cells for the correction of vesicoureteral reflux in children. The same technology has been recently expanded to treat adult patients with urinary incontinence. Trials involving urethral tissue replacement using processed collagen matrices are in progress at our center for both hypospadias and stricture repair. Bladder replacement using tissue-engineering techniques is being explored. Recent progress suggests that engineered urologic tissues may have a wider clinical applicability in regenerative medicine.

IV

CLINICAL METHODS

CLINICAL EVALUATION

T. MARTIN BARRATT
PATRICK NIAUDET

Section IV is concerned with methods for evaluating children with kidney disease. This chapter addresses their presentation, the relevant features in their clinical history, and the findings to be sought on physical examination. This wide canvas is illustrated by didactic algorithms and frequent reference to other chapters in the book rather than by conventional citations of the medical literature, and we have drawn on our personal experience in the selection of material presented.

The clinical evaluation should follow the classic path of history, physical examination, and urinalysis, leading to a problem list with differential diagnoses, plan of investigation, and proposals for immediate management. It must, however, be modified to take into account the age of the child, the socioeconomic circumstances and medical resources available, the local epidemiology of renal disease, and the mode of presentation of the problem.

The proper recording of the clinical findings in the medical notes is essential for the management of the case, audit, retrospective review, and medicolegal purposes. It is the duty of the medical staff to maintain accurate records and of the clinical director of the service to ensure that this is done.

AGE AND RENAL DISEASE

The span of pediatric nephrology runs from conception to adolescence. At one end there is an overlap of responsibility with the geneticist and obstetrician, at the other with the “adult” nephrologist, and throughout with the pediatric urologist.

Fetus

The risk of inherited renal disease in the child may be evident from the family history, and several techniques are available for confirming the diagnosis in early pregnancy (see Chapter 21).

Structural malformations of the fetal kidneys or urinary tract are frequently revealed by the midtrimester maternal

ultrasound scan that is part of routine obstetric care and is now the most common route for infants to reach pediatric urologic services (see Chapter 4). Some abnormalities such as unilateral hydronephrosis are relatively minor; others like renal agenesis or severe bladder outflow obstruction are accompanied by oligohydramnios, a consequence of intrauterine renal failure, and pulmonary hypoplasia (the Potter sequence) (see Chapter 5).

Neonates

Congenital renal abnormalities and inherited disorders are present at birth but may not be immediately apparent, in part because the placenta is an efficient excretory organ masking renal failure and in part because the low glomerular filtration rate of the neonatal kidney may conceal genetically determined disorders of renal tubular function. The congenital nephrotic syndrome is present *in utero*: Affected infants are edematous at birth and have a high placenta/body weight ratio (see Chapter 25). Polycystic kidneys, particularly the autosomal recessive variety, are easily palpable (see Chapter 36).

Congenital abnormalities such as a posterior urethral valve may be missed in a midtrimester scan and present in the neonatal period with urinary retention and overflow. Urologic malformations may be associated with absent abdominal wall muscles and undescended testicles. Congenital abnormalities in other systems may suggest a syndrome with renal involvement (see Chapter 6).

The immaturity of glomerular and tubular function in the neonate is exaggerated in the premature infant, predisposing them to acidosis and hyponatremia. Perinatal crises may be associated with renal venous thrombosis, characterized by hematuria, firm enlarged kidneys, and renal failure (see Chapter 64). A urinary tract infection (UTI) may be a pointer to an underlying urologic abnormality.

Children

The clinical evaluation of young children requires special pediatric skills. They cannot articulate their symptoms: A

UTI may present as fever or vomiting (see Chapter 53) and chronic renal failure (CRF) as failure to thrive. The presentation of renal disease in older children is similar to adults, but it must be remembered that growth failure may be a pointer to occult renal disease (see Chapter 22). The psychosocial problems of chronic renal disease may be particularly troublesome in adolescents, and the possibility of noncompliance with therapy must be borne in mind.

SOCIAL AND ECONOMIC CIRCUMSTANCES

The clinical practice of pediatric nephrology described in this book is largely derived from and in reality only applicable to the 10% of the World's children who inhabit the industrialized countries of what might be called (without entering the political debate) the *Developed World* (see Chapter 75A). Three patterns can be discerned on the basis of the development of the specialty itself and the availability of renal replacement therapy for children. In the *Developed World* there are approximately one to two pediatric nephrologists per million total population, and renal transplantation is available for all children for whom it is clinically appropriate; in the *Developing World*, such services are patchy, and in the *Underdeveloped World* they are inappropriate in relation to the other medical needs of children.

The sick in poor countries are doubly disadvantaged: The gross national product is low, and a smaller proportion of it is made available for health care. Medical equipment and drugs are expensive, access to medical centers for children in rural communities is difficult, and civil war may disrupt services.

Children fare badly in the competition with adults for limited resources. Those with renal disease may be lost among the many who die from malnutrition and diarrhea: They tolerate salt and water depletion poorly. Protein-calorie malnutrition predisposes to postinfectious glomerulonephritis, aggravates the edema of the nephrotic syndrome, and is a major factor in the growth failure of CRF (see Chapter 68).

EPIDEMIOLOGY

There are considerable differences in the pattern of renal disease in children around the world. A major distinction exists between tropical and temperate regions, arising from racial variations in the susceptibility to renal disease, compounded by the socioeconomic factors described earlier. Thus, sickle cell nephropathy is restricted to Afro-Caribbean children, whereas vesicoureteric reflux (VUR) and associated UTI are more common in white children. The high incidence of glomerulonephritis in children in tropical countries is related to frequent bacterial and viral infections, and human immunodeficiency virus nephropathy is emerging as a major problem (see Chapter 51).

PRESENTATION

A renal or urologic disorder may present with symptoms such as hematuria or dysuria, obviously pointing to the urinary tract, or the kidneys may be involved as part of a more widespread syndrome (e.g., systemic lupus erythematosus). Similarly, a disordered pattern of micturition or change in urine volume or composition may indicate renal pathology. However, serious renal disease may be present without any symptoms at all or be associated with symptoms and signs that do not point directly to the urinary tract.

Abnormalities of Urine Appearance

Hematuria

The addition of even small amounts of blood to urine results in obvious macroscopic hematuria (Fig. 20.1). However, apparently clear urine may contain an abnormal number of red blood cells (RBCs), referred to as *microscopic hematuria*. If the bleeding is brisk, the urine will be red and may even contain clots, but usually the pigment changes to the more brown color of acid hematin. The presence of blood in the urine should be confirmed by dipstick testing with Hemastix (Bayer Diagnostics, Pittsburgh) (see Hemastix). Microscopy will distinguish hematuria from hemoglobinuria and myoglobinuria, which are also characterized by dark brown Hemastix-positive urine but without RBCs.

Bleeding may originate from the glomeruli or from the urinary tract: A distinction may be made by careful microscopy of the urine, with "glomerular hematuria" being characterized by deformed, misshapen RBCs. Red cell casts and proteinuria also point to a glomerular origin, but a urologic disorder, particularly tumor, hydronephrosis, or stone, must always be ruled out by careful ultrasound examination, even if there is obvious evidence of glomerular disease (see Chapters 57 and 58). Hematuria may be associated with hypercalciuria even without evident calculi. Blood in the initial part of the urinary stream suggests a urethral origin of the bleeding; terminal hematuria, particularly if associated with suprapubic pain or a disturbance of micturition, points to a bladder cause requiring investigation by cystourethroscopy. However, in most affected children, hematuria has its origin in the upper urinary tract, and endoscopy is not necessary as a routine investigation unless other features suggestive of lower tract pathology accompany the bleeding.

If the hematuria is persistent and accompanied by heavy proteinuria or reduced renal function, it is usually necessary to proceed to renal biopsy to determine the glomerular lesion. Recurrent episodes of isolated macroscopic hematuria with normal urine in between are usually benign and suggestive of immunoglobulin A nephropathy (see Chapter 31). Persistent microscopic hematuria, particularly with a suggestive family history, should prompt

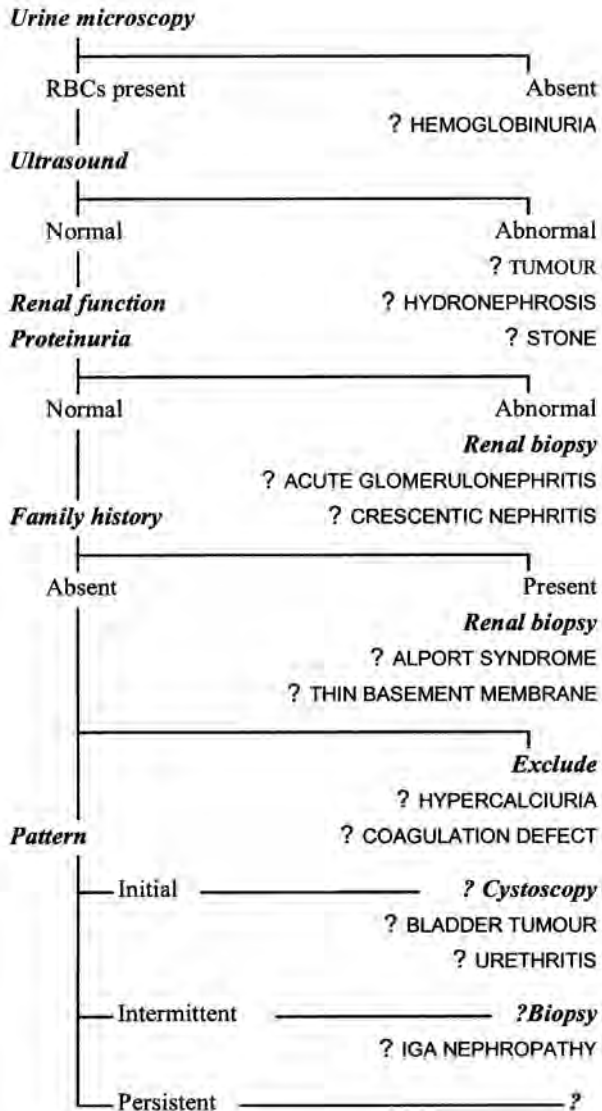

FIGURE 20.1. Hematuria. (Hemastix + ve.) RBC, red blood cell.

urine screening of all first-degree relatives and is best evaluated by renal biopsy, provided full facilities for its evaluation (including electron microscopy) are available (see Chapters 24 and 26).

Cloudy, Offensive Urine

Cloudy, offensive urine suggests a UTI, particularly if associated with local symptoms of dysuria and frequency or systemic symptoms of fever and loin pain, although significant bacteriuria may be asymptomatic (see Chapter 53) (Fig. 20.2). However, normal concentrated urine, when cooled, will form a precipitate of calcium phosphate; conversely, significant bacteriuria may be present without obvious macroscopic abnormality of the urine. Microscopy and culture of a properly collected and pro-

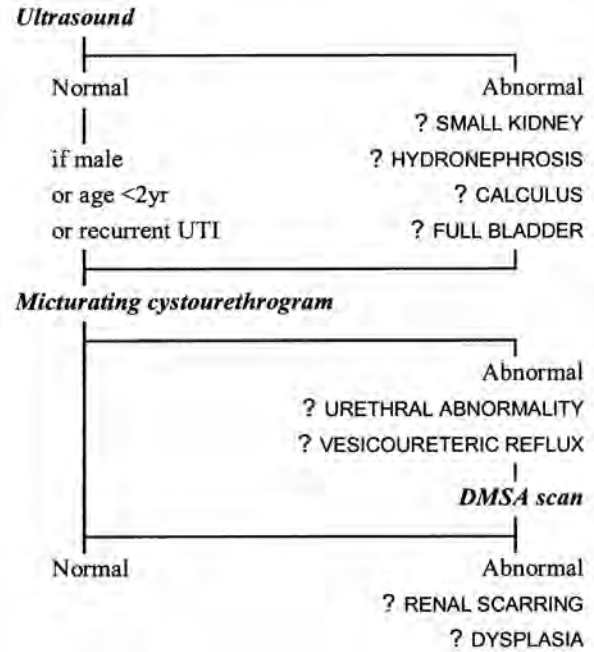

FIGURE 20.2. Urinary tract infection (UTI). (Hemastix + ve.) DMSA, dimercaptosuccinic acid.

cessed urine sample are essential in making the diagnosis of UTI, and screening tests are unreliable. Children with a proven UTI should have a careful abdominal ultrasound examination to exclude a urologic abnormality; boys and younger girls or those with recurrent UTI may require a cystogram to exclude VUR or other lower urinary tract abnormality. If VUR is present, a technetium-99m dimercaptosuccinic acid is the most sensitive method for determining the extent of associated renal scarring, but there is currently debate about protocols for the investigation of children with UTI (see Chapters 23, 53, and 54).

Stone

The passage of a stone is an unusual event in childhood (see Chapter 57) (Fig. 20.3). Renal calculi may cause hematuria or UTI and, if obstructive, renal colic. They may consist of calcium salts (phosphates or oxalates), struvite (the triple salt of magnesium, ammonium, and phosphate with organic matrix), cystine, uric acid, or rarely one of the other purines (xanthine or dihydroxyadenine). In the United Kingdom, the most common variety is struvite, typically found in the upper urinary tract of young boys with a UTI caused by *Proteus*. In the United States, the most common variety is calcium-containing stones in older children living in the "stone belt." Children with renal calculi, especially if associated with nephrocalcinosis, require full investigation to rule out an underlying metabolic cause, particularly distal

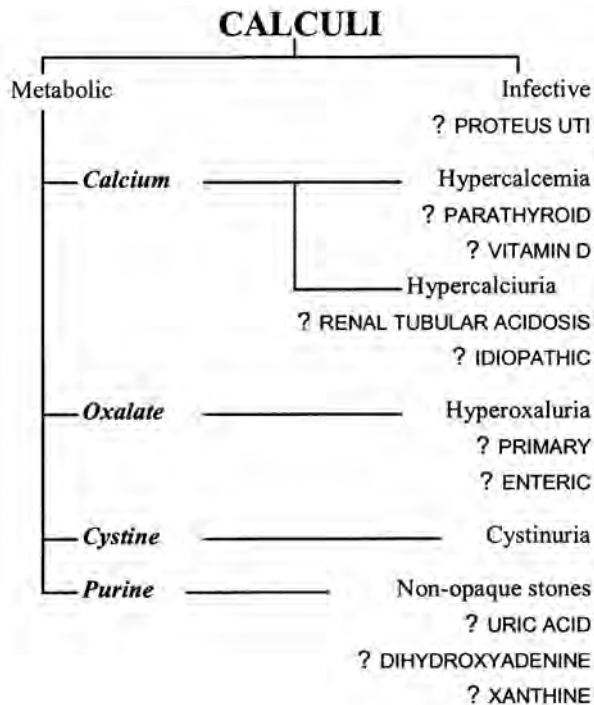

FIGURE 20.3. Calculi. UTI, urinary tract infection.

renal tubular acidosis (see Chapter 39) and primary hyperoxaluria (see Chapter 42). By comparison with adults, primary hyperparathyroidism is rare.

