burns, and disease states associated with third-space losses such as sepsis, nephrotic syndrome, tissue trauma, and capillary leak syndrome. Decreased effective blood volume occurs when the true blood volume is normal or increased but renal perfusion is decreased due to diseases such as congestive heart failure, cardiac tamponade, and hepatorenal syndrome (16–19). Whether prerenal failure is caused by true volume depletion or decreased effective blood volume, correction of the underlying disturbance returns renal function to normal.

Urine osmolality, urine sodium concentration, fractional excretion of sodium, and the renal failure index have all been proposed to help differentiate prerenal failure from vasomotor nephropathy (acute tubular necrosis). This differentiation is based on the concept that the tubules are working appropriately in prerenal failure and are therefore able to conserve salt and water appropriately, whereas in vasomotor nephropathy the tubules have progressed to irreversible injury and are unable to appropriately conserve sodium (1,16,20–22). During prerenal failure, the tubules are able to respond to decreased renal perfusion by appropriately conserving sodium and water so that the urine osmolality is greater than 400 to 500 mOsm/L, the urine sodium level is less than 10 to 20 mEq/L, and the fractional excretion of sodium (FE_{Na}) is less than 1%. FE_{Na} is calculated by the following formula:

$$FE_{Na} = [(U_{Na}/P_{Cr})/(P_{Na}/U_{Cr})] \times 100 \quad [\text{Eq. 1}]$$

where U_{Na} is urine sodium level, P_{Na} is plasma sodium level, U_{Cr} is urine creatinine level, and P_{Cr} is plasma creatinine level. Because the renal tubules in newborns and premature infants are relatively immature compared to those in older infants and children, the corresponding values suggestive of renal hypoperfusion are a urine osmolality higher than 350 mOsm/L, urine sodium lower than 20 to 30 mEq/L, and an FE_{Na} lower than 2.5% (27–29). When the renal tubules have sustained injury as occurs in acute tubular necrosis, they cannot appropriately conserve sodium and water, so that the urine osmolality is lower than 350 mOsm/L, the urine sodium is higher than 30 to 40 mEq/L, and the FE_{Na} is higher than 2%. However, the use of these values to differentiate prerenal failure from acute tubular necrosis requires that the patient have normal tubular function initially. Although this may be the case in some children, newborns with immature tubules and children with preexisting renal disease, salt-wasting renal adrenal disease, as well as other diseases may have prerenal failure with urinary indices suggestive of acute tubular necrosis. Therefore, it is essential to consider the state of the function of the tubules before the potential onset that might precipitate vasomotor nephropathy and acute tubular necrosis.

In adult patients it has been shown that calculation of the fractional excretion of urea nitrogen (FE_{UN}) is a more sensitive test than FE_{Na} to differentiate prerenal failure from acute tubular necrosis, particularly in patients who have received diuretic therapy (30). FE_{UN} is given by:

FIGURE 64.1. Mercaptotriglycylglycine renal scan for a 1-year-old with acute tubular necrosis (A) and a newborn with cortical necrosis (B). Each scan was made 4 hours after injection of the isotope. A: Shows delayed uptake of isotope with parenchymal accumulation of isotope and little or no excretion of isotope into the collecting system. B: In contrast, demonstrates no renal parenchymal uptake of isotope.

$$FE_{UN} = [(UUN/U_{Cr})/(BUN/P_{Cr})] \times 100 \quad [\text{Eq. 2}]$$

where UUN is urine urea nitrogen. An FE_{UN} value of less than 35% typically signifies prerenal azotemia and FE_{UN} of more than 50% indicates acute tubular necrosis. FE_{UN} was found to be at least as sensitive and specific an indicator as FE_{Na} in prerenal azotemia, but FE_{UN} did not lose its sensitivity or specificity in differentiation of prerenal failure and acute tubular necrosis when patients had received diuretic therapy (30). Whether FE_{UN} is more sensitive or specific than FE_{Na} in pediatric patients is unknown, and such studies need to be performed to determine if FE_{UN} is a more sensitive measure of tubular function in children.

Intrinsic Renal Disease

Acute Tubular Necrosis

Acute tubular necrosis can evolve from prerenal failure if the insult is severe and sufficient enough to result in vasoconstriction and tubular damage. The pathophysiology of ischemic-hypoxic acute tubular necrosis is thought to be related to early vasoconstriction followed by patchy tubular necrosis. Acute tubular necrosis may also result from toxic injury of tubular epithelial cells caused by drugs, including aminoglycoside antibiotics, cisplatin, ifosfamide, amphotericin B, acetaminophen, and radio-contrast dye, as well as exogenous toxins such as ethylene glycol, methanol, or bromate or endogenous toxins such as myoglobin and hemo- globin (Table 64.1).

Hypoxic-Ischemic Acute Tubular Necrosis

Hypoxic-ischemic acute tubular necrosis evolves from prolonged prerenal failure or severe hypoxic insults. Results of the urinalysis may be unremarkable or may demonstrate low-grade proteinuria and granular casts, and urine indices of tubular function demonstrate an inability to conserve sodium and water as described earlier. The creatinine level typically increases by 0.5 to 1.0 mg/dL/day. Radiographic studies demonstrate kidneys of normal size with loss of corticomedullary differentiation, whereas a radionuclide renal scan using technetium-99–mercaptotriglycylglycine or technetium-99–diethylenetriaminepenta-acetic acid shows normal or slightly decreased renal blood flow with poor function and delayed accumulation of the radioisotope in the renal parenchyma without excretion of the isotope in the collecting system (Fig. 64.1A).

The prognosis of acute tubular necrosis is good except in cases in which the insult is of sufficient severity to lead to vasculature injury and microthrombi formation with the subsequent development of cortical necrosis. The recovery of the child and the recovery of renal function depend on the underlying events that precipitated the ischemic-hypoxic insults. The mortality and morbidity of acute renal failure is much worse in children and neonates with multi-organ failure, and the child does not succumb to renal failure but rather the child succumbs to renal failure and the associated conditions that precipitated the multiorgan failure (8,11,31–37). In children who recover from acute tubular necrosis, renal function returns to normal, but the

length of time before recovery is quite variable. Some children begin to recover renal function within days of the onset of renal failure, whereas recovery may not occur for several weeks in other children. Return of renal function may be accompanied by a diuretic phase with excessive urine output at a time when the tubules have begun to recover from the insult but have not recovered sufficiently to appropriately reabsorb solute and water. When the diuretic phase occurs during recovery, close attention to fluid and electrolyte balance is very important to ensure adequate fluid management so as to promote recovery from acute tubular necrosis and prevent additional renal injury.

Nephrotoxic Acute Renal Failure

Many different drugs and agents may result in nephrotoxic acute renal failure (38,39). Nephrotoxic acute renal failure may result from the administration of a number of different medications as well as the ingestion of poisons or from a nephrotoxic insult from indigenous compounds such as hemoglobin or myoglobin.

Drug-Induced Acute Renal Failure. Medications that are associated with acute renal failure at least in part due to toxic tubular injury include aminoglycoside antibiotics, intravascular contrast media, amphotericin B, chemotherapeutic agents such as ifosfamide and cisplatin, acyclovir, and acetaminophen; other medications have been implicated less commonly (38–49). Aminoglycoside nephrotoxicity usually presents with nonoliguric acute renal failure with a urinalysis showing minimal urinary abnormalities (40). The incidence of aminoglycoside antibiotic nephrotoxicity is related to the dose and duration of the antibiotic therapy as well as the level of renal function before the initiation of aminoglycoside therapy. The cause of aminoglycoside nephrotoxicity is thought to be related to the lysosomal dysfunction of proximal tubules and is reversible once the aminoglycoside antibiotics have been discontinued. After the aminoglycoside is discontinued, however, the serum creatinine level may continue to increase for several days due to ongoing tubular injury from continued high parenchymal levels of the aminoglycoside. Studies have demonstrated that once-daily dosing of aminoglycoside antibiotics is associated with a slightly decreased incidence of nephrotoxicity without compromising efficacy (50,51).

Intravascular contrast media may also precipitate acute renal failure, particularly in patients who are at higher risk for contrast nephropathy, including patients with dehydration, diabetes, or preexisting renal disease and patients with hypergammaglobulinemia (41,42). The incidence of contrast nephropathy can be reduced through the use of nonionic, low-osmolality contrast media (41,42). Use of the iso-osmolar, dimeric nonionic contrast medium iodixanol is associated with an even lower risk of contrast nephropathy (52). The prophylactic administration of *N*-acetylcysteine may decrease the decline in GFR associated with the admin-

istration of an intravascular contrast agent in adults at risk for contrast nephropathy (25). Similar studies have not been performed in pediatric patients, and the potential hazards and benefits of *N*-acetylcysteine in pediatric patients at risk for contrast nephropathy are unknown.

Nonsteroidal antiinflammatory drugs may also precipitate acute renal failure by their effect on intrarenal hemodynamics (16–21). Cisplatin, ifosfamide, acyclovir, amphotericin B, and acetaminophen are also nephrotoxic and may precipitate acute renal failure (43–51). Predictors of amphotericin B nephrotoxicity include high daily dosage and concomitant use of cyclosporine (43). The combination of a cephalosporin and acyclovir may be particularly nephrotoxic (49). Several other drugs have also been associated with acute renal failure, but the incidence of acute renal failure with these other drugs is lower.

Exogenous Toxin-Induced Acute Renal Failure. Ingested toxic compounds, either in their native state or after metabolism, may precipitate acute renal failure. The best known of such toxins are ethylene glycol and methanol (53–57). Both ethylene glycol and methanol are not toxic until they are metabolized by alcohol dehydrogenase to organic acids and oxalate for ethylene glycol, and formic acid and formaldehyde for methanol. Once sufficient quantities of the metabolites have been generated, the patient will present with severe metabolic acidosis with a large anion gap. Ethylene glycol intoxication may also be characterized by calcium oxalate crystalluria and hematuria on urinalysis; other laboratory findings may include hypocalcemia. Both ethylene glycol and methanol intoxication can result from the accidental ingestion of antifreeze or transmission fluid or from a suicide attempt in older children. In the past ethylene glycol and methanol intoxication were best treated with an ethanol drip to competitively inhibit ethanol dehydrogenase and decrease the metabolism of ethylene glycol and methanol to their toxic metabolites. In addition, for patients with moderate to severe intoxication as indicated by a substantial metabolic acidosis and/or an initial ethylene glycol or methanol level higher than 50 mg/dL, the patient should be urgently treated with bicarbonate hemodialysis (43–45). This allows removal of ethylene glycol or methanol before it is metabolized to its toxic compounds and treats the acidosis as well. Fomepizole (4-methylpyrazole), an inhibitor of alcohol dehydrogenase, has been shown to be effective in the treatment of ethylene glycol intoxication in adults and pediatric patients (56,57). Fomepizole does not have the adverse effects of ethanol infusion in pediatric patients.

Other compounds that may cause acute renal failure upon ingestion include potassium sodium bromate, which is contained in hair permanent-wave solutions (58,59). Other less common causes of acute renal failure include the ingestion of carbon tetrachloride and heavy metals such as mercury and other compounds (39).

Endogenous Toxin–Induced Acute Renal Failure Including Hemoglobinuria and Myoglobinuria. Hemolysis and rhabdomyolysis from any cause can result in sufficient hemoglobinuria or myoglobinuria to induce tubular injury and precipitate acute renal failure (60–65). Risk factors for acute renal failure during an episode of rhabdomyolysis in children include dehydration, a high serum concentration of myoglobin, the presence of other organ failure, and the presence of the systemic inflammatory response syndrome (61). The mechanisms of injury are complex but may be related to vasoconstriction, precipitation of the pigments in the tubular lumen, and/or heme protein–induced oxidant stress (62–64). If the rhabdomyolysis is a result of tissue injury with substantial third-space fluid losses as occurs in a crush injury, rapid fluid resuscitation can prevent or limit the renal injury (65). Once intravascular volume has been established, diuretic therapy with mannitol or other loop diuretics to promote flow, prevent precipitation of the heme proteins in the tubules, and alkalize the urine to potentially increase the solubility of hemoglobin and myoglobin has been proposed to decrease tubular injury (65). Hyperkalemia, acidosis, and other electrolyte abnormalities may develop rapidly and require prompt therapy.

Uric Acid Nephropathy and Tumor Lysis Syndrome

Acute renal failure may be detected at the time of diagnosis of leukemia or lymphoma due to infiltration of tumor cells in the kidney or due to uric acid nephropathy. Radiographic studies demonstrate either mass lesions in the kidney in the case of lymphoma or diffuse infiltrative disease in the case of leukemia (66–68). Children with acute lymphocytic leukemia and B-cell lymphoma are at the highest risk for uric acid nephropathy and tumor lysis syndrome (68,69). Although the pathogenesis of uric acid nephropathy is complex, an important potential mechanism of injury is the precipitation of uric acid crystals in the tubules to obstruct urine flow or in the renal microvasculature to obstruct renal blood flow (68,69). A more common cause of acute renal failure in leukemia is the development of the tumor lysis syndrome during chemotherapy (68,69). Administration of allopurinol limits the increased excretion of uric acid with chemotherapy, but allopurinol treatment results in a markedly increased excretion of uric acid precursors, including hypoxanthine and xanthine (69). Xanthine is less soluble than uric acid, and precipitation of hypoxanthine and xanthine may play a role in the development of acute renal failure during tumor lysis syndrome. Tumor lysis syndrome results in rapid increases in the levels of serum potassium, BUN, purine metabolite products, and phosphorus with a reciprocal decrease in the serum calcium level as tumor cells are lysed. Acute renal failure due to tumor lysis syndrome is transient, and the patient eventually recovers renal function once tumor lysis is complete.

However, frequent hemodialysis or continuous hemofiltration may be necessary to control hyperkalemia and other metabolic abnormalities resulting from the rapid lysis of tumor cells (70–72).

Acute Interstitial Nephritis

Acute interstitial nephritis resulting from a reaction to a drug or idiopathic acute interstitial nephritis may cause acute renal failure. Children with acute interstitial nephritis may have rash, fever, arthralgias, eosinophilia, and pyuria with or without eosinophiluria (73). Uveitis has been reported in several cases of acute interstitial nephritis and is important to recognize, because treatment with topical steroids may be indicated for the uveitis (74). Radiographic studies demonstrate large echogenic kidneys, and a kidney biopsy specimen demonstrates interstitial infiltrate with many eosinophils. The pathogenesis of drug-induced acute interstitial nephritis is thought to be related to a hypersensitivity reaction, with the development of anti-tubular basement membrane antibodies in some cases (73–75). Medications commonly associated with acute interstitial nephritis include methicillin and other penicillin analogues, cimetidine, sulfonamides, rifampin, and nonsteroidal antiinflammatory drugs; other drugs have been associated with acute interstitial nephritis less commonly (73,75). Acute interstitial nephritis associated with nonsteroidal antiinflammatory drugs may also present with high-grade proteinuria and nephrotic syndrome (75). Specific therapy for acute interstitial nephritis includes the withdrawal of the drug implicated in causing the acute interstitial nephritis. In addition, corticosteroids may aid in the resolution of the renal failure.

Rapidly Progressive Glomerulonephritis

Any form of glomerulonephritis at its most severe can present with acute renal failure and rapidly progressive glomerulonephritis. The clinical features include hypertension, edema, hematuria, which is frequently gross, and rapidly rising BUN and creatinine levels. The characteristic pathologic finding in rapidly progressive glomerulonephritis is extensive crescent formation. Some glomerulonephritides, such as postinfectious glomerulonephritis, membranoproliferative glomerulonephritis, Henoch-Schönlein purpura nephritis, and lupus nephritis, present with a rapidly progressive course in a minority of cases. However, other glomerulonephritides, such as antineutrophil cytoplasmic antibody (ANCA)–positive glomerulonephritis, Goodpasture syndrome, and idiopathic rapidly progressive glomerulonephritis, typically present with acute renal failure (76–78). Serologic tests including tests for antinuclear antibodies and ANCA, anti-glomerular basement membrane titers, and complement studies are required to evaluate the cause of the rapidly progressive glomerulonephritis. The

presence of active lesions in biopsy specimens is associated with recovery of renal function, and the disorder may be reversible with immunosuppressive therapy (75). Because the treatment depends on the pathologic findings, a biopsy should be performed quite promptly when a child presents with clinical characteristics suggestive of rapidly progressive glomerulonephritis so that specific therapy can be initiated as soon as possible.

Vascular Insults

Large vessel insults such as renal artery thrombosis and renal vein thrombosis present with acute renal failure only if they are bilateral or if they occur in a solitary kidney. Microvascular insults occur in cortical necrosis, in typical (diarrhea positive) and atypical (diarrhea negative) HUS, and in HUS after bone marrow transplantation.

Renal Artery Thrombosis and Renal Venous Thrombosis

Renal artery thrombosis, cortical necrosis, and renal venous thrombosis occur most commonly in newborns and small children. Renal artery thrombosis is strongly associated with an umbilical artery line and a patent ductus arteriosus (79,80). In addition to acute renal failure, children may demonstrate hypertension, gross or microscopic hematuria, thrombocytopenia, and oliguria. In renal artery thrombosis, the initial ultrasonographic image may appear normal or may demonstrate minor abnormalities, whereas a renal scan demonstrates little or no blood flow. In renal vein thrombosis, the ultrasonographic image demonstrates an enlarged, swollen kidney, and the renal scan typically shows decreased blood flow and function. Therapy should be aimed at limiting extension of the clot by removal of the umbilical arterial catheter, and anticoagulant or fibrinolytic therapy can be considered, particularly if the clot is large (79–82).

Cortical Necrosis

Cortical necrosis as a cause of acute renal failure is much more common in young children, particularly in the neonate. Cortical necrosis is associated with hypoxic-ischemic insults due to perinatal anoxia, placental abruption, and twin-twin or twin-maternal transfusions with resultant activation of the coagulation cascade. Children and newborns with cortical necrosis usually have gross or microscopic hematuria and oliguria, and may have hypertension as well (83). In addition to laboratory features of elevated BUN and creatinine levels, thrombocytopenia may also be present due to the microvascular injury. Radiographic features include a normal renal ultrasonogram in the early phase, but in the later phases ultrasonography may show that the kidney has undergone atrophy and has substantially decreased in size. A radionucleotide renal scan shows decreased or no perfusion with delayed or no function (Fig. 64.1B) in contrast to the delayed uptake of the radioisotope

that is observed in acute tubular necrosis (Fig. 64.1A). The prognosis of cortical necrosis is much worse than that of acute tubular necrosis. Children with cortical necrosis may have partial recovery or no recovery at all. Typically, children with cortical necrosis will need short- or long-term dialysis therapy, but children who do recover sufficient renal function are at risk for the late development of chronic renal insufficiency and end-stage renal disease.

Hemolytic Uremic Syndrome

HUS is a common cause of intrinsic acute renal failure in children and leads to substantial morbidity and mortality as well as long-term complications that may not become apparent until adulthood (84–110). Typical HUS usually follows a gastrointestinal illness characterized by hemorrhagic colitis associated with infection with vero cytotoxin-producing *Escherichia coli*, of which O157:H7 is the most common serotype. Shiga toxin-producing *E. coli* was first linked to human disease in the early 1980s (89–91). Several well-publicized outbreaks of hemorrhagic colitis and HUS have highlighted the morbidity and mortality of infection with vero cytotoxin-producing *E. coli*. In 1993, an outbreak in the western United States resulted in several cases of severe HUS with substantial extrarenal complications (95). In 1996, over 5000 Japanese schoolchildren were infected with vero cytotoxin-producing *E. coli*. An outbreak in Scotland resulted in 20 deaths. One outbreak in the United States was traced to contaminated apple juice, and several million pounds of contaminated hamburger was recalled by the manufacturers (96,97). In case-control studies, consumption of a beef burger and/or consumption of cold cooked sliced meat was found to be associated with vero cytotoxin-producing *Escherichia coli* O157 infection (98). Although undercooked beef is the most common vector for O157:H7 infection, apple juice, radish sprouts, sausages, and other food sources have been implicated in the spread of vero cytotoxin-producing *E. coli* infections. In the United States and Europe, the O157:H7 serotype is the serotype most commonly implicated in infection with vero cytotoxin-producing organisms, but in other areas of the world non-O157:H7 strains are emerging as important pathogens (99–101). *E. coli* O111:H– caused a large outbreak of hemorrhagic colitis and HUS in Australia, and other serotypes have been associated with hemorrhagic colitis and HUS as well (100,101).

Among persons infected with vero cytotoxin-producing *E. coli*, the percentage of patients who progress to HUS ranges from 5 to 15%. In children under 5 years of age, the rate of progression to hemolytic anemia or HUS is 12.9%, whereas the rate is 6.8 for children aged 5.0 to 9.9 years and 8% for those older than 10 years of age (92). In another separate study, children with a white blood cell count higher than 13,000/mm³ during the initial 3 days of illness with vero cytotoxin-producing *E. coli* infection had a sevenfold increase in the risk of developing HUS compared to

age-matched children with a white blood cell count lower than 13,000/mm³. The use of antimotility agents was also associated with a higher risk for the development of HUS (102). One study demonstrated that children with hemorrhagic colitis associated with shiga toxin-producing *E. coli* who received antibiotic therapy were much more likely to progress to HUS (103). Environmental or genetic factors that might predispose to the progression of hemorrhagic colitis associated with shiga toxin-producing *E. coli* to HUS are currently unknown. It has been suggested that alterations in the gene for factor H now described in patients with atypical HUS may also be relevant to epidemic diarrhea-positive HUS (93).

At the time the diarrhea is subsiding, the child appears pale and lethargic due to the hemolytic anemia. Irritability is very common, although some children may also develop petechiae due to the thrombocytopenia. Oliguria or anuria occurs in 30 to 50% of children, and 40 to 75% of children will need dialysis therapy. The kidney and gastrointestinal tract are the organs most commonly affected in HUS, but evidence of central nervous system, pancreatic, skeletal, and myocardial involvement may also be present (105–109). Gastrointestinal involvement may lead to rectal prolapse, ischemic colitis, and transmural colonic necrosis requiring surgical intervention. Pancreatic involvement manifested as elevated pancreatic enzyme levels occurs in 10 to 20% of children, whereas glucose intolerance due to pancreatic islet cell involvement occurs in fewer than 10% of children (107). Central nervous system disease may present as seizures, coma, lethargy, and irritability.

Management of HUS requires appropriate attention to fluid and electrolyte balance and nutritional status, and careful attention to the extrarenal complications of HUS. Hemolysis may be brisk and may require frequent transfusions of packed red blood cells (approximately 10 mL/kg given over several hours). Early initiation of dialysis or CVVH (continuous venovenous hemofiltration) may be necessary if the child is oliguric. Because platelet transfusions may add fuel to the fire, platelet transfusions are reserved for patients with active bleeding or for children with severe thrombocytopenia who need to undergo a surgical procedure such as placement of a dialysis catheter or a central line. In general, antibiotic therapy is not indicated, because antibiotic therapy has the theoretical potential to alter the bacterial production of toxin and/or result in the increased release of toxin. Similarly, use of antimotility agents is also not indicated, because they may increase the systemic absorption of toxin due to the slower gastrointestinal transit time. Some studies have demonstrated a harmful effect of antibiotic therapy in hemorrhagic colitis. Children with hemorrhagic colitis associated with shiga toxin-producing *E. coli* who received antibiotic therapy were more likely to develop HUS than were children who did not receive antibiotic therapy (103). Other studies have not demonstrated such an association, and a meta-analysis con-

cluded that administration of antibiotics in people infected with shiga toxin-producing *E. coli* was not associated with the development of HUS (110,111). Although there is no consensus on the benefit versus harm of antibiotic therapy for shiga toxin-producing *E. coli* infection, *in vitro* studies have shown that subinhibitory concentrations of several antimicrobial agents promote and increase the release of vero cytotoxins (112). Plasmapheresis has not been shown to alter the natural history of diarrhea-associated HUS (113).

A diatomaceous silicon diamide compound linked to an oligosaccharide chain (Synsorb Pk) has been developed and has been shown to avidly bind and neutralize shiga toxin. A clinical trial designed to determine if oral administration of Synsorb Pk could decrease the rate of progression of hemorrhagic colitis to HUS or if it could decrease the need for dialysis or the development of extrarenal complications in children who have developed HUS has been completed (114,115). Unfortunately, Synsorb Pk was not found to be beneficial in preventing extrarenal complications nor in decreasing the duration of dialysis in children with new-onset HUS (115). Starfish is a new compound that has been developed and has been shown to bind to shiga toxin 1000 times more efficiently than Synsorb Pk. Starfish is a pentamer that binds shiga toxin and has the potential to be administered intravenously (116).

Atypical HUS is not associated with diarrhea and occurs much less frequently in children. Atypical HUS may be associated with a number of immunologic diseases including systemic lupus erythematosus, with infections such as streptococcal pneumonia, or with the administration of medications such as cyclosporin or birth control pills or chemotherapeutic agents such as mitomycin (94). Acute renal failure may also occur after bone marrow transplantation. The cause is likely to be multifactorial, but a high incidence of microvascular disease resembling HUS has been observed, usually in association with venoocclusive disease (94). Acute renal failure after bone marrow transplantation in children usually has a multifactorial cause and may be associated with long-term renal insufficiency in some children (117). Atypical HUS may lead to end-stage renal disease and can recur in patients with kidney transplants.

SUPPORTIVE THERAPY AND MEDICAL MANAGEMENT

In clinical situations in which renal hypoperfusion and toxic insults are anticipated (such as cardiac surgery, administration of a contrast medium or amphotericin), therapy with fluids, mannitol, diuretics, and dopamine is frequently used to prevent or limit renal injury. Although whether use of these agents helps to prevent or limit renal injury is controversial, increasing urine output makes fluid management easier, aids in maintaining homeostasis of potassium and other electro-

lytes, and simplifies addressing the nutritional needs of the child. As described earlier, therapy with *N*-acetylcysteine has been shown to significantly decrease the rise in serum creatinine level after the intravascular administration of contrast medium (23). Once intrinsic renal failure has become established, management of the metabolic complications of acute renal failure continues to involve appropriate management of fluid balance, electrolyte status, acid-base balance, and nutrition. Additional renal injury from hypoperfusion or hypoxic-ischemic and nephrotoxic insults that could delay and complicate recovery should be prevented as much as possible.

Vasoactive Agents

The use of “renal-dose” dopamine (0.5 to 5.0 µg/kg/min) to improve renal perfusion after an ischemic insult has become very common in intensive care units. Although dopamine increases renal blood flow by promoting vasodilatation and may improve urine output by promoting natriuresis, there are no definitive studies to demonstrate that low-dose dopamine is effective in decreasing the need for dialysis or improving survival in patients with acute renal failure (118,119). In fact, a placebo-controlled, randomized study of low-dose dopamine therapy in adult patients demonstrated that low-dose dopamine was not beneficial and did not confer clinically significant protection from renal dysfunction (120). When the group receiving dopamine was compared with the placebo group, no difference was found in peak serum creatinine level, the number of patients whose creatinine level exceeded 300 µmol/L, the number of patients who received renal replacement therapy, the duration of intensive care unit stay, the number of hospital days required, or mortality (120). Other studies have demonstrated that renal-dose dopamine is not effective in the treatment of acute renal failure (121,122).

Fenoldopam mesylate is a selective dopamine 1 receptor agonist that has been approved for short-term use in severe hypertension (123). Studies in animals have shown that the effects of fenoldopam on renal hemodynamics may lead to improvement in renal perfusion and carry the potential to preserve renal function. The negative results of studies using low-dose dopamine along with the potential side effects of low- and high-dose dopamine and the nonselective stimulation of dopamine 1 and 2 receptors by dopamine has prompted interest in the use of fenoldopam in the management of acute renal failure. Intravenous fenoldopam increased renal perfusion, urine flow, and excretion of both sodium and potassium in hypoxemic adults (123). Randomized trials are important to determine if selective dopamine agonists are safe and efficacious in acute renal failure.

Anaritide, an atrial natriuretic peptide, increases the GFR by dilating afferent arterioles while constricting efferent arterioles and has been shown to improve GFR, urinary output, and histologic findings in animal models of acute

renal failure and in humans with acute renal failure (124). In a randomized clinical trial of anaritide treatment involving over 500 adults with acute renal failure, anaritide did not improve the overall rate of dialysis-free survival (125). However, survival may have been increased in oliguric patients receiving anaritide, whereas survival may have been worse in patients with nonoliguric acute renal failure receiving anaritide. It is hoped that future studies will delineate the clinical conditions under which anaritide may be indicated in the management of acute renal failure.

Diuretic Therapy

Stimulating urine output eases management of acute renal failure, but the conversion of oliguric to nonoliguric acute renal failure has not been shown to alter the course of the disorder (126,127). In theory, diuretic therapy has potential mechanisms to prevent, limit, or improve renal function. Mannitol (0.5 to 1.0 g/kg delivered over several minutes) may increase intratubular urine flow to limit tubular obstruction and may limit cell damage by preventing swelling or by acting as a scavenger of free radicals or reactive oxygen molecules. Furosemide (Lasix) (1 to 5 mg/kg/dose) also increases urine flow rate to decrease intratubular obstruction and inhibits Na⁺-K⁺-adenosine triphosphatase, which limits oxygen consumption in already damaged tubules with a low oxygen supply. In studies published many years ago, loop diuretic therapy did not alter the need for renal replacement therapy or mortality (127–129).

When mannitol is used in children with acute renal failure, a lack of response to therapy can precipitate congestive heart failure, particularly if the child's intravascular volume is expanded before mannitol infusion. In addition, lack of excretion of mannitol may result in substantial hyperosmolality. Similarly, administration of high doses of furosemide in renal failure has been associated with ototoxicity (127). When diuretic therapy is used in children with acute renal failure, potential risks and benefits need to be considered. When the child is unresponsive to therapy, continued administration of high doses of diuretics is not justified and is unlikely to be beneficial to the child. In patients who do respond to therapy, continuous infusions may be more effective and may be associated with less toxicity than bolus administration (128).

Fluid Balance

Depending on the cause of acute renal failure and the presence or absence of associated symptoms such as vomiting or diarrhea, children with acute renal failure may present with hypovolemia, euolemia, or fluid overload and pulmonary edema. Patients with salt-wasting renal or adrenal disease, diarrhea, or vomiting may present with fluid deficits that need correction to a euolemic state, whereas patients with oliguria or anuria more commonly present with hyper-

volemia and need fluid restriction and/or acute fluid removal to achieve a euvolemic state. Weight, blood pressure, heart rate, skin turgor, and capillary refill are each used to assess the intravascular volume. In children who are intravascularly volume depleted, 10 to 20 mL/kg of normal saline can be infused to reestablish intravascular volume. If urine output does not increase and azotemia does not improve after fluid resuscitation, then central venous pressure monitoring may be necessary to further guide fluid therapy. If the child presents with fluid overload, then fluid restriction and/or fluid removal with dialysis or hemofiltration may be instituted if the child does not respond to diuretic therapy.

Once normal intravascular volume has been reached, euvolemia can be maintained by providing the child with fluid to replace normal water losses from the skin, respiratory tract, and gastrointestinal tract (insensible losses, 400 mL/m²/24 hr). Excess stool losses such as may occur with diarrhea or excess skin and respiratory tract losses such as may occur with hyperthermia need to be accounted for as well and replaced with the appropriate fluid. Urine losses may also be replaced milliliter for milliliter with the appropriate fluid, which is usually determined by measuring urine electrolytes. Daily weight measurements, blood pressure, accurate fluid input and output records, physical examination, and nutritional needs of the child guide ongoing fluid therapy. Without supplemental enteral or intravenous nutrition, weight loss may be 0.5 to 1.0% of the body weight per day. Children in the diuretic phase of acute tubular necrosis may have substantial fluid and electrolyte losses that require replacement.

Electrolyte and Acid-Base Balance

Mild hyponatremia is very common in acute renal failure and may be due to hyponatremia dehydration, but fluid overload with dilutional hyponatremia is much more common. If the serum sodium level is higher than 120 mEq/L, fluid restriction or water removal by dialytic therapy corrects the serum sodium. However, if the serum sodium level is lower than 120 mEq/L, the child is at higher risk for seizures due to hyponatremia, and correction to a sodium level of approximately 125 mEq/L with hypertonic saline should be considered. The amount of sodium required can be calculated by the following formula:

$$(125 - P_{Na}) (Wt) (0.6) = \text{mEq Na} \quad [\text{Eq. 3}]$$

where P_{Na} is the current plasma sodium concentration, Wt is the weight in kilograms, and 0.6 is the fraction of the weight that is total body water. The required amount is usually infused over several hours to avoid rapid correction of the serum sodium level. Rapid correction of the serum sodium concentration in adults with chronic hyponatremia has been associated with neurologic injury, particularly central pontine myelinolysis, although the incidence of such injury in children is unknown (130). Restriction of free water further helps to correct hyponatremia.

Because the kidney tightly regulates potassium balance and excretes approximately 90% of dietary potassium intake, hyperkalemia is a common and potentially life-threatening electrolyte abnormality in acute renal failure. Hyperkalemia results from decreased filtration, impaired tubular secretion, altered distribution of potassium by acidosis, which shifts potassium from the intracellular to the extracellular compartment, and release of intracellular potassium due to the associated catabolic state. For each 0.1-unit reduction in arterial pH, the serum potassium level may increase by 0.3 mEq/L. The serum potassium level may be falsely elevated if the technique of the blood draw causes hemolysis or tissue destruction, or if the child has a high white blood cell or platelet count, which can falsely elevate the potassium level (131).

True hyperkalemia results in disturbances of cardiac rhythm by its depolarizing effect on the cardiac conduction pathways. The concentration of serum potassium that results in arrhythmia is dependent on the acid-base balance and the levels of other serum electrolytes. Hypocalcemia, which is common in renal failure, exacerbates the adverse effects of the serum potassium level on cardiac conduction pathways. Tall, peaked T waves are the first manifestation of cardiotoxicity, and prolongation of the PR interval, flattening of P waves, and widening of QRS complexes are later abnormalities. Severe hyperkalemia eventually leads to ventricular tachycardia and fibrillation. Symptoms of hyperkalemia include malaise, nausea, and progressive muscle weakness.

Treatment of hyperkalemia is indicated if cardiac conduction abnormalities are noted or if levels are higher than 6 to 7 mEq/L. Therapy for hyperkalemia is summarized in Table 64.4. Sodium bicarbonate (0.5 to 1.0 mEq/kg/dose) transfers potassium into cells, but, as described later, this therapy may precipitate seizures and tetany if the serum calcium level is low, which results in a decreased ionized calcium level. Intravenous administration of glucose and insulin also transfer potassium from the extracellular to the intracellular compartment (132). Intravenous administration of calcium gluconate increases the threshold potential of the excitable myocardial cells and counteracts the depolarizing effect of the hyperkalemia. Studies in adults have shown that the β -agonist albuterol, given via a nebulizer, can acutely lower the serum potassium level by stimulating intracellular uptake of potassium (133). Each of the aforementioned are temporizing measures and do not remove potassium from the body. Sodium polystyrene sulfonate (Kayexalate) given orally, by nasogastric tube, or by rectum exchanges sodium for potassium in the gastrointestinal tract and results in potassium removal (131,134). Complications of sodium polystyrene sulfonate therapy include possible hypernatremia, sodium retention, and constipation. In addition, sodium polystyrene sulfonate therapy has been associated with intestinal necrosis in adult patients after surgery (135). Depending on the degree of hyperkale-

TABLE 64.4. TREATMENT OF HYPERKALEMIA

Agent	Mechanism	Dose	Onset of effect	Complications
Sodium bicarbonate	Shifts K ⁺ into cells	1 mEq/kg IV over 10–30 min	15–30 min	Hypernatremia Change in ionized calcium level
Calcium gluconate (10%)	Stabilizes membrane potential	0.5–1.0 mL/kg IV over 5–15 min	Immediate	Bradycardia Arrhythmias Hypercalcemia
Glucose and insulin	Stimulates cellular uptake of K ⁺	Glucose 0.5 g/kg Insulin 0.1 U/kg IV over 30 min	30–120 min	Hypoglycemia
β-Agonists (albuterol) ^a	Stimulates cellular uptake of K ⁺	5–10 mg nebulizer (adult dose)	30 min	Tachycardia Hypertension
Sodium polystyrene sulfonate (Kayexalate)	Exchanges Na ⁺ for K ⁺ across colonic mucosa	1 g/kg PO or PR in sorbitol	30–60 min	Hypernatremia Constipation

^aLimited pediatric use.

mia and the need for correction of other metabolic derangements in acute renal failure, hyperkalemia frequently requires the initiation of dialysis or hemofiltration.

Because the kidney excretes net acids generated by diet and intermediary metabolism, acidosis is very common in acute renal failure. As long as the child's central nervous system is intact, respiratory compensation provides partial correction of the acidosis, but if the child is obtunded, respiratory compensation may be compromised, which results in severe acidosis. Severe acidosis can be treated with intravenous or oral sodium bicarbonate, oral sodium citrate solutions, and/or dialysis. When treatment of acidosis is contemplated, it is important to consider the serum ionized calcium level. Under normal circumstances, approximately one-half the total calcium is protein bound; half is free and in the ionized form, and this is what determines the transmembrane potential and electrochemical gradient. Hypocalcemia is common in acute renal failure and acidosis increases the fraction of total calcium in the ionized form. Treatment of acidosis can then shift the ionized calcium to the more normal ratio, decreasing the amount of ionized calcium and precipitating tetany and/or seizures. Thus, base therapy for acidosis should not be considered without knowledge of the total and ionized calcium levels. When base therapy is given, an amount of 0.5 to 1.0 mEq/kg administered over approximately 1 hour is reasonable. Administering sodium bicarbonate generates CO₂ and an intact respiratory system to excrete the excess generated CO₂ is required for bicarbonate therapy to be effective.

Calcium and Phosphate Balance

Because the kidney excretes a large amount of ingested phosphorus, hyperphosphatemia is a very common electrolyte abnormality during acute and chronic renal failure. Hyperphosphatemia should be treated with dietary phosphorus restriction and with oral calcium carbonate or other calcium compounds to bind phosphorus and prevent gastrointestinal absorption of phosphorus (136,137). Sevelamer hydrochloride has been shown to be an effective

non-calcium-containing phosphorus binder in chronic renal failure but has not been tested or used in acute renal failure (138). Because most patients with acute renal failure have hypocalcemia, use of calcium-containing phosphate binders provides a source of calcium as well as phosphate-binding capacity. Aluminum-containing compounds should be avoided, because several studies have demonstrated that oral administration of aluminum-containing phosphorus binders results in substantial aluminum absorption and leads to severe aluminum intoxication (139). Dialysis therapy also effectively removes phosphorus, but because phosphorus is a divalent cation, it will cross dialysis membranes less readily than uncharged molecules such as urea or monovalent anions such as potassium.

The cause of hypocalcemia in acute renal failure is multifactorial, and hypocalcemia may result from hyperphosphatemia, inadequate gastrointestinal calcium absorption due to inadequate 1,25-dihydroxyvitamin D production by the kidney, and skeletal resistance to the action of parathyroid hormone. As described earlier, acid-base balance has a profound effect on the ionized calcium level and the interpretation of the calcium level, and therapy must take into consideration the degree of acidosis. If hypocalcemia is severe and/or if bicarbonate therapy is necessary for hyperkalemia, treatment with 10% calcium gluconate (100 mg/kg up to a minimum of 1 g, or 1 mL/kg up to a maximum of 10 mL) should be given over 30 to 60 minutes with continuous electrocardiographic monitoring. Hypocalcemia may also be treated by oral administration of calcium carbonate or other calcium salts.

Medications

When medications are prescribed in acute renal failure, the mechanism of drug elimination and the metabolic pathway of the drug must be considered and adjustments made for renal failure. Many drug adjustment tables are based on the level of renal function (GFR greater than 50 mL/min/1.73 m², GFR of 20 to 50 mL/min/1.73 m², or GFR less than 20 mL/min/1.73 m²), and it is important to estimate the

child's level of renal function appropriately and to consider the rate of increase in the serum creatinine level rather than the absolute creatinine level. To prevent further insults to the kidney, it is best to avoid nephrotoxic drugs in acute renal failure; however, if potentially nephrotoxic drugs are needed, it is appropriate to use them while monitoring drug levels and potential adverse effects.

Hypertension

Hypertension in acute renal failure is commonly related to volume overload and/or to alterations in vascular tone. If hypertension is related to volume overload, appropriate fluid removal with dialysis or hemofiltration is necessary if the patient has not responded to diuretic therapy. Depending on the degree of blood pressure elevation and the cause of the hypertension, antihypertensive therapy may also be indicated. The choice of antihypertensive therapy depends on the degree of blood pressure elevation, the presence of central nervous system symptoms of hypertension, associated conditions, and the cause of the acute renal failure. For the child who has severe hypertension and/or is encephalopathic, intravenous therapy with sodium nitroprusside (beginning dose, 0.5 to 1.0 $\mu\text{g}/\text{kg}/\text{min}$) is indicated with monitoring of the serum levels of thiocyanate, a metabolic product of nitroprusside that is excreted by the kidney. Alternative therapies include intravenous labetalol (0.5 to 3.0 $\text{mg}/\text{kg}/\text{hr}$), diazoxide (1 to 5 $\text{mg}/\text{kg}/\text{dose}$), enalaprilat (0.005 to 0.01 $\text{mg}/\text{kg}/\text{day}$), and nifedipine (1 to 3 $\mu\text{g}/\text{kg}/\text{min}$) (140). Intravenous hydralazine or sublingual nifedipine can be used for less severe hypertension. Severe hypotension and tissue ischemia after sublingual administration of nifedipine, which has been observed in adult patients, is distinctly uncommon in pediatric patients (141). Once the blood pressure is controlled, treatment with oral long-acting agents can be initiated.

Nutritional Support

In many instances acute renal failure is associated with marked catabolism, and malnutrition can develop rapidly, leading to delayed recovery from acute renal failure. Prompt and proper nutrition is essential in the management of the child with acute renal failure. Although studies suggesting that proper nutritional support improves the outcome of acute renal failure in children have not been documented, it is reasonable to suppose that the complication rate is reduced and recovery is enhanced by adequate nutrition. If the gastrointestinal tract is intact and functional, enteral feedings with formula (PM60/40 for newborns and infants) should be instituted as soon as possible. In older children, a diet of high-biologic-value protein, low-phosphorus, and low-potassium foods can be used. Dilute formula should be given initially and then feedings can be increased and concentrated to achieve optimal caloric intake. Infants should receive maintenance calories (120 $\text{kCal}/\text{kg}/\text{day}$) and older children

appropriate maintenance calories or higher if needed due to the catabolic state and malnutrition. If enteral feedings are not possible, then hyperalimentation, usually through a central line, with a high concentration of dextrose (25%), lipids (10 to 20%), and protein (1.0 to 2.0 $\text{g}/\text{kg}/\text{day}$) should be instituted. If the child is oliguric or anuric and sufficient caloric intake cannot be achieved while appropriate fluid balance is maintained, dialysis should be initiated earlier than in the usual case.

Renal Replacement Therapy

The purpose of acute renal replacement therapy is to remove endogenous and exogenous toxins and to maintain fluid, electrolyte, and acid-base balance until renal function returns. Renal replacement therapy may be provided by peritoneal dialysis, intermittent hemodialysis, or continuous renal replacement therapy (CRRT) consisting of hemofiltration with or without a dialysis circuit. CRRT is discussed in detail in Chapter 65 and peritoneal and hemodialysis are discussed in Chapters 70 and 71. It is important to point out that renal replacement therapy for children with acute renal failure has evolved substantially over the past several years (142). The preferential use of CRRT by pediatric nephrologists is increasing, whereas the use of peritoneal dialysis is decreasing except in neonates and small infants (143–145). The choice of a dialytic membrane and daily dialysis in adults with acute renal failure has been shown to affect recovery of renal function and survival substantially (146,147). Although similar studies have not been performed in pediatric patients, these findings should be considered in treating the child with acute renal failure.

Therapy to Decrease Injury and Promote Recovery

Exciting advances in understanding of the cellular and molecular events that precipitate acute renal failure has allowed for the development of strategies to potentially decrease injury and/or promote recovery from acute renal failure. Recovery of renal function after acute tubular necrosis requires a complex and not fully understood set of events that leads to restoration of renal blood flow and regeneration of renal tubular epithelial cells (148). Interesting studies suggest that infusion of RGD peptides prevents renal tubular obstruction and accelerates improvement of renal function after an ischemic injury in an animal model of acute renal failure (149). In other animal studies of acute renal injury, postischemic infusion of growth factors, including insulin-like growth factor-1 (IGF-1), epidermal growth factor, and hepatocyte growth factor, resulted in an accelerated recovery of renal function, less severe histologic alterations, and decreased mortality (150–152). Similar results were seen in nephrotoxic acute renal failure (153). In animal models, administration of melatonin-stimulating hormone, thyrox-

ine, C5a receptor antagonist, selective inhibitors of inducible nitric oxide synthase, statins, and a novel inhibitor of the Na⁺/H⁺ exchange subtype 3, as well as inhibition of monocyte chemoattractant protein-1 by gene therapy, has been shown to ameliorate acute renal failure (154–161).

Although multiple interventions decrease the severity of acute renal failure and promote recovery in animal models, results of interventional studies in patients with acute renal failure have been disappointing. In a study comparing use of IGF-1 and placebo in adults with acute renal failure, IGF-1 therapy did not accelerate the recovery of renal function and was not associated with differences in dialysis needs or in mortality (162). Thyroxine therapy in adult patients with acute renal failure did not improve scores on a measure of the severity of acute renal failure and was associated with a substantially higher mortality in treated patients due to prolonged suppression of thyroid-stimulating hormone (163). As described earlier, randomized, placebo-controlled trials demonstrated that administration of renal-dose dopamine and atrial natriuretic peptide was ineffective in treating acute renal failure (120,125).

In children in the intensive care unit, the systemic inflammatory response is thought to contribute to renal failure and multiorgan failure by activation of the inflammatory cascade with the participation of cytokines, reactive oxygen species, proteolytic enzymes, and adhesion molecules. Ischemic injury stimulates the activation of neutrophils and the expression of adhesion molecules with resultant tissue injury. Activated neutrophils generate reactive oxygen molecules, including superoxide anion, hydrogen peroxide, hydroxyl radical hypochlorous acid, and peroxynitrate. In addition, activated neutrophils release proteolytic enzymes that can result in substantial tissue injury (62,164,165). Melatonin-stimulating factor has an antiinflammatory activity and has been shown to inhibit ischemic reperfusion injury in mice and rats, even when infused 6 hours after the insult (154). In studies of hypoxic-ischemic acute renal failure in the rat, scavengers of oxidants and free radicals have been shown to decrease renal injury (62,165,166). Infusion of the membrane-permeable scavenger of reactive oxygen molecules resulted in significantly reduced BUN level, creatinine level, and kidney myeloperoxidase activity, and decreased lipid peroxidation in rats undergoing bilateral clamping of the renal pedicle (166). Other studies demonstrate that anti-adhesion molecule therapy markedly decreases ischemic renal injury by preventing adhesion of activated neutrophils to renal cells (167). Potential future therapy to interfere with the inflammatory cascade might modify the severity and/or duration of acute renal failure.

OUTCOME AND PROGNOSIS

The prognosis and recovery of the child with acute renal failure are highly dependent on the underlying cause (31–37).

Children who have acute renal failure as a component of multisystem failure have a much higher mortality rate than children with intrinsic renal disease such as HUS, rapidly progressive glomerulonephritis, or acute interstitial nephritis. Factors that are associated with mortality include multiorgan failure, hypotension, need for pressors, hemodynamic instability, and need for mechanical ventilation and dialysis (35–37,168–171). The cause of mortality is nearly always related to associated conditions and not to the renal failure per se. Although the inhospital mortality of patients with acute renal failure is high, studies involving adults have shown that patients who recover from renal failure have a reasonable survival rate and a good quality of life (172). Other factors that affect recovery of renal function and mortality (discussed in detail in the next chapter) include the mode of renal replacement therapy, the type of membrane used in hemodialysis, the use of daily versus alternate-day dialysis, and the dose of dialysis or hemofiltration (146,147,173–175).

Recovery of renal function is also highly dependent on the underlying cause of the acute renal failure. Children with acute interstitial nephritis and acute tubular necrosis typically recover normal renal function and are at low risk for any late complications. In animal models of acute tubular necrosis, however, recovery after a severe ischemic insult resulted in alteration in urinary concentrating ability, diminished capacity to generate a hypertonic medullary interstitium, and tubulointerstitial fibrosis (176). Children who may have suffered substantial loss of nephrons such as may occur in HUS or rapidly progressive glomerulonephritis are at risk for late development of renal failure long after the initial insult. Several studies in animal models and some studies in adults have documented that hyperfiltration of the remnant nephron may eventually lead to progressive glomerulosclerosis of the remaining nephrons (177). Thus, children who have experienced cortical necrosis during the neonatal period and have recovered renal function or children who have experienced an episode of severe Henoch-Schönlein purpura or HUS are clearly at risk for the late development of renal complications. Such children need life-long renal function monitoring, blood pressure monitoring, and urinalysis. Typically, the late development of chronic renal failure first becomes apparent with the appearance of hypertension, proteinuria, and eventually elevated BUN and creatinine levels.

MANAGEMENT OF ACUTE RENAL FAILURE

MARK R. BENFIELD
TIMOTHY E. BUNCHMAN

Acute renal failure (ARF) represents a sudden reduction in kidney function to a level insufficient to adequately filter and excrete solute and water and maintain fluid and electrolyte balance. In spite of many years of clinical recognition, intervention, and research, a precise definition of ARF remains elusive, and commonly used definitions, including oliguria and azotemia, have shortcomings in pediatric practice. Although oliguria is often a presenting finding, this is not invariable, and urine output is a poor indicator of kidney function. ARF is often asymptomatic and noted only on routine screening laboratory evaluation as elevated blood urea nitrogen (BUN) and creatinine (Cr) levels. BUN and Cr are also insensitive markers of kidney function, however. Glomerular filtration rate (GFR) may fall by as much as 50% before serum Cr begins to rise, whereas a large rise in serum Cr may reflect only a small change in GFR in infants and patients with chronic renal insufficiency (1,2). These inaccuracies are further exaggerated in patients with reduced muscle mass, decreased protein intake, or underlying renal anomalies. Early recognition of ARF is important, however, to appropriately treat hypoperfusion, remove nephrotoxic agents or other factors contributing to ARF, and appropriately adjust fluids, electrolytes, and medications (3).

Kidney function is dependent on the adequacy of blood supply to the kidney, the integrity of the renal parenchyma, and the patency of the urinary tract (4). Because of this, the well-established approach to the classification of AFR as prerenal, renal, or postrenal continues to be useful and is employed in this chapter. Although few studies are available to determine the incidence of ARF in pediatric patients, most large studies of adults report the cause of ARF to be prerenal azotemia in 55 to 60% of cases, intrinsic renal parenchymal disease in 35 to 40% [90% of which cases are acute tubular necrosis (ATN)], and secondary to postrenal obstructive disease in fewer than 5% (5). Smaller pediatric studies have similarly demonstrated that hypoxia- and ischemia-induced renal injury is an important cause of ARF in children (6–8).

In developing countries, volume depletion from diarrhea continues to be the most common cause of ARF (9,10). In industrialized countries, however, ARF is more often seen in hospitalized patients with complex conditions who frequently have preexisting kidney disease. ARF is a particularly common complication in critically ill children in intensive care units (ICUs). In the neonatal ICU 3 to 24% of all admissions and as many as 60% of infants with severe asphyxia develop ARF (8,11–13). In adult studies, ARF complicates 5% of hospital admissions and 30% of ICU admissions (14).

In these patients, the causes of ARF are almost always multifactorial, related to underlying diseases and required therapies. Many of these patients have multiple renal insults, none of which alone would be expected to cause ARF. A detailed discussion of the clinical aspects of ARF is found in Chapter 64. This chapter describes in detail the management of ARF, especially in the ICU setting. The following section describes circumstances in which decisions concerning treatment must be made.

CATEGORIES OF ACUTE RENAL FAILURE

Prerenal Causes

Prerenal azotemia is the most common cause of ARF and represents an appropriate physiologic response to renal hypoperfusion (15). During early or mild hypoperfusion states a series of neural and humoral responses are active to maintain renal perfusion and GFR, including increased adrenergic activity, stimulation of the renin-angiotensin-aldosterone system, and the release of antidiuretic hormone. The adrenergic nerves cause diffuse vasoconstriction maintaining systemic blood pressure. However, this leads to increased renal vascular resistance and decreased glomerular blood flow. In response to hypovolemia and hypoperfusion, the renin-angiotensin system is stimulated, which causes increased production of angiotensin II. This has a direct

TABLE 65.1. PATHOGENESIS OF ACUTE RENAL FAILURE: PRERENAL CAUSES

Hypovolemia	
Gastrointestinal losses	Vomiting Diarrhea Nasogastric drainage
Renal losses	Salt-wasting nephropathy Diabetes insipidus Adrenal insufficiency Diuresis (drug induced or osmotic)
Blood losses	Surgery Trauma Gastrointestinal bleeding Pancreatitis
Insensible losses	Hyperthermia Burns
Redistribution	Sepsis Nephrotic syndrome Heart failure Liver failure Third-space sequestration

effect on the proximal tubule and, through aldosterone, on the distal tubule, causing reabsorption of salt and water. Furthermore, angiotensin II preferentially increases glomerular efferent arteriolar constriction, which increases the glomerular filtration pressure (15–17). These vasoconstrictive factors are counterbalanced by increased production of prostaglandins and nitric oxide, which stimulate afferent arteriolar vasodilatation (18–20). Cumulatively, these changes may cause an increased filtration fraction and maintain GFR. As the hypoperfusion state worsens, however, these compensatory mechanisms are overwhelmed, which leads to excessive vasoconstriction, decreased glomerular blood flow, and decreased GFR (15,21).

Overall, 60% of cases of ARF are prerenal, usually due to excessive fluid losses from trauma and bleeding or losses from the gastrointestinal system, kidneys, or skin (22,23). Prerenal ARF can complicate any disease process associated with hypovolemia and decreased renal perfusion (Table 65.1). Many of these cases are obvious on initial evaluation and involve overt loss of volume such as through vomiting and diarrhea, or blood loss through surgery or trauma. Other disease states, however, result in reduced effective vascular volume without overt volume loss. These situations include excessive insensible volume loss during hyperthermia or with severe burns, and gastrointestinal losses, as well as redistribution of volume such as seen with sepsis, nephrotic syndrome, heart failure, liver failure, or third-space sequestration.

Infants are particularly susceptible to excessive volume loss. The immature kidney is unable to develop maximally concentrated urine and adequately conserve salt and water, which makes infants particularly vulnerable to dehydration. Furthermore, neonates have a relatively large body surface area compared to body mass, and insensible water loss through the skin during febrile illnesses, while under radi-

ant warmers, and during bilirubin phototherapy can be excessive (24).

Renal losses of salt and water leading to prerenal azotemia are often difficult to recognize. Many of these children have underlying abnormalities causing polyuria, which makes urine output an insensitive tool in assessing kidney function. They also frequently have chronically reduced kidney function, which makes BUN and Cr less useful as diagnostic tools. This form of nonoliguric ARF can be seen in diseases with renal concentrating defects (cystic dysplasia, polycystic kidney diseases, diabetes insipidus) or those with large osmotic loads (hyperglycemia). In many of these illnesses, other laboratory findings of volume contraction, including weight loss, increased BUN, hypernatremia, and increased hematocrit, are clues to the excessive loss of free water (15,25).

In diseases with redistribution of volume, patients often have signs and symptoms of total body volume overload. Because of excessive third-space fluid loss or vasodilatation, however, the effective intravascular volume and renal perfusion are inadequate. In these situations it is important to maintain a high index of suspicion and search carefully for signs and symptoms suggestive of volume contraction and the physiologic responses to inadequate vascular volume. In most cases of prerenal azotemia, careful correction and maintenance of intravascular fluid and perfusion can prevent progression and more profound ARF (ATN).

Renal Causes

When renal causes of ARF are considered, it is useful to classify diseases according to the location of renal injury: vascular, glomerular, tubular, or interstitial (Table 65.2). Large clinical epidemiologic studies involving adults demonstrate that approximately 50% of ARF is due to ischemic ATN, 35% to nephrotoxic injury, and 15% to acute interstitial nephritis or acute glomerulonephritis (14,26–29).

TABLE 65.2. PATHOGENESIS OF ACUTE RENAL FAILURE: RENAL CAUSES

Arterial	Thrombosis Arteritis Hemolytic uremic syndrome Malignant hypertension
Venous	Renal venous thrombosis
Glomerular	Acute glomerulonephritis
Tubular	
Acute tubular necrosis	Ischemia Nephrotoxicity Pigment nephropathy
Obstructive	Crystal nephropathy
Interstitial	Acute interstitial nephritis Pyelonephritis
Congenital anomalies	Hypoplasia and dysplasia Polycystic kidney disease
All	Tumor lysis syndrome

The causes of intrinsic renal ARF in pediatrics vary significantly by age. In infancy the most common causes of ARF include (a) hypoxic-ischemic insults secondary to severe gastroenteritis and dehydration, perinatal asphyxia, respiratory distress syndrome, sepsis, necrotizing enterocolitis, and congenital heart disease (8,11,30); (b) nephrotoxic insults from antibiotics (aminoglycosides), antifungal agents (amphotericin B), nonsteroidal antiinflammatory agents given for patent ductus arteriosus, and maternal ingestion of angiotensin-converting enzyme inhibitors; (c) renal vascular obstruction secondary to renal artery and venous thrombosis; and (d) congenital renal anomalies, including obstructive uropathies (posterior urethral valves, bilateral ureteropelvic junction obstruction, ureterocele), hypoplasia and dysplasia syndromes, and autosomal recessive polycystic kidney disease. In the school-aged child glomerular diseases, especially postinfectious glomerulonephritis, and hemolytic uremic syndrome are the most common causes. Finally, trauma and rapidly progressive glomerulonephritis are the most common causes of ARF in adolescent patients.

Vascular

Arterial obstruction is seen almost exclusively during the neonatal period and is most often due to thromboembolic events secondary to the use of umbilical artery catheters. Thromboembolism from umbilical artery catheters most often leads to hypertension; however, with a solitary kidney or massive thromboemboli, ARF can occur (3,31,32). More commonly sepsis, perinatal asphyxia, hypovolemia, shock, maternal diabetes, or polycythemia leads to renal venous thrombosis (RVT) (3,33–37). Outside of the neonatal period RVT is also seen in children with severe dehydration or with hypercoagulable states associated with nephrotic syndrome, systemic lupus erythematosus, antiphospholipid syndrome, and congenital deficiencies in proteins of the coagulation cascade, including protein C, protein S, antithrombin III, plasminogen, factor V Leiden mutation, prothrombin variant, methylenetetrahydrofolate reductase variant, and increased lipoprotein(a) (14,38–43). RVT typically presents with enlarged kidneys, gross hematuria, thrombocytopenia, hypertension, decreased urine output, and increasing BUN and Cr levels (3,44,45). Anatomicallly, venous thrombosis usually involves the entire venous system, and thrombectomy is rarely indicated or possible. Controversy exists as to the usefulness of anticoagulation or thrombolytic therapy. Multiple single-center reports describe the use of heparin, streptokinase, urokinase, and tissue plasminogen activator (34,36,46–48). Although some reports suggest recovery of renal function, others have noted significant incidence of bleeding complications and significant renal atrophy on long-term follow-up (46). Clearly, different approaches would be used and different outcomes expected for patients with RVT secondary to congenital

absence of coagulation factors and for those with severely altered blood flow secondary to sepsis and shock. Nevertheless, recovery has been reported and is likely because of patchy venous thrombosis and/or associated ATN. It is certainly possible that anticoagulation may prevent progression of existing thrombosis to uninvolved parenchyma or to the contralateral kidney; however, carefully controlled multicenter studies are needed to answer these questions.

Other diseases lead to direct injury of renal vasculature that leads to ischemia-hypoxia and ARF. Hemolytic uremic syndrome is a largely reversible disorder usually initiated by verotoxin-producing organisms (especially *Escherichia coli* O157:H7) causing endothelial damage, hemorrhagic colitis, microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. The care for hemolytic uremic syndrome continues to be supportive and frequently involves early dialysis to prevent fluid and electrolyte imbalance and allow transfusions of red blood cells and adequate nutritional support.

Malignant hypertension is a clinical diagnosis defined as severely elevated blood pressure with signs or symptoms of acute target organ damage (central nervous, cardiovascular, renal systems) (49). The primary pathophysiology involves blood pressure elevation beyond the level at which local autoregulation can control blood flow to tissues. This is usually associated with frank inflammation, arteritis, and ischemia, and in the case of the kidneys has been described to cause ARF. These patients often present with hematuria and worsening kidney function. In cases of ARF, recovery of renal function is quite variable and may take a prolonged period of time (49–56).

Glomerular

Acute glomerulonephritis as a cause of ARF is seldom subtle. These patients often have findings that include edema, hypertension, and active urinary sediment which help guide the diagnosis to this category. Acute glomerulonephritis is rare in infants and toddlers. In school-aged children, postinfectious glomerulonephritis continues to be the most common acute glomerulonephritis and is often associated with mild to moderate ARF. However, almost any of the glomerulonephritides of childhood can present with a rapidly progressive course and ARF. Patients with ARF secondary to acute glomerulonephritis require prompt evaluation, and diagnosis with renal biopsy is important to guide definitive therapies.

Tubular

Although prerenal azotemia and ischemic ATN are discussed as separate entities, they represent a spectrum of disease, and all of the diseases in Table 65.1 can be associated with either prerenal azotemia or ischemic ATN. In each of the diseases described earlier, unless renal perfusion is restored or nephrotoxic agents withdrawn, prerenal azotemia often progresses to

the intrinsic renal disease of ischemic-nephrotoxic ATN. Nephrotoxic agents are important causes of ARF. The number of nephrotoxins is large, and the mechanisms by which they contribute to ARF are diverse (Table 65.3) (57-59).

Pigment nephropathy is caused by the sudden release of large quantities of heme proteins, especially hemoglobin from breakdown of red blood cells and myoglobin from breakdown of muscle cells, into the blood (60-62). Pigment nephropathies are seen clinically in the setting of

rhabdomyolysis secondary to trauma, crush injury, heat stroke, sepsis, or underlying myopathy and during episodes of rapid hemolysis.

Although hemoglobin and myoglobin are not toxic, the heme proteins associated with their breakdown have multiple toxicities. The renal damage caused by pigment nephropathy has three distinct mechanisms: (a) renal vasoconstriction, (b) direct heme protein-induced tubular cell toxicity, and (c) intraluminal cast formation. Renal vasoconstriction is likely the prominent mechanism, and the reduced renal blood flow and urine production accentuate the other mechanisms of injury. Rhabdomyolysis is invariably associated with rapid movement of fluid from the vascular space into injured muscles, which causes severe contraction of the extracellular fluid volume. Without aggressive volume resuscitation, this causes ischemic ATN. The heme proteins are rapidly filtered in the glomerulus, and in the renal tubule produce reactive oxygen metabolites that are directly toxic to the tubules and are scavengers of nitrous oxide, which causes unopposed renal medullary vasoconstriction (60,63-66). In an acidic environment myoglobin and hemoglobin also dissociate to ferriheme, which is directly toxic to the renal tubule. Finally, tubular pigment can precipitate, which causes tubular obstruction (63,67). This precipitation of heme proteins is also enhanced in an acid environment (60,68,69).

Pigment nephropathy is usually diagnosed by noting obvious precipitating events in the history and by urine that gives positive dipstick results for hemoglobin but has minimal cellular elements on microscopic examination. Confirmatory tests include evaluation of serum creatine phosphokinase levels. Treatment includes expansion of the vascular volume to assure adequate renal blood flow, forced diuresis and alkalinization of urine to reduce the production of reactive oxygen metabolites and ferriheme, and maximization of urine flow to reduce the precipitation of heme proteins.

In contrast-induced nephropathy, ARF is produced predominantly by acute vasoconstriction and ATN (70,71) and is best minimized by assuring adequate hydration before exposure. The use of newer nonionic contrast materials and alternate imaging techniques (e.g., magnetic resonance imaging) and contrast materials has not reduced the incidence of contrast-induced nephropathy (26,72-74).

Other causes of intrinsic renal disease leading to ARF include direct toxicities of drugs and other substances. These include aminoglycoside antibiotics, cisplatin, cyclosporine, tacrolimus, mannitol, amphotericin B, methotrexate, foscarnet, pentamidine, organic solvents, heavy metals, cocaine, intravenous immunoglobulin, and radiocontrast agents. Amphotericin B has been clearly described as causing distal tubular damage leading to decreased urinary concentrating capacity, distal renal tubular acidosis, potassium wasting, and magnesium wasting. Amphotericin B nephrotoxicity can best be minimized by assuring adequate hydration and renal perfusion. Liposomal preparations of amphotericin B have been associated with less nephrotoxicity.

Interstitial Disease

A long list of medications has been associated with acute interstitial nephritis. Many of these are considered to be very safe and are in broad usage. Acute interstitial nephritis is discussed in detail elsewhere. Although these drugs are often associated with peripheral and urinary eosinophilia, a high index of suspicion is necessary to accurately diagnose this disorder.

Postrenal Causes

Obstructive uropathy is one of the most common causes of renal failure in pediatrics. Obstruction of the urinary tract is an uncommon cause of ARF. However, patients with chronic obstructive uropathies and urinary concentrating defects are at significantly increased risk of renal failure associated with prerenal hypoxic-ischemic insults and nephrotoxic agents. Proper diagnosis of urinary obstruction is obviously necessary to provide appropriate treatment.

ASSESSMENT OF THE PATIENT WITH ACUTE RENAL FAILURE

In most patients with ARF, the causes of renal disease are evident from the history and physical examination. Historical findings of surgery or trauma associated with large blood loss, sepsis or other cause of unstable blood pressure and generalized hypoperfusion, excessive vomiting and diarrhea, burns, and so on, would quickly suggest a renal hypoperfusion state and either prerenal azotemia or ischemic ATN. In the hospitalized patient this is further enhanced by review of hospital records for serially determined fluid balance, weight, and urine output to assess volume status as well as for drug exposures and other procedures or interventions that may contribute to azotemia. ARF often has a multifactorial cause, however. In many patients, no single instigating event can be identified; a

combination of chronic disease, relative hypoperfusion, and nephrotoxic medications cause decreased kidney function.

The physical examination also gives many clues to the cause of ARF. Findings suggestive of hypovolemia, including tachycardia, orthostatic blood pressure changes, dry mucous membranes, and decreased skin turgor, would support the diagnosis of prerenal azotemia. Patients with nephrotic syndrome, heart failure, liver failure, and other diseases with decreased effective intravascular volume often have obvious physical findings of the primary organ dysfunction. On the other hand, patients with inflammatory diseases of the kidney have evidence for volume overload, including edema and hypertension.

Prerenal ARF is often associated with oliguria, elevated BUN and Cr levels, and other metabolic derangements. By definition, however, renal parenchymal integrity is maintained, and recovery is complete when perfusion is restored. The diagnosis of prerenal ARF is made by identifying the normal systemic responses to hypovolemia and the normal renal tubular responses to hypoperfusion. These include history and physical examination findings of volume contraction, including increased thirst, dry mucous membranes, decreased skin turgor, and tachycardia. The normal renal tubular response to hypoperfusion is seen with decreased urine flow, increased urinary concentration, and decreased urinary excretion of sodium. Several urine tests have been developed to help demonstrate these tubular responses (Table 65.4).

Although evaluation of BUN and Cr is important in making the diagnosis of ARF, and electrolyte analysis is helpful in determining complications related to ARF, urinary sediment and indices are perhaps the most important factors in determining the cause of ARF. Urine specific gravity begins to give clues related to effective vascular volume and renal blood flow. Significant hematuria and proteinuria are suggestive of a glomerulonephritis. Urine dipstick test results positive for blood with no cells on

TABLE 65.4. LABORATORY EVALUATIONS OF ACUTE RENAL FAILURE

Test	Prerenal	Intrinsic renal	Postrenal
BUN/Cr ratio	>20	10–20	10–20
Urine specific gravity	>1.020	~1.010	<1.010
Urine osmolality	>350	~300	~300

^aFalse low FE_{Na} seen with acute GN, radiocontrast-induced nephropathy, rhabdomyolysis.
 From Albricht RC Jr. Acute renal failure: a practical update. *Mayo Clin Proc* 2001;76:67–74, with permission.

microscopic examination of the urine is highly suggestive of myoglobin or hemoglobin in the urine and pigment nephropathy. Urine indices are designed to assess renal tubular function and are useful in differentiating prerenal from intrinsic renal causes of ARF (75,76). A particularly useful test is the fractional excretion of sodium (FE_{Na}):

$$FE_{Na} = (P_{Na}/U_{Na})/(P_{Cr}/U_{Cr})$$

where P_{Na} and P_{Cr} are the plasma levels of sodium and creatinine, and U_{Na} and U_{Cr} are the urine levels of sodium and creatinine, respectively.

Multiple studies have demonstrated that an FE_{Na} of less than 1% is seen with prerenal azotemia and a value higher than 2% is seen in intrinsic renal causes of ARF. However, it is important to note that several causes of intrinsic renal ARF are associated with a falsely low FE_{Na} , including some acute glomerulonephritides, contrast-induced nephropathy, and rhabdomyolysis. Also the FE_{Na} is difficult to interpret in the presence of medications that alter Na reabsorption, such as diuretics.

TREATMENT OF THE PATIENT WITH ACUTE RENAL FAILURE

Nondialytic Therapy

Although dialysis remains the only proven complete treatment for ARF, many other treatment regimens have been used to prevent or treat ARF. Many clinical trials of pharmaceutical agents have been conducted, but none of these has demonstrated convincing results. To date the only effective nondialytic treatment of ARF entails restoration of adequate renal blood flow, avoidance of nephrotoxic medications or those that interfere with renal compensatory mechanisms, and assurance that renal perfusion has been maximized before exposure to nephrotoxic agents.

A long-followed medical approach to management of patients at risk for ARF has been the use of "renal-dose dopamine" (1 to 3 μ g/kg/min). Although this approach has been associated with increased urine output, the effect is short lived (1 to 3 days), and existing data demonstrate no effect on survival or delay in the need for dialysis (6,26,77–82).

Similarly, diuretics have also been used in patients with oliguric ARF. Diuretics occasionally improve urine flow and thus may provide enough urine output to allow medications and nutrition to be provided safely. Furthermore, the increased urine flow may decrease the concentration of toxins such as myoglobin or hemoglobin in the renal tubules. The increased urine flow does not reflect improved GFR, however, and has not been demonstrated to prevent or ameliorate ATN (26,83–87). In fact, diuresis may worsen ARF in prerenal azotemia and radiocontrast-induced ARF, as well as ARF after cardiac surgery (26,88,89).

Mannitol is an osmotic diuretic that has also been used to treat a variety of diseases with high risk of ARF (26,90).

Although mannitol may be beneficial in organ preservation solutions and when given extremely early after a crush injury to produce diuresis, it has not been shown to be useful in prevention or treatment of ARF.

Hyperkalemia is a common life-threatening complication of ARF. Until removal of potassium is possible, other methods are often needed to shift potassium from the intravascular to intracellular space. Infusions of calcium (10 mg/kg elemental calcium as calcium chloride or calcium gluconate) have been demonstrated to stabilize cell membranes and decrease the risk of cardiac arrhythmias but do not change the serum potassium concentration. Intravenous glucose and insulin (0.25 U regular insulin per gram of glucose) have been demonstrated to cause a shift of potassium from the extracellular to the intracellular space. The β -agonists have also been demonstrated to lower serum potassium acutely and can be administered by inhalation in situations in which intravenous access is not available (91,92). Enteric exchange resins (sodium polystyrene sulfonate, or Kayexalate, 1 g/kg body weight, repeated up to hourly) effectively remove potassium from the body. However, this removal may be slow and inconsistent, and administration may be difficult, especially if multiple treatments are necessary. Although parenteral bicarbonate therapy (1 mEq/kg body weight) has been widely used to alkalinize the blood and drive intracellular shifting of potassium, multiple studies have demonstrated that bicarbonate therapy has little to no effect on potassium levels in the long term (93).

Acidosis related to enhanced metabolic rate and inflammation frequently occurs in ARF and complicates its management. In this setting, removal of the acid load can be accomplished only by some method of dialysis. Buffering by administration of an oral or parenteral bicarbonate may provide temporary improvement, but its use is often limited because of the concomitant provision of sodium.

Other solutes such as sodium phosphorus or uric acid accumulate in the blood of patients with ARF. Attention should be paid to avoiding the compounding of those abnormalities in the conservative management of ARF. If the concentrations of these substances reach critical levels, treatment by some form of dialysis is indicated.

Adequate nutrition is a critically important component of the treatment of ARF, especially in the ICU setting. Provision of nutrition may be very difficult when oliguria is present. Nutrition should not be compromised, however, and the need for its provision may itself be an indication for initiation of dialysis.

Dialytic Therapy

Because of the complex metabolic abnormalities associated with ARF, dialysis is often the treatment of choice to quickly restore fluid and electrolyte balance. There are currently three dialysis modalities in common use for ARF: peritoneal dialy-

sis (PD), hemodialysis (HD), and continuous renal replacement therapy (CRRT). The choice of dialysis modality is best made in keeping with the local standard of care and is based on a number of considerations (94). The first consideration is experience with the modality. It would be inappropriate to introduce a new or unfamiliar form of dialysis therapy during the care of an acutely ill patient with a complex condition. The second consideration is access. If the peritoneal membrane is disrupted or scarred, PD is impossible. If sufficient vascular access cannot be attained, HD cannot be attempted. The third consideration is hemodynamic stability of the patient. Patients who are hemodynamically unstable often will not tolerate the rapid fluid shifts associated with intermittent HD as opposed to more continuous modalities such as PD or CRRT. The fourth consideration is the goal of the dialysis. When the goal is fluid removal, any of these modalities works effectively. When solute clearance is critical, however, HD is the most efficient method and is often preferred over other modalities to obtain the maximum solute clearance in the least amount of time (95). Optimum care of the child with ARF is best achieved by assuring access to multiple forms of treatment.

Other chapters in this book describe the technical details of PD and HD, and their application in the child with ARF is very similar to their use in children with end-stage renal disease. This chapter focuses on CRRT as a treatment for ARF in the ICU.

Types of Continuous Renal Replacement Therapy

CRRT is a term coined to describe a continuous mode of dialysis at the bedside. Historically this included PD or hemofiltration (HF), but now the term is used almost interchangeably with HF. Continuous HF can be accomplished via either arteriovenous or venovenous access. The major difference between the two is that arteriovenous HF uses an arterial access and arterial blood pressure to pump blood through the circuit, whereas venovenous HF uses a pump to circulate blood through the extracorporeal system. Studies have shown that arteriovenous HF is associated with inadequate solute clearance, more serious vascular complications, and a more frequent need to change to other modalities compared with venovenous HF (96). As a result, arteriovenous HF has largely fallen from use. Therefore the major focus of this discussion is on venovenous HF.

Venovenous HF can be accomplished by three methods. These include continuous venovenous HF (CVVH), CVVH with dialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). The major difference between CVVH and CVVHDF is that convective solute removal is used in CVVH whereas solute is removed by diffusion in CVVHDF.

Continuous Venovenous Hemofiltration

CVVH combines ultrafiltration with convective clearance. An ultrafiltrate of blood passes through a membrane and is

replaced with either a prefilter or a postfilter sterile infusion of an isotonic solution. Based on the principles of convective clearance, solute is removed in the ultrafiltrate and replaced with a solution free of this solute. Over time the remaining solute is diluted. Both small and mid-sized molecules are convectively cleared based on their concentration in the blood, the rate of ultrafiltration, and the molecule's sieving coefficient. The sieving coefficient is related to the molecular weight, the charge of the HF membrane, and the protein binding of the solute. Convection is effective but is not as efficient as diffusion.

Continuous Venovenous Hemofiltration with Dialysis

CVVHD is achieved by perfusing the space on the opposite side of the membrane from the patient's blood with a dialysate solution. As with HD, this permits diffusion of solutes across the membrane driven by a concentration gradient. The components of the dialysate must be physiologic. The transfer of solute across the membrane is again related to the sieving coefficient of the solute as well as the charge and pH of the membrane and the concentration gradient across the membrane. Low-molecular-weight compounds have a sieving coefficient approaching 1.0, and transfer is similar with convective or diffusive clearance. For compounds of middle and higher molecular weight, the sieving coefficient becomes less than 1.0, and better transfer is achieved by convective therapies. Work by Maxvold et al. has compared the mass transfer of urea in CVVH to that in CVVHD (97). In the former, clearance is related to the ultrafiltration rate, whereas in the latter, the dialysate flow rate is generally rate limiting.

Continuous Venovenous Hemodiafiltration

CVVHDF methods include a combination of both convective and diffusive solute removal. During CVVHDF, prefilter or postfilter infusion of replacement fluid is combined with high ultrafiltration rates to achieve convection, and a dialysis fluid is used to achieve diffusion. This combination of diffusive and convective clearance may improve clearance over that using either method alone. However, the data have not shown a practical increase in solute clearance sufficient to compensate for the increased complexity of the procedure.

Ultrafiltration

Ultrafiltration in a setting of CRRT is based on the concept of net fluid removal. As opposed to PD, in which ultrafiltration is controlled by osmolar fluid shifts, the ultrafiltration in CRRT is achieved by a transmembrane pressure. Ultrafiltration can be increased either by increasing the venous return pressure or by creating a higher vacuum ("negative pressure") across the membrane on the ultrafiltrate side. The newer generation of CRRT devices controls ultrafiltration by computer software and is accurate to 1 to 2%.

Equipment

Historically, in the late 1980s and early 1990s all equipment related to HF was adapted from previously existing blood pumps, intravenous pumps, and/or HD machines. Adapted devices were easy to use at the bedside but lacked technical safeguards such as air leak detectors, blood warmers, and ultrafiltration controllers. These adapted devices allowed for the early provision of CRRT at the bedside but also increased the work of the nursing staff and also increased the potential for errors associated with temperature control and ultrafiltration (98,99).

Newer equipment has taken the historical benefits of adapted devices at bedside and added a warming device for replacement or dialysate fluid, very accurate ultrafiltration control devices, and appropriate failure detectors. These additional three components have made CRRT much safer. These devices incorporate computer modules that allow for continuous readout of several parameters. In North America, these modern devices include the B. Braun Diapact System, the Gambro Prisma system, the Aquarius system (Edwards LifeScience, Missisagua, Ontario), and the Baxter BM-25 and, in the near future, Accura systems (Baxter, McGaw Park, IL); also available is the CRRT option for the model 2008H and 2008K HD machines by Fresenius. Outside North America, HF machines include the Hygieia Plus (Kimal, Middlesex, UK), EQUASmart (Medica, Medolla, Italy), and Rand Performer (Italy). All of these devices provide variable blood flow rates from 10 to 300 mL/min, variable dialysate flow rates from 0 to 3 L/hr, variable replacement flow rates from 0 to 5 L/hr, variable ultrafiltration rates including accurate ultrafiltration controllers with a range of ± 1 to 2%, and accurate temperature control. In addition, all these devices have air leak detectors as well as blood-side pressure monitors.

The B. Braun, Edwards Life Sciences, Baxter, and Fresenius devices allow the user to choose a dialysis membrane. The membrane can be any of the commercially available membranes. The Gambro Prisma system has a cassette system that enhances the ease of administration and commencement of CRRT but requires the operator to use the specific membrane associated with their cassette.

Membranes

The membranes used for CRRT are similar to those used for HD. They vary in the components of the membranes, sieving coefficient, and surface area. The two major types of membranes for HF are composed of polysulfone or acrylonitrile. Both have the advantages that they are slightly negatively charged, they have a fairly high sieving coefficient that allows for adequate ultrafiltration and solute clearance either by convective or by diffusive techniques, and they are considered "biocompatible." Table 65.5 lists the various membranes available.

The acrylonitrile (AN69) membrane has a unique property that is problematic in acidotic patients. When the acidic plasma interacts with the membrane, bradykinin production ensues. When infused back into the patient, these activated bradykinins can cause an anaphylactic-like response. This response is accentuated in patients who are small or who require blood priming during the onset of HF. Blood bank blood has a pH between 6.2 and 6.4, a very high concentration of potassium, and a very low concentration of calcium. There have been several reports of anaphylaxis in patients during blood priming with the AN69 membrane. This is easily prevented by dialyzing the blood for a period of time to bring the pH close to 7.6 and the potassium and calcium to physiologic levels. Alternatively, a bypass maneuver may be used (100).

TABLE 65.5. PEDIATRIC CIRCUIT VOLUMES AND HEMOFILTER PROPERTIES

Patient weight (kg)	Hemofilter	Material and surface area	Priming volume (mL)	Arterial/venous line volume
<10	Amicon Minifilter Plus	Polysulfone 0.07 m ²	15	3 mL/3 mL TCV = 21 mL
>10	Renaflo II HF	Polysulfone		7 mL/7 mL
	400	0.3 m ²	28	TCV = 42 mL
	700	0.7 m ²	53	TCV = 67 mL
	1200	1.25 m ²	83	TCV = 97 mL
>10	Hospal (Lyon, France) Multiflow 60	Acrylonitrile and sodium methallyl sulfonate copolymer 0.6 m ²	48	6.5 mL/13.8 mL TCV = 67.3 mL
>10	Asahi PAN	Polyacrylonitrile		
	0.3	0.3 m ²	33	
	0.6	0.6 m ²	63	
	1.0	1.0 m ²	87	

TCV, total circuit volume.

Note: Venovenous hemofiltration requires larger circuit volume depending on the pumps used. For the nonadapted systems, such as the Prisma, the filter is the Multiflow 60, and the circuit volume is fixed at around 100 mL.

Tubing

Tubing for CRRT is available from several companies. Presently the Edwards LifeScience Aquarius and the Baxter Accura devices are in production. Edwards systems with the Aquarius now has pediatric tubing, whereas the Baxter Accura system does not. The Fresenius HD machine that can be adapted for CRRT can use all HD tubing, including neonatal, pediatric, and adult tubing. Gambro (Prisma system) is in the process of developing a system that is 50% smaller. The B. Braun device has both pediatric and adult tubing that allows for various sizes of membranes. The current Baxter BM-25 has both low- and high-volume tubing.

Historically, many nephrologists have been told that if one has more than 10% of blood volume in an extracorporeal device, blood priming is necessary to maintain hemodynamic stability. This approach is probably inappropriate, because one is taking a process used for an outpatient stable population with chronic disease and applying it to an inpatient unstable population. Therefore, blood priming should no longer be based on the extracorporeal blood volume but on a combination of the extracorporeal blood volume and the hemodynamic stability of the patient. Except with the AN69 membrane, blood priming should be considered necessary for any patient with hemodynamic instability at the time of onset of need for HF.

Access

Access for CRRT can be achieved with either a cuffed or a noncuffed catheter. In most settings a noncuffed catheter is used for acute treatment. Table 65.6 provides a list of vascular catheters for CRRT. The noncuffed catheter can be placed in the internal jugular (IJ), subclavian, or femoral space. Many nephrologists would prefer to avoid the use of subclavian catheters in patients who may develop end-stage renal disease and whose subsequent treatment is complicated by subclavian stenosis. The advantage of the IJ catheter is that it is not compromised by the patient's motion and appears to give adequate blood flow with minimal resistance or recirculation. The disadvantage of the IJ catheter is the increased risk of both pneumothorax and hemothorax at the time of placement. The advantage of a femoral catheter is that it is associated with less risk at the time of placement than is a subclavian or IJ catheter. The disadvantages of the femoral line includes a theoretical increased risk of infection and the possibility that movement during therapy may affect blood flow or cause intermittent inhibition of blood flow.

Solutions

The U.S. Food and Drug Administration (FDA) considers anything that is placed in the vascular space to be a drug. The FDA has yet to approve any specific solution as a replacement fluid in CVVH. Therefore, many programs are

TABLE 65.6. SUGGESTED SIZE AND SELECTION OF HEMOFILTRATION VASCULAR ACCESS DEVICES FOR PEDIATRIC PATIENTS

Patient weight	Catheter size and source	Site of insertion
Neonate	Single-lumen 18, 16, 14 gauge (Cook)	Femoral artery or vein
	Single-lumen 5.0 French (Medcomp)	Femoral artery or vein, or umbilical vein
	Dual-lumen 7.0 French (Cook, Medcomp)	Internal/external jugular, subclavian, or femoral vein
3–6 kg	Dual-lumen 7.0 French (Cook, Medcomp)	Internal/external jugular, subclavian, or femoral vein
	Triple-lumen 7.0 French (Medcomp, Arrow)	Internal/external jugular, subclavian, or femoral vein

using either saline or lactated Ringer solution as the standard replacement fluid. Furthermore, many programs are having the pharmacy make solutions to meet the needs of each specific patient. The FDA Modernization Act of 1997 (<http://www.fda.gov/opacom/backgrounders/modact.htm>) does allow for local judgment in using a device (i.e., a dialysis solution) as a drug (replacement) if it is safer than other options. Therefore, many programs use dialysis solutions as replacement fluids for CRRT.

Dialysis solutions are not considered drugs but are considered devices that have been approved by the FDA. Two solutions are available for dialysis in the United States. These are the Baxter (lactate-based) hemofiltration solution and Dialysis Solutions (Richmond Hills, Ontario, Canada) Normocarb (bicarbonate-based) solutions. In Canada, Hemosol L0 and B0 (Hospal, Lyon, France) are also available.

Lactate-based and bicarbonate-based solutions are available for CRRT. If bicarbonate is placed directly into plastic bags, over a short period of time the bicarbonate will leach out as CO₂ and the solution will lose its buffering capacity. Lactate has been used because it is stable in these solutions.

When these solutions are used, lactate is delivered to the patient. The use of lactate solutions can be associated with rising lactate levels in patients, and it can be difficult to discriminate whether this level is related to endogenous lactate resulting from conditions such as bowel ischemia or low cardiac output, or is due to the lactate in the solution. One could discriminate between these two by determining

whether the lactate is the L or the D form. To make that determination, however, frequently requires a protracted time, and this limits its usefulness.

The development of a Normocarb concentrate stored in a glass bottle permits the fresh preparation of a physiologic bicarbonate-based solution for dialysate or replacement. Comparison data have shown that not only is bicarbonate solution more physiologic but its use is also correlated with improved outcome, fewer instances of hemodynamic instability, lower vasopressor requirements, and less frequent requirement for bicarbonate replacement. These data reinforce that lactate solutions should not be used in CRRT (101).

Anticoagulation

At least three options are available for anticoagulation in CRRT. The first approach is to use none; the second is to use heparin; and the third is to use citrate.

The use of no anticoagulation during CRRT has been shown repeatedly to decrease the duration of each circuit. No anticoagulation is typically used in a patient with disseminated intravascular coagulation who has a low platelet count and abnormal coagulation test results. Many of these patients, however, have a paradoxical hypercoagulability that requires some anticoagulation to prevent clotting in the system. Furthermore, many of these patients are being given continuous fresh frozen plasma replacement and platelet infusions that will correct the underlying anticoagulation problem.

Historically, many programs have used heparin. Heparin is infused in the system prefilter and is used to anticoagulate the system. Heparin's anticoagulation effect is assessed by measuring postfilter partial thromboplastin time or activated clotting time.

When heparin is used as an anticoagulant, the target is an activated clotting time between 180 and 220 seconds or a partial thromboplastin time between 1.5 and 2 times normal (98). A significant disadvantage of heparin usage is that it is associated with systemic anticoagulation of the patient. Furthermore, heparin use can be associated with heparin-induced thrombocytopenia, which further increases the risk of bleeding. In many patients with multiorgan system failure who require CRRT, systemic heparinization may be an additional risk factor.

Citrate anticoagulation is carried out by infusing citrate into the system postpatient and prefilter. Citrate then binds to the plasma calcium. Because coagulation is a calcium-dependent process, the patient is partially anticoagulated. To avoid citrate toxicity and systemic hypocalcemia, calcium must be infused into the patient separately from the dialysis system. Therefore, two processes must be monitored when citrate anticoagulation is used. The first is infusion of the citrate into the system to maintain the ionized calcium level in the extracorporeal system at between 0.25 and 0.4 mmol/L. The second is infusion of calcium back

into the patient to maintain the patient's ionized calcium level at between 1.1 and 1.3 mmol/L (102,103).

The use of citrate anticoagulation may cause citrate toxicity or a metabolic alkalosis. Citrate toxicity occurs when the delivery rate of citrate exceeds the clearance rate. The clearance rate of citrate is related to both the clearance of the dialysis membrane and hepatic metabolism. One millimole of citrate is converted to 3 mmol of bicarbonate by the liver. Therefore, one sign of excessive citrate exposure is metabolic alkalosis (102).

The second sign of citrate excess is the "citrate gap." The citrate gap is seen when there is a rise in total calcium with a drop in ionized calcium. The citrate gap can be easily corrected by stopping the citrate delivery for 20 minutes to 2 hours and restarting the citrate at 70% of the previous rate.

Metabolic alkalosis can easily be corrected by decreasing the citrate exposure, by increasing the clearance of citrate by dialysis, or by infusing an acidic solution back into the patient. Many programs use citrate anticoagulation with a bicarbonate-based solution such as Normocarb and the result will be metabolic alkalosis. The pH of normal saline is 5 to 5.4; therefore, the use of replacement fluid of normal saline can easily correct this metabolic alkalosis.

Nutrition

CRRT provides continuous ultrafiltration, thus permitting a continuous delivery of nutrition. This continuous treatment, however, inevitably results in some loss of nutrients through the clearance of CRRT. A prospective crossover study by Maxvold et al. demonstrated that a standard CVVH or CVVHD prescription with a delivery of 1.5 g/kg/day of protein results in clearance of approximately 20% of amino acids by CRRT (97). If not accounted for, this could result in a negative nitrogen balance. Furthermore, many of the parenteral formulas are lacking in glutamine, which is also cleared by CRRT. Therefore a negative glutamine balance could place the patient at risk of impaired protein synthesis, which is controlled in part by glutamine. A more recent study by Bellomo et al. demonstrated that a delivery rate of 2.5 g/kg/day in adults with multiorgan system failure was only partially successful in restoring nitrogen balance (104).

Thus many pediatric programs provide delivery of 2 to 3 g/kg/day of protein and adjust to a target BUN level of 40 to 50 mg/dL.

Drug Clearance

The proper dosing of medications is based on the balance between the rate of administration of the drug, the dose of the drug, the metabolism of the drug, and the CRRT clearance of the drug. Understanding the factors that affect mass transfer helps the clinician determine a reasonable estimate of medication losses (105).

1. Convective transfer through CVVH yields a greater proportional solute clearance of middle- and larger-sized molecules than the diffusive transfer through CVVHD.
2. Protein binding affects clearance, with greater binding resulting in less transfer.
3. The molecular weight of the solute affects clearance. Large molecules pass through the membranes less readily than smaller ones.
4. The type of membrane and the charge of the membrane affect adherence of the particle to the membrane as well as the permeability of the membrane.

Therefore, when the renewal of medications is determined, all of the aforementioned need to be considered. For a septic child on CRRT, many err on the side of putting the child at risk for overtreatment instead of undertreatment.

Complications of Continuous Renal Replacement Therapy

The complications of CRRT include overanticoagulation associated with heparin use, citrate toxicity, citrate hypocalcemia, as well as metabolic alkalosis associated with citrate use. All these complications are easily identifiable and correctable.

Excessive ultrafiltration can occur in patients on CRRT. This happened more commonly with older systems when intravenous pumps were used as a way to inhibit ultrafiltration rates. These pumps may have been useful to measure ultrafiltration but have been found to have up to a 30% error rate in control of ultrafiltration. The newer devices allow for accurate ultrafiltration within a 1 to 2% error rate (97). Temperature control instability can be seen in patients treated with CRRT. This needs to be monitored closely, especially in small children.

Initiation of Continuous Renal Replacement Therapy

No prospective data exist to determine the optimal point at which to begin CRRT. Ronco et al. showed that, in adults on CRRT, increasing doses of replacement fluid statistically improved outcome. Patients given prescriptions of both 35 and 45 mL/kg/hr showed better survival rates than those receiving 25 mL/kg/hr. Furthermore, they showed that there was a statistical improvement in survival when patients were placed on CRRT by the time BUN had risen to 80 mg/dL as opposed to higher levels. These results suggest that early intervention based on solute clearance may improve outcome (106).

Goldstein et al. showed that the amount of fluid overload at the time of commencing CRRT affected outcome in a series of children receiving CRRT. Survivors had an average fluid overload of 16%, whereas nonsurvivors

had an average of 32% (107). These data suggest that early intervention from an ultrafiltration perspective also affects survival.

Outcome

ARF continues to be a devastating complication and is associated with a high risk of mortality. Simple ARF without other underlying illness has been reported to have a 7 to 23% mortality rate. When it is associated with other diseases in the ICU setting, the mortality rate for patients with ARF is 50 to 80% (26,27,108–116). Although it is difficult to determine the role of ARF as opposed to that of other comorbid diseases, these numbers illustrate the serious nature of this complication.

CHRONIC RENAL FAILURE

PATHOPHYSIOLOGY OF PROGRESSIVE RENAL DISEASE

**AGNES B. FOGO
VALENTINA KON**

Progressive renal disease occurs in all age groups. The incidence of chronic renal insufficiency among children younger than 16 years varies between 1.5 and 3.0 per million. Congenital structural anomalies, including reflux, obstruction, hypoplasia, and dysplasia are the principal underlying causes of end-stage renal disease, particularly in the very young child. Older children also develop end-stage renal disease from glomerulopathies, including focal segmental glomerulosclerosis (FSGS), hemolytic uremic syndrome, immune complex diseases, and hereditary nephropathies, such as Alport's disease (1) (Fig. 66.1). Although diabetic nephropathy does not result in chronic renal insufficiency in childhood, most patients with diabetes who develop end-stage renal disease in their 20s and 30s are those whose diabetes presented during childhood. This period between onset of disease during childhood and later development of diabetic nephropathy in adolescence or adulthood is an example of an opportunity for the physician to apply new therapeutic strategies outlined in this chapter, which may affect ultimate development of what has become the number one cause of end-stage renal disease in adults.

The remarkably similar histologic appearance of chronic renal diseases regardless of the primary insult suggests a common final pathway, with variations dependent on unique disease-specific factors and individual susceptibility. The alterations and adaptations in nephrons remaining after the initial insult are thought ultimately to cause scarring and further nephron loss, thus perpetuating a vicious cycle that results in the end-stage kidney. However, individual genetic variations and disease-specific mechanisms contribute to variability in progression and response to therapy (2). Possible mechanisms of progressive renal damage include, but are not limited to, hemodynamic factors, shear stress, growth factors, cell-specific damage, and metabolic factors such as a diabetic milieu and hyperlipidemia. The balance of cell growth versus cell death and the balance of matrix accumulation versus degradation determine whether

injury results in healing with remodeling and resolution of damage or ongoing sclerosis (Fig. 66.2).

EXPERIMENTAL EVIDENCE

Systemic and Glomerular Hypertension

Systemic hypertension often accompanies renal disease. It results from and contributes to progression of renal damage. Hypertension accelerates progression of chronic renal disease in humans, as discussed later. Systemic blood pressure not only can affect the glomerulus by transmission of pressures but also may affect other determinants of progressive injury. In addition, intrarenal factors related to the unique aspects of kidney structure and function may be important. The glomerulus has both an afferent and an efferent arteriole, which permits modulation of perfusion and pressure within the glomerular capillary bed differentially from systemic blood pressure. Therefore, attention has been focused on the potential impact of local (i.e., glomerular) hemodynamic changes in structural glomerular injury.

Numerous studies in the last decade have examined the remnant kidney or renal-ablation model of progression in the rat. The ablation model was initially described nearly 100 years ago (3). In this model, removal of a large portion of renal mass results in progressive hyperperfusion, hyperfiltration, and sclerosis in a heterogeneous pattern (i.e., focal and segmental glomerulosclerosis) (4–6). Kidney weight increases, and tubular and glomerular growth occur. The structural changes after loss of nephrons include hyperplasia and hypertrophy. So-called glomerular hypertrophy represents both cellular hypertrophy (increase in cell size) and hyperplasia (increase in cell number). Age and the extent of renal ablation affect the relative contributions of hypertrophy and hyperplasia. Although new nephrons do not form after term birth, hyperplasia is more prominent in the young and is greater after extensive nephron loss (7–9). The postulated intermediary factors for progressive glomer-

FIGURE 66.1. Causes of end-stage renal disease in combined series of 4136 children. Glomerulopathy includes immune complex diseases and focal segmental glomerulosclerosis. Hereditary disorders include cystinosis, oxalosis, and Alport's disease. Vascular diseases include hemolytic uremic syndrome, hypertensive nephrosclerosis, arteritis, renal vein thrombosis, and diabetes. (Data from Foreman JW, Chan JCM. Chronic renal failure in infants and children. *J Pediatr* 1988;113:793-800.)

ulosclerosis have also been investigated in other models in which nephrons are not removed and the initial injury is more diffuse. Thus, both the puromycin aminonucleoside and Adriamycin models of renal disease show initial proteinuria and epithelial cell damage similar to human minimal-change disease, followed by progressive focal and segmental glomerulosclerosis.

The initial observations that single nephron function was increased after renal ablation led to further studies (3) and

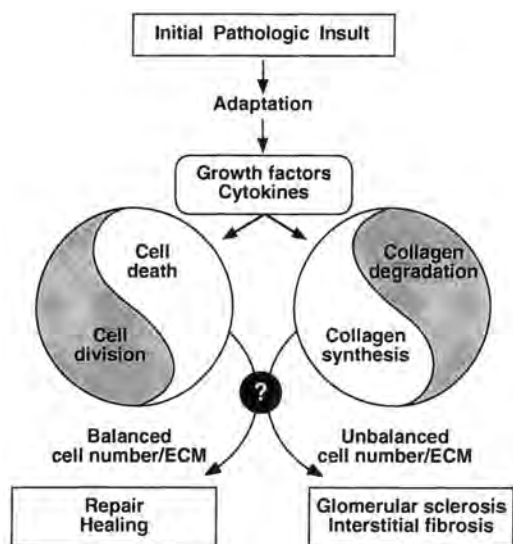

FIGURE 66.2. Postulated mechanisms for progressive sclerosis in chronic renal disease. Glomerulosclerosis results from the net effects of growth promoters and inhibitors on cell growth and matrix accumulation. The balance of cell proliferation versus apoptosis and matrix production versus degradation determines whether scarring or healing ensues in response to injury. ECM, extracellular matrix. (From Neilson EG, Couser WG, eds. *Immunologic renal disease*. Philadelphia: Lippincott-Raven, 1997, with permission.)

the hypothesis that hyperfiltration was injurious (6). It was postulated that this maladaptive change after removal of nephrons results in the ongoing loss of glomeruli, and, thus, a cycle of hyperfiltration and glomerulosclerosis is perpetuated (10). Manipulations of hyperfiltration by feeding a low-protein diet or by giving angiotensin I-converting enzyme inhibitors (ACEIs), lipid-lowering agents, or heparin were effective in ameliorating glomerular sclerosis. However, in some studies, glomerular sclerosis was decreased without altering glomerular hyperfiltration (11). In addition, experimental maneuvers that actually increased glomerular hyperperfusion (such as thromboxane synthase inhibitors or exercise training) not only did not accelerate progression but also actually slowed the process. Finally, glomerular sclerosis was noted to occur even in the absence of intervening hyperperfusion (9,12).

The absence of a tight link between hyperperfusion and glomerular sclerosis shifted focus from hyperperfusion/hyperfiltration to glomerular hypertension, another element of the increased glomerular stress that follows renal ablation. Glomerular hypertension is typical in many models of chronic renal failure. Maneuvers that increase glomerular capillary pressure, such as therapy with erythropoietin, glucocorticoids, or high-protein diet, accelerated glomerulosclerosis. Maneuvers that induce systemic and/or glomerular hypertension, such as uninephrectomy, superimposed on other forms of renal disease, including nephrotoxic serum nephritis, immune complex nephritis, or diabetic nephropathy, worsen both functional and structural deterioration (9,12).

There appears to be better correlation between increased glomerular pressure and glomerulosclerosis than hyperfiltration/hyperperfusion and sclerosis. Mechanisms by which increased pressure might promote sclerosis include altered mechanical and/or shear stress. Mesangial cells in culture subjected to pulsatile mechanical stretch/relaxation cycles changed production of cytokines that affect matrix production and proliferation of glomerular cells and altered type and amount of matrix production (13). Many maneuvers that had been used to ameliorate matrix accumulation and, thus, glomerulosclerosis *in vivo* also affected glomerular pressures. Decreased glomerular pressure, in response to dietary protein restriction (14) or antihypertensive drugs (9,12,15,16), is associated with slower progression. As discussed later, these maneuvers also have other effects. Of special interest are the findings of protection against glomerulosclerosis with ACEIs (17). This has been attributed to the unique actions of ACEIs to decrease glomerular capillary pressure by preferential dilation of the efferent arteriole (1). ACEIs also act as kininase inhibitors and activate bradykinin. Bradykinin is postulated to be the mediator effecting vasodilatation of the efferent arteriole by ACEIs (18). Newer antihypertensive drugs that inhibit the renin-angiotensin system include angiotensin II (Ang II) type 1 receptor antagonists (RAs). They do not have kininase

activity and therefore do not alter bradykinin activity. Because both of these modes of inhibition of the renin-angiotensin system are effective in protecting against glomerulosclerosis, the specific effect of ACEI to decrease efferent arteriolar resistance does not appear to be critical for amelioration of glomerulosclerosis. Rather, inhibition of Ang II actions per se is postulated to be involved in the effect of these drugs (17). Ang II also affects mesangial and vascular smooth muscle cell growth and matrix production (see later).

After loss of nephrons, whether removed surgically or damaged by disease, the remaining glomerular tufts enlarge. One study in rats examined the heterogeneous changes in function in individual nephrons after renal ablation. Glomerular filtration and pressure were assessed repeatedly by micropuncture in the same nephrons over a 6-week period. When the single-nephron glomerular filtration rate (GFR) and glomerular capillary pressure were correlated with the degree of sclerosis in the same glomerulus, no correlation was found between the levels of these hemodynamic parameters and the degree of sclerosis. Thus, the nephrons with the greatest hyperfiltration or highest glomerular capillary pressure did not show the most severe sclerosis at the end of the study, indicating that glomerular hypertension or hyperperfusion per se did not directly account for the glomerular damage (19). Similar conclusions were reached based on experiments in another nonhypertensive model, the puromycin aminonucleoside nephropathy, in which ACEIs also were effective in slowing glomerulosclerosis (9).

Further along these lines are observations of disorders characterized by glomerular hypertension, which do not develop sclerosis (15,20). For example, in the diabetic nephropathy model in the rat, although glomerular capillary hypertension is typically seen, only mild mesangial expansion results rather than overt glomerulosclerosis (12). In another study, hyperfiltration was induced either by renal ablation or by diversion of urine into the peritoneal cavity. Similar degrees of glomerular hyperperfusion, hyperfiltration, and hypertension developed in both ureter-diverted and renal-ablation groups. Glomeruli of the ureter-diverted rats did not hypertrophy, whereas those of the renal-ablation rats did. Significant glomerulosclerosis developed only in the renal-ablation group (20). Overall, these findings indicate that glomerulosclerosis can develop without glomerular hypertension, and glomerulosclerosis can be ameliorated without altering glomerular hemodynamics. These results suggest that glomerular hyperfiltration, hyperperfusion, or glomerular hypertension alone do not fully explain the development of glomerular hypertrophy or sclerosis.

On the other hand, it has been postulated that individual factors such as glomerular hypertrophy and glomerular pressures interact to produce heightened injury by affecting factors such as wall tension. Increased wall tension, resulting from a combination of increased pressures and increased size of the glomerular capillary as predicted by Laplace's law, has

been proposed as a mechanism for progressive glomerulosclerosis (21,22). However, in several animal models, glomerular enlargement occurs through lengthening and/or branching of the capillaries rather than by increased capillary diameter (23–25). In children with reflux nephropathy, glomerular growth resulted from increased capillary branching and not increased capillary diameter (26). These observations cast doubt on whether increased wall tension actually occurs, at least in such settings of glomerular growth. Other synergistic contributions proposed to be deleterious include systemic blood pressure, which may modulate glomerular injury either by direct transmission of altered shear stress and pressures or by altering the elaboration of vasoactive substances that affect the microcirculation (9).

Growth Factors

After initial loss of nephrons, growth promoters are increased and act on remaining glomeruli. Glomerular sclerosis is often closely associated with glomerular hypertrophy in a variety of animal and human diseases (9). Stimuli that induce glomerular hypertrophy often accelerate glomerular sclerosis, which has focused research on possible roles of these growth factors in progression of renal disease (Fig. 66.3). In the remnant kidney in rats, structural lesions

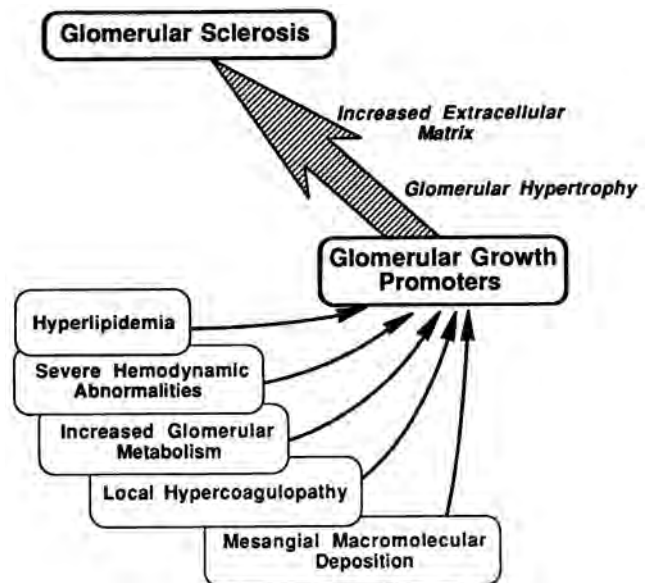

FIGURE 66.3. Speculation on relationship between glomerular growth promoters and other potentially pathogenic intermediary mechanisms for glomerular sclerosis. Currently available experimental observations in renal and nonrenal tissues suggest the possibility that these other mechanisms may interact with glomerular growth promoters, which have the capacity to induce both glomerular hypertrophy and mesangial matrix accumulation, leading to the typical glomerular sclerotic lesion. (From Fogo A, Ichikawa I. Role of glomerular growth promoters in progression of renal disease. In: Andreucci VE, Fine LG, eds. *International yearbook of nephrology*. Boston: Kluwer Academic Publishers, 1991:21–45, with permission.)

develop that closely resemble human FSGS. Like those seen in humans, these changes occur initially in the deep juxtamedullary glomeruli (7,27). In young animals in which maturational growth is occurring, injury after renal ablation is more severe than in adults (8,28). Detailed analysis of the distribution of this glomerular injury revealed more focal and severe glomerulosclerosis in the deep (vs. the superficial) glomeruli in the young rats. Hemodynamic factors did not differ between the two age groups. Although after renal ablation more glomerular enlargement occurred in the young rat than in the adult rat, glomerular enlargement occurred proportionally in both superficial and deep nephron populations. The more severe injury of the deep glomeruli in the young immature rat was, therefore, postulated to be related to factors unique to the young growing kidney, which is characterized by centripetal growth and differentiation. The mechanisms that promote hyperplasia rather than hypertrophy in the accentuated growth and wound healing in response to nephron loss may also promote scarring (28).

Uninephrectomy, a stimulus for hypertrophy, also accelerates glomerular sclerosis in other models (e.g., experimental glomerulonephritis, minimal-change disease, focal sclerosis, and diabetic nephropathy) (9,12). Excess growth hormone, whether endogenously produced (i.e., transgenic mice) (29) or exogenous (30,31), is associated with marked glomerular hypertrophy and accelerated glomerulosclerosis. Even in normal young rats, recombinant human growth hormone (rhGH) caused glomerular hypertrophy and severe sclerosis (31). Although these normal rats did not develop uremia over the course of observation, these findings raise important issues for the treatment of children with rhGH, as discussed in Growth Hormone.

Although hypertrophic stimuli accelerate glomerular sclerosis, the converse is also true: Decreasing the hypertrophic response is associated with decreased glomerular sclerosis. Dwarf rats with a defect in growth hormone are resistant to the development of glomerulosclerosis after renal ablation (30). A rat strain characterized by a larger number of small glomeruli and a minimal hypertrophic response to loss of nephrons, the PVGc strain, has proved resistant to the development of glomerulosclerosis after the removal of one kidney (9). Interventions that ameliorate glomerulosclerosis have a similar effect on glomerular hypertrophy. Treatment with low-protein diets ameliorates sclerosis; however, it may be effective only when the diet is low enough in calories to inhibit growth (32). Antihypertensive drugs also inhibit both glomerular growth and glomerulosclerosis.

In vivo and *in vitro* evidence suggests that many cytokines can promote glomerular cell growth and enhance extracellular matrix release, thus promoting sclerosis as well as growth. Numerous growth factors affect renal growth and scarring. Several growth factors appear to play key roles in progression of glomerular and tubulointerstitial scarring. These factors

and their roles may differ at the various stages of injury. Altered gene expressions in pathophysiologic settings implicate factors, including the following: platelet-derived growth factor (PDGF), transforming growth factor β (TGF β), TGF α , insulin-like growth factor-1 (IGF-1), growth hormone, epidermal growth factor, interleukin-1 (IL-1) and -6, tumor necrosis factor- α (TNF- α), Ang II, basic fibroblast growth factor (basic FGF), and endothelin (9,33,34). A recent study showed that inhibition of a specific growth factor, either TGF β or PDGF, could decrease mesangial matrix expansion in the anti-Thy1 model (35,36). Conversely, animals transgenic for TGF β develop progressive renal disease (37). The biologic actions of TGF β are complex, and depend not only on cell state, but on presence of decorin, which binds and modifies its activity (38). Further study is necessary to determine the specific role each of these factors plays at varying stages of glomerular injury.

The contribution of Ang II is particularly relevant because it can be inhibited by currently clinically available agents, and extensive clinical evidence shows the efficacy of Ang inhibition on progression of renal disease. The mechanisms by which Ang II affects growth and matrix include both direct and indirect effects via induction of other growth factors, including basic FGF, PDGF, and TGF β , and modulation of fibrinolysis/proteolysis (9,38). The effects of Ang to induce plasminogen activator inhibitor-1 (PAI-1) provide a link of the renin-angiotensin system to thrombosis (39,40). Importantly, PAI-1 inhibits proteolysis as well as fibrinolysis. Recent studies have also shown linkage of injury and increased PAI-1 expression *in vivo* in a model of radiation-induced endothelial injury with thrombosis followed by glomerulosclerosis. Inhibition of Ang II or aldosterone, either by ACEI or Ang type 1 (AT1) RA, or with the aldosterone RA spironolactone, prevented PAI-1 upregulation and injury (41,42).

Recent studies have examined whether Ang II and aldosterone induce PAI-1 expression and subsequent fibrosis independent of TGF β activation (43). These studies examined the effect of Ang II and aldosterone on tubulointerstitial fibrosis induced by unilateral ureteral obstruction (UUO) in $\alpha_v\beta_6$ knock-out mice, in which the local activation of TGF β is impaired. The integrin $\alpha_v\beta_6$ serves as a ligand for latency-associated peptide (LAP) and is expressed in epithelia in lung, skin, and kidney (44). TGF β circulates bound to LAP and is locally activated when LAP binds to $\alpha_v\beta_6$ and TGF β is cleaved. Consistent with prior studies indicating that $\alpha_v\beta_6$ mice are protected against bleomycin-induced pulmonary fibrosis (44), the knock-out animals demonstrated attenuated PAI-1 expression, collagen I and III expression, and markedly decreased renal fibrosis after UUO compared to wild-type animals, even though macrophage infiltration was not altered in the $\alpha_v\beta_6$ mice (43). However, treatment with Ang II, aldosterone, or both increased PAI-1 expression and rendered the animals equally susceptible to UUO-induced fibrosis as the wild-

type animals. This study suggests that Ang II or aldosterone can induce PAI-1 expression and fibrosis through a TGF β -independent pathway (43).

Ang II has additional effects on the vascular system, promoting migration of endothelial and vascular smooth muscle cells and hypertrophy and hyperplasia of smooth muscle cells and mesangial cells (9,45). Ang II is present in monocytes, which may thus serve as yet another source of Ang II in immune-mediated glomerular injuries (46). Local transfection to the carotid artery of ACE resulted in increased DNA synthesis and medial hypertrophy, associated with local Ang II generation without systemic changes (47). Glomerular transfection *in vivo* with angiotensinogen or renin similarly induced activation of mesangial cells and increased matrix (48). Recent data implicate the Ang type 2 receptor in growth inhibition and apoptosis in vascular injury and remodeling as well as in development (49–51). Pharmacologic inhibition or absence of the AT₂ receptor in null mutant mice, with resulting deficient apoptosis after injury, leads to increased fibrosis in models of kidney and heart fibrosis (52,53). Apoptosis may serve as a healing mechanism, eliminating injured cells with minimal stimulation of immune/inflammatory mechanisms and cytokines. However, disproportionate apoptosis of cells that cannot regenerate may have deleterious consequences. Indeed, combined therapy with AT₁ and AT₂ RAs was more effective than monotherapy in amelioration of progression in the remnant kidney model (54). In contrast, mechanisms of regression of existing injury are distinct, with recent data suggesting a particular advantage of maintaining activity of the AT₂ receptor to achieve optimal remodeling (55). Furthermore, the AT₂ receptor tonically inhibits ACE activity, which may dampen Ang II generation (56). Thus, AT₂ receptor-transduced Ang actions may counter some of AT₁-mediated effects and has potential implications for effects of ACEI versus newly available AT₁ RAs in various disease settings. The net effect of Ang II thus depends on the balance of AT₁- and AT₂-mediated effects, as well as induction of proliferative growth factors, such as PDGF and basic FGF, and matrix modulators, such as PAI-1, versus TGF- β 1, which promotes matrix synthesis and inhibits or promotes cellular proliferation depending on conditions.

Combined ACEI and AT₁ RA treatment thus could have theoretic advantage, allowing further blockade of Ang II actions while maintaining preferential local availability of the AT₂ receptor. However, in the remnant kidney model, combined ACEI+AT₁RA therapy did not result in added benefit on glomerulosclerosis when compared to single-drug therapy with similar blood pressure control (57). However, in the rat transgenic for renin (mREN-2) 27, combination therapy was more effective than monotherapy in reducing blood pressure and in limiting end-organ injury (58). Combination of AT₁RA and ACEI in small clinical studies in normotensive patients with either immunoglobulin A (IgA) nephropathy

or diabetic nephropathy resulted in more profound decrease in proteinuria than treatment with either drug alone, not attributable to effects on systemic blood pressure (59,60). In a large study of hypertensive patients with diabetic nephropathy and microalbuminuria, combined therapy resulted in greater blood pressure and albuminuria reduction than either drug alone (61). Combination therapy appears to be safe, and may even have additional antifibrotic effects versus monotherapy by decreasing urinary TGF β independent of blood pressure or proteinuria effects (62). In this connection, patients receiving ACEI long term still have measurable ACE in plasma, and, in an experimental rat model, even suprapharmacologic doses of ACE inhibition did not achieve complete suppression of the local RAS (63). It is possible that non-ACE-dependent Ang II generation by chymotrypsin-sensitive generating enzyme occurs in humans. New directions under investigation include development of renin antagonists that could obviate these effects.

Further study is necessary to determine the specific role of each of the many potential growth factors that can affect matrix accumulation at varying stages of glomerular injury. Increased release of growth factors may be triggered by local increase in shear stress or hydraulic pressures or by insults that include, but are not limited to, increased glomerular metabolism, heightened reactive oxygen species, altered lipid metabolism, mesangial deposition of macromolecules, and abnormal hemostasis (Fig. 66.3) (9,12,64,65).

Glomerular Cells in Progression

The endothelial cells interact with other cells and affect both growth-promoting and growth-inhibiting factors. Some of the factors upregulated after endothelial injury, such as plasminogen activators and inhibitors and collagenases, not only affect coagulation and thrombosis but also have been linked to matrix remodeling. Thus, scarring may be a late sequela of endothelial cell injury. Endothelial cells release cytokines that affect vascular tone and express adhesion molecules for circulating cells. Normally, endothelial cells inhibit smooth muscle cell migration and proliferation. When injured, they release growth factors that promote proliferation and matrix, lipoproteins, and cholesterol accumulation (66). Endothelial cells produce numerous cytokines that modulate mesangial cell growth (e.g., endothelin, PDGF, and endothelial-derived relaxing factor); some endothelial-derived factors act in synergy with heparin-like substances. For example, endothelin, a powerful vasoconstrictor, results in hyperplasia, hypertrophy, and increased matrix in mesangial cells in culture; it also enhances PDGF release, another key factor augmenting these processes (67).

Recent studies have pointed to a primary importance in progressive renal disease of endothelial cells in an extraglomerular site, namely in the peritubular capillary. Decreased peritubular capillary density, possibly modulated by decreased

vascular endothelial derived growth factor or other angiogenic factors, has been proposed as a mechanism in various progressive renal diseases (68). Future studies may demonstrate whether these interstitial microvascular lesions are causal or consequential in the development of interstitial injury.

Glomerular visceral epithelial cells are the primary targets in many glomerular diseases, including FSGS and the experimental models of Adriamycin and puromycin aminonucleoside-induced nephropathies. Specific antigens of these cells (e.g., megalin) are targets in immune-mediated glomerulonephritis (69,70). The glomerular visceral epithelial cells are pivotal for maintenance of normal permselectivity and are a source of matrix in both physiologic and pathophysiologic settings. In contrast to the ability of mesangial and endothelial cells to regenerate after injury, the glomerular visceral epithelial cell is growth challenged. This limited proliferation in the mature glomerular visceral epithelial cell is accompanied by high expression of a cyclin-dependent kinase inhibitor, p27kip1 (71). This cyclin-dependent kinase inhibitor seems to be a rate-limiting step for the growth response of the visceral epithelial cell. Either too much or too little proliferation of the visceral epithelial cell in response to genetic manipulation of p27kip1 is postulated to be detrimental (72). Inadequate growth of the visceral epithelial cell is postulated to give rise to areas of dehiscence and insudation of plasma proteins, which progress to adhesions and sclerosis (73). Another cyclin-dependent kinase inhibitor, p21, appears necessary for development of injury after 5/6 nephrectomy in mice, pointing to the crucial importance of cell growth responses in determining response to injury (74).

Glomerular visceral epithelial cells normally produce an endogenous heparin-like substance that inhibits mesangial cell growth; thus, injury may decrease this growth inhibitory effect and allow increased mesangial growth. Glomerular visceral epithelial cells are the main renal source of vascular endothelial growth factor, an endothelial cell-specific mitogen that plays a key role in both physiologic and pathologic angiogenesis and vascular permeability (75). Epithelial cell integrins are key modulators of cell interactions and cell-matrix binding, and antibodies to β_1 integrins or epithelial slit pores caused proteinuria acutely (76,77). Decreased α_3 and α_5 integrins are seen localized to areas of sclerosis (78). Together, these structural changes may underlie the foot process fusion and altered cell-cell and cell-matrix interactions.

New studies of the molecular biology of the podocyte and identification of genes mutated in rare familial forms of nephrotic syndrome or FSGS, such as nephrin, α -actinin-4, and podocin, have given important new insights into mechanisms of progressive glomerulosclerosis. The gene mutated in congenital nephrotic syndrome, nephrin (*NPHS1*), is localized to chromosome region 19q13 (79). Nephrin localizes to the slit diaphragm over the podocyte and is tightly associated with CD2-associated protein (CD2AP). Nephrin functions as a zona occludens-type

junction protein and, along with CD2AP, provides a crucial role in receptor patterning and cytoskeletal polarity. Mice engineered to be deficient in CD2AP develop congenital nephrotic syndrome, similar to congenital nephrotic syndrome of Finnish type (80). Additional important genes interacting with this complex have been identified in rare cases of familial FSGS. Autosomal dominant FSGS is caused by mutation in α -actinin-4, also localized to chromosome 19q13 (81). This is hypothesized to cause altered actin cytoskeleton interaction, causing FSGS through a gain-of-function mechanism, and contrasting the loss-of-function mechanism implicated for disease caused by the nephrin mutation (81). Patients with α -actinin-4 mutation progress to end stage by age 30 years, with rare recurrence in a transplant. Podocin, another podocyte-specific gene (*NPHS2*), is mutated in autosomal recessive FSGS that has an early onset in childhood with rapid progression to end stage (82). Podocin is an integral stomatin protein family member and interacts with the CD2AP-nephrin complex, indicating that podocin could serve in the structural organization of the slit diaphragm.

An additional interesting connection to progressive renal disease has been discovered from new insights in the nail-patella syndrome. This is caused by a mutation in the *LMX1B* gene, which codes a LIM-homeodomain transcription factor. The knock-out mouse for this gene has abnormal podocytes lacking typical slit diaphragms, and also has greatly reduced CD2AP and podocin, indicating a primary dependency of slit diaphragm development on *LMX1B* gene expression (83). Recently, an overlap in the *NPHS1/NPHS2* mutation spectrum has been detected, modifying the phenotype of congenital nephrotic syndrome of Finnish type to congenital FSGS when mutations in both are inherited. These findings further point to key functional interrelationships between *NPHS1* and *NPHS2* (84). Currently, investigators are examining whether acquired FSGS also may involve alteration in expression of some of these key podocyte genes. Indeed, occasional patients with nonfamilial forms of FSGS have been found to have podocin mutations (85).

Acquired disruption of some of these complexly interacting podocyte molecules has been demonstrated in experimental models and in human proteinuric diseases. Thus, in puromycin aminonucleoside nephropathy, a model of FSGS, nephrin localization, and organization were altered (86). Similar decreases in nephrin were observed in hypertensive diabetic rat models with significant proteinuria (87). The recently developed *NPHS1*-mutated mouse, generated by gene trapping, shows severe glomerulosclerosis and proteinuria and diffuse effacement of foot processes. The few remaining interpodocyte junctions lacked slit diaphragms, implicating that nephrin is essential for the integrity of both the foot processes and slit diaphragms (88). New molecular technologies targeting specific podocyte genes using podocyte-specific promoters exist and will elu-

cidate the pathogenesis of FSGS (89). Treatments that ameliorated these experimental models preserved glomerular nephrin expression, providing further support for a key causal role for slit diaphragm and nephrin preservation in nephrotic syndrome (90). Of interest, the Na⁺/H⁺ exchanger regulator factor 2 (Nherf2) also functions in maintenance of the foot processes by linking the podocyte protein podocalyxin to the cytoskeleton. In the puromycin aminonucleoside nephropathy model of FSGS, this complex is disrupted, and leads to the dramatic loss of foot processes and nephrotic syndrome (91).

Recent observations underscore the importance of the interactions between the podocyte and the underlying basement membrane. Dystroglycan is an integral component of the glomerular basement membrane. Decreased dystroglycan staining was observed in patients with minimal change disease (92). Dystroglycan expression was maintained in the nonsclerotic segments in FSGS, suggesting that minimal change disease and FSGS are indeed different disease processes and not merely different stages of one disease.

Because sclerosis ultimately is comprised of obliterated capillary loops and excess matrix, the mesangial cell also contributes to glomerular sclerosis (34). The mesangial cells share many characteristics with vascular smooth muscle cells; they contract and proliferate in response to numerous vasoactive substances, such as Ang II, and growth factors/cytokines, such as IGF-1 and TNF- α (9). After initial injury, the activated mesangial cell changes phenotype, expressing fibroblast-like myosin (93). These changes may alter their susceptibility to injury. Ang II induces mesangial cell hypertrophy, increases matrix production from mesangial cells *in vitro*, and induces the smooth muscle cell *c-fos* oncogene (34). TGF β , a cytokine released from a variety of cells, increases both collagen and proteoglycan production by mesangial cells and, depending on the cell-cycle stage, acts synergistically with other growth factors (9,38). Many growth factors initially may be released from infiltrating macrophages, platelets, or resident glomerular cells (i.e., endothelial and epithelial cells). Macrophage influx is associated with PDGF production; prevention of this influx, by dietary or other maneuvers, decreases subsequent injury (94). PDGF is increased in several models of glomerulosclerosis (67). Mesangial cells in culture release both IL-1 and a PDGF-like factor, suggesting that both autocrine and paracrine regulation of mesangial cell proliferation occur.

Therapy and Growth Factors

An important role for growth factors in glomerulosclerosis is underscored by the observation that therapies that reduce sclerosis may do so through antiproliferative effects. Antihypertensive therapies, in addition to altering blood pressure, have effects on growth. Results with ACEIs are of particular interest in view of the potent effects Ang II has on renal hemodynamics and mesangial cell growth. Treatment with

ACEIs markedly attenuates glomerular hypertrophy, ameliorates glomerulosclerosis in the renal ablation model (16), and decreases glomerulosclerosis, even in a nonhypertensive model (puromycin aminonucleoside nephropathy) (9). Furthermore, ACEIs attenuate hypertrophy of nonrenal blood vessels independently of their vasodilating effects in animals with hypertension (17). Similar effects on vascular lesions and glomerulosclerosis were seen with AT1 RAs (17). Other antihypertensives, including combination therapy (with vasodilators and diuretics) and calcium channel blockers, have shown varying efficacy. Combination therapy in large doses ameliorated both glomerulosclerosis and glomerular hypertrophy without affecting glomerular pressures (16). In spontaneously hypertensive rats after uninephrectomy, both nifedipine and enalapril prevented glomerular sclerosis and decreased glomerular hypertension and renal hypertrophy. Nifedipine decreased glomerular hypertrophy and sclerosis in desoxycorticosterone acetate-salt hypertension and the renal ablation model without normalizing glomerular pressure. Verapamil, another calcium-channel blocker, has shown differing effects: In the renal ablation model, renal injury was worsened, whereas, in another study, doses insufficient to decrease blood pressure showed protection (12).

Dietary Factors

A high-protein diet accelerates progression of renal disease in rats regardless of the primary injury. Conversely, protection with low-protein diets has been observed in the renal ablation model, Adriamycin nephropathy, nephrotoxic serum nephritis, and in the nonclipped kidney of Goldblatt hypertensive rats (95,96). The studies are difficult to assess, because altering dietary protein also results in change in other dietary components. Postulated dietary mediators of progressive renal disease include calcium, salt, phosphate, and fat. Reduction in caloric intake per se may be pivotal in the protection against progressive injury (32). A low-protein diet slows progression in the nonhypertensive puromycin aminonucleoside nephropathy model; when combined with ACEI, sclerosis was even reversed. A high-protein diet that accelerates progression augments gene expression of the renin-angiotensin system both in normal rats and in those with renal ablation; this provides a potential basis for the augmented effects of the combined ACEI and low-protein therapy. Among other mechanisms postulated for the effect of low-protein diets are altered T-cell function, decreases in macrophage influx, calcium-phosphate precipitation-induced tubular injury, proteinuria, and oxygen radicals (97).

Other dietary manipulations shown to affect glomerulosclerosis include salt. A low-salt diet decreased systemic blood pressure and attenuated glomerular hypertrophy and sclerosis in the remnant kidney model. Stimulation of glomerular growth by androgens did not affect intraglomerular pressures but increased sclerosis (94). A high-salt diet increased glomerular volume, sclerosis, and proteinuria in

the ablation model without affecting arterial or intraglomerular pressures (21). Thus, in addition to its well-known effect on blood pressure, salt restriction affects glomerular growth.

A further caveat in extrapolating from these studies is to consider the differences in the experimental models and human renal disease (97). The renal ablation model in the rat is characterized by marked compensatory growth as well as ongoing maturational growth. Rats continue to have renal, especially glomerular, growth during most of their life span; human glomerular growth is complete when body growth is completed. Therefore, the effects of restricted diets that affect both maturational and pathophysiologic growth processes may be more extreme in rats than they are in humans.

Lipids and Hyperlipidemia

Lipids are important in modulating glomerular sclerosis in rats; analogous studies in humans are incomplete (64,98). Hypercholesterolemia per se appears to have little effect on glomerular injury in humans or in animal models. However, glomerular injury was increased in experimental models of kidney disease when excess cholesterol was added to diets of rats with preexisting glomerular disease, ablation nephropathy, or hypertension. Histologic evidence of abnormal renal lipid accumulation has long been noted (9). Glomerular disease has been reported in the rare familial disease, lecithin cholesterol acyltransferase deficiency, and with excess apolipoprotein E. However, renal disease is not typical in the more common forms of primary hyperlipidemias. Patients with minimal-change disease or membranous glomerulonephritis, characterized by hyperlipidemia as part of their nephrotic syndrome, usually do not develop glomerular scarring. Evidence of the effects of manipulation of lipids is currently limited to animal studies (64).

Lipoprotein levels are also modulated by severe proteinuria. Proteinuria itself has been proposed to be injurious by affecting glomerular mesangial and epithelial cells or by cast formation with subsequent tubular epithelial damage and interstitial inflammation (99). When glomerular disease is accompanied by severe proteinuria, the prognosis is worse. Whether proteinuria is merely a marker of injury or a contributor to progressive injury has been debated.

Glomerulosclerosis shares several features with atherosclerosis: Both are affected by macrophages, PDGF, and lipids. Macrophage accumulation resulting from high cholesterol levels has been postulated to be a key early step for glomerulosclerosis. These cells are potential sources of numerous cytokines and eicosanoids that affect the glomerulus (64,98). Support for this hypothesis is seen with the protective effects of maneuvers that decrease macrophage influx (100). In a rat model of UUO, administration of ACEI ameliorated interstitial monocyte/macrophage infiltration and decreased fibrosis (101). However, macrophages may also play a benefi-

cial role in scarring. The specific role of the macrophage AT1a receptor in renal fibrosis was examined in studies of bone marrow transplantation in wild-type mice with UUO mice reconstituted with either wild-type macrophages or macrophages devoid of the AT1a receptor. There was more severe interstitial fibrosis in mice with the AT1a-deficient macrophages even though fewer infiltrating macrophages were observed, suggesting that the macrophage AT1a receptor functions to protect the kidney from fibrogenesis (102).

Interesting new data have pointed to the importance of the tubulointerstitial lesion in progression. Elegant morphometric studies of human diabetic nephropathy show that the earliest changes in the interstitium are due to an increase in total interstitial cell volume (which may represent increased cell size and/or number), preceding the accumulation of interstitial collagen (103). This is in stark contrast to the diabetic mesangial lesion in which the expanded mesangial area is largely due to increased matrix accumulation rather than hypercellularity. Further understanding of the nature of these interstitial cells, which do not appear to be accounted for by infiltrating lymphocytes and/or macrophages, will shed additional light onto an important pathogenetic mechanism in progressive diabetic nephropathy. These cells could possibly represent interstitial myofibroblasts, postulated to play a key role in interstitial fibrosis. These activated interstitial cells are a major source of collagen synthesis, and increased expression of α -smooth muscle actin, a marker of myofibroblasts, predicts progressive renal dysfunction both in human and experimental renal disease. The source of myofibroblasts is a topic of controversy. Bone marrow-derived or potential renal stem cells may give rise not only to interstitial cells but also to regenerating parenchymal cells (104).

Epithelial-mesenchymal transformation is another possible mechanism for generation of interstitial myofibroblasts (105). This seamless plasticity of cells changing from epithelial to mesenchymal phenotypes exists during early development. Data indicate that epithelial-mesenchymal transformation may also occur in the adult after injury. Injured tubular epithelial cells can change phenotype both *in vivo* and *in vitro*, with *de novo* expression of a fibroblast-specific protein (FSP1) and possibly migrate into the interstitium as myofibroblasts. The components of the surrounding matrix regulate this process.