Abnormalities of Urine Volume

Oligoanuria

Anuria is the complete suppression of urine; oliguria is the passage of an insufficient volume to maintain homeostasis, usually taken to be less than 500 mL/24 hr/1.73 m² surface area, which in infants approximates 1.0 mL/hr/kg body weight. Urine volume in breast-fed, full-term babies averages 20 mL/24 hr in the first 2 days of life, rising to 200 mL by the tenth day. In newborn infants, 92% pass urine in the first 24 hours, and 98% do so within the first 48 hours of birth (see Chapter 56). Oliguria with acute renal failure may represent the physiologic response of a healthy kidney to inadequate perfusion (“prerenal”), parenchymal renal disease (“renal”), or obstruction of the urinary tract (“postrenal”) (Fig. 20.4) (see Chapter 64).

Polyuria

Polyuria results from an excessive intake of fluid, a failure of release of antidiuretic hormone, osmotic diuresis, or renal resistance to the action of antidiuretic hormone (see Chapter 40) (Fig. 20.5). The distinction between

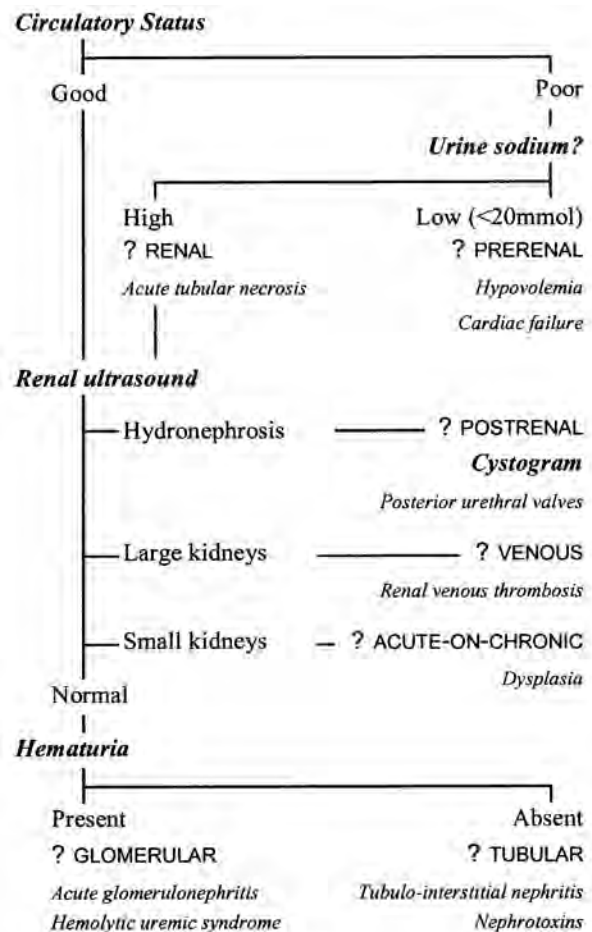

FIGURE 20.4. Acute renal failure. Oliguria <500 mL/1.73 m² SA/24 hr.

primary polydipsia and primary polyuria may be inferred from the relative osmolality of plasma and urine and the response to controlled water deprivation. The distinction between pituitary and renal causes of polyuria may be made by the plasma arginine-vasopressin concentration and the urinary response to des-D-amino-arginine vasopressin.

A defect of urine concentration should be suspected in any infant with unexplained irritability, failure to thrive, fever, dehydration, or hypernatremia. Older children are more likely to have nocturnal enuresis accompanied by a clear history of polyuria and polydipsia. However, it is difficult to define the threshold of polyuria with accuracy, but it is usually not apparent as an isolated clinical symptom unless the urine is persistently hypotonic to plasma. Under these circumstances there is increased thirst, and infants in particular are at risk of dehydration. The principal renal diseases that result in antidiuretic hormone-resistant polyuria of this severity are nephrogenic diabetes insipidus (see Chapter 40), cystinosis (see Chapter 41), Bartter’s syndrome (see Chap-

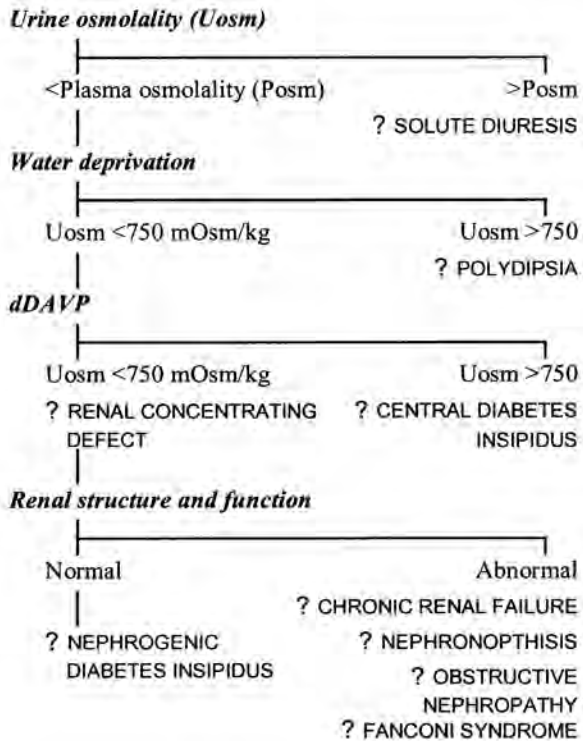

FIGURE 20.5. Polyuria (>200 mL/1.73 m² SA/24 hrs). dDAVP, des-D-amino-arginine vasopressin.

ter 38), obstructive nephropathy (see Chapter 55), and juvenile nephronophthisis (see Chapter 35).

Abnormalities of Micturition

Incontinence and Enuresis

Daytime urinary continence usually is achieved by 3 years of age (see Chapter 56). At the age of 5 years, approximately 15% of children wet the bed at night, falling to approximately 7% at 10 years. Nocturnal enuresis on its own is usually a benign self-limiting condition, whereas incontinence by day is commonly a behavioral problem. The development of incontinence in a child who has previously been dry raises the possibility of either organic disease or a psychological disturbance. Diurnal incontinence requires careful evaluation for the possibility of a neuropathic bladder, especially if associated with chronic constipation. Persistent dribbling incontinence associated with otherwise apparently normal micturition suggests an ectopic ureter opening below the bladder neck.

Giggle incontinence is usually a complaint of girls and younger women and is often associated with urgency. The definition is implicit in the name and is often a pointer to an unstable bladder with inappropriate detrusor contractions during filling. Younger girls with this complaint may squat on their heels to prevent voiding, a trick known as Saint Vincent's curtsy.

Poor Urinary Stream

Infrequent or difficult micturition may indicate inadequate bladder contraction or a functional failure of coordination between detrusor contraction and sphincter relaxation, suggesting a neuropathic bladder. A poor urinary stream in a male infant, particularly if associated with a full bladder, strongly suggests an obstructive pathology such as a posterior urethral valve. Observation of the urinary stream is an essential part of the physical examination of a child suspected of having a disorder of the urinary tract. Urinary retention is an uncommon problem in childhood and demands urgent and expert urologic attention to exclude a congenital anomaly, neuropathic bladder, tumor, or stone.

Frequency and Dysuria

Children of both genders between 5 and 14 years of age pass urine approximately four to eight times per day. Increased urinary frequency is seldom a primary complaint and is usually associated with other symptoms, such as urgency. An increased frequency of micturition may be due to polyuria, a reduced bladder capacity, or, most commonly, bladder irritability as with a UTI. Painful passage of urine (dysuria) usually indicates urethritis or cystitis secondary to UTI, but dysuria may also be a consequence of vulvovaginitis in girls and balanitis in boys.

Abnormalities of Hydration

Dehydration

Pure water depletion, resulting, for example, from defects in urine concentration, is associated, particularly in infants, with feeding difficulties and fever. If there is no concomitant salt depletion, there will be hypernatremia. The extracellular fluid (ECF) volume may be relatively well maintained, with the brunt of the fluid depletion being borne by the intracellular fluid (ICF) compartment, in which case the principal symptom is thirst. With salt depletion as well, ECF volume is depleted, resulting in hypotension and sensations of faintness and fatigue. Chronic salt-wasting is often associated with an increased salt appetite and a preference for savory rather than sweet foods (see Chapter 7).

Edema

ECF expansion results in edema, often first evident as swelling of the eyelids and sometimes mistaken for an allergic phenomenon; more generalized edema is characterized by pitting of the legs and abdominal swelling caused by ascites (Fig. 20.6). There are two distinct renal mechanisms of edema formation. In the first, characteristic of the acute nephritic syndrome and renal failure, a primary failure to excrete salt and water results in edema accompanied by expansion of the intravascular volume, hypertension, and

FIGURE 20.6. Edema. CVP, central venous pressure.

pulmonary congestion (see Chapter 30). In the second, as in the nephrotic syndrome, edema results from hypoproteinemia, the diminished colloid osmotic pressure of plasma leading to seepage of fluid from the intravascular into the interstitial compartment, with contraction of the plasma volume secondarily causing salt and water retention. In the nephrotic syndrome, there is also evidence for a primary increase in distal tubular sodium reabsorption. Hypoproteinemic edema is more gravity dependent than the edema of renal failure and may be accompanied by the symptoms of faintness and abdominal pain attributable to hypovolemia (see Chapter 27). The distinction between the edema of the acute nephritic syndrome, with its accompanying hematuria and hypertension, and the nephrotic syndrome is usually straightforward, but intermediate cases occur.

General Symptoms

Malaise

The symptoms associated with uremia are vague ill health, lassitude, anorexia, and vomiting. It is now rare for a child to reach such a condition without having come to medical attention, but an occasional case presenting as acute renal failure will in fact be found to have CRF. Anemia may contribute to the symptomatology, as attested by the improvement in general well-being with erythropoietin therapy.

Growth Failure

Children with CRF and some renal tubular disorders grow poorly and may indeed present with this problem. The causes are numerous and their interaction complex: poor caloric intake, acidosis, uncontrolled osteodystrophy, ane-

mia, chronic salt and water depletion, and uremia per se, as well as (in some cases) a disordered pattern of growth hormone release (see Chapters 67 and 68). CRF may be overlooked as a cause of growth failure in young children because the plasma creatinine concentration may not be significantly elevated if muscle bulk is poor.

Gastrointestinal Problems

Feeding difficulties, vomiting, and anorexia dominate the clinical picture of CRF in young children. Again, the situation is complex: There is a disturbance of foregut motor function, often with gastroesophageal reflux; taste sensation is disturbed, leading to anorexia because of chronic salt and water depletion; and there may well have been a seriously disturbed weaning period. These factors combine to produce a situation in which inadequate caloric intake becomes a major factor in the failure to grow.

Asymptomatic Presentation

Renal disease is often asymptomatic, only coming to light as a consequence of routine examination or screening programs. This has led to various proposals for population screening. However, the issue is complicated because it can be assumed neither that the natural history of a disorder detected in this way is necessarily the same as one that presented symptomatically nor that it requires the same protocol of investigation and treatment.

Antenatal Ultrasound

The routine use of diagnostic ultrasound in pregnancy has led to the detection of urologic abnormality in many fetuses (see Chapter 4). The most common abnormality detected is simple hydronephrosis caused by presumed pelviureteric junction obstruction, followed by multicystic dysplastic kidney. Bilateral renal dysplasia or agenesis associated with oligohydramnios may be detected, and severe infravesical obstruction has led to attempts of uncertain benefit to drain the urinary tract *in utero*. However, the antenatal diagnosis of posterior urethral valves may be missed unless a scan is undertaken late in pregnancy. There is still much to be learned about the natural history and implications for postnatal investigation and management of urologic disorders diagnosed antenatally.

Routine Neonatal Examination

The routine examination of the neonate should include abdominal palpation, which may reveal evidence of renal disease (e.g., a palpable bladder or renal masses caused by hydronephrosis, cystic disease, venous thrombosis, or tumor). Renal agenesis or severe dysplasia should be sus-

pected if there is a history of oligohydramnios associated with compression deformities [e.g., crumpled ears, Potter's facies, talipes, dislocated hips, or pulmonary hypoplasia (sometimes with pneumothorax)] (see Chapter 5). An absence of abdominal wall muscles (prune belly syndrome) is associated with bilateral cryptorchidism and a wide range of urologic abnormalities. There is an increased incidence of renal anomalies in association with other congenital defects, particularly those of the cardiovascular system, gastrointestinal tract (especially imperforate anus), and genitalia (see Chapter 6).

Urine Screening Programs

Because of the association between UTI, VUR, and renal scarring, a large number of studies have been directed at the role of screening for bacteriuria to prevent renal damage. Because some 5% of schoolgirls will at some stage develop bacteriuria, the yield of such surveys is large. However, it is by no means established that the widespread application of screening will reduce the incidence of end-stage renal failure. Regular urinalysis of school children is practiced in Japan (see Chapter 75C).

Family Studies

The diagnosis of an inherited disorder in a child, particularly if dominant or X-linked, should lead to a review of the extended family, which may identify several individuals previously unaware of having a renal abnormality. This raises ethical problems (see Chapter 18).

Routine Biochemical Evaluation

The kidney is involved in a wide variety of multisystem disorders, and, with the modern generation of multichannel biochemical analyzers, the serendipitous discovery of renal disease in a sick child is now not an uncommon occurrence.

HISTORY

Family History

A detailed family history is an essential part of the clinical evaluation because it may well provide an important clue to the diagnosis. Genetic factors are relevant in a wide variety of renal diseases such as inherited disorders of renal tubular function, familial glomerulonephritis, and cystic disease of the kidneys. The relevance may not be immediately obvious. Knowledge of the genetic abnormality carries implications for counseling the family. It is good practice to obtain the family tree for the case records.

A clue to dominantly inherited conditions may sometimes come from minor abnormalities in a parent: the diag-

nosis of autosomal dominant polycystic kidney disease may only become clear when the parents have had an ultrasound, and a family history of diabetes in a child with cystic kidneys may be a pointer to a hepatocyte nuclear factor-1 β mutation (see Chapter 36).

Disorders transmitted as autosomal recessive traits are usually readily apparent and should be considered if there is parental consanguinity. They may have escaped notice if the expression of the disease is mild, as in some cases of recessive polycystic kidney disease, or in the early stages (e.g., in younger siblings of patients with juvenile nephrophtosis or familial idiopathic nephrotic syndrome).

Clues to X-linked recessive disorders may sometimes only be revealed on inquiry into the history of previous generations, such as the loss of the male infant relative of a mother of a child with nephrogenic diabetes insipidus or a male relative with deafness and renal failure in an Alport kindred (see Chapter 26).

Polygenic inheritance, genetic heterogeneity, or incomplete penetrance of a dominant gene may be operative in the etiology of VUR, with at least 10% of first-degree relatives being affected (see Chapter 54).

Obstetric and Neonatal History

The role of antenatal ultrasonography in the detection of urologic abnormalities and oligohydramnios is described earlier. An edematous or hypertrophied placenta, more than 25% of the child's birth weight, is a feature of the congenital nephrotic syndrome (see Chapter 25). Perinatal asphyxia, particularly if associated with macroscopic hematuria, may have been responsible for renal venous thrombosis and should be considered in the differential diagnosis of an older child with renal scarring, particularly if there is no suggestion of VUR.

General Medical History

Because the kidney or urinary tract is commonly involved in syndromes of congenital malformation or multisystem disorders, attention must be paid to all aspects of the child's medical history. Consultation with the department of otolaryngology for a deaf child may point to Alport's or the branchiootorenal syndromes; at the ophthalmology department, a diagnosis of retinitis pigmentosa may suggest Laurence-Moon-Biedl syndrome or juvenile nephrophtosis. The orthopedic department may be involved because of bony deformity as a result of osteodystrophy; slipped femoral capital epiphysis; or Perthes' disease, which is more common with renal abnormalities even without renal failure. Renal involvement may be part of a multisystem disorder, such as systemic lupus erythematosus, juvenile rheumatoid arthritis, or other vasculitic disorders (see Chapter 46). Drug nephrotoxicity may arise in many different groups of patients, particularly from antimicrobials, diuretics, and anticancer drugs

(see Chapter 52). In a major children's hospital, the nephrologist may be as much involved with internal as with external referrals and must be familiar with the renal complications of systemic disorders and iatrogenic problems.

Urine and Micturition

A micturition history with specific detail about urinary stream is essential. The ages at which daytime and nocturnal urinary continence were achieved should be documented. A history of hematuria or features suggesting UTI may be relevant to the current renal problem.

Dietary History

A review of nutrition and feeding problems, beginning with the neonatal period, should be undertaken: whether the child was breast- or bottle-fed, episodes of vomiting or anorexia, thirst, or dietary preferences. Chronic salt-wasting, a feature of CRF, is commonly associated with an increased salt appetite and a preference for savory rather than sweet foods. For children with growth retardation or renal failure, a formal assessment of protein, energy, and other nutrient intake should be undertaken by a dietitian skilled in the management of problems of renal disease in childhood (see Chapter 67).

Gastrointestinal Symptoms

A prodrome of diarrhea strongly suggests infection with a verotoxin-producing *Escherichia coli* as the cause of hemolytic uremic syndrome (see Chapter 47).

Psychosocial Review

Many children with renal disease come from families with severe social problems. Some disorders (e.g., nephritis secondary to skin sepsis) are more common in deprived social classes. However, more important is the effect that social circumstances have on the ability of the family to cope with such minor symptoms as enuresis or to participate in the major upheaval of a renal replacement program. The involvement of a skilled social worker is essential in all cases. The commitment of the family to the child must be assessed. If the disease is congenital, particularly if prolonged hospitalization has been required or an inappropriately pessimistic prognosis has been given, problems may arise from inadequate mother-child bonding, and the opinion of a family-oriented child psychiatrist is often helpful.

The impact of the disease on the child's intellectual, emotional, and social progress must be assessed. In general, renal disease does not retard cognitive development, although there may be some delay if renal failure is severe in early life. A more common feature is emotional immaturity amounting to infantilism as a consequence of growth retardation, eliciting a response from society more appropriate

to the child's size than chronologic age. Later, toward puberty, there will always be concern as to whether or when dialysis and transplantation will be necessary. A detailed educational history should be obtained and communication with the school authorities established. A children's renal unit should have a dedicated teacher whose opinion should be sought in individual cases, and an appropriate educational program should be worked out for each child.

Expertise in this area, as much as experience in organic renal disease in childhood, distinguishes skilled pediatric nephrologists from their colleagues in internal medicine.

PHYSICAL EXAMINATION

General Assessment

A preliminary rapid assessment should be made of how sick the child is, whether there is circulatory failure or shock, if ventilation is adequate, what the level of consciousness is, and whether the child is in pain. The child's mood and demeanor should be noted (e.g., whether happy or fractious, alert and lucid, or somnolent and obtunded). The child's state of care should be assessed (i.e., does the child appear to be kempt or disheveled?). Inspection of the mucous membranes, conjunctivae, and nailbeds may provide evidence of anemia. Other features suggesting long-standing CRF are growth retardation and skeletal deformity caused by uremic osteodystrophy.

Growth and Nutrition

Proper assessment of the child's growth necessitates accurate measurement of height with a stadiometer and weight with scales, both accurate to 0.1%, together with charts of height and weight percentiles appropriate for the child's age, race, and gender (see Chapter 22). Pubertal development must be formally assessed. An impression should be formed of muscle bulk and body fat, but nutritional status is difficult to assess. The relationship between weight and height may underestimate the degree of loss of muscle tissue because there is often subclinical expansion of ECF.

State of Hydration

Assessment of the state of hydration is a skilled matter. Consideration should first be given to total body water and its partition between ECF and ICF, then to ECF and its partition between intravascular and interstitial compartments, and finally to intravascular volume and circulatory status (see Chapters 7 and 13). There is, unfortunately, no simple clinical way to estimate total body water, although some clues may be obtained from a review of recent changes in body weight, which largely reflect changes in total body water. In isotonic states (i.e., with normal plasma sodium concentra-

tion), dehydration of moderate severity implies a deficit of total body water of some 5% of body weight and severe dehydration, a deficit of 10%. The partition of fluid between ICF and ECF is determined by osmotic forces, in effect by sodium; changes in body water alone without changes in body sodium principally affect ICF volume and are difficult to detect clinically. Both ICF contraction and expansion (water intoxication) principally affect the brain because of the volume constraints imposed by the skull.

Changes in ECF volume are easier to detect clinically than changes in ICF volume, although edema is not usually evident until the ECF has been expanded by some 10%. The partition of fluid between the intravascular and interstitial compartments is determined by colloid osmotic forces, in effect the plasma albumin concentration; and the integrity of the capillary wall. Expansion of the interstitial compartment results in peripheral edema, most easily detected by pretibial pitting; expansion of the intravascular compartment results in hypertension, raised central venous pressure (CVP), and pulmonary edema. Conversely, contraction of the interstitial compartment causes diminished skin turgor, and a reduction of the intravascular compartment (hypovolemia) results in hypotension and circulatory failure with a low CVP. Occult hypovolemia may be revealed by an exaggerated fall in blood pressure on standing.

System Review

Circulatory Status

Hypotension and poor peripheral perfusion, characterized by cold extremities and a peripheral-to-central temperature gap greater than 2°C indicate poor cardiac output. If the CVP is low, hypovolemia is the cause; if the CVP is raised, the problem is cardiac. Assessment of the CVP is an important observation. In the older child, inspection of the jugular venous pressure in the semirecumbent position may be helpful, but it is often impossible to be confident of the situation in a younger child. Cardiac size as shown on chest radiograph may be helpful, but the sick child under intensive care usually requires formal CVP monitoring.

Cardiorespiratory System

Pulse

The pulses should be examined and the rate, rhythm, and volume recorded. The femoral pulses should always be palpated; coarctation of the aorta may present with renal failure and/or hypertension. Auscultation for bruits over major arteries (e.g., carotid and renal) may indicate extensive vascular disease or renal artery stenosis.

Blood Pressure

Frequent observation of the blood pressure is an integral part of the management of the child with renal disease. It is one of the most difficult aspects of the physical examination and

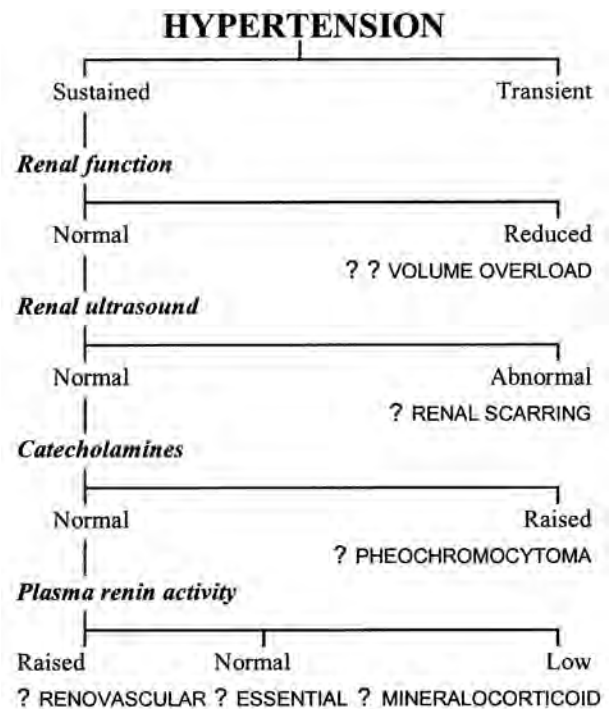

FIGURE 20.7. Hypertension.

should not be delegated to the most junior doctor or nurse. Technical aspects of measuring the blood pressure are important, along with standards of blood pressure for age and height (see Chapter 61). Twenty-four-hour monitoring gives a more accurate assessment of the situation. Sustained hypertension in children requires full investigation (Fig. 20.7).

Precordium

Cardiomegaly may reflect volume overload or long-standing hypertension. Murmurs may indicate a congenital cardiac anomaly that might be the seat of subacute bacterial endocarditis or may simply reflect a high-output state arising from anemia. Pericarditis with rub is a feature of a severe uremic state.

Lungs

Adequacy of ventilation should be assessed clinically by cyanosis, but the anemia that accompanies uremia may mask desaturation. If there is any doubt, particularly with incipient or actual pulmonary edema, pulse oximetry or formal blood gas analysis is essential. Hyperventilation suggests metabolic acidosis (Kussmaul respiration). The lungs should be examined in the conventional manner, the most important physical sign being the diffuse fine crepitations at both lung bases, which indicate pulmonary edema.

Skin

Examination of the skin may reveal the maculopapular rash of Henoch-Schönlein syndrome typically most severe on

the buttocks, the painful purple lesions involving the fingers or toes of a vasculitis, or the butterfly rash across the nose and cheeks characteristic of systemic lupus erythematosus (see Chapters 45 and 46). Multiple café-au-lait spots point to neurofibromatosis, which may be associated with renal artery stenosis and hypertension; adenoma sebaceum and shagreen patches point to tuberous sclerosis; and angiokeratoma to Fabry's disease. Dystrophic nails suggest the possibility of the nail-patella syndrome. Ichthyosis is associated with a lethal variant of Fanconi syndrome.

Inspection of the mouth is an important part of the physical examination. Poor or mixed primary and secondary dentition is a feature of CRF; gingival hypertrophy may be a consequence of cyclosporin toxicity, a tongue too large for the mouth may point to Beckwith-Wiedemann syndrome (associated with renal medullary dysplasia), and lumps on the tongue suggest the orofacioidigital syndrome (associated with polycystic kidneys).

Abdomen

Abdominal Distention

Abdominal distention in relation to renal disease may be a consequence of ascites, renal enlargement because of hydronephrosis or tumor, or retention of urine in the bladder. Absent abdominal wall musculature, characteristic of the prune belly syndrome and a consequence of intrauterine abdominal distension, is obvious in infancy but is sometimes less evident in older children or in cases of partial absence, and it may be revealed only by asking the recumbent child to put his arms across the chest and raise his shoulders off the bed. In affected cases, upward movement of the umbilicus will be observed.

Renal Enlargement

Detection of renal enlargement by palpation is a skilled physical maneuver. The kidneys can often be palpated in a healthy neonate but not in an older child. Palpable enlargement of the kidneys has the following characteristics: the mass can be lifted from the loin, and in contrast to the spleen, it is possible to get above it; there is not much movement of the mass with respiration; and it is resonant to percussion anteriorly because the bowel intervenes. Some inferences can be drawn from the nature of the mass, although it is difficult to distinguish clinically between the firm enlargement of polycystic disease and tumor or, in an infant, between the soft enlargement of hydronephrosis and a multicystic kidney.

Hepatosplenomegaly

The causes of hepatic enlargement are legion, among which glycogen storage disease should be noted for its association with glomerulosclerosis (see Chapters 50). Hepatosplenomegaly in association with renal disease has a more restricted differential diagnosis, suggesting a multisystem disorder, such

as systemic lupus erythematosus or juvenile rheumatoid arthritis; an infection, such as bacterial endocarditis or shunt nephritis; a neoplastic process, perhaps complicated by uric acid nephropathy; or hypersplenism as a consequence of the hepatic fibrosis associated with the autosomal recessive form of polycystic kidney disease.