Obesity and Renal Scarring

Obesity in adult and pediatric populations is increasing at an epidemic proportion in the United States and other industrialized countries. The prevalence of obesity in childhood and adolescence ranges from 12 to 40% of the population (106). Obesity has been shown to be a precursor to various disorders, including hypertension, type II diabetes mellitus, lipid abnormalities, obstructive sleep apnea, and orthopedic problems. Recently, obesity has also been recognized to lead to

glomerulosclerosis. Glomerular hypertrophy is a common feature in obesity-associated FSGS and may be implicated in its genesis. Other additional mechanisms contributing to sclerosis have been suggested, including hyperlipidemia, hyperfiltration, glomerular hypertension, reactive oxygen species, and abnormal growth factor environment (107). In particular, hyperinsulinemia may contribute to the genesis of the glomerulomegaly (106). The pediatric patients reported in a study of obesity-linked FSGS were all African American, nephrotic, and had rapid deterioration in renal function, a finding that contrasts a large review of obesity-related glomerulopathy in adults, in which patients were more often white, had less than nephrotic range proteinuria, and had slow progression (108,109). Renal biopsies revealed some features suggestive of a contribution of diabetic injury, including glomerulomegaly, mesangial matrix expansion, and glomerular basement membrane thickening, in addition to the segmental sclerosis. Of note, weight reduction dramatically reduced proteinuria in some of these patients. Approaches with combined therapies are now being investigated. Experimental studies suggest that inhibition of the renin angiotensin system and HMG Co-A reductase inhibitor (so-called statins) have further beneficial effects in a severe experimental nephropathy model (110).

Obese patients are particularly at risk for developing glomerulopathy in the setting of additional injuries. Thus, among patients undergoing unilateral nephrectomy, approximately one-fourth had significant proteinuria. More than one-half of these patients also had renal insufficiency associated with a significantly higher body mass index (BMI) compared to those with preserved renal function (111). The adverse effect of obesity in addition to other risk factors has also been shown in a transplant setting, in which renal transplant recipients with elevated BMI showed inferior patient survival compared to patients with lower BMI. This elevated BMI was also associated with worse graft survival independent of patient survival (112).

Recent studies have examined the possible role of leptin in obesity. Leptin is the product of the *ob* gene and is produced by adipose tissue. Its concentration in plasma is related to the total amount of body fat. Administration of leptin to mice with a genetic defect in its production, the *ob/ob* mice, increases energy expenditure, reduces food intake, and causes loss of body weight, mediated through the leptin receptor localized in the hypothalamus. Leptin may also have direct tissue effects. Some patients with obesity have high circulating leptin levels. *In vitro* and *in vivo* studies support a moderate effect of leptin to promote growth and profibrogenic mechanisms, such as increased TGF β and collagen type IV expression (113).

Thrombosis/Fibrinolysis

Altered hemostasis is postulated to be another mechanism for progressive renal disease. Several anticoagulant agents

and platelet inhibitors ameliorate glomerulosclerosis *in vivo* and affect the proliferation of glomerular cells in culture. Heparin is of particular interest, because epithelial cells produce a heparin-like substance that inhibits mesangial cells. Fractions of heparin, both with and without anticoagulant activity, when added to cell cultures decrease glomerulosclerosis and suppress mesangial cell growth and matrix production. Thromboxane is another vasoactive substance that affects coagulation and renal injury. Antagonism of thromboxane's actions is protective in several forms of progressive renal disease (9). Mechanisms may relate to prevention of microthrombi, a finding seen with severe injury, or prevention of platelet and monocyte activation with ensuing release of cytokines.

The plasmin-plasminogen activator system is comprised of the plasminogen activators and their inhibitors, which together modulate the production of plasmin. Plasmin, which is generated from the inactive precursor plasminogen by the action of plasminogen activators, is not only the primary effector of fibrinolysis but also a major contributor to the degradation of matrix glycoproteins and vascular remodeling (39,114). PAI-1 modulates plasminogen activation, and thereby fibrinolytic activity, by inhibiting tissue-type plasminogen activator and urokinase-type plasminogen activator. Increased PAI-1 levels have been identified in atherosclerosis, in some patients with myocardial infarction, in diabetics, and in animal models of glomerulosclerosis (39,41,115). A PAI-1 polymorphism (4G vs. 5G) has been associated with increased risk for cardiovascular complications in diabetics (39). Interestingly, Ang, in addition to its established effects on vasoconstriction and as a growth factor, increases PAI-1 expression, and aldosterone enhances this effect (40,42). Thus, Ang inhibition has the potential to modulate thrombotic/fibrinolytic and remodeling mechanisms (114–116) (see Growth Factors).

CLINICAL FACTORS THAT INFLUENCE PROGRESSION

Severity of Initial Renal Damage

The renal parenchyma in two normal kidneys has more than adequate reserve. Loss of even one-half of the total renal parenchyma (uninephrectomy) results in prompt compensation by the remaining tissue. Within 2 to 3 months, the remaining kidney increases in size by one-half, and the GFR is within 10 to 20% of the prenephrectomy level and therefore adequate to maintain metabolic function of a normal individual. While these compensatory responses return renal mass and GFR toward normal values, the compensatory response places the kidney at increased risk for progressive renal damage. For example, adults who have lost one kidney because of trauma or individuals who donate a kidney for transplantation have a slightly higher incidence of hypertension and more pro-

teinuria than the normal population. Similarly, individuals with unilateral renal agenesis are at greater risk for progressive renal damage (117,118). Thus, the loss of even 50% of renal parenchyma does expose the remaining nephron population to a small but clinically significant risk for renal damage. Greater nephron loss brings greater risk for progressive renal damage. The reason for this deterioration likely relates to limited renal reserve and increased risk of progressive structural damage from superimposed injury from infection, dehydration, drugs, and toxins that activate or promote mechanisms outlined in the preceding sections. The extent of initial nephron loss necessary for initiating progression, while unclear, probably exceeds 75% of renal mass. A study of 14 patients undergoing up to 7/8 nephrectomy for removal of tumor showed mild to severe proteinuria in most. Renal biopsies in four who had lost the most renal mass showed focal segmental or global glomerulosclerosis (119). Most renal disease in humans that leads to chronic renal failure is diffuse; the remaining nephrons have great heterogeneity in function. Whereas some nephrons are severely affected, others have enhanced function. However, if the removal/destruction of renal parenchyma is extensive, this apparent initial compensation may subsequently result in a progressive downward course.

Removal of one kidney in children (e.g., due to Wilms' tumor) has somewhat more ominous consequences than loss of nephrons in adults: Renal growth was most marked in those who had surgery at a younger age, and this increased kidney growth was associated with microalbuminuria, which developed in 11 of 34 patients (120). Likewise, in patients with unilateral renal agenesis there is significantly increased risk for proteinuria (in 19%), hypertension (47%) and renal insufficiency (13%), with death due to renal disease in 6 of 157 patients in a large series (121). These findings suggest that the number of remnant nephrons in the congenital solitary kidney may, in fact, be decreased (i.e., hypogenesis), thereby representing a more severe form of reduction in nephron population than surgical unilateral nephrectomy. The possibility that the remnant glomeruli of congenital solitary kidney are under greater hypertrophic stress is indeed supported by quantitative morphometric studies. The volume of each glomerulus in solitary kidneys was found to be 5 to 6 times normal, a value close to that found in oligomeganephronia, an extreme condition of decreased nephron number (see Nature of Insult and Host Factors) (122).

Nature of Insult and Host Factors

The initial renal injury may be limited or it may affect all nephrons; it may be a one-time episode, continuous, or recurrent (Fig. 66.4). A single episode affecting a limited number of nephrons, as occurs with pyelonephritis, usually does not have long-term consequences. Multiple episodes that damage many nephrons lead to progression and renal

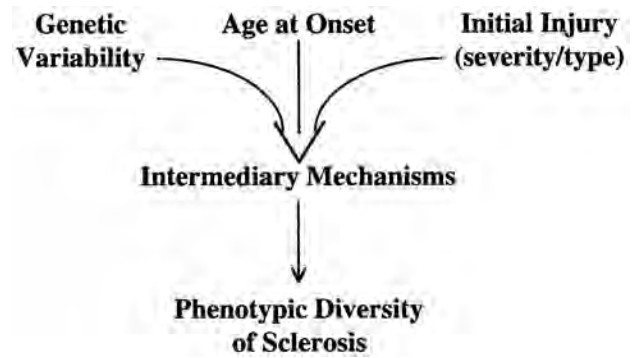

FIGURE 66.4. Diversity of morphologic appearance of sclerosis reflects specific contributions of an individual's genetic make-up, type and severity of the initial injury, and the patient's age at disease onset. These factors activate diverse intermediary mechanisms that determine the course of renal damage.

failure. Diseases that are diffuse, such as poststreptococcal glomerulonephritis, usually do not damage glomerular structure severely enough to cause progressive injury and sclerosis. However, injury that is diffuse and either prolonged or recurrent, such as occurs in diabetes, lupus nephritis, or membranoproliferative glomerulonephritis, increases the risk of irreversible damage and progressive renal injury. Delay in therapy prolongs the initial injury and potentially increases both the initial and subsequent renal damage.

Individual patients also vary in their susceptibility to particular injuries (Fig. 66.4). For example, individual differences in susceptibility to renal damage have been described in patients with urinary tract infections; the uroepithelium in some patients binds bacteria more avidly than in others (see Chapter 53). Heightened inflammatory response to immunologic or infectious injury leads to enhanced leukocyte infiltration and greater release of free radicals, which also damage renal parenchyma. (See also Chapter 29.) Individual differences in host response may contribute to the great variability in the degree of renal injury in patients with hemolytic uremic syndrome. A recent study suggests that weakened or absent PI antigen expression on red blood cells increases risk for hemolytic uremic syndrome and for more severe involvement (123).

Predisposition of certain populations to the pathophysiologic factors outlined in the preceding section also varies. Glomerular size is greater in African Americans than in whites (124). The Pima Indians, who have a high incidence of diabetic nephropathy, also have larger glomeruli, even before development of renal disease (125). The increased risk of development of end-stage renal disease does not only reflect increased incidence of renal disease in these populations but also reflects the course of progression for given diseases. Thus, even when controlled for blood pressure levels, the risk of end-stage renal disease associated with hypertension is greater in African Americans than whites. Microalbuminuria is also more prevalent in African

American versus white hypertensive patients even at similar age, BMI, degree or duration of hypertension, or antihypertensive treatment (126). Hypertension and moderate renal insufficiency are associated with extensive global glomerulosclerosis in the African American patients, far greater than reported in other populations (127). The phenotype of this global glomerulosclerosis differs in African Americans versus whites, with more of the solidified type (i.e., replacement of the glomerular tuft by collagen) in the former and the usual obsolescent type (i.e., collagenous material filling in Bowman's space with a globally sclerosed glomerulus) prevalent in whites. These findings suggest possible different mechanisms of glomerular scarring associated with hypertension in these two populations (128). Of note, the African American Study of Kidney Disease trial demonstrated that ACEI was a superior treatment to preserve GFR in African Americans with moderate renal insufficiency and hypertension, although multiple additional antihypertensive drugs and higher doses were necessary to achieve target blood pressure goals (129).

It is possible that factors that underlie kidney development and glomerular number/size also contribute to the increased susceptibility of African Americans to develop end-stage renal disease. The course of lupus nephritis in a prospective, randomized National Institutes of Health trial was more severe in African Americans than whites, with more extensive crescent formation and interstitial fibrosis and greater likelihood of end-stage renal disease in the former population (130). Even the manifestations of human immunodeficiency virus (HIV) infection in the kidney differ markedly in the two populations: HIV-associated renal disease in African Americans is typically an aggressive FSGS, contrasting HIV-positive whites with renal disease who more frequently have immune-complex-mediated glomerulonephritides (131). These observations underscore the importance of genetic factors in response to injuries.

Impact of Genetics

The extent or virulence of a given disease varies among individuals. Even when patients are stricken with a given disease, the risk of progressive organ damage varies greatly (Fig. 66.4). Only a portion of patients with diabetes mellitus, IgA nephropathy, or postinfectious glomerulonephritis develop progressive glomerulosclerosis. Thus, a patient's genetic burden impacts assessment of organ damage due to increased variability of the disease process and also influences the choice and efficacy of therapeutic interventions.

Occurrence of renal diseases has been linked to genotype. In African-Americans, HLA-DR3 was consistently associated with end-stage renal disease due to hypertension, diabetic nephropathy due to insulin-dependent diabetes mellitus, or membranous glomerulonephritis. Excess HLA-D3 was present in whites with end-stage renal disease when end-stage renal dis-

ease was caused by insulin-dependent diabetes mellitus, lupus, or membranous glomerulonephritis, although no association was found with end-stage renal disease due to hypertension, IgA nephropathy, or FSGS. The possibility that the HLA class II association is due to linkage disequilibrium with the HLA class III TNF locus is currently being investigated, owing to the close physical proximity of these two genes on chromosome 6 (132). Taken together, differences in genetic make-up among different racial groups appear to influence the occurrence of renal disease.

Genetic background also modulates susceptibility in experimental models. The hypertrophic response, or lack thereof, and subsequent development of sclerosis are dependent on the genetic background, suggesting that complex genetic traits modulate the response of glomerular cells to pathogenic stimuli. Mice with reduced nephron number due to a radiation-induced mutation that results in approximately 50% nephron reduction in association with oligosyndactyly (*Os^{+/+}*) developed severe glomerular enlargement and sclerosis when this abnormality occurred on the sclerosis-prone ROP genetic background but not in the sclerosis-resistant C57BL6/J strain (133). Glomerular hypertrophy was proportional to reduction of nephron mass in the former strain. In contrast, a threshold for glomerular size was observed in the C57BL6/J mice.

Susceptibility may be influenced by renin gene polymorphisms. Some mouse strains (e.g., C57BL6/J) have one gene (*Ren-1^c*), whereas other strains (e.g., 129) have two (*Ren-1^d* and *Ren-2*) (134). The *Ren-1* genes govern expression of renin in the kidney in the juxtaglomerular apparatuses, whereas the *Ren-2* gene controls submaxillary gland renin expression and has very low renal expression. Mice with two renin genes (i.e., 129 strain) have tenfold higher plasma renin activity, angiotensin-dependent hypertension, and increased blood pressure and cardiac and renal hypertrophic responses to salt compared to one renin gene mice (i.e., C57BL6/J). Renin gene status, thus, could have a major effect on susceptibility to injuries where the renin angiotensin aldosterone system plays a role (134).

There is also accumulating evidence that genes in humans modulate the course and rate of organ damage. Polymorphisms in several genes within the RAS system, including ACE, angiotensinogen, and the angiotensin type 1 receptor, have been linked with cardiovascular and renal disorders, including diabetic nephropathy, IgA nephropathy, and uropathies (135–139). Polymorphisms of all three genes were evaluated in patients with IgA nephropathy as well as in diabetics (135,136,140,141). The ACE DD genotype frequency was increased in the patients who ultimately experienced progressive decline in renal function during follow-up compared to those whose function remained stable over the same time. Notably, exclusion of patients with known risk factors for progression, such as hypertension and significant proteinuria, strengthened the association of the DD genotype and progression of renal dysfunction in IgA nephropathy (140). Although environ-

mental and other genetic factors may contribute, similar ACE polymorphism distributions in progressive IgA nephropathy in genetically distinct and geographically remote populations point to a significant functional role for the deletion allele of the ACE polymorphism (139,141).

Intron 16 encompassing the ACE I/D segment has a repeated sequence, comprising the terminal bases of one end of the "insert" and flanking the opposite end. This arrangement suggests a possible origin of the D allele. During meiosis, one of these two repeats could align with the complement of the other, thus producing a "loop-out" of the intervening fragment. This structure implies that the mutational event may actually occur by a deletion rather than insertion (140). Interestingly, in normal as well as diabetic whites, those with the II genotype have the lowest serum ACE levels, DD subjects have the highest, and those with the ID genotype have intermediate levels, supporting that the D allele contributes to the activation of ACE (142). This suggests that the "insert" may contain a silencer element, the absence of which activates the ACE gene. A functional relevance of this genetic variant is supported by the observation that normotensive men with the DD genotype had increased systemic pressor responsiveness to infusion of Ang I when compared with II genotype (143). Moreover, the plasma Ang II levels were also higher across the dose range of angiotensin I infusion, implying increased generation of Ang II in the DD individuals. It is interesting that in a recent large-scale study of diabetics, in addition to ACE polymorphism, an angiotensinogen gene polymorphism also predicted occurrence of nephropathy and progression of renal dysfunction. The angiotensinogen polymorphism modulates circulating angiotensinogen levels and, together with ACE I/D phenotype, affects constitutive levels of Ang II and, therefore, renal parenchymal damage and response to Ang inhibition. Thus, it appears that these polymorphic loci likely directly affect renal disease and are not just markers for another gene variant which more directly contributes to progression. Polymorphisms of TGF β are also implicated in hypertension and progressive fibrosis. The Arg 25 polymorphism may be increased in African Americans, who also may have greater elevation of circulating TGF β when they reach end-stage renal disease, compared to whites (144).

Congenital Disease/Nephron Number

Several factors contribute to the importance of age at time of injury as a variable affecting progression (Fig. 66.4). First, duration of the disease process before diagnosis and institution of therapy may be prolonged. Also, underlying developmental/structural abnormalities amplify the destructive process because of the decreased number of nephrons in these congenital abnormalities. In addition, these disorders reflect abnormal organization of the nephron, which may predispose it to subsequent injury.

There is clinical and experimental evidence that loss of nephrons early in life leads to a more active growth response

that is followed by a greater tendency to glomerulosclerosis later on (117,118). Children with agenesis of one kidney show exaggerated glomerular hypertrophy and glomerulosclerosis relative to individuals who have a nephrectomy later in life. In the child, increased metabolic load associated with growth may augment these risks for injury. Focal and segmental glomerulosclerosis is particularly pronounced and often commences in the deep nephrons, which develop first and attain larger glomerular size. These changes are postulated to relate to the environment of the young host, including growth factors that, when overstimulated, may promote scarring. In a three-dimensional study of the distribution of lesions in idiopathic FSGS, children showed a predominance of peripheral, small lesions, in contrast to adults, who showed frequent lesions with a hilar component. The location of sclerosis (i.e., hilar vs. peripheral) and the extent of involvement may have impact on the course and response to therapy (145). Of interest, children with FSGS may have a good response to intensive treatment with IV methylprednisolone and oral alkylating agents (146).

Recently, variations in nephron endowment at birth, not related to prematurity, have been recognized. Experimental models have demonstrated that various intrauterine insults, such as gentamicin exposure, hyperglycemia, corticosteroids, and vitamin A deficiency can result in decreased nephron number (147–149). Decreased nephron number has been postulated to occur secondary to low term birth weight, defined as less than 2500 g. Lower nephron number may increase risk of renal disease and may be one of the mechanisms whereby individuals with low birth weight have increased incidence of progressive renal disease in adulthood (150). These fewer nephrons are postulated to be under greater hemodynamic stress, thus contributing to progressive sclerosis. Of interest, glomerular size in normal African Americans is larger than in whites and could possibly reflect smaller nephron number (124). This finding could contribute to the increased incidence of end-stage renal disease in African Americans compared to whites. Mechanisms other than hemodynamic stress, which could underlie these differences in normal glomerular populations and also relate to increased incidence of end-stage renal disease, include functional polymorphisms of genes that are involved both in renal and glomerular development and contribute to amplified scarring mechanisms, such as the renin-angiotensin system (151).

Glomerular Growth and Glomerulosclerosis

Abnormal glomerular growth and glomerulosclerosis are associated in many diseases (151). The most extreme glomerulomegaly described in humans is that seen in oligomeganephronia. This congenital renal disease is characterized by a decreased number of nephrons, each of which is markedly enlarged, and an increase in FSGS (152). In diabetic nephropathy, the number of functioning nephrons is normal at the

early stage, but the glomeruli enlarge and hyperfunction from the onset of diabetes (153,154). The severity of glomerular sclerosis correlates with the degree of glomerular growth. Mean glomerular size and mesangial volumes are smaller in diabetic patients after pancreas and renal transplantation than in control renal transplant patients (155).

In patients with FSGS, the processes linked to glomerular growth appear to be primary and not secondary to nephron loss (Fig. 66.3) (i.e., glomerular growth precedes nephron dropout due to sclerosis). Kidney biopsies from patients with FSGS or minimal-change disease were compared with tissue from patients with no renal disease. Both adults and children with FSGS had substantially larger glomeruli than age-matched normal individuals or those with minimal-change nephrotic syndrome (156). Children with apparent minimal-change disease who in repeat biopsies progressed to overt FSGS had enlarged glomeruli in their initial biopsies, compared with glomeruli of age-matched normal controls. Patients with minimal-change disease who continued with typical benign clinical courses and who, on repeat biopsies (performed in two-thirds) continued with minimal-change disease, had normal-sized glomeruli on the initial biopsy. In patients aged 1 to 5 years with minimal-change disease, initial glomerular size was equal to or less than that of autopsy control. These patients continued to have a benign clinical course. In contrast, all those with an initial glomerular size more than 1.5 times the average size of normal glomeruli developed FSGS. Thus, this cutoff level of glomerular size was a highly sensitive and specific predictor of those patients who develop FSGS among those with an initial diagnosis of apparent minimal-change disease. Increased glomerular size also predicted subsequent glomerular sclerosis in the setting of recurrent FSGS in the transplant kidney. Thus, children who did not develop FSGS in their transplants did not show increased glomerular size in the initial months after transplantation. In contrast, children who developed recurrent FSGS had marked abnormal glomerular growth, which preceded overt manifestation of FSGS (157). The linkage of growth with glomerular sclerosis has been noted in patients with reflux nephropathy and those with sickle cell glomerulopathy, obesity, HIV nephropathy, and a remnant kidney resulting from removal of more than one kidney (9,119). Glomerular enlargement could therefore be a marker in the early phase of disease—before overt sclerosis is detectable—for aberrant growth factor expression ultimately leading to scarring of the kidney. Molecular detection of these early processes could potentially be an even earlier, more sensitive marker of progression.

CLINICAL IMPLICATIONS/INTERVENTION

Treatments Associated with Progression

Treatments directed to some of the complications of renal failure may accelerate progression. We describe one exam-

ple: growth hormone. Other factors, such as calcium and vitamin D, also affect progression.

Growth Hormone

rhGH has been used to stimulate growth in children who are growth retarded owing to renal failure and also as treatment of short stature after renal transplantation where its effects have been impressive (158). However, experimental evidence and clinical experience have raised questions about whether treatment may accelerate progression in compromised kidneys and, in rats, injure even normal kidneys. rhGH given to rats with renal ablation accelerated progression of glomerulosclerosis. Normal young rats treated chronically with hGH developed glomerulosclerosis (31). Although renal function in the latter group was not affected, the severity of the lesions indicated that functional potential had been compromised. In one clinical report, eight children who were post-renal transplant and growth retarded were given hGH for 6 to 21 months. In four of these patients, creatinine clearances decreased, one sufficient to cause the physician to stop treatment (159). Recent study of children with renal transplants showed, although renal function was not compromised, there was more proximal tubule atrophy in patients receiving hGH than in transplanted patients without hGH treatment (160). Increased urinary albumin excretion rate was observed in children with short stature who received hGH even without underlying renal disease (161). These studies hint that treatment of short stature, whether accompanying renal failure or not, may be a double-edged sword. There is somatic growth. However, because hGH can enhance B- and T-lymphocyte function, development of cytotoxic T cells, and natural killer cell activity, there is the possibility of increased acute and chronic rejection (162–164). The proinflammatory properties of hGH can also accelerate sclerosis (164). The study further suggests that the destructive process takes root and progresses, even when at the onset of growth hormone treatment renal damage is not profound or there is no initial renal damage. A recent study showed that rhGH in transplanted children did result in increased somatic growth. There was not an observed increase in acute rejection, although, of note, immunosuppression was such that 2 of the 68 patients developed posttransplant lymphoproliferative disease, and one developed Hodgkin's lymphoma. Furthermore, two of the rhGH-treated patients had graft loss due to chronic allograft nephropathy, compared to one graft loss due to noncompliance in the control group (165).

Treatment Used to Slow Progression

Intervention strategies aimed at slowing progression include early detection of patients with primary diseases,

diet modification, antihypertensive drugs, and therapy aimed at forestalling diabetic nephropathy.

Early Detection and Treatment

Identification of those with renal disease is important in initiating treatment to slow progression. Sonography of fetuses during gestation identifies those with urologic abnormalities. Preschool screening of urine for abnormalities has been disappointing in detecting urinary tract infections and glomerular disease. Programs now are directed at identifying children with urinary tract infections and/or urinary tract abnormalities in the first 1 to 2 years of life, when treatment will have more impact (see also Chapter 53). If effective, these measures would detect children with urinary tract abnormalities, who currently constitute the largest population of children developing chronic renal failure (Fig. 66.1). Microalbuminuria, most commonly used to detect early diabetic nephropathy, may prove to be a useful indicator of renal damage in reflux nephropathy and hypertension (166,167). Although some patients with ureteral reflux/obstruction corrected before the age of 1 year still progress to end-stage renal disease, early detection and treatment are likely beneficial (168). Probability of progressive renal damage relates to the extent of the original damage, associated abnormalities, superimposed infections or nephrotoxic antibiotics, and compensatory changes that are discussed in this chapter.

Potential Regression of Sclerosis

Glomerulosclerosis is an ongoing, dynamic process. Various diseases show heterogeneous appearance of glomerulosclerosis. Thus, nodular, collapsing, cellular, hilar, peripheral, or "tip" (i.e., at the tubular pole) patterns of sclerosis have been postulated to have etiologic and also prognostic significance and may also reflect distinct mechanisms of sclerosis (169) (Fig. 66.4). Glomeruli also show heterogeneous injury at a given time in an individual patient. Heterogeneity in glomerulosclerosis was examined in humans with FSGS. This relationship, as well as the response to therapy, was assessed in animals with progressive renal failure after 5/6 nephrectomy. Morphologic analyses of the size and degree of sclerosis of individual glomeruli were done by three-dimensional methods (16,169). A biphasic relationship between glomerular hypertrophy and sclerosis was noted. There was a strong positive correlation between these two indices in glomeruli with early sclerosis, whereas the correlation was negative in glomeruli with advanced sclerosis (Fig. 66.5). This biphasic pattern was maintained after treatment with antihypertensives in the rat; the effectiveness of treatment appeared to depend on the stage of glomeruli along the pathway to sclerosis. Rats with remnant kidneys treated with an ACEI after injury were established and showed continued progression in the glomeruli

FIGURE 66.5. Relationship of glomerular hypertrophy and sclerosis in individual glomeruli within one kidney at 12 weeks after 5/6 nephrectomy. When sclerosis index (0–4 scale by serial section) and maximum planar area (PAmax) were evaluated for each of 22 glomeruli in a single remnant rat kidney 12 weeks after subtotal nephrectomy, a significant correlation with a biphasic pattern was found between these parameters. Thus, there was a negative correlation for the glomeruli with advanced sclerosis and a positive correlation for the glomeruli with early-stage sclerosis, pointing to a potential linkage between the pathogenesis of glomerular hypertrophy and sclerosis. (From Fogo A, Ichikawa I. Evidence for the central role of glomerular growth promoters in the development of sclerosis. *Semin Nephrol* 1989;9:329–342, with permission.)

that were already severely sclerotic. In contrast, glomeruli with only moderate degrees of sclerosis at the onset of treatment were protected by treatment.

Regression of injury can be accomplished. A shift in the balance of synthesis/degradation must occur to accomplish regression of sclerosis. Most challenging is the remodeling of obliterated capillary lumina (Table 66.1). Injured cells have to be replenished, repaired, or deleted to regenerate or restore capillary loops that may affect filtration. The following obstacles have to be overcome: (a) the net loss of endothelial cells, which must regenerate; (b) the variable increase in mesangial cells before the sclerotic acellular lesion develops, and mesangial cells must regrow; and (c) the limited growth capacity of the visceral epithelial cell. New glomeruli cannot be generated after term birth in humans, so regeneration of open loops has to occur by new capillary loop growth within injured glomeruli, with reabsorption of the sclerosed segments within that glomerulus. Regression could thus be mediated by new growth of capillaries, which take the place of the sclerosed, reabsorbed segments. Evidence in humans and animals indicate that glomerular growth with injury may indeed be achieved by lengthening or branching of the capillary loops (23–26). Consideration of the biologic potential of each of these processes in the glomerulus indicates that remodeling and regression of glomerulosclerosis indeed is theoretically possible. Emerging data show that this can actually be accomplished in practice as well.

TABLE 66.1. POTENTIAL MECHANISMS OF REGRESSION VS. PROGRESSION OF GLOMERULOSCLEROSIS

Factors favoring regression	Factors favoring progression
Proteases expressed in glomerulus (e.g., MMP-2, MMP-9, t-PA, u-PA)	Protease inhibitors expressed in glomerulus (e.g., TIMP-1, TIMP-2, PAI-1)
Factors decreasing ECM synthesis (e.g., ACEI, AT1RA)	Resistance to proteolysis (e.g., glycation, cross-linking)
Growth factors stimulating cell regeneration (e.g., VEGF)	Growth factors causing increased ECM synthesis (e.g., angiotensin, TGF- β)
New capillary growth within the glomerulus (capillary lengthening/branching)	Growth factors causing apoptosis Limited growth potential of the podocyte No glomerulogenesis after birth

ACEI, angiotensin I-converting enzyme inhibitor; ECM, extracellular matrix; MMP, matrix metalloproteinase; PAI, plasminogen activator inhibitor; TGF, transforming growth factor; TIMP, tissue inhibitor of metalloproteinase; t-PA, tissue-type plasminogen activator; u-PA, urokinase-type plasminogen activator; VEGF, vascular endothelial growth factor.

In contrast to the extensive investigation of factors promoting matrix synthesis, modulators of increased matrix degradation, which could allow resolution, have not been well characterized. Several proteases and protease inhibitors are expressed in the glomerulus, indicating that modulation of matrix can occur (114,115). Recent evidence has added PAI-1 to this array of matrix modulators in the kidney. PAI-1 inhibits not only fibrinolysis but also proteolysis by inhibiting activation of plasminogen activators. PAI-1 has been linked to sclerosis, and regression of sclerosis is tightly linked to its downregulation (114–116).

Higher doses of an ACEI or AT1RA (having the same hemodynamic effects) resulted in regression of existing glomerulosclerosis, linked to decreased extracellular matrix synthesis with decreased TGF β , and increased extracellular matrix degradation, linked to marked decrease of PAI-1 (115). In a study of rats with puromycin aminonucleoside nephropathy that were treated with combined therapy—low-protein diet and an ACEI—this potential to decrease established glomerulosclerosis also was demonstrated (170). These findings emphasize that early aggressive treatment is important not only in limiting initial injury but also in controlling progression. The application of these conclusions has been investigated in diabetic patients with normal renal function and no overt proteinuria. The results show that early aggressive therapy with an ACEI given to diabetics with normal blood pressure and GFR maintained GFR and decreased proteinuria (171,172). Either ACEI or AT1RA was also effective in slowing progression in hypertensive patients with established diabetic nephropathy (173–175). Cure of diabetes by pancreas transplant in patients with

moderate diabetic nephropathy resulted in regression of existing glomerulosclerosis and tubulointerstitial fibrosis over a 10-year period (176). Regression of existing lesions also occurred in relatively early IgA nephropathy in response to high-dose corticosteroids and tonsillectomy (177).

Dietary Protein

A relationship between diet and progressive loss of renal function has long been recognized. The potentially nephrotoxic factors in the diet include protein, carbohydrate, lipid, calcium, phosphorus, and sodium. Among these, low-protein diets have been studied most for several reasons:

1. Low-protein diets alleviate uremic symptoms.
2. Compared with other dietary constituents, dietary protein intake and output can be monitored. Protein restriction preserves renal function and morphology in several rat models of chronic renal failure (96).

Protein restriction has several effects that may ameliorate the pathophysiologic processes leading to progressive renal failure. These include reduction in glomerular perfusion and pressure and decrease in glomerular hypertrophy. Protein restriction also decreases serum lipid levels, reduces immune cell activation, and alters cellular growth factors. The recently published data of the Modification of Diet in Renal Disease study did not demonstrate the expected dramatic effects of protein restriction on progression, perhaps not surprising in view of the diverse underlying conditions in the populations studied (178). The resistance to therapy in some diseases, such as polycystic kidney disease, also underscores the heterogeneous mechanisms in different renal diseases. Furthermore, protein restriction has side effects that include malnutrition, which is emerging as an important contributor to morbidity and mortality of patients with end-stage renal disease. Overall, the current sentiment in treating children with progressive renal disease is to not restrict the diet other than to limit protein and phosphorus to recommended daily allowance levels.

Antihypertensive Treatment

Long-term clinical evidence clearly demonstrates the benefit of reducing blood pressure in patients with hypertension with or without renal disease. Untoward clinical events occur not only in the relatively few individuals with severe disease, but also affect the large number of patients with only mild hypertension. This recognition has led to changes in both the definition of hypertension and treatment recommendations. The Joint National Committee on the Detection, Evaluation, and Treatment of High Blood Pressure has, for the first time since the original report in 1977, reclassified normal diastolic blood pressure as less than 85 mm Hg (179). The report also emphasizes the

importance of systolic blood pressure as a predictor of adverse events, in that normal systolic blood pressure is now taken to be less than 130 mm Hg. In parallel, clinical practice has evolved from treating only markedly high blood pressures to intervening when pressures are only modestly elevated. In diabetics, decreased systemic blood pressure below normal levels may benefit progression (171) by decreasing systemic and/or glomerular pressures, as well as modulating specific endothelial-derived factors. Control of blood pressure, however, does not necessarily prevent progression nor does its presence predict inevitable dire consequences. Other factors, such as genetic predisposition and race, may modulate the effects of systemic blood pressure on progression.

Independent of effects on systemic blood pressure, antihypertensive treatment preserves glomerular function and structure through its effects at specific sites within the renal circulation, as well as its nonhemodynamic effects (12,22,180,181). Among the various antihypertensives, ACEIs appear to be most consistent in arresting glomerular destruction in animals (115,180,182). This effect has been ascribed to the intrarenal effects of ACEIs that decrease glomerular pressure. However, the benefits of inhibiting the renin-angiotensin system go beyond systemic or glomerular antihypertensive effects. In this regard, protection similar to that with ACEIs is seen with AT1RA. Furthermore, greater benefit on scarring was observed with higher doses of ACEIs or AT1RAs, although systemic and local glomerular pressures were not further altered. Finally, contrasting potentially adverse effects on glucose and lipid metabolism ascribed to other antihypertensive treatment, notably hydrochlorothiazide, ACEIs may have beneficial effects on potential mediators of the pathophysiologic processes. Therapies that inhibit the renin-angiotensin system appear particularly effective in both human and animal models (181). However, the efficacy in humans has been assessed only by GFR and not by long-term effects on structural lesions. These studies have shown benefit of ACEI over other antihypertensive treatments in both normotensive diabetics and in patients with nondiabetic progressive renal disease (173,182,183).

Another class of antihypertensive vasodilators that is being studied is the calcium antagonists. The results on renal function and histology in animal models are mixed. Several animal models, including diabetes, renal ablation, and several forms of hypertension, showed protection (22,184), but this was not a uniform finding. Calcium-channel blockers appear to have particularly beneficial effects in preserving renal allograft function. The mechanisms for this preservation include decreased vasoconstriction (primarily by dilating the afferent arteriole); augmenting immunosuppression, either directly or by increasing cyclosporine levels; and antiproliferative effects (184). The complementary mechanisms of actions of ACEI and calcium-channel blockers suggest synergistic benefit with combined therapy by decreasing both Ang

II and downstream calcium-mediated effector mechanisms linked to vascular injury (185).

In addition to antihypertensive treatment being applied to a variety of renal diseases, new therapies are aimed at affecting progression in specific disorders. Diabetic nephropathy develops in approximately 40% of diabetics. On average, 17 years after diagnosis of juvenile-onset diabetes, diabetic nephropathy manifests as proteinuria followed by declining renal function within a few years. The dire consequences of diabetic nephropathy and the long preclinical phase before it becomes overt have targeted this entity for intense investigation for therapeutic maneuvers, including control of systemic blood pressure, low-protein diets, strict glucose control, and inhibitors of advanced glycation end products (186). Pancreas transplantation has become more successful in diabetic patients, and early studies indicate that restoring normal insulin control does decrease and even regress structural renal injury (155,176). Future efforts may be directed toward not only altering secondary, intermediary mechanisms of sclerosis but also the cure of the initial disease (e.g., with islet cell transplant in diabetes mellitus).

ASSESSMENT OF EFFICACY OF INTERVENTIONS

To assess which new therapies are most effective, we need to evaluate critically their effects on renal function and structure. The most commonly used indicators of renal function are GFR and proteinuria. Proteinuria has commonly been used as an indicator for progressive renal injury, and a change in proteinuria in response to treatment has been viewed as a beneficial effect of therapy. However, proteinuria is determined by several factors. Thus, proteinuria may reflect an underlying structural injury and disruption in the integrity of the permeability barrier. Proteinuria may also reflect abnormal glomerular hemodynamics in structurally, relatively intact glomeruli. In this regard, high glomerular pressure alters the sieving properties of the glomerular capillary bed. Glomerular hypertension can increase the relative number of large pores postulated to be the sole channel for macromolecular (i.e., protein) transport to the urinary space. Decreased protein excretion does not necessarily reflect improvement in progression of renal disease. This is particularly relevant for interpretation of data from short-term studies in which lessened proteinuria accompanies a decrease in GFR in response to antihypertensive therapy. In these studies, the mechanisms underlying decreased proteinuria include lower glomerular pressure (187). In particular, ACEI, by augmenting bradykinin, decreases efferent arteriolar resistance and, thus, decreases GFR and proteinuria acutely via these reversible hemodynamic effects (18). These ACEI effects make interpretation of clinical trials more challenging, as this decrease in GFR acutely masks anticipated benefit on sclerosing mecha-

nisms, which ultimately result in preserved GFR over a longer time course.

The biopsy is frequently used as a diagnostic tool in nephrology. Based on new insights into pathogenesis, this technique may be used as a prognosticator as well. The renal biopsy may allow us to gauge long-term responses to therapy. Future evaluation may include more sophisticated techniques, such as morphometry, to assess glomerular size or degree of tubulointerstitial injury, *in situ* hybridization, or PCR of specific areas by laser capture microdissection to examine specific abnormal gene expression and its alteration by therapy (188).

Finally, due to the limitations of prospective randomized, controlled studies to address issues such as the proposed pathogenetic mechanisms outlined in this chapter, metaanalysis has been applied to cumulatively study results of clinical trials (189). Although there may be potential bias from selection and heterogeneity of studies, this method may yield answers to some key questions. This approach has been applied to the many studies of effects of antihypertensive treatment on the kidney in diabetes (182).

CONSERVATIVE MANAGEMENT OF CHRONIC RENAL INSUFFICIENCY

RICHARD N. FINE
DILYS A. WHYTE
IVY I. BOYDSTUN

Chronic renal insufficiency (CRI) causes substantial morbidity in virtually every major organ system of the body. Many of these complications can be controlled through diet and medications, a regimen generally termed *conservative management*. This chapter describes these therapies in detail. Moreover, CRI inevitably progresses to end-stage renal disease (ESRD), which is, by definition, a degree of renal insufficiency that requires either dialysis or renal transplantation to sustain life. Because chronic dialysis therapy replaces only some of the ultrafiltration and clearance functions of the native kidneys, the same therapies used during conservative management of CRI must be continued or enhanced during chronic dialysis therapy. Any changes in these treatments required by either peritoneal dialysis or hemodialysis are addressed in the chapters covering these specific treatments. Because renal transplantation restores normal renal function, these conservative measures can generally be discontinued at the time of the procedure, although some of the consequences of long-standing CRI must be addressed after the procedure.

GROWTH RETARDATION IN CHRONIC RENAL INSUFFICIENCY

Etiology of Growth Retardation

Growth retardation is one of the most onerous complications of CRI. The initial use of the therapeutic modalities of dialysis and transplantation was successful in extending the lives of children afflicted with ESRD, but neither treatment was completely successful in restoring normal growth.

The cause of the growth retardation has been considered to be multifactorial. Age at onset of CRI and primary renal disease are clearly correlates of the severity of growth retardation. Metabolic acidosis, inadequate nutritional (caloric) intake, anemia, and renal osteodystrophy are each identified as sufficient contributing factors. However, individual correction of each of these factors was found to be

insufficient to restore normal growth rates. More recently, perturbations of the growth hormone (GH)–insulin-like growth factor (IGF) axis have been shown to be preeminent in altering normal growth patterns in children with CRI, and treatments for these abnormalities have been far more successful.

Although an unequivocal precise defect that impairs linear growth in association with reduced renal function has not been described, the following abnormalities have been identified: (a) reduction in the number of hepatic GH receptors with a concomitant reduction in circulating levels of GH-binding protein; (b) increase in the levels of various IGF-binding proteins, especially IGF-binding protein 3; and (c) reduction in “free” IGF levels. The latter presumably stimulates the epiphyseal growth plate and thus produces increments in linear height.

The classical data of Betts and McGrath (1) published more than a quarter century ago demonstrated that suboptimal growth associated with CRI was apparent during the initial 2 years of life and at the time of puberty. Accelerated growth velocity is normally present during these two time periods, with impairment adversely affecting stature. More recent data from the North American Pediatric Transplant Cooperative Study (NAPRTCS) CRI registry indicate that with current management practices accelerated growth in infants and young children with CRI is possible, but maximization of the pubertal growth spurt remains a challenge (Fig. 67.1).

Even when dialysis is initiated, growth retardation persists, and growth velocity may decrease compared to that occurring in CRI. Because peritoneal dialysis is the modality of choice for infants and young children, and hemodialysis is primarily used for adolescents, it is difficult to determine currently if either modality offers any advantage regarding increments in growth velocity.

Accelerated growth after renal transplantation occurs primarily in infants and preschool-aged children, with

FIGURE 67.1. Change in height standard deviation score (SDS) of patients enrolled in the North American Pediatric Transplant Cooperative Study chronic renal insufficiency (CRI) registry. No improvement during puberty is demonstrated in patients who were older than 12 years of age at enrollment.

school-aged children and adolescents either maintaining normal growth velocity for age or demonstrating a worsening of standard deviation score (SDS). This pattern has not changed for more than a decade despite changes in the immunosuppressive regimens and improvement in patient and graft survival rates as shown by NAPRTCS data.

There are limited data detailing the precise variation in pubertal growth associated with CRI. Schaefer et al. (2) detailed the most extensive study, which demonstrated a reduction in the pubertal height gain in both boys and girls compared to unaffected adolescents. The length of the pubertal growth spurt was also shortened. Most children with CRI do not reach final adult height until after they have developed ESRD and have undergone successful transplantation. Data from NAPRTCS indicate that the mean Z score of 1075 individuals who were at least 19 years of age was -1.51 ; however, 25% had scores of -2.4 or worse, and 10% had scores higher than -3.4 . Although there has been significant improvement in final adult height during the past decade, most of these children do not reach their genetic potential in final height. Importantly, much of the improvement has been related to treatment during CRI rather than growth after transplantation.

Management of Growth Retardation

Optimal management of growth retardation would entail prevention throughout the course of CRI. Because the maximum growth velocity occurs during infancy, a strat-

egy directed toward this patient population has evolved. In addition to assiduous attention to correcting any fluid and electrolyte imbalances and concomitant acidosis, assurance of optimal caloric (nutritional) intake with supplemental nasogastric or gastrostomy tube feeding is necessary. Control of secondary hyperparathyroidism is obtained through close attention to the prevention of hypophosphatemia or hyperphosphatemia and judicious use of hydroxylated vitamin D and calcium supplementation. This regimen has been associated with normal growth patterns in young infants with CRI. For children with ESRD, there are limited data about the effects of the dialysis regimen on growth. Tom et al. (3) demonstrated an improvement in growth velocity associated with increments in hemodialysis Kt/V.

Suboptimal growth after renal transplantation has been attributed primarily to graft dysfunction, which leads to a reduction in glomerular filtration rate (GFR), and the deleterious impact of corticosteroids on growth. Data on steroid withdrawal (4) and steroid avoidance (5) after transplantation are encouraging. Improvements in SDS are not currently realized after transplantation in school-aged children and adolescents, however, and it is likely that the height centile at transplantation will be the final adult height centile. In this regard, it is encouraging that between 1987 and 2001 the mean SDS of children at the time of transplantation markedly improved (Fig. 67.2), presumably because of changes in treatment practices. This may be reflected in improvement in final adult height in this patient population in the future.

FIGURE 67.2. Height Z scores at the time of transplantation over a 15-year period from 1987 to 2001, demonstrating that height of recipients at the time of transplantation has steadily improved during this time interval.

Recombinant Human Growth Hormone

After the initial report of the safety and efficacy of recombinant human GH (rhGH) in treating children with CRI (6), a randomized, double-blind, placebo-controlled study was undertaken to obtain U.S. Food and Drug Administration (FDA) approval of the use of rhGH to improve the growth velocity of growth-retarded children with CRI and those undergoing dialysis (7). After 2 years there was a significant difference in the change in Z score between the rhGH-treated children and an untreated control group (Fig. 67.3). This led the FDA to approve the use of rhGH in this patient population. The indication for the use of rhGH in children with CRI is the presence of growth retardation (SDS more negative than -2.00) in children with irreversible renal insufficiency (GFR less than $75 \text{ mL/min/1.73 m}^2$). No provocative testing for GH levels is required before initiation of rhGH treatment. The dosage of rhGH that has been recommended is 0.05 mg/kg/day , 7 days per week, subcutaneously. A newer depot formulation of rhGH is likely effective, but precise recommendations for the dose and frequency are not yet available.

Before rhGH therapy is initiated, it is imperative to correct acidosis and any fluid electrolyte abnormalities, assure optimal caloric intake, and minimize the coexistence of renal osteodystrophy. Suppression of excessive secondary

hyperparathyroidism [parathyroid hormone (PTH) level more than three times the normal value] is advantageous because either the response to rhGH will be suboptimal in the presence of secondary hyperparathyroidism or rhGH will accentuate the deformities of osteodystrophy. Care must be taken, however, to simultaneously prevent adynamic bone disease.

Because of the potential adverse events of intracranial hypertension, avascular necrosis, and slipped capital femoral epiphysis associated with rhGH treatment, it is recommended that an ophthalmologic consultation and hip radiographs be obtained before initiating rhGH treatment.

During the first year of life, growth is minimally dependent on GH; therefore, limited data are available on the use of rhGH in infants younger than 2 years of age. Data from a multicenter study, however, have demonstrated the efficacy and safety of its use in infants as young as 6 months of age at initiation of therapy (8). Likewise, rhGH has been effective in adolescents at stages III and IV of puberty (9).

A dilemma that has not been resolved unequivocally is the approach to the child who reaches target height (fiftieth percentile for midparental height) after initiation of rhGH treatment. Because occasionally the child will track along the fiftieth percentile after discontinuation of rhGH, a pause of treatment has been recommended in this circumstance. Immediate resumption is indicated, however, if a significant reduction in growth velocity results.

Growth of children with CRI after long-term treatment with rhGH has demonstrated continued improvement in SDS (10). Although the greatest magnitude of increase in SDS occurs in the first and second year of rhGH treatment, continued positive change in SDS can be demonstrated for at least 5 years of treatment.

Numerous adverse events have been attributed to rhGH treatment in children with GH deficiency. Although isolated cases of some adverse events have been reported in children with CRI treated with rhGH, an NAPRTCS report noted no increased incidence of intracranial hypertension, aseptic necrosis, slipped capital femoral epiphyses, and malignancy compared with an untreated control population (11).

Early reports of the use of rhGH in an ESRD population had suggested the efficacy of its use in children undergoing peritoneal dialysis. However, a European report indicated that the effectiveness of rhGH therapy was suboptimal in children undergoing dialysis (12). Nevertheless, a multicenter study in France demonstrated that the short-term efficacy of rhGH therapy in children undergoing hemodialysis was comparable to that achieved in CRI patients (13).

As indicated previously, growth is frequently suboptimal after transplantation, especially in school-aged children and adolescents. Isolated reports and four controlled studies (14–17) (Table 67.1) have demonstrated the efficacy and safety of rhGH treatment of children after transplantation. The major concern that rhGH would either precipitate acute rejection episodes or accelerate the course of chronic

FIGURE 67.3. Change in height standard deviation (SD) score during a 2-year period of treatment with recombinant human growth hormone (rhGH) or placebo. Marked improvement in height SD score is demonstrated in the rhGH-treated group, whereas no improvement is seen in the placebo-treated group. The white line indicates patients receiving rhGH and the gray line indicates patients receiving a placebo. Those in the latter group received rhGH after 2 years.

TABLE 67.1. RESULTS OF RECOMBINANT HUMAN GROWTH HORMONE (rhGH) TREATMENT IN PEDIATRIC RENAL ALLOGRAFT RECIPIENTS

rejection has not been substantiated in any of the controlled studies. However, rhGH is not yet currently approved by the FDA for use in renal transplant recipients with growth retardation.

DEVELOPMENTAL ABNORMALITIES ASSOCIATED WITH CHRONIC RENAL INSUFFICIENCY

Although the adverse impact of uremia on the functioning of the nervous system has been appreciated in the past, it is only more recently that the magnitude of the problem in children has been described. Baluarte and coworkers described a distinct syndrome in six children, aged 26 months to 10 years, with congenital renal disorders that was characterized by myoclonus, dysarthria, seizures, dementia, and coma (18). The syndrome was evident when there was significant renal functional impairment (GFR less than or equal to 5 to 10 mL/min/1.73 m²) and was irreversible, despite dialysis and successful transplantation. Bale and colleagues noted similar neurologic abnormalities of seizures and intellectual impairment in three children with congenital renal abnormalities (19). The findings were observed initially when the GFR was 15 to 25 mL/min/1.73 m². Aluminum intoxication was implicated by Baluarte et al. (18); however, the cerebrospinal fluid aluminum concentration was measured in one child by Bale et al. (19) and was found to be normal.

The magnitude of the problem was emphasized in the report of Rotundo et al. (20), who undertook a retrospective analysis of 23 children with chronic renal failure diagnosed before 1 year of age. Of the 23 children, 20 had progressive encephalopathy characterized by developmental delay (19), microcephaly (15), hypotonia (13), seizures (13), and dyskinesia (11). A specific cause was not identified; however, four patients developed central nervous system symptoms before receiving any oral aluminum therapy,

and all patients had symptoms before initiation of dialysis. All of these patients had associated significant growth impairment, and 15 of the 20 patients with progressive encephalopathy had progressive reduction in head size.

The relationship between the onset of CRI during the first year of life and subsequent developmental delay was emphasized in the report of McGraw and Haka-Ikse (21), who studied 12 boys with onset of chronic renal failure at less than 1 month of age. Developmental testing at 13 to 54 months of age in 10 of the 12 patients revealed the following: normal development in 2 of 10 (20%), developmental quotient (DQ) of 60 to 80 in 3 of 10 (30%), DQ of 40 to 60 in 4 of 10 (40%), and DQ of less than 40 in 1 of 10 (10%). Serial head circumference measurements were less than 2 standard deviations below the mean in 9 of 12 patients, and 9 of 12 patients had a history of seizures. Linear growth retardation was present in eight patients (67%). A progressive neurologic disorder occurred in one patient who did not remit after successful transplantation.

These reports implicate an adverse impact of uremia on the developing brain, because all patients had evidence of renal functional impairment during the first year of life. An additional etiologic possibility is the toxic effect of aluminum on the developing brain. All of the patients described in the report of McGraw and Haka-Ikse (21) had received aluminum-containing phosphate binders; only 4 of the 20 patients reported by Rotundo et al. (20) had not received aluminum-containing compounds.

A report by Freundlich et al. (22) described elevated aluminum levels in the brains of two infants with chronic renal failure who died in the first year of life without receiving aluminum-containing phosphate binders and implicated the infants' formula as the source of the high aluminum levels in the brain. The latter finding suggests that aluminum toxicity may be the cause of the neurologic manifestations in infants with chronic renal failure who did not receive aluminum-containing phosphate binders. Although an unequivocal relationship between neurologic impairment and aluminum toxicity does not exist, it would be prudent to avoid aluminum-containing compounds in infants with CRI and to use other phosphate-binding agents (23). Bale et al. (19) and Rotundo et al. (20) suggested that earlier initiation of dialysis and/or transplantation should be considered in infants with congenital renal abnormalities to avoid these neurologic sequelae.

A more recent follow-up report to that of McGraw and Haka-Ikse (21) from the same institution (24) was considerably less pessimistic regarding neurologic development of infants with chronic renal failure. Thirty-three children in whom chronic renal failure was detected in the first year of life were tested for neurologic function on two occasions approximately 2 years apart. Aluminum usage was exceptional, and assiduous attempts were made to optimize caloric intake. Initially, 11 of 33 children had a DQ of less than 80; 10 of 11 children were mildly delayed, and 1 child

was moderately delayed in development. When last evaluated, 10 of 33 children had a DQ of less than 80; 8 of 10 children were mildly delayed, and 2 of 10 children were moderately delayed. The latter two patients had experienced cerebrovascular accidents. This incidence of developmental delay ($\pm 30\%$) was much lower than the 60 to 85% previously reported (25).

Additional experience continues to provide a more optimistic outlook for infants with CRI and ESRD. In 1999 Warady et al. (26) reviewed the outcome of 34 infants who began dialysis before 3 months of age. Calcium carbonate was the only phosphate binder used, and 27 of 28 infants who survived longer than 1 year received supplemental nasogastric tube feeding. At 1 year of age, the 28 patients had a mean head circumference SDS of -0.96 ± 1.2 . The mental developmental score of 22 patients (79%) fell in the average range, whereas only 1 child (4%) was significantly delayed. Of 19 children retested at 4 years of age or older, 15 (79%) performed in the average range and 1 (5%) performed in the impaired range. Of 16 patients 5 years of age or older, 15 (94%) attended school full time and in age-appropriate classrooms. Twenty-four patients received their initial kidney transplant at a mean age of 2.1 ± 0.8 years. This experience provides evidence that the combination of aggressive nutrition, elimination of aluminum as a phosphate binder, and appropriate provision of dialysis and transplantation all contribute to a favorable developmental outcome in children who have ESRD in early infancy.

This optimism regarding the neurologic development of infants with CRI and ESRD was substantiated by the report of Qvist et al. (27). These authors evaluated 33 children who received an initial renal allograft at less than 5 years of age. Twenty-nine of the patients (88%) had Finnish-type congenital nephrotic syndrome, and the mean age at initial transplant was 2.4 ± 1.1 years with a mean duration of dialysis of 1.3 ± 1.2 years. It is apparent that this group of patients would be at high risk for neurodevelopmental abnormalities. At a mean age of 8 years at follow-up, 26 of the children (79%) attended regular school and 76% had normal motor performance. Risk factors for abnormal neurodevelopment were an increased number of hypertensive crises ($p = .002$) and seizures ($p = .03$) during dialysis and not serum aluminum levels or number of septic episodes. The authors concluded that, in a previously lethal disease, the overall neurodevelopmental outcome of infants with ESRD is now reassuring.

Further evidence that current clinical practice results in acceptable neurologic development of infants with CRI and ESRD was provided by Ledermann et al. (28), who treated 20 infants (mean age, 0.34 years) with long-term dialysis and subsequent renal transplantation. Head circumference SDS improved from -1.9 at initiation of peritoneal dialysis to -0.9 at 1 year of age ($p = .015$). Fourteen of the 16 survivors (88%) achieved normal developmental milestones or attended mainstream schools.

The current clinical practice of avoiding any additional aluminum intake in infants, optimizing nutritional intake with supplemental feeding, preventing the emergence of secondary hyperparathyroidism, and avoiding hypertensive crisis should optimize neurologic development in infants with CRI and ESRD.

Limited data are available that have addressed the concern that cognitive functioning in children may be impaired during dialysis and/or renal transplantation. Brouhard et al. (29) undertook an elegant study to compare cognitive function in 62 patients with ESRD with that of their sibling controls. The controls were chosen so as to neutralize the impact of ethnicity and economic status. The average intelligence quotient rank of the patients was significantly lower than that of their siblings, and the patients tended to score lower on achievement tests than did their siblings. Increased dialysis time predicted lower scores on achievement tests. The authors concluded that factors related to ESRD are the risk factor for lower intelligence quotient and academic achievement. These data suggest that optimizing cognitive development requires limitation of the time that children experience ESRD.

The current approach to the infant with chronic renal failure includes careful surveillance of growth and head circumference with the intent to initiate dialysis once growth deviates from the normal curve. Developmental testing in infants is not sufficiently precise to warrant therapeutic intervention only on the basis of deviant test results. Abnormalities of growth and head circumference may be more precise indicators of the adverse effects of uremia. Whether the earlier initiation of ESRD care in these infants might prevent the development of the neurologic sequelae of uremia has not been completely proven. Nonetheless, this issue should be carefully considered when making clinical decisions about individual infants.

There are no definitive answers to the two other philosophical issues regarding management of the mentally challenged child with CRI. Observation of children with mild to moderate degrees of mental retardation has indicated that they do not respond as well to the imposed constraints of ESRD care as do children with normal intellectual capacity (30). The family of a mentally retarded child should be given a dispassionate assessment of the various therapeutic options. If the family decides against ESRD care, it is imperative that the health care team provide continued psychological, emotional, and medical support. Abandonment of the child and family after the decision not to embark on ESRD care could lead the family to question the wisdom of their decision.

Also, if the child presents with a history of long-standing chronic renal failure that had its onset in infancy and the child is mentally retarded, it is appropriate to assume that the child's intellectual impairment is not related to a sudden decline in renal function. It is important, however, to detail the premorbid mental capacity of the child with a sudden onset of ESRD who appears to be functioning at a subnor-

mal level. The uremic milieu depresses cognitive function and the reality of ESRD produces psychological depression, both of which may be reversed by successful renal transplantation. A detailed analysis of the child's intellectual functioning in the premorbid state is vital before the family is counseled regarding the potential therapeutic options.

CARDIOVASCULAR ABNORMALITIES ASSOCIATED WITH CHRONIC RENAL INSUFFICIENCY

Cardiovascular disease is the leading cause of mortality in adults with ESRD, accounting for almost 50% of all deaths (31). Mortality related to cardiovascular disease is 10 to 20 times higher in adult patients with ESRD than in the general population (32). In adults with ESRD the two major risk factors for cardiovascular disease mortality are atherosclerotic coronary artery disease (CAD) and left ventricular hypertrophy (LVH) (33).

Mortality in children with CRI and ESRD is substantially lower than that reported in adult patients. Of 5039 children with CRI enrolled in the NAPRTCS CRI registry between 1994 and 2001, only 50 (2.7%) died. Of the 2361 children enrolled in the NAPRTCS dialysis registry since 1992, whose first reported course appears to be the first ever without a history of renal transplantation, the 3-year patient survival rate was $86.8 \pm 1.5\%$ (standard error). Of the 436 deaths, cardiopulmonary reasons were cited in 92 (21.1%). Patient survival among 7247 index transplant patients enrolled in NAPRTCS since 1987 (3704 given living donor organs and 2964 cadaveric organs) was $94.0 \pm 0.4\%$ at 5 years. There were 329 deaths (5.5%), with cardiopulmonary death cited in 55 (15.1%) (34).

The 1999 U.S. Renal Data System report indicated that 33% of deaths in children with ESRD were related to cardiovascular causes (35). Similarly, data on European pediatric patients who died while receiving renal replacement therapy between 1987 and 1990 indicated a cardiovascular cause of death in 51% of those on dialysis and 37% of those who had undergone transplantation (36).

Therefore, although mortality in children with CRI and ESRD does not approach the magnitude observed in adult patients, cardiovascular events are a significant cause of death. Little is known about the development of cardiovascular disease in children and adolescents with CRI and ESRD. Moreover, current treatment modalities are extending longevity into adulthood, and the factors responsible for subsequent development of clinical cardiovascular disease may be prevalent in childhood and adolescence.

In 1976 Pennisi et al. (37) noted a significant prevalence of fasting hypertriglyceridemia and hypercholesterolemia in 35 pediatric renal allograft recipients and 15 children and adolescents undergoing maintenance hemodialysis. Autopsy material from 12 children who had undergone maintenance

hemodialysis and/or renal transplantation was compared to that from age-matched controls. An increased collagenous content of the intima that was possibly an early indication of CAD was noted more frequently in the patients with ESRD than in the control subjects ($p < .0006$). More recently, Goodman et al. (38) used electron beam computed tomography to screen for coronary artery calcification in 39 patients with ESRD undergoing dialysis who were 7 to 30 years of age (mean of 19 ± 7 years). None of the patients younger than 20 years of age had evidence of coronary artery calcification; however, 14 of 16 patients 20 to 30 years of age did have such evidence. These data emphasize that the factors responsible for the development of cardiovascular disease may have their origins in childhood and adolescence in those with CRI and ESRD. Scharer et al. (39) reviewed cardiac function and structure in children with CRI. The authors delineated the hemodynamic, vascular, humoral, metabolic, and toxic factors influencing cardiac function and structure in patients with CRI. Most of the available information was from studies of adult patients. Limited data were available regarding LVH and hypertension.

Morris et al. (40) in 1994 noted a reduction in left ventricular mass (LVM) in seven children undergoing dialysis after correction of anemia with recombinant human erythropoietin (rHuEpo). After transplantation this group was compared with a group who did not require rHuEpo during dialysis to determine the impact of correction of the uremic milieu on cardiovascular function. Because limited improvement was seen in the latter group after transplantation, the authors concluded that anemia had an important influence on cardiovascular function in ESRD.

In 1996 Johnstone et al. (41) described left ventricular abnormalities in 32 children, adolescents, and young adults with CRI, 10 undergoing chronic peritoneal dialysis, and 30 who had received renal transplants. The results were compared with data for 60 controls. Using echocardiographic measurement of LVM, the authors noted an increase compared to controls in 22% of the CRI group, 30% of the peritoneal dialysis group, and 63% of the transplant group. An important correlation between serum creatinine level and LVH was noted in the CRI group, which indicates that progressive uremia may correlate with increasing LVM. The incidence and severity of the LVH in the transplant group, which was not correlated with the presence of hypertension, indicates the potential for cardiovascular disease with longevity in children with ESRD.

More recently, Matteucci et al. (42) performed echocardiography, 24-hour ambulatory blood pressure monitoring (ABPM), and treadmill testing in 28 pediatric allograft recipients. LVH was found in 82% of the recipients; however, only 43% (10 of 23) of those with LVH were hypertensive by 24-hour ABPM. Unfortunately, serial evaluations were not undertaken to determine the impact of prior LVH on the posttransplantation abnormalities.

Factors prevalent during the course of CRI may affect the incidence of cardiovascular disease in pediatric patients with ESRD. Mitsnefes et al. (43) in 2000 retrospectively evaluated echocardiographic findings in 64 dialysis patients 20 months to 22 years of age. LVH was present in 75%, including 85% of those on hemodialysis and 68% of those on peritoneal dialysis. The duration of CRI before initiation of dialysis was significantly related to the severity of the LVH. The relationship between hypertension and LVH has been validated in adults, and LVH has been identified as one of the indicators of end-organ damage in children with hypertension (44). Data delineating the incidence of hypertension in children with CRI and the relationship to the development of LVH are limited.

NAPRTCS does not collect data on specific blood pressure readings; however, the latest report of NAPRTCS indicated that 37% of patients with CRI were receiving antihypertensive medications at enrollment. A special analysis of NAPRTCS data encompassing 5251 renal allograft recipients indicated that hypertension persists during the course of ESRD care (45). At 5 years after transplantation, 58% of recipients were receiving antihypertension medications.

If a precise relationship between the incidence and prevalence of hypertension and the relationship to the development of LVH in pediatric patients with CRI and ESRD is to be ascertained, more precise serial measurements of blood pressure must be obtained. The use of 24-hour ABPM has received limited attention. Sorof (46) used 24-hour ABPM in pediatric ESRD patients and noted a reclassification of more than one-third of the patients when 24-hour ABPM results were compared with casual blood pressure recordings. The author correlated 24-hour ABPM findings with a 20% incidence of LVH in transplant recipients. Similarly, Koch et al. (47) demonstrated that casual recordings were not representative of blood pressure measurements assessed by 24-hour ABPM in children undergoing dialysis. End-organ damage was also noted in patients judged normotensive by casual readings.

Because of the relationship between hyperlipidemia and CAD in the general population (48) and because CAD contributes to the 10 to 20 times greater incidence of cardiovascular mortality in adults with ESRD (32), it is important to delineate the incidence and prevalence of hyperlipidemia in pediatric patients. Querfeld (49) reviewed the problem of hyperlipidemia in children with CRI. Initial reports suggested that children with CRI have mild hypertriglyceridemia and slightly elevated serum cholesterol levels (50,51). With reduction in the GFR (10 to 20 mL/min/1.73 m²), a decrease in high-density lipoprotein cholesterol was noted. Evaluation of 68 pediatric patients at initiation of dialysis noted that 90% had hypertriglyceridemia and 69% had hypercholesterolemia (52). Subsequently, Querfeld et al. (53) noted that 8 of 20 children (40%) with CRI had elevated lipoprotein(a) levels.

More recently, Silverstein et al. (54) analyzed the risk factors for hyperlipidemia in long-term pediatric renal allograft

recipients. Of 62 pediatric recipients surviving with a functioning graft for a mean of 6.7 ± 3.1 years, more than 50% had hypercholesterolemia; 45% had high low-density lipoprotein levels and 9% had low levels of high-density lipoprotein. A prominent risk factor for posttransplantation hyperlipidemia was pretransplantation hyperlipidemia, which indicates the importance of identification and management of hyperlipidemia in children during the course of CRI. No data are available on the optimal therapeutic approach to management of hyperlipidemia in children with CRI.

Hyperhomocysteinemia has been identified as a risk factor for CAD in adult patients with CRI and ESRD (55). Limited data are available addressing this issue in a pediatric population. Schroder et al. (56) measured plasma homocysteine levels in 21 children with ESRD undergoing dialysis and compared the results with those for 234 healthy controls. The median level was 9.1 mol/L in the control population and 20 mol/L in the ESRD population. Four weeks of treatment with folic acid reduced the plasma homocysteine concentration to 12 mol/L in the patients undergoing dialysis. The potential contribution of elevated homocysteine levels to CAD in a pediatric population with CRI and ESRD remains to be identified, and an optimal approach to lowering the plasma homocysteine level requires delineation.

A consensus conference on the prevention of posttransplantation cardiovascular disease noted that "little information is available regarding long-term cardiac morbidity and mortality in pediatric solid organ recipients" (57). The following risk factors were identified: (a) pretransplantation cardiovascular disease, (b) hypertension, (c) hyperlipidemia, (d) obesity and sedentary lifestyle, (e) diabetes mellitus, and (f) hypertriglyceridemia. Guidelines were provided to manage these risk factors; however, the authors acknowledge that "further research is required to develop definitive guidelines."

One of the potential reasons for the incidence of cardiovascular morbidity and mortality in children with CRI and ESRD is the development of arrhythmias consequent to the prolongation of corrected QT interval (QTc). Prolonged QTc has been proposed as a cause of sudden infant death syndrome (58). It has also been described with electrolyte abnormalities such as hypokalemia (59) and hypocalcemia (60) and as a side effect of some medications (61).

Limited data are available delineating the incidence of prolonged QTc in children with CRI and ESRD. Bosch et al. (62) have noted a high incidence of prolonged QTc in a limited number of children with CRI and ESRD using Holter monitoring. No data are available, however, correlating serial electrocardiographic evidence of prolonged QTc, echocardiographic findings, and electrolyte abnormalities in a pediatric population with CRI and ESRD.

In summary, acute cardiovascular events lead to significant morbidity and mortality in pediatric patients with CRI and ESRD. Risk factors for the development of long-term cardiovascular disease in children with CRI and

ESRD are evident in childhood and adolescence. Limited data are available to identify these putative factors precisely so that potential therapeutic approaches could be initiated to limited long-term consequences of cardiovascular disease in a population of patients with anticipated increasing longevity. In the meantime, blood pressure, anemia, and lipid levels should be carefully controlled, and appropriate diet and exercise should be maintained in children with CRI and ESRD.

ANEMIA IN CHRONIC RENAL INSUFFICIENCY

Definition

Anemia is defined as a reduction in the red blood cell volume or hemoglobin concentration below the range of values occurring in healthy persons (63). Anemia should be addressed in patients with chronic renal disease when hemoglobin levels decline to 80% of the mean level defined for healthy subgroups (64). Generally, a significant reduction in hemoglobin concentrations develops in patients with CRI when the GFR declines below 35 mL/min/1.73 m² (65). Based on morbidity, mortality, and quality-of-life data, the Dialysis Outcomes Quality Initiative guidelines recommend a target range of 33 to 36% for hematocrit and 11 to 12 g/dL for hemoglobin for patients with CRI (66).

Impact of Anemia

Before the availability of rHuEpo, transfusions were required in almost all pediatric patients with ESRD. These transfusions were associated with the development of total body iron overload as well as increased exposure to HLA antigens and infectious agents. It now appears that the development of anemia, and not the accumulation of ill-defined uremic toxins, was responsible for many of the symptoms seen in CRI and ESRD. Appetite, physical activity, libido, school attendance in children, and in, some studies, performance on intelligence quotient testing are all improved after the correction of anemia using rHuEpo. Because children with CRI have complex conditions that contribute to morbidity, the impact of anemia may best be assessed by improvements that occur with correction of hemoglobin concentrations. It has been proposed that anemia contributes to impaired cognitive function, exercise intolerance, growth retardation, and school absences. Studies of adult and pediatric patients have shown improved memory, concentration, and speed of information processing in cognitive evaluations, improved cardiac function, improved exercise performance, and decreased mortality after partial correction of anemia (67,68). In anemic children without kidney disease, investigators have demonstrated elevations in heart rate with physical activity (69), blunted cardiovascular response to exercise, and decreased peak exercise duration (70) compared to nonanemic age-

matched control children. Growth impairment has been documented in children with anemia due to sickle cell disease and thalassemia, with improved growth in thalassemia patients on hypertransfusion protocols (71,72). Studies of children with anemia secondary to kidney disease have involved mostly children with ESRD, and have found improved exercise capacity with correction of hematocrit from 21.7 to 33.4% (73). Objective improvement in exercise tolerance and subjective improvement in physical performance, general health, and school attendance was reported by Morris et al. (74) for this population. The effects of correction of anemia on growth and nutritional status in children with CRI were reviewed by Jabs (75). Although most patients reported subjective improvements in appetite and food, correction of mean hematocrit from 21 to 31% did not improve weight gain, anthropometric measures, or SDS height scores in any age group. In children who had had multiple transfusions, the levels of previously formed panel-reactive antibodies and cytotoxic antibodies to a T-cell panel decreased after the initiation of rHuEpo treatment and the cessation of transfusions (76,77). A lower level of preformed antibodies may allow this group of children to be transplanted more readily. Montini et al. evaluated brainstem auditory evoked responses and peripheral nerve conduction velocity at baseline and during rHuEpo treatment (78). At baseline, five of nine children evaluated had abnormal auditory evoked responses, and in four of them the responses normalized after the hematocrit increased. In contrast, there was no improvement in peripheral nerve conduction velocity. An additional benefit of rHuEpo treatment is a decrease in uremic coagulopathy. The bleeding time as measured by the Ivy method improved significantly during rHuEpo treatment (78,79). The improved bleeding time and platelet aggregation (79) may decrease uremic bleeding, including gastrointestinal blood loss.

Causes of Anemia

Anemia in children with CRI may be secondary to inadequate erythropoiesis due to insufficient production of erythropoietin by diseased kidneys (80) or to iron deficiency (81). Children with CRI are at increased risk for development of iron deficiency for several reasons. There is often decreased appetite with progressive disease or poor iron intake due to dietary restrictions. In addition, only a small percentage of ingested iron is actually absorbed by the gut, and the amount is further decreased by medications, including phosphate binders, prescribed to be taken with meals. In addition to poor intake, the annual iron loss via the gastrointestinal tract has been estimated to be 0.9 g/1.73 m² in predialysis pediatric patients (82). Not only is red cell production inadequate, but red cell survival is shortened (83), and often iatrogenic blood loss as well as occult gastrointestinal bleeding occur. Contributing factors

that inhibit effective erythropoiesis include infection, severe hyperparathyroidism (84), and coexisting acute and chronic inflammation (85).

After successful renal transplantation, anemia may be present in a significant number of patients, with reports indicating that from 12 to 39% of kidney transplant patients have persistent anemia (86,87). Data concerning anemia in pediatric kidney transplant recipients are unavailable. In patients with renal insufficiency of the allograft, inadequate production of erythropoietin may play a role. Iron deficiency may be present at the time of transplantation or may develop over the subsequent months (88). Special consideration must be given to the potential effects of immunosuppressive agents in the development of chronic as well as acute anemia. Azathioprine and mycophenolate mofetil may cause anemia associated with leukopenia and thrombocytopenia (89) but may also exert a selective erythroid toxicity (90). Children younger than 6 years of age treated with mycophenolate mofetil were more likely to develop anemia and other side effects of this drug than were older children (91). Microangiopathic hemolytic anemia may be caused by cyclosporine (92), tacrolimus (93), or OKT3 (muromonab-CD3) (94), often in association with hypertension, thrombocytopenia, and acute renal failure. This process may be reversed by withdrawal of the drug and treatment of the hypertension (89). Minor ABO incompatibility between recipient and donor may also result in hemolytic anemia in as many as 14 to 20% of cases (95). Clinically, hemolysis may begin 3 to 22 days after transplantation, with spontaneous remission occurring after 7 to 10 days, and patients treated with cyclosporine may be at increased risk (96). Other drugs used in the posttransplantation period may also be implicated, especially angiotensin-converting enzyme (ACE) inhibitors, which may cause a fall in hematocrit of 10% or more that is reversible with discontinuation of the drug (97). Kidney transplant patients with anemia must also be evaluated for gastrointestinal blood loss, occult infection, chronic inflammation, and vitamin B₁₂ deficiency.

Evaluation of Anemia

Careful evaluation of anemia is warranted to assure effective therapy for its correction. A complete blood count with red cell indices, hemoglobin concentration and hematocrit, and reticulocyte count, and a review of the smear provide initial information and a baseline. Stool should be tested for occult blood, and coexisting conditions such as hyperparathyroidism or systemic inflammatory disease should be considered. Parameters for assessment of iron status include serum iron level and total iron-binding capacity. Transferrin saturation (TSAT) can be calculated by multiplying the serum iron value by 100 and dividing by the total iron-binding capacity. Serum iron level and TSAT measure the iron immediately available for hemoglobin synthesis, with a target for TSAT of above 20%. TSAT values lower than 20% indicate the need

for iron replacement therapy. Serum ferritin levels reflect total body iron stores, but because ferritin is also an acute-phase reactant, results may be affected by systemic inflammation. Ferritin target values in the absence of significant inflammation are higher than 100 ng/mL (98). Adequate iron stores and TSAT with a low reticulocyte count may reflect inadequate erythropoietin production. In patients who do not respond to adequate iron and erythropoietin therapy, folic acid and vitamin B₁₂ levels should be checked. Drugs that suppress bone marrow function must also be considered, including ACE inhibitors, antibiotics, and immunosuppressive agents. Elevated PTH levels may also diminish the efficacy of erythropoietin (99,100).

Treatment of Anemia

Laboratory evidence of iron deficiency begins with decreases in serum ferritin levels, followed by a fall in serum iron and increase in total iron-binding capacity. These findings are accompanied by a fall in the calculated TSAT. If iron deficiency persists, hypochromia and microcytic anemia develop. Effective therapy with iron results in reticulocytosis by 72 hours, which peaks by 5 to 7 days. Increased hemoglobin concentrations are detectable by 4 to 30 days, with repletion of stores after 1 to 3 months of continuous effective supplementation (101).

Oral iron therapy should target delivery of 2 to 3 mg/kg/day of elemental iron in two to three divided doses. Iron is best absorbed without food and is recommended to be taken 1 to 2 hours after meals, which would also avoid interference in absorption by phosphate binders. Side effects include gastric irritation, constipation, and diarrhea. For patients with ongoing blood loss or inability to tolerate or absorb adequate iron via the oral route, parenteral iron therapy should be considered. Especially after the initiation of hemodialysis, in which significant additive blood loss occurs with each treatment, even well-tolerated oral supplementation is often inadequate to maintain iron stores. Parenteral iron supplements are currently available as iron dextran, iron gluconate, and iron sucrose. Use of iron dextran requires administration of a test dose due to risk of allergic or anaphylactic reaction, which is less likely with iron gluconate. Iron sucrose preparations have been used in Europe and Japan and are under review by the FDA for use in the United States. Protocols for parenteral iron therapy are available in the literature (98).

Erythropoietin use is almost universal in children with advanced CRI. NAPRTCS reports showed that 96% of children were receiving erythropoietin at the time of initiation of chronic dialysis, which resulted in an increase of hematocrits to a median of 31% at 6-month follow-up (102). Erythropoietin can be administered either intravenously, subcutaneously, or intraperitoneally. The subcutaneous route is the most common method of administration for children with CRI and for those receiving chronic peri-

toneal dialysis (103). Subcutaneous injections of erythropoietin are generally given once or twice per week. This method of administration leads to a prolonged half-life and a decrease in the total weekly dose (104). Reported total initial weekly doses have ranged between 30 and 300 U/kg, whereas maintenance dosages varied between 60 and 600 U/kg/wk (105). Most pediatric patients respond to between 100 and 200 IU/kg/wk (106–110). The large dosage variation appears to be related to several factors: the target hematocrit; ongoing blood loss (either gastrointestinal or via dialysis) (82); patient age, with younger children requiring higher dosages than older individuals (105,109); presence of infection or inflammation (110); and, in some studies, hyperparathyroidism (99,100,111). The best predictor of response to erythropoietin appears to be the patient's iron status.

The intravenous route is generally reserved for children receiving chronic hemodialysis. Although the subcutaneous route is more cost effective, amelioration of the discomfort associated with that method of administration is generally used to justify intravenous administration in those with a hemodialysis access site. The initial dose should be sufficient to eliminate the need for transfusions while increasing the hematocrit slowly enough to allow adjustments in volume status and antihypertensive medications to maintain a normal blood pressure. A reasonable starting dose is 40 to 60 U/kg administered intravenously at each hemodialysis treatment three times a week (98). The dose of rHuEpo required to maintain the hematocrit in the target range varies with patient age. Children younger than 5 years of age frequently require higher weekly doses than older children and adults (greater than 300 U/kg vs. 80 to 120 U/kg) (109,112). In one multicenter European trial of rHuEpo in hemodialysis patients 2 to 21 years of age, the median weekly maintenance rHuEpo dose varied from 136 U/kg in those over 15 years to 321 U/kg in children younger than 5 years of age (109). Similar results have been found in a multicenter U.S. trial (112).

Intraperitoneal administration was developed for peritoneal dialysis patients and was found to be most effective if the agent was instilled in small volume into a "dry" peritoneal cavity where absorption could be maximized (113). Subsequent studies have shown that approximately 7% of the medication may be adsorbed onto plastic components of the dialysis delivery system (114). Although some studies have shown that erythropoietin can be administered effectively via the intraperitoneal route to patients receiving chronic peritoneal dialysis (115), there is concern about the side effects of this method and its cost effectiveness (115–117).

A longer-lasting formulation of an erythropoiesis-stimulating drug, darbepoietin alpha, has been studied and its pharmacokinetic profile seems to be similar in adults and children (118). This formulation has a terminal half-life two to four times longer than that of the traditional formulation, which permits less frequent dosing. Long-term studies

designed to determine optimal administration in children are ongoing.

ELECTROLYTE DISORDERS IN CHRONIC RENAL INSUFFICIENCY

With advancing CRI, the total number of remaining functional nephrons is reduced, which requires the residual nephrons to compensate by increasing their fractional excretion of solutes to maintain homeostasis (119). Fluid and electrolyte balance is generally well maintained until 75% of function is lost, due to compensatory mechanisms that develop as nephron mass declines. Limitations to this adaptation are related to the magnitude and time frame for adjustment in filtered load. Gradual changes are met by appropriate adjustments in fractional excretion. Sudden changes in volume status or solute load may result in loss of homeostasis, because already compensating nephrons cannot respond instantaneously (120). In addition, the degree of adaptation to nephron loss depends on the substance that must be handled by the kidney. No adaptive mechanism exists for clearance of urea and creatinine; hence, the serum concentration increases almost inversely with the fall in GFR. For other substances, such as phosphate and hydrogen ion, there is significant adaptation by residual nephrons, which maintain serum concentrations at normal physiologic values until only approximately 25% of function remains. Adaptation for sodium and potassium handling is relatively complete until GFR falls to very low levels (121,122).

Water Balance

Depending on the cause of CRI, patients may have a fixed volume of urine output. There may be difficulty in excreting an acute water load due to loss of filtration or renal injury, which results in defects of normal diluting mechanisms. Conversely, and perhaps more commonly in children, a significant concentrating defect may be present, as seen in patients with sickle cell nephropathy, juvenile nephronophthisis, or obstructive uropathy. Even with a very low GFR, the kidneys filter 14 L of plasma per day, which can lead to a large urine volume if water reabsorption mechanisms cannot respond appropriately to concentrate urine. In addition, there remains an obligate urine output volume necessary to excrete the daily filtered load. Some patients maintain fairly steady fluid balance even in advanced insufficiency, in part due to an intact thirst mechanism if the child is old enough and has free access to water. Difficulties arise when these children are challenged by an acute dehydrating illness such as gastroenteritis or poor intake from pharyngitis, or when they are stressed iatrogenically by being restricted to nothing by mouth before a procedure, or conversely, suffer fluid overload from injudicious use of intravenous fluids.

In CRI, defective urinary concentrating ability may be the result of one or more impaired mechanisms, including tubu-

lar resistance to antidiuretic hormone. Vasopressin-resistant hyposthenuria in patients with CRI caused by primary tubular or interstitial disorders has been characterized by Holliday et al. (122). As CRI progresses, there develops an increased osmotic diuresis per residual nephron as fractional excretion of solutes rises to compensate for a decreased number of functional units. This adaptation results in continual osmotic diuresis and hyposthenuria (123). There may be structural anatomic derangement of renal tubules and medullary vasculature impairing the development of hypertonic interstitium, necessary for appropriate concentrating ability (123,124). Conversely, the functional defect affecting water and solute clearance in CRI in response to a fluid challenge is characterized by impairment in the ability to increase urinary volume after water loading. This is in part due to a decreased ability to dilute urine due to a fixed ratio of free water clearance to GFR (123).

Sodium Balance

Sodium balance is generally maintained in CRI by a progressive increase in the fractional excretion of sodium by remaining nephrons (125). This increase in sodium excretion is due to decreased sodium reabsorption by both the proximal and distal tubules in CRI (126) but is poorly understood. Water diuresis leads to increased sodium excretion because of a limited capacity of the distal nephron to reduce tubular fluid sodium concentration; therefore sodium excretion becomes dependent on urine flow rate (127). Children with polyuria may thus have difficulty conserving sodium and develop a salt-wasting state that requires careful supplementation. Clinically, hyponatremia may develop acutely due to a significant free water load or gradually due to depletion from chronic urinary losses. Use of diuretics, antihypertensive agents, and prostaglandin synthesis inhibitors alters sodium handling in normal and diseased kidneys. Urinary tract obstruction or infection may result in tubular hyporesponsiveness to aldosterone, described in infants with hyperkalemia and hyponatremia (128). One further concern regarding sodium balance involves removal of significant amounts of NaCl by peritoneal dialysis, especially in infants, which results in a clinically significant NaCl deficit (123).

Conversely, hypernatremia may be seen from an excess exogenous sodium load. Fractional excretion of sodium cannot exceed 20 to 30% of the filtered load in normal or diseased kidneys (129). If remaining nephrons have already reached maximal sodium excretion capacity, no further compensation can take place with further increases in sodium load. If some reserve remains, nephrons require time to increase sodium excretion and reestablish sodium balance.

Potassium Balance

Potassium handling in healthy and diseased kidneys involves reabsorption of almost all the filtered load by the proximal

tubule and loop of Henle, with distal nephron secretion determining potassium excretion in the urine (130,131). Up to 90% of daily dietary potassium intake is secreted by the kidneys in normal individuals. As CRI progresses, potassium homeostasis is maintained by increasing distal tubular potassium secretion by remaining nephrons (132,133). With significant loss of kidney function, increased potassium secretion occurs through the colon (134–137), with as much as 35% of dietary potassium excreted in the stool (135). Aldosterone stimulates increasing sodium-potassium exchange in both the distal tubule (138,139) and colonic mucosa (140,141).

Hyperkalemia may result from increased dietary load that exceeds the ability of the compensatory mechanisms to maintain homeostasis. Certain drugs may lead to significant elevations in serum potassium through, for example, competitive inhibition of aldosterone by spironolactone, inhibition of distal potassium secretion by triamterene or amiloride, or decrease in remaining glomerular filtration by ACE inhibitors (142). ACE inhibitors may also cause transient pseudohypoaldosteronism, which contributes to their hyperkalemic effects (143). Repair of obstructive uropathy in infants may result in a similar phenomenon (144,145). Acute metabolic acidosis may create life-threatening hyperkalemia by moving intracellular potassium to the extracellular compartment in patients who maintain a fragile balance while well. Some patients with CRI secondary to diabetes mellitus or interstitial nephritis have been determined to have low plasma renin and aldosterone levels, which lead to hyperkalemia in excess of that usually associated with their level of renal failure (146,147). In children with CRI, the renin-aldosterone axis and potassium handling were studied by Rodriguez-Soriano and colleagues, who found hyperkalemia in 13% of 23 children studied. These hyperkalemic children had low aldosterone levels and plasma renin activity, without overt salt wasting (148). CRI patients with sickle cell disease, lupus nephritis, or a kidney transplant may develop hyperkalemia due to diminished distal tubular secretory capacity (149). Chronic obstructive uropathy may lead to tubular resistance to aldosterone (150), which puts these patients at particular risk for hyperkalemia and salt wasting.

Hypokalemia may be present in patients with tubular defects involving potassium loss, such as renal tubular acidosis or Fanconi syndrome. These patients may require potassium supplementation, although careful monitoring and adjustments must be made as renal function declines. Iatrogenic hypokalemia may also develop through the use of diuretics, especially in patients with poor nutritional status.

Acid-Base Balance

Impairment of mechanisms responsible for normal acid-base balance in CRI include abnormal reabsorption of filtered bicarbonate, reduction in renal ammonia synthesis, decreased excretion of titratable acid, and decreased acidification of tubular luminal fluid by the distal nephron (130,151). When GFR

declines below 50% of normal, systemic metabolic acidosis becomes a significant clinical feature (152). Bicarbonate reabsorption per unit GFR is reduced in humans with CRI (130) and is further reduced by hyperkalemia, increased extracellular fluid volume, and hyperparathyroidism (153–155). Declining reabsorption of bicarbonate is clinically important in that it limits the effectiveness of base therapy to correct acidosis (155). Other patients with CRI due to tubular defects may have bicarbonate wasting, which is seen in proximal forms of renal tubular acidosis.

Although net ammonia production per remaining proximal tubule has been demonstrated to increase in response to nephron loss (156,157), as CRI progresses the compensation becomes inadequate and absolute ammonia excretion declines (158). Structural abnormalities may also lead to disruption of the tubulomedullary ammonium concentration gradient, decreasing ammonium trapping, which results in ammonium excretion (158,159). Excretion of titratable acid and distal urinary acidification generally remain well preserved as CRI progresses (142) but may also be decreased in advanced disease. The titratable acid excretion remains relatively normal primarily through increased excretion of phosphate per remaining nephron (160). Eventually, fractional excretion of phosphate cannot increase further, so that total urinary titratable acid excretion diminishes (120).

Therapy for acid-base disturbances involves correction of acidosis through oral base therapy, because persistent acidosis may adversely influence growth. A serum bicarbonate level of 20 to 22 mEq/L should be maintained, and sudden increases in endogenous hydrogen ion production through catabolic states, volume depletion, and phosphate deficiency should be avoided (123).

Renal Osteodystrophy

The kidney plays a major role in mineral homeostasis. Calcium, phosphorus, and magnesium balance are maintained via the kidney. The substances 1,25-dihydroxyvitamin D₃ and 24,25-dihydroxyvitamin D₃ are synthesized within the kidney, and PTH is degraded and cleared by the kidney. Hence, it is easy to see how renal failure can affect bone development and maintenance. In chronic renal failure, secondary hyperparathyroidism develops because of several factors. There is resistance to the calcemic action of PTH, low calcitriol levels, hyperphosphatemia, and downregulation of PTH bone cell receptors (161,162). High-low bone turnover and histologic as well as radiologic changes are the resultant features of renal osteodystrophy. The goal is to initiate a therapeutic intervention before endosteal resorption leads to osteitis fibrosa and fractures.

Secondary hyperparathyroidism can be controlled in several ways. The two most important mechanisms are adequate hydroxylated vitamin D replenishment and correction of hyperphosphatemia and hypocalcemia. Synthesis of 1,25-dihydroxyvitamin D₃ from 25-dihydroxyvitamin D₃

is stimulated by hypocalcemia, PTH, and decreased dietary intake of phosphate. Without sufficient 1,25-dihydroxyvitamin D₃, intestinal absorption of calcium is reduced, which causes hypocalcemia. Hypocalcemia then allows for increased PTH formation (163–165). Initial studies were performed on patients undergoing regular dialysis treatment, and it was noted that intravenous administration of calcitriol suppressed PTH secretion (166,167). Subsequent studies demonstrated that both intravenous and oral calcitriol administration reduced PTH secretion. The available forms of vitamin D are dihydrotachysterol, 25-hydroxyvitamin D₃ (calcifediol), 1 α -hydroxyvitamin D₃, and 1,25-dihydroxyvitamin D₃ (calcitriol), all of which have been shown to reduce PTH secretion.

The role of hyperphosphatemia in the development of secondary hyperparathyroidism has been demonstrated in several studies (167,168). Prevention of hyperphosphatemia can be achieved with the use of phosphate binders such as calcium carbonate, calcium acetate, and noncalcium binders (Renagel). The use of calcium-containing binders helps to increase calcium levels and thus suppresses PTH secretion. Aluminum-based binders should be avoided in the pediatric age group, especially in infants, because of the increased possibility of aluminum toxicity in renal failure (169,170). Restriction of dietary phosphorus also decreases hyperphosphatemia as well as PTH secretion (171).

Another mechanism to control secondary hyperparathyroidism is the use of calcimimetic drugs to decrease the secretion of PTH. These drugs stimulate the calcium-sensing receptors in the parathyroid glands, making them more sensitive to extracellular calcium. Initial studies of therapy with these medications indicated that plasma levels of intact PTH were decreased in uremic patients (172,173), and further investigations into their benefits are in progress.

Parathyroidectomy should be considered in patients when levels of intact PTH are more than five to seven times the upper limit of normal in the presence of hypercalcemia after assiduous medical management has failed. Coexistent abnormal radiologic findings and metastatic calcification provide additional indications (174).

Serum alkaline phosphatase activity has been demonstrated to correlate with histologic features of osteitis fibrosa (165,175). Monitoring the activity of this bone isoenzyme may be more specific in the management of patients with renal osteodystrophy; however, patients receiving rhGH may also have an increase in alkaline phosphatase unrelated to bone disease (175,176).

PROTEIN RESTRICTION IN PREVENTION OF PROGRESSION OF CHRONIC RENAL INSUFFICIENCY IN CHILDREN

Reduction in dietary protein has been associated with delayed progression of CRI (177,178) as a result of a

decrease in one or more of the following: uremia (179), metabolic acidosis, hypertension, hyperkalemia, or renal osteodystrophy (179,180). Restriction in protein intake leads to a reduction in levels of metabolites that may be detrimental to the kidney, such as phosphates, sulfates, sodium, and potassium. Definitive correlation between protein restriction and progression of CRI in humans has not been clearly established, however. Initial animal studies demonstrated that a high-protein diet was associated with an increased incidence of interstitial damage and hypertension as well as a higher mortality rate (180,181). The pathogenesis was thought to involve hyperfiltration that led to increased glomerular pressure and ultimately to glomerular sclerosis (182). The baboon model, however, did not show this association (183). Human studies in which protein intake was restricted to a level of 0.6 to 1.1 g/kg/day produced variable results (184,185).

The pathophysiology of fasting involves breakdown of stored proteins into amino acids, which are required for (hepatic) gluconeogenesis (186). Feeding induces anabolism and thus suppression of protein degradation. This occurs with or without stimulation of protein synthesis (187). As a result of this response, lean body mass is preserved and nitrogen balance is maintained (188,189). Protein restriction leads to decreased amino acid oxidation and use of essential amino acids, which thereby produces suppression of protein degradation and synthesis. In CRI, protein restriction thus theoretically would reduce the amount of protein byproducts. In addition, acidosis, a factor leading to growth impairment, would also be diminished (190).

Restriction of dietary protein in childhood raises concern for impaired growth in comparison with that of older children and adults, because growing children require a higher protein intake (191). Growth factors such as IGF-1 are necessary for normal bone growth (192). Both animal and human studies implicate IGF-1 in mediation of hyperfiltration and glomerular hypertrophy (193). In children, restricted protein intake has been found to be associated with decreased IGF-1 levels (194). However, further studies are necessary to determine the effect of IGF-1 on CRI progression.

The Modification of Diet in Renal Disease study in adults demonstrated that consumption of low-protein diets of approximately 0.6 g/kg/day was not associated with any physical changes such as changes in midarm circumference or body weight (185). None of the patients enrolled in this study appeared to have suffered malnutrition. However, analysis of the data on protein restriction revealed minimal benefit in reducing the rate of progression of renal disease (195). The European Study Group for Nutritional Treatment of Chronic Renal Failure in Childhood found that consumption of a low-protein diet with a protein level of 0.8 to 1.1 g/kg/day did not have a deleterious effect on height in children with CRI; however, no correlation between protein restriction and progression of CRI was

established (196). Studies have demonstrated that the use of low-protein diets supplemented with ketoacids slowed progression to renal failure (197). These supplements increase the energy intake, which is required in renal failure. Limited data are available on the efficacy of this approach in children.

Proteinuria has been implicated in the causal pathway of renal failure (198). Studies have shown that the progression of CRI centers on impaired glomerular permselectivity to plasma macromolecules, such as proteins (199), which is thought to be due to long-standing glomerular hypertension. High glomerular capillary pressure may increase the radii of pores within the glomerular basement membrane, which leads to excessive ultrafiltration of plasma proteins in the proximal tubule lumen. Furthermore, this alteration may be partially mediated by angiotensin II, and the proteins may be potentially nephrotoxic (200), giving rise to the inflammatory component leading to CRI progression. In addition, upregulation of various genes that encode proinflammatory and vasoactive molecules occurs as a result of protein reabsorption. Inflammatory mediators such as endothelin-1 (201,202), as well as cytokines such as RANTES (regulated upon activation, normal T cell expressed and secreted) and MCP-1 (monocyte chemoattractant protein-1), have all been shown to be produced in response to this protein reabsorption (203,204). These factors may play a significant role in the pathogenesis of renal scarring (205). In addition to the aforementioned processes, telomere shortening has now been proposed as another cause of deterioration in renal function. At a crucial point in cell division, if the telomere is too short, cell senescence and finally apoptosis will result (206).

ACE inhibitors are useful therapeutic agents in the reduction of proteinuria associated with progression of CRI (207). This therapeutic effect of ACE inhibitors was initially observed in patients with renal disease secondary to scleroderma and later was demonstrated in animal models (208–210). The animal studies suggested that the antiproteinuric effect of ACE inhibitors may be due to reduced glomerular hydraulic pressure resulting from a decrease in one or more of the following factors: postglomerular arteriolar resistance, GFR, and filtration fraction (211). Angiotensin II, however, may produce an increase in glomerular capillary hydraulic pressure via vasoconstriction of the afferent arterioles. These data demonstrate that the mechanism by which ACE inhibitors reduce proteinuria is a decrease in glomerular capillary hydraulic pressure. Remuzzi et al. showed that ACE inhibitors also improved glomerular basement permselectivity (212).

In clinical practice, it is difficult to separate proteinuria and hypertension as two distinct risk factors for progression of CRI. Early studies attempted to evaluate this concept in diabetic patients with CRI. In these clinical trials, diabetic

patients treated with captopril were found to have a decreased incidence of CRI, independent of blood pressure changes (213). Later studies examining the use of enalapril in non-insulin-dependent diabetes mellitus demonstrated stabilization of renal function as well as proteinuria (214,215). Furthermore, the Ramipril Efficacy in Nephropathy trial demonstrated a correlation between improved renal function and reduction in proteinuria in nondiabetic adult patients with nephropathy (216).

The European Study Group for Nutritional Treatment of Chronic Renal Failure in Childhood analyzed the nutritional status of children in the mid-1990s and concluded that proteinuria and hypertension were independent predictors of progression of renal disease (196). This study showed that children with decreased protein excretion had a slower progression to CRI. In addition, lower blood pressure was associated with a better creatinine clearance.

In addition to the ACE inhibitors, angiotensin II receptor antagonists (ARAs) are another class of antihypertensive agents. The mechanism of action involves the renin-angiotensin system, as with the ACE inhibitors. Specifically, the ARAs block the angiotensin II type 1 receptor, which leads to a reduction in blood pressure. Unlike the ACE inhibitors, the ARAs do not typically accentuate kinin activity or enhance prostaglandin synthesis (217). Therefore, ARAs appear to have an antiproliferative effect.

ARAs are currently considered to be an additional class of agents useful in reduction of proteinuria. Lafayette and colleagues (218) were among the first to demonstrate ARAs to be effective in reducing the progression of renal injury in rats with a five-sixths nephrectomy. This study demonstrated that both the ACE inhibitors, enalapril, and the ARA losartan decreased proteinuria as well as blood pressure. Other studies demonstrated that candesartan, another ARA, prevented the development of proteinuria (219). ARAs also are being used in combination with ACE inhibitors to maximize the antiproteinuric effect produced by the administration of each agent (220).

Therefore, currently the control of hypertension, the reduction in the magnitude of proteinuria using ACE inhibitors and/or ARAs, and the potential minimization of hyperfiltration by ACE inhibitors and ARAs are used to modulate the progression of CRI in children. These treatments are widely used despite the lack of controlled studies demonstrating efficacy in this patient population.

HEALTH MAINTENANCE AND IMMUNIZATIONS IN CHRONIC RENAL INSUFFICIENCY

Children who have chronic diseases are seen frequently in medical facilities, and general health issues are sometimes overlooked. It is essential that primary care providers con-

tinue to monitor these children for routine health maintenance and preventive medicine issues. Similarly, these children should be encouraged to participate in educational, social, and athletic activities appropriate for age, developmental level, and physical capabilities.

The provision of routine immunizations to children with CRI and ESRD has been shown to be safe and generally effective, even after renal transplantation. Thus, as much as possible, these immunizations should be provided at routine intervals, in a strategy that permits the best opportunity for adequate response (221,222). Immunizations that are routinely administered to children include diphtheria and tetanus toxoids and pertussis vaccine, measles-mumps-rubella vaccine, varicella vaccine, *Haemophilus influenzae* type b vaccine, and hepatitis B virus vaccine. Children with chronic diseases often receive influenza and pneumococcal vaccines. In some cases, booster immunizations are necessary. Antibody responses of children with CRI and ESRD to several currently recommended vaccines have been variable (223–226). Possible explanations for the reduced protection include lower seroconversion rate due to immunocompromise related to chronic disease or to the concomitant use of immunosuppressive medications, lower peak antibody titers, and a more rapid decline of antibody levels as a consequence of diminished production or loss of immunoglobulins in urine or in peritoneal dialysate (227–231).

Diphtheria-pertussis-tetanus vaccine is routinely administered to infants and diphtheria-tetanus boosters are given throughout life. Some concerns have been raised about their immunostimulatory effects after transplantation. However, a study of 42 children with renal transplants demonstrated safety and a protective response in 95% (237). Interestingly, a study of 71 hemodialysis patients with an unknown previous immunization history revealed only a 38% protective conversion rate after a single diphtheria-tetanus immunization, which suggests a worse response on dialysis than after transplantation (234). Thus, not only should immunization be ensured before transplantation, but protective antibody levels should be ascertained frequently.

Varicella vaccine has been available in Europe for over 15 years but has only more recently been made available in the United States. Varicella is a potentially fatal infection in immunosuppressed individuals (238). Pretransplantation vaccination of children is successful in preventing or mitigating the disease (239). Pretransplantation vaccination is generally successful and cost effective (236,240). Even posttransplantation vaccination seems to be safe and reasonably effective (241).

Hepatitis B vaccination of patients who have CRI or are receiving dialysis is frequently less successful than that of normal individuals, and increased vaccine administration, change of route of administration, or the use of adjuvant immunomodulating therapy have been suggested (224, 225,232).

The most commonly administered form of the pneumococcal vaccine contains 23 antigens from pneumococcal

serotypes. The vaccine is generally given only once, when the patient reaches at least 2 years of age. However, revaccination should be considered for children younger than 10 years of age who are at risk for severe pneumococcal disease, such as those with CRI, particularly those receiving chronic peritoneal dialysis. Revaccination should also be considered in older children maintained on chronic peritoneal dialysis for more than 6 years. Administration to children with CRI or those on dialysis is successful in the majority of cases, but protection seems to decline rapidly (233), and failures have been reported (235). Provision after kidney transplantation seems to be at least safe (233,242).

Influenza vaccine has been recommended for children with chronic renal disease, including those who have CRI and those who have undergone transplantation (221,222, 243). The vaccine is generally given annually in the fall, and young children may need repeated doses.

In general, therefore, children with CRI should receive routine immunizations. Even live virus vaccines appear to be safe after transplantation, and no increased incidence of rejection has been reported after immunostimulation due to the immunization. Vigilance with regard to sustained protection is important in these children.

ENDOCRINE AND GROWTH DISORDERS IN CHRONIC RENAL FAILURE

FRANZ SCHAEFER

ENDOCRINE DISORDERS IN CHRONIC RENAL FAILURE

Pathophysiologic Mechanisms

Uremia interferes with metabolism and regulation of hormones by various mechanisms. Disturbed endocrine function may arise either from inappropriate circulating hormone concentrations or from altered hormone action at the target tissue level. Both conditions may be present in the uremic state.

Increased Plasma Hormone Concentrations

Renal catabolism accounts for one-third to two-thirds of the metabolic clearance rates of various polypeptide hormones (1). Most polypeptide hormones are almost freely filtered in the glomerulus, followed by either intratubular degradation (brush-border peptidases) or intracellular degradation (cytosolic or lysosomal) in tubular cells. Moreover, certain hormones are subject to receptor-mediated uptake across the basolateral tubular cell membrane. Hence, any reduction of renal mass results in a decrease in the metabolic clearance of most peptide hormones (Fig. 68.1). If catabolic mechanisms differ for different isoforms or subunits of a hormone, an imbalance of these constituents may arise, altering the relation between biologically active and inactive hormone fragments (see later). In addition to renal clearance, *extrarenal hormone elimination* may also be reduced in renal failure. For example, degradation of insulin in skeletal muscle tissue is diminished (2), and hepatic catabolism of biologically active parathyroid hormone (PTH) is reduced in uremia (3). Finally, *hypersecretion* of various hormones or hormone-binding proteins occurs in renal failure, either as an appropriate response to secretory stimuli (e.g., PTH) or without an apparent homeostatic signal (e.g., prolactin).

Decreased Plasma Hormone Concentrations

The reduction in functional renal mass is assumed to be the main cause for decreased levels of hormones produced by the *kidney* (erythropoietin; 1,25-dihydroxyvitamin D₃). In

addition, the uremic milieu may suppress the production of these hormones by alterations of the internal milieu. For example, intracellular phosphate accumulation may inhibit 1 α -hydroxylase even before the reduction of renal mass becomes quantitatively important. Levels of *extrarenal hormones* may be decreased when the hormone-producing gland is the final effector organ of a complex hormonal axis (e.g., testis–testosterone, ovary–estradiol). In these cases, insufficient production of hormones may result either from direct toxic damage to the endocrine gland, from insufficient stimulatory input from the superior part of the hormonal axis, or from hyporesponsiveness of the gland.

Disorders of Hormone Action

Disturbed Activation of Prohormones

Concentrations of certain prohormones are elevated in chronic renal failure (CRF), for example, pro–insulin-like growth factor IA, a precursor of insulin-like growth factor-1 (IGF-1), which is not detectable in normal serum (4), and proinsulin, which is not converted appropriately to insulin or C-peptide in patients with end-stage renal disease (ESRD) (5). Peripheral conversion of thyroxine (T₄) to tissue-active triiodothyronine (T₃) is impaired (6). Some prohormones may block hormone action by competitively inhibiting receptor binding at the tissue level.

Multimolecular Forms of Variable Bioactivity

Some polypeptide hormones circulate in plasma in multiple isoforms characterized by varying composition of their carbohydrate side chains. In CRF, altered glycosylation and sialization (7) may shift the isohormone spectrum toward less bioactive forms [e.g., luteinizing hormone (LH) (8)]. This may be due to alterations of posttranslational processing or to differences in the renal clearance of individual isoforms.

Hormone Binding to Plasma Proteins

Excessive concentrations of several IGF-binding proteins are found in CRF (9,10). Binding proteins can compete for

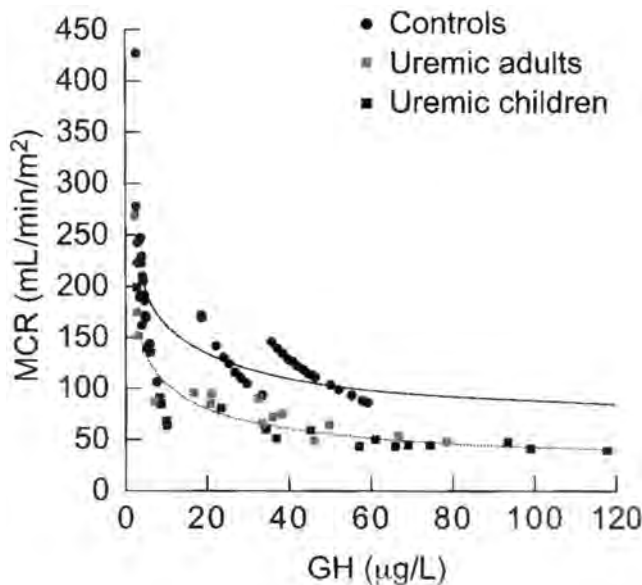

FIGURE 68.1. Total metabolic clearance rate (MCR) as a function of steady-state plasma growth hormone (GH) concentrations in controls and patients with chronic renal failure (CRF). MCR is reduced in children and adults with CRF at any prevailing plasma GH level. (From Haffner D, Schaefer F, Girard J, et al. Metabolic clearance of recombinant human growth hormone in health and chronic renal failure. *J Clin Invest* 1994;93:1163-1171, with permission.)

the hormone with target organ receptors, and this explains in part the reduced somatomedin bioactivity in the presence of normal total serum IGF. Abnormal concentrations of other polypeptide binding proteins may similarly be related to abnormal hormone action in uremia.

Alterations of Target Tissue Sensitivity

Diminished target organ responsiveness is observed in various endocrine systems in uremia. Mechanisms for altered target tissue sensitivity include reduced cellular receptor activation due to the diminished receptor abundance, the presence of inhibitory substances, the accumulation of molecules inhibiting hormone-receptor interaction (e.g., IGF-1), and structural changes of either the hormone or its receptor (9). Moreover, defects of hormone-receptor complex-dependent intracellular signaling may occur. Such postreceptor events seem to play a key role in the pathogenesis of insulin (11) and growth hormone (GH) (12) resistance in uremia.

Gonadotropic Hormone Axis

Clinical Findings

The onset of puberty is usually delayed in adolescents with CRF. At least 50% of adolescents with ESRD enter puberty beyond the normal age range (13) and achieve the pubertal milestones beyond the normal age range (14-16). Late puberty is observed both in children on dialysis and after

renal transplantation. In the Cooperative Study for Pubertal Development in CRF, the onset of puberty was delayed by 2 to 2.5 years on average (17). The start of genital maturation (Tanner stage G2) was delayed by 1.8 years in uremic boys and 2.5 years in boys undergoing transplantation. Full genital maturation was achieved with a delay of 2.2 and 3.2 years, respectively. Thus, once started, puberty appears to proceed at a normal rate. However, in individual patients, particularly those on long-term dialysis, pubertal maturation may arrest for years. Almost half of the girls treated by dialysis or renal transplantation fail to menstruate before the upper normal age limit of 15 years. Menarche tends to occur even later in girls undergoing transplantation than in girls on dialysis (14).

Unlike the development of secondary sexual characteristics, which is delayed but not permanently halted in CRF, reproductive function may be permanently impaired. In autopsy studies of boys with CRF, germ cell depletion in the testicular tubules has been described (18). These changes do not appear reversible after renal transplantation (19). Persistently reduced sperm counts were observed in 10 of 12 young adults who successfully underwent transplantation who had suffered from ESRD during childhood (19). Erectile dysfunction, decreased libido, and decreased fertility are primarily organic in nature and are due to uremia as well as to other comorbid conditions, fatigue, and psychosocial factors (20). The frequency of conception is decreased in women with chronic renal insufficiency, and pregnancy is very uncommon in adolescents with ESRD. The percentage of surviving infants ranges from 70 to 100% in women with CRF on conservative treatment or after renal transplantation (19) and from 50 to 80% in women on dialysis (21-23). Intrauterine growth retardation is frequent, and the birth weight is reduced by nearly 1 kg (16,20,21).

Gonadal Hormones

In adults with CRF plasma concentrations of *testosterone* (T) are usually low or low normal (24), due to reduced synthesis and, perhaps, increased metabolic clearance (25,26). In prepubertal children with predialytic renal failure, low total and free T and dihydrotestosterone (DHT) plasma concentrations have been reported (27). However, because the adrenal cortex is the major site of androgen production before puberty and the levels of specific adrenal androgens are also low in children with CRF (28), low prepubertal plasma androgen levels do not provide evidence for gonadal damage before puberty (29,30). In pubertal patients, normal or slightly subnormal plasma T concentrations are observed (31-33). In late puberty, however, DHT concentrations are significantly lower in children with CRF than in healthy children or those who have undergone transplantation (F.S., unpublished observation). Impaired conversion of T to DHT due to decreased 5 α -reductase activity has been suggested (34,35). Because this metabolite is responsible for many tissue actions of the andro-

FIGURE 68.2. Evidence for circulating luteinizing hormone (LH) inhibitor in sera of boys with chronic renal failure. Inhibition is suppressed in presence of serum of patients on conservative treatment or continuous ambulatory peritoneal dialysis (CAPD). Human chorionic gonadotropin (HCG)-induced production of cyclic adenosine monophosphate (cAMP) by cell line expressing human LH/HCG receptor is suppressed by a fraction containing 30- to 60-kDa proteins (data not shown). [Adapted with permission from Dunkel L, Raivio T, Laine J, et al. Circulating luteinizing hormone receptor inhibitor(s) in boys with chronic renal failure. *Kidney Int* 1997;51:777-784.]

gens, reduced conversion of T to DHT may explain the frequently sparse development of secondary sexual characteristics in boys with advanced renal failure.

The testicular response to supraphysiologic stimulation by human chorionic gonadotropin is impaired in adult men (24) as well as in prepubertal and pubertal boys with CRF. Testicular insufficiency is most prominent in boys on hemodialysis (31). Leydig cell resistance is caused by a cyclic adenosine monophosphate (cAMP)-dependent mechanism (36). The presence of an endogenous LH inhibitor in uremic serum has been demonstrated (37) (Fig. 68.2). The disorder is reversible after renal transplantation (31).

The physiologic age-related decrease of sex hormone-binding globulin is conserved in prepubertal children on dialysis (32); however, at a given age sex hormone-binding globulin concentrations are higher and the unbound T fraction is lower than in normal children. The increase of sex hormone-binding globulin may be due to accumulation in end-stage renal failure; a normal fraction of free T has been reported in prepubertal children on conservative treatment (27).

The plasma concentration of *inhibin*, a polypeptide produced by the Sertoli and granulosa cells, is elevated in prepubertal boys with CRF (38).

Estradiol plasma concentrations in the low-normal range are observed in women with CRF (39). In pubertal girls with CRF, estradiol plasma levels are normal or low when

related to pubertal stage (40,41). An inverse correlation between serum creatinine levels and estradiol concentrations was found in patients with predialytic CRF. Longitudinal analysis revealed an insufficient increase in estradiol during puberty in those patients whose renal function deteriorated, whereas after renal transplantation, even after several years of dialysis, estradiol concentrations increased (41).

Gonadotropins

Plasma LH levels are high normal or elevated in adult men, women, and prepubertal and pubertal boys and girls with CRF (8,24,27,39,40,42); follicle-stimulating hormone (FSH) concentrations are also usually elevated in both adults and children with CRF. After transplantation, LH levels usually return to normal, whereas plasma FSH frequently remains elevated.

The combination of elevated gonadotropins and decreased or low-normal gonadal hormone levels has been taken as evidence for a state of compensated hypergonadotropic hypogonadism (27,43). However, the degree of hypergonadotropism in CRF is usually inadequate for the prevailing degree of hypogonadism, which suggests an additional defect of hypophyseal gonadotropin secretion.

An alteration at the pituitary level is suggested by the blunted increase of plasma LH and FSH after stimulation by a bolus of exogenous gonadotropin-releasing hormone (GnRH) in men, women, boys, and girls with CRF (24,27,40). These abnormalities appear even more marked when the diminished metabolic clearance of gonadotropins is taken into account (44). The gonadotropin response to GnRH is normalized after successful transplantation (40).

LH is released from the pituitary gland in episodic (pulsatile) bursts occurring every 90 to 120 minutes. The plasma LH concentration peaks reflect intermittent secretion of hypothalamic GnRH into the hypophyseal-portal bloodstream (45). Hence, the analysis of plasma LH pulses gives indirect information about the functional state of the hypothalamic GnRH "pacemaker." A differentiation of the secretion and elimination components underlying the fluctuating plasma LH concentration patterns by means of deconvolution methodology (46) revealed that the elevation of basal plasma LH concentrations is entirely due to the diminished renal metabolic clearance of the hormone (44) both in humans (47) and in rats (48). Plasma half-life of LH is inversely correlated with GFR (47). In contrast, actual pituitary LH secretion rates are decreased in CRF; pubertal dialysis patients secrete 3 times less immunoreactive LH and 2.5 times less bioactive LH in episodic nocturnal peaks than normal adolescents (47). This abnormality, which has been reproduced in experimental uremia (49), gives strong evidence for a dysregulation of the gonadotropic axis at the hypothalamopituitary level. After transplantation, a regular pattern of LH pulses is reestablished (8,50). Because the onset of puberty is heralded by the emergence of a nocturnal pattern of pulsatile LH secre-

FIGURE 68.3. Selective inhibition of gonadotropin-releasing hormone (GnRH) secretion from cultured neurons of a hypothalamic cell line by incubation with a high-molecular-weight fraction of uremic serum. GnRH supernatant concentrations observed with serum fractions from control animals were defined as 100%. *, $p < .05$; **, $p < .01$. (Adapted from Daschner M, Philippin B, Nguyen T, et al. Circulating inhibitor of gonadotropin releasing hormone secretion from hypothalamic neurons in uremia. *Kidney Int* 2002;62:1582–1590.)

tion, the observed disturbance of pulsatile LH secretion suggests that the delayed pubertal development in CRF is caused by a primary hypothalamic defect. Experimental evidence confirms that the subnormal pituitary gonadotropin secretion is caused by diminished release of GnRH into the hypophyseal portal circulation (48,51). In cultured GnRH-producing neurons an inhibition of GnRH release was observed on addition of a high-molecular-weight fraction of uremic serum. Further investigation suggested that the inhibitor is a hydrophilic protein suppressing GnRH exocytosis but not synthesis (52) (Fig. 68.3). Moreover, with the use of *in vivo* intracerebral microdialysis in experimentally uremic rats, we observed an increased tone of the neuroinhibitory amino acid γ -aminobutyric acid in the extracellular fluid of the hypothalamic medial preoptic area, the region where the GnRH neurons reside (53). Hence, the accumulation of γ -aminobutyric acid in the central nervous system may be another mechanism of downregulation of the gonadotropin hormone axis in uremia.

In summary, clinical and experimental evidence indicates that the neuroendocrine control of pulsatile LH secretion is altered in CRF. Although overt hypogonadotropism is masked by a simultaneous reduction of metabolic clearance rates, the deficient physiologic pulsatile GnRH-LH signal may be the key abnormality underlying the delayed

onset of puberty in chronic renal disease. The observed disorders of LH secretion and metabolism appear to be reversible after successful renal transplantation.

Not only is there quantitative insufficiency of the hypothalamopituitary unit, but the biologic *quality* of the circulating gonadotropins is also altered in uremia. LH bioactivity, measured by the potency of a plasma sample in inducing testosterone secretion in a Leydig cell culture, depends on the degree of glycosylation and sialization of this glycoprotein hormone (54). During normal puberty, the relative bioactivity of LH gradually increases (55). In pubertal (56,57) and adult patients (50) on dialysis, the ratio of bioactive to immunoreactive plasma LH is reduced, which suggests that the spectrum of circulating LH molecules is shifted toward bioinactive forms (8,47,50,58). This may be attributed to altered glycosylation of plasma proteins in uremia (7). The physiologic increase in hormone bioactivity during puberty is absent in dialysis patients (57). The inhibitor of LH action circulating in the serum of uremic boys may represent an accumulating LH fragment (37) (Fig. 68.2). After successful renal transplantation, LH biopotency tends to normalize.

Prolactin

Prolactin is a proteohormone secreted by the pituitary that is involved in the hormonal regulation of lactation. Its function in nonpuerperal women, in men, and in children is not clear. However, prolactin attenuates gonadotropin release. Plasma prolactin levels are elevated in men (59) and, more markedly, in women and pubertal girls (40,59) with CRF. Uremic hyperprolactinemia appears to result from both decreased metabolic clearance rate and increased production of the hormone (60). Hyperprolactinemia may play a role in the pathogenesis of uremic hypogonadism, because elevated prolactin levels exert a suppressive effect on the GnRH-LH pulse generator (61). The physiologic sleep-related nocturnal prolactin surge is absent (62), and the circadian rhythm of secretion is deranged (63). Prolactin secretion in CRF patients is insensitive to stimulation by thyrotropin-releasing hormone (TRH) (64), chlorpromazine, metoclopramide, arginine, or insulin-induced hypoglycemia (65). Neither L-dopa nor dopamine is effective in suppressing prolactin secretion (65); however, hyperprolactinemia may be corrected by long-term treatment with dopaminergic agonists (66,67). Uremic hyperprolactinemia may be related to other complications of CRF such as vitamin D deficiency and renal anemia. Administration of 1,25-dihydroxyvitamin D₃ (68) and erythropoietin (69) leads to a partial normalization of plasma prolactin levels.

In conclusion, various physiologic studies and pharmacologic tests reveal a partial disintegration of the gonadotropin hormone axis at the hypothalamopituitary level, in addition to alterations of gonadal function. The analysis of hormone secretory patterns has confirmed that the central nervous dysregulation is not restricted to the functional

reserve capacity of the reproductive hormone system but affects physiologic spontaneous hormone secretion. The reversibility of the observed changes after successful renal transplantation gives further evidence that regulatory mechanisms, rather than toxic end-organ damage, affect gonadal function in uremia. It remains to be shown to what extent the apparent dysregulation of hormone secretion represents a “physiologic” adaptation to an adverse metabolic environment.

Growth Hormone–Insulin-Like Growth Factor Axis

During normal childhood, the somatotrophic hormone axis plays a key role in the regulation of body growth. In addition, GH is part of a complex system of counterregulatory hormones maintaining the homeostasis of carbohydrate metabolism.

Growth Hormone

Serum Concentrations and Kinetics

Fasting GH concentrations are variably elevated in uremic children and adults depending on the extent of renal failure (70,71). The kidney is a major site of GH degradation (72). In patients with end-stage renal failure, the metabolic clearance rate of GH is reduced by approximately 50% (73,74) (Fig. 68.1). Deconvolution analyses of GH plasma concentration profiles revealed that the increase in plasma GH concentrations is due mainly to an increased plasma half-life of the hormone; the actual pituitary GH secretion rate varied among patients and across studies. GH secretion rate was high normal in prepubertal children with ESRD and increased in adult patients on hemodialysis, possibly as a result of attenuated bioactive IGF-1 feedback of the hypothalamopituitary unit (75,76). In pubertal patients with advanced CRF, reduced GH secretion rates were observed, which indicated an altered sensitivity of the somatotrophic hormone axis to the stimulatory effect of sex steroids during this stage of development (77). The variability of plasma GH levels in CRF may be due in part to associated conditions such as acidosis and malnutrition, which independently affect GH secretion. Metabolic acidosis suppresses GH release in both rodents and humans (78).

Neuroendocrine Control of Growth Hormone Release

Dysregulation of GH secretion may be related to abnormalities of central neuroendocrine control mechanisms. Evidence for this is provided by several hypothalamopituitary function tests. The GH response to intravenous administration of GH-releasing hormone is augmented and prolonged in children (79). Exogenous TRH, which does not affect GH release in healthy subjects, markedly enhances GH secretion in subjects with renal failure (70,80). Also, CRF patients respond to acute hyperglycemia with a paradoxical

increase of GH secretion (70,81). Stimulation tests such as arginine infusion and insulin-induced hypoglycemia lead to a sustained, exaggerated increase of GH (70,82,83). However, the altered metabolic clearance rates of GH as well as of the provocative agents in renal failure (84) make a meaningful clinical interpretation of such tests virtually impossible.

Growth Hormone Receptor Signaling and Tissue Action

Growth failure despite elevated circulating GH concentrations suggests a state of GH resistance in children with CRF. Indeed, GH-induced hepatic IGF-1 synthesis is markedly reduced in rats with CRF (12,85). This GH insensitivity may in part be due to deficient GH receptor expression, although this is controversial. Reduced hepatic GH receptor messenger RNA (mRNA) and receptor binding has been reported in some but not all studies carried out with animals (12,85–88). These discrepancies may be related to the effect of reduced nutritional intake. Indeed, controlling for the anorexia of chronic uremia by pair-feeding control animals abolished the difference in GH receptor protein expression and binding to liver plasma membranes seen when ad lib feeding controls and uremic animals are compared (12,87), although receptor mRNA levels remained subnormal (12). On the other hand, reduced GH receptor protein expression was observed in the growth cartilage of rats with CRF even though nutritional intake was controlled (89). In humans serum levels of GH-binding protein, putatively reflecting hepatic GH receptor status, were found to be decreased in some studies but normal in others (74,90–93).

Another mechanism accounting for the resistance to GH in uremia is provided by a marked *postreceptor* GH signaling defect observed in livers of chronically uremic rats (12). Despite unaltered GH receptor protein levels, phosphorylation of the GH receptor–associated tyrosine kinase janus kinase 2 (JAK2) was diminished by 75% (Fig. 68.4). This resulted in a similar suppression of GH–JAK2–dependent phosphorylation of specific downstream signaling molecules, namely, signal transducer and activator of transcription 1 (STAT1), 3 (STAT3), and 5 (STAT5). This defect was possibly caused by upregulation of two intracellular JAK2 inhibitors, suppressors of cytokine signaling 2 (SOCS2) and 3 (SOCS3). Because these regulatory proteins are induced by inflammatory cytokines, it may be postulated that GH resistance in uremia is caused by a microinflammatory state.

Insulin-Like Growth Factors

Because most metabolic effects of GH are mediated by IGF-1, GH insensitivity in uremia may also be due to IGF resistance. Indeed, numerous studies in the rat as well as in humans have clearly documented marked IGF-1 resistance in CRF (94–97).

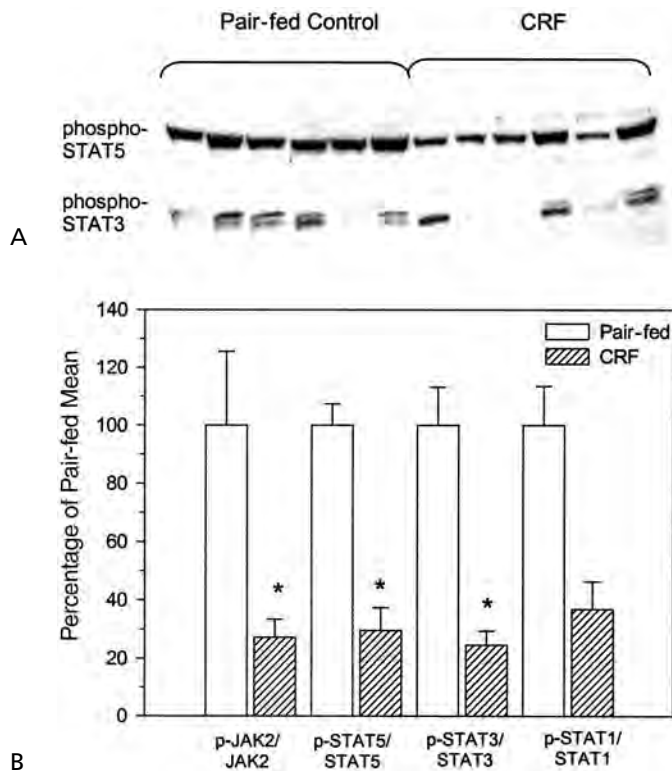

FIGURE 68.4. Impaired postreceptor growth hormone signaling in rats with experimental uremia. **A:** Deficient nuclear accumulation of tyrosine-phosphorylated signal transducer and activator of transcription 5 (STAT5) and 3 (STAT3) protein in livers of rats with chronic renal failure (CRF) compared to pair-fed controls. **B:** Increased messenger RNA abundance of suppressor of cytokine signaling 2 (SOCS2) in rats with CRF treated with recombinant growth hormone. SOCS2 inhibits STAT phosphorylation by binding to tyrosine kinase janus kinase 2 (JAK2). p-JAK2, phosphorylated janus kinase 2; p-STAT1, p-STAT3, p-STAT5, phosphorylated signal transducer and activator of transcription 1, 3, and 5. (From Schaefer F, Chen Y, Tsao T, et al. Impaired JAK-STAT signal transduction contributes to growth hormone resistance in chronic uremia. *J Clin Invest* 2001;108:467–475, with permission.)

Insulin-Like Growth Factor Serum Concentrations

The effect of GH on longitudinal growth is partially mediated by stimulation of the production of somatomedins, the two most important of which are the IGF-1 and IGF-2. Serum IGF-1 and IGF-2 levels in children with preterminal CRF are in the normal range, whereas in ESRD mean age-related serum IGF-1 levels are slightly decreased and IGF-2 levels are moderately elevated (98). Hence, total immunoreactive IGF levels in CRF serum are normal. In contrast, IGF *bioactivity* is markedly reduced. Similarly, the level of free IGF-1 is reduced by 50% in relation to the degree of renal dysfunction (99). This is one of the key abnormalities of the GH-IGF axis in children with CRF.

Insulin-Like Growth Factor Plasma Binding and Tissue Action

The discrepancy between low somatomedin activity by bioassay and normal or elevated IGF by radioimmunoassay or

FIGURE 68.5. Molar concentrations of insulin-like growth factors (IGFs) and IGF-binding proteins (IGFBPs) in children with pre-terminal chronic renal failure (CRF) and children with end-stage renal disease (ESRD) on dialysis compared with age-matched healthy children. [From Ulinski T, Mohan S, Kiepe D, et al. Serum insulin-like growth factor binding protein (IGFBP)-4 and IGFBP-5 in children with chronic renal failure: relationship to growth and glomerular filtration rate. *Pediatr Nephrol* 2000;14:589–597, with permission.]

radioreceptor assay suggests the presence of circulating somatomedin inhibitors in uremia. An early study indicated the presence of a low-molecular-weight IGF inhibitor (approximately 1 kDa), but its molecular structure has not been characterized further (100).

The most likely explanation for the inhibition of somatomedin action in uremia has emerged from the identification of six IGF-binding proteins (IGFBP1 to IGFBP6). IGFBP3 appears to be the most abundant in humans, constituting more than 95% of total circulating IGFBP. In children with CRF, the serum concentrations of IGFBP1, IGFBP2, IGFBP4, and IGFBP6 are increased in a manner inversely related to GFR (9,10,98,101–104) (Fig. 68.5). Ligand blotting shows that the elevation of radioimmunoassayable IGFBP3 is due to an increase in low-molecular-weight forms mainly in the range of 14 to 19 kDa, whereas intact IGFBP3 (38 to 41 kDa) is markedly reduced (105,106). IGFBP1, IGFBP2, and IGFBP6 inhibit somatomedin bioactivity *in vitro* (107). Somatomedin bioactivity in uremic serum can be returned to normal by removing unsaturated IGFBP (108). Experimental evidence suggests that the increase of IGFBP1 and IGFBP2 is due not only to reduced renal metabolic clearance but also to increased hepatic synthesis (109). An important question is whether the imbalance between normal total IGF and the excess of unsaturated IGFBPs contributes to growth failure in children with CRF. Serum levels of IGFBP1, IGFBP2, and IGFBP4 correlate inversely with standardized height in children with CRF (98,104,110). Although it is tempting to speculate that these IGFBPs could contribute to growth failure in these children, proving causality is difficult because IGFBP levels and height standard deviation score (SDS) are all correlated with GFR.

Apart from the increased plasma IGF-1-binding capacity, a postreceptor IGF-1 signaling defect may also contribute to IGF-1 resistance in CRF. In uremic rats the effect of IGF-1 and various IGF-1 analogues on protein turnover

was suppressed (94). The observation that the inhibitory effect of IGF-1 and its analogues were affected to a similar degree indicates that the resistance arises because of a defect at a cellular level and not because of changes in IGFBP levels. Deficient autophosphorylation of the IGF-1 receptor in skeletal muscle of uremic rats has been reported (94) but was not confirmed in a later study (111).

Growth Hormone–Insulin-Like Growth Factor-1 Homeostasis in Chronic Renal Failure

The pattern of elevated GH, normal total IGF, and markedly elevated IGFBP plasma concentrations in uremia has interesting implications with respect to the estimated IGF production rate. In a functioning homeostatic system, the diminished free IGF-1 levels would be expected to stimulate IGF production to restore the steady state between bound and unbound hormone at a higher level. In uremia, however, total IGF concentrations are normal rather than increased. Kinetic modeling suggests that the metabolic half-life of IGFs is markedly elevated, and the IGF production rate is decreased 10- to 100-fold in uremia (112). Taken together, the markedly deficient IGF-1 synthesis and the modest elevation of plasma GH levels, which is due mainly to impaired metabolic clearance, in the presence of increased IGF-binding capacity strongly support the notion of a multilevel homeostatic failure of the GH–IGF-1 system in uremia. Pituitary GH secretion is insufficiently feedback-stimulated by reduced free IGF-1 levels, and marked tissue GH resistance prevents an increase in total IGF-1 levels in the presence of elevated GH levels.

Glucocorticoids and the Growth Hormone–Insulin-Like Growth Factor-1 Hormone Axis

After renal transplantation, the use of glucocorticoids for immunosuppression interferes with the GH–IGF-1 axis on various levels. Endogenous GH secretion is reduced in pediatric renal allograft recipients, mainly by a reduction of amplitudes of the GH secretory bursts (33,113). The physiologic increase of GH burst amplitudes during puberty is blunted, and the normal correlation between sex steroid plasma levels and GH secretion rate is absent (33). GH release after insulin-induced hypoglycemia is inadequate (113). The insufficiency of spontaneous and stimulated GH secretion in patients after transplantation is most likely explained by a glucocorticoid-induced enhancement of hypothalamic somatostatin release (114). On the target tissue level, glucocorticoids suppress GH receptor and IGF-1 gene transcription (115,116). Nevertheless, basal IGF-1 plasma levels in renal transplant recipients are in the normal range (117–119). This discrepancy between clinical and experimental findings suggests that glucocorticoids alter translation, synthesis, and/or secretion of IGF-1 in such a way that the IGF-1 mRNA redundancy no longer reflects IGF-1 protein synthesis. Whereas circulating immunoreactive IGF-1 concentrations are not consistently reduced, IGF bioactivity is markedly diminished in patients on glucocorticoid

treatment (117,120). This may be due to the induction of IGF inhibitors of 12 to 20 kDa molecular weight and/or to increased serum IGFBP3 levels (117,120). Moreover, increased IGFBP2 concentrations are found in patients with Cushing syndrome (121). IGFBP2 may be another functional IGF-1 inhibitor in patients receiving long-term glucocorticoid treatment.

Glucocorticoids also interfere with chondrocyte growth and enchondral bone formation in various ways. They inhibit sulfate incorporation into cartilage matrix as well as mineralization and formation of new bone (122). In cultured epiphyseal chondrocytes, dexamethasone decreases DNA synthesis and cell proliferation, GH receptor expression, and paracrine IGF-1 secretion (123).