Bladder

Enlargement of the bladder should be sought by palpation and percussion. If detected, the child should be asked to pass urine and then be reexamined. It is sometimes difficult to detect bladder enlargement in the neonate when the umbilical cord is still *in situ*; an ultrasound scan easily resolves the issue.

Genitalia

There is a natural but inexcusable tendency to omit examination of the genitalia. The presence of the foreskin in a male and the position of the urethral meatus must be ascertained in both genders because anomalies are common. However, hypospadias is only rarely associated with upper tract abnormalities. Bilateral cryptorchidism is a feature of prune belly syndrome. Male pseudohermaphroditism with cryptorchidism is associated with nephroblastoma and glomerular disease in the Denys-Drash syndrome. Female pseudohermaphroditism suggests the possibility of adrenal hyperplasia with salt-wasting.

Anus

In the neonate, an imperforate or abnormally positioned anal opening may represent only one feature of complex congenital abnormalities, including those affecting the renal tract.

Nervous System

Neurologic Examination

A careful examination of the central nervous system is always appropriate, particularly in children who have severe hypertension, multisystem disorders, or are in intensive care. Convulsions may be due to uremia, hypertension, hyponatremia or hypernatremia, hypocalcemia, hypomagnesemia, or disorders such as hemolytic uremic syndrome or a systemic vasculitis, which affects both the kidney and the brain. Tetany may be due to hypocalcemia or alkalosis.

Severe hypertension may present with a facial palsy, may cause a cerebral hemorrhage, and, if the blood pressure is controlled too vigorously, may be associated with anterior visual pathway infarction, blindness, and abnormal pupillary responses.

Eyes

The eyes offer many clues in the evaluation of renal disease, and the assistance of an experienced pediatric ophthalmologist is helpful. Scleral calcification may be a consequence of hypercalcemia or uncontrolled hyper-

phosphatemia. The crystal deposits in the cornea characteristic of cystinosis are best detected by slit lamp examination, but the earliest manifestation in this disorder is a peripheral retinal pigmentary disorder. Alport's syndrome may be associated with keratoconus or, more commonly, with a macular abnormality. Buphthalmos is a feature of Lowe's syndrome. Aniridia is accompanied by an increased incidence of nephroblastoma. Iridocyclitis may complicate juvenile rheumatoid arthritis and associated amyloid nephropathy or may be found in association with idiopathic interstitial nephritis (see Chapter 43). Cataracts occur in many disorders, among which galactosemia may be noted for its association with renal tubular dysfunction. Posterior lenticular opacities may be a consequence of long-term corticosteroid therapy and with careful examination are commonly found, but they rarely give rise to visual handicap.

The examination of the fundus may reveal the ravages of hypertension with arterial narrowing, hemorrhages, exudates, and papilledema. Papilledema is also the major sign of raised intracranial pressure, as, for example, with cerebral edema in acutely ill children or after corticosteroid withdrawal. Diabetic retinopathy tends to parallel nephropathy and is rarely observed in childhood. Tapetoretinal degeneration is found in some cases of juvenile nephronophthisis (see Chapter 35), and retinitis pigmentosa is characteristic of Laurence-Moon-Biedl syndrome in which renal failure caused by medullary dysplasia is the principal cause of early death. The retinal changes in infantile oxalosis are striking (see Chapter 42).

Ears

Deformities of the external ear may result from oligohydramnios and even in its absence may be associated with renal anomalies. Preauricular tags and branchial fistulae are features of the branchiootorenal syndrome. High-tone sensorineural deafness is characteristic of Alport's syndrome and may be insidious in its onset, detectable at first only by audiography. Nerve deafness is also associated with some cases of distal renal tubular acidosis (see Chapter 39). Deafness may be a consequence of the previous administration of aminoglycoside antimicrobials, particularly in the neonatal period, or of high dosages of furosemide.

Skeletal System

Bones

The classic features of rickets may be a consequence of the early osteomalacic phase of renal osteodystrophy or of renal tubular disease. Hypophosphatemic vitamin D-resistant rickets is a feature of several genetically determined renal tubular disorders (see Chapter 11). Genu valgum is common with renal osteodystrophy and should be quantified by measuring the intermalleolar distance. Congenital

dislocation of the hips is common in infants with renal disease and should be sought with great care. Slipped femoral capital epiphysis is a feature of uremic osteodystrophy, and avascular necrosis of the head of the femur may complicate corticosteroid therapy, particularly in transplanted patients (see Chapter 69). Polydactyly is found in many syndromes with a renal component (see Chapter 6) and may be missed because the accessory digit was removed in infancy.

Deformities of the spine, such as meningocele, are obvious, but subtle signs, such as a patch of pigmentation or a tuft of hair, may point to an underlying spinal dysraphism responsible for a neuropathic bladder. Sacral agenesis, in particular, is easily overlooked. Unequal leg growth may be a consequence of spinal abnormalities. Hemihypertrophy is occasionally associated with nephroblastoma, with or without Beckwith-Wiedemann syndrome, or with medullary sponge kidney.

Joints

Arthropathy is a classic feature of systemic lupus erythematosus and the Henoch-Schönlein syndrome. It is occasionally observed in children with idiopathic membranous nephropathy. Juvenile rheumatoid arthritis may be complicated by amyloid or interstitial nephritis or associated with drug nephrotoxicity. The Lesch-Nyhan syndrome may present as a renal disorder, either as calculi or renal failure in infancy, and may be associated with a gouty arthropathy affecting the interphalangeal joints.

ROUTINE URINALYSIS

Examination of the urine is an integral part of the clinical evaluation and is the responsibility of the clinician. In today's increasingly busy clinical practice, dipstick testing of the urine is frequently delegated to the clinic nurse and microscopy to the microbiology laboratory. Nonetheless, the clinician must be conversant with the methods of urinalysis, their interpretation, and their sources of error and ensure that the correct procedures are followed.

Dipstick Tests

Urine samples should be inspected and routinely tested for blood, protein, and glucose, using commercially available dipsticks.

Hemastix

Hemastix rely on the peroxidase-like activity of hemoglobin to catalyze the reaction of a hydroperoxide with tetramethylbenzidine to give a green-blue color; myoglobin also gives a positive reaction. The test is capable of detecting as little as

150 µg/L of free hemoglobin and is so sensitive that a negative test excludes significant hematuria.

Albustix

Protein in urine is most conveniently detected by the so-called protein error of indicators principle with Albustix (Ames Company). These reagent strips are impregnated with tetrabromphenol blue buffered with citrate. Protein binds with the dye and causes a color change from yellow to green by displacement of the transformation range of the indicator. Free light chains (Bence-Jones protein) and other low-molecular-weight “tubular proteins” are not readily detected by Albustix. A dilute urine specimen may give a false-negative result. False-positive results occur with very alkaline urine, with concentrated samples, and with those contaminated with quaternary ammonium salts such as chlorhexidine. If the stick is left to soak in the urine or if there is a delay in reading the strip, false-positive readings can also occur.

Occasionally, protein is excreted in the urine in the upright posture but not when recumbent. Such postural proteinuria does not indicate renal disease and should be ascertained by examination of an overnight specimen of urine. Sustained proteinuria requires full investigation (Fig. 20.8) (see Chapter 21).

Clinistix

Clinistix (Ames Company) detect glucose in urine by a glucose oxidase-peroxidase linked reaction. The system is sensitive to a glucose concentration of approximately 0.5 mmol/L, but it is inhibited to some degree by glutathione and other substances in the urine, so the trace amounts of glucose in normal urine are below the threshold of the test.

Multistix

Multistix (Ames Company) combine the above with tests for pH (based on a double-indicator principle), osmolality (based on the change of pKa of certain polyelectrolytes in relation to ionic concentration), ketones, bilirubin, urobilinogen, and nitrite. The pH and osmolality are not sufficiently accurate for diagnostic purposes; pH should be measured in the laboratory by a pH meter and osmolality with an osmometer (see Chapter 21).

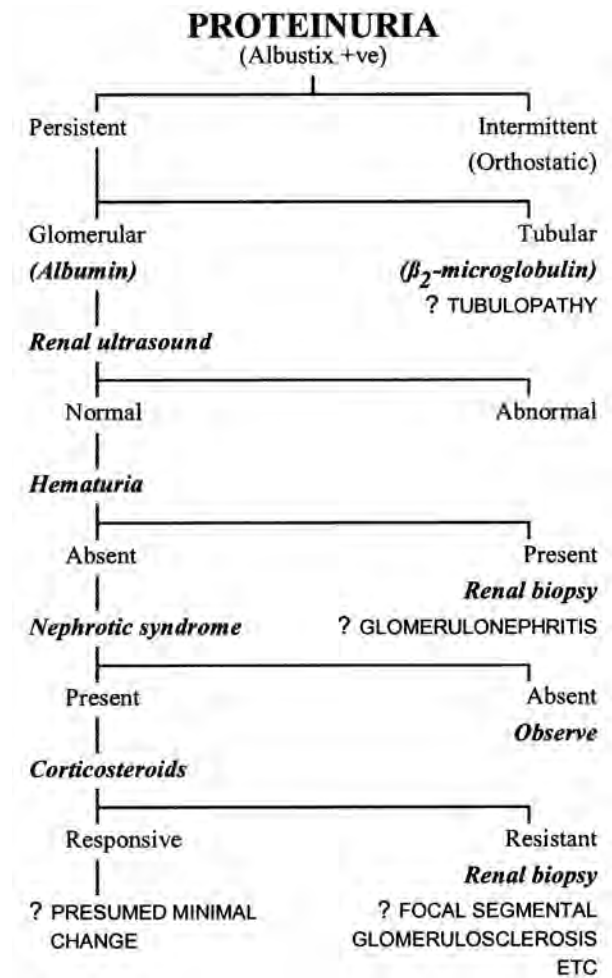

FIGURE 20.8. Proteinuria.

Microscopy and Culture

Urine microscopy in wards or clinics used to be part of the repertoire of every clinical nephrologist. Now, the availability of dipsticks for routine urinalysis and the sophistication of equipment have tended to transfer urine microscopy to the laboratory. There are some disadvantages in this: The immediate relevance of the findings to the clinical situation is lost, and it is difficult to ensure that the sample is fresh.

Midstream urine specimens should be collected and dispatched to the laboratory for microscopy and culture without delay (see Chapter 53).

LABORATORY INVESTIGATIONS

JEAN-PIERRE GUIGNARD
FERNANDO SANTOS

The validity of the recommendation by the American Academy of Pediatrics that all asymptomatic children have screening urinalyses at four intervals from infancy through adolescence has been questioned recently (1). The usefulness of routine multidipstick has, on the contrary, been emphasized by experienced pediatric nephrologists (2). Routine dipstick urinalysis is discussed in Chapter 20. The child with positive dipstick screening should be investigated to exclude or confirm the presence of renal disease.

PROTEINURIA

Pathophysiology of Proteinuria

The normal glomerulus restricts the filtration of proteins on both size and electrical charge. The size selectivity of the glomerular capillary is largely determined by the cellular layers rather than by the glomerular basement membrane (GBM) (3). With a molecular weight (MW) of 69 kDa, albumin passes the filter in small quantities, so that the ultrafiltration in Bauman's capule contains 10 mg/L or less of albumin. The permeability of the glomerular capillary to large proteins also depends on the electrical charge. The glomerular capillary wall is indeed charged negatively due to its rich heparan sulfate content (4). Because of the electrostatic interaction with the filtration barrier, negatively charged macromolecules are more restricted than are neutral or positively charged molecules of similar MW. The electrical charge does not influence the filtration of small molecules of ions. The combined impairment of both barrier charge selectivity and size selectivity is required to account for the massive proteinuria observed in nephrotic patients.

Almost all of the filtered proteins are reabsorbed in the proximal tubule by endocytosis at the luminal membrane. Significant proteinuria occurs when this energy-requiring mechanism is saturated. In the tubular cells, the proteins are degraded by lysosomal enzymes to low-molecular-weight (LMW) fragments and amino acids. By this mechanism, the kidney plays a major role in the catabolism of many polypeptide hormones such

as insulin and parathormone. Smaller peptides, such as angiotensin and vasopressin, are directly catabolized by peptidases located in the proximal luminal plasma membranes.

Types of Proteinuria

In normal individuals, the major constituent of nonplasma proteins is the Tamm-Horsfall protein (Uromodulin) (5). It is a glycoprotein (MW, 95 kDa) actively secreted by the tubular cells in the ascending thick limb. The Tamm-Horsfall protein has no clinical significance. Significant proteinuria can be classified into (a) glomerular proteinuria, (b) tubular proteinuria, and (c) overflow proteinuria.

Glomerular Proteinuria

Altered permselectivity of the glomerular barrier results in the abnormal passage of an increased fraction of the glomerular ultrafiltrate through the large nonselective pores (3). The altered permselectivity may be the consequence of physical damage to the filtering membranes or may be transient and hemodynamically or hormonally mediated (6). Glomerular proteinuria may be selective or nonselective. Selective proteinuria is characterized by the predominance of albumin as compared to other proteins of higher MW.

Albumin, immunoglobulin G (IgG), and transferrin are proteins used to characterize the selectivity of glomerular proteinuria. A permeability index based on the IgG/albumin or the IgG/transferrin clearance ratios can be used. An index below 0.1 is indicative of highly selective proteinuria (7). The clinical usefulness of this index is questionable. A high selectivity index is usually found in the steroid-sensitive minimal changes nephrotic syndrome as well as in the Finnish-type congenital nephrotic syndrome. The selectivity is low in orthostatic proteinuria (8). The excretion rate of urinary proteins and/or albumin is probably the best independent predictor of end-stage renal disease in nondiabetic proteinuric chronic nephropathies (9).