Thyroid Hormone Axis

Clinical Findings

The thyroid hormone axis plays an important role in the regulation of tissue metabolism. Throughout childhood, thyroid hormone is involved in growth and skeletal maturation, stimulating both cartilage proliferation and epiphyseal differentiation.

The prevalence of goiter is increased in patients with ESRD (124,125). The prevalence of hypothyroidism ranges between 0 and 9.5% (124). Whereas primary hypothyroidism is observed 2.5 times more frequently in dialysis patients than in patients with other chronic nonrenal diseases, the prevalence of hyperthyroidism is not different (124). In children, the prevalence of hypothyroidism may be higher due to the greater proportion of patients treated for cystinosis and nephrotic syndrome. In cystinotic patients, deposition of cystine crystals in the thyroid can lead to destruction of the gland and frank hypothyroidism (126). Children with severe nephrotic syndrome, particularly those with the congenital form (127), may become hypothyroidal due to the renal loss of thyroid hormone-binding globulin (TBG).

Because some manifestations of hypothyroidism, such as hypothermia, pallor, and dry skin, also occur in uremia, the exclusion of the diagnosis of hypothyroidism on clinical grounds may be difficult in a uremic child. Therefore, exploration of the hormonal status of a patient is essential for the recognition of an accompanying thyroidal disorder.

Thyroid Hormones

Inorganic iodine is physiologically excreted by the kidney, and plasma inorganic iodine levels increase as kidney function decreases (128).

The plasma levels of total T_4 (thyroxine) and T_3 (triiodothyronine) are decreased in patients with CRF (129). Significant depression of T_4 and T_3 levels usually occurs once the GFR falls below 50%. Thyroid hormone *production rates* are normal in patients with CRF (130,131). Met-

abolic clearance rates of the hormones may (132) or may not (131) be increased. Due to impaired peripheral deiodination of T_4 to T_3 (6,132), there is a more distinct suppression of T_3 than of T_4 levels. In ESRD, diminished T_4 levels are found in one-third of patients and diminished T_3 levels in 50% of patients (125,133–136), including children (137). Concentrations of reverse T_3 (rT_3), the inactive metabolite of T_4 in plasma, are low (138) or normal (136). Production and metabolic clearance rates of rT_3 are normal (130), but extravascular binding of rT_3 is increased (131).

The more pronounced decrease of plasma T_3 than of T_4 levels in CRF resembles the thyroid hormone pattern observed in other states of chronic nonthyroidal diseases (sick euthyroid or low T_3 syndrome). However, whereas in the sick euthyroid syndrome rT_3 levels are elevated as a result of impaired peripheral conversion of T_4 to T_3 , rT_3 levels are in the low-normal range in CRF. This constellation has been explained by a redistribution of rT_3 into extravascular compartments in uremia (131).

Binding Proteins

Circulating thyroid hormones are bound to TBG, albumin, and prealbumin. TBG levels usually are normal in hemodialysis patients (133,139); they are frequently low in patients on continuous ambulatory peritoneal dialysis (CAPD), who lose thyroid hormone-binding proteins via the dialysate (139,140). Patients with severe nephrotic syndrome may have markedly low TBG plasma levels due to urinary protein loss. Only the unbound (free) T_4 (fT_4) and T_3 (fT_3) fractions are biologically active. Plasma levels of fT_4 and fT_3 as measured by radioimmunoassay are low (141), and dissociation constants for specific T_4 and T_3 binding are normal (142).

Thyroid-Stimulating Hormone

Despite low plasma total and free T_4 and T_3 levels, thyroid-stimulating hormone (TSH) concentrations are usually normal in adults (133,141) and children with CRF (137). Normal TSH in the face of low fT_3 and fT_4 points to altered regulation of the hypothalamopituitary–thyroid axis. Experimental evidence suggests that the sensitivity of the thyrotroph to feedback inhibition is increased in uremia. In addition, TRH administration causes a blunted, delayed rise of plasma TSH (6,80,142). The duration of the TSH response is prolonged due to decreased metabolic clearance and increased half-lives of both TRH and TSH (84,143). Although basal iodine uptake is low (133), thyroid responsiveness to stimulation by TSH is normal (144).

The most convincing evidence for a primary hypothalamic defect comes from studies on the temporal organization of TSH release. The physiologic nocturnal TSH surge is frequently blunted in children and adults with ESRD (137,145), and the pattern of pulsatile TSH secretion is altered toward low-amplitude, high-frequency pulses (145).

In summary, CRF is associated with a resetting of the central thyrostat toward lower levels of circulating thyroid hormones. The lacking upregulation of spontaneous TSH secretion despite low thyroid hormone levels either may indicate a failure of the thyrotroph to respond to the physiologic stimulus of low thyroid hormone concentrations or may be interpreted as a “physiologic” downregulation resulting from a reduced *demand* for thyroid hormone in the specific state of metabolism caused by uremia.

Children with nephropathic cystinosis are exceptional in that, even in advanced renal failure, they exhibit an exaggerated TSH response to TRH stimulation. This reflects primary hypothyroidism due to destruction of the thyroid gland by deposition of cystine crystals (126). TSH level may also be elevated in children with severe nephrotic syndrome (127), which reflects a hypothyroid state due to renal loss of TBG-bound thyroid hormones.

Thyroid Hormone Action

Clinically, patients with CRF usually appear euthyroid. Measurements of basal metabolic rate and rough clinical indices yield normal results (134,146). Normal TSH concentrations suggest that euthyroidism is also present in pituitary thyrotrophs. In experimental uremia an upregulation of T_3 receptor expression, possibly as a compensatory mechanism to low circulating levels of T_3 , and normal expression of T_3 -dependent hepatic proteins have been observed (147,148). Although endogenous hormone action appears efficient, CRF patients show a marked resistance against exogenous thyroid hormone administration with regard to thermogenesis. Oxygen uptake is neither stimulated by administration of T_3 nor suppressed by its antagonist sodium ipodate (149) (Fig. 68.6). In contrast to normal subjects, in CRF patients T_3 supplementation results in exaggerated protein degradation and a negative nitrogen balance (138,150,151), similar to that observed in patients with chronic illness or malnutri-

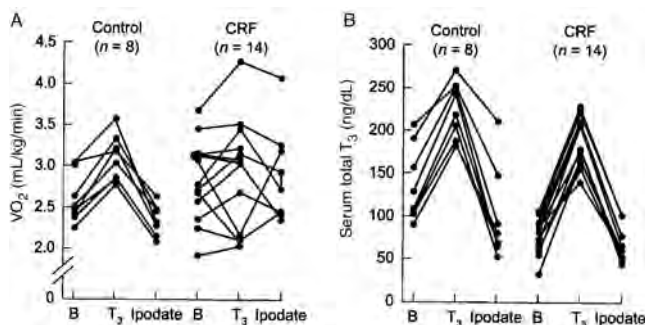

FIGURE 68.6. Failure of thyroxin administration to stimulate, and of thyroid suppression to reduce, oxygen consumption (VO_2) (A) despite adequate changes in plasma triiodothyronine (T_3) levels (B) in patients with chronic renal insufficiency (CRF). B, baseline level. (From Lim VS, Zavala DC, Flanigan MJ, et al. Blunted peripheral tissue responsiveness to thyroid hormone in uremic patients. *Kidney Int* 1987;31:808–814, with permission.)

tion (152). Hence, the low T_3 syndrome of uremia may in part be interpreted as a physiologic adaptation to conserve energy in an adverse metabolic environment, and supplementary thyroid hormone treatment might be not only useless but even harmful.

Diagnosis and Clinical Management of Thyroid Disorders in Chronic Renal Failure

In a uremic patient, hypothyroidism should be diagnosed only if total and free T_4 levels are distinctly low, the TBG concentrations are normal, and basal TSH levels are elevated ($>20 \mu\text{U/mL}$). A normal plasma TSH level is probably a valid indicator of tissue euthyroidism. Treatment with thyroid hormones should be limited to patients with clinical hypothyroidism and elevated plasma TSH levels. The increased risk for induction of tissue catabolism by thyroid hormone treatment needs to be recognized.

In hemodialysis patients heparin may interfere with the thyroid hormone status. Heparin competes with T_4 at intra- and extravascular binding sites, and thus increases total and free T_4 serum levels for at least 24 hours after dialysis (153). Therefore, strict standardization of the timing of investigations relative to dialysis is essential. Other substances, for example, high-dose furosemide, can cause similar artifacts (154).

Patients with CRF who undergo repeated radiologic investigations with iodinated contrast agents may be at increased risk of developing iodine-induced hyperthyroidism because of reduced iodine clearance.

Adrenal Hormone Axis

Clinical Findings

Dysfunction of the pituitary-adrenal axis may be difficult to diagnose in patients with CRF. Uremia shares certain clinical signs and symptoms with Cushing syndrome, such as osteopenia, proximal muscle weakness with atrophy, glucose intolerance, negative nitrogen balance, and hypertension (155); therefore, Cushing syndrome may easily be missed if it occurs concomitantly with renal failure. Similarly, adrenal insufficiency may present with symptoms that are not uncommon in renal failure, for example, hypotension, weakness, and hyperkalemia. To confirm or reject the diagnoses of Cushing syndrome or adrenal failure, the clinician must rely on the evaluation of the patient's hormonal status under basal and stimulated conditions.

Cortisol

Cortisol is conjugated in the liver to water-soluble metabolites, which are predominantly excreted by the kidney and accumulate in renal failure. Although normal morning fasting cortisol levels are found in the majority of adult and

pediatric patients with CRF (156–159), 24-hour integrated mean total and free cortisol concentrations are consistently elevated (160). Basal hypercortisolism is particularly prevalent in patients on hemodialysis (159). The diurnal rhythm and the pulsatile mode of cortisol secretion is conserved in renal failure; however, the half-life of the endogenous secretory peaks is prolonged (156,160,161). In hemodialysis patients, the secretory activity is shifted toward the dialysis hours, whereas a normal pattern is observed on days off dialysis (160).

Stimulation of the zona fasciculata with exogenous adrenocorticotrophic hormone (ACTH) in uremic patients yields a normal cortisol response, irrespective of whether supraphysiologic (159,162,163) or low doses of ACTH are used (163). Zona glomerulosa steroids (aldosterone, 18-hydroxycorticosterone) are stimulated normally in CAPD (163) but not in hemodialysis patients (164). Transient hyporesponsiveness to ACTH is observed in the majority of patients who returned to dialysis after transplant failure (165).

Adrenal Androgens

Adrenarche marks an important milestone in endocrine maturation. Adrenarche occurs approximately 2 years before the initiation of puberty and is independent of it. Low plasma levels of dehydroepiandrosterone and dehydroepiandrosterone sulfate, the marker hormones of the zona reticularis, are observed in adult men as well as in pre- and midpubertal boys on hemodialysis, whereas normal levels are found in patients on conservative treatment (30,166,167). Conversely, levels of androstenedione, an adrenal androgen produced by the ACTH-dependent zona fasciculata, are elevated in patients on conservative treatment, and normal or elevated in hemodialysis patients (30,159). A similar elevation of androstenedione level is observed in girls with CRF (41). In renal allograft recipients, glucocorticoid treatment invariably lowers adrenal androgen production to almost undetectable levels (29,30,159).

Adrenocorticotrophic Hormone

Basal ACTH levels are normal (159) or elevated (157,162) in patients with CRF. The functional status of pituitary corticotrophs in uremia is still under discussion. ACTH secretion is not suppressible by standard oral doses of dexamethasone (162,168). Oral absorption of dexamethasone is reduced in uremia (156), however, and suppression of ACTH can be achieved at higher doses (156,160). After intravenous administration of dexamethasone, only incomplete suppression of plasma cortisol levels is observed; however, the metabolic clearance of dexamethasone is possibly increased in uremia (156,169). The responsiveness of the corticotroph to stimulation by metapyrone may (162) or may not (156) be reduced in uremia. The ACTH release after administration of corticotropin-releasing hormone occurs early but is

blunted (157). In normal subjects acute hypoglycemia elicits a counterregulatory stimulation of the corticotropin-releasing hormone–ACTH–cortisol axis. In patients with CRF this stress reaction is markedly suppressed. The increase of ACTH and cortisol after insulin-induced hypoglycemia is blunted in patients on hemodialysis (156), which provides further evidence of a disordered hypothalamopituitary regulation of the corticotropic axis in uremia.

Diagnosis and Management of Pituitary-Adrenal Disorders

The most frequent circumstance in which a pediatric nephrologist encounters adrenocortical failure is on discontinuation of glucocorticoids in patients returning to dialysis after transplant failure. Also, accidental adrenalectomy can occur during nephrectomy, particularly in young infants, and adrenal hemorrhage leading to functional disorders is not uncommon in the perinatal period, in children with coagulation disorders, and as a side effect of therapeutic anticoagulation. Also, adrenal insufficiency is occasionally seen as a complication of amyloidosis that also compromises renal function, as typically seen in patients with severe chronic vasculitis or familial Mediterranean fever. Demonstration of low cortisol levels and insufficient cortisol response to ACTH is required to confirm the diagnosis.

In transplant recipients adrenal responsiveness is suppressed by steroid treatment (165). This poses the risk of acute adrenal insufficiency during severe stress, for example, surgical procedures or abrupt steroid withdrawal.

The diagnosis of Cushing syndrome in a patient with CRF requires the finding of elevated plasma cortisol levels, measured by a radioimmunoassay in extracted serum. Although a single measurement of cortisol may be misleading, loss of diurnal rhythm (24-hour cortisol profile) is a characteristic of Cushing syndrome not seen in uremia-related adrenal dysfunction. Failure of high-dose dexamethasone given orally (0.11 mg/kg) or intravenously (0.03 mg/kg) to suppress ACTH and cortisol levels is confirmatory evidence.

Hormones Involved in Carbohydrate Metabolism

Glucose intolerance is a common feature of CRF. The introduction of the euglycemic and hyperglycemic clamp techniques has been important in understanding insulin and glucose metabolism in patients with CRF (170). In the euglycemic insulin clamp technique, a given level of insulinemia is maintained and blood glucose is kept constant by infusing glucose at a continuously adjusted rate. Thus, the infusion rate equals tissue glucose uptake and metabolism. This allows quantitation of tissue sensitivity to insulin. In the hyperglycemic clamp technique, blood glucose levels are acutely raised by a priming infusion of glu-

cose and then maintained constant at approximately twice the fasting level by a variable glucose infusion. Under these steady-state conditions, the glucose infusion rate is a measure of glucose uptake and metabolism by all cells of the body. The early plasma insulin response is an index of beta cell responsiveness to the hyperglycemic stimulus, whereas the late insulin response is a measure of peripheral tissue sensitivity to insulin.

Insulin Secretion

Fasting serum insulin levels are usually normal or slightly elevated in patients with CRF. In contrast, serum levels of proinsulin and C-peptide are elevated. This discrepancy is explained by differences in the relative contribution of the kidney to the metabolic clearance rates of these peptides (171). Nevertheless, insulin half-life is increased two- to threefold in CRF. When this is taken into account, a relative insulin hyposecretion is present under fasting conditions in CRF patients (172).

In hyperglycemic clamp studies, the early insulin response, an indicator of the pancreatic beta-cell sensitivity to glucose, is variable: Decreased (173), delayed (174), normal (175), and even increased (176,177) responses have been reported. A decreased initial insulin release in response to high glucose concentrations is found in isolated pancreatic islets of uremic rats (178). The late insulin response is invariably increased in uremic patients, which indicates tissue resistance to insulin, and improves with dialysis (179).

Insulin is physiologically secreted in frequent (every 8 minutes), low-amplitude oscillations that are superimposed on slow, high-amplitude secretory pulsations (every 75 minutes). Unlike in other states of insulin resistance, a characteristic slowing of both rhythms as well as hyper-rhythmicity and exaggerated width and amplitude of the low-frequency insulin pulses in response to meals was observed in patients with CRF, which points to a specific abnormality in the neuroendocrine regulation of insulin secretion (172).

The variable beta-cell response may explain why only some patients develop overt glucose intolerance despite constant peripheral insulin resistance. Glucose intolerance becomes manifest only when the beta-cell insulin response to glucose is so impaired that it can no longer increase and overcome peripheral insulin resistance (81).

Some evidence suggests a role for PTH in the deranged beta-cell function of CRF. In children with CRF and severe secondary hyperparathyroidism, glucose intolerance resolves after parathyroidectomy through an improvement of the pancreatic insulin secretory capacity, whereas insulin insensitivity persists (180,181). High PTH levels, with or without uremia, impair insulin secretion by a cAMP-independent mechanism (182). Chronic hyperparathyroidism might enhance calcium entry into the pancreatic islets,

which results in an accumulation of calcium that impairs insulin release. This hypothesis is supported by the prevention of glucose intolerance and the normalization of islet insulin secretion in uremic rats treated with the calcium channel blocker verapamil (183).

Tissue Resistance to Insulin

Euglycemic insulin clamp studies in adults (184) and children (185) with preterminal renal failure unanimously show marked decreases in tissue sensitivity to insulin, glucose uptake, and metabolic clearance of insulin. After 10 weeks of dialysis treatment all indices are markedly improved. The two major sites of carbohydrate metabolism are the liver and the muscle tissue. Impaired insulin action may be characterized by diminished splanchnic glucose extraction, increased hepatic gluconeogenesis, decreased peripheral glucose uptake, or a combination of these. Most studies of uremic patients report normal basal and insulin- or glucose-suppressed hepatic glucose output (11,184,186). However, these observations may be valid only for supra-physiologic insulin concentrations. When endogenous insulin secretion is blocked by somatostatin and insulin infused in physiologic doses, suppression of hepatic gluconeogenesis is incomplete in uremic patients (187). Moreover, isotope studies suggest reduced glucose oxidation to CO_2 and increased glucose recycling (186). In contrast to these subtle changes of hepatic glucose turnover, glucose metabolism in the peripheral tissue is markedly impaired (184,188,189). Hence, the major site of resistance to insulin-mediated glucose uptake in uremia is the peripheral tissue, mainly skeletal muscle.

In principle, insulin resistance may be due to changes at the membrane receptor level, the postreceptor level, or a combination of these. Studies of adipocytes, monocytes, hepatocytes, and human muscle tissue showed normal or even elevated density and binding affinities of the insulin receptor and normal receptor-mediated transmembranous hexose transport (11,190–194). In uremic patients, glucose disposal was subnormal even after suppression of endogenous insulin secretion by somatostatin (195). This observation suggests that the stimulation of glucose uptake by insulin is unchanged, but insulin-independent glucose uptake is impaired. Thus, receptor expression and binding are normal or even increased, possibly as a result of homeostatic upregulation in response to insulin resistance, and the stimulation of glucose uptake by insulin is intact.

Insulin membrane receptors are expressed in abundance, and maximal hormone action occurs when only 10% of receptors are occupied. Consequently, insulin resistance at the receptor level can be overcome by high insulin concentrations, whereas a postreceptor defect cannot. Glucose uptake evaluated by the euglycemic clamp technique remains severely reduced in uremic patients even at the highest dose of insulin (11) (Fig. 68.7). This observation is

FIGURE 68.7. Dose-response relationship between the plasma insulin concentration and insulin-mediated glucose metabolism in patients with chronic renal failure (dashed line) and control subjects (solid line). Diminished maximal insulin-mediated glucose metabolism suggests insulin resistance by postreceptor defect. (From Smith D, DeFronzo RA. Insulin resistance in uremia mediated by post binding defects. *Kidney Int* 1982;22:54–62, with permission.)

The exact step in the sequence of insulin-induced signaling events that accounts for the postreceptor defect is not yet known. In human muscle tissue, insulin-receptor kinase activity is normal (194). Insulin stimulates glycogen synthesis and glycolysis by increasing the activity of glycogen synthase, phosphofruktokinase, pyruvate kinase, and pyruvate dehydrogenase. Glycogen levels are normal and maximal glycogen synthase activity is even elevated in muscle tissue of uremic patients (194), whereas phosphofruktokinase activity is diminished (196). On the other hand, basal and stimulated lactate formation is normal or even increased in erythrocytes of uremic patients, which suggests no impairment of glycolysis in this tissue (191). Kalhan et al. demonstrated diminished glucose oxidation and increased recycling of glucose carbon in uremic patients, which suggests impaired glucose metabolism via the Krebs cycle (186).

Etiology of Insulin Resistance

Glucose intolerance in patients with CRF is partially corrected by dialysis (179,197). This observation suggests the presence of one or more dialyzable factors in uremic serum that compromise the biological actions of insulin. Apart from dialysis, glucose metabolism is also improved by consumption of low-protein diets in children (198) and adults (199) with CRF. It was hypothesized that low protein intake reduces the synthesis of a peptide inhibiting insulin

action. Several peptides possibly interfering with glucose metabolism in uremia have been isolated (200–202). Evidence suggests that 1,25-dihydroxyvitamin D₃ deficiency may play a role in the pathogenesis of insulin resistance in uremia (203). Furthermore, insulin resistance improves in adolescents on dialysis after correction of anemia and amelioration of iron overload by recombinant erythropoietin therapy (204).

Glucagon

Glucagon plasma levels are markedly increased in uremia. This increase is in part due to cross reactivity with the bioinactive 9-kDa proglucagon molecule (205). The biologically active 3.5-kDa glucagon moiety is increased threefold. This increase is entirely due to decreased metabolic clearance; secretion is normal (206). Glucagon exerts its hyperglycemic action primarily by stimulating hepatic gluconeogenesis. Patients with CRF exhibit reduced endogenous glucose output after a glucagon challenge (187). Diminished glucagon binding with unchanged binding affinity by hepatic membranes was demonstrated in chronically uremic rats (207). Normal basal but diminished stimulated adenylate cyclase activity was found. These results may be explained by receptor downregulation in response to chronic glucagon excess, because healthy rats treated with exogenous glucagon exhibit similar changes.

Carbohydrate Metabolism during Peritoneal Dialysis

Long-term peritoneal dialysis is characterized by continuous glucose absorption from the peritoneal fluid, which amounts to 2 to 3 g/kg/day in children on an average peritoneal dialysis regimen. In view of the known glucose intolerance of uremia, this has raised some concern. Basal glucose and insulin levels are normal or increased in CAPD patients (174,208,209). A transient increase of plasma glucose and insulin levels occurs during a CAPD cycle, which is correlated with the glucose content of the peritoneal dialysis fluid (208). The area under the curve after an oral glucose load is higher in uremic patients on CAPD than in nondialyzed and hemodialyzed patients (191). Conflicting results have been reported with respect to the effect of CAPD on glucose tolerance and glucoregulatory hormones (190,209). Peripheral insulin sensitivity improves after initiation of CAPD (210); the improvement is significantly better with peritoneal dialysis than with hemodialysis treatment (197). Insulin-binding affinity and receptor numbers decrease on adipocytes of CAPD patients within the first 3 months of CAPD treatment, but no change in insulin sensitivity is observed as assessed by the effect of insulin on glucose uptake and lipogenesis (190).

The presently available information indicates that glucose intolerance is not exaggerated in patients on CAPD.

Insulin resistance tends to improve after initiation of peritoneal dialysis, even more so than in newly hemodialyzed patients. This may be explained by removal of circulating inhibitors of insulin action. The observed decrease of membrane insulin-binding capacity *in vitro* (190) may reflect receptor downregulation due to chronic hyperinsulinemia. Whether the chronic hyperinsulinemia in CAPD patients has deleterious long-term effects is as yet unknown.

GROWTH AND DEVELOPMENTAL DISORDERS IN CHRONIC RENAL FAILURE

Impact of Developmental Stage on Growth in Chronic Renal Failure

The regulatory mechanisms of statural growth during childhood differ at the successive stages of development. During the first 2 years of life, growth is driven mainly by nutritional factors, particularly the intake of energy and protein. In later childhood, growth appears to depend mainly on the somatotrophic hormone axis, with nutrition exerting a more permissive influence. In puberty, the growth process is dominated by the gonadotropic hormone axis, which stimulates and finally terminates body growth by direct action on the growth cartilage and by modulation of the somatotrophic hormone axis. In view of these differences in growth regulation, the description of growth in renal disorders deserves to be separated for the periods of infancy, mid-childhood, and puberty.

The first 2 years of life are the most dynamic period of growth. Some 30% of total postnatal statural growth normally is achieved during this period. Any disturbance of growth in infancy has a greater impact on growth potential than disturbance at later stages of development. Spontaneous growth in children with congenital CRF is characterized by a rapidly increasing height deficit during the first 2 years of life, followed by a rather percentile-parallel growth pattern in the mid-childhood years. In the late prepubertal period, height velocity again decreases disproportionately, resulting in a further deviation from the normal percentiles. A late pubertal growth spurt of diminished amplitude eventually results in an irreversible loss of growth potential, which leads to a stunted adult height.

Infancy

Untreated CRF during early infancy is usually associated with severe growth retardation (211–214). The mean loss in relative height in untreated patients is as high as 0.6 standard deviation (SD) per month during the first year of life. A detailed analysis of the early infantile growth pattern observed in children with congenital CRF by means of the infancy-childhood-puberty model revealed that the infancy growth phase, starting in intrauterine life and vanishing during the second year of life, is affected in 50% of patients

(215). Height SDS was already reduced at birth, decreased further during the first 3 postnatal months, behaved normally between the third and ninth months, and again decreased between the tenth and twelfth months of life. The intrauterine period, the first 3 postnatal months, and the period preceding the first birthday each contributed by approximately one-third to the overall reduction in height SDS observed in infants with congenital CRF. The observed intrauterine growth retardation raises the question of whether the prenatal accumulation of certain circulating substances not cleared by the placenta in children with severe renal hypoplasia may compromise fetal growth. Conversely, intrauterine malnutrition could be the primary cause not only of fetal growth retardation but also of abnormal renal morphogenesis, if it is present in the early stages of pregnancy. In early postnatal life, anorexia, water and electrolyte imbalances due to uremia, recurrent vomiting, catabolic responses to infections, metabolic acidosis, and secondary hyperparathyroidism are the main factors compromising growth. If appropriate management is instituted early enough, severe stunting can usually be prevented. Forced enteral feeding using nasogastric tubes, gastrostomies, and even fundoplication as required appears essential to prevent or reverse malnutrition (216,217). Under optimal conditions it is possible to keep infants with CRF within 1 to 2 SD below the mean height for age (217,218).

After a transient stabilization of growth rates, a variable further loss in relative height is commonly seen between 9 and 18 months of age. According to the infancy-childhood-puberty model, this period reflects the transition from the infancy growth phase to the childhood growth phase. An irregular onset or maintenance of the childhood growth component was observed in 60% of patients and resulted in a further decrease in mean standardized height of 0.7 SDS (215). The reasons for this secondary deterioration of growth in infancy, which may occur despite adequate nutritional and medical supplementation, are poorly understood.

Mid-Childhood

After the period of rapid infantile growth, height velocity slows down to an almost constant increment per year. During this period endocrine mechanisms regulate growth.

In mid-childhood, patients with hypoplastic renal diseases usually grow in keeping with the percentile attained around the end of infancy (219). Patients who develop CRF after the second year of life exhibit a loss of relative height early in the course of disease and follow the growth percentile reached after stabilization of the disease process. The degree of renal dysfunction is the principal determinant of the variability in growth during this period. Spontaneous mid-childhood growth tends to be subnormal when GFR is below 25 mL/min/1.73 m² (212,219–221) (Fig. 68.8). Mid-childhood growth rates are consistently correlated with GFR, although only 10 to 15% of the variability in growth is actually

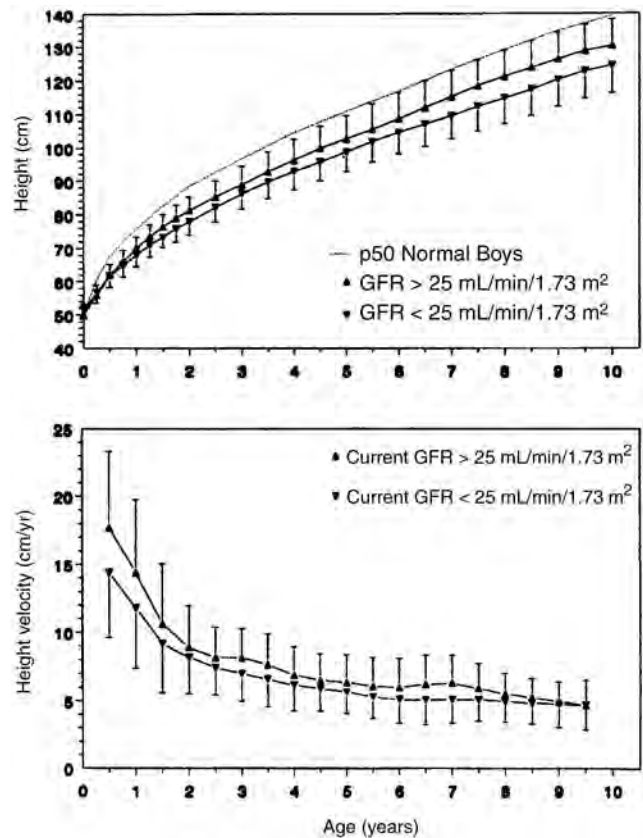

FIGURE 68.8. Glomerular filtration rate (GFR)–dependent growth pattern in children with chronic renal failure due to hypoplastic and dysplastic renal disorders. Approximately 100 children per age interval were evaluated. Mean \pm 1 standard deviation of height is shown for children with average GFR less than and greater than 25 mL/min/1.73 m². p50, fiftieth percentile. (Adapted from Schaefer F, Wingen AM, Hennicke M, et al. Growth charts for prepubertal children with chronic renal failure due to congenital renal disorders. European Study Group for Nutritional Treatment of Chronic Renal Failure in Childhood. *Pediatr Nephrol* 1996;10:288–293.)

accounted for by this parameter (219). The degree of anemia, metabolic acidosis, and malnutrition contributes only marginally to annual growth rates.

The more or less percentile-parallel growth of uremic children in mid-childhood has been interpreted as a “normal” growth pattern that could be expected after a loss of growth potential in early infancy. Such readjustment of the growth channel is seen in children with cardiac diseases after surgery or in children with adrenal insufficiency overtreated in infancy (222). However, the observation that complete catchup growth, although not common, does occur in children in whom renal function is normalized by successful renal transplantation, and that glucocorticoid treatment can be withdrawn (223), suggests that catchup growth is continuously suppressed in the uremic milieu. The percentile-parallel growth pattern during this period may therefore reflect a net balance between the growth-

suppressive effect of uremia and the organism's inherent tendency for catchup growth.

Puberty

The height gain achieved during the pubertal growth spurt is usually reduced (17,118,224,225). In a longitudinal analysis of the growth curves of 29 adolescents with various degrees of CRF, the growth spurt started with an average delay of 2.5 years (17). The degree of the delay was correlated with the duration of CRF. Although a distinct acceleration of growth occurred during puberty, the total pubertal height gain was reduced in both sexes to approximately 50% of that of healthy late-maturing children. This reduction was due to a marked suppression of the late prespurt height velocity, a subnormal peak height velocity, and a shortening of the pubertal growth period by 1 year in boys and 1.5 years in girls. Notably, the prolonged prepubertal growth phase, which resulted from the delayed onset of the pubertal growth spurt, permitted the patients to grow up to an almost normal immediately prespurt height (-1 SDS in boys, $+0.1$ SDS in girls). Subsequently, relative height was gradually lost during the pubertal growth spurt, so that patients ended up with an average relative height of -2.9 SDS in boys and -2.3 SDS in girls. This pattern of pubertal growth was confirmed in a control group of ESRD patients followed in the late 1990s who were not treated with rGH (226).

In prepubertal children with long-standing renal failure, bone maturation is invariably retarded (227–230). In dialysis patients, skeletal maturation is increasingly retarded before the start of puberty and then accelerates dramatically. This observation and the fact that uremic boys respond to exogenous application of testosterone esters by an exaggerated increase in skeletal maturation (230) suggest that the sensitivity of the growth plate to sex steroids is at least conserved. Because proliferation (i.e., growth) cannot keep pace with differentiation (i.e., bone maturation), growth potential may irreversibly be lost during puberty in uremia.

In contrast, in many transplant patients, an apparent standstill of bone maturation is observed, even when the patient is growing and puberty is progressing. This phenomenon is thought to be related to direct interference of corticosteroids with the differentiation of the growth plate. Despite the delayed bone maturation, late growth is usually not observed (17,231,232). In fact, the successive stages of the pubertal growth spurt seem to occur at increasingly earlier bone ages than would be assumed in a normal population (17).

Final Height

A crucial question in the rehabilitation of children with chronic renal disease is the degree to which final height is compromised. Of the patients with childhood-onset ESRD in the European Dialysis and Transplant Association Regis-

try, 50% achieved adult heights below the third percentile. Children who underwent continued dialysis until adulthood reached a lower mean final height than children who received a renal transplant (231,233–238). Final height appears to be more severely compromised in boys than in girls, which reflects the higher incidence of congenital nephropathies in boys. Final height is most compromised in patients with severe congenital renal disorders, among which nephropathic cystinosis leads to the most obvious growth retardation (239). However, patients with acquired glomerular diseases usually exhibit a very marked loss in height SDS in the early course of the disease, which results in the need for growth-promoting treatment in a large proportion of this patient group as well.

Impact of Underlying Renal Disease on Statural Growth

Hypoplastic and Dysplastic Nephropathies

Congenital renal hypoplasia or dysplasia, with or without urinary tract obstruction, is the most common cause of ESRD during the first 5 years of life. Renal dysplasia is characterized by tubular dysfunction with electrolyte losses and polyuria, and a gradual decline of GFR. The time to ESRD is highly variable and depends on the degree of hypoplasia and tubular dysfunction, and the incidence of infections. Growth failure usually develops during the first year of life. Thereafter, growth rates remain more or less stable and are usually sufficient to keep the patient's height parallel to the centiles. In the care of these patients, it is important to compensate for tubular electrolyte losses and acidosis. Pharmacologic renoprotective therapy with renin-angiotensin system antagonists may slow the progression of renal failure and thereby have a positive long-term impact on statural growth.

Glomerulopathies

Progressive glomerular injury may appear as acute or chronic glomerulonephritis, or as nephrotic disease. Growth rates decline in patients with progressive glomerulonephritis as glomerular function deteriorates. Growth velocity is affected even in mild renal insufficiency (220). In patients with nephrotic syndrome, proteinuria per se impairs growth, both in congenital nephrosis and resistant nephrotic syndrome that appears later in childhood (240,241). The dosage and duration of glucocorticoid treatment in nephrotic syndrome and the evolution of renal function are predominant factors affecting growth. Prolonged high-dose corticosteroid administration suppresses growth rates (241–244). Although partial catchup growth occurs after steroid withdrawal, final height is correlated with the cumulative glucocorticoid dose (241). Congenital nephrotic syndrome usually is associated with severe stunting during the first months of life while

GFR still is in the normal range but massive edema and proteinuria are present. Growth failure in these infants may be secondary to edema, recurrent infections, endocrine alterations due to losses of peptide and protein-bound hormones, and protein-calorie malnutrition. Bilateral nephrectomy, which replaces proteinuria, edema, and cachexia by ESRD, may be associated with improved growth (245).

Tubular and Interstitial Nephropathies

Primary *tubular dysfunctions* and *interstitial disorders* may lead to severe growth impairment even in the absence of chronic renal insufficiency. Patients with either proximal or distal renal tubular acidosis may present with growth failure during the first years of life (246,247). Growth impairment may be due to tissue catabolism, volume depletion, electrolyte disorders, and/or malnutrition. Catchup growth is observed after correction of *acidosis* with alkaline therapy in distal renal tubular acidosis (246,248). Growth retardation occurs in approximately 50% of patients with nephrogenic *diabetes insipidus*; hypernatremia, volume contraction, and malnutrition interfere with growth. Maintenance of water balance and treatment with indomethacin are associated with catchup growth (249). Bartter's syndrome and related disorders with chronic *potassium depletion* usually are characterized by a failure to thrive (250). Experimental potassium deficiency leads to growth failure characterized by both reduced endogenous GH secretion and complete resistance to exogenous GH (251,252). In patients with hyperprostaglandin E syndrome, indomethacin medication leads to partial catchup growth (253). In view of the various isolated tubular deficiencies that can cause growth impairment, it is conceivable that children with complex disorders of proximal and distal tubular function, such as idiopathic *Fanconi syndrome* (254,255) or hereditary *fructose intolerance*, may develop severe growth failure. In these cases, only partial catchup growth is possible even with rigorous electrolyte supplementation (246,248,250,253). Severe growth failure may also develop in children with systemic diseases such as *cystinosis* or *oxalosis* that involve not only the kidneys but also other organs. In patients with *cystinosis*, growth failure is usually the first clinical symptom of tubular dysfunction, which generally develops around 6 to 18 months of age. Growth failure occurs even with optimal substitution of tubular losses, however, due to the generalized deposition of cystine crystals, which results in local growth plate and hypothalamopituitary dysfunction and hypothyroidism. In a survey by the EDTA only 13 of 106 cystinotic patients on renal replacement therapy who were between 8 and 21 years of age had a height above the third percentile (256). The introduction of cystine-depleting agents has offered new prospects for children with *cystinosis*. Treatment with cysteamine or phosphocysteamine appears to slow the rate of deterioration of GFR and to improve growth rates (257–259). Recombinant GH is

effective in stimulating growth independently of renal function and cysteamine treatment (239).

In patients with chronic or recurrent interstitial disease, a minor degree of growth retardation may develop. Persistent or recurrent *urinary tract infections* may cause growth impairment by tubular dysfunction, the catabolic effect of chronic disease, and/or progressive renal insufficiency. Growth rates may increase after medical and/or surgical intervention (260–262). In patients with vesicoureteric reflux, moderate growth retardation has been demonstrated in cases of bilateral disease and significant renal scarring (263). Whereas previous reports noted a growth spurt after successful antireflux surgery (261,262), multiple regression analysis encompassing 54 patients with obstructive urinary tract malformations suggested a positive relationship between the increase in relative height and the duration of antibiotic treatment, but no independent effect of surgical intervention (264). Severe growth failure was observed in patients with posterior urethral valves; it was most marked in patients with severe symptoms diagnosed early (265).

Etiology of Growth Failure in Chronic Renal Failure

The pathogenesis of impaired growth in CRF is complex and only partially understood. Although a particular cause can occasionally be found, a combination of several factors is generally responsible for growth impairment. Furthermore, the patient's age; the type, duration, and severity of renal disease; the treatment modality; and the patient's social environment all play important roles.

One of the cardinal abnormalities associated with CRF is a *loss of appetite*. Adequate energy intake is required for anabolism and growth. Energy intake is inversely related to the degree of renal failure (266) and is correlated with growth rates if it is lower than 80% of the recommended dietary allowance (267). However, further augmentation of energy intake above this level results in obesity rather than in a further stimulation of growth (267,268). Energy malnutrition is particularly prevalent in uremic infants during the first year of life, when metabolic rate is high in relation to body mass. Height SDS is correlated with body cell mass and serum transferrin or albumin levels in infants, which emphasizes the importance of malnutrition in growth failure in this age group (211,269,270). In later childhood, spontaneous food intake is usually low for the patient's age but normal when adjusted for body mass (271,272). Thus, it is difficult to differentiate whether low energy intake is the cause or the consequence of impaired growth. The same is true for the body protein content of children with CRF and short stature, which generally is adequate for height but not for age (273).

At any given protein intake, the conversion of dietary protein to body protein is less efficient in uremic animals than in pair-fed controls (274). Resistance to the anabolic effects of insulin and IGF-1 and increased protein break-

down by activation of proteolytic pathways may contribute to poor growth. In contrast to deficient calorie intake, protein malnutrition is infrequently seen in children with CRF (271,272). In a prospective study that deliberately limited protein intake to the safe levels set by the World Health Organization (e.g., 0.8 to 1.1 g/kg/day) but ensured adequate calorie intake, no impairment of weight gain and length gain was seen over 3 years (275).

Disturbances of Water and Electrolyte Metabolism

Many congenital renal diseases that slowly progress toward CRF lead to a loss of electrolytes and a reduced ability of the kidney to concentrate urine. In particular, sodium chloride is lost in patients with obstructive uropathies and renal hypoplasia, and potassium is lost in patients with tubular damage, particularly those with nephropathic cystinosis. Polyuria, an expression of the reduced ability of the kidney to concentrate the urine, is seen in Fanconi syndrome and nephronophthisis, but also in hypoplastic kidney disease.

It is not possible to independently assess the extent to which disturbances in water and electrolyte metabolism contribute to growth retardation in individual patients with CRF. The probability of these factors' being significant, however, has been shown by analogous clinical and animal studies. In rats, sodium deficiency leads to a decrease in protein synthesis and growth, which is only partially reversible by sodium repletion (276,277). Part of the effects usually attributed to sodium deficiency are actually caused by concomitant depletion of chloride; selective removal of chloride from a sodium-replete diet causes growth retardation and diminished muscle protein synthesis (278).

Metabolic Acidosis

Metabolic acidosis is inevitably observed in CRF if a 50% reduction in normal GFR is noted, due to the kidney's reduced ability to excrete ammonia. The acidosis is aggravated by nutritional protein and acid load, catabolism, and altered electrolyte balance. Metabolic acidosis is associated with increased glucocorticoid production and increased protein degradation by the activation of branched-chain ketoacid catabolism and the ubiquitin-proteasome pathway (279–281). In young children with CRF, the degree of protein wasting is tightly correlated with serum bicarbonate levels (282). Moreover, metabolic acidosis has profound suppressive effects on the somatotrophic hormone axis by downregulating GH secretion (78), GH receptor and IGF-1 gene expression (283), and serum IGF-1 levels (284). Hence acidosis per se causes a state of GH insensitivity.

Anemia

Children with CRF develop increasing anemia as a result of erythropoietin deficiency. It is not certain if or to what extent

chronic anemia leads to growth impairment. Children with chronic anemia (e.g., thalassemia major) show retardation of growth and development. When these patients are treated with high-frequency transfusion regimens to keep hematocrits close to the normal range, growth rates may improve (285). Theoretically, anemia may interfere with growth via various mechanisms such as poor appetite, intercurrent infections, cardiac complications, and poor oxygenation of the cartilage cells in the growth plate. The introduction of recombinant erythropoietin for the treatment of renal anemia has offered the opportunity to study whether changes in growth are induced by compensation for renal anemia. Whereas short-term stimulatory effects of erythropoietin were observed in single patients (286), no persistent growth improvement was seen in prospective trials (287). Likewise, blood transfusion and erythropoietin treatment of uremic rats did not result in improved growth (288).

Renal Osteodystrophy

Although gross skeletal deformities can contribute to the retardation of a child's growth, the appearance of renal osteodystrophy is not inevitably paralleled by alterations in epiphyseal growth of the long bones. Severe metaphyseal skeletal changes are often detected radiologically in patients with relatively good growth rates. In such cases, osteopathy is unmasked by rapid growth. Growth is arrested completely only when secondary hyperparathyroidism results in severe destruction of the metaphyseal bone architecture.

Whereas treatment with vitamin D and 1,25-dihydroxyvitamin D₃ improves growth in uremic rats (289), an equivalent therapeutic success has not been achieved in children with CRF. Treatment with 5000 to 10,000 IU vitamin D₃ per day did not affect growth in children on dialysis (290). An early optimistic report involving four patients receiving 1,25-dihydroxyvitamin D₃ (291) could not be validated in the long term (292).

The extent to which secondary hyperparathyroidism contributes to growth impairment is unclear. PTH is an anabolic hormone and an intrinsic growth factor, stimulating mitosis in osteoprogenitor cells and growth plate chondrocytes and upregulating the vitamin D receptor (293,294). Intermittent PTH administration stimulates the skeletal growth of normal and uremic rats (295). However, resistance to the effect of PTH is observed in uremia, characterized by reduced cAMP production in growth plate chondrocytes (293). A low bone turnover state induced by relatively low PTH levels may contribute to growth impairment (296). At the other end of the spectrum, excessive secretion of PTH can lead to the destruction of growth plate architecture (297), epiphyseal displacement (298), and metaphyseal fractures (299).

Hormonal Factors

The multiple alterations of endocrine systems associated with CRF have been described earlier. Of particular rele-

vance for statural growth is the complex state of GH and IGF-1 resistance, which results in an impaired promotion of endochondral and appositional growth by IGF-1.

Impact of Treatment on Growth in Chronic Renal Failure

General Aspects

Adequate *nutritional intake* is the most important prerequisite for early infantile growth. Growth rates in this period are correlated with energy intake (267). Consequently, forced feeding via nasogastric tube, gastrostomy, or even fundoplication is an essential component in the management of infantile CRF (216,217,300). In later childhood, adequate nutrition is a permissive factor for growth; however, catchup growth cannot be obtained by dietary manipulations alone. *Metabolic acidosis* should be treated systematically, and *water and electrolyte losses* must be consequently compensated (218,301,302). Prevention of renal osteodystrophy by *vitamin D* treatment is a further precondition for optimal growth rates. Except in the period of infancy, however, none of the aforementioned therapeutic procedures has been demonstrated to induce catchup growth in short children with CRF.

The initiation of *dialysis* usually does not improve growth in uremic children. Several large studies found mean annual losses of 0.4 to 0.8 SD standardized height (303–305). This is conceivable if the hypothesis is correct that uremic growth failure inhibition is caused mainly by the accumulation of IGF-BPs, which are not removed by standard hemodialysis. On the other hand, a single-center study reported improved growth, with an annual height gain of 0.3 SD, under intensified hemodialysis achieving a Kt/V of 2.0 by almost 15 hours of dialysis per week (306).

As with standard hemodialysis, catchup growth is not commonly observed in children on *peritoneal dialysis*. Whereas early experience suggested continued significant losses of standardized height with treatment by CAPD or continuous cyclical peritoneal dialysis (214,307–309), more recent studies suggest percentile-parallel growth patterns or slight losses of less than 0.5 SD per year (310,311). Residual renal function is a more important predictor of growth in patients on peritoneal dialysis than is dialytic clearance (311). In addition, a high peritoneal transporter state, a known morbidity and mortality risk factor in adults, predicted poor growth (–0.5 SD/yr) in a prospective study of 51 children followed for 18 months (310). It is currently believed that, apart from causing increased dialytic protein losses, the high transporter status may be an indicator of microinflammation, a putative cause of GH resistance in uremia (see earlier). In fact, growth failure may represent the pediatric equivalent of the malnutrition-inflammation-atherosclerosis syndrome of adult ESRD patients (312,313). Adverse clinical outcomes including a

two- to threefold elevated risk of death have been associated with growth failure in children on dialysis (314,315).

Only successful *renal transplantation* is able to restore the conditions for normal growth compromised by the uremic state. Growth rates after transplantation vary widely, however, from further deterioration of height SDS to complete catchup growth (118,224,316–324). In an analysis of the North American Pediatric Renal Transplant Cooperative Study, the mean effect of transplantation before puberty on adult height was 0.0 SDS (325), which confirms that the relative height achieved at the time of transplantation is the most important predictor of final height (322,323). Whereas pubertal patients tend to lose relative height after transplantation (326), a potential for posttransplantation catchup growth exists in patients younger than 6 years of age (321,324,327,328) (Fig. 68.9). Infant allograft recipients typically exhibit excellent spontaneous growth rates, with a relative height gain of 1.5 SD within 2 to 7 years (316,324,329). Apart from the inverse relationship with age, the degree of growth retardation positively predicts posttransplantation growth rate (321,323,324,328,330). Furthermore, posttransplantation growth critically depends on graft function (236,321,323–325,328–330). A marked deceleration in posttransplantation growth is observed when GFR is below 60 mL/min/1.73 m², and in the French experience catchup growth occurred only in children with a GFR above this value (225).

The daily dose as well as the cumulative dose of corticosteroids seems to be inversely related to the posttransplantation growth rate (17,331,332). The hope that the prednisolone derivative deflazacort would interfere less with catchup growth

FIGURE 68.9. Change in standardized height during the first 2 years after transplantation. Improvement in mean height Z score is limited to children of preschool age. The North American Pediatric Renal Transplant Cooperative Study. *J Pediatr* 1993;122:397–402, with permission.)

at equivalent immunosuppressive biopotency has not been substantiated so far (333,334). Alternate-day corticosteroid administration has been demonstrated in a controlled, randomized trial to improve growth by 0.25 to 0.5 SD of height per year (318,335). The most impressive catchup growth has been observed in patients in whom steroids could be completely withdrawn (223,317,336–338). In these patients, an improvement of 0.6 to 0.8 SD during the first posttransplantation year was observed. Ellis et al. found a cumulative height increment of 1.5 SD within 3 years in children younger than 5 years of age given tacrolimus monotherapy and apparent catchup growth even in pubertal patients (337). The results of steroid withdrawal studies should be interpreted with caution because usually only patients with low risk for rejection and good allograft function were included. Nevertheless, several potent new immunosuppressive agents have been developed that may allow the option to completely withdraw or even primarily avoid steroid use in pediatric renal transplantation cases (338,339). The risk of rejection and loss of renal function by steroid withdrawal, historically rated as 40 to 50% (317,340,341), may have diminished considerably with the new immunosuppressive protocols, but this awaits confirmation in prospective trials. Hence, alternate-day steroid administration should be standard, and complete cessation should be considered after transplantation in short children with good renal function who do not exhibit spontaneous catchup growth.

Treatment of Renal Growth Failure with Recombinant Growth Hormone

The GH resistance observed in uremia and during glucocorticoid treatment and the experimental proof that GH resistance can be overcome by supraphysiologic doses of exogenous GH (342) have provided a rationale for treating children with CRF and those undergoing renal transplantation with rGH. Administration of rGH raises IGF-1 production to a greater degree than it raises IGFBP concentrations and thereby increases the availability of free IGF-1 at the tissue level (93) (Fig. 68.10).

Use of Recombinant Growth Hormone in Prepubertal Children

In prepubertal children with predialytic CRF numerous studies, including two double-blind placebo-controlled trials, demonstrated that rGH induces a nearly twofold increase in height velocity during the first treatment year, with a diminishing but still significant effect on growth rate during the second year (343–350). Although the maximal height increment occurs in the first three treatment years, standardized height continues to increase slightly during extended treatment. After 5 or 6 years of rGH administration, mean height SDS had increased from -2.6 at baseline to -0.7 in a North American study (349), from -3.4 to -1.9 in German chil-

FIGURE 68.10. Balance between insulin-like growth factor-binding proteins (IGFBPs) and IGFs in serum of children with chronic renal failure before (baseline) and after 12 months of treatment with recombinant growth hormone (GH). Recombinant GH increases the IGF/IGFBP ratio in the 35-kDa complex. BP, binding protein. (Adapted from Powell DR, Durham SK, Liu F, et al. The insulin-like growth factor axis and growth in children with chronic renal failure: a report of the Southwest Pediatric Nephrology Study Group. *J Clin Endocrinol Metab* 1998;83:1654–1661.)

dren (348), and from -3 to -0.5 in Dutch patients (350). The remarkable prepubertal growth acceleration was not associated with a disproportionate advancement of bone age, which resulted in a remarkable increase in predicted adult height at the end of the prepubertal phase (348). Prepubertal children on dialysis respond less well to rGH than children with CRF on conservative treatment (348,351). In the German multicenter study, 13 prepubertal dialysis patients gained only 0.8 SDS in height on average during the first two treatment years, compared to an increment of 1.3 SDS in 41 CRF patients (348) (Fig. 68.11). These results were confirmed in a large cohort of French children on hemodialysis, who had only a 0.5-SDS height gain during the first treatment year, with continued small annual increments for up to 5 years (352). Children on long-term peritoneal dialysis do not respond differently to rGH than do hemodialysis patients (353). In prepubertal children with *nephropathic cystinosis*, GH administration increased height by 0.8 SDS during the first year and by 1.7 SDS within five treatment years (354). In *prepubertal renal allograft patients*, in whom alternate-day corticosteroid treatment does not induce catchup growth and discontinuation of corticosteroid medication is not considered an option for safety reasons, a therapeutic trial with GH may be considered. Several studies have demonstrated a growth-promoting effect of GH in prepubertal children with renal allografts over average treatment periods of 1 to 3 years (119,355–360). Treatment efficacy was slightly inferior to that observed in CRF patients on conservative treatment, with mean cumulative height gains of 1 to 1.5 SD during the first 3 years.

Recombinant Growth Hormone Use in Puberty

A systematic analysis of rGH treatment efficacy in pubertal children is difficult due to methodologic problems (361).

FIGURE 68.11. Superior efficacy of recombinant growth hormone (rGH) treatment in children with pre-end-stage chronic renal failure (●, $n = 19$) compared to children on dialysis (○, $n = 6$). SDS, standard deviation score. (Adapted from Haffner D, Wühl E, Schaefer F, et al. Factors predictive of the short- and long-term efficacy of growth hormone treatment in prepubertal children with chronic renal failure. German Study Group for Growth Hormone Treatment in Children with Chronic Renal Failure. *J Am Soc Nephrol* 1998;9:1899–1907.)

These include delayed puberty with a lack of appropriate growth reference data, potential effects of rGH on the onset and duration of the pubertal growth spurt, and frequent changes in treatment modalities with variable relative efficacy of rGH. In addition, rGH administration is usually discontinued at the time of transplantation but is sometimes reinsti-

tuted if the growth rate remains low, which introduces large variability in the duration of rGH treatment during puberty. Hence, only controlled long-term observations, ideally recording total pubertal height gain in treated and untreated patients with comparable distributions of treatment modalities, permit a meaningful analysis of rGH efficacy in puberty.

Haffner et al. followed 38 children with CRF in whom rGH administration was initiated at a prepubertal age and continued until they reached adult height (226) (Figs. 68.12 and 68.13). Because rGH was stopped at the time of transplantation, the patients received GH during 50% of the pubertal observation time. Fifty children, matched for age and degree of CRF, who did not receive rGH because they still had normal height served as controls. The children receiving rGH showed sustained catchup growth, whereas the control children developed progressive growth failure (Fig. 68.12). Dissection of the prepubertal and pubertal growth phases disclosed that the additional height gain relative to the control group was limited almost entirely to the prepubertal period, whereas pubertal height gain was insignificantly greater in the rGH-treated patients than in the controls (Fig. 68.13). The apparent inefficacy of rGH administration in puberty may be explained in part by the incomplete continuation of treatment, as is suggested by a positive correlation of the fractional duration of rGH therapy with total pubertal height gain. In fact, Hokken-Koelega et al. demonstrated that allograft recipients may respond very well to rGH even in late puberty (346), with an almost threefold greater 2-year height gain compared to untreated historical controls (362).

In neither the German children nor the Dutch cohort (350) was an advanced onset of puberty observed, although a subtle acceleration of bone maturation and a slight shortening of the pubertal growth spurt was noted by Haffner et al. (226).

Adult Height after Recombinant Growth Hormone Treatment

Fifteen years after the start of the first therapeutic trials with rGH, final height outcome data are beginning to

FIGURE 68.12. Favorable effect of long-term treatment with recombinant growth hormone (GH) on final adult height in children with chronic renal failure (CRF). Synchronized mean growth curves during GH treatment for 38 children (32 boys and 6 girls) with CRF are compared with those for 50 control children with CRF not treated with GH. Normal values are indicated by the third, fiftieth, and ninety-seventh percentiles. The circles indicate the time of the first observation (the start of GH treatment in the treated children) and the end of the pubertal growth spurt. (From Haffner D, Schaefer F, Nissel R, et al. Effect of growth hormone treatment on adult height of children with chronic renal failure. *N Engl J Med* 2000;343:923–930, with permission.)

FIGURE 68.13. Synchronized mean height velocity curves during growth hormone (GH) treatment for the same children as shown in Figure 68.12. The circles indicate the time of the first observation (the start of GH treatment in the treated children), the time of minimal prespurt height velocity, and the end of the pubertal growth spurt. CRF, chronic renal failure. (From Haffner D, Schaefer F, Nissel R, et al. Effect of growth hormone treatment on adult height of children with chronic renal failure. *N Engl J Med* 2000;343:923–930, with permission.)

emerge, which will permit assessment of the ultimate efficacy of rGH therapy. In the German multicenter study, the mean adult height of 38 children who received rGH for a mean of 5.3 years was -1.6 SDS, with two-thirds of patients ending up at a height above the third percentile (226). The patients ultimately gained 1.4 SD compared to their standardized height at baseline. Conversely, mean height SDS decreased in the untreated control group from -1.5 to -2.1 SDS at attainment of adult height (Fig.

68.13). Figures in the same range were reported from several other trials (Table 68.1). Of course, the variability in final height outcomes is large. Cumulative height gain appears to be positively affected by the height deficit at the start of rGH treatment and the total duration of rGH administration (226), and negatively affected by the cumulative time spent on dialysis. Height gain was positively associated with the initial target height deficit and the duration of rGH therapy, and was negatively associated with the

^bPercent patient years spent in each treatment category.

FIGURE 68.14. Age-dependent relative efficacy of growth hormone (GH) treatment exemplified by individual growth curves predicted for two patients aged 2 and 8 years, started on GH at a basal height standard deviation score (SDS) of -3.5 and a height velocity SDS of -2.0 . The reference lines indicate the third, fiftieth, and ninety-seventh percentiles of the healthy population. Growth is accelerated over baseline height velocity in both patients by 4.5 cm in the first treatment year, 1.9 cm in the second, and 1.0 cm in the third (empirical means observed in patients on conservative treatment followed for 3 years). The younger child reaches the third percentile within 3 years, whereas the older child does not. (From Haffner D, Wühl E, Schaefer F, et al. Factors predictive of the short- and long-term efficacy of growth hormone treatment in prepubertal children with chronic renal failure. German Study Group for Growth Hormone Treatment in Children with Chronic Renal Failure. *J Am Soc Nephrol* 1998;9:1899–1907, with permission.)

percentage of the observation period spent on dialysis (226,350). The relative height attained at the time of transplantation seems to be maintained to final height; neither spontaneous catchup growth nor catchdown growth after discontinuation of GH seems to be common (363,364).

Strategies to Optimize Growth by Recombinant Growth Hormone Treatment

The response to rGH is influenced positively by the residual GFR, target height, initial target height deficit, and duration of GH treatment, and is influenced negatively by the age at the start of treatment (361). A curvilinear dose-response relationship appears to exist. Although a dosage of 4 IU/m²/day was more efficient than 2 IU/m²/day in a double-blind trial (365), no further improvement of the growth response was observed with 8 IU/m²/day, at least in a pubertal cohort (362). Daily dosing is more efficacious than three administrations per week (366). Discontinuation of GH treatment results in loss of height SDS in 75%

of children with CRF on conservative treatment (367), whereas catchdown growth seems to be uncommon when rGH is discontinued due to renal transplantation (363).

Because the absolute growth response to rGH (in centimeters of height gain per year) is independent of age but the reference range increases with age (348), rGH treatment should be started as early as possible in the course of renal disease (Fig. 68.14). A fixed daily dose of 4 IU/m² (= 12 mg/m²) should be used. Treatment should not be stopped if the annual gain of height SDS diminishes after the third treatment year to avoid the risk of catchdown growth. Treatment should also be continued when the patient becomes dialysis dependent. If rGH therapy is initiated in a small child already on dialysis, transplantation should not be postponed for the sake of approved rGH treatment, because the efficacy of rGH therapy in dialysis patients is limited and short lasting. Treatment should be stopped at the time of renal transplantation to observe the spontaneous evolution of growth. If no growth or insufficient catchup growth occurs within 12 months, glucocorticoid withdrawal is the first option. If this is unsuccessful, rGH reinstatement should be considered. Treatment decisions should be made without delay to preserve growth potential. The question of rGH continuation through puberty is still controversial. The pubertal growth spurt occurs independent of concomitant rGH treatment, which renders any judgment about treatment efficacy exceedingly difficult. Controlled prospective study results are not available. Hence, the decision to continue or restart rGH therapy in puberty must be made on an individual basis, with consideration of the degree of growth retardation, the residual growth potential, and the expected therapeutic compliance of the adolescent.

Whether a low growth rate (height velocity below the twenty-fifth percentile over several years) should also be a treatment indication in a child whose relative height is still in the normal range remains uncertain. Such preventive therapy might prove to be more effective in increasing adult height than initiation of treatment when short stature is already established. This treatment strategy appears justified if a growth arrest is noted that is not explained by nonendocrine factors. It is also an issue of current consideration whether in patients with imminent or early puberty skeletal maturation should be delayed by pharmacologic intervention with GnRH analogues or aromatase inhibitors to prolong the prepubertal growth phase to facilitate GH treatment.

Adverse Effects of Growth Hormone Treatment

Given its remarkable efficacy, GH treatment causes surprisingly few side effects in children with CRF.

Concern was raised initially that prolonged GH treatment might provoke *diabetes mellitus*, because patients with CRF already show impaired glucose tolerance due to peripheral insulin resistance (see earlier). Notwithstanding

this concern, oral glucose tolerance remained unaltered in children with CRF and in those undergoing transplantation who were treated with GH for up to 5 years (368). Insulin secretion increased during the first treatment year, however, and remained elevated thereafter. This increase was most pronounced in transplant recipients. The long-term consequences of increased insulin secretion are uncertain. Theoretically it may contribute to atherosclerosis or induce diabetes mellitus by exhaustion of pancreatic beta cells. Although not a single case of irreversible diabetes mellitus has been observed in children with CRF (369,370), a report of increased incidence of type 2 diabetes mellitus in nonrenal children undergoing GH therapy requires prospective surveillance (371).

Epiphyseal slipping (372,373) and femoral head necrosis (374) have been reported as rare events during treatment with rGH. Whether these complications were caused or intensified by rGH is unclear, because both complications are noted with increased incidence in children with CRF who do not receive GH treatment (297,299). An aggravation of secondary *hyperparathyroidism* has been reported rarely (375,376). This seems not to be due to direct stimulation of the parathyroid gland by GH, but to represent an indirect effect of small decreases of ionized calcium as a consequence of GH-stimulated bone apposition or an increase in serum phosphate concentration secondary to improved appetite. Furthermore, preexisting renal osteodystrophy may be unmasked by an increased growth rate and may become radiographically apparent (377).

Concern has also been raised that GH may cause glomerular hyperfiltration and accelerated deterioration of *renal function*. However, the physiologic acute increase in GFR induced by GH in healthy subjects is obliterated in patients with CRF (378). Long-term observations of up to 8 years showed no acceleration of renal failure progression in predialytic patients with CRF due to cystinosis (354) or other renal disorders (226,348,350), or in renal allograft recipients (226).

Because GH is an immunomodulatory substance (379), *allograft rejection* might be triggered by rGH administration in patients after transplantation. However, several controlled trials provided evidence that an increased risk of rejection is limited to high-risk patients with more than one acute rejection episode before the start of GH treatment (358,360,380,381).

Contrary to previous concerns (382), an extended survey of thousands of patients failed to disclose any significant relationship between GH treatment and *malignancy* (383–385). A review of adverse events in 583 patients with CRF and ESRD treated with GH revealed one solid tumor and one B-cell lymphoma among patients undergoing peritoneal dialysis and one lymphoma in a transplant recipient (386). Reports of renal cell carcinoma in two patients who had received GH occurring 9 and 11 years after transplantation, a case of leukemia in an 18-year-old GH-treated

patient with a failing transplant (383), and a report of pre-malignant tubuloepithelial changes in a pediatric renal allograft (387) raise the suspicion that tumor risk may be selectively increased by GH in posttransplantation children receiving long-term immunosuppression.

GH induces an IGF-1-mediated increase in distal tubular sodium reabsorption and upregulates the renin-angiotensin system (388,389). As a consequence, a transient, usually mild *retention of sodium and water* occurs during the first few days of treatment. In this context, *benign intracranial hypertension* has been reported as a rare adverse effect of GH treatment in patients with various underlying diseases. In CRF, the risk for this complication is increased tenfold (390,391). One survey noted signs or symptoms of intracranial hypertension in 15 out of 1670 patients with renal disease receiving rGH (0.9%) (392). All but two patients were symptomatic; the symptoms generally abated when GH therapy was discontinued, but two patients had persistent blindness. At least four of these patients experienced recurrence of intracranial hypertension after reinitiation of GH therapy. Intracranial hypertension manifested within a median of 13 weeks of treatment. We therefore recommend performing a baseline funduscopy and gradually increasing the dose from 50 to 100% of the maintenance dose within 4 weeks. Because hypertension and fluid overload may be predisposing factors, the state of hydration should be well controlled at the start of treatment. Headache, vomiting, and other clinical signs of increased intracranial hypertension mandate careful clinical investigation, including funduscopy. The risk-benefit ratio should be evaluated carefully when considering reinitiation of rGH treatment after reversal of symptoms.

RENAL OSTEODYSTROPHY

**BEATRIZ D. KUIZON
ISIDRO B. SALUSKY**

The association between renal failure and bone disease in children was described more than a century ago. The kidney plays a major role in bone and mineral homeostasis: It regulates calcium, phosphorus, and magnesium metabolism; participates in the catabolism of parathyroid hormone (PTH); excretes aluminum and β_2 -microglobulin; and, more importantly, synthesizes calcitriol or 1,25-dihydroxyvitamin D₃, the most potent and active vitamin D metabolite, through the action of the 1 α -hydroxylase enzyme. As such, renal bone disease is a common consequence of chronic renal insufficiency (CRI) and may lead to growth retardation and osseous deformities if left untreated during the critical years of skeletal growth and development. As the longevity of children with CRI increases because of advances in medical management, dialysis, and renal transplantation, the prevention and treatment of renal osteodystrophy should remain a major component in the overall management of these children.

Renal osteodystrophy encompasses a spectrum of high- to low-turnover skeletal lesions, and the impact of various therapies may change the histologic pattern. Because renal osteodystrophy changes with progression of CRI, reference is made to the stages of CRI, which are based on the measured or estimated glomerular filtration rate (GFR), as recommended by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) (Table 69.1). This chapter summarizes the major aspects of the pathogenesis, clinical manifestations, histologic features, and therapeutic interventions currently used in the management of renal osteodystrophy in children. The clinical and histologic features of bone diseases after successful kidney transplantation are also provided.

PATHOGENESIS OF RENAL BONE DISEASE

High-Turnover Bone Lesions (Bone Lesions Associated with Secondary Hyperparathyroidism)

Several factors contribute to the development of secondary hyperparathyroidism in most patients with end-stage renal

disease (ESRD). These factors include phosphate retention, hypocalcemia, impaired renal calcitriol synthesis, alterations in PTH secretion, skeletal resistance to the calcemic actions of PTH, and alterations in the calcium-sensing receptor (CaR). The severity of secondary hyperparathyroidism varies considerably depending on the cause, duration, and rate of progression of renal disease. Some patients with mild CRI may have elevated serum PTH levels and bone histologic patterns characteristic of secondary hyperparathyroidism (1). If left untreated, the severity of secondary hyperparathyroidism worsens with the progressive decline in renal function. Indeed, the majority of patients demonstrate bone histologic abnormalities when the GFR decreases to less than 50 ml/min and serum PTH levels inversely correlate with the GFR (1–3). Serum PTH levels remain significantly elevated with accompanying enlargement of the parathyroid glands, leading to overt hyperparathyroid bone disease and adverse effects on other tissues. Therefore, the major objective in the treatment of these patients is to prevent or reverse the effects of excess PTH secretion on the skeleton and nonskeletal organs.

Phosphorus Retention

Normal serum phosphorus levels are usually maintained in patients with mild to moderate CRI by increasing urinary phosphate excretion. However, hyperphosphatemia develops when the GFR declines to 25 to 30% of normal (4,5). Hyperphosphatemia promotes the secretion of PTH indirectly by lowering serum calcium levels and by reducing calcitriol synthesis through inhibition of the enzyme 1 α -hydroxylase, which is responsible for conversion of 25-hydroxyvitamin D to the active metabolite 1,25-dihydroxyvitamin D₃. Indeed, dietary phosphorus restriction has been shown to ameliorate the development of secondary hyperparathyroidism in uremic dogs and completely abolish parathyroid cell proliferation in nephrectomized rats (6–9). In children and adults with moderate renal failure, dietary phosphorus restriction has likewise suppressed serum PTH levels and increased serum calcitriol levels (10) (Fig. 69.1).

TABLE 69.1. STAGES OF CHRONIC RENAL INSUFFICIENCY

Stage	Description	GFR (mL/min/1.73 m ²)
1	Kidney damage with normal or increased GFR	>90
2	Kidney damage with mild decreased GFR	60–89
3	Moderate decreased GFR	30–59
4	Severe decreased GFR	15–29
5	Kidney failure	<15 or dialysis

GFR, glomerular filtration rate.

In addition, the direct effects of phosphorus on parathyroid gland function were demonstrated in uremic animals that developed increased serum PTH levels and parathyroid gland hyperplasia independent of changes in serum calcium or calcitriol levels during phosphorus supplementation (11,12). This effect of phosphorus appeared to involve posttranscriptional mechanisms because pre-pro-PTH mRNA levels were not increased in the animals given a high phosphorus diet (11). Conversely, when animals with established secondary hyperparathyroidism were then given dietary phosphorus

restriction, serum phosphorus and PTH levels normalized, but the parathyroid glands remained hyperplastic, and no evidence of apoptosis was found (13). Moreover, no difference in PTH synthesis, parathyroid gland cytosolic PTH, or the parathyroid gland secretory response to calcium was demonstrated, suggesting alterations in PTH exocytosis (13). It is not yet known whether there is a specific receptor for phosphorus, but a specific parathyroid cell sodium-dependent phosphate co-transporter (PiT-1) has been demonstrated (14). Because PiT-1 mRNA levels are upregulated by vitamin D and phosphorus restriction, this co-transporter may mediate the actions of phosphate and vitamin D on PTH secretion (14).

Hyperphosphatemia has also been implicated in pathogenesis of parathyroid gland hyperplasia in renal failure. Phosphorus supplementation increases parathyroid cell proliferation, whereas phosphorus restriction inhibits this process in animal models of renal failure (8,15). There is limited information, however, regarding the mechanism by which phosphorus stimulates parathyroid cell proliferation in renal failure. Recently, Dusso et al. demonstrated the potential role of cyclin/cyclin-dependent kinase (Cdk) inhibitor p21 and transforming growth factor α (TGF α) in mediating the effects of phosphorus on parathyroid cell proliferation in uremia (16). These investigators demonstrated that phosphorus restriction may prevent parathyroid hyperplasia in early renal failure by stimulating p21. In contrast, parathyroid hyperplasia induced by phosphorus supplementation is mediated by upregulating parathyroid TGF α expression (16).

FIGURE 69.1. Effects of dietary phosphorus restriction on plasma levels of parathyroid hormone (PTH) and children in moderate renal failure. iPTH, intact PTH. (From Portale AA, Booth BE, Halloran BP, et al. Effect of dietary phosphorus on circulating concentrations of 1,25-dihydroxyvitamin D and immunoreactive parathyroid hormone in children with moderate renal insufficiency. *J Clin Invest* 1984;73:1580–1589, with permission.)

Alterations in Vitamin D Metabolism

The proximal tubule is the primary site of calcitriol synthesis, in which the conversion of 25-hydroxyvitamin D₃ (predominant form in the blood) to 1,25-dihydroxyvitamin D₃ occurs through the action of the rate-limiting enzyme 1 α -hydroxylase (17,18). The gene encoding 1 α -hydroxylase has been cloned from rat, mouse, and human tissues, and mutations in the gene result in vitamin D-dependent rickets, type 1 (19–21). The activity of this enzyme is modulated by PTH, calcium, phosphorus, insulin-like growth factor-1 (IGF-1), and other factors. The activity of this enzyme is also dependent on the availability of 25-hydroxyvitamin D₃, which is bound to its plasma carrier; vitamin D-binding protein, filtered through the glomerulus; and, more recently, has been shown to require reabsorption by megalin, an endocytic receptor located in the proximal tubule (22,23). With progressive impairment in renal function, a significant reduction in calcitriol synthesis occurs, leading to subnormal blood levels (Fig. 69.2) (24–26). The decline in calcitriol production may be compensated in part by reduced metabolic clearance of calcitriol in CRI (27,28). The factors responsible for this change have not been determined, but inhibition of the normal pathways of calcitriol degradation by substances retained in uremic plasma may contribute to this problem (29).

FIGURE 69.2. Changes in serum PTH (IRMA) (A) and calcitriol (B) levels in patients with different degrees of chronic renal insufficiency. iPTH, intact PTH. (From Reichel H, Deibert B, Schmidt-Gayk H, et al. Calcium metabolism in early chronic renal failure: implications for the pathogenesis of hyperparathyroidism. *Nephrol Dial Transplant* 1991;6:162-169, with permission.)

Low levels of calcitriol impair the absorption of calcium, causing hypocalcemia and hypocalciuria, which are characteristic of patients with CRI. In addition, calcitriol deficiency contributes to alterations in parathyroid gland function and parathyroid gland hyperplasia. Calcitriol inhibits pre-pro-PTH gene transcription through the negative vitamin D response elements in the PTH gene both *in vitro* in bovine parathyroid cells and *in vivo* in rats (30,31). Moreover, calcitriol regulates PTH synthesis via the vitamin D receptor (VDR). By increasing VDR gene expression in the parathyroid gland, calcitriol enhances the feedback inhibition of PTH gene transcription, particularly, because renal failure is associated with reduced binding of VDR to the osteocalcin VDR element and because parathyroid glands of animals and humans with secondary hyperparathyroidism have diminished VDR expression (32-35).

Vitamin D is also one of the major factors involved in the regulation of parathyroid cell proliferation in renal failure, but the mechanism is poorly understood (36-38). Vitamin D has been shown to inhibit parathyroid gland hyperplasia by upregulating Cdk inhibitor p21 expression and decreasing parathyroid TGF α expression in animal models of renal failure (39). Furthermore, because vitamin D exerts potent antiproliferative effects, calcitriol deficiency and diminished VDR expression in parathyroid tissues may contribute to the pathogenesis of parathyroid hyperplasia. Another mechanism may involve the CaR, the expression

of which is reduced in hyperplastic parathyroid tissues obtained from patients with renal secondary hyperparathyroidism (40). Vitamin D has been shown to modify CaR expression in parathyroid tissue (41). Indeed, vitamin D-deficient animals had decreased parathyroid CaR mRNA expression, and vitamin D therapy resulted in a dose-dependent increase in CaR mRNA levels (41).

Whereas these studies have demonstrated the inhibitory effects of vitamin D on PTH release and parathyroid cell proliferation in renal failure, recent studies in mice with null mutations of the VDR suggest that vitamin D actions are not necessary to inhibit the development of parathyroid gland hyperplasia. These animals had hypocalcemia, markedly elevated serum PTH levels, parathyroid gland hyperplasia, and histologic evidence of rickets (42). When these animals were given dietary calcium and phosphorus supplementation to normalize serum calcium and phosphorus levels, the development of rickets was prevented despite the absence of VDR (43,44). However, the significance of these findings in secondary hyperparathyroidism remains uncertain.

Abnormalities in Parathyroid Gland Function

Hyperplasia of the parathyroid glands and alterations in the regulation of PTH release are generally considered the two major determinants of excess PTH secretion in CRI. *In vitro* studies of parathyroid tissues and parathyroid cells, the appli-

cation of molecular biology techniques, and *in vivo* clinical assessments each provide insight into the regulation of PTH secretion in normal and pathologic conditions, and they have substantially increased our understanding of the role of certain factors as key modifiers of parathyroid gland function in CRI.

Results from early *in vitro* studies of dispersed parathyroid cells indicated that the set point for calcium-regulated PTH release was greater than normal in cells obtained from patients with primary hyperparathyroidism, whereas less significant increases in set point were found in parathyroid cells obtained from patients with secondary hyperparathyroidism (45,46). These *in vitro* observations using the four-parameter model provide the basis for the concept that the set point for calcium-regulated PTH release is greater than normal not only in primary hyperparathyroidism but also in secondary hyperparathyroidism due to CRI. Thus, the sigmoidal curve depicting the relationship between ionized calcium levels and PTH secretion is shifted to the right, and higher *in vitro* concentrations of calcium are required to achieve equivalent reductions in PTH release in parathyroid cells from adenomatous or hyperplastic parathyroid glands (45,46).

Over the last decade, dynamic tests of parathyroid gland function have been widely used to examine the regulation of PTH release by calcium in patients with CRI. However, differences in either experimental methods and/or mathematic modeling of PTH secretion have, in part, contributed to inconsistencies in the results of *in vivo* assessments of parathyroid gland function. Indeed, initial studies demonstrated abnormalities of set point in patients undergoing hemodialysis with different types of renal osteodystrophy and after calcitriol therapy (47–49). However, using the four-parameter model originally described by Brown et al., we found no difference in set point between normal subjects and dialysis patients with mild and moderate secondary hyperparathyroidism or those with adynamic renal osteodystrophy (45,50–53). The set point for calcium-regulated PTH release was higher than normal only in patients with ESRD and advanced secondary hyperparathyroidism before parathyroidectomy (Fig. 69.3) (54). Such observations are in accord with *in vitro* data on dispersed parathyroid cells analyzed using the same four-parameter method.

A shortcoming of *in vivo* dynamic testing of parathyroid gland function as currently applied is the inability to correct for variations in the size of the parathyroid glands. Such methodologic considerations may account for the disparity between *in vivo* findings in patients with secondary hyperparathyroidism, in whom basal serum PTH varies widely, and those of *in vitro* studies using defined numbers of cells obtained from hyperplastic parathyroid tissues; they also serve as a reminder of the limitation of *in vivo* models for studying the physiology of PTH secretion (48,50,52,53,55).

Because of the controversy about the various methods for evaluating parathyroid gland function *in vivo* in patients with CRI, alternative approaches to examining PTH secretion in

FIGURE 69.3. Set point values for calcium-regulated parathyroid hormone release in volunteers with normal renal function (NL), dialysis patients with mild or moderate secondary hyperparathyroidism (2°HPT), dialysis patients with severe secondary hyperparathyroidism before parathyroidectomy (pre-PTX), and patients with primary hyperparathyroidism (1°HPT).

CRI are of considerable interest (56–58). In this regard, intravenous infusions of calcium have been used to assess parathyroid gland function in other clinical disorders, such as familial hypocalciuric hypercalcemia (FHH) and primary hyperparathyroidism (59); therefore, this technique has been used to compare the responses among patients with various types of renal osteodystrophy. The responses to calcium infusion suggest that the inhibitory effect of calcium on PTH release *in vivo* did not differ between adynamic renal osteodystrophy and secondary hyperparathyroidism (53). The results of that study suggest that differences in functional parathyroid gland mass rather than alterations in calcium sensing by the parathyroid glands are the major determinants of the prevailing serum PTH level in patients with renal osteodystrophy. Assessment in patients with secondary hyperparathyroidism undergoing regular hemodialysis reached similar conclusions (60). Although the histologic type of tissue hyperplasia, variations in VDR expression, and monoclonal expansion of subpopulations of parathyroid cells may contribute, variations in the degree of parathyroid gland hyperplasia are likely to account not only for the marked difference in basal serum PTH levels between adynamic renal osteodystrophy and secondary hyperparathyroidism but also for the moderate but persistent elevations in serum PTH values commonly seen in patients with adynamic renal osteodystrophy.

Alterations in the Calcium-Sensing Receptor

The homeostasis of extracellular calcium concentration is maintained by the rapid actions of PTH and the ability of bone, intestine, and kidney to respond to changes in circulating levels of PTH and 1,25-dihydroxyvitamin D. The CaR cloned by Brown et al., which has been localized in the kidney, parathyroid gland, brain, and gastrointestinal tract and other tissues, plays an important role in calcium-regulated

PTH secretion by detecting minute changes in extracellular calcium ion concentration and activating other G protein-coupled receptors (61,62). In the parathyroid glands, the CaR allows for precise regulation of the extracellular ionized calcium concentration. Changes in CaR expression may play a role in the alterations of the set point for calcium-regulated PTH secretion described in patients with primary and advanced secondary hyperparathyroidism (63).

Mutations of the CaR gene have been demonstrated in patients with benign FHH, autosomal dominant hypocalcemia, and neonatal severe hyperparathyroidism (64,65). Although no mutations of the CaR have been demonstrated in the parathyroid glands of patients with primary and secondary hyperparathyroidism, a significant reduction in the immunoreactivity of the CaR has been shown in adenomas and hyperplastic glands (40,66). Moreover, Gogusev et al. describe downregulation of the CaR in the nodular areas of the parathyroid glands obtained from patients with uremic hyperparathyroidism (63). It is unclear whether phosphorus or calcitriol plays a role in the regulation of the CaR. Several investigators have shown that phosphorus, calcium, and calcitriol did not affect CaR mRNA expression when administered in the uremic and vitamin D-deficient rat (67,68). In contrast, Brown et al. describe upregulation of the CaR expression in the kidney and parathyroid gland of the vitamin D-deficient rats that were treated with calcitriol (41) and moderate changes in serum-ionized calcium did not affect CaR expression.

The localization of the CaR protein in the parathyroid glands has led to development of novel therapeutic agents for the management of hyperparathyroid states. Calcimimetic compounds decrease the threshold for calcium-mediated activation of the CaR and reduce PTH secretion from parathyroid cells. Clinical trials have demonstrated their efficacy in lowering PTH levels in patients with primary hyperparathyroidism and in adult dialysis patients with secondary hyperparathyroidism (69–71) (*vide infra*).

Skeletal Resistance to Parathyroid Hormone

Rapid mobilization of calcium and phosphorus from the skeleton occurs in the presence of PTH. In patients with moderate to severe CRI, however, this rapid response to intravenous infusion of PTH is greatly diminished (72). Moreover, delayed recovery after hypocalcemic stimulation was shown in patients with early renal failure and in uremic dogs despite marked elevation of PTH levels (73). Although the precise mechanisms by which skeletal resistance to PTH affects the calcemic response in patients with renal failure are unclear, unspecified uremic toxins, hyperphosphatemia, and alterations in vitamin D metabolism have been implicated. Additional mechanisms may involve

the PTH/PTH-related protein receptor; diminished PTH/PTHrP receptor mRNA expression has been demonstrated in the kidney and growth plate of uremic rats and in the osteoblasts of patients with ESRD (74–76). The potential role of molecular markers localized in skeletal tissues of patients with CRI may provide more information on the pathogenesis of this abnormality. Also, calcitriol administration has been shown to partially restore the calcemic response to PTH in patients with moderate CRI and in experimental animals (77).

Low-Turnover Bone Lesions (Adynamic Bone and Osteomalacia)

In children with CRI, osteomalacia may result from inadequate dietary intake of calcium, phosphorus, or vitamin D, particularly during rapid growth, when the skeletal demand for these nutrients is high. In young children with tubulointerstitial disease, renal calcitriol production may decline at an early stage of renal failure and may contribute to the development of osteomalacia. In the 1980s, osteomalacia and adynamic bone lesions associated with aluminum toxicity were prevalent (78–80); the main sources were aluminum-containing phosphate-binding agents and contaminated dialysate solutions. Aluminum-related bone disease has become much less common with the greater use of calcium-containing phosphate-binding agents and avoidance of other sources of aluminum loading.

Over the last decade, the occurrence of adynamic renal osteodystrophy without aluminum deposition has increased in adult patients undergoing hemodialysis or peritoneal dialysis and in those immediately before commencing dialysis therapy (81,82). Although the prevalence of adynamic lesions of bone has remained less than 20% in children and adolescents with ESRD who were treated with daily doses of calcitriol, adynamic bone developed in 33% of patients who were given high intermittent calcitriol therapy for control of secondary hyperparathyroidism (82).

Adynamic renal osteodystrophy is characterized by decreased osteoblastic activity and rates of bone formation. Serum PTH and alkaline phosphatase levels are often low to normal, suggesting a relative state of hypoparathyroidism (83). Often, patients develop hypercalcemic episodes, reflecting the skeleton's inability to incorporate an increased calcium load (84). Disorders that are associated with long-standing or irreversible reductions in osteoblastic activity and bone formation include age-related or postmenopausal osteoporosis, steroid-induced osteoporosis, idiopathic or surgically induced hypoparathyroidism, and diabetes mellitus. Reversible causes of adynamic renal osteodystrophy include lesions that develop after subtotal parathyroidectomy in patients with ESRD, prolonged treatment with calcium-containing phosphate-binding medications, use of high dialysate calcium concentration, aggressive vitamin D therapy and aluminum toxicity (85).

CLINICAL MANIFESTATIONS

Renal osteodystrophy in children presents with nonspecific signs and symptoms and often goes unnoticed. Clinically, patients may restrain physical activity, making early diagnosis difficult, and radiographic changes may not reflect the severity of bone disease. Careful and detailed physical examination must be performed in the evaluation of these patients.

Growth Retardation

A substantial proportion of children with CRI have significant growth impairment. Based on the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS), the mean height standard deviation scores (SDSs) were 1.64 below the appropriate age- and gender-adjusted height levels at the start of dialysis in more than 3000 patients studied; of these, males and younger patients were more growth impaired (86). At time of transplant, the mean height SDS was -1.91 in more than 6600 patients studied, with greater height deficits in males, younger patients, and in those with previous renal transplants.

Multiple factors may be responsible for growth retardation in children with CRI, including persistent metabolic acidosis, calcitriol deficiency and renal osteodystrophy, inadequate protein and caloric intake, and disturbances in certain growth factors. Acidosis has been linked to delayed linear growth in patients with renal tubular acidosis and normal renal function, and correction of metabolic acidosis often leads to acceleration in growth velocity (87). Acidotic rats have been found to have decreased growth hormone (GH) secretion, serum IGF-1, and hepatic IGF-1 mRNA expression. Moreover, metabolic acidosis has been shown to inhibit the effects of GH in rats with normal and decreased renal function (88–90). In the growth plate, incubation of murine mandibular condyles in acidic medium diminished the expressions of the GH receptor, IGF-1 receptor, and IGF-1 (both with and without GH treatment) and upregulated the expressions of IGF-binding proteins (IGFBPs) 2 and 4, which are negative modulators of IGF-1 (91). However, the role of metabolic acidosis in renal failure remains to be determined.

Calcitriol deficiency has also been thought to contribute to growth retardation and bone disease in children with CRI. Indeed, treatment with daily doses of calcitriol, or 1,25-dihydroxyvitamin D₃, has been reported to improve linear growth in small numbers of children with stable CRI and in those receiving regular dialysis (92–94). Such findings provide the rationale for the routine administration of calcitriol to nearly all children with CRI. However, enhanced growth velocity was not demonstrated on long-term follow-up (94) and further studies have not shown that calcitriol consistently improves linear growth in children with CRI (95–97).

Secondary hyperparathyroidism remains prevalent in children with advanced renal disease, and osteitis fibrosa continues to be the most common skeletal lesion of renal osteodystrophy in those undergoing regular dialysis despite regular treatment with daily doses of oral calcitriol (78,98). Large intermittent doses of calcitriol have thus been used to treat secondary hyperparathyroidism (82,99–102). This approach has been shown to significantly reduce bone formation and suppress osteoblastic activity in both adults and children (77,101). However, diminished linear growth has been reported in prepubertal children with secondary hyperparathyroidism who developed adynamic renal osteodystrophy after treatment with large intermittent doses of calcitriol (103). It is not known whether impaired growth resulted from a direct inhibitory effect of either high doses or intermittent dosing of calcitriol on chondrocyte activity or whether it was a consequence of oversuppression of PTH (103). In a recent study, linear growth and PTH suppression did not differ during daily or twice-weekly administration of similar doses of calcitriol in prepubertal patients with CRI. Nonetheless, a direct correlation between growth velocity and PTH levels was found, suggesting that PTH levels may act as an additional modulator of growth (104).

Although the mechanisms responsible for the inhibitory actions of calcitriol on epiphyseal growth plate cartilage remain poorly understood, it is well-known that calcitriol, or 1,25-dihydroxyvitamin D, exerts dose-dependent inhibitory effects on cell proliferation *in vitro* both in chondrocytes and in osteoblast-like cells, and neither GH nor IGF-1 can overcome these inhibitory effects (36–38). In addition, recent studies demonstrate that vitamin D sterols increase expressions of a number of IGFBPs (IGFBP-2, -3, -4, -5), which may indirectly suppress proliferation by sequestering IGF-1 and/or may exert IGF-1-independent antiproliferative effects through its own receptors (105–108). IGFBPs may also inhibit IGF-1R signaling, block the cell cycle in the G1/G0 phase, or promote apoptosis (109,110).

GH resistance has been described as one of the factors responsible for impaired linear growth in renal failure. Poor growth develops despite normal or increased serum GH levels due to enhanced pituitary GH secretion and decreased renal clearance of GH (111,112). There is limited information, however, regarding the underlying molecular mechanisms for GH insensitivity in CRI. Animals with renal failure have been found to have diminished expressions of the hepatic GH receptor and IGF-1 mRNA and postreceptor defects in GH-mediated signal transduction in the liver (113,114). Moreover, reductions in serum GH-binding protein levels (derived from the extracellular domain of the GH receptor) have been described in children and adults with CRI (115). In addition, increased synthesis and reduced clearance of IGFBP-1, -2, -4, and -6 and low-molecular-weight fragments of IGFBP-3 are found in uremic serum, and levels of IGFBP-1, -2, and -4 inversely correlate with height (116–118). These excess IGFBPs, which have high affinity for IGF-1, may decrease the

bioavailability of IGF-1 and may also exert direct, IGF receptor-independent actions on cell proliferation via their own receptors (107,108). As such, improved growth velocity during recombinant human GH (rhGH) therapy has been ascribed to increased bioavailability of IGF-1 to target tissues because GH stimulates each component of the 150-kDa serum ternary complex (acid-labile subunit, IGFBP-3, IGF-1, and IGF-2) and reduces serum IGFBP-1 level. However, children who are undergoing regular dialysis respond less well to rhGH therapy than children with less severe CRI. The mechanisms for the differences in response to GH therapy remain to be determined, but the potential interaction between calcitriol and rhGH in the growth plate cartilage should be considered.

Bone Pain

In the early course of renal osteodystrophy, bone pain is nonspecific and difficult to distinguish from common aches and pains. Pain is more often present in patients with low-turnover bone lesions associated with aluminum toxicity. A great variability in clinical presentation occurs among patients. As the disease progresses, the pain localizes to the lower back and to weight-bearing joints, including hips, knees, and ankles. Symptoms worsen with pressure and changes in posture. Limping requires prompt and thorough evaluation in a previously ambulatory child with secondary hyperparathyroidism because of the increased prevalence of fracture and slipped epiphysis in this population (119).

Slipped Epiphyses

Slipped epiphyses are one of the most severe and physically incapacitating manifestations of bone disease in children with CRI. In preschool children, the upper and lower femoral epi-

physes are often affected, whereas, in older children, the upper femur and the radial/ulnar epiphyses are involved. Other epiphyses that can be affected include the distal radius and metacarpal and metatarsal heads (119). In one report, slipped epiphyses were found in 10 of 33 children with newly diagnosed CRI and in 1 of 82 of those who are undergoing dialysis therapy (119). Clinical presentation may include limping, waddling gait, limitation of the range of motion, and inability to ambulate. Mehls et al. demonstrated that children with epiphysiolysis have severe osteitis fibrosa with high serum PTH levels and marked endosteal fibrosis; a dense fibrous tissue may be present between the growth plate cartilage and the adjacent metaphysis, where the plane of slippage may occur (120). The diagnosis is usually established by roentgenograms. Total joint replacement is often required when the proximal femur is involved.

Skeletal Deformities

Bone deformities may be one of the major manifestations of renal osteodystrophy in children with long-term untreated CRI. The pattern of bone deformities varies with the child's age. Bowing may affect both the upper and lower extremities (Fig. 69.4). Patients younger than 4 years will have skeletal abnormalities similar to those due to vitamin D-deficient rickets, which include rachitic rosary; metaphyseal widening, leading to wrist and ankle enlargement; craniotabes; and frontal bossing (121). Because of the rapid increase in growth velocity in children younger than 10 years, bone deformities in the long bones, particularly in the lower extremities, are much more evident. Radiographic changes similar to Blount disease are commonly seen, although these changes occur in the lateral aspect of the proximal tibial metaphysis and epiphysis. Cor-

FIGURE 69.4. Roentgenographic evidence of genu valgum in a 14-year-old boy with secondary hyperparathyroidism.

rective orthopedic surgeries may be required in some patients despite calcitriol therapy. Patients may also present with ulnar deviation, pes varus, pseudo-clubbing, and dental abnormalities.

Muscle Weakness

Myopathy in children with CRI may present in a progressive manner. Initially, patients may complain of nonspecific aches and pains, which can progress to inability to perform activities of daily living. Gait disturbances may be seen with the characteristic waddling gait, which resembles the proximal muscle weakness seen in patients with nutritional vitamin D deficiency (122,123). An underrecognized but significant consequence of myopathy in children is the restriction of physical activity, which impairs the quality of life and social development. Progressive and debilitating myopathy that develops in association with severe bone pain is a common manifestation of aluminum-related bone disease. The mechanism for the development of proximal myopathy in children is not well understood, although contributing factors include secondary hyperparathyroidism, phosphate depletion, aluminum bone disease, and disorders of vitamin D metabolism (124,125).

The diagnosis of proximal myopathy is usually made from a complete history and physical examination, because no specific tests are available. Electromyographic studies do not show specific findings, and serum levels of various muscle enzymes such as creatine phosphokinase, aldolase, and transaminases are usually within normal limits. No specific treatment is available, although an improvement in muscle strength in both proximal and distal muscles has been shown after treatment with vitamin D (126). Improvement in symptoms during vitamin D therapy may be due, in part, to the presence of VDRs in skeletal muscle (127). Subtotal parathyroidectomy also results in clinical improvement.

Extraskelatal Calcification

Soft tissue calcifications are more commonly seen in adults with CRI but they also occur in children with ESRD (128). Autopsy data from 120 children who had undergone dialysis or renal transplantation identified soft tissue calcifications in 60%, and the most commonly affected sites were blood vessels, lung, kidney, myocardium, coronary arteries, central nervous system, and gastric mucosa (128). Calcification was associated with multiple factors such as treatment with vitamin D, peak calcium-phosphorus product, age at onset of CRI, and male gender. Of these, vitamin D sterols, particularly calcitriol, had the strongest correlation with calcification. Consistent with data in adults with CRI, such results suggest a potential role of altered mineral metabolism in extraskelatal calcification.

There are three types of soft tissue calcification: visceral, tumoral or periarticular, and vascular. Deposition of cal-

FIGURE 69.5. Diffuse bilateral lung calcifications diagnosed by scintigraphy with technetium-labeled diphosphonate in a 17-year-old girl with severe secondary hyperparathyroidism.

cium and phosphorus in the conjunctiva results in inflammation often called the *red-eye syndrome*, which has been described in approximately 10% of dialyzed patients. Calcifications in the cornea are demonstrated by slit-lamp examination and they can result in band keratopathy. Pulmonary calcifications may lead to restrictive lung disease, which may progress despite optimal dialysis therapy (Fig. 69.5). Often, parathyroidectomy and renal transplantation are the best therapeutic options (129). Calcific periartthritis is characterized by episodes of acute inflammation in and around small joints, with periarticular warmth and erythema. Radiographic findings demonstrate small effusions within the joint and calcifications in adjacent periarticular tissues.

Cardiac calcifications, particularly in the mitral valve and aortic valve, occur in more than 50% of adult patients who have been on chronic dialysis therapy, and these findings were even more common in the presence of hypertension (130,131). Vascular calcification in renal failure occurs in the media, where it is more common (Mönckeberg's sclerosis), and in the intima, where it is usually associated with atherosclerosis. Schwarz et al. have recently shown that patients with CRI have heavily calcified plaques compared to subjects with intact renal function who have fibroatheromatous plaques (132). Vascular calcifications may contribute to the exceedingly high mortality rate in CRI. In addition, it may complicate the establishment of vascular access for hemodialysis (133), and the rigid wall may make blood pressure and pulse determinations more difficult and may also be falsely elevated.

Cardiac calcifications involving valves and coronary vessels can be assessed using the high-resolution electron beam com-

FIGURE 69.6. Coronary artery calcification scores assessed by electron beam computed tomography according to age in children and young adults undergoing dialysis. (From Goodman WG, Goldin J, Kuizon BD, et al. Coronary artery calcification in young adults with end-stage renal disease who are undergoing dialysis. *N Engl J Med* 2000;342:1478–1483, with permission.)

puted tomography (EBCT), whereas vascular calcifications in the extremities are best demonstrated in the lateral radiographs of the ankles or anteroposterior views of the hands and feet (134). For subjects with normal renal function, reports indicate that coronary calcification measured by EBCT corresponds to the extent and severity of lesions detected by angiography. Using this technique in adult patients with ESRD, markedly elevated calcification scores were found compared to subjects of the same age with normal renal function, and the scores in these patients increased after 1 year (130). Likewise, positive EBCT scans were found in young adult patients who had started dialysis in childhood (135–137) (Fig. 69.6), and calcification scores doubled after less than 2 years of follow-up (135) (Fig. 69.7). Factors associated with positive EBCT scans include older age, longer treatment with dialysis, increased calcium-phosphorus ion product (135,137), higher intake of calcium-containing phosphate-binders (135), hyperparathyroidism (137), microinflammation (137), and hyper-

FIGURE 69.7. Coronary calcification scores in ten patients with positive scores on initial scan and in two patients whose scans became positive after less than 2-year follow-up. Calcification scores nearly doubled in nine of the ten patients who had an initial positive scan. (From Goodman WG, Goldin J, Kuizon BD, et al. Coronary artery calcification in young adults with end-stage renal disease who are undergoing dialysis. *N Engl J Med* 2000;342:1478–1483, with permission.)

homocystinemia (137). These findings underscore the role of disturbances in mineral metabolism in the development and progression of coronary artery calcification in patients with ESRD, and they may contribute to the markedly high mortality rate from cardiovascular disease in these patients (138).

Although vascular calcification has been thought to develop from passive tissue deposition of calcium in the past, recent data indicate that it is an active and regulated process similar to bone ossification. Several studies have demonstrated the expression of factors normally involved in skeletal metabolism in both intimal and medial calcification. In fact, PTH-related peptide and the PTH/PTHrP receptor, bone morphogenetic protein-2, and osteocalcin and osteopontin expressions were localized within human intimal atherosclerotic lesions (139–143). In medial calcification, Shanahan et al. reported diminished expressions of constitutively inhibitory proteins such as matrix Gla protein, osteonectin, osteoprotegerin, and aggrecan by vascular smooth muscle cells and increased expressions of alkaline phosphatase, bone sialoprotein, bone Gla protein, and collagen in association with transcription factors that control the expression of these genes (144–146). When the vascular smooth muscle cells obtained from vessels with medial calcification were examined, features that were characteristic of osteoblasts were found, and they were able to calcify *in vitro* (146).

Likewise, the expressions of osteopontin, bone sialoprotein, alkaline phosphatase and type I collagen have been reported in calcified vessels obtained from adult patients with ESRD (147). Greater expressions of Cbfa1, a transcription factor for osteoblast differentiation, and osteopontin were demonstrated in calcified vessels than in normal vessels. Furthermore, uremic serum upregulated the expression of Cbfa1 and osteopontin in bovine smooth muscle cells *in vitro* (148). Overall, these results emphasize the role of abnormalities in bone and min-

FIGURE 69.8. Follow-up of young adults with childhood-onset chronic renal insufficiency showed that one-half of the patients died from a cardiovascular or cerebrovascular event. (From Oh J, Wunsch R, Turzer M, et al. Advanced coronary and carotid arteriopathy in young adults with childhood-onset chronic renal failure. *Circulation* 2002;106:100–105, with permission.)

eral metabolism in vascular calcification in the context of CRI. Thus, it is critical that therapeutic measures for the prevention of such complications in the growing child are taken into consideration, particularly because cardiovascular disease is the leading cause of death in children and adults with ESRD, and the mortality rate is markedly higher than in the general population (137,138,149) (Fig. 69.8).

DIAGNOSTIC EVALUATIONS

Biochemical Determinations

Calcium

Serum calcium levels are usually low in patients with moderate or advanced CRI. Hypocalcemia often resolves during treatment with calcium-containing phosphate binders, vitamin D, and with initiation of dialysis. The concentration of calcium in most dialysis solutions is 2.5 mEq/L; this concentration is generally adequate to maintain serum calcium within acceptable limits.

Recurrent or persistent hypercalcemia in patients with CRI is not common. Possible etiologies include severe secondary hyperparathyroidism, aluminum-related bone disease, adynamic bone, vitamin D sterols, use of large amounts of calcium-containing phosphate-binding agents, and prolonged immobilization (46,97,150–152). Malignancy and extrarenal production of calcitriol in disorders such as sarcoidosis or tuberculosis result in hypercalcemia, but these conditions are uncommon in the pediatric age group. Patients with adynamic bone lesion without evidence of aluminum toxicity are prone to develop hypercalcemic episodes, which are related to the skeleton's inability to incorporate an acute calcium load (84).

Phosphorus

Serum phosphorus levels are often maintained within normal limits in early CRI. However, when the GFR falls below 30 mL/min/1.73 m² (stage 4 CRI), phosphorus excretion decreases and leads to hyperphosphatemia (4). Hyperphosphatemia is a common problem in patients with more advanced CRI, and measures to maintain serum phosphorus levels within age-appropriate levels and calcium phosphorus product lower than 55 mg²/dL² must be initiated to prevent the development and progression of secondary hyperparathyroidism and vascular calcifications. Indeed, disturbances in mineral metabolism (hyperphosphatemia, hypercalcemia, increased calcium phosphorus product) and vitamin D therapy have been associated with vascular calcification. Although extraskeletal and vascular calcification are well-recognized consequences of CRI in adult dialysis patients and were regarded as rare in the pediatric population, more recent studies demonstrate evidence of vascular calcifications in young adult dialysis patients who had started dialysis in childhood

(135,137). Moreover, elevations in levels of serum phosphorus and calcium-phosphorus product have been demonstrated to be independent risk factors for mortality in adult patients treated with dialysis (153).

The normal range for serum phosphorus levels is age-adjusted. Values are higher in infants and decline to adult values by late adolescence. During the first 3 months of life, values range from 4.8 to 7.4 mg/dL (mean, 6.2 mg/dL); levels decrease to 4.5 to 5.8 mg/dL (mean, 5.0 mg/dL) at age 1 to 2 years, and 3.5 to 5.5 mg/dL (mean, 4.4 mg/dL) during childhood (154).

Alkaline Phosphatase

Serum total alkaline phosphatase is a biochemical marker of osteoblastic activity. Values generally correspond to the histologic severity of osteitis fibrosa, and serial measurements may be helpful in the follow-up of children with renal osteodystrophy. During intermittent calcitriol therapy, serum alkaline phosphatase levels have been found to be good predictors of adynamic renal osteodystrophy (103). Indeed, serum alkaline phosphatase levels often decrease below baseline in patients with bone biopsy-proven secondary hyperparathyroidism, and such changes correspond to marked reductions in bone formation documented by bone biopsy. In addition, changes in Z-scores for height during intermittent calcitriol therapy correlate with serum alkaline phosphatase levels, although a similar relationship is not observed during daily calcitriol therapy (103). Bone-specific alkaline phosphatase may be useful in predicting the histologic lesion of renal osteodystrophy. Values below 27 U/L have been used to exclude high-turnover bone lesions.

Parathyroid Hormone

Accurate measurements of the concentration of PTH in serum or plasma are essential for the proper assessment of renal osteodystrophy (81,155–158). Indeed, determinations of PTH levels are used as surrogates for bone histology, which remains the most reliable method to establish the diagnosis of renal osteodystrophy (78,159,160).

Serum PTH levels are usually elevated in patients with moderate and severe CRI (10,161). Previous assays measuring the epitopes located in the midregion or carboxy-terminal portions of the PTH molecule resulted in high values because of inactive fragments that are retained in renal failure (155). Andress et al. demonstrated that the amino terminal, which cross-reacts with the intact PTH molecule, may be a better predictor of osteitis fibrosa than the inactive carboxyterminal/midregion PTH fragments (162). The first clinically useful two-site immunometric PTH assay (PTH-IMA) used two antibodies directed against amino- and carboxyl-terminal epitopes, respectively, and was, therefore, predicted to measure only full length PTH(1-84) (163).

Over the last decade, this first-generation PTH-IMA (1st PTH-IMA) proved to be a reasonably reliable predictor of the different subtypes of renal osteodystrophy, and it performed well in assessing the therapeutic response to active vitamin D sterols in patients with renal failure (81,157,158). Serum PTH levels greater than 200 pg/mL were 95% sensitive and 86% specific for identifying those with high-turnover bone lesions from secondary hyperparathyroidism in patients treated with dialysis (157). In contrast, in adult patients with stable stage 3 CRI (GFR, 30 to 59 mL/min/1.73 m²), serum PTH levels between 100 and 150 pg/mL were associated with bone biopsy findings consistent with osteitis fibrosa (2). On the other hand, serum PTH levels less than 200 pg/mL were 100% sensitive but only 79% specific for diagnosing patients with adynamic bone lesion; specificity was increased when serum calcium greater than 10 mg/dL was included in patients treated with dialysis. In dialysis patients receiving intermittent calcitriol therapy, however, serum PTH levels were not as predictive; the levels remained elevated despite a significant decline in bone formation rate (82). This disparity between histologic and biochemical findings suggests that intermittent calcitriol administration can reduce bone formation in patients with secondary hyperparathyroidism, at least in part, by a mechanism that is independent of vitamin D-induced reductions in serum PTH levels (82).

On the other hand, recent observations highlight important shortcomings of this and other PTH-IMAs (164,165). In particular, a series of studies by D'Amour and colleagues (164–166) demonstrated that 1st PTH-IMAs detect not only the intact hormone, but also additional PTH fragments truncated at the amino-terminus [ntPTH(1-84)]. Indeed, most of the detection antibodies, which are usually directed against epitopes within the amino-terminus of the hormone, detect not only PTH(1-84) but also one or several ntPTH(1-84) fragments, some of which co-elute from reverse-phase high-performance liquid chromatography column with synthetic PTH(7-84) (165). In contrast, a more recently developed second-generation PTH-IMA (2nd PTH-IMA) using a detection antibody raised against the first four amino-terminal amino acids of human PTH recognizes only PTH(1-84) and possibly PTH fragments that are truncated at the carboxyl-terminus but not PTH(7-84) (Fig. 69.9) (167–169). Consistent with this assessment, human PTH(1-34) but not human PTH(2-34) or other amino-terminally truncated fragments of human PTH(1-34) cross-reacted with the detection antibody (167–169). 1st PTH-IMAs, thus, overestimate the true concentration of PTH(1-84) in serum or plasma both in patients with ESRD and in those with normal renal function (166,167,169–172) (Fig. 69.10).

Recent *in vitro* and *in vivo* experimental data also indicate that one or more amino-terminally truncated PTH(1-84) fragments antagonize the calcemic actions of

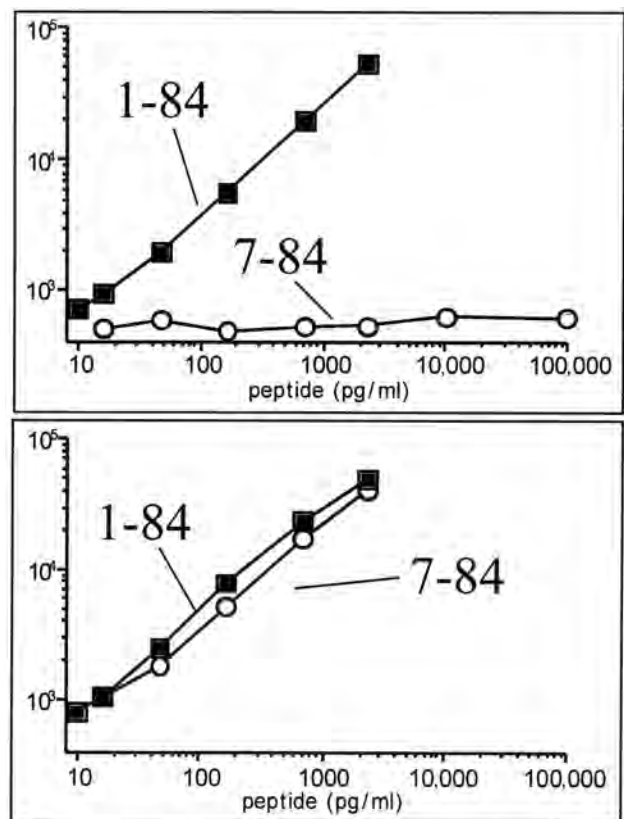

FIGURE 69.9. A: The first generation immunoradiometric assay (IRMA) uses an antibody directed against the 13-34 region of the parathyroid hormone (PTH) molecule, whereas the second generation IRMA uses an antibody against an initial epitope within the amino terminus (residues 1-3). Both assays use antibodies against epitopes within the 39-84 region of the PTH molecule. (From Salusky IB, Goodman WG, Kuizon BD, et al. Similar predictive value of bone turnover using first- and second-generation immunometric PTH assays in pediatric patients treated with peritoneal dialysis. *Kidney Int* 2003;63:1801–1808, with permission.) **B:** The first generation IRMA assay (*top*) had similar cross-reactivity for PTH(1-84) and PTH(7-84), whereas the second generation IRMA assay (*bottom*) detected only PTH(1-84) and possibly PTH fragments that are truncated at the carboxyl-terminus but not PTH(7-84) even at markedly high concentrations. (From Jon MR, Goodman WG, Gao P, et al. A novel immunoradiometric assay detects full-length human PTH but not amino-terminally truncated fragments: implications for PTH measurements in renal failure. *J Clin Endoc Metab* 1999;84:4287–4290, with permission.)

FIGURE 69.10. Serum parathyroid hormone (PTH) levels measured using the first (*hatched bars*) and second (*open bars*) generation immunometric assays (IMA) in patients with high and normal or low bone formation rates (BFR). First generation IMAs also detect additional PTH fragments truncated at the amino-terminus [ntPTH(1-84)].

PTH(1-84) and diminish bone cell activity and may, thereby, modulate bone metabolism. These actions are possibly mediated through a receptor distinct from the type I PTH/PTHrP receptor (168,173). Such findings suggest that amino-truncated PTH(1-84) fragments may contribute to the skeletal PTH resistance that occurs in patients with renal failure (168,173). It, therefore, appears plausible that an independent assessment of PTH(1-84) and amino-truncated PTH(1-84) fragments may have better value for diagnosis of the different subtypes of renal osteodystrophy than each parameter alone. Indeed, it has been suggested that estimates of the ratio between PTH(1-84) and amino-truncated PTH(1-84) fragments more accurately predicts bone remodeling and turnover in patients with ESRD (170). On the other hand, two reports in adult and pediatric patients treated with dialysis failed to confirm such findings (172,174).

Taking into consideration the crucial role of serum PTH concentrations in the diagnosis and treatment of renal osteodystrophy, 2nd PTH-IMA may provide important new insights into the physiology of parathyroid gland func-

tion. However, current findings demonstrated that measurements of PTH using either 1st or 2nd PTH-IMAs provided similar accuracy for predicting bone turnover in pediatric patients undergoing maintenance peritoneal dialysis (Fig. 69.11) (172,174). Therefore, the current recommendations for indications of therapy with active vitamin D sterols should be based on the relationship between indices of bone formation and PTH levels determined by first-generation immunometric assays. The following are the target values of PTH in patients' varying stages of CRI:

Stage 3 CRI (GFR, 30 to 59 mL/min/1.73 m²): 6 to 65 pg/mL

Stage 4 CRI (GFR, 15 to 29 mL/min/1.73 m²): 100 to 200 pg/mL

Stage 5 CRI (GFR, less than 15 mL/min/1.73 m² or dialysis): 150 to 300 pg/mL

Further studies are needed to establish the value of the new generation of PTH assays for assessing bone disease in renal failure and during therapy with vitamin D and to address

FIGURE 69.11. the need for higher PTH levels determined by either assay for preventing the development of adynamic osteodystrophy and its consequences on the growing skeleton (175).

Aluminum

Plasma aluminum levels are useful in the monitoring of patients who are undergoing chronic dialysis therapy and receiving aluminum-containing phosphate-binding agents for prolonged periods. Plasma aluminum values measured using electrothermal atomic absorption spectrometry are often accurate and reproducible. Although plasma aluminum levels reflect more recent exposure, the levels do not reflect aluminum deposits accurately. The presence of aluminum deposits in the bone and liver do not correlate with the plasma levels (176). Aluminum toxicity occurs in dialysis patients or CRI patients with GFR less than 30 mL/min/1.73 m² because aluminum that is absorbed from the gut or enters the body from the dialysate or other parenteral route is not excreted or is inadequately excreted by the diseased kidney. The accumulation occurs in various tissues, including bone, brain, parathyroid glands, and other organs. Such accumulation can produce toxicity with several distinct syndromes depending on the rate and magnitude of the aluminum loading. The first to be described was dialysis encephalopathy, as well as fracturing dialysis osteomalacia and microcytic anemia.

A deferoxamine (DFO) test should be performed if the plasma aluminum levels are between 60 and 200 µg/L or if clinical signs and symptoms of aluminum toxicity are present or before parathyroid surgery if the patient has had aluminum exposure. The DFO infusion test is performed by infusing 5 mg/kg of DFO during the last hour of the dialysis session. Serum aluminum should be measured before DFO infusion and, 2 days later, before the next dialysis session (177). The test is considered positive if the increment of serum aluminum is greater than 50 µg/L. The presence of aluminum bone disease can be predicted by a rise in serum aluminum of 50 µg/L, combined with a plasma PTH (1st PTH-IMA) of less than 150 pg/mL. However, the gold standard for the diagnosis of aluminum bone disease is a bone biopsy showing increased aluminum staining of the bone surface (greater than 15 to 25%) and histologic evidence of adynamic bone or osteomalacia. A DFO test should not be performed if the serum levels of aluminum are more than 200 µg/L to avoid DFO-induced neurotoxicity.

Radiographic Features

The primary radiographic feature of children with secondary hyperparathyroidism is evidence of increased bone resorption, which is usually located in the subperiosteal or endosteal surfaces of cortical bone within cortical regions. The extent of bone resorption correlates with serum PTH

FIGURE 69.12. Subperiosteal erosions of the midphalanges in a patient with severe secondary hyperparathyroidism.

levels (162,178). Subperiosteal resorption may occur at the distal ends of the clavicles, ischial and pubis surfaces, sacroiliac joints, junction of the metaphysis and diaphysis of long bone, and in the phalanges (Fig. 69.12) (179,180). A diffuse ground-glass appearance, generalized mottling, focal radiolucencies, and sclerotic areas may be evident in the skull (181). Metaphyseal changes, called *growth zone lesions* or *rickets-like lesions*, are best demonstrated in hand radiographs (182). Although subperiosteal erosions are a hallmark of secondary hyperparathyroidism, these lesions can also be seen in patients with aluminum-related bone disease, which may represent unhealed lesions from a previous state of secondary hyperparathyroidism (183). To enhance the sensitivity of hand radiographs, the use of fine-grain films and magnification by hand lens has been recommended (180).

The radiographic features of osteomalacia are less evident, particularly in older children and adolescents. In young children, widening of the epiphyseal growth plate and other deformities of the growth plate cartilage are evident, whereas pseudofractures and looser zones, which appear as straight, wide radiolucent bands within the cortex, may be the only findings in older children and adults. The radiographic density of bone on conventional skeletal radiographs is reduced in many patients with renal osteodystrophy, but osteosclerotic changes or localized increases in bone density are a prominent finding in children with chronic renal failure.

Bone Scintigraphy

Bone scans using the technetium-99–labeled diphosphate are helpful in estimating the severity of bone disease and differentiating between high-turnover lesions of osteitis fibrosa and low-turnover lesions of osteomalacia (184). Uptake is usually diffuse and symmetric in patients with

severe secondary hyperparathyroidism, whereas patients with osteomalacia exhibit a more diffuse and less intense uptake (184). Extraskeletal calcifications may also be demonstrated using the bone scan in various organ systems, such as the lungs and heart (185).

Bone Biopsy

Iliac crest bone biopsy provides valuable diagnostic information in children with renal osteodystrophy (186). The procedure is safe and well tolerated in children and is done in an outpatient setting (78). Bone biopsy provides information about the histologic appearance and dynamics of bone formation and mineralization. For bone labeling, tetracycline is administered at 15 mg/kg/day in two to three doses for 2 days, 14 days apart. For children younger than 8 years, tetracycline dosage is usually kept below 10 mg/kg/day to avoid toxicity. Histochemical staining procedures demonstrate the deposition of abnormal components within bone such as iron, aluminum, and oxalate (78,187). Indications for bone biopsy include investigation of persistent hypercalcemia before parathyroidectomy with and without vitamin D therapy, unexplained hypercalcemia associated with PTH levels between 200 and 500 pg/mL, assessment of skeletal response to certain therapeutic modalities, and diagnosis of aluminum bone disease.

Osteitis fibrosa is one of the most common histologic lesions in children with chronic renal failure (78,186). Histologically, large numbers of osteoclasts are present, with a proportional increase in bone resorption (Table 69.2). Fibrous tissue often accumulates within the bony trabeculae, and, in severe cases, fibrous tissue deposition occurs in the marrow space (Fig. 69.13). The development of severe osteitis fibrosa may worsen the anemia of CRI by displacing erythroid precursors from the marrow space.

In uncomplicated osteitis fibrosa, bone formation rates are elevated to approximately two to three times normal (78,186); this is coupled with a marked increase in osteoblastic number and activity (188). Peritrabecular fibrosis is absent in mild lesions of secondary hyperparathyroidism. Nevertheless, activity of both osteoclasts and osteoblasts is

FIGURE 69.13. Histologic lesion of osteitis fibrosa characterized by increased resorptive surface on mineralized bone by osteoclasts and fibrosis.

increased, and the rate of bone formation is greater than normal (78,186). Tetracycline-based measurements of bone formation are valuable in differentiating this less severe lesion of secondary hyperparathyroidism from the low-turnover disorders (78,186).

Osteomalacia is the most striking histologic feature of low-turnover bone disease. Excess osteoid or unmineralized bone collagen accumulates because of a defect in skeletal mineralization (189). Osteoid seams are thickened, with a multilaminated or lamellar appearance. Osteoblastic activity is usually reduced, and the rate of bone formation often cannot be measured because of absence of tetracycline uptake into bone. In patients with suspected aluminum-related bone disease, histochemical staining provides useful information. In these cases, the severity of histochemical changes of osteomalacia corresponds with the amount of surface-stainable aluminum in the cancellous bone (190).

Adynamic or aplastic bone is characterized by the presence of normal to reduced osteoid formation, absence of fibrosis, and diminished numbers of osteoblasts and osteoclasts; bone formation rate is characteristically absent to subnormal (78,186,191) (Table 69.3). The absence of osteoid accumulation differentiates it from osteomalacia (Fig.

TABLE 69.2. HIGH-TURNOVER LESIONS OF RENAL OSTEODYSTROPHY

	Mild lesion	Osteitis fibrosa

69.14). In the past decade, aluminum deposits in the bone were evident in patients with adynamic bone; however, currently, an increasing proportion of patients have been reported to have adynamic bone lesions without aluminum deposition (78,192).

Occasionally, patients may exhibit mixed lesion of renal osteodystrophy, which is characterized by histologic changes of both osteitis fibrosa and osteomalacia (159). These patients often have high serum PTH levels and histologic manifestations of impaired bone formation and mineralization. Mixed lesions are seen with high-turnover bone disease in patients who are developing aluminum toxicity or in patients with low-turnover aluminum-related bone disease during DFO therapy (193). In these cases, mixed lesion represents a transitional stage between high-turnover and low-turnover bone disease.

TREATMENT

Particular attention must be made to the bone and mineral metabolism of children with CRI to minimize complications in the growing skeleton and to prevent extraskeletal, particularly, vascular calcifications.

Dietary Manipulation

Evaluation of dietary intake and growth must be performed at regular intervals to maximize the growth potential of children with CRI. Nutritional requirements are based on the recommended dietary allowances for energy and protein. Nutritional supplements, which may be given orally or through a nasogastric or gastrostomy tube, are recommended when recommended dietary allowances for energy and protein are not achieved by dietary intake alone or when there is impaired linear growth and/or weight gain.

The dietary reference intake (DRI) for phosphorus for the different age groups is based on the report from the

TABLE 69.4. DIETARY REFERENCE INTAKE FOR PHOSPHORUS

Age (yr)	Dietary reference intake (mg/d)	Tolerable upper intake (mg/d)
0–0.5	100	Not determined
0.6–1.0	275	Not determined
1–3	460	3000
4–8	500	3000
9–18	1250	4000

Food and Nutrition Board (Table 69.4) (194). Based on this report, the average phosphorus intake of children in the United States is higher than the DRI and is approximately 1500 to 2000 mg/day, of which 60 to 70% is absorbed. Phosphorus is present in nearly all foods and its highest concentration is in meat and dairy products. Dietary phosphorus intake is frequently restricted to 600 to 1200 mg/day when serum phosphorus levels exceed age-appropriate normal levels and to keep the calcium phosphorus product less than $55 \text{ mg}^2/\text{mL}^2$ (177). Similar restrictions are recommended for patients with serum PTH levels that are higher than the target range according to the stage of CRI. In dialysis patients, phosphorus removal by peritoneal dialysis (240 to 440 mg/day) or hemodialysis (600 mg during a 4-hour session) is inadequate to maintain target phosphorus levels (195,196); therefore, dietary phosphorus restriction is usually required. More frequent hemodialysis, however, such as nocturnal hemodialysis, which is performed 6 to 7 nights per week for 8 to 10 hours during sleep at home, has been shown to remove twice as much phosphate per week than conventional hemodialysis (197). As such, adult patients undergoing nocturnal hemodialysis do not require phosphate binders, are able to ingest higher dietary phosphate and protein intake, and some require phosphorus supplementation in the dialysate (197,198). However, this dialytic modality has not been performed in pediatric dialysis patients.

Although dietary phosphorus restriction is recommended in the majority of patients with more advanced CRI, long-term compliance to such restrictions is difficult because of protein requirements for growth and the unpalatability of low phosphate diets. Accordingly, the use of phosphate-binding agents becomes an integral component of the treatment of these children. Serum phosphorus levels should be measured at least every 3 months after starting the phosphorus-restricted diet to prevent hypophosphatemia, particularly in those who are also given large doses of phosphate-binding agents. Infants are particularly at risk for hypophosphatemia because of the use of low phosphorus-containing formulas, aggressive use of phosphate binders, increased phosphate removal by peritoneal dialysis probably due to higher surface area, and possibly nutritional repletion (199). Patients with severe and persistent hypophosphatemia have been reported to develop

TABLE 69.5. DIETARY REFERENCE INTAKE FOR CALCIUM

Age (yr)	Dietary reference intake (mg/d)	Tolerable upper intake (mg/d)
0–0.5	210	420
0.6–1.0	270	520
1–3	500	1000
4–8	800	1600
9–18	1300	2500

bone disease such as osteomalacia and rickets, proximal myopathy, rhabdomyolysis, and congestive heart failure (199,200). The use of calcitriol may also complicate the management of hyperphosphatemia because it enhances intestinal phosphorus absorption; in these cases, higher dosages of phosphate binding agents are required (201).

The DRI for calcium for the different age groups is shown in Table 69.5 (194). Calcium intake to meet the DRI and regular exercise are strongly recommended throughout childhood and adolescence to increase peak bone mass, and thereby reduce fracture rates and prevent osteoporosis later in life. In patients with CRI stages 1 to 4, the recommended calcium intake is based on the DRI for age (177). The main source of calcium is milk and dairy products, although various foods such as orange juice and cereals are fortified with calcium. Calcium supplementation is recommended when the DRI is not met by dietary intake. In patients with CRI stage 5 or those undergoing dialysis, calcium intake from both diet and calcium containing phosphate binders should be limited to no more than 2500 mg/day (Table 69.5) (177).

Phosphate-Binding Agents

Phosphate-binding agents are recommended in patients with hyperphosphatemia despite dietary phosphorus restriction. They form poorly soluble complexes with phosphorus in the intestinal tract, thereby decreasing phosphorus absorption. Calcium-containing phosphate binders are widely used as the initial agent for the management of hyperphosphatemia. They also provide an additional source of calcium. Several calcium-containing salts, such as calcium carbonate, calcium acetate, and calcium citrate are commercially available. Schaefer et al. found similar effectiveness in controlling serum phosphorus levels using calcium carbonate or calcium acetate, but calcium acetate has been shown to bind twice more phosphorus using equivalent doses in adult studies (202). Calcium citrate is not recommended in patients with CRI who are also receiving aluminum-containing phosphate binders, because citrate increases intestinal aluminum absorption (203).

Overall, calcium carbonate is the calcium salt that is largely prescribed, and its effectiveness in reducing serum phosphorus levels has been reported in adult and pediatric patients (152,204). In addition, calcium carbonate therapy

alone decreased serum intact PTH levels in adult patients with secondary hyperparathyroidism (205,206). The dose of calcium-based phosphate binders varies widely among children and should be adjusted to maintain normal calcium levels and age-appropriate serum phosphorus levels. Calcium salts should be given immediately after meals if they are used as phosphate binders and they should be given between meals if used for hypocalcemia. Hypercalcemia is a major complication associated with the long-term use of high doses of calcium-based phosphate-binding agents, particularly in patients treated with vitamin D or those with adynamic bone lesion (207,208). Hypercalcemia usually resolves with lowering the dose of vitamin D and calcium-based binders. Vitamin D should be given at bedtime in patients treated with calcium-based binders to decrease intestinal calcium absorption. In patients with CRI stage 5 or those undergoing dialysis, calcium intake from both diet and calcium-containing phosphate binders should be limited to no more than 2500 mg/day (177).

Over the last few years, the use of calcium-containing binders has been linked with the development of vascular calcifications in adult and pediatric patients treated with maintenance dialysis (135). Furthermore, there is substantial evidence that abnormalities in mineral metabolism, hypercalcemia, hyperphosphatemia, and elevated calcium-phosphorus ion product are associated with the development of soft tissue and vascular calcifications (128,135,137,209). Thus, intake of calcium from calcium-containing phosphate binders as well as the use of active vitamin D sterols have been implicated in the process of vascular calcifications, and they may play a role in the development of accelerated cardiovascular disease that occurs in adult patients treated with dialysis (128,135). Although the mortality rate is low in children with ESRD, current evidence indicates that vascular calcifications are present in young adults treated with dialysis or renal transplantation with childhood-onset renal disease (135–137). Thus, in dialysis patients, it is recommended that the amount of elemental calcium from these compounds and from diet should not exceed 2500 mg/day (177).

Alternative phosphate binders have thus been developed because of the risks of hypercalcemia and vascular calcification associated with the use of calcium salts and because of toxicity from long-term ingestion of aluminum-containing phosphate binders. Sevelamer hydrochloride (Renagel), a calcium- and aluminum-free hydrogel of cross-linked poly(allylamine-hydrochloride), has been reported to lower serum phosphorus, calcium-phosphorus ion product, and intact PTH without inducing hypercalcemia in adult and pediatric patients with ESRD (210–213). Serum total cholesterol and low-density lipoprotein cholesterol levels also decreased, whereas high-density lipoprotein increased during sevelamer treatment (212), and these effects may offer additional benefits in reducing cardiovascular complications in patients with ESRD. More importantly, the process of vascular calcification was halted during treatment with sevelamer hydrochloride

ride when compared to calcium-containing binders in adult patients treated with hemodialysis (214). Sevelamer may be used as the primary agent, particularly in patients who are prone to develop hypercalcemia and in those requiring large doses of vitamin D, but further studies are warranted to evaluate the long-term effects of this new therapy on bone disease in children with renal failure.

Additional phosphate binders include magnesium, iron, and lanthanum compounds. Magnesium carbonate reduces serum phosphorus levels, but, because of the risk of developing hypermagnesemia in patients treated with dialysis, a dialysate with lower magnesium content is recommended (215). Diarrhea can also develop if large doses of magnesium carbonate are used, therefore limiting its use as a single agent. Iron compounds, such as stabilized polynuclear iron hydroxide and ferric polymaltose complex, are novel phosphate binders that are effective in short-term studies in adults with CRI (216,217). Another new agent, lanthanum chloride hydrate, decreased intestinal phosphate absorption in experimental studies and in a clinical trial (218,219). Because it is a heavy metal, however, studies to address its potential for long-term complications should be considered.

Aluminum-containing gels are effective phosphate-binding agents that were primarily used before the 1980s. The development of bone disease, encephalopathy, and bone disease associated with long-term administration, however, led to the restriction of its use to patients with hypercalcemia or increased calcium phosphorus product, because both conditions worsen with calcium salts. Plasma aluminum levels in children correlate well with the quantity of aluminum-containing phosphate-binding agents (220). Thus, guidelines for maximum safe dosages of aluminum hydroxide have been proposed: 30 mg/kg/day for children and 2000 to 3000 mg/day for adults (80,221). Despite the recommended dosages, aluminum accumulation still occurs, as seen by a rise in plasma aluminum level after DFO infusion and by histologic evidence of aluminum deposits in the bone (222). The lowest possible dose must be used for a limited period of approximately 4 to 6 weeks, and plasma aluminum levels should be followed closely. The simultaneous use of aluminum-containing agents and citrate must be avoided to prevent toxic accumulation of aluminum, because citrate enhances aluminum absorption by altering tight junctions in the intestinal epithelium (203). Citrate-containing medications that are usually used in patients with CRI include calcium citrate, Alka-Seltzer, Shohl's solution, sodium citrate (Bicitra/Polycitra), and even citrus fruits.

Vitamin D Therapy

One of the goals in the management of secondary hyperparathyroidism with vitamin D is to inhibit PTH release through its direct effects on pre-pro-PTH gene transcription and the VDR or indirectly through hypocalcemia. In

pediatric patients with CRI, additional benefit was reported on promoting linear growth during treatment with daily doses of calcitriol (92,93). Several vitamin D sterols are currently available, and clinical trials have demonstrated their efficacy in lowering PTH levels. In the United States, calcitriol is frequently prescribed, whereas 1α -hydroxyvitamin D is commonly administered in Europe and Japan.

In patients with CRI stage 3 (GFR, 30 to 59 mL/min/1.73 m²), vitamin D therapy is indicated when PTH levels measured by 1st PTH-IMA are above 65 pg/mL; in those with stage 4 CRI (GFR, 15 to 29 mL/min/1.73 m²), when values are above 100 pg/mL; and in patients undergoing dialysis (stage 5 CRI), therapy is indicated when PTH levels exceed 300 pg/mL (177). Before starting treatment with vitamin D, however, it is important to ensure that serum phosphorus levels are within the normal range for age. Calcitriol or alfacalcidol may be started at a daily dose of 0.25 to 0.5 μ g, and the dose is gradually titrated in 0.25- to 0.5- μ g increments to achieve 1st PTH-IMA levels within the normal range. Dosage regimens have generally ranged from 0.25 to 1.0 μ g/day. Serum levels of calcium, phosphorus, and 1st PTH-IMA should be monitored monthly for the first 3 months after start of vitamin D therapy. Hypercalcemia is the most common side effect, but it is often reversible by withholding or reducing the dose. Although initial studies have demonstrated a more rapid deterioration in renal function during vitamin D therapy, subsequent studies have shown no adverse effects on progression of renal failure (223–225).

In patients with CRI stage 5 or those requiring regular dialysis, vitamin D therapy is recommended when 1st PTH-IMA levels exceed 300 pg/mL despite maintaining serum phosphorus within age-appropriate levels (177). Daily calcitriol or alfacalcidol therapy may be initiated at a dose of 0.25 to 0.5 μ g, and the dose is gradually increased in 0.25- to 0.5- μ g increments to achieve first PTH-IMA levels between 150 and 300 pg/mL. Intermittent doses may be considered when serum PTH levels are greater than 500 to 600 pg/mL. The initial dose is 0.5 to 1.0 μ g three times per week administered by the oral or intravenous route. The intraperitoneal route of calcitriol administration is currently not approved by the U.S. Food and Drug Administration. The use of a dialysate calcium concentration of 2.5 μ g/L is recommended for patients treated with either hemodialysis or peritoneal dialysis. Decreasing the dialysate calcium concentration may allow higher doses of calcitriol to be given. Long-term treatment with high pulse doses of calcitriol should be undertaken with caution in prepubertal children with secondary hyperparathyroidism. Suppressing PTH levels below 200 pg/mL should be avoided because of the risk for growth retardation in those who develop adynamic renal osteodystrophy (103). Findings by Schmitt et al. in 2003 in children with CRI before dialysis support this initial observation (104). Additional studies are needed to define the optimal PTH levels during calcitriol treatment

that would support normal rates of bone formation and linear growth in pediatric patients with renal osteodystrophy.