TABLE 21.1. MARKERS USED FOR THE CLASSIFICATION OF PROTEINURIA

Diagnosis	Marker	MW (d)	Excretion/creatinine	
			g/mol creatinine	mg/mol creatinine
Glomerular proteinuria	Proteins	—	<20	<180
Glomerular selectivity	Albumin	67'000	<1.17	<0.21
	Transferrin	80'000	—	—
	Immunoglobulin G	150'000	<5.8	<50
Tubular proteinuria	β_2 -microglobulin	11'800	<0.040	<0.35
	α_1 -microglobulin	30'000	<2.2	<19
	Retinol-binding protein	21'400	<0.024	<0.21
Tubular injury	Lysozyme	14'400	<0.065	<0.6

The loss of charge selectivity of the GBM can be assessed by the clearance of two proteins of similar MW but with different electric charges. Two pairs of molecules can be used: (a) the nonglycated and the negatively glycated albumin and (b) the neutral IgG and the negatively charged IgG₄ subclass. The ratio of their clearances is modified when the GBM has lost its charge selectivity (3). Loss of glomerular anionic charges may be the first step in the development of some nephropathies, as, for instance, type 1 diabetic nephropathy.

Tubular Proteinuria

Most LMW proteins (MW below 40 kDa) are filtered and reabsorbed in the proximal tubule. Impaired proximal tubular reabsorption of LMW proteins results in tubular proteinuria. This is observed in tubulopathies such as the Fanconi syndrome. Drug (aminoglycosides) or heavy-metal intoxication may induce tubular proteinuria.

The exclusive presence of LMW proteins in the urine characterizes the tubular proteinuria. Three markers are commonly used (Table 21.1) (10).

1. β_2 -microglobulin, which is not bound to proteins, is easy to measure, but is unstable in acid urine.
2. α_1 -microglobulin is stabler than β_2 -microglobulin but has a higher MW and thus a more variable filterability.
3. Retinol-binding protein is stable at low urine pH, but it strongly binds to plasma proteins.

Overflow Proteinuria

An unusual increase in the protein filtered load results in significant proteinuria. Overflow proteinuria may be seen in multiple myeloma (Bence-Jones proteins), hemoglobinuria, and myoglobinuria.

Markers of Acute Tubular Necrosis

Two enzymes synthesized in the proximal tubular cells, the lysosomal enzyme *N*-acetyl-glucosaminidase and alanine-aminopeptidase, present in the brush border are urinary markers of tubular necrosis. The urinary excretion of these

two enzymes is increased in various conditions associated with acute tubular necrosis. *N*-acetyl-glucosaminidase is stabler than alanine-aminopeptidase. Other enzymes may detect an injury of the proximal tubular cells (α -glutathione transferase) or the distal tubular cells (π -glutathione transferase). Lysozyme (MW, 14.4 kDa) is a marker of tubular proteinuria and of acute tubular necrosis (11) but is less sensitive than other markers.

Quantification of Urinary Proteins

Reagent Test Strips

Positive dipstick screening for proteinuria warrants quantification of the proteinuria.

Protein/Creatinine Ratio

The protein/creatinine (prot/creat) ratio is measured in a random urine sample. The second morning urine specimen is most suitable. The urine prot/creat ratio correlates well with the 24-hour urine protein excretion (13,14). Comparison of the ratio measured in the first morning urine specimen with that of urine collected during the day is used for the diagnosis of orthostatic proteinuria. Normal values of the urine prot/creat ratio observed at different ages are given in Table 21.2. By definition, nephrotic range proteinuria is superior to 400 g/mol creatinine. The albuminuria can also be expressed as an albumin/creatinine ratio. The upper-normal value is 1.17 g/mol creatinine.

Quantitative Proteinuria

Quantitative urine protein excretion can be made using a 24-hour urine collection, an overnight collection, or a shorter urine collection over a few hours. The 24-hour collection in children is cumbersome for the patient and subject to errors. Normal values are defined as less than 4 mg/m²/hr or 100 mg/m²/day. Values above 40 mg/m²/hr define the nephrotic range proteinuria. *Microalbuminuria* is defined as an albumin excretion between 0.7 and 7.0 mg/m²/hr or 170 mg/m²/day.

TABLE 21.2. NORMAL VALUES OF PROTEIN EXCRETION AS A FUNCTION OF AGE

Age (yr)	Proteinuria	
	g/mol creatinine	g/g creatinine
0.1–0.5	80	0.70
0.5–1.0	60	0.55
1–2	45	0.40
2–3	30	0.30
3–5	20	0.20
5–7	19	0.15
7–17	18	0.15

Analytic Procedures

The urinary proteins are usually measured by an autoanalyzer-adapted turbidimetry micromethod that uses benzethonium chloride to precipitate the urinary proteins at an alkaline pH. The quantification of albuminuria is achieved by enzyme-linked immunoabsorbent assays, immunoturbidimetry, or laser nephelometry (12).

Electrophoretic separation of urinary proteins by means of polyacrylamide or agarose gel electrophoresis is used to distinguish glomerular, tubular, and mixed proteinuria. Different markers are used to differentiate glomerular from tubular proteinuria (Table 21.1).

Etiology of Proteinuria

Orthostatic Proteinuria

Orthostatic proteinuria is only present when the patient is upright. The proteinuria is usually mild and not selective (8). Orthostatic proteinuria is often seen in slender adolescent patients. The prognosis of orthostatic proteinuria is excellent. No treatment is needed.

Transient Proteinuria

Transient proteinuria is usually associated with exercise, stress, fever, and dehydration. It does not reflect renal disease.

Persistent Proteinuria

Persistent proteinuria indicates renal disease. Proteinuria may *per se* also lead to renal injury (15) and should be thoroughly investigated (16).

URINE SOLUTE EXCRETION

Quantification

The renal elimination of a given solute is highly dependent on a number of factors such as diet content, water intake, intesti-

nal absorption, extrarenal losses, and internal distribution of the solute in the body. Solute excretion varies with age.

Urine solute excretion can be expressed in mg or mmol/day/kg or per m², by the solute/creatinine concentration ratio, and/or by calculating the solute fractional excretion (FE). Solute/creatinine concentration ratios and FE can be calculated in random urine samples without the need for timed urine collection. Calculation of FE requires drawing a blood sample at the time of urine collection. The FE is calculated as follows: $FE_S = (U_S/P_S) \times (P_{Cr}/U_{Cr}) \times 100$, where U_S and P_S represent the urine and plasma concentrations of a solute (S) and P_{Cr} and U_{Cr} represent the plasma and urinary concentrations of creatinine, respectively. FE_S expresses the percent of filtered solute that is excreted in the urine. This concept is equivalent to the fractional clearance of S (FC_S), which is calculated with the same formula but expressed as mL/dL of glomerular filtrate. Calculation of glomerular filtration rate (GFR) by means of the creatinine clearance is $GFR = (U_{Cr} / P_{Cr}) \times V$, where V represents the mL of urine eliminated by minute and GFR is expressed in mL/min. For a $GFR = 100$ mL/min, $V = 100 \times (P_{Cr} / U_{Cr})$ and represents the mL of urine eliminated by 100 mL of GF. Thus, FC_S may be calculated by the formula $FC_S = U_S / P_S \times (P_{Cr} / U_{Cr}) \times 100$, which is identical to that used to calculate FE_S . FC_S represents the mL of each 100 mL of GF that have been cleared of S and is expressed in mL per 100 mL GFR. As noted in the above formula, its calculation is independent of the volume of urine and, therefore, does not require timed urine collection.

For those solutes not undergoing tubular secretion, the difference $100 - FE_S$ represents the percentage of solute that is reabsorbed. Thus, the tubular reabsorption of phosphate (TRP) equals $100 - FE_p$ and represents the percentage of filtered phosphate that is reabsorbed in the convoluted proximal tubule. The TRP is frequently expressed as TmP/GFR . TmP , representing the maximum tubular phosphate reabsorption, may be calculated by using phosphate infusions (see Glucose Titration Test and Fig. 21.1). However, TmP can also be deduced using a more practical approach. TRP is the difference between filtered phosphate and excreted phosphate. Individuals on a normal Western diet ingest a large amount of phosphate. Therefore, in the presence of normal GFR, the rate of phosphate reabsorption approaches the maximal capacity of proximal tubules to reabsorb phosphate. Thus, $TmP = GFR \times S_p - U_p \times V$, where S_p and U_p are the phosphate concentrations in serum and urine. In this equation, S_p represents the renal threshold for phosphate (as explained in the section Glucose Titration Test) when $U_p \times V$ is equal to 0. Therefore, TmP/GFR value equals the threshold concentration for serum phosphate and is considered as the best indicator of the renal tubular handling of phosphate (17).

According to Bijvoet et al., TmP/GFR can be calculated as follows: $TmP/GFR = TRP \times S_p$, or $TmP/GFR = [1 - (U_p \times S_{Cr} / S_p \times U_{Cr})] S_p$, or $TmP/GFR = S_p - (U_p \times S_{Cr} / U_{Cr})$ (18).

A nomogram for the determination of TmP/GFR based on the plasma phosphate concentration and TRP has been

FIGURE 21.1. Representative renal titration curve for a substance (X) with an active and saturable mechanism of proximal tubular reabsorption, like that of glucose or phosphate.

developed by Walton and Bijvoet (19). The usefulness of this nomogram in children has been questioned, the use of TmP/GFR or the simple use of TP/GFR in well-nourished children appearing more relevant (20–23).

Sodium, Chloride, and Potassium

The daily urinary excretion of sodium varies widely in response to change in dietary salt intakes. On a normal Western diet, children excrete approximately 3 to 4 mmol/kg/day of sodium. Body fluid composition requires independent regulation of sodium and water balances as intake of water and sodium may vary separately. Thus, concentration of sodium in the final urine is highly related to the degree of urinary concentration or dilution. The extracellular fluid volume is regulated by changes in sodium excretion and when

the extracellular fluid volume is contracted (i.e., dehydration, nephrotic syndrome), sodium can be virtually undetectable in the urine. Although there is no predictable relationship between the plasma sodium concentration and urinary sodium excretion, mild hypernatremia has recently been shown to induce natriuresis in humans (24). Normal urinary sodium/creatinine ratios in children are shown in Table 21.3.

Urinary chloride excretion is closely associated with that of sodium. Chloride excretion is dependent on the salt content of diet, and it is also retained during volume depletion. The measurement of urinary chloride concentration may be particularly useful in the diagnostic approach to metabolic alkalosis, because urine sodium and chloride concentrations may be dissociated. A urinary chloride concentration above 10 mmol/L is indicative of metabolic alkalosis of renal origin, whereas lower concentrations of urinary chloride or a reduced chloride/creatinine concentration ratio (25) suggests volume contraction as the cause of the metabolic alkalosis. However, even in the presence of volume contraction and active renal reabsorption, urinary sodium may be high because it is eliminated in the urine with the bicarbonate anion to keep electroneutrality. Normal urinary chloride/creatinine values are given in Table 21.3.

Urinary potassium excretion ranges from 1 to 2 mmol/kg/day in a child on a normal diet. The kidney regulates potassium balance by changing the secretion rate of potassium in the distal nephron. This regulation is mostly dependent on aldosterone and the amount of sodium and water delivered to the distal nephron. The renal ability to retain potassium is not as efficient as that of sodium, and, in the face of potassium depletion, urinary potassium does not decrease to less than 15 mmol/L. Normal urinary potassium/creatinine ratios are shown in Table 21.3.

The excretion of sodium, chloride, and potassium is frequently expressed as FE rates. In European children older

TABLE 21.3. URINARY SOLUTE/CREATININE (CREAT) RATIOS (FIFTH AND NINETY-FIFTH PERCENTILES) AS A FUNCTION OF AGE

Solute/creat	Age (yr)

Adapted from Matos V, Melle G van, Boulat O, et al. Urinary phosphate/creatinine, calcium/creatinine, and magnesium/creatinine ratios in a healthy pediatric population. *J Pediatr* 1997;131:252–257; and Matos V, Melle G van, Werner D, et al. Urinary oxalate and urate to creatinine ratios in a healthy pediatric population. *Am J Kidney Dis* 1999;34:1–6.

than 1 year of age, not fasted, and on a normal diet, FE_{Na} has been shown to range from 0.3 to 1.6%, this variation being the result of the different dietary salt intakes (26). Calculation of FE_{Na} is widely used to explore whether the kidney responds adequately to extracellular volume depletion. In this situation, FE_{Na} is expected to fall as a result of compensatory avid sodium reabsorption. Thus, in patients with prerenal acute renal failure, FE_{Na} is expected to fall below 1%, whereas it is generally above 3% in acute tubular necrosis. In normal conditions, FE_K approximates 10 to 15%. Values of FE_K above 100% can be found in renal failure patients as a compensatory mechanism to maintain potassium balance.

Calcium

Urinary elimination of calcium is highly dependent not only on the diet but also on the child's age. Although the range of normal urinary calcium elimination may vary in different geographical regions, *hypercalciuria* is usually defined as urinary calcium excretion rates above 4 to 5 mg/kg/day (0.100 to 0.125 mmol/kg/day) and is suspected when the calcium/creatinine ratio is above 0.20 mg/mg (0.60 mol/mol) (27–29). The upper-normal limit of the urinary calcium/creatinine ratio is much higher in infants (30). Recent reference values for urinary calcium to creatinine concentration ratios in spot urines of children of different ages have been provided by Matos et al. and are shown in Table 21.3 (31). Under identical dietary conditions, urine calcium has been shown to be lower in black than in white children (32).

Phosphate

Similarly to calcium, phosphaturia expressed per unit of weight, as well as phosphatemia, markedly decreases with age. In adults, normal urinary phosphate excretion equals 10 to 15 mg/kg/day (0.3 to 0.5 mmol/kg/day), whereas values up to 20 to 25 mg/kg/day (0.6 to 0.8 mmol/kg/day) are found in young children. Recent reference values for urinary phosphate to creatinine concentration ratios in children are shown in Table 21.3 (31). Values of TP/GFR vary from 6.9 in neonates to 4.4 at 5 years of age and 3.2 mg/dL GFR at 6 years of age (21).