Control of secondary hyperparathyroidism should be considered before initiation of rhGH in children with CRI. It is recommended that serum phosphorus levels are less than 1.5 times the upper limit for age and 1st PTH-IMA levels less than 1.5 times the upper target values for the CRI stage before starting rhGH (177). It is expected that therapy with rhGH will increase serum PTH levels during the initial first months of therapy; therefore, monthly PTH should be monitored more frequently during that period. Therapy with rhGH should be temporarily discontinued if PTH levels exceed three times the upper target value for the CRI stage despite at least 3 months of vitamin D therapy and restarted once values are below 1.5 times the upper target value for the CRI stage (177). In addition, it is important to maximize the control of serum phosphorus levels.

New vitamin D compounds that retain the suppressive effects on PTH but induce less hypercalcemia and hyperphosphatemia are being evaluated. However, studies that compare the biochemical and histologic responses of these new compounds with standard therapy (calcitriol or alfacalcidol) are not yet available. 22-Oxacalcitriol inhibits PTH mRNA expression *in vitro* and *in vivo*, and it prevents the reduction in VDR in the parathyroid glands of rats with renal failure (226). Short-term treatment with OCT lowered serum PTH levels and bone formation rates without inducing hypercalcemia in experimental animals with either normal or reduced renal function (227). Long-term administration, however, resulted in hypercalcemia and hyperphosphatemia in uremic dogs (228). Moreover, although OCT diminished abnormal woven osteoid, lamellar osteoid, and fibrosis, it did not decrease bone formation rates on repeat biopsy (228). In early clinical trials, OCT controlled secondary hyperparathyroidism, but hypercalcemia prevented further increases in dose for one-half of the subjects (229,230). Although controlled studies are needed, preliminary findings involving a small number of patients do not support an advantage of OCT over calcitriol.

Another new vitamin analog is $1\alpha(\text{OH})$ -vitamin D_2 ($1\alpha\text{D}_2$, doxercalciferol), which is equipotent to $1, \alpha(\text{OH})$ -vitamin D_3 in intestinal calcium absorption and bone calcium mobilization in vitamin D-deficient rats, but it requires larger doses than $1\alpha\text{D}_3$ to induce hypercalcemia and toxicity in normal rodents (231). Initial clinical trials demonstrated suppression of PTH levels during treatment with daily or intermittent oral doses of $1\alpha\text{D}_2$ (starting dose $4 \mu\text{g}/\text{day}$ or $4 \mu\text{g}$ thrice weekly) in 24 adult hemodialysis patients with moderate to severe secondary hyperparathyroidism. Serum calcium levels increased moderately, from 8.8 ± 0.18 to 9.5 ± 0.21 ($p < .001$), and treatment had to be stopped only once for hypercalcemia (232). In a subsequent multicenter trial involving 80 adults undergoing hemodialysis, treatment with larger intermittent oral doses of $1\alpha\text{D}_2$ ($10 \mu\text{g}$ thrice weekly) effectively decreased serum PTH levels with

minimal hypercalcemia and hyperphosphatemia (233). While these results are encouraging, studies that compare this compound to either calcitriol or $1\alpha\text{D}_3$ are needed. Doxercalciferol has recently been approved for treatment of secondary hyperparathyroidism in the United States.

Another vitamin D analog, 19-nor- $1\alpha,25(\text{OH})_2\text{D}_2$ (paricalcitol), was initially reported to reduce PTH secretion without changing the concentrations of plasma ionized calcium or plasma phosphorus in rats with renal failure (234). In addition, parathyroidectomized rats fed either a low-calcium or a low-phosphate diet had less increments in plasma calcium or phosphorus levels during treatment with paricalcitol than with similar doses of calcitriol (235). Results of double-blind, placebo-controlled, randomized clinical trials demonstrate the efficacy of paricalcitol in suppressing PTH, and these were associated with increases in final mean serum calcium levels compared to baseline values, although levels were still within normal range (236,237). In a comparative study of intravenous paricalcitol versus calcitriol, paricalcitol reduced PTH levels more rapidly with fewer episodes of hyperphosphatemia, but with no differences in serum calcium levels between the groups (238). Similarly, comparison studies against standard treatment regimens and trials using this agent in pediatric patients have yet to be done.

CALCIMIMETIC COMPOUNDS

Calcimimetic compounds are allosteric activators of the CaR in the parathyroid gland, kidney, and other tissues. They lower the set point for activation of the CaR by calcium, thereby decreasing PTH secretion from parathyroid cells. Thus, they offer a novel approach for the treatment of secondary hyperparathyroidism in patients with CRI, because they inhibit PTH secretion without resulting in hypercalcemia and/or hyperphosphatemia. First-generation calcimimetic compounds, which are based on a phenylalkylamine structure as typified by R-568, have been reported to reduce PTH secretion and parathyroid gland proliferation and ameliorate histologic evidence of osteitis fibrosa in animal models of secondary hyperparathyroidism (239–241). Inhibition of PTH release has likewise been shown after a single dose of NPSR-568 in patients with primary hyperparathyroidism and after two consecutive daily doses of the drug in adult dialysis patients with mild secondary hyperparathyroidism (242,243). In a subsequent study, administration of R-568 for 15 days lowered serum PTH levels in adult dialysis patients with moderate to severe secondary hyperparathyroidism (70).

Second-generation calcimimetic agents, such as AMG 073, were developed because of the low bioavailability of the first-generation compounds. In an 18-week double-blind, randomized, placebo-controlled, dose titration study, AMG 073 decreased PTH levels in adult hemodialysis patients with secondary hyperparathyroidism (69,244). PTH levels

declined by 26%, and calcium phosphorus product decreased by 12% in AMG 073–treated patients compared to the placebo group. There were no major side effects noted. Thus, these short-term trials have consistently shown the efficacy of calcimimetic agents in suppressing PTH secretion in patients with primary hyperparathyroidism and in those with varying degrees of secondary hyperparathyroidism due to CRI. Calcimimetic agents may be advantageous for patients who are refractory to calcitriol or in whom calcitriol treatment is limited by hypercalcemia and/or hyperphosphatemia. Although these studies have all been conducted in adult patients, there is concern for its use in pediatric patients because the CaR expression has also been localized to chondrocytes in the growth plate cartilage (245).

PARATHYROIDECTOMY

Parathyroid gland hyperplasia, which is characterized by serum PTH elevations and osteitis fibrosa on bone biopsy, is a result of poorly controlled secondary hyperparathyroidism. Calcitriol resistance may develop in the presence of an enlarged nodular hyperplastic parathyroid gland because of the decrease in the number of VDRs and the presence of monoclonal proliferation in the nodular areas (35,246). When vitamin D therapy fails to correct the signs of secondary hyperparathyroidism, parathyroidectomy must be considered. Urgent indications for parathyroidectomy include persistent or recurrent hypercalcemia (particularly when associated with intractable pruritus not responding to intensive dialysis), progressive extraskelatal calcifications, bone pain, multiple and recurrent fractures, and the appearance of calciphylaxis (128).

Before the 1980s, the development of hypercalcemia in patients receiving little or no vitamin D suggested that aluminum-related bone disease may have been present. Currently, hypercalcemia is more commonly due to administration of high doses of vitamin D and calcium-containing compounds. A substantial proportion of patients develop adynamic/aplastic bone lesions not related to aluminum deposition. Parathyroidectomy may be indicated for persistent hypercalcemia in patients with PTH levels of 200 to 500 pg/mL (247).

Hypocalcemia may develop after parathyroidectomy in patients with severe secondary hyperparathyroidism. This condition, called *hungry bone syndrome*, is caused by a high rate of skeletal calcium uptake, which may continue for some time after serum PTH levels are lowered by parathyroidectomy. Serum calcium decreases 24 to 36 hours after surgery; daily doses of calcitriol at 0.5 to 1.0 µg/day for 2 to 6 days before surgery can be administered to prevent hypocalcemic episodes. Once the serum calcium declines below 8.5 mg/dL, calcium gluconate infusion should be started to provide 100 to 150 mg of elemental calcium per hour for the first 4 to 6 hours and infusion rate adjusted

according to serum calcium measurements. Hypophosphatemia may develop concurrently, but supplemental phosphorus is not given because it may aggravate hypocalcemia unless the serum level is below 2.0 mg/dL. Ideally, serum phosphorus levels should be maintained between 3.5 and 4.5 mg/dL to avoid further reductions in serum calcium levels.

BONE DISEASE AFTER SUCCESSFUL KIDNEY TRANSPLANTATION

Successful kidney transplantation corrects many of the metabolic abnormalities associated with the development of renal osteodystrophy, but despite a well-functioning graft, osteopenia, growth failure, spontaneous fractures, and avascular necrosis remain prevalent in adult and pediatric kidney recipients (248–254). Significant bone loss has been described by several investigators to occur as early as 3 to 6 months after kidney transplantation (253,254). Several factors have been implicated in the development of bone disease after transplantation; these include persistent secondary hyperparathyroidism, prolonged immobilization, and, most important, use of immunosuppressive agents, which are required to maintain graft function.

Bone loss has been attributed largely to prolonged and often high-dose corticosteroid use. Corticosteroids have been demonstrated to directly and indirectly affect skeletal metabolism by decreasing intestinal calcium absorption, enhancing urinary calcium excretion, inhibiting osteoblastic activity, decreasing bone formation, and significantly increasing osteoclastic activity and bone resorption (255–258). Likewise, cyclosporine has been reported to increase both bone formation and bone resorption and reduce cancellous bone volume in the rat (259,260); similar findings have been described in adult renal transplant recipients (261). In contrast, Bryer et al. demonstrated in rat studies that azathioprine does not have a significant impact on skeletal remodeling (262). The role of other immunosuppressive agents, such as mycophenolate mofetil, as potential modifiers of bone formation and bone resorption has not been evaluated.

After successful kidney transplantation, growth may be accelerated by an improvement in kidney function, but several investigators have shown that catch-up growth may not be observed even in children who undergo transplantation very early in life (263). Moreover, height deceleration occurs in approximately 75% of patients who undergo transplantation before the age of 15 years (264). The use of alternate-day steroids and a better SDS for height at the time of transplant may serve as better predictors of the final height attained (263–265); rhGH has been used in children with significant height deficit after kidney transplantation. A substantial increase in linear growth has been reported within the first year of rhGH therapy, but the magnitude of growth response may decline thereafter (266).

In the adult kidney recipients, Julian et al. reported that histologic changes associated with secondary hyperparathyroidism resolved 6 months after kidney transplantation (254). However, an imbalance of bone remodeling still occurred, because the mineral apposition rate was markedly reduced, and these changes were accompanied by substantial reductions in bone mass as determined by dual-energy x-ray absorptiometry (254). Moreover, Velasquez-Forero et al. described findings of adynamic bone lesion in 12 of 16 adult kidney recipients 7 years after kidney transplantation despite moderately elevated serum PTH levels (267). A recent report describes the spectrum of bone disease in 47 pediatric kidney recipients with stable graft function: 67% had histologic features of normal bone formation, 10% had adynamic bone lesion, and 23% had bone lesions characteristic of secondary hyperparathyroidism (268). Although there was restoration of normal bone formation in the majority of patients, a number of these patients exhibited increases in osteoid perimeter and eroded bone perimeter when compared with reference values obtained from children and adolescents with normal renal function. These findings may reflect a component of persistent secondary hyperparathyroidism because serum PTH levels remained elevated in some patients, or perhaps they were related to cyclosporine therapy (268). The factors responsible for the persistent increase in osteoid formation and resorption surface despite normalization of kidney function and the role of multiple immunosuppressive agents required to maintain the allograft remain to be determined.

PERITONEAL DIALYSIS

**BRADLEY A. WARADY
BRUCE Z. MORGENSTERN
STEVEN R. ALEXANDER**

Pediatric nephrologists have long recognized the importance of peritoneal dialysis (PD) as a renal replacement therapy (RRT) for children. PD was first used to treat children with acute renal failure more than 50 years ago and to treat children with end-stage renal disease (ESRD) more than 30 years ago (1,2). Recent developments have dramatically increased reliance on PD as a maintenance RRT for children with ESRD. As more pediatric nephrologists have become directly involved in the management of children receiving maintenance PD, our understanding of the technique and its pediatric applications has increased substantially.

This chapter reviews current approaches to the clinical applications of PD in pediatric patients. However, entire textbooks have been published on the subject of PD (3,4), as have extensive monographs focused on various aspects of the use of this therapy in children (5,6). Although every effort has been made in this chapter to summarize accurately current knowledge specific to this field, no attempt has been made to do so completely; interested readers are encouraged to consult source materials cited throughout this chapter for more details. In addition, topics such as growth, osteodystrophy, and anemia, which are pertinent to all pediatric patients with ESRD irrespective of dialysis modality, are discussed in other chapters of this book.

NOTES ON THE HERITAGE OF PEDIATRIC PERITONEAL DIALYSIS

The peritoneal cavity has been used in the treatment of serious illness in children for at least 80 years. In 1918, Blackfan and Maxcy described the successful use of intraperitoneal injections of saline solution in dehydrated infants (7), a method that is still used today in rural areas of some developing countries. The first reports of the use of PD to treat children with renal failure were published by Bloxsum and Powell in 1948 and by Swan and Gordon in 1949 (1,8). These papers appeared when the worldwide reported clinical experience with PD was less than 100 patients (9). As

detailed by Swan and Gordon (8), the technique allowed large volumes of dialysate to flow continuously by gravity from 20-L carboys through a rigid metal catheter that had been surgically implanted into the upper abdomen. Dialysate was constantly drained from the peritoneal cavity by water suction through an identical catheter implanted in the pelvis. This technique today is termed *continuous peritoneal lavage*, and, in some ways, it foretold the current emphasis on continuous as opposed to intermittent PD (IPD) therapies.

Swan and Gordon maintained fluid balance in their young patients by adjusting the dialysate dextrose content between 2 and 4 g/100 mL, as is generally done today. Excellent solute removal was achieved with an average dialysate delivery of 33 L daily. Dialysate temperature was regulated by adjusting the number of illuminated 60-watt incandescent light bulbs in a box placed over the dialysate inflow path. Although two of the three children treated for acute renal failure by Swan and Gordon survived after 9 and 12 days of continuous peritoneal lavage, this technique did not attract much interest among physicians treating children with renal failure during this period because it was more than a decade before the use of PD in children was again reported. During the 1950s, the development of disposable nylon catheters and commercially prepared dialysis solutions made PD a practical short-term treatment for acute renal failure (10). Successful adaptation of the technique, known then and now as *acute IPD*, for use in infants and children with acute renal failure was first reported in 1961 by Segar et al. (11) and in 1962 by Etteldorf et al. (12).

Although successful in treating acute renal failure, PD did not appear to be useful in the treatment of children with ESRD. Early acute IPD techniques required reinsertion of the dialysis catheter for each treatment (2), making prolonged use in small patients essentially impossible. The development of a "permanent" peritoneal catheter, first proposed by Palmer et al. (13,14) and later perfected by Tenckhoff and Schecter (15), made long-term IPD an accessible form of RRT for pediatric ESRD patients. When Boen et al. (16) and then Tenckhoff et al. (17) devised an

automated dialysate delivery system that could be used in the home, long-term IPD became a practical and potentially desirable alternative to long-term hemodialysis (HD) for children with ESRD.

A new era in the history of PD as a treatment for children with ESRD was heralded by the description in 1976 by Popovich et al. of a "novel portable/wearable equilibrium dialysis technique" that is now called continuous ambulatory PD (CAPD) (18). Pediatric nephrologists were quick to recognize the potential advantages CAPD offered to their young patients, perhaps because PD was familiar to those who regularly treated children with acute renal failure. Advantages over HD of special importance to children included near steady-state biochemical control, no disequilibrium syndrome, greatly reduced dietary restrictions and fluid limits, and freedom from repeated dialysis needle punctures. CAPD also allowed children of all ages to receive dialysis in the home and thus to have more normal childhoods. Importantly, CAPD made possible the routine treatment of very young infants with ESRD, thereby extending the option of RRT to an entire patient population previously considered too young to be suitable for chronic treatment.

CAPD was first used in a child in 1978 in Toronto (19,20). Since 1975, CAPD and its many modifications [which together can be called *continuous PD* (CPD)] have become the dialysis treatment modalities most commonly prescribed for children with ESRD throughout much of the world (21). Because CPD is now so important to pediatric dialysis programs, much of the information presented is devoted to a review of current CPD practices that are, in many instances, based on the results of clinical investigative efforts conducted since 1999.

PERITONEAL MEMBRANE ANATOMY AND PHYSIOLOGY IN CHILDREN

Peritoneal Ultrastructure

The peritoneum is a serous membrane composed of thin layers of loose connective tissue covered by a sheet of mesothelium. It is a "living membrane" considered to have two principal parts: the parietal peritoneum lining the inner surface of the abdominal and pelvic walls (including the diaphragm) and the visceral peritoneum, which covers the intraperitoneal organs, forms the visceral mesentery and omentum, and connects loops of bowel (22). The peritoneal cavity ordinarily contains only small amounts of fluid.

The arterial blood supply to the parietal peritoneum comes from the vasculature of adjacent structures; the visceral peritoneum receives arterial blood from the celiac and superior and inferior mesenteric arteries. Almost all venous blood from both visceral and parietal peritoneum is drained ultimately to the portal vein. The portion of the peritoneal capillary bed that actually participates in solute and fluid

exchange during PD is unknown and is the subject of some controversy. Studies in the rat have suggested that most of the small vessels capable of exchange are located in the reflections of peritoneum over loops of bowel (23), whereas other experimental data in eviscerated rats demonstrated that the visceral peritoneum is not necessary for fluid and solute exchange (24,25). The peritoneum has an active lymphatic system, which is comprised of specialized structures located on the undersurface of the diaphragm (the lacunae). Drainage via these subdiaphragmatic lacunae ultimately reaches the right lymphatic duct and, to a lesser extent, the thoracic duct.

Peritoneal Surface Area

The precise overall size of the peritoneal membrane relative to the body size of the child is uncertain. Clearly, the peritoneal membrane grows along with a growing child. This then raises the question of whether the membrane bears some constant relationship to body size, either for weight, height, or surface area. Clinical and experimental data (26) suggest that throughout life the membrane is proportional more to body surface area (BSA) than body weight.

There are few actual measures of the peritoneum that have been published. Originally estimated to equal BSA (27), it is clear that the size of the membrane that actually participates in exchange is significantly smaller than that (28,29). The total membrane size is likely less relevant than the total membrane pore area or, more precisely, the membrane pore area of that part of the peritoneum which is engaged in exchanges. There are limited data available on this topic in children, and that which is available has been derived from kinetic modeling of transperitoneal exchanges. It has been estimated from three-pore models of transperitoneal solute and solvent movement that the total pore area with respect to the diffusion distance (A_0/Δ_x) is between 1.53 and 2.40 m^2/cm of diffusion distance/ 1.73 m^2 (30,31). Further data using the same model and both lactate-based and bicarbonate-based dialysate found a steady-state A_0/Δ_x of $2.65 \pm 0.98 \text{ m}^2/\text{cm}/1.73 \text{ m}^2$. To demonstrate the varying nature of a living membrane, the A_0/Δ_x at 30 minutes into the exchange was much higher than the steady-state value, $4.27 \pm 1.37 \text{ m}^2/\text{cm}/1.73 \text{ m}^2$ using bicarbonate-based buffer and $4.56 \pm 1.20 \text{ m}^2/\text{cm}/1.73 \text{ m}^2$ with lactate-based fluid (32). The mechanisms underlying the vasodilation that is presumed to be the etiology of this finding have not yet been elucidated.

Peritoneum as a Dialyzing Membrane

The peritoneal exchange process is the sum of two simultaneous and interrelated transport mechanisms: diffusion and convection. *Diffusion* refers to the movement of solute down a concentration gradient, whereas *convection* refers to movement of solutes that are "transported" in a fluid flux,

the magnitude of which is determined by the ultrafiltration rate (33). As noted, it is the functional and not the anatomic peritoneal surface area that is important in peritoneal exchange.

Diffusion and convection are clinically linked processes under most circumstances, since the most commonly used agent to generate a gradient to drive the fluid flux that is necessary for convection is glucose. Glucose acts osmotically, and the osmotic forces serve to draw water from the vascular space into the peritoneal cavity. Glucose, however, is a small molecule and is subject to the diffusive process, because intraperitoneal glucose concentrations at the start of an exchange are much greater than blood glucose concentrations.

The living nature of the peritoneum and the interdependence between the processes of diffusion and convection make the scientific study of transperitoneal exchange quite complex and difficult. Several theories have been developed to model the movement of water and solute across the peritoneal membrane, each progressively more complex but each, in turn, more accurate. The development of CAPD in the mid-1970s was also accompanied by the development of a distributed pore model. Recently, a more comprehensive model has been developed that is known as the three-pore model. As one would expect from the name, the model postulates three types of pores:

1. Ultra-small transcellular water pores or channels, which comprise perhaps 1 to 2% of the total pore area, yet account for 40% of water flow, and are driven by osmotic forces.
2. Small pores, which are 4 to 6 nm in diameter and comprise 90% of total pore area. These pores are subject to both concentration gradients (diffusive forces) and osmotic gradients (convective forces).
3. Large pores, which are greater than 40 nm in diameter and comprise the remaining 5 to 7% of total pore area. These pores allow larger molecules, such as albumin, to leave capillaries, probably driven by hydrostatic forces within the capillary bed.

Although water moves through all three pores, only the small and large pores allow convective solute transfer (34). The three-pore model has been applied to PD studies in infants and children (30,31).

Diffusive Transport

In the absence of an osmotic gradient between blood and dialysate, the rate of diffusive transfer of a solute is directly related to the product of the concentration gradient of the solute across the peritoneal membrane and the mass transfer area coefficient (MTAC) of that solute. The solute concentration gradient is dynamic during an exchange and decreases exponentially for small solutes. For larger solutes, diffusion is so slow that the loss of the gradient is essentially

linear. The MTAC is equal to the theoretic maximum clearance the membrane allows for a given solute—at the point when the dialysate concentration is zero—and is the product of the permeability of the peritoneum and the effective surface area. MTAC is a parameter that, as a physiologic principle, is independent of dialysis mechanics (i.e., exchange volume, dialysate dextrose concentration) (33). The MTAC, as applied to current three-pore models of transperitoneal solute and water flux, is equal to the product of the free diffusion coefficient for the solute, the fractional area available for diffusion (which is a percent of the area of the unrestricted pores), and the term A_0/Δ_x , which was described in Peritoneal Surface Area (35). There are no simple methods for determining MTACs. Precise estimates require rigorously performed PD exchanges and computer solutions of complex equations. There are some formulas that allow reasonable estimates of MTAC (36).

A few studies have measured MTAC values in pediatric patients; some have been calculated based on the mathematic model of peritoneal membrane transport devised by Popovich et al. (37); some by the simpler formulas, often from data obtained during a peritoneal equilibration test (PET) test (see later); and still others using the three-pore models. In an early study, Morgenstern et al. found MTAC values for urea, creatinine, uric acid, and glucose in eight children, 1.5 to 18.0 years of age, to be similar to adult reference values (38). Geary et al. determined MTAC values in 28 pediatric patients and provided evidence to suggest that solute transport capacity varies with age and does not approach adult values until later childhood (39).

Warady et al. determined the MTACs for urea, creatinine, glucose, and potassium in 95 children ranging in ages from less than 1 to 20 years of age who were evaluated in a standardized manner with the test exchange volume scaled to BSA (i.e., 1100 mL/m²) (36). When MTAC was scaled for BSA, using analysis of variance, there were only differences by age for the MTAC for glucose and potassium (the younger children having a higher value). However, by quadratic regression analysis, there was greater transport capacity in the youngest patients (those younger than 3 years) for these two solutes and creatinine. This enhanced transport is likely the result of differences in either permeability or effective surface area (36). MTAC has also been determined in children undergoing PD studies based on the three-pore model. The values for children, when scaled for BSA, are similar to those of adults (40).

Diffusive transfer, as noted earlier, is dependent on the MTAC and the transmembrane concentration gradient, which diminishes during exchanges. The rate of diminishment is influenced by factors such as cycle frequency and dialysate volume. The impact of dialysate volume is felt to rest on the principle of geometry of diffusion (41), which simply states that the larger the dialysate volume, the longer the transperitoneal concentration gradient will persist to drive diffusion. In children, this principle has been a con-

foundings variable in many studies of PD, because the studies have often been performed with fill volumes that were not scaled properly to body size (currently accepted to be scaling to BSA).

This issue has been particularly apparent in studies of PD in infants, who have a greater ratio of BSA to weight than do older children and adults. Therefore, a 40-mL/kg body weight exchange in an infant represents a smaller volume/m² BSA than a 40-mL/kg exchange does in an adult. This relatively smaller volume results in more rapid equilibration of solute and the inaccurate perception of enhanced membrane transport capacity (26,42). The importance of scaling fill volume to BSA has been verified by Kohaut et al. (26), Schaefer et al. (43), de Boer et al. (44), and Warady et al. (45) in association with the Pediatric Peritoneal Dialysis Study Consortium (PPDSC).

The concentration gradient and hence diffusive transport is also impacted by the presence of residual peritoneal volume from previous exchanges. Residual volume can be substantial in children (36,46). Small solutes in the residual fluid will likely have equilibrated with serum; this will lead to a time “zero” solute concentration that is much greater than zero, despite the fact that the instilled dialysate concentration of a solute was zero. This will limit fluid flux and solute transport.

Convective Mass Transfer and Ultrafiltration

The removal of fluid during a PD exchange reflects the interaction of many factors: the hydraulic permeability of the peritoneal membrane, the permeability of the peritoneum to the osmotically active solutes on either side of the membrane, the absorption of fluid into peritoneal tissue, and lymphatic absorption. These latter phenomena serve to counteract transperitoneal ultrafiltration. Convective mass transfer, which is dependent on fluid removal, is not thought to participate to a great degree in the mass transfer of small solutes, whereas large solutes are removed almost exclusively by convection (33). Pyle has estimated that the contribution of convection to urea transport in a 4-hour CAPD exchange with 4.25% glucose is 12%; for inulin, 45%; and for total protein, 86% (47).

Although early reports and much clinical experience suggested that adequate ultrafiltration was more difficult to achieve in infants and young children, subsequent studies have failed to confirm these differences. As mentioned previously, proper scaling of the exchange volume is an important determinant of the rate of dissipation of the osmotic gradient that determines ultrafiltration. Other aspects of solute flux and convection have been far more difficult to solve, and these difficulties reconciling theory with clinical findings have been critical in the development of the three-pore model of fluid and solute transfer (48). The third pore has been postulated to be composed of water-only chan-

nels, a theory supported by the finding of aquaporin-1 channels in the peritoneum (49).

Peritoneal Fluid and Lymphatic Absorption

During PD, fluid is lost continuously from the peritoneal cavity both directly into the tissues surrounding the peritoneal cavity and via lymphatic vessels. Fluid absorption out of the peritoneal cavity remains poorly understood (48). Initially, flow through lymphatic vessels was believed to be the dominant pathway (50). Most recently, fluid absorption is believed to move primarily directly into the tissues surrounding the peritoneal cavity (51). Lymphatic absorption is only thought to account for 20% of fluid reabsorption (52). The limited data on lymphatic absorption in children are conflicting (53,54).

Fluid absorption rates can be determined when a PD exchange is modeled using the three-pore model. It is believed to be driven by intraperitoneal hydraulic pressure (51) and may be explained by the movement of dialysate into interstices in the peritoneal cavity, which allow for water absorption at the same time that ultrafiltration is occurring in the portion of the peritoneum where the bulk of the fluid remains (48). There are limited data available on fluid absorption using the three-pore model in children. In one study, the absorption rate increased with body size in absolute terms but decreased when normalized to body size. The decrease was slight when scaled to BSA but marked when scaled to body weight (30).

Principles of the Peritoneal Equilibration Test

The PET was developed by Twardowski et al. as a simple means of characterizing solute transport rates across the peritoneum that could have direct clinical applications (55). The construction of reference curves based on the kinetics of solute equilibration between dialysate and plasma (D:P ratio) after a 2-L exchange volume made possible the categorization of adult patients into those with high, high-average, low-average, and low peritoneal membrane solute transport rates and served as the basis for dialysis prescription (see later).

Twardowski's adult PET reference curves have not enjoyed widespread application in the pediatric PD population for two reasons. First, there has been the widely acknowledged but unproven perception that the solute transport function of the pediatric peritoneal membrane is different from that of the adult (56,57). The second reason is the uniform 2-L test exchange volume that is provided to all study patients, regardless of their size, in the Twardowski scheme. Obviously, this approach does not allow for modification of the exchange volume to reflect differences in body size (e.g., pediatric patient, small adult, large adult) and has contributed to the limited usefulness of this approach in children.

FIGURE 70.1. Peritoneal equilibration test results for creatinine. Shaded areas represent high, high-average, and low transport rates. The white band represents the low-average transport rate. The four categories are bordered by the maximal, mean +1 SD, mean, mean -1 SD, and minimal values for the population. D/P, dialysate:plasma ratio. (From Warady BA, Alexander SR, Hossli S, et al. Peritoneal membrane transport function in children receiving long-term dialysis. *J Am Soc Nephrol* 1996;7:2385-2391, with permission.)

Application of a standardized PET procedure for children has resulted from an appreciation of the previously mentioned age-independent relationship between BSA and peritoneal membrane surface area and the recommended use of an exchange volume scaled to BSA whenever one conducts studies of peritoneal transport kinetics (26,36,44,58,59). In the largest pediatric study to date, the PPDSC evaluated 95 children using a test exchange volume of 1100 mL/m² BSA to develop reference kinetic data (e.g., D:P and D:Do ratios), which can be used to categorize an individual pediatric patient's peritoneal membrane solute transport capacity (Figs. 70.1 and 70.2) (36). Similar reference data have been generated from pediatric studies in Europe with a test exchange volume of 1000 mL/m² BSA (59).

Because the transport capacity of a patient's peritoneal membrane is such an important factor to consider when determining the dialysis prescription, a PET evaluation should be conducted soon after the initiation of dialysis (60,61). However, there is evidence that a PET performed within the first week after initiation of PD may yield higher transport results than a PET performed several weeks later (62). Accordingly, whereas it may be most convenient to perform the initial PET at the conclusion of PD training, the results after 1 month of PD may more accurately reflect peritoneal transport properties (62,63). The PET evaluation should be repeated when knowledge of the patient's current membrane transport capacity is necessary for determination of the patient's PD prescription, especially when

FIGURE 70.2. Peritoneal equilibration test results for glucose. Shaded areas represent high, high-average, and low transport rates. The white band represents the low-average transport rate. The four categories are bordered by the maximal, mean +1 SD, mean, mean -1 SD, and minimal values for the population. D/DO, dialysate glucose:initial dialysate glucose concentration ratio. (From Warady BA, Alexander SR, Hossli S, et al. Peritoneal membrane transport function in children receiving long-term dialysis. *J Am Soc Nephrol* 1996;7:2385-2391, with permission.)

clinical events have occurred (e.g., repeated peritonitis) that may have altered transport characteristics. In addition, knowledge of a patient's transport capacity may have a profound impact on their overall care because of the important relationships that exist between transport status and patient outcome in children and adults (64–67).

Proper evaluation of the data obtained requires that dialysate creatinine values be corrected for glucose interference because falsely elevated creatinine values may result when creatinine is measured by the Jaffe method (55). In addition, measured plasma solute concentrations must be divided by 0.9 to account for their presence in plasma water only and not in whole plasma. Failure to do so has resulted in solute D:P ratios greater than unity (68).

In summary, the contributions of diffusion and convection to peritoneal membrane kinetics in children have been characterized by the careful performance of standardized assessments of peritoneal membrane transport capacity. The uniform use of BSA as the scaling factor for the peritoneal exchange volume used in these evaluations has been particularly important. The accurate use of such assessments on a clinical basis (e.g., PET evaluation) requires the same attention to detail.

PERITONEAL DIALYSIS FOR ACUTE RENAL FAILURE

Indications and Contraindications

The conservative management of acute renal failure in infants and children requires meticulous attention to every detail of fluid and electrolyte balance. In these small patients, relatively minor errors can have grave consequences. However, several factors at work in pediatric patients tend to defeat even the most carefully conceived conservative management plans. Children have higher metabolic rates and thus can generate harmful solutes more rapidly. It is difficult to meet relatively greater dietary energy requirements in the oliguric child while abiding by stringent limitations on allowable fluid intake. Children with acute renal failure typically are profoundly catabolic, resulting in accumulation of potentially harmful amounts of potassium, phosphate, and other solutes at surprisingly rapid rates. Consequently, RRT tends to be used sooner and more often in pediatric patients with acute renal failure, especially neonates and young children (69,70). Widely accepted clinical indications for RRT in children with acute renal failure are covered in the Section X. Acute Renal Failure.

Traditionally, the convenience, simplicity, and relative safety of PD have allowed the nephrologist to begin dialysis in the child as soon as it is needed, without undue alarm over possible complications associated with the procedure itself. Two factors may make PD more suitable than HD for critically ill pediatric patients: ready access to the perito-

neum (vs. typically more difficult vascular access) and better tolerance of PD by hemodynamically unstable children. The recent development of continuous hemofiltration techniques for children has provided a third option for treatment of the most critically ill pediatric patients (71–74). Although continuous hemofiltration does require vascular access similar to HD, it appears to be well tolerated by hemodynamically unstable children, especially those with cardiac failure in whom peritoneal perfusion is often poor, thereby interfering with the effectiveness of PD. Clear indications for one RRT over the others in the individual child with acute renal failure are rarely present, and often the experience of the treating center weighs most heavily in the choice of RRT modality (75,76).

Contraindications to acute PD are few. Absolute contraindications all relate to the lack of an adequate peritoneal cavity. Neonates with omphalocele, diaphragmatic hernia, or gastroschisis cannot be treated with PD. Recent abdominal surgery is not an absolute contraindication to PD as long as there are no draining abdominal wounds. However, such patients can often be treated more effectively with continuous venovenous hemofiltration or with HD if hemodynamically stable. Children with vesicostomies and other urinary diversions, polycystic kidneys, colostomies, gastrostomies, prune belly syndrome, and recent bowel surgery have been successfully treated with PD (77–79). PD has also been used routinely to treat acute renal failure related to allograft dysfunction after renal transplantation, as long as the allograft has been placed in an extraperitoneal location.

Technical Considerations

Catheters: Temporary versus Permanent

As with long-term PD, a reliable catheter is mandatory for successful therapy. The choice between a percutaneously placed temporary catheter and a “permanent” catheter placed surgically under direct vision is usually somewhat arbitrary, reflecting local practice. An increased incidence of peritonitis historically has been associated with the use of temporary catheters for longer than 72 hours (80), although a longer period of peritonitis-free use has also been documented (81).

Surgical placement of the same catheter that would be used for long-term PD has the advantage of assurance of good immediate function. The use of fibrin glue at the site of catheter entry into the peritoneum also may facilitate prompt catheter use without dialysate leakage (82). This advantage must be weighed in the patient against the risks and delays associated with a surgical procedure requiring general anesthesia in the operating room. Anesthesiologists are often reluctant to administer anesthesia to a child with the metabolic derangements of acute renal failure, despite the fact that those very metabolic derangements (e.g., hyperkalemia, acidemia, fluid overload) dictate the need for a PD catheter and thus an operative procedure. It may be

more reasonable to initially place a percutaneous PD catheter under local anesthesia in patients who are to receive PD and who are considered to be at high risk for general anesthesia for any reason and then proceed to surgical catheter placement after the child is stable, and it is clear that more than 3 to 5 days of dialysis will be needed. For unstable infants in intensive care units, surgical catheter placement at the bedside using local anesthesia is readily accomplished in many pediatric centers (83,84).

Temporary catheters inserted percutaneously at the bedside have been used for decades. The classic nylon stylet-type catheter (Trocat, McGaw, Irvine, CA) has been replaced in most pediatric centers by a soft polyurethane or Teflon catheter that is placed over a guide wire using the Seldinger technique and a peel-away sheath (Cook Critical Care, Bloomington, IN). A similar technique has been developed for bedside placement of the same silastic Tenckhoff catheter that is used in chronic PD (85). Although percutaneously placed catheters rarely leak, poor dialysate drainage due to omental wrapping during outflow can be a common problem that is best remedied by replacement with a surgically placed catheter (86,87).

Dialysate

Dialysate is available from several manufacturers in standard hydrous dextrose concentrations of 1.5, 2.5, and 4.25%. Acute dialysis often is begun with 2.5% dextrose solution to obtain better ultrafiltration at the outset, when fluid overload often is a problem. Higher dextrose concentrations can be used but increase the risk of hyperglycemia and hypernatremia in small infants.

The usual electrolyte composition of commercially available dialysate is sodium, 132 mEq/L; chloride, 102 mEq/L; lactate, 35 mEq/L; magnesium, 1.5 mEq/L; and calcium, 3.5 mEq/L. Lower calcium (2.5 mEq/L) and magnesium (0.5 mEq/L) concentrations are readily available. Some critically ill infants do not tolerate the lactate that is absorbed from standard dialysate (88). These babies are often hypoxic and hypotensive, with an ongoing metabolic acidosis that is primarily due to accumulation of lactic acid. Additional lactate absorbed from the dialysate only worsens

the situation. Such infants may do better if they are treated from the outset with a dialysate that has been specially formulated to contain bicarbonate instead of lactate. One approach to such a prescription is shown in Table 70.1. Note that calcium should be given by an alternate route when bicarbonate-based dialysate is used; typically, calcium may be provided as part of the total parenteral nutrition solutions in such critically ill infants. The recent development of pH-neutral, bicarbonate-buffered dialysis solutions designed for use in children with ESRD offers another possible approach to PD in the acidic infant that has yet to be tested in the acute renal failure setting (32).

Newly available (outside the United States) CPD solutions that contain a bicarbonate/lactate mixture, amino acids, or glucose polymers (89–91) may provide additional treatment options to meet the specific needs of selected patients with acute renal failure. A recent review from the European Paediatric Peritoneal Dialysis Working Group summarizes available information on the use of these new solutions in children receiving CPD (92).

Dialysate must always be warmed to body temperature before infusion into the child. Whereas adults may complain of discomfort during the inflow of unwarmed dialysate, small infants commonly respond to cool dialysate with a sudden fall in blood pressure. To avoid this problem, either blood transfusion warming devices placed in the dialysate inflow circuit or the heating device on an automated cycler can be used to warm the dialysate bags.

Acute Peritoneal Dialysis Equipment

A simple manual exchange method using a three-way stopcock, several intravenous line extension tubes, one or two in-line volumetric infusion chambers (Buretrol, Baxter Healthcare Corp., Deerfield, IL), and a urinary drainage bag can be easily prepared in an emergency for use in infants requiring only small exchange volumes. A closed infant dialysis administration set is also commercially available (Gesco Dially-Nate Set, Gesco, San Antonio, TX) and adds the advantage of an in-line warming coil for infused dialysate. When the exchange volume exceeds 100 mL, an automated cycler can be used in most patients. Recent

advances in cycler technology have allowed the use of exchange volumes as low as 50 mL (93).

Acute Peritoneal Dialysis Prescription

The PD prescription must specify dialysate composition, exchange volume, inflow, dwell, and drain times of each exchange and the number of exchanges to be performed in 24 hours. During the initial 24 hours after catheter placement, the exchange volume is kept low, no more than 500 mL/m² (i.e., 10 to 20 mL/kg) to reduce the risk of dialysate leakage. Over the ensuing 5 to 10 days, the exchange volume is increased gradually to reach a maximum of 1100 mL/m² (i.e., 35 to 45 mL/kg). Respiratory embarrassment and hydrothorax have been reported with the use of exchange volumes approaching 50 mL/kg (94–96).

Initial stabilization on PD often requires several days of continuous short exchanges (e.g., 30 to 60 minutes each) to remove accumulated solutes and excess fluid. This period corresponds to a traditional acute IPD regimen. Once the patient is stabilized, dialysis may be continued indefinitely. By gradually increasing exchange volumes toward 1100 mL/m² while either extending dwell periods (as in CAPD and continuous cycling PD) or introducing time off dialysis (as in nightly IPD), a typical maintenance CPD regimen may be reached in a few days. Familiarity with CPD as a treatment for ESRD has led to the popularity of standard CPD regimens in the treatment of acute renal failure. Although there have been no systematic studies of this approach to the acute PD prescription, the advantages of near steady-state biochemical and fluid control achievable with CPD are compelling, especially in infants and small children whose cardiovascular and nutritional status is often precarious. Finally, there is no need to periodically suspend CPD to see whether renal function will return; in the euvoletic child, renal function improves at its own pace, regardless of the presence or absence of CPD.

Complications of Acute Peritoneal Dialysis

Peritonitis

Peritonitis is a common complication of both acute and chronic PD that is discussed later.

Bleeding

Blood-tinged dialysate that clears after a few exchanges is frequently seen at dialysis initiation and is due to localized bleeding from the catheter insertion wound. Heparin should be added to bloody dialysate (250 to 500 U/L) to prevent catheter obstruction by small blood clots. Of much greater concern is bleeding from a laceration or perforation of a major organ or large vessel, as can be rarely seen with percutaneously placed catheters. The use of abdominal ultrasound guidance at the time of bedside catheter placement reduces the risk of serious catheter trauma and should

be used routinely or whenever abdominal distention clouds the findings on physical examination.

The severity of intraperitoneal bleeding can be difficult to judge from the color of drained dialysate; as little as a few mL of blood will give a blood-tinged appearance to a relatively large volume of dialysate. When in doubt, a hematocrit can be obtained on the effluent.

Bladder Perforation

Perforation of the bladder can occur when the bladder is not completely emptied immediately before percutaneous catheter placement. Infants (in whom the normal bladder position frequently rises above the pelvis) and children with neuropathic or obstructed bladders are at particular risk. Bladder perforation may not be detectable until dialysis commences, when the sudden appearance of a suprapubic mass, polyuria, gross hematuria, and glycosuria make the diagnosis obvious. Careful catheter drainage of the bladder before dialysis catheter insertion and the use of abdominal/pelvic ultrasound to guide percutaneous catheter placement help prevent this complication.

Pain

After the catheter insertion wound has healed, PD should be a painless procedure. The presence of pain on inflow can be due to peritonitis, dialysate that is not at body temperature, local reaction to the low pH of commercial dialysate, local irritation from rapid dialysate inflow when straight catheters are used, omental or adhesion trapping of the catheter tip, and excessive distention of the abdomen. Rectal or suprapubic pain is usually due to migration or faulty placement of the catheter tip too deep in the pelvis between the bladder and the rectum. Shoulder pain is due to air under the diaphragm. Outflow pain can be seen early in the course of dialysis when the peritoneal cavity is drained too completely.

Investigation of painful dialysis should include abdominal radiographs (flat plate and cross-table lateral views) that provide a three-dimensional picture of catheter location. Constipation is a frequent contributing factor to both poor catheter drainage and painful dialysis. The use of laxatives and increased physical activity can sometimes relocate a poorly placed, painful catheter, but most often surgical repositioning, either open or laparoscopically, is required. The temporary addition of a low concentration of sodium bicarbonate to the dialysate often results in the resolution of pain that is secondary to the low dialysate pH (97).

Dialysate Leakage

Leakage most often occurs during the first few days of dialysis and can occur when initial exchange volumes are too large, when the catheter is frequently manipulated (as in too aggressive exit site care), or when traction of any type is placed on the catheter, as can occur during weighing or repositioning of the patient. Leakage is less likely when use of a new catheter can be delayed for 24 hours.

Temporary suspension of dialysis may be necessary. When this is not an option, the replacement of a percutaneous catheter over a guide wire with a larger catheter can be effective.

Poor Dialysate Flow

Reduced dialysate drainage is most often due to omental trapping of the catheter. Typically, dialysate inflow is adequate, but poor outflow leads to abdominal distention and fluid overload. Constipation, intraperitoneal adhesions, fibrin, blood clots, catheter migration or faulty position, tubing kinks, and running the dialysate directly into the drainage bag are additional considerations. Drainage will occasionally improve with simple flushing of the catheter using heparinized saline or dialysate. The instillation of a solution containing a fibrinolytic agent such as urokinase or tissue plasminogen activator may be helpful (98,99).

Hyponatremia/Hypernatremia

Hyponatremia is frequently seen in infants receiving nutrition based on human breast milk or standard formulas that are low in sodium (100). Both the removal of relatively large amounts of sodium in the ultrafiltrate that is in electrolyte equilibrium with serum and ongoing urinary sodium losses contribute to overall negative sodium balance. Aggressive oral or intravenous sodium supplementation is necessary to prevent symptomatic hyponatremia, which can present as the sudden onset of seizures.

Hypernatremia may occur as a consequence of peritoneal membrane sodium sieving during vigorous ultrafiltration with hypertonic dialysate (101). Additional free water may correct the hypernatremia but will make overall fluid removal goals more difficult to achieve.

Hypokalemia/Hyperkalemia

Hypokalemia can develop early in the course of acute dialysis, especially when high concentrations of dextrose are used in the dialysate and in parenteral nutrition solutions. Addition of potassium chloride to the dialysate at concentrations of 3 to 4 mEq/L should be undertaken when the serum potassium concentration falls below 4 mEq/L. The use of higher dialysate potassium concentrations (up to 20 mEq/L) has been reported but should be avoided in all but the most urgent situations; the intraperitoneal administration of nonphysiologic concentrations of potassium can be painful and may be damaging to the peritoneum (102).

Life-threatening hyperkalemia should not be treated with acute PD except as a last resort when no other RRT is available. Although potassium quickly equilibrates between serum and dialysate during an exchange, overall mass transfer of potassium is slow and inefficient. Acute HD remains the treatment of choice for severe hyperkalemia.

Respiratory Distress

Increased intraperitoneal pressure due to excessive or retained dialysate can cause dyspnea, hypoxemia, and respi-

ratory failure, especially in small infants whose respiratory status is often fragile in the setting of acute renal failure and multiple organ system dysfunction. Hydrothorax due to a diaphragmatic hernia or eventration of the diaphragm (103) must also be ruled out. Thoracentesis can be used to establish the diagnosis of a diaphragmatic defect by demonstrating the high dextrose content of aspirated fluid. The addition of the dye methylene blue to the dialysate before thoracentesis can cause chemical peritonitis and is no longer recommended (104). In difficult cases, isotope scanning may be helpful (105).

Hypotension

Critically ill infants and small children may experience fluctuations in blood pressure as a consequence of the PD exchange procedure. Dialysate that is infused at room temperature can produce acute hypotension. Rapid infusion of dialysate can sometimes cause blood pressure to fall during aggressive ultrafiltration. A more frequent observation is hypotension during dialysate drain cycles. Both of the latter situations are usually the result of marginal hypovolemia and can be remedied by intravascular volume expansion.

Chyloperitoneum

Chylous ascites occurs when major intraperitoneal lymphatic drainage channels are interrupted and the patient ingests a fatty meal. Thus, chyloperitoneum will not occur until the patient with acute renal failure has begun oral feeds. Although the complication is rare, it can occur spontaneously in neonates (106) and has been reported in association with catheter insertion (107). The presence of cloudy, almost milky dialysate in the absence of any indication of peritonitis suggests the diagnosis; a dialysate triglyceride level that exceeds the plasma triglyceride level can confirm it, as can lipoprotein electrophoresis analysis of drained dialysate (108). A diet containing only medium chain triglycerides may allow continuation of PD (106).

PERITONEAL DIALYSIS FOR END-STAGE RENAL DISEASE

Indications for End-Stage Renal Disease Therapy

The indication for initiating dialysis therapy in children with ESRD depends on a combination of the biochemical and clinical characteristics of the child. When possible, dialysis should be initiated early enough to prevent the development of malnutrition and/or any significant uremic symptomatology. Although there is no definite level of blood urea nitrogen or serum creatinine concentration that mandates dialysis initiation, in most cases, dialysis should be started when the residual creatinine clearance has

declined to a value between 9 and 14 mL/min per 1.73 m² or the weekly renal Kt/V_{urea} falls below 2.0 (63).

Selection of Peritoneal Dialysis or Hemodialysis for Children with End-Stage Renal Disease

It is not surprising that CPD is the most commonly used dialysis modality in specialized pediatric dialysis centers (109). Because CPD proceeds over prolonged periods (i.e., 24 hours per day for CAPD or continuous cycling PD; 8 to 12 hours for nightly IPD), body fluid composition and volume change slowly, resulting in a near steady state (110). The disequilibrium syndrome does not occur in children receiving CPD. Almost all children receiving CPD may be encouraged to eat an essentially unlimited diet, relatively high in protein, and with generous allowances for fluid and sodium. The relative simplicity and safety of CPD allow performance at home in all but the most exceptional circumstances, thereby returning the child with ESRD to regular school attendance (109) and facilitating family vacations and other normal childhood activities. CPD avoids the many difficulties associated with the maintenance of vascular access in children and eliminates the need for regular dialysis needle punctures.

It must be remembered, however, that there have been no randomized comparative studies of CPD and HD in children. Pediatric dialysis programs that once focused almost entirely on CPD have recognized that the availability of a chronic HD program designed for pediatric patients is of equal importance to the provision of optimum care for children with ESRD (111). Recent advances in HD techniques and equipment have made chronic HD an attractive alternative to CPD in many centers. Whenever possible, patients and families must be given the opportunity to participate fully in the selection of the chronic dialysis modality that is best suited to their individual needs and lifestyle.

Use of Continuous Peritoneal Dialysis for Children with End-Stage Renal Disease

Dramatic growth in the use of CPD as a maintenance dialysis treatment for children occurred throughout the world during the 15 years after its introduction to pediatric dialysis in 1978 (21). By 1993, ESRD patient registry reports showed that CPD was the most commonly prescribed long-term dialysis modality for children younger than 15 years in the United States, Canada, Australia, New Zealand, United Kingdom, former West Germany, Israel, Netherlands, and a few other countries (109,112).

Data on more recent CPD use in North American children have been compiled by the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS). The NAPRTCS collects data on pediatric dialysis from more than 152 pediatric dialysis centers located in the United States, Canada, Mexico, and Costa Rica. Between 1992 and 2001, the NAPRTCS enrolled 4139 pediatric dialysis

patients ages 1 day to 20 years (113). Of these, 2971 (65.4%) were receiving CPD. Although the majority of patients in all age groups were receiving CPD, the preference for CPD over HD was most pronounced among younger patients. Eighty-seven percent of infants and young children 0 to 5 years of age were receiving CPD, compared to 67% of children 6 to 12 years and 54% of patients older than 12 years.

It must be remembered that participation in the NAPRTCS is restricted to specialized pediatric dialysis centers staffed by pediatric nephrologists, a fact that may influence such observations as dialysis modality choice. Recent studies by Furth et al. have shown that older children treated in nonpediatric units are more likely to receive maintenance HD than CPD (114).

Patient Selection

CPD can be attempted in any child whose peritoneal cavity is intact and will admit a sufficient volume of dialysate. Experience has shown that CPD can be used successfully in children with the following conditions: polycystic kidney disease (usually after unilateral or bilateral nephrectomy), vesicostomy, cutaneous ureterostomy, colostomy, prune belly syndrome, bilateral Wilms' tumor, recent abdominal surgery (if no draining wounds are present), ventriculoperitoneal shunt, and concurrent immunosuppressive therapy (77,79,115–117). Patient age, gender, primary renal disease, and renal transplant status have no apparent influence on CPD outcome.

CPD is the clear treatment of choice for infants (113,118,119). Before the introduction of CPD, some pediatric dialysis programs did not accept infants for treatment. It is now widely recognized that CPD can be an effective maintenance RRT in babies who develop ESRD as early as the first few days or weeks of life (120). Despite these successes, mortality rates among infants on CPD are higher than in all other age groups. The NAPRTCS has shown that 1-year mortality risk for infants is more than three times greater than that for older age groups (121). Recent studies have suggested that the presence of extrarenal organ system injury and oligoanuria are the major contributing mortality risk factors for patients receiving CPD during the first 2 years of life (122,123).

Finally, a treating facility that provides CPD to children also should be able to provide the necessary multidisciplinary services required by the child and family. Successful CPD for children is a team effort. The team consists of CPD nurse specialists, nephrologists, urologists, general surgeons, renal dietitians, renal social workers, child psychologists, child psychiatrists, child development specialists, child life therapists, speech pathologists, and chaplains, all of whom are pediatric specialists. Children require a great investment of time and resources from the CPD team, and the effort that is involved is often several orders of magnitude greater than that required to care for the typical adult CPD patient (111).

Permanent Peritoneal Catheters for CPD

A reliable peritoneal catheter is the cornerstone of successful CPD, well worth the attention and effort required to “perfect” the procedure in each center that proposes to treat children with long-term PD. There are multiple types of PD catheters presently available, with a variety of configurations. In general, most long-term PD catheters are constructed of soft material, such as silicone rubber or polyurethane. The catheters can be thought of as having two separate regions: the intraperitoneal portion and the extraperitoneal portion. The intraperitoneal portion contains holes or slots to allow passage of peritoneal fluid. The shape of the intraperitoneal portion typically is straight or curled, the latter configuration often associated with less patient pain with dialysate inflow and a decreased predisposition to omental wrapping of the catheter. The most common catheters with these characteristics used by pediatric patients have been the straight and curled Tenckhoff catheters. The extraperitoneal portion of each of these catheters has one or two Dacron cuffs to prevent fluid leaks and bacterial migration and to fix the catheter’s position. The shape of this portion of the catheter is variable and may be straight or have a preformed angle (e.g., swan neck or pail handle) to help create a downward-directed catheter exit site.

In general, it is believed that infants and young children with vesicostomies, ureterostomies, or colostomies require placement of the catheter exit site as far from the stoma as possible to prevent contamination and infection. Placement of the exit site on the chest wall has successfully limited the number of infections in such high-risk situations in a small number of children and adults (124–126). The primary reason for catheter revision is catheter malfunction, often caused by omental wrapping of the catheter (109). However, the decision to perform an omentectomy in conjunction with catheter placement is not universal (127). Catheter occlusion by fibrin may also occur but can usually be successfully relieved by the installation of fibrinolytic agents into the catheter (98,99).

In a 1995 report from the 18 centers of the PPDSC, most preferred a curled Tenckhoff catheter (88%), with fewer centers using a catheter with a straight intraperitoneal segment (127). The most common extraperitoneal design consisted of a straight tunnel with a single cuff (69%). Fewer centers used dual-cuff catheters with angled extraperitoneal regions. In most of the centers, the peritoneal catheter was placed by a surgeon, and in 53% of the centers, an omentectomy was performed. Finally, the exit site was directed downward in 69% of the centers, and 25% of centers indicated an upward exit site. Although no correlation between catheter characteristics and infection rate was provided, this small experience confirmed the significant variation in PD catheter choice and implantation strategies.

Daschner et al. have reported on the laparoscopic placement of 25 two-cuff Tenckhoff catheters in 22 pediatric patients (128). Postoperative leakage occurred in only two

patients, and the procedure facilitated the performance of adhesiolysis and inguinal hernia repair at the time of catheter placement.

In the most recent report of the NAPRTCS, catheter characteristics were reported from 2971 independent courses of CPD accumulated from 1992–2001 (113). As was shown in previous reports, the annualized peritonitis rate decreased with increasing age and was best in association with Tenckhoff catheters with straight intraperitoneal segments, double cuffs, swan-neck tunnels, and downward pointed exit sites (109,121,129). In addition, time to first peritonitis episode was longer for catheters with two cuffs compared to one, with swan-neck tunnels compared to straight tunnels, and with downward exit sites compared to lateral exit sites or exit sites directed upward. These results confirm findings from the adult PD population (130).

Peritoneal Dialysis Prescription

In general, the PD prescription for children has evolved empirically from guidelines that adapted adult CAPD for pediatric patients. A CAPD regimen of four to five exchanges per day with an exchange volume of 900 to 1100 mL/m² BSA (35 to 45 mL/kg) of 2.5% dextrose dialysis solution has routinely yielded net ultrafiltration volumes of up to 1100 mL/m² per day. Using similar exchange volumes, the greatest percentage of children receiving CPD receive cycler dialysis with a regimen consisting of 6 to 10 exchanges over 8 to 10 hours per night.

The current goal of achieving dialysis adequacy in the most cost-effective manner has highlighted the need to be cognizant of a patient’s BSA, peritoneal membrane solute transport capacity, and residual renal function when designing the dialysis prescription (36,61,131,132). In most patients (except for the rapid transporter), the most effective way to increase solute clearance is to initially increase the exchange volume followed by an increase in dialysis duration by prolonging the dwell time. Ideally, the prescription for all children should include an exchange volume of 1100 to 1400 mL/m² BSA, as tolerated by the patient. Measurement of the intraperitoneal pressure generated by escalating exchange volumes can be useful in determining the optimum dialysis prescription (133–135). In the case of the rapid transporter, an increase in the number of exchanges and a reduction of the dwell time per cycle can result in improved solute clearance.

As mentioned, the categorization of a patient’s peritoneal membrane transport capacity can best be determined by the performance of a PET and comparison of the individual patient data to reference values (36). In turn, this information makes it possible to optimize the dialysis prescription in terms of dwell time. Recognizing that it is often impractical to consider the provision of a dialysis prescription based solely on kinetic data without reference to social constraints (e.g., school attendance, working parent), the use of the results of a PET evaluation can be particularly

helpful in determining a cost-effective approach to PD modality selection (e.g., high transporter–cycling PD; high-average to low-average transporter CAPD or cycling PD \pm additional daytime exchange). Often, this can be most easily achieved with the use of one of several computer-modeling programs that have been validated in pediatric patients and that can provide accurate estimates of solute clearance (30,136,137). It must be emphasized that in pediatrics, as well as in adults, predicted values are only estimates and do not substitute for actual measurements of solute clearance (see Peritoneal Dialysis Adequacy).

The residual renal function, a characteristic that appears to be better preserved by PD versus HD, is calculated as the average of urea and creatinine clearance and assumes greatest importance in the patient who does not attain target clearances with dialysis alone (63,138). Whereas the contribution of residual renal function toward a target goal may be significant early in the course of dialysis, a progressive loss of residual renal function usually occurs and mandates an associated enhancement of the dialysis prescription if target clearances are to be maintained (139–141).

Peritoneal Dialysis Adequacy

Until recently, most studies with adult PD patients in which clinical outcome parameters (e.g., frequency of hospitalization, patient mortality) have been monitored have characterized dialysis adequacy in terms of small solute clearance as a total (residual renal + PD) weekly Kt/V_{urea} greater than or equal to 2.0 and a total weekly creatinine clearance greater than or equal to 60 L/1.73 m² for the patient receiving CAPD (63). Minor differences in the recommendations exist for the cyclical dialysis patient. Over the past several years, however, two publications have provided data that challenge current recommendations and require consideration. An analysis of data generated in the Canada-USA study by Churchill et al. has revealed superior patient and technique survival in the adult CAPD population with low/low average transport capacity and lower total creatinine clearance values compared to those patients who are high transporters (66). This has resulted in a change of the target creatinine clearance recommendation to 50 L/1.73 m²/wk for this subset of patients in the guidelines of the National Kidney Foundation-Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI) and the Canadian Society of Nephrology (63,142). In the ADEMEX study, adult CAPD patients were prospectively randomized to their routine CPD prescription versus a prescription targeted to a creatinine clearance of 60 L/1.73 m²/wk. This study found no improvement in patient survival when the peritoneal clearance of small solutes was increased to the adequacy targets recommended by K/DOQI (143). However, deaths attributable to uremia and inadequate fluid removal were higher in the control population. Not unexpectedly, this experience has prompted a further reassessment of PD adequacy criteria in adults.

Current clinical experience supports the use of similar (or greater) target clearances for children. Reports by Hölta et al., McCauley et al., and Chadha et al. have all presented data suggestive of a correlation between patient outcome and solute clearance (144–147). The experience of Chadha et al. was also significant for demonstrating the influence that residual renal function has on patient outcome and the apparent contradiction of the presumed equivalence of PD and native solute clearance (147). The contribution of residual renal function is most apparent with respect to total creatinine clearance, as well as middle molecule clearance (148).

Can the solute clearance targets be achieved by children on CPD without introducing a prescription that has a significant negative impact on their quality of life? Whereas data by van der Voort et al. (149) suggests otherwise, the clinical experiences of Hölta et al. and Chadha and Warady provide good evidence that if the dialysis exchange volume is maximized and if the frequency of the exchanges is individualized and adjusted according to the peritoneal membrane transport characteristics, it should be possible to achieve the current K/DOQI clearance targets, at least for Kt/V_{urea} in most children receiving CPD (144,150).

The ability to accurately estimate a patient's total body water (or V) is integral to the determination of Kt/V_{urea} as an adequacy measure. The K/DOQI guidelines have recommended the use of the gender-specific formulas of Mellics-Cheek for total body water assessment, despite the fact that the formulas were derived from studies of healthy children (151). Recently, more accurate estimates of V have at last become feasible after the analysis of additional body water data in the literature and after study of pediatric dialysis patients by bioelectrical impedance analysis as well as with the use of D₂O or H₂O¹⁸ (152–155). It is noteworthy, however, that there are few data to support the preference of one solute clearance measure (Kt/V_{urea} vs. creatinine clearance) over another and that discrepancies in the results may occur in as many as 20% of patients. This has prompted the recommendation that the evaluation of adequacy be based on the results of both clearance measures and an ongoing assessment of the patient's clinical condition (156,157). If there is discordance in achieving these targets, it has been suggested that the Kt/V_{urea} be the immediate determinant of adequacy because it directly reflects protein metabolism and is less affected by extreme variations in residual renal function (63).

Implicit in the approach to achieve and maintain dialysis adequacy is the need to repeatedly measure total solute clearance. Ideally, 24-hour collections of urine and dialysate fluid should be obtained three times per year or when there have been significant changes in the patient's clinical status that may influence dialysis performance (e.g., severe or repeated peritonitis).

In summary, current knowledge supports the clinical use of a target total weekly Kt/V_{urea} of greater than or equal to

2.0 and a total weekly creatinine clearance of greater than or equal to 60 L/1.73 m² to achieve dialysis adequacy in most children receiving CAPD (63). Patients receiving cycling PD likely require slightly greater clearances, and low transporters may do well with lower clearances if the pediatric experience is comparable to that of the adults. The continued accumulation of patient outcome data is critical to the ongoing assessment of these criteria.

Nutritional Management of Children Receiving Continuous Peritoneal Dialysis

The achievement of normal growth is uncommon among children treated with CPD, despite access to an essentially unlimited diet (158,159). Compared with normal healthy children, pediatric patients receiving CPD have significantly lower energy intake, as well as diminished height, weight, triceps skinfold thickness, and mid-arm muscle circumference (160). Hypoalbuminemia, hypertriglyceridemia, and hypercholesterolemia are commonly seen (161). Current guidelines from the National Kidney Foundation's K/DOQI program suggest the need to provide an energy intake of at least 100% of the recommended daily allowance (RDA) for children of the same gender and chronological age (162). High-calorie formulas are often helpful to meet these requirements, particularly in infants who may require supplemental tube feeding by the nasogastric or gastrostomy routes (163–165). The K/DOQI guidelines recommend that supplemental nutritional support be considered when a child does not have a normal height velocity or is failing to consume the RDA for energy and/or protein, the latter problem often magnified by protein losses into dialysate (166,167). Supplementation by the oral route is preferred followed by enteral tube feeding (162).

The potential need for sodium, potassium, and phosphorus supplementation requires special attention. Young infants may have significant sodium loss in dialysate, as well as from their native kidneys as a result of underlying obstructive uropathy. Hypophosphatemia is especially common in association with the use of low phosphorus infant formulas (168). Either hyperkalemia or hypokalemia can also result from a combination of dialysate losses and dietary intake.

The nutritional status of every pediatric patient must be repeatedly and regularly evaluated to be certain that individual patient needs are constantly met. According to K/DOQI guidelines, the most valid measures of protein and energy nutrition status in children treated with maintenance dialysis include a dietary interview/diary, the serum albumin, the child's height or length, the estimated dry weight, the weight-for-height index, anthropometric measures (mid-arm circumference, muscle circumference or area, and skinfold thickness), head circumference for children younger than 3 years, and the standard deviation score (or Z score) for height (162).

Little prospective evidence is available to support supplementing water-soluble vitamins above the RDA or the

dietary reference intakes for age (162,169,170). Supplements of the fat-soluble vitamins A, E, and K should be avoided, because elevated levels of vitamin A have been reported in children receiving CPD (171).

Peritonitis

The single most common complication that occurs in children maintained on CPD is peritonitis (121,172–176). Unfortunately, present data make it clear that children have a significantly greater rate of peritonitis than adults, with a substantial number of children experiencing an episode of peritonitis during their first year of CPD treatment. Reductions in observed peritonitis rates have been reported in both adults and children in association with treatment of *Staphylococcus aureus* nasal carriage; use of a two-cuff catheter, as well as with recent technical developments such as newer disconnect systems; and the flush-before-fill technique (172,176–181). The important contribution of prolonged dialysis training has also been demonstrated (182).

Recent evaluation of the NAPRTCS database has revealed a total of 2965 reported episodes of peritonitis in 3621 years of follow-up, resulting in an annualized peritonitis rate of 0.82 or one infection every 14.7 patient months (113). The rate of peritonitis was highest in the youngest patients (0 to 1 years of age) who had an annualized peritonitis rate of 1.02 or 1 infection every 11.8 months versus an annualized rate of 0.75 or 1 episode every 16.1 patient months in children more than 12 years of age. In this same report, gram-positive infections comprised slightly more than 50% of the episodes of peritonitis and gram-negative infections slightly more than 20%. Fungal peritonitis represented 2.3% of peritonitis episodes.

The current approach to the treatment of peritonitis relies primarily on the intraperitoneal administration of antibiotics. A key development has been the recent publication of the *Consensus Guidelines for the Treatment of Peritonitis in Pediatric Patients Receiving Peritoneal Dialysis* by an international committee of physicians and nurses under the auspices of the International Society of Peritoneal Dialysis (180). This set of 15 guidelines includes recommendations for empiric antibiotic therapy, treatment of gram-positive, gram-negative, and fungal peritonitis, and indications for catheter removal and replacement (Figs. 70.3, 70.4, and 70.5). The concern that has arisen regarding the development of vancomycin-resistant organisms and the vestibular, renal, and audiological complications of aminoglycosides has influenced the content of several of the recommendations (183–185). An international registry is currently accumulating data regarding the application of these guidelines into clinical care.