Magnesium

Daily elimination of urinary magnesium has been reported to decrease from a mean value of 2.44 ± 0.69 (SD) mg/kg/day (0.10 ± 0.03 mmol/kg/day) in Italian children 3 to 5 years of age to 1.77 ± 0.65 (SD) mg/kg/day (0.07 ± 0.03 mmol/kg/day) in children 15 to 16 years old (33). These values are quite similar to those obtained in other European studies and markedly higher than those found in children from Oriental origin (34–37). Reference values for urinary magnesium to creatinine concentration ratios in a pediatric population are shown in Table

21.3 (31). Calculation of FE_{Mg} allows an assessment of magnesuria in relation to the level of plasma magnesium. Under normal conditions, approximately 5% of filtered magnesium is excreted in urine, but in the face of magnesium deprivation, FE_{Mg} quickly falls below 1% (38). Thus, an FE_{Mg} equal to or greater than 5% with simultaneous hypomagnesemia indicates inappropriate loss of magnesium in the urine.

Uric Acid and Oxalate

Elevated urinary concentrations of uric acid and oxalate and decreased levels of urinary citrate are significant risk factors for the development of urolithiasis and/or nephrocalcinosis. It has been shown that the urinary excretion of uric acid corrected to 1.73 m^2 is independent of age in children aged 2 to 15 years, mean values being 520 ± 147 (SD) mg/ 1.73 m^2 /day (3093 ± 874 $\mu\text{mol}/1.73 \text{ m}^2/\text{day}$) (39). Calculation of urine uric acid concentration corrected for creatinine clearance in single fasting morning urine and blood specimens (urine uric acid \times plasma creatinine/urine creatinine) has been used as a diagnostic criterion of hyperuricosuria, defined by a value above 0.53 mg/dL of GFR ($32 \mu\text{mol/L}$ of GFR) in children between 2 and 12 years of age (40,41). Mean values of urinary oxalate have been reported to be 36.9 ± 13.7 (SD) mg/ $1.73 \text{ m}^2/\text{day}$ (0.42 ± 0.16 mmol/ $1.73 \text{ m}^2/\text{day}$) and 1.0 ± 0.6 (SD) mg/kg/day (0.01 ± 0.06 mmol/kg/day) in Spanish and Italian children older than 3 years, respectively (33,42). Reference values for urinary oxalate and urate to creatinine ratios in infants, children, and adolescents are shown in Table 21.3 (43). There is a high positive correlation ($R = 0.75$) between oxalate excretion measured in 24-hour urine and the oxalate/creatinine ratio measured in the first morning urine sample (44).

Citrate

Values of citrate excretion in healthy children aged 3 to 14 years followed a normal distribution and were equal to 9.62 ± 4.05 (SD) mg/kg/day (45.78 ± 19.28 $\mu\text{mol}/\text{kg}/\text{day}$) (45). A moderate correlation ($R = 0.49$) was found between citruria determined in 24-hour urine specimens and citrate/creatinine concentration ratios in the second morning urine samples. A citrate to creatinine concentration ratio measured in 24-hour urine below 300 mg/g (0.176 mol/mol) in girls and 125 mg/g (0.074 mol/mol) in boys has been proposed as indicative of hypocitruria (41,46). Blau et al. have recently reported the simultaneous determination of oxalate, glycolate, citrate, and sulfate in spot urine samples dried on filter papers (47). This procedure may facilitate the study of these anions in large series of children.

Anion Gap

Metabolic acidosis may be classified according to whether it is associated with elevated or normal serum anion gap

(AG). To keep the electroneutrality of the extracellular fluid, the sum of the cation concentrations must equal that of the anions. This can be expressed by the equation: $\text{Na}^+ + \text{UC} = \text{Cl}^- + \text{HCO}_3^- + \text{UA}$, where UC and UA represent unmeasured cations and unmeasured anions, respectively. UC includes K^+ , Ca^{2+} , and Mg^{2+} , whereas PO_4^{3-} , SO_4^{2-} , proteins, and organic anions form the UA. The serum AG is defined by the formula $\text{AG} = \text{Na}^+ - (\text{HCO}_3^- + \text{Cl}^-) = \text{UA} - \text{UC}$. The normal values range from 8 to 16 mmol/L.

A related concept is that of the urine AG, which can be calculated by the formula: $\text{Urine AG} = (\text{Na}^+ + \text{K}^+) - \text{Cl}^-$, where Na^+ , K^+ , and Cl^- represent the urinary concentrations of these solutes in mmol/L (48–50). During metabolic acidosis, urine AG is a rough and inverse estimate of the ammonium (NH_4^+) eliminated in the urine. If large amounts of NH_4^+ are present in urine, the urinary chloride concentration is greater than the sum of sodium and potassium concentrations, and urinary AG becomes negative. Thus, in subjects with type II proximal renal tubular acidosis (RTA) or in patients with metabolic acidosis associated with diarrhea, urine AG is negative. In acidotic patients with impaired NH_4^+ excretion, such as those with type I RTA, type IV RTA, or chronic renal failure, urine AG remains positive.

Transtubular Potassium Concentration Gradient

The transtubular potassium concentration gradient (TTKG) provides an estimation of the regulatory mechanisms of distal potassium secretion, thus facilitating the clinical approach to disorders of potassium excretion. The measurement of the final concentration of potassium in urine gives limited information because this concentration depends not only on the distal secretion of potassium induced by aldosterone but also on the degree of water reabsorption along the medullary collecting duct.

The TTKG index attempts to evaluate the gradient between luminal and peritubular potassium concentrations in the late distal tubule and the cortical collecting duct as a reflection of aldosterone bioactivity. The test assumes that the systemic venous plasma potassium equals the peritubular potassium concentration in the renal cortex and that the luminal potassium concentration in the distal tubule and the cortical collecting duct can be deduced by dividing the urine potassium concentration by the urine to plasma osmolality ratio—that is, adjusting the urinary potassium concentration for medullary water reabsorption. These assumptions require that sufficient sodium be delivered to the distal nephron for exchange with potassium and that urine be hypertonic (51,52).

Based on the preceding rationale, TTKG can be calculated as follows:

$$\text{TTKG} = U_K / (U_{\text{OSM}} / P_{\text{OSM}}) / P_K, \text{ or}$$

$$\text{TTKG} = (U_K \times P_{\text{OSM}}) / (P_K \times U_{\text{OSM}})$$

In adults, a TTKG value greater than 5 indicates that aldosterone is acting, whereas a value at or below 3 indicates lack of mineralocorticoid activity (52). In the face of hyperkalemia, a TTKG below 4.1 in children or below 4.9 in infants should be taken as indicative of a state of relative hypo- or pseudohypoaldosteronism. A TTKG higher than 2 in a hypokalemic child should be taken as indicative of lack of aldosterone suppression (53).

GLOMERULAR FILTRATION RATE

GFR is the best estimate of the functional renal mass. It is the most widely used indicator of kidney function in patients with renal disease. The severity and the prognosis of the disease are predicted on this parameter. The assessment of GFR is thus invaluable in the follow-up of patients with progressive renal failure. It is also of great value in a variety of clinical conditions, as an estimate of GFR may be required to rationally prescribe fluids, electrolytes, or drugs excreted by the kidney.

Physiology of Glomerular Filtration

Ultrafiltration occurs through the permselective capillary wall. Ultrafiltration is driven by Starling forces across the glomerular capillaries. Changes in renal perfusion and in the Starling forces alter GFR. Both renal blood flow (RBF) and GFR are held within narrow limits by the phenomenon of autoregulation. Autoregulation is an intrarenal mechanism with two components: (a) the “myogenic mechanism” and (b) the “tubuloglomerular feedback mechanism.” Both mechanisms represent an effective means for uncoupling renal perfusion and GFR from abrupt changes in blood pressure.

The glomerular barrier filters molecules on the basis of size and electric charges. It behaves as if it were a filtering membrane containing aqueous pores with a diameter of 7.5 to 10.0 nm. Molecules with a diameter smaller than 3.6 nm are filtered freely. Molecules with a diameter larger than 7.2 nm are not filtered. Albumin, with an effective diameter of 7.1 nm, is filtered in minute amounts. The electrical charges of the molecules play an important role in their filterability. Filtration of large anionic molecules is restricted by the presence of negatively charged glycoproteins on the surface of all components of the glomerular membrane barrier. In the glomerulus, the MW cut-off for the filter is approximately 70 kDa. With an MW of 69 kDa, albumin passes through the filter in minute quantities. The glomerular filter is freely permeable to those molecules with an MW less than 7 kDa. Filtration of proteins, with consequent proteinuria, is increased in a number of glomerular diseases associated with the loss of negative charges on the glomerular filtration barrier.

The GFR is proportional to the sum of the Starling forces across the glomerular capillaries ($\Delta P - \Delta\pi$) times the

ultrafiltration coefficient (K_f): $GFR = K_f \times (\Delta P - \Delta\pi)$, where ΔP and $\Delta\pi$ represent the capillary transglomerular hydrostatic and oncotic pressure difference, respectively.

K_f is the product of the intrinsic permeability of the glomerular capillary and the glomerular surface area available for filtration. The permeability of the glomerular capillaries is 100 times higher than that of the capillaries elsewhere in the body.

Concept of Clearance

The most common measurement of GFR is based on the concept of clearance, which relates to the volume of plasma that in a given unit of time would be completely “cleared” of a substance. The clearance of substance (x) is expressed by the formula $C_x = U_x \times V/P_x$, where V represents the urine flow rate and U_x and P_x the urine and plasma concentration of substance x, respectively.

For its plasma clearance to be equal to the rate of glomerular filtration, a marker must have the following properties: (a) it must be freely filterable through the glomerular capillary membranes—that is, not bound to the plasma proteins or sieved in the process of ultrafiltration; (b) it must be biologically inert and neither reabsorbed nor secreted by the renal tubules; (c) it must not be toxic; and (d) it must not alter renal function when infused in quantities that permit adequate quantification in plasma and urine. Several substances, endogenous or exogenous, have been claimed to have the preceding properties: creatinine, inulin, iohexol, and three compounds labeled with radioisotopes: diethylenetriaminepenta-acetic acid (DTPA), ethylenediaminetetra-acetic acid (EDTA), and sodium iothalamate. The experimental evidence that this is true has only been produced for inulin. Although inulin is the most accurate marker, creatinine is the most commonly used in children.

Methods Available for Assessing Glomerular Filtration Rate

A variety of markers (Table 21.4) can be used to assess GFR using different methods, the principles of which are described in the following sections.

Standard Urinary Clearance

Endogenous Markers

The urinary excretion of the endogenous marker is measured over a few hours, and its excretion rate is divided by the plasma concentration present during the urine collection period. When urine flow rate is expressed in mL/min/1.73 m², the standard urinary clearance (UV/P) formula also expresses GFR in mL/min/1.73 m². Duration of the collection may last from 3 to 24 hours. Short periods are best in children to avoid inaccuracies in urine collection. Creatinine is the endogenous marker that is used for assessing GFR.

Exogenous Markers

The exogenous marker is infused at a constant rate over 3 to 4 hours to achieve constant plasma concentrations. To shorten the time of equilibration, a priming dose of the marker is administered at the onset of the clearance study. When stable plasma concentrations are attained, urine and blood samples are collected at regular intervals, and the UV:P ratio is calculated. The ideal exogenous marker is inulin. Other markers include iohexol and unlabeled iothalamate.

Constant Infusion Technique without Urine Collection

The constant infusion technique assumes that the rate of infusion (IR) of a marker (x) needed to maintain constant its plasma concentration is equal to the rate of its excretion (54,55). After equilibration of the marker in its distribution space, the excretion rate must thus be equal to the IR, hence the formula:

$$C_x = U_x \times V/P_x = IR_x/P_x$$

The flow rate of the test solution containing the marker is expressed in mL/min/1.73 m² and so is the clearance C_x .

To accelerate the achievement of a steady concentration of the marker, a loading dose precedes the constant intravenous (i.v.) infusion. The constant infusion method may overestimate GFR if steady concentration of the marker is not achieved when the plasma concentration is measured. Depending on the conditions, the equilibration of the

TABLE 21.4. CHARACTERISTICS OF THE GLOMERULAR MARKERS

	Inulin	Creatinine	Iohexol	DTPA	EDTA	Iothalamate

DTPA, diethylenetriaminepenta-acetic acid; EC, extracellular space; EDTA, ethylenediaminetetra-acetic acid; TBW, total body water.

marker within its distribution space may only be achieved after several hours of constant infusion. In newborn infants, the proportionally greater extracellular space and the low GFR require a much longer period for steady plasma concentrations to be attained. Inulin is the marker of choice for this technique, which is used when urine collection is not possible.

Plasma Disappearance Curve (Single Injection Technique)

The mathematical model for the plasma disappearance curve (single injection technique) is an open, two-compartment system (56). The glomerular marker is injected in the first compartment, equilibrates with the second compartment, and is excreted from the first compartment by glomerular filtration. The plasma disappearance curve of the marker follows two consecutive patterns. In the first, the plasma concentration falls rapidly but at a progressively diminishing rate. This reflects the diffusion of the marker in its distribution volume as well as its renal excretion. In the second, the slope of the decline of the plasma concentration reflects its renal excretion rate only. During this phase, the marker concentration decreases at the same exponential rate in all the compartments where it is distributed.

To obtain a well-defined plasma disappearance curve, and therefore an accurate calculation of the plasma clearance, numerous blood samples are required. Extension of the sampling period to 4 to 5 hours improves the precision of the results. Simplified techniques have been proposed that are based on a single-compartment model. They obviate the need for frequent blood sampling but result in greater accuracy.

The plasma disappearance curve is most often used when assessing GFR with radionuclides. Infusion of radionuclides for several hours is indeed undesirable, and they are best reserved for single injection studies in which the radioisotope is more rapidly eliminated from the kidney. Commonly used markers include technetium 99m (^{99m}Tc)-DTPA, chromium 51 (^{51}Cr)-EDTA, and iodine 125 (^{125}I)-iothalamate, and, more recently, cold iothexol. Clearance values derived from the plasma disappearance curve should be analyzed critically, particularly in patients with reduced GFR and those with edema and circulatory disturbances.

Plasma Concentration

The concentration of endogenous markers, such as creatinine, increases when GFR decreases. The increase in plasma creatinine is not linear, however. Several attempts have thus been made to develop reliable methods that will allow a correct estimate of creatinine clearance from its plasma concentration (P_{creat}) alone, without urine collection. The following formula has been developed that allows

an estimate of GFR derived from the child's creatinine plasma concentration and height.

$$\text{GFR} = k \times \text{Height} / P_{\text{creat}}$$

where k is a constant, Height represents the body height, and P_{creat} the plasma creatinine concentration. This formula is based on the assumption that creatinine excretion is proportional to body height and inversely proportional to plasma creatinine (57). The value of factor k can be obtained from the formula $k = \text{GFR} \times \text{Height} / P_{\text{creat}}$. Under steady state conditions, k should be directly proportional to the muscle component of body weight, which corresponds reasonably well to the daily urinary creatinine excretion rate.

The serum concentration of cystatin C has been proposed to assess GFR. Although the serum concentration of cystatin C may be superior to P_{creat} in distinguishing normal from abnormal GFR, a rational numerical estimate of GFR cannot be derived from its plasma concentration (58).

Estimation of Glomerular Filtration Rate in Clinical Practice with Different Markers

Inulin

The Marker

Inulin, a fructose polysaccharide derived from dahlia roots and Jerusalem artichokes, has an Einstein-Stokes radius of 1.5 nm and an MW of approximately 5.2 kDa. It diffuses as would a spherical body of such radius. Inulin is inert, not metabolized, and can be recovered quantitatively in the urine after parenteral administration. Evidence that inulin is neither reabsorbed nor secreted by the renal tubules has been well demonstrated in experimental micropuncture studies (59,60).

The rate of excretion of inulin is directly proportional to the plasma concentration of inulin. Its clearance (UV/P) is consequently independent of its plasma concentration. Because the renal excretion of inulin occurs exclusively by glomerular filtration, its clearance is the most accurate index of GFR. Estimates of inulin clearance provide the basis for a standard reference against which the route or mechanism of excretion of other substances can be ascertained.

Sinistrin is a readily soluble preparation of polyfructose with side branching (extracted from the bulb of *Urginea maritima*), which is more suitable for clinical use and readily available in Europe. This compound is identical to inulin.

Measurement of Inulin

In the classical anthrone method, inulin is hydrolyzed to fructose by sulfuric acid, and the fructose is then measured by colorimetry (61). Carbohydrates present in the plasma and urine also react in the assay (62). The method has a variation coefficient close to 6%. A specific, highly sensitive, enzymatic method has been described by Kuehnle et al. (63).

FIGURE 21.2. Inulin clearance as a function of age \pm SD.

In this method, inulin is hydrolyzed by insulinase, with simultaneous oxidation of the native glucose using glucose oxidase and H_2O_2 . The fructose generated by insulinase is then converted to glucose-6-phosphate. This method has a variation coefficient below 5% in serum and urine samples. A fully automated enzymatic inulin assay, with minimal sample prehandling and capable of complete sinistrin hydrolysis, has been described (64). The coefficient of variation was reported at 4.4%.

Inulin Urinary Clearance

Inulin or sinistrin urinary clearance (UV/P) is the gold standard for the assessment of GFR. In the classical method, inulin is administered as a priming dose to achieve plasma concentrations close to 200 to 400 mg/L. It is then constantly infused to maintain constant levels over the 3-hour clearance study. After an equilibration period of 90 minutes, urine and blood samples are collected at intervals of 30 minutes. The mean value of three to four clearance periods is considered as representing the child's GFR. In small children, the urine samples are collected through an indwelling bladder catheter. In preschool and school children, urine is collected by spontaneous voiding. Generous oral water loading (~ 300 mL/m²/hr) is given to maintain high urine flow rates. Sugar (e.g., glucose, fructose, and saccharose)-containing drinks must be avoided, as these glucosides interfere with the measurement of inulin in both the plasma and urine.

The use of sinistrin has been associated with anaphylactic reaction (65) in a 45-year-old white patient, whereas anaphylaxis from inulin in vegetables has been reported in a 39-year-old man (66).

The rise in GFR from birth to adulthood is illustrated in Figure 21.2 and given in Table 21.5. Mature values of GFR range from 100 to 120 mL/min/1.73 m². In a study by Koopman et al. in adult volunteers, GFR, as assessed by inulin clearance, had a circadian rhythm (67). It started to decrease during late afternoon or evening and rose again at the end of the night. The mean amplitude of the rhythm was 36 mL/min.

Constant Infusion Technique of Inulin without Urine Collection

The constant infusion technique of inulin without urine collection yields reproducible results, as long as sufficient time is given for steady concentrations to be reached (54,55,68). This may take as long as 12 hours in adults and even longer in infants (68,69). During the equilibration period, inulin is excreted by filtration, while at the same time diffusing into the extracellular space. Calculations of the infusion (IR/P) clearance before equilibration overestimate clearance values up to 30% above the urinary clearance. The shorter the time of infusion, the larger is the overestimation. The constant infusion method is useful when timed urine collections are difficult or unreliable, such as in small babies, children with hydronephrosis, or those with neurogenic bladder.

The result of the study comparing the "3-hour constant infusion" with the urinary clearance of inulin in 60 children older than 1 year showed a significant correlation, but the calculated regression line differed significantly from the line of identity, and the scatter of points was considerable (70). These results did not confirm an earlier report by Cole et al. demonstrating virtual superposition of inulin clearance values generated with and without urine collection (55). The constant infusion technique should be reserved for studies when the precise collection of urine cannot be performed and its result interpreted with caution.

Plasma Disappearance Curve of Inulin

The total body clearance of inulin can be estimated from the plasma disappearance curve after a bolus i.v. short infu-

sion (<5 minutes) of inulin at a dose of 100 mg/kg. The amount of inulin injected is such as to acutely increase the plasma concentration to 0.5 to 1.0 g/L (71). The concentration of inulin is ideally followed for at least 4 hours after the injection. Studies comparing the single injection with the urinary clearance of inulin have reported significant correlations between the two methods (72,73), but the single injection significantly overestimated the urinary clearance in a study by Florijn et al. (72). Pharmacokinetic adaptation of the standard technique can probably reduce the overestimation, but the procedure implies the collection of a blood sample for as long as 10 hours after the bolus injection in patients with impaired renal function (74).

Inulin as a Marker of Glomerular Filtration Rate in the Neonate

Studies comparing the clearance of inulin with that of other glomerular markers have led to the hypothesis that glomerular pore size could be related to body size and that inulin may not be freely filtered by the immature glomerulus (75). This hypothesis has not been confirmed by studies of inulin handling in rats or fetal lambs, both failing to demonstrate any restriction to the filtration of inulin (76,77). The same conclusion was reached from clinical studies in preterm infants showing that high-molecular-weight inulin or polysaccharides did not accumulate in the plasma of very immature babies infused with these glomerular markers for several days, thus excluding any retention of the larger molecules (78,79).

Studies on standard urinary inulin clearance in neonates are scarce. Those performed during the first 2 days of life of preterm and term neonates have shown that GFR at birth approximates 20 mL/min/1.73 m² in term neonates and 12 to 13 mL/min/1.73 m² in preemies of 28 to 30 weeks of gestation (80). The GFR matures rapidly in the early postnatal period, doubling during the first 2 weeks of life (80) (Fig. 21.3). The velocity of the maturation is somewhat slower in the most premature infants.

Conflicting results have been observed in neonates studied by the inulin constant infusion technique over a few hours. Although Cole et al. and Leake et al. found an excellent correlation between the constant infusion clearance and the urinary clearance of inulin ($R = 0.999$), Alinei and Guignard found the constant infusion technique to greatly overestimate (~30%) the urinary clearance of inulin in infants (55,81,82). The overestimation declined with time but remained substantial after 3 hours of infusion. The same conclusion was reached by Coulthard, who also observed an overestimation of GFR by the constant infusion technique in spite of the fact that the plasma inulin concentration was apparently stable (69). Reliable estimates of GFR could, however, be obtained when inulin was constantly infused for 24 hours, with or without a bolus injection at the start of the test. The main disadvantage of the method is that of requiring a constant infusion of long

FIGURE 21.3. Postnatal increase in glomerular filtration rate in term and preterm infants. Open part in columns represents mature levels of glomerular filtration rates. duration, as well as careful supervision of the test. Using the 24-hour constant infusion method in preterm infants, Van der Heijden et al. confirmed that GFR increases rapidly after birth (83).

Results comparing data obtained by the single injection technique with those obtained with the urinary clearance of inulin are conflicting. Early optimistic results have not been confirmed (84). A 30% overestimation of the true GFR was described by Fawer et al. in neonates 1 to 3 days old (85). These results were confirmed by Coulthard in preterm babies, who also described a large coefficient of variation for the single injection technique (69).

Creatinine

The Marker

Creatinine is the anhydride of creatine, a compound present in skeletal muscle as creatine phosphate. It has an MW of 113 d. The serum creatinine levels reflect total body supplies of creatinine and correlate with muscle mass. After initial decrease during the first month of life (Table 21.6), it increases steadily with age (Table 21.7). The excretion rate varies according to body weight and age, both reflecting muscle mass. The renal excretion pattern of endogenous creatinine is similar to that of inulin in humans and several animal species. However, in addition to being filtered through the glomerulus, creatinine is secreted in part by the renal tubular cells.

The validity of creatinine as a marker of GFR has been questioned because creatinine is not only secreted by the renal tubular cells, but could also be reabsorbed under certain conditions. Such reabsorption has been shown to occur in rats and dogs at low urine flow rates (86,87). Substantial tubular secretion and reabsorption of creatinine has been suggested in humans in relation to the degree of hydration (88,89).

TABLE 21.6. MEAN VALUES OF PLASMA CREATININE DURING THE FIRST WEEKS OF LIFE OF TERM AND VERY LOW BIRTH WEIGHT NEONATES

Birth weight (g)	Plasma creatinine ($\mu\text{mol/L}$) ^a			
	Postnatal period (d)			
	1–2	8–9	15–16	22–23

Term	66 \pm 3	40 \pm 4	30 \pm 8	27 \pm 7

^aMean values \pm SEM.

Overestimation of GFR by creatinine clearance is more pronounced at low GFR. Indeed, as GFR falls progressively during the course of renal diseases, the renal tubular secretion of creatinine contributes to an increasing fraction of urinary excretion, so that creatinine clearance may substantially exceed the actual GFR. Diffusion of creatinine into the gut may also interfere with the accuracy of its clearance in uremic patients. At a normal plasma concentration, the amount of creatinine entering the gut is negligible. It may become significant during renal failure when the plasma creatinine concentration increases (90). This phenomenon explains in part why creatinine clearance overestimates true GFR in patients with renal failure.

Measurement of Creatinine

Creatinine concentration in plasma and urine is usually based on the Jaffe reaction, characterized by the production of an orange-red color when creatinine reacts with alkaline sodium picrate. The method is not very specific, noncreatinine chromogens generating sufficient color to account for 0.2 to 0.3 mg/dL (\sim 30 $\mu\text{mol/L}$) of “false creatinine.” The interference of noncreatinine chromogen obviously is highest at the lowest values of creatinine, as present in newborn infants (91). Negative interference by conjugated and unconjugated bilirubin makes the use of the Jaffe reaction questionable in neonates. Other interference substances include acetoacetate, pyruvate, uric acid, the cephalosporins, and

TABLE 21.7. PLASMA CREATININE IN CHILDREN

Age (yr)	Plasma creatinine		Creatininuria	
	$\mu\text{mol/L}$	mg/dL	$\mu\text{mol/kg/d}$	mg/kg/d
<2	35–40	0.4–0.5	62–88	7.1–9.9

cotrimoxazole (91). The noncreatinine chromogens do not interfere significantly in the urine.

Modified kinetic Jaffe techniques have improved the specificity of creatinine measurement. Enzymatic methods have subsequently been developed that are more specific than the Jaffe reaction. Their cost and questionable precision have limited their widespread use.

Determination of serum creatinine by isotope dilution mass spectrometry has been described as the potential “definitive” method (92). High-performance liquid chromatography (HPLC) will undoubtedly become the reference method for creatinine determination (93,94), even if its routine use is still not possible in most clinical laboratories.

Creatinine Urinary Clearance

The urinary clearance of creatinine (UV/P) is the most commonly used method for assessing GFR in children. The urine is collected over 4 to 24 hours, with the plasma sample collected at the middle of the urine collection period. The plasma creatinine concentration can be significantly increased by cooked-meat feeding (95). Drugs, such as trimethoprim and cimetidine, increase the plasma creatinine by interfering with the renal tubular secretion, presumably by competition for the organic cation secretory passageway (96,97).

Estimation of GFR by measuring the urinary clearance of creatinine yields values that have been shown to correlate variably with inulin clearance. The best correlation is seen when GFR is normal. This results from the balance between two artifacts: (a) the excretion rate of creatinine is higher than the filtered rate because of the tubular secretion of creatinine and (b) the measured plasma creatinine is higher than the true creatinine because of the presence of noncreatinine chromogens that interfere with a standard colorimetric analysis of creatinine in the Jaffe reaction.

Overestimation of GFR by the urinary creatinine clearance is usually maximal at low levels of GFR (98). The ratio of the urinary creatinine clearance to urinary inulin clearance has been shown to vary between 1.14 and 2.27 in adult subjects. Dodge et al. and Kim et al. have long ago suggested that creatinine clearance should not be used for the estimation of GFR, as this clearance varies with tubular secretion of creatinine, which follows no apparent pattern (99,100). In the latter study, 42% of patients with decreased renal function would have been diagnosed as normal using urinary creatinine clearance. Like those of Rosenbaum, data obtained by Guignard et al. in 72 children older than 1 year showed a substantial overestimation of GFR by creatinine clearance at all levels of GF (70,101).

Assessment of Glomerular Filtration Rate

by the Formula ($2 C_{\text{creat}} + C_{\text{urea}}$)/3

In children undergoing simultaneous inulin and creatinine urinary clearance studies, the overestimation of GFR by creatinine clearance was “corrected” when the clearance of urea was also taken into account (70). When using the for-

FIGURE 21.4. Relationship between standard urinary clearance of inulin and the $(2 C_{\text{creat}} + C_{\text{urea}}) / 3$ formula. (Adapted from Guignard JP, Torrado A, Feldmann H, et al. Assessment of glomerular filtration rate in children. *Helv Paediatr Acta* 1980;35:437-447.)

mula $(2 C_{\text{creat}} + C_{\text{urea}}) / 3$, the regression line correlating this formula to inulin clearance was indistinguishable from the line of identity (Fig. 21.4). The scatter of points around the regression line was, however, not negligible.

Clearly, creatinine clearance alone is not a good alternative to inulin clearance when a precise measurement of GFR is needed. The use of the formula $(2 C_{\text{creat}} + C_{\text{urea}}) / 3$, calculated over 3 to 4 hours in well-hydrated children, is recommended when the clinical situation does not warrant the cumbersome measurement of inulin clearance or when the technique is not available.

The $\text{GFR} = k \times \text{Height} / P_{\text{creat}}$ Formula

Numerous studies have used the $\text{GFR} = k \times \text{Height} / P_{\text{creat}}$ formula, first described in 1976 by Counahan et al. and Schwarz et al. (102,103). A critical review of the use of this formula has been published by Haycock (104). The formula provides useful data when used cautiously. It cannot be used in obese or malnourished children in whom body height does not accurately reflect muscle mass. Ideally, the exact value of k should be derived from the laboratory where the plasma creatinine is measured and from inulin clearance as the reference method for estimating GFR. The values of k , as derived from creatinine clearance in different age groups by Schwarz et al., are given in Table 21.8 (57). In a study involving 200 patients aged 1 month to 23 years, Haenggi et al. compared the values of k derived from the urinary inulin clearance to that derived from simultaneous urinary creatinine clearance (89). The value of k derived from creatinine or inulin clearance differed significantly, being lower when calculated from C_{inulin} . The effect of the state of hydration was assessed in 18 children in a "hydropenic state" (urine flow rate, $3.5 \pm 0.6 \text{ mL/min}/1.73 \text{ m}^2$; mean urine osmolality,

TABLE 21.8. VALUES OF K FOR VARIOUS AGE GROUPS

	k values when P_{creat} expressed in:	
	$\mu\text{mol/L}$	mg/dL
Low-birth-weight infants <2.5 kg	29	0.33
Normal infants 0–18 mo	40	0.45
Girls 2–16 yr	49	0.55
Boys 2–13 yr	49	0.55
Boys 13–16 yr	62	0.70

ity, $407 \pm 61 \text{ mOsm/kg H}_2\text{O}$) or undergoing water diuresis (urine flow rate, $8.5 \text{ mL/min}/1.73 \text{ m}^2$; mean urine osmolality, $163 \text{g} \pm 20 \text{ mOsm/kg H}_2\text{O}$). In hydropenic children, the values of k were identical when derived from C_{inulin} or C_{creat} (49 ± 2 and 50 ± 3 , respectively). They differed significantly when k was derived from urinary creatinine clearance in children undergoing water diuresis (50 ± 3 vs. 64 ± 4 ; $p < .001$). Increased secretory rates of creatinine at high urine flow rates probably account for the elevated value of k calculated from C_{creat} in well-hydrated children. Extensive tubular secretion and reabsorption of creatinine in relation to the degree of hydration has been well described in humans (86). In spite of its relative inaccuracy, the $k \times \text{height} / P_{\text{creat}}$ formula has proved valuable as a rapid rough estimate of GFR in clinical practice.

Creatinine as a Marker of Glomerular Filtration Rate in the Neonate

In tiny premature neonates, the clearance of creatinine underestimates inulin clearance (105,106). Studies in piglets and newborn rabbits suggest that the filtered creatinine is significantly reabsorbed by the immature tubule (107,108). Creatinine reabsorption by the immature kidney probably occurs by passive back-diffusion of filtered creatinine across leaky tubules. Significant reabsorption of filtered creatinine supposedly accounts for the transient increase in plasma creatinine in the first 3 days of life of very low birth weight infants (Fig. 21.5) (109-111). After the neonatal period, P_{creat} rises steadily throughout infancy and childhood toward adult levels (Table 21.7).

In spite of these drawbacks in the assessment of GFR by creatinine clearance in newborn infants, the latter method has been used commonly in this age group. Studying very low birth weight infants, Stonestreet et al. have reported a correlation coefficient of 0.78 when values of creatinine clearance were compared to those of inulin clearance (106). In recent studies in premature and term neonates, creatinine clearance has been shown to be low at birth and to rise

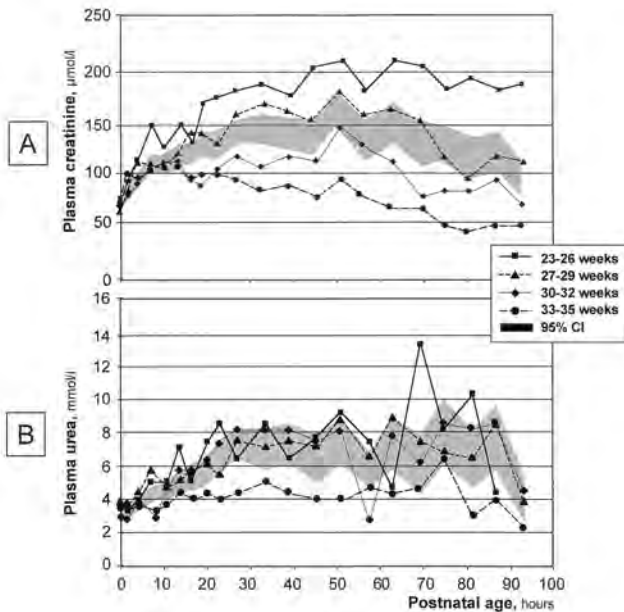

FIGURE 21.5. Changes in plasma creatinine (A) and urea (B) concentrations during the first 100 hours of life of premature neonates of variable gestational age. The shaded area represents 95% CIs for the mean plasma creatinine or urea of all infants. (Adapted from Miall LS, Henderson MJ, Turner AJ, et al. Plasma creatinine rises dramatically in the first 48 hours of life in preterm infants. *Pediatrics* 1999;104:e76.)

rapidly after birth (111,112). The slope of maturation was steeper in the most mature infants (112). The increase in creatinine clearance correlated with the postnatal increase in systemic blood pressure as well as with gestational and postnatal age (111–113). Creatinine clearance close to 42 mL/min/1.73 m² in term neonates and 27 mL/min/1.73 m² in premies younger than 27 weeks of gestation were recorded on the fifty-second day of life (111). Mature levels close to 100 mL/min/1.73 m² are reached at the end of the first year of life.

Iohexol

Iohexol is a nonionic contrast agent with an MW of 821 d. It does (almost) not bind to plasma proteins, diffuses into the extracellular space (114), and is eliminated exclusively via the kidneys (115). Iohexol has an elimination half-life of approximately 90 minutes. Total urine recovery of iohexol after i.v. injection occurs within 12 hours (114). Iohexol can be measured by x-ray fluorescence and HPLC methods (74). More recently, iohexol has been successfully measured by the capillary electrophoresis technique, with results similar to those obtained by the HPLC method (74). The capillary electrophoresis technique is less expensive, more rapid, and more sensitive than both the HPLC and x-ray fluorescence methods. Good correlations have been reported between plasma iohexol clearance and that of ⁵¹Cr-EDTA (116). Clinical studies have, however, sug-

gested that the diffusion of iohexol in its distribution volume is slow, and that it may take more than 4 to 6 hours to reach equilibrium after an i.v. injection of the agent (117). This may limit the usefulness of iohexol as a marker of GFR, even if significant correlations have been demonstrated between standard inulin clearance and values generated by the plasma disappearance curve of iohexol (74).

Cystatin C

Cystatin C, a nonglycosated, 13-d basic protein, is a proteinase inhibitor involved in the intracellular catabolism of proteins (118). It is produced by all nucleated cells at a constant rate apparently independent from inflammatory conditions, muscle mass, and gender (119). It is freely filtered across the glomerular capillaries, almost completely reabsorbed, and catabolized in the proximal tubular cells (120). Being reabsorbed, cystatin is not a classical glomerular marker as strictly defined (121). Fully automated assays using particle-enhanced turbidimetry or particle-enhanced nephelometry are available for the measurement of cystatin in plasma and serum (122,123). The assays are precise, rapid, and usable in clinical routine practice.

Cystatin C does not cross the placenta, and there is no correlation between maternal and neonatal serum cystatin C levels (124). Cystatin C concentrations are high at birth and then decrease to stabilize after 12 months of age (119) (Fig. 21.6). Whether cystatin C is significantly higher in premature infants as compared to term infants is not yet clear (119,125). Bökenkamp et al. found serum cystatin levels between 0.70 and 1.38 mg/L in children older than 1 year (126).

Serum cystatin C concentrations are closely related to GFR as are serum creatinine levels. Serum cystatin C increases when GFR decreases. The reciprocal values of cystatin C correlate linearly with GFR, and cystatin C has been claimed to be at least as good as serum creatinine for the evaluation of GFR in adults (127). In children aged 1.8 to 18.8 years with various levels of GFR, serum cystatin C has been found to be broadly equivalent or even superior to serum creatinine as an estimate of GFR (58,126). The fact that cystatin C is independent of age, gender, height, and body composition has been considered an advantage (126).

The major drawbacks in using cystatin C are that it is not a true glomerular marker and its clearance cannot be calculated. A recent study by Martini et al. compared the reliability of different estimates of GFR to distinguish impaired from normal GFR, with a cut-off at 100 mL/min/1.73 m² (128). Although plasma cystatin was slightly superior to plasma creatinine in diagnosing renal insufficiency, it was significantly less sensitive than both urinary creatinine clearance and the estimated $k \times \text{Height} / P_{\text{creat}}$. The authors concluded that simply measuring the child's height in addition to the plasma creatinine was a simpler, cheaper, and better means of rapidly assessing GFR in children than measuring the plasma cystatin C. The recent observation that the urine cystatin C/

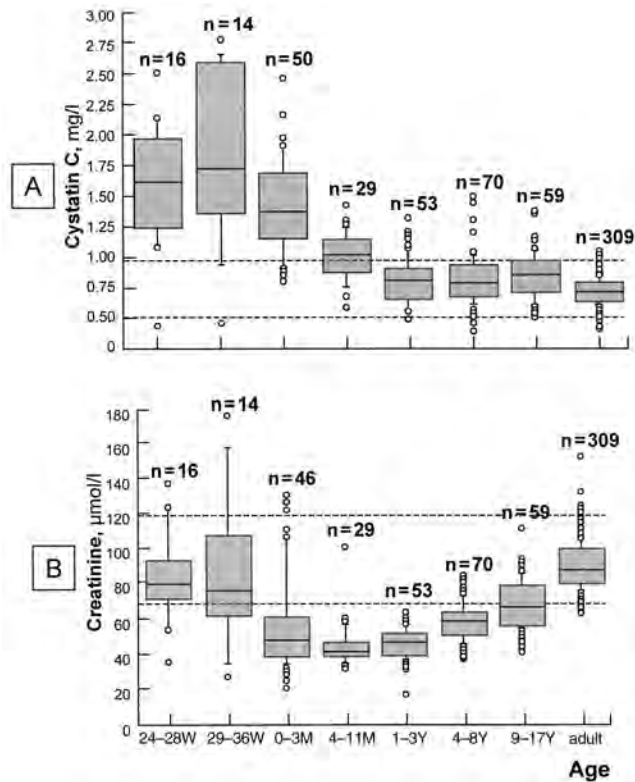

FIGURE 21.6. Box plot distributions showing (A) cystatin C and (B) creatinine values (tenth, twenty-fifth, fiftieth, and ninetieth percentiles) across the age groups. The categories of 24 to 36 and 29 to 36 weeks refer to gestational ages of preterm babies. Dotted lines indicate 95% confidence interval of adult range. Preterm babies born between 24 to 36 weeks' gestation were 1 day old. (Adapted from Finney H, Newman DJ, Thakkar H, et al. Reference ranges for plasma cystatin C and creatinine measurements in premature infants, neonates and older children. *Arch Dis Child* 2000;82:71-75.)

creatinine ratio could provide information on both glomerular function and tubular injury casts doubts on the real value of cystatin C as the best estimate of GFR (129).

Radionuclides

Radionuclides, such as ^{51}Cr -EDTA, $^{99\text{m}}\text{Tc}$ -DTPA, and ^{125}I -iothalamate, have been used as alternative filtration markers (Table 21.4). They permit accurate detection of minute concentrations of the markers in plasma and urine samples. Their urinary clearance, as calculated after a constant infusion of the marker, was initially reported as fairly similar to that of inulin (130). Prolonged radioactive exposure during the infusion of radiolabeled markers has limited the use of these compounds to single injection studies only. Even in these conditions, radioactive markers are best avoided in pregnant women and small children.

$^{99\text{m}}\text{Tc}$ -DTPA

DTPA has an MW of 393 d. It appears to be excreted mainly by glomerular filtration (131). Protein binding of DTPA is

minimal. Its clearance approximates that of inulin (132). The occurrence of extrarenal elimination of DTPA is, however, suggested by the observation that the plasma clearance of $^{99\text{m}}\text{Tc}$ -DTPA exceeds the urinary clearance of the compound by a variable but significant amount (130,132). A significant drawback in using $^{99\text{m}}\text{Tc}$ -DTPA as a glomerular marker is the fact that the $^{99\text{m}}\text{Tc}$ -DTPA can significantly dissociate from DTPA during a clearance study (133). In the neonate, $^{99\text{m}}\text{Tc}$ -DTPA scans are characterized by poor visualization of the kidneys and a relatively flat renal curve. Better-quality dynamic isotope scans are generally only achieved at the end of the neonatal period, when GFR has reached higher values.

^{51}Cr -EDTA

EDTA is a glomerular marker similar to DTPA. EDTA has an MW of 292 d and is used as a chelate of ^{51}Cr . Its plasma disappearance curve measured after a bolus i.v. injection exceeds its urinary clearance by an average of 6 mL/min, thus suggesting an extrarenal route of elimination (134). This phenomenon is particularly evident at low filtration rates.

Iothalamate