Finally, sclerosing encapsulating peritonitis is a rare but extremely serious clinical entity characterized by the presence of continuous, intermittent, or recurrent bowel obstruction associated with gross thickening of the perito-

Consensus guidelines for the treatment of peritonitis in pediatric patients receiving peritoneal dialysis. *Perit Dial Int* 2000;20:610–624, with permission.)

neum (186). Although primarily diagnosed in adults, it may also occur in children, typically those who have received CPD for more than 5 years (187,188). The presence of peritoneal calcifications on abdominal computed tomography scan in association with ultrafiltration failure is highly suggestive of the diagnosis and may be an indication to discontinue CPD.

TREATMENT OUTCOME

Functional Integrity of the Peritoneal Membrane

The stability of the peritoneum as a dialyzing membrane is of particular interest because of the potential for the long-term need for CPD. Infection would seem to be a likely contributor to decreased long-term membrane function,

but the data are conflicting. In a retrospective study in children, it has been reported that peritonitis caused by *Pseudomonas aeruginosa* or alpha streptococcal organisms was an independent predictor of membrane failure, defined as the severe loss of ultrafiltration capacity (189). When two other groups of children were assessed by means of solute D:P ratios derived during the performance of a PET conducted without standardized study mechanics, either no change over time or a deterioration was demonstrated (190,191). The peritonitis history of the cohort of children studied to develop the pediatric PET curves was reanalyzed and revealed higher MTAC for glucose and creatinine in those who had previous episodes of peritonitis (36,192). Similarly, in the one pediatric prospective evaluation of the peritoneal membrane as assessed by PET testing over a mean of 20 months between studies, there were no changes in MTAC for glucose or creatinine over time. However, in

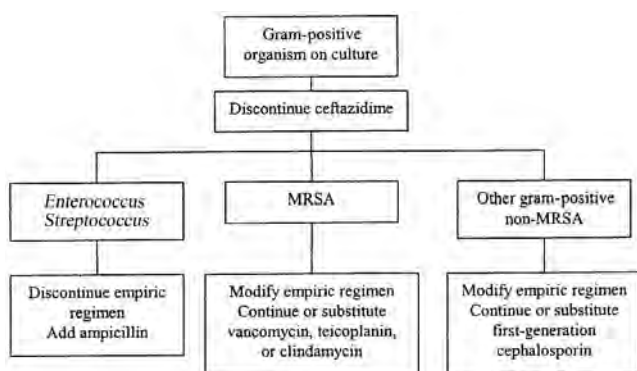

FIGURE 70.4. Treatment algorithm for gram-positive peritonitis. MRSA, methicillin-resistant *Staphylococcus aureus*. (From Warady BA, Schaefer F, Alexander S, et al. FIGURE 70.5. Treatment algorithm for gram-negative peritonitis. (From Warady BA, Schaefer F, Alexander S, et al. Consensus guidelines for the treatment of peritonitis in pediatric patients receiving peritoneal dialysis. *Perit Dial Int* 2000;20:610–624, with permission.)

the children with a history of peritonitis, the MTAC values increased (193). Finally, in one of the few studies evaluating peritoneal biopsy material from children, a reduced density of mesothelial microvilli presumably related to the duration of PD treatment and the presence of peritonitis was documented, as was fibrosis of the peritoneal membrane (194). However, the latter did not correlate with the frequency of peritonitis or the duration of PD therapy.

Quality-of-Life Issues

Health-related quality of life refers to the measure of a patient's functioning, well-being, and general health perception in each of three domains: physical, psychological, and social (195). In turn, a patient's quality of life is an important indicator of the effectiveness of the medical therapy he or she receives (196). Several characteristics of CPD permit an improved quality of life for many children and their families as reflected in one report in which older children who experienced both therapies preferred CPD over HD (197). The ability to attend school every day may be one of the most beneficial features of CPD for children. Data from the NAPRTCS showed that among patients maintained on PD, 77% were attending school full-time and 15% part-time or at home (113). Comparable values for the HD population were 46 and 36%, respectively. Very few restrictions to physical activities are necessary. However, children receiving CPD should avoid tackle football, wrestling, and some gymnastic exercises involving appliances (e.g., uneven parallel bars). Swimming is permitted, although attention must be paid to securing the catheter while in the water, and only chlorine-treated swimming pools (rather than lakes or rivers) are recommended. This philosophy also facilitates the ability of these children to participate in summer camping experiences that are commonly coordinated by dialysis team personnel (198). Nevertheless, data suggesting a decline in the quality of life over time for adult patients on CPD mandate the performance of formal investigations of quality of life in pediatric CPD patients to better evaluate this critical aspect of patient care (196,197,199).

Termination of Continuous Peritoneal Dialysis

Data on termination of CPD therapy are available from the NAPRTCS Registry (113). Of the 472 children who terminated CPD for reasons other than transplant, 45% of the children changed dialysis modality because of excessive infection. Patient/family choice and access failure were the reasons for modality change in 8% and 7%, respectively. In a single center study, Gulati et al. found the likelihood of technique failure to be increased in PD patients with hypoalbuminemia 1 month after dialysis initiation (200).

Patient Mortality

In the most recent annual report of NAPRTCS, an overall mortality rate of 8.5% was noted for the pediatric CPD population (113). An assessment related to age revealed a mortality rate of 14.9% for patients younger than 5 years at dialysis initiation, which was significantly greater than the mortality rate of 5.7% and 4.5% for patients in the 6 to 12 and older than 13 years age groups. The mortality rate for patients 0 to 1 years and 2 to 5 years was 18.9% and 8.3% with 1- and 3-year postinitiation mortality rates of 15.3% and 32.5% for the youngest patients, and 5.8% and 13.7% for the 2- to 5-year age group. These data confirm the high-risk status of the infant and young child with ESRD and are similar to data collected from children in Italy and Japan (112,201). The primary reported causes of death for all PD patients were infection (27.9%) and cardiopulmonary disease (20.9%). The primary causes of death for patients 0 to 5 years of age were the same with infection accounting for 27.1% of deaths and cardiopulmonary disease 19.8%. Although the specific reasons for the higher death rates seen in infants receiving CPD have not been well delineated, recent work has suggested that the presence of extrarenal disease, particularly pulmonary disease/hypoplasia and oliguria or anuria, are important risk factors (122,123).

HEMODIALYSIS

STUART L. GOLDSTEIN
KATHY JABS

Hemodialysis is a procedure that uses extracorporeal perfusion to clear accumulated solutes or toxins from the blood by diffusion and convection across a semipermeable membrane. End-stage renal disease (ESRD) and acute renal failure are uncommon disease states in children. As a result, technologic advances and professional expertise specific for pediatric patients with renal failure have often developed relatively slowly. The hemodialysis procedure has become increasingly sophisticated, however, and many of the theoretical and technological advances studied previously in adult patients have been applied to children receiving hemodialysis. Provision of optimal pediatric hemodialysis requires a specialized and integrated health care team to manage the medical, nursing, nutrition, development, and psychosocial aspects of care for the pediatric patient with ESRD. In addition, neonates, children, and adolescents with acute renal failure often require short-term dialysis treatment until adequate renal function is restored. This chapter reviews the fundamental principles of hemodialysis and provides practical information regarding the provision of hemodialysis to children with acute and chronic renal failure.

INCIDENCE AND ETIOLOGY OF END-STAGE RENAL DISEASE

The incidence rate of ESRD in the United States is 11 to 14 per 1 million for individuals under 20 years of age and has remained relatively stable over the past 30 years. In 1999, 5935 children in the United States carried the diagnosis of ESRD; 939 of them received hemodialysis as long-term renal replacement therapy (1). The number of neonates and infants receiving acute and chronic hemodialysis has steadily increased over the past decade as a result of improved pediatric dialysis nursing expertise and the availability of pediatric- and neonatal-sized catheters and blood tubing that minimize the blood volume of the extracorporeal circuit (2–4). The success of renal transplantation in young children has further stimulated programs to develop

satisfactory dialysis treatment facilities to prepare these infants optimally for transplantation (4).

PHYSIOLOGY OF HEMODIALYSIS

The goal of the hemodialysis treatment is to remove prescribed quantities of solutes and fluid that have accumulated between dialysis sessions. Solute removal (clearance) and fluid removal (ultrafiltration) are accomplished via blood perfusion of an extracorporeal filter membrane across which runs a countercurrent balanced electrolyte solution.

Solute clearance during hemodialysis occurs by two physiologic mechanisms: diffusion and convection. Diffusion refers to solute migration across a semipermeable membrane. The factors governing the rate of transfer are membrane permeability (i.e., the number and size of the pores in the membrane), solute size and charge, membrane surface area, and magnitude of the concentration gradient across the membrane. Solute transfer rates are inversely proportional to particle size—smaller particles diffuse more rapidly than larger particles. On the other hand, solute transfer rates are directly proportional to membrane surface area and concentration gradient, both of which can be manipulated by prescription to improve clearance.

Convection refers to the phenomenon of solute movement (or solute drag) across the membrane independent of concentration gradient. The main determinant of solute drag is the osmotic gradient achieved by the amount of plasma water pushed across the membrane (ultrafiltrate). The amount of convective transfer of a particular solute is proportional to both the amount of ultrafiltrate achieved during the treatment and the sieving properties of particular dialyzers. A sieving coefficient for each solute-dialyzer pair reflects the interaction between the size and charge of the solute, and the pore number and pore size of the dialyzer.

Because the extracorporeal circuit is in contact with only the intravascular component of the extracellular space, clearance of solute by dialysis and fluid removal via ultrafiltration do not occur simultaneously through the various

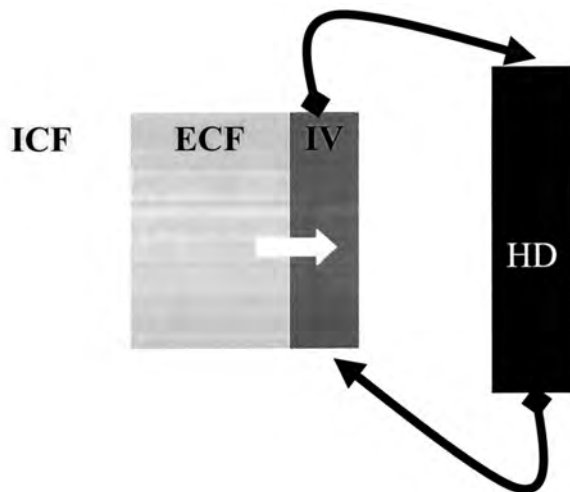

FIGURE 71.1. This extracorporeal circuit model demonstrates that the dialysis circuit has access only to the intravascular (IV) space. As a result, both solute and fluid removal occur initially from the IV space. Removal from the interstitial and intracellular spaces occurs after fluid and solutes move down dialysis-induced hydrostatic and concentration gradients, respectively. ECF, extracellular fluid; HD, hemodialysis; ICF, intracellular fluid.

body compartments. Before the initiation of dialysis, accumulated solutes are distributed across patient total body water, which is comprised of the intracellular and extracellular spaces. Solute clearance and fluid removal occur instantaneously from the extracorporeal circuit in the dialyzer space. Fluid in the extravascular space must move down the concentration and hydrostatic gradients created during the dialysis treatment into the intravascular space before being processed in the extracorporeal circuit (Fig. 71.1). The extravascular to intravascular transfer rates have important practical effects on the quantification of solute removal and tolerable ultrafiltration rates. These effects are discussed later in the chapter.

HEMODIALYSIS TREATMENT AND EQUIPMENT

Hemodialysis Circuit

The hemodialysis circuit is comprised of the patient's blood compartment access in the form of an arteriovenous fistula (AVF) or arteriovenous graft (AVG) or a venous catheter, polyethylene tubing through which the patient's blood travels to and from the dialyzer, and the dialyzer itself. Blood tubing is produced in a variety of sizes and should be matched to patient size to allow for optimal blood flow while minimizing the volume of the extracorporeal circuit, which is the sum of the blood tubing volume and hollow fiber dialyzer volume. To prevent excessive repeated blood loss in the circuit and hemodynamic instability, the extracorporeal circuit should not exceed 10% of the patient's

calculated blood volume. Neonatal lines with a volume of 40 mL are available for use in children who weigh less than 15 kg. A wide variety of dialyzers with different blood volumes are available from various manufacturers that can be matched to pediatric patient sizes.

To prevent hypovolemia during initiation of a dialysis treatment, the circuit should be primed with either saline or colloid. For some infants, for whom even the smallest blood tubing-dialyzer volumes exceed 10% of patient blood volume, the circuit should be primed with colloid (5% albumin or packed red blood cells diluted with albumin to a measured hematocrit of 35%) instead of crystalloid. Weekly serum hematocrit values should be obtained to monitor for anemia resulting from excessive blood loss in the hemodialysis circuit for infants of less than 10 kg maintained on chronic hemodialysis. Special considerations for infants receiving chronic hemodialysis are discussed at the end of the chapter.

A primary determinant of the amount of solute clearance during the hemodialysis treatment is the blood pump flow rate (Q_b , in milliliters per minute) through the dialyzer. A calibrated roller pump housed in the hemodialysis machine drives extracorporeal blood from the patient access through the blood tubing to the dialyzer and then back to the patient access. The Q_b should be prescribed to provide safe and optimal clearance of solute. Use of a maximum Q_b of less than 400 mL/min/1.73 m² of patient body surface area minimizes the risk of cardiovascular compromise.

Ultrafiltration is achieved via creation of a hydrostatic pressure gradient across the dialyzer membrane (transmembrane pressure or TMP). Newer dialysis machines equipped with volumetric control automatically establish the necessary TMP to provide the ultrafiltration volume prescribed over the duration of the treatment. Volumetric control machines can provide ultrafiltration volumes within 10 to 100 mL of prescribed volumes and have eliminated the need for dialysis staff to calculate and create the appropriate TMP.

Hemodialyzer

Current dialyzers are manufactured with a hollow fiber design to minimize blood volume and provide reliable and predictable solute clearance and ultrafiltration coefficients. Advancements in dialyzer manufacturing processes have led to improvements in clearance efficiency and biocompatibility.

Dialyzer clearance is a function of the dialyzer surface area and its clearance characteristic (K_oA , in milliliters per minute) for a particular solute (5), the blood flow rate (Q_b , in milliliters per minute), and the countercurrent dialysate flow rate (Q_d , in milliliters per minute). To enhance diffusion and prevent saturation of dialysate with solute, the prescribed Q_d should exceed the Q_b by at least 50%. In fact, *in vitro* and *in vivo* studies have shown that increasing Q_d has a significant affect on urea clearance and may further improve clearance in patients with sufficient Q_b and

dialysis times and add very little to the cost of the procedure (6). The clearance rate for a particular solute is generally inversely proportional to the molecular size of the solute. Most modern dialyzers permit clearance of solutes up to a molecular weight of 5000 to 10,000 daltons.

Figure 71.2 depicts different relative clearance characteristics for dialyzers with a different K_oA at various blood pump flow rates. This figure demonstrates that clearance is equivalent for both dialyzers at low blood flow rates, because equilibration of solute occurs between the blood space and dialysate space within the dialyzer at low flow rates. The figure also illustrates the nonlinear association between blood flow rates and dialyzer clearance (K_d), because at higher blood flow rates, diffusion and convection are maximized at a point at which blood travels rapidly through the dialyzer and back to the patient. The differences between the two dialyzers are the blood flow rate at which the maximum clearance is achieved and the maximum clearance that can be achieved.

The ultrafiltration coefficient of the dialyzer is determined by the charge of the dialyzer surface area and the size of the pores through which solutes traverse from the blood space to the dialysate space. The ultrafiltration coefficient should be sufficient to allow for the prescribed volume of fluid removal during the 3- to 4-hour hemodialysis treatment. Hemodialysis machines with volumetric control have been a major advancement to prevent excessive fluid removal by ultrafiltration in smaller children receiving hemodialysis.

Activation of proinflammatory cytokines, leukocytes, and other mediators can occur when blood comes into contact with an inorganic surface. Although few pediatric data currently exist, numerous studies in adults have suggested that repeated exposure to certain dialysis membranes may result in prolonged immune system activation, protein catabolism, and alteration of host proteins, which may have long-term adverse clinical consequences (7–14). For instance, proinflammatory cytokine induction by dialysis membrane exposure has been posited to lead to glycosylation of β_2 -microglobulin. The advanced glycosylation end-products are thought to contribute to dialysis-associated amyloid deposition in soft tissues (15,16). Furthermore, inflammation may be a contributory factor for development of the coronary artery calcifications often observed in adult patients receiving chronic hemodialysis, which in turn are thought to contribute to the increased cardiovascular mortality rates seen in young adult patients with ESRD (17).

Newer-generation dialysis membranes constructed from materials such as polysulfone and polymethylmethacrylate cause less proinflammatory cytokine activation than older generation membranes made from cellulose or cuprophane (18,19). There are no data available on changes in outcomes with polysulfone or polymethylmethacrylate membranes, although the incidence of anaphylactoid, complement-mediated immediate membrane reactions is far lower with biocompatible membranes.

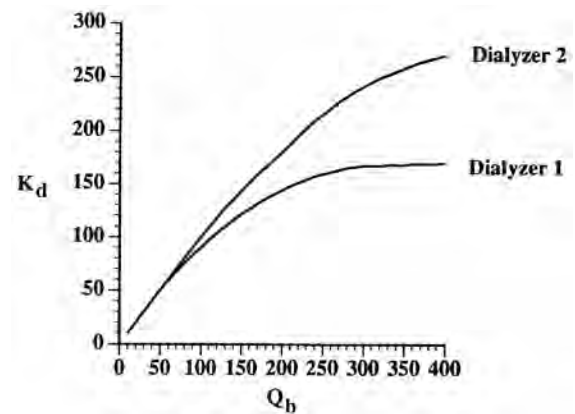

FIGURE 71.2. The relationship between blood flow (Q_b) and dialyzer clearance (K_d) for two different dialyzers. Dialyzer 2 has a K_oA value (clearance characteristic) twice as large as that of dialyzer 1.

Water Treatment System

The hemodialysis water treatment system must remove all potentially hazardous substances from source water before distribution to the unit's dialysis machines. Source water is usually derived from a municipal water supply. Although standards for hemodialysis water treatment vary from state to state, compliance with minimum standards and components outlined by the Association for the Advancement of Medical Instrumentation is required for all systems operating in the United States (20).

The components of hemodialysis water treatment systems and their basic functions are listed in Table 71.1. Critical components include sediment filters to remove particulates, softener tanks to remove calcium and magne-

TABLE 71.1. COMPONENTS AND FUNCTIONS OF A HEMODIALYSIS WATER TREATMENT SYSTEM

Component	Function
Backflow preventer	Prevents reverse flow of water through the valve
Temperature blending valve	Maintains constant water temperature of 25°C
Multimedia filter	Filters out particulates 10–20 μm or larger
Softener and exchange filter	Removes water hardness (calcium and magnesium) in exchange for sodium
Carbon tank (two needed)	Removes chlorine and chloramines: 6 min EBCT for chlorine, 10 min EBCT for chloramine
Prefilter	Filters out particulates 3–5 μm in size
Reverse osmosis membrane	Removes 96–99% of incoming particles >200 molecular weight, endotoxins, viruses, and bacteria
Deionization tank	Removes charged ions from water
Ultraviolet light	Kills or alters DNA of bacteria as water passes through lamp

EBCT, empty bed contact time.

sium, ultrafilters to remove bacteria and endotoxins, carbon tanks to remove chlorine and chloramines, and ultraviolet irradiators to destroy bacteria. The heart of the water treatment system is the reverse osmosis membrane, which removes 99% of bacteria and 95% of charged ions.

Once the source water has been treated and rendered safe for dialysis, it is delivered to the unit and each patient station by means of distribution piping. Bacterial overgrowth and the resultant establishment of biofilm is a constant hazard for all water treatment systems. Measures that help prevent bacterial overgrowth include use of nonporous tubing, minimization of dead ends and bends in the distribution loop, and generation of high water flow rates of greater than 3 ft/sec to create turbulent flow and thereby prevent bacterial attachment. Regular monitoring for bacterial contamination of dialysis water from various segments of the treatment system and at each patient station is crucial to assure the safety of hemodialysis. In addition, regular periodic disinfection of the water treatment system is warranted.

Data demonstrate that dialysis water levels of endotoxin below levels that produce pyrogenic reactions (and below the limits set by Association for the Advancement of Medical Instrumentation standards) may still cause chronic inflammation in some patients. Ultrapure water, similar to that used for pharmaceutical injection and semiconductor manufacturing, leads to a decrease in cytokine-mediated inflammation when used for dialysis fluid (21) but is extremely expensive to produce.

The electrolytic composition of dialysis water is critical to ensure safe diffusive treatment. Standard dialysis baths contain sodium (140 mEq/L), potassium (2 to 3 mEq/L), chloride (100 to 102 mEq/L), bicarbonate (40 mEq/L), magnesium (1.5 to 2.0 mEq/L), calcium (ionized concentration 1.5 to 3.0 mEq/L), and glucose (100 mg/dL). Bicarbonate is preferred to acetate for acid buffering, because the use of acetate has been associated with hypotension in dialysis patients (22,23). Current dialysis machines can alter the sodium concentration during the course of the treatment. Use of sodium-modeling programs, which deliver higher sodium concentrations earlier in the treatment followed by lower concentrations later in the treatment, has been shown to decrease both intra- and interdialytic patient symptoms (24–26).

VASCULAR ACCESS

Adequate provision of hemodialysis depends on a properly functioning vascular access. Current hemodialysis access options are divided into two categories: permanent access in the form of an AVF or AVG and semipermanent access in the form of catheters with a subcutaneous cuff for long-term dialysis or without a cuff for short-term hemodialysis.

Permanent vascular access of an AVF or AVG can function for many years and is preferred over indwelling catheters

in children and adults. However, the majority of children receiving hemodialysis in the United States are still dialyzed via a catheter (27). Reasons for high catheter prevalence rates include lack of local surgical experience in permanent access creation in smaller patients, anticipation of a short dialysis course before transplantation, or dialysis unit philosophy to decrease painful procedures (i.e., repeated needle sticks for children with AVFs or AVGs).

AVFs are created by connection of a patient's native artery to vein. The most common sites for AVFs are the wrist (radiocephalic or Brescia-Cimino fistula) and the antecubital fossa (brachial artery to cephalic vein). If possible, the wrist location is preferable for the first access to preserve more proximal vessels for future access placement [National Kidney Foundation Kidney-Dialysis Outcomes Quality Initiative (NKF-KDOQI) recommendation] (28). The arterial to venous connection results in a communication between the high-pressure arterial system and the low-pressure venous system. Before initial use, the venous portion of the AVF must be allowed to "mature" or expand to produce a size large enough for safe needle placement. Maturation time depends on patient size and AVF location but should be a minimum of 4 weeks and preferably 3 to 4 months (28). Some AVFs in smaller children require 4 to 6 months to mature (29). Thus, to allow for ample maturation time and avoid the use of temporary venous catheters, AVF placement should occur in advance of the patient's immediate need for dialysis if possible. Current guidelines recommend placement of an AVF or AVG when patient glomerular filtration rate (as measured by creatinine clearance) is less than 25 mL/min/1.73 m² (28).

AVGs are composed of prosthetic polytetrafluoroethylene (Gore-Tex) tubing connecting a patient's artery to vein. The advantages of AVGs over AVFs include increased options for site placement (thigh, forearm, and upper arm) and configuration (straight and looped). In addition, AVGs are technically easier to construct and do not require maturation times as prolonged as those for AVFs. AVGs should not be used within 4 weeks of placement to allow the luminal portion to become lined with endothelium (28).

AVF complications include development of venous collaterals, arterial inflow stenosis with resultant poststenotic dilatation, and aneurysm formation caused by repeated needle puncture in the same site. Furthermore, patients with very high flow rates of greater than 2000 mL/min may be at risk for hypoxia from extracardiac shunting or ischemia of the limb distal to the AVF anastomosis. A thorough physical examination should be performed before AVF placement to ensure that the limb receives good blood flow from an artery other than the vessel planned for arterial anastomosis.

Thrombosis of permanent access sites is a significant cause of morbidity for the hemodialysis patient population (30). In many instances, thrombosis results from decreased access flow caused by a stenosis of the access venous outflow tract (31,32).

FIGURE 71.3. Ultrasound dilution monitor configuration. The patient's dialysis lines are temporarily reversed to create recirculation. A 20-mL saline bolus is injected upstream of the first sensor. The saline enters the patient access site, and most of the bolus goes into the patient circulation. In the presence of venous stenosis, more saline returns to the dialysis circuit and is detected by the second sensor. Both sensors are connected to a computer, which interprets the data and calculates the flow by the Fick equation. Q_A , access flow. (Courtesy of Transonic Systems, Inc., Ithaca, New York.)

Substantial clinical research has been performed over the past decade to devise methods to assess for vascular access outflow stenosis in adult patients receiving hemodialysis, but many methods have significant drawbacks that preclude routine use (33–38). Ultrasound dilution (UD) is a practical, noninvasive, and reliable indicator of vascular access flow and has been used effectively to identify venous stenosis in adult patients receiving hemodialysis (39–43). The technique employs two reusable sensors, one attached to the venous and one to the arterial line while the patient is receiving hemodialysis. During the first hour of a hemodialysis treatment, the hemodialysis lines are temporarily reversed (to create temporary recirculation) and a 20-mL bolus of saline is then injected quickly into the venous line proximal to the venous sensor. The sensors are attached to a computer that interprets the changes in Doppler velocity within each line as the hematocrit changes in relation to dialyzer blood flow (Fig. 71.3).

When the access flow (Q_A , in milliliters per minute) reported by the UD monitor is corrected for patient size (Q_{Acorr} , in milliliters per minute per 1.73 m^2), a Q_{Acorr} lower than $650 \text{ mL/min}/1.73 \text{ m}^2$ is extremely sensitive and specific for predicting AVG and AVF stenosis in pediatric patients receiving hemodialysis (44). Furthermore, when patients with a Q_{Acorr} lower than $650 \text{ mL/min}/1.73 \text{ m}^2$ were referred for venography and balloon dilatation angioplasty within 48 hours of UD measurement, a 90% reduction in vascular access thrombosis rate was observed (45). This reduction in thrombosis rate was associated with

TABLE 71.2. CUFFED HEMODIALYSIS CATHETER AND PATIENT SIZE GUIDELINE

Patient size (kg)	Catheter options
<20	8 French dual lumen
20–25	7 French twin Tesio
25–40	10 French dual lumen 10 French Ash split 10 French twin Tesio
>40	10 French twin Tesio 11.5 or 12.5 French dual lumen

decreased patient hospitalization and a 40% reduction in unit cost per patient for vascular access management.

Other noninvasive venoarterial flow measurements include ionic dialysance and transcutaneous access flow, but neither has been studied in a pediatric hemodialysis patient population (46,47).

Long-term survival of AVGs and AVFs has recently been evaluated for pediatric patients (48). One-, 3-, and 5-year pediatric AVF survival rates are 90, 60, and 40%, respectively. One-, 3-, and 5-year pediatric AVG survival rates are 90, 50, and 40%, respectively. The data demonstrated that, although 5-year AVG and AVF survival rates are not significantly different, AVGs do exhibit higher thrombosis and surgical intervention rates.

Although the method is not preferred for hemodialysis vascular access, lack of local surgical expertise and small patient size have rendered semipermanent access in the form of cuffed catheters crucial for provision of hemodialysis to children. Current catheter configurations can be divided into three types: dual-lumen catheters with both lumens fixed to each other for the entire length of the catheter, dual-lumen catheters that have split the venous and arterial lumens of the distal portion of the catheter to allow for free tip movement within the vein (Ash split catheter), and twin separate single-lumen catheter systems that can be inserted into the same vein with different exit sites or in different veins altogether (Tesio catheter system). Table 71.2 lists some of the available cuffed hemodialysis catheter options and provides a guideline for matching catheter size and type with patient size.

Hemodialysis catheter tip placement in the right atrium allows for the blood flows required to provide adequate dialysis; catheter tips that rest in the superior vena cava may be at risk for collapse against the vessel wall. In considering sites for placement of temporary or cuffed catheters, the risk of central venous stenosis should be considered. A central venous stenosis may increase venous pressure and result in poor flow or thrombosis of the AVF or AVG. The right internal jugular site is associated with venous thrombosis less frequently than subclavian sites. It is also preferable to place the catheter on the contralateral side to a planned AVF or AVG (28). A chest radiograph should be obtained before the first use of a catheter to ensure proper catheter placement and absence of pneumothorax or hemothorax.

To prevent catheter thrombosis, packing with concentrated heparin (1000 U/mL for children smaller than 40 kg, 2000 U/mL for children larger than 40 kg) is recommended. Even with heparin packing, catheter thrombosis remains a significant problem that can preclude the delivery of adequate dialysis. Initial studies of the use of trisodium citrate to lock hemodialysis catheters demonstrated significant reduction in thrombosis rates in adult patients, but cases of inadvertent infusion of citrate into the bloodstream and resultant patient hemorrhage lead to the discontinuation of approval for citrate catheter locking.

Treatment of catheter thrombosis is currently limited to the instillation of tissue plasminogen activator into the catheter (1 to 2 mg/mL for 2 hours) and intraluminal brushing to dislodge the clot. The presence of intra- and extraluminal fibrin sheaths can be diagnosed reliably only by injecting venous contrast through the catheter. Pharmacologic treatment of fibrin sheaths around catheters has been unrewarding. Some centers currently strip fibrin sheaths from catheters using wire-guided scrapers that are inserted into the patient's femoral vein and advanced to the catheter tip under fluoroscopic imaging.

A few pediatric studies have assessed the survival rates and complications for pediatric hemodialysis catheters (49–51). The most common complications observed include infection (either tunnel infection or line sepsis), kinking of the catheter, and thrombosis. Gram-positive organisms, especially *Staphylococcus* species, are the most common causative organisms in hemodialysis catheter infections. Because hemodialysis is a life-sustaining procedure and cannot be interrupted, many centers attempt to treat hemodialysis catheter infections with antibiotics alone and do not immediately remove the catheter. Catheter removal should be performed when patients are repeatedly symptomatic from shedding of bacteria in the bloodstream during the dialysis treatment, as manifested by high fever, rigors, chills, and/or hypotension, or when the infection cannot be eradicated. In addition, catheter removal will likely be necessary in patients with fungal line infections, which are very difficult to eradicate with antimicrobials alone.

Pediatric studies demonstrate a median survival of 204 to 280 days for a dual-lumen hemodialysis catheter (49–51). In a single-center comparison, pediatric Tesio catheters exhibited significantly longer survival and provided adequate hemodialysis more reliably than dual-lumen catheters of similar size (50).

TARGET DRY WEIGHT AND ULTRAFILTRATION PRACTICE

For many reasons, accurate determination of patient target weight is a challenging task when treating hemodialysis patients. Symptoms of hypovolemia may be difficult to assess, as the behavior of small children receiving dialysis is often hard to interpret. Although overly rapid acute fluid removal may cause temporary intravascular volume deple-

tion and patient cramping, hypotension, dizziness, and/or nausea, some young children are not able to verbalize their symptoms to dialysis personnel or may act distressed because of anxiety or fear unrelated to true physical discomfort. Month-to-month target weight assessment is difficult in children due to widely ranging ratios of total body water to body mass that vary with age. Furthermore, children are growing and have variable appetites, so that real weight loss and weight gain may occur more frequently than in adults.

Nonetheless, accurate determination of pediatric target weight is critical, because an underestimation of dry weight can lead to hypovolemia with acute symptoms noted earlier and to enhanced postdialysis thirst that results in immediate posttreatment overdrinking and increased interdialytic fluid gain. Continual overestimation of target weight can lead to chronic volume overload with resultant hypertension, pulmonary edema, congestive heart failure, and left ventricular hypertrophy. Ultrafiltration-associated symptoms may occur with an appropriately determined dry weight, especially in patients with large interdialytic weight gains. These symptoms are the result of intravascular volume depletion while awaiting refilling from the extravascular space. Approaches to minimize ultrafiltration-associated symptoms include sequential ultrafiltration and dialysis (or isolated ultrafiltration at the start of a treatment), sodium modeling, and noninvasive monitoring (NIVM) of hematocrit.

Sodium Modeling

Sodium modeling is a machine-programmed algorithm that varies the dialysate sodium concentration during the treatment. Most modeling programs use hyperosmolar dialysate sodium concentrations at the beginning of treatment and then decrease sodium concentration, either by linear, logarithmic, or stepwise algorithms, throughout the remainder of the treatment. The increase in sodium concentration caused by sodium diffusion into the serum at the beginning of the treatment is designed to offset the decrease in serum osmolality resulting from urea removal during dialysis. A return to normal sodium concentrations at the end of the treatment decreases the interdialytic thirst that would result from dialysis against a constantly high sodium level. Sodium modeling has been shown to be effective in decreasing both intradialytic and interdialytic symptoms in adolescent and adult patients receiving hemodialysis (25,56). Similarly, isolated ultrafiltration at the start of dialysis maintains the osmolality of the intravascular space by removing solutes only by convection and helps with refill of the intravascular space during ultrafiltration.

Noninvasive Monitoring

Because red cell volume remains constant during dialysis, changes in hematocrit are inversely proportional to changes in intravascular volume. Continuous optical methods of NIVM of hematocrit take advantage of this relationship to demon-

strate a real-time association between fluctuating hematocrit and intravascular volume during the hemodialysis treatment.

Optical methods of NIVM to continuously monitor changes in intravascular volume can help decrease symptomatology during a dialysis treatment (52–54). For example, if fluid removal is too rapid as detected by a rapidly increasing hematocrit and steep declining slope on the NIVM monitor, the ultrafiltration rate can be decreased before hypovolemic symptoms occur. If fluid removal is too slow as suggested by a stable hematocrit and a flat slope on the NIVM monitor, then the ultrafiltration rate may be increased safely to achieve the patient's actual target weight.

The use of NIVM has been studied in pediatric patients receiving hemodialysis (55,56). Rates of ultrafiltration-associated events (defined as hypotension, headache, or cramping that required a nursing intervention such as administration of a saline bolus, placement in the Trendelenburg position, or a slowing or stopping of ultrafiltration) were lower when NIVM was performed, especially among patients weighing less than 35 kg. The decrease in symptom event rates with NIVM occurred without a sacrifice in target weight achievement. When NIVM was performed, symptom events occurred in the first 90 minutes of treatment only with a blood volume change of greater than 8% per hour as registered on the NIVM monitor. Seventy-one percent of events occurring after 60 minutes of treatment initiation were associated with a blood volume change greater than 4% per hour. These treatment time and event observations have been used to model ultrafiltration rates to optimize fluid removal during dialysis, lessen the need for antihypertensive medications, and minimize intra- and interdialytic patient symptoms (57). The model prescribes half of the total treatment ultrafiltration volume to be removed in the first 90 minutes of treatment with a maximum of a total 12% blood volume change as registered on the NIVM monitor. The remainder of the ultrafiltration volume is then removed during the final hours of treatment.

DIALYSIS PRESCRIPTION

Initiation of Hemodialysis

The first few hemodialysis treatments may be associated with large transcellular osmolar shifts if the pretreatment blood urea nitrogen (BUN) levels are very high, with resultant disequilibrium syndrome, cerebral edema, and seizures. Maneuvers aimed at limiting large osmolar shifts include infusion of mannitol (0.5 g/kg over 1 hour starting 30 minutes into the treatment) or limiting the amount of clearance until the pretreatment BUN is lower than 100 mg/dL. The amount of urea reduction can be prescribed using the following equation:

$$-\ln(C_t/C_0) = Kt/V \quad [\text{Eq. 1}]$$

where C_t is the BUN concentration after t minutes of dialysis, C_0 is the time 0 or prehemodialysis BUN concentra-

tion, K is the urea clearance of the dialyzer (in milliliters per minute) at the blood flow prescribed, t is the duration of dialysis in minutes, and V is the patient urea distribution volume (total body water). The initial estimate of V is 600 mL/kg body weight. To prevent dialysis disequilibrium, one can prescribe a 30% urea reduction for the first treatment as depicted in the following example.

Hemodialysis is being initiated for a 13-year-old 50-kg girl with focal segmental glomerulosclerosis. A dialyzer with a surface area of 1.3 m² and a K of 210 mL/min at a Q_b of 200 mL/min is chosen. Her estimated V is 50 kg × 600 mL/kg, or 30,000 mL. To determine the duration of dialysis needed to effect an approximate 30% urea reduction, the equation is solved as follows:

$$\begin{aligned} -\ln(70/100) &= 210 \text{ mL/min} \times t/30,000 \text{ mL or} \\ 0.35 &= 210 \text{ mL/min} \times t/30,000 \text{ mL} \\ t &= 0.35 \times 30,000 \text{ mL}/210 \text{ mL/min or} \\ t &= 51 \text{ min} \end{aligned}$$

A pretreatment and posttreatment BUN level should be measured for the first treatment. Using the measured C_t and C_0 from the first treatment, one can solve for V and obtain a more accurate estimate of the patient's total body water. The new V can be used to prescribe an approximate 50% clearance for the second treatment, and this iterative process can be repeated to prescribe an approximate 70% urea clearance for the next few treatments. Once a prescription is found that maintains the pretreatment BUN at a relatively consistent value below 100 mg/dL, the adequacy of the patient's dialysis can then be evaluated more formally.

Hemodialysis Adequacy

The concept of hemodialysis adequacy is derived from the mechanistic analysis of the National Cooperative Dialysis Study (NCDS) published in 1985 (58). A main result inferred from the NCDS was a higher probability of "patient failure" (i.e., patient death or hospitalization) in adult patients who received lower doses of hemodialysis and/or had worse nutrition. The definition of hemodialysis adequacy that should ensue from the NCDS result is the minimum amount of urea clearance and nutritional intake to prevent these failure outcomes (59–61).

Figure 71.4 graphically depicts the serum concentration changes of urea, or any readily dialyzable solute, during and between dialysis treatments. The total mass of urea removed during the treatment is based on the fractional reduction of urea during the hemodialysis treatment. The interdialytic accumulation of urea reflects the amount of protein catabolized during the time between dialysis treatments (62). In a steady state, this protein catabolic rate (in grams per day) is indicative of the amount of protein ingested by the patient and hence is a marker of nutritional status (63–69).

FIGURE 71.4. Changes in concentration of a readily dialyzed solute during (t ; hours) and between (Θ ; hours) hemodialysis treatments. C_0 depicts solute concentration at the beginning of dialysis. C_1 depicts the concentration of solute at the end of dialysis. The concentration fall during dialysis is depicted in a first-order fashion. Between treatments, the solute concentration increases in a zero-order fashion until it reaches the predialysis concentration, C_{01} .

Most studies of hemodialysis adequacy since the NCDS analysis have focused on refinement of Kt/V measurement and determination of the potential effect of the dose of hemodialysis on adult patient outcome. Decreasing all-cause mortality in adult hemodialysis patients has been correlated with progressively increasing Kt/V levels up to 1.3 (59). Current NKF-DOQI recommendations on dialysis adequacy in adult hemodialysis patients call for a minimum Kt/V of 1.2 (70). Although routine measurement of urea clearance by Kt/V has been reported for children receiving hemodialysis, there are no data on the association between delivered dialysis dose and outcomes for pediatric patients (71–78). Until such data are available, it is reasonable to provide children with at least a single-pool Kt/V of 1.2.

Formal urea kinetic modeling (UKM) solves two differential equations to yield the two variables of patient urea distribution volume (V_d , total body water in milliliters) and urea generation rate (G , in milligrams per minute). Treatment data needed for calculation of V_d are pretreatment and posttreatment BUN levels, the dialyzer urea clearance at a particular blood flow rate (K , in milliliters per minute), the hemodialysis treatment duration (t , in minutes), and the patient's pretreatment and posttreatment weight (in kilograms). Normalized urea clearance during hemodialysis can then be expressed by the unitless term Kt/V . Normalized protein catabolic rate (NPCR, in grams of protein per kilogram per day) is calculated from the urea generation rate (G) using the modified Borah equation (62).

The superiority of formal UKM over other methods for hemodialysis adequacy measurement resides in the ability of UKM to provide a unique solution for urea clearance by Kt/V and nutritional status by NPCR. Although formal UKM is recognized as the gold standard for hemodialysis adequacy measurement, evaluation of simpler surrogate methods to approximate Kt/V has been an active area of investigation. The natural logarithm formula of Daugirdas has been recognized and endorsed as the only valid alternative to formal UKM for Kt/V calculation in adults (28,78):

$$Kt/V = -\ln(C_1/C_0 - 0.008 \times t) + (4 - 3.5 \times C_1/C_0) \times UF/W \quad [\text{Eq. 2}]$$

where C_0 is predialysis BUN (in milligrams per deciliter), C_1 is postdialysis BUN (in milligrams per deciliter), t is session duration (in hours), UF is ultrafiltration volume (in kilograms), and W is postdialysis weight (in kilograms). The accuracy of the Daugirdas natural logarithm formula lies in its accounting for dialysis treatment duration and urea removed by ultrafiltration.

The natural logarithm formula has been shown to be a reliable and practical alternative to formal UKM for estimation of Kt/V in a large group of pediatric patients receiving hemodialysis (71,79,80) and has been validated in comparison with formal UKM in children. In this same study, NPCR was also accurately and reliably estimated using a urea generation rate derived from the difference between the posttreatment and pretreatment BUN levels:

$$\text{est}G \text{ (mg/min)} = [(C_2 \times V_2) - (C_1 \times V_1)]/t \quad [\text{Eq. 3}]$$

where C_1 is postdialysis BUN (in milligrams per deciliter), C_2 is predialysis BUN (in milligrams per deciliter), V_1 is postdialysis total body water (in deciliters; $V_1 = 5.8 \text{ dL/kg} \times \text{postdialysis weight in kilograms}$), V_2 is predialysis total body water (in deciliters; $V_2 = 5.8 \text{ dL/kg} \times \text{predialysis weight in kilograms}$), and t is time (in minutes) from the end of the dialysis treatment to the beginning of the following treatment. Then, estNPCR was calculated using the modified Borah equation:

$$\text{estNPCR} = 5.43 \times \text{est}G/V_1 + 0.17 \quad [\text{Eq. 4}]$$

where V_1 is total body water (in liters) postdialysis ($0.58 \times \text{weight in kilograms}$).

Single-Pool versus Double-Pool Kt/V

Kt/V calculation is based on sampling of pretreatment and posttreatment BUN level. In adults and children, the posthe-

FIGURE 71.5. Depiction of urea rebound after a hemodialysis treatment. Blood urea nitrogen (BUN) moves from the extravascular space to the intravascular space by first-order kinetics until it reaches equilibration, a process that occurs over 30 to 60 minutes.

modialysis BUN concentration rises in a logarithmic fashion until equilibration occurs 30 to 60 minutes after a hemodialysis treatment (73,81,82). This rise in BUN concentration has been termed *urea rebound* (Fig. 71.5). As the BUN rises with equilibration after hemodialysis, the resultant calculation of Kt/V yields lower values. Urea rebound includes the early phenomena of access and cardiopulmonary recirculation, that is, the flow of the most recently dialyzed blood through urea-rich tissues and the later process of transcellular movement of urea after the cessation of dialysis.

Calculation of Kt/V by single-pool kinetics (spKt/V) using the immediate, 30-second postdialysis BUN ($BUN_{30\text{ sec}}$) sample does not take urea rebound into account and leads to overestimation of the true urea mass removed during dialysis. Calculation of Kt/V by double-pool kinetics (eqKt/V) is based on a postdialysis BUN level actually determined through blood draw or estimated after the completion of urea rebound. Numerous studies of both children and adults have demonstrated that urea rebound ranges from 7.6 to 24.0% and accounts for a 12.3 to 16.8% difference between spKt/V and eqKt/V values (72–76). Despite inaccuracies, single-pool kinetic assessment has remained in use at some centers as a matter of convenience.

Because it is impractical to wait 1 hour after a treatment to obtain an equilibrated BUN (eqBUN) level for calculation of eqKt/V, several formulas have been devised to estimate eqKt/V by applying a cofactor to spKt/V and relying solely on a pretreatment and 30-second posttreatment BUN level (74,83–85). Because urea rebound is primarily characterized by a first-order logarithmic, concentration-dependent movement of urea from intracellular fluid to extracellular fluid, a more recent method (73) for estimating eqBUN extrapolates the rise in BUN from 30 seconds to 15 minutes after treatment (ΔBUN). Because urea rebound is 69% complete at 15 minutes after dialysis (72),

eqBUN can be estimated (estBUN) using the following formula:

$$\text{estBUN} = [(BUN_{15\text{ min}} - BUN_{30\text{ sec}})/0.69] + BUN_{30\text{ sec}} \quad [\text{Eq. 5}]$$

The difference between eqKt/V using a measured eqBUN and estimated eqKt/V using the estBUN by logarithmic extrapolation was less using this approach than with other published eqKt/V estimation methods (83–85).

The important relationship between nutritional status and outcome for patients with ESRD prompted the NKF-KDOQI to create guidelines to assess for and treat malnutrition in both children and adults with ESRD. The pediatric NKF-DOQI guidelines recommend measurement of serum albumin level, height or length, dry weight, midarm circumference, skinfold thickness, fronto-occipital circumference, and height Z score to monitor nutritional status and intensive enteral nutrition administration to treat protein energy malnutrition (86). Data also show that prealbumin is a more sensitive measure of current nutritional status. Although these measures may be important to monitor for and treat protein energy malnutrition, they may not be sufficient in all cases. Many adult outcome studies use NPCR as an independent marker of nutritional status. NPCR is derived from the interdialytic rise in BUN levels and has been shown to correlate with nutritional status in adult patients receiving hemodialysis (65–67). Minimal investigation into the validity of NPCR has been carried out since the early 1980s and demonstrated a positive correlation between dietary protein intake and NPCR (67,68). These studies suggested that positive nitrogen balance, which is essential for growth, could be achieved with moderate protein intake and without an increase in dialysis requirements. Research is now showing NPCR to be more sensitive and specific than serum albumin as a marker for nutritional status in pediatric hemodialysis patients (69,87).

Provision of adequate nutrition is essential to the delivery of optimal dialysis. Research has correlated increased protein administration and urea clearance with improved growth in well-nourished children undergoing hemodialysis (77). Intradialytic parenteral nutrition has been used effectively to treat severe protein energy malnutrition in children receiving hemodialysis (69,88). Intradialytic parenteral nutrition is comprised of dextrose (70%) and amino acids (15%) and is delivered during the dialysis treatment to provide 1.3 g/kg of protein.

Medications for Patients Receiving Hemodialysis

The physiology and treatment for ESRD-related anemia, renal osteodystrophy, and growth failure are discussed elsewhere in Chapter 67. Just as advances have been made in hemodialysis techniques, ongoing advances are being realized in the development of intravenous forms of medications for treatment of complications of ESRD. As a result of these advances, recombinant erythropoietin (rHuEpo) rather than

red cell transfusion is administered during dialysis. Although higher rHuEpo doses may be required to correct anemia when given intravenously than when administered subcutaneously (89,90), ease of administration continues to make the intravenous route the preferred one in most pediatric dialysis units. Oral iron supplementation is rarely sufficient to maintain the iron stores, so treatment with intravenous iron complexes (iron dextran, ferric gluconate, iron sucrose) is necessary for optimum erythropoiesis (91–94). Investigation into maintenance intravenous iron dosing demonstrates decreased rHuEPO requirements with such dosing in both children and adult patients receiving hemodialysis (95–97). Intravenous forms of the vitamin D analogues calcitriol and paricalcitol are currently available to treat the secondary hyperparathyroidism associated with renal failure (98,99); pediatric dosing and efficacy trials are under way in the United States. Increased use of intravenous medications has led to increased nursing responsibilities during the hemodialysis treatment.

Acute Hemodialysis Considerations

The epidemiology and pathophysiology of acute renal failure are discussed in the Acute Renal Failure section. Acute hemodialysis requires the same type of equipment discussed earlier. Most acute dialysis access occurs via a temporary, uncuffed dual-lumen catheter placed in the femoral, internal jugular, or subclavian vein. Infants often require dialysis via two separate single-lumen venous catheters, for example, via umbilical vessels, because dual-lumen catheters may not be of appropriate size for their smaller vessel diameters. Many patients with acute renal failure are too ill to be transported to a chronic hemodialysis unit, so water treatment is accomplished using commercially available portable reverse osmosis machines. Many medications, including antimicrobials, anticonvulsants, sedatives, and chemotherapeutic agents, are removed by hemodialysis. Therefore, additional doses of these medications may be required during or after the hemodialysis treatment to maintain therapeutic serum concentrations. Patients who require two or more pressors to maintain normotension may be too unstable for intermittent hemodialysis and attendant intermittent ultrafiltration and might be treated more appropriately with continuous renal replacement therapy (100–102).

Acute hemodialysis is also indicated in certain clinical situations that are not accompanied by renal failure, such as tumor lysis syndrome in patients with newly diagnosed leukemia or lymphoma, and hyperammonemia in patients with inborn errors of metabolism and drug intoxications. In such clinical cases, close attention to and supplementation of the patient's serum phosphorus and potassium are required, because protracted hemodialysis can rapidly lead to hypophosphatemia and hypokalemia in a patient with normal renal function. Hemodialysis is indicated for the elimination of a toxin if there is a potential clinical benefit to the patient of removing the

toxin more quickly than the endogenous clearance rate, if a significant amount of the toxin can be removed, and if there is a clear relationship between the blood levels of an agent and toxic effects. Toxins that can be successfully removed by dialysis are distributed in body water, have low molecular weights, and are not bound to plasma or tissue proteins.

HEMODIALYSIS FOR INFANTS

Although all pediatric hemodialysis requires specialized nursing and medical expertise, hemodialysis for neonates is an especially complicated procedure. As noted previously, neonatal-sized blood tubing is available to minimize the blood volume of the extracorporeal circuit. The neonatal tubing is one-fourth the diameter of standard tubing, so the blood pump speed must be quadrupled to deliver the same blood volume per minute (e.g., an apparent Q_b of 160 mL/min on the dialysis machine yields an actual blood flow of 40 mL/min through the dialyzer when neonatal tubing is used). Even with smaller neonatal tubing, the extracorporeal volume is usually greater than 10% of the patient's blood volume, so the circuit should be primed with packed red blood cells mixed to a concentration of 35%.

Current volumetric hemodialysis machines produce an ultrafiltration accuracy of 50 to 100 mL, which is acceptable for most pediatric patients but is not tolerable for neonates. Digital scales, which are accurate to within 10 g, can be placed under an infant warmer and help guide ultrafiltration during a neonatal hemodialysis treatment.

OPTIMAL PEDIATRIC HEMODIALYSIS

Evaluation and refinement of methods and technologies addressed in this chapter have been important steps toward establishing an evidence-based standard of optimal care for children receiving hemodialysis. Optimal pediatric hemodialysis care requires not only attention to these specific medical and nursing areas but also provision of adequate psychosocial, educational, and dietary support to patients and their families. Child-life specialists lend critical expertise to provide developmentally appropriate evaluation and assistance for pediatric patients with ESRD, who undergo many surgical procedures and are faced with the never-ending cycle of dialysis and renal transplantation. ESRD-trained social work personnel are essential to assess the psychosocial development of children with ESRD and to assist families with the complex socioeconomic challenges and barriers associated with ESRD. Dieticians expert in the nutritional requirements and restrictions imposed by ESRD are vital to develop palatable menus for children with ESRD and to monitor a multitude of nutritional status markers, including weight, growth, body mass index, NPCR, mid-arm circumference, triceps skinfold thickness, and results of bioimpedance analysis.

Furthermore, relevant short-term and long-term outcome measures for children with ESRD are lacking. Although standard outcome measures used for adult patients, such as death and hospitalization rates, are important outcome measures for children, they are clearly insufficient. In addition, factors to assess adult health-related quality of life (HRQOL), including work status and sexual function, are not generally appropriate for a pediatric population. Other factors including growth, exercise capacity, school attendance and performance, self-reliance, and functional development are crucial components for assessing the HRQOL for a pediatric patient with ESRD. Currently, no HRQOL measurement tool exists that is specific for a pediatric patient with ESRD. In addition, few data exist to describe the physical functioning capabilities and limitations for children with ESRD, and the data that are available do not follow children longitudinally over extended periods and are not linked with an assessment of HRQOL (103–106).

Most research into the HRQOL of pediatric ESRD patients occurred a number of years ago (106–112). These studies demonstrate that, although pediatric patients with ESRD certainly have some developmental and psychosocial issues similar to those of children with other chronic illnesses, they also have challenges specifically related to ESRD. Obstacles common to most chronically ill children include physical changes related to illness, the need to take many medications and undergo medical treatment, and time away from school and peers, which can lead to perceived differences and isolation. Children with ESRD have additional challenges such as maintaining a restricted dietary and fluid regimen, chronic dependence on medical equipment to sustain life, very obvious physical changes associated with transplantation, and the knowledge that they will live their whole lives with the recurrent cycle of dialysis and transplantation. To date, no follow-up from these studies has been published.

Both the acute and chronic effects of hemodialysis on short-term and long-term outcomes must be assessed. Potential areas for investigation include evaluation of the effects of different ultrafiltration modeling algorithms on postdialysis thirst, fatigue, interdialytic weight gain, exercise capacity, and patient attitude toward dialysis. In addition, establishing pediatric vascular access monitoring standards with UD or other noninvasive techniques will likely prolong vascular access survival rates and decrease patient morbidity and hospitalization. Such studies can only help to optimize patient physical and psychological well-being.

MULTICENTER END-STAGE RENAL DISEASE REGISTRIES

Although long-term prospective interventional outcome studies must be multicenter in design and will likely follow patients from hemodialysis through transplantation, current

descriptive multicenter pediatric registries have been crucial to outline the state of pediatric ESRD-associated care.

Continued advances in acute and chronic hemodialysis treatment in children require accurate data on treatments and their outcomes in children. Improvements in hemodialysis techniques over the last 20 years have come from lessons learned in adults, results of single-center trials or surveys, and registry studies. The number of pediatric patients in even the largest pediatric centers is not large or diverse enough to provide sufficient data to optimally advance the practice of hemodialysis in children. Multiple national or multinational ESRD-related registries have been established in the last several decades, including the European Dialysis and Transplantation Association–European Renal Association (EDTA-ERA) registry, the United States Renal Data System (USRDS), the Canadian Organ Replacement Register (CORR), the Registry of the Japanese Society for Dialysis Therapy, and the Australia and New Zealand Dialysis and Transplant Registry (ANZ DATA) (113). Center participation in all the registries is voluntary with the exception of the USRDS. Few of the registries have a focus or special analysis of pediatric patients. Detailed description of these registries is beyond the scope of this text; however, an overview of selected registries with significant pediatric components follows.

The EDTA-ERA registry, the oldest and largest of the registries of renal replacement therapy, has collected data since 1964. It currently covers 670 million people in 36 countries in Europe and the Mediterranean coastal region and is funded by the European Renal Association, some participating countries, industry, and educational grants. Participation varies by country with 50 to 90% of patients included in the database (114,115). In 1970 a survey of the members of the European Society of Pediatric Nephrology found a death rate from chronic renal failure of 0.75 per 1 million total population. Although that figure was thought to be an underestimate, the decision was made to develop a separate registry for “pediatric cases” within the EDTA (115). Pediatric patients are defined as those younger than 15 years at the start of renal replacement therapy. In 1971 there were 296 children registered; this increased to a total of 8850 by 1990 with an overall rate of 4.6 children per 1 million child population. Survey materials include questionnaires sent to centers about current practices as well as individual patient questionnaires. There are yearly dialysis and transplant reports providing a snapshot of the characteristics and status of patients with ESRD. There have also been special studies examining topics such as oxalosis, focal segmental glomerulosclerosis, and rehabilitation in adults who received renal replacement therapy as children. These studies are conducted through occasional mini-questionnaires. Information is also collected on the number of children cared for in “pediatric centers,” defined by the presence of a pediatrician, a dietitian, a social worker, a child psychologist, school facilities, a children’s ward, and a

combined dialysis and transplantation program. In 1989, 77% of children were treated in pediatric centers (113).

The USRDS was established in 1988 with research funds from the National Institutes of Health with the following goals: to characterize patients receiving dialysis in the United States; to report trends in incidence, modalities, and outcomes over time; and to identify opportunities for more focused special studies (116). Data have been collected from Medicare-approved ESRD facilities since 1972 and include information on dialysis and transplantation. All patients whose treatment is paid for by the U.S. government are included in the United States, so the database includes approximately 94% of patients receiving dialysis in the United States. Data are transmitted through 18 regional ESRD networks to the Centers for Medicare and Medicaid Services (CMS; formerly the Health Care Financing Administration) and then to the National Institutes of Health. The data are analyzed by a coordinating center, currently at the Minneapolis Medical Research Foundation. Annual data reports are available at the USRDS web site, and individual investigators can download portions. Investigators can submit special data requests (117).

Subanalyses of pediatric dialysis and transplant patients, defined as those younger than 20 years of age, are performed using information in the USRDS database. In the 1997 to 1999 cohort, the ESRD incidence rates ranged from 7.0 per 1 million population for children 5 to 9 years of age to 26.5 per 1 million population for those 15 to 19 years of age (118). The data reported here have been supplied by the USRDS. The interpretation and reporting of these data are the responsibility of the authors and in no way should be viewed as an official policy or interpretation of the U.S. government.

In addition to the USRDS database analyses, CMS currently funds the ESRD Clinical Performance Measures Project based on periodic data collection involving a random sample of adult dialysis patients. Since 2000, a supplemental project has collected demographic data and information on dialysis adequacy, vascular access, management of anemia, and serum albumin levels on all in-center hemodialysis patients 12 to 18 years of age. The 2000 project included 433 patients. Seventy-nine percent of these had a mean calculated delivered Kt/V of more than 1.2; 41% had a catheter for vascular access; 55% had a mean hemoglobin level of more than 11 g/dL; and 83% had a serum albumin level within the normal range (119).

The North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) is a voluntary registry that includes children and adolescents younger than 21 years of age at the initiation of dialysis or transplantation who receive care at 130 pediatric dialysis centers in the United States, Canada, Mexico, and Costa Rica. NAPRTCS is unique among the registries described in this section in that it includes only pediatric patients. Investigators organized NAPRTCS, and the registry portion of this study is funded by grants from industry. The registry was organized in 1987

to study renal transplantation in children and adolescents; it was expanded in 1992 to include pediatric hemodialysis and peritoneal dialysis patients at participating NAPRTCS centers, and in 1994 also included children with chronic renal insufficiency who did not yet require renal replacement therapy. Data-gathering forms soliciting information on patient demographics, treatment characteristics (e.g., dialysis access type, erythropoietin and growth hormone treatment), school attendance, and adverse effects are collected at enrollment, at 30 days, and then every 6 months. A clinical coordinating center and data-coordinating center organize data collection and analyses. Annual reports are generated and circulated to the participating investigators and are available on the World Wide Web (<http://www.naprtcs.org>). Registry reports describing trends in treatment and outcomes are periodically published. The 1996 annual report summarized data collected from 1992 to 1996 on 2208 patients in whom 2787 courses of dialysis were carried out (27). The 2002 annual report listed 4886 children in the dialysis registry, 2184 of whom had had at least one course of hemodialysis. In addition, periodic special studies (in which additional data are collected) or special analyses (in which additional analyses of existing data are carried out) are performed. Special analyses or studies may be requested by participating center investigators. A special studies committee reviews such requests, and the performance of these studies is based on scientific merit, the amount of additional time that will be required by the center investigators and coordinators, and the cost. In some cases, investigators must solicit additional funding to perform special studies or analyses. The NAPRTCS organization has also performed prospective clinical trials, funded principally by the National Institutes of Health.

The strength of these registries lies in the numbers of patients included and their descriptions of patients, treatments, and outcomes in a defined region during a specific time period. In theory, the existence of multiple registries should allow comparisons of different patient populations and treatment practices. The registries also share the weakness of including centers that dialyze varying numbers of patients and have varying personnel responsible for data collection, which may affect the patient population and the nature of the data collected. These registries describe children with ESRD and the outcomes of their treatment in hopes of improving patient care. However, they can only generate and not test specific hypotheses. Therefore, there is room for a more selective multicenter study of pediatric hemodialysis to address the unanswered questions in the care of children requiring acute and chronic hemodialysis.

A multicenter prospective pediatric continuous renal replacement therapy registry has been established with the purpose of identifying optimal continuous renal replacement therapy intervention strategies and rapidly testing new devices and medications for the treatment of critically ill children with acute renal failure.

TRANSPLANTATION IMMUNOBIOLOGY

ALAN M. KRENSKY
CAROL CLAYBERGER

A basic understanding of the cellular and molecular basis of organ transplant acceptance and rejection helps in diagnosing and treating rejection more readily and prolonging allograft survival. Although much is already understood about the basic processes involved, the mechanisms of discrimination of self from nonself are complex. This chapter reviews current knowledge of the immunobiology of transplantation; another chapter discusses the current status of clinical renal transplantation.

MAJOR HISTOCOMPATIBILITY COMPLEX

A major function of the immune system is the discrimination of self from nonself. Although this system almost assuredly arose to allow the individual to keep out foreign infectious invaders, the same basic mechanisms are responsible for the cascade of events that result in organ transplant rejection. T lymphocytes recognize antigen as proteolyzed fragments (peptides) bound to major histocompatibility complex (MHC) molecules (1–3). MHC molecules, called HLA for human leukocyte antigens in the human, are polymorphic, and most individuals differ in their expression of these cell-surface antigens. When lymphocytes from one individual interact with cells from an unrelated individual, the lymphocytes recognize antigens on the unrelated tissue as nonself and are activated (called the *alloresponse*). These cells proliferate in numbers and differentiate to activate effector arms of the immune system (Fig. 72.1) (4–8). The major histocompatibility antigens responsible for these events are encoded by a cluster of genes on human chromosome 6 (Fig. 72.2) (9,10). These genes encode proteins of three distinct structural and functional groups, designated HLA class I, class II, and class III. The HLA class I antigens are constitutively expressed by most cells and tissues. They are composed of a 44,000-d polymorphic heavy chain associated with an invariant 12,000-d light chain, β_2 -microglobulin (encoded on chromosome 15). These class I antigens can be subdivided based on genetic clustering and sequence homologies into families designated HLA-A, HLA-B, and HLA-C.

Although HLA class I typing arose from microcytotoxicity assays using antisera, these reactivity patterns correlate well with the sequence information that has been obtained (11). The most common HLA class I type is HLA-A2, as originally identified by typing antisera. Subsequent serotyping, biochemical analysis, and sequence information shows that there is microheterogeneity within HLA molecules, which gives rise to subtypes within particular HLA families. For instance, there are currently 31 recognized subtypes for HLA-A2 and 16 for HLA-B27 (12,13). It is certain that the number of subtypes, based on sequence microheterogeneity, will continue to grow and that HLA types will prove to be even more complex than previously thought. Although the HLA-C antigens are structurally very similar to the HLA-A and HLA-B antigens, they are less polymorphic and do not elicit as strong an allogeneic response (antigenic response between individuals of the same species) as the HLA-A and HLA-B antigens.

The function of HLA class I molecules is to present peptide antigens to a subpopulation of T lymphocytes that perform specific functions, including HLA-restricted cytotoxicity and suppression (see later). The crystal structure of HLA-A2 revealed a groove on its external surface that allows a peptide to bind and in turn be “presented” to the immune system (Fig. 72.3) (14,15). Subsequent crystallographic studies showed that these peptides fit into anchoring pockets along the groove, which determines which peptides can fit into a particular HLA molecule and thereby be presented to the immune system (16). HLA class I molecules bind peptide antigens within the endoplasmic reticulum, which biases the peptides bound to those derived from intracellular (or endogenous) antigens (17,18).

HLA class II molecules are structurally and functionally distinct. They are constitutively expressed by a relatively small number of cell types—B lymphocytes, macrophages, monocytes, and follicular dendritic cells—but they can be induced by interferon and other agents on several other cell types, including T lymphocytes, endothelial cells, renal tubular cells, and pancreatic islet cells. HLA class II molecules are composed of a 44,000-d heavy chain associated

FIGURE 72.1. Cellular basis of transplant rejection. CD4+ T helper lymphocytes recognize HLA class II antigens expressed on allograft cells and release lymphokines, which in association with foreign antigens, activate the effector arms of the immune system. APC, antigen-presenting cell; CTL, cytotoxic T lymphocyte; IL, interleukin; IFN, interferon; NK cell, natural killer cell; TGF, transforming growth factor. (Adapted from Krensky AM. Molecular basis of transplant rejection and acceptance. *Pediatr Nephrol* 1991;5:422-427.)

with a 39,000-d light chain. Although both chains are polymorphic, most of the allelic polymorphism resides in the aminoterminal domains (α_1 and β_1), which correlates well with the key role these external parts are known to play in antigen presentation and T cell recognition (19). HLA class II molecules are divided into three subgroups: HLA-DR, HLA-DP, and HLA-DQ. These molecules bind peptides in compartments of the endocytic pathway and, therefore, generally present exogenously supplied antigens

(17,18). HLA class II molecules present antigen to helper T lymphocytes, which, in response, proliferate, amplify, and coordinate the immune response. HLA-DR antigens are the strongest inducers of the proliferative response to non-self. The specialized functions of HLA-DP and HLA-DQ antigens are less clear, although there is some evidence that HLA-DQ may be involved in tolerance induction (20) (see later).

HLA class III molecules are structurally and functionally more diverse (21). Included in this region are the genes for several proteins of the complement cascade, including C4, C2, and factor B (Bf). Although these molecules are important components of the effector arm of the immune response, they do not appear to be relevant to proximal events in transplant rejection.

Subsequent work uncovered non-class II genes in the class II region (22). Although several of these genes have no obvious relevance to the immune system, others are part of the antigen-processing machinery for HLA class I molecules. Two genes (*transporter associated with antigen processing 1*, or TAP 1 [RING 4], and TAP 2 [RING 11]) encode peptide transporters (23,24), whereas closely linked genes (*large multifunctional protease 2*, or LMP 2 [RING 12], and LMP 7 [RING 10]) encode components of a large cytoplasmic organelle, the proteasome, which generates peptide fragments (25,26). A current model (Fig. 72.4) suggests that intact antigen binds to the proteasome, which then degrades the protein into peptide fragments (27). These peptides in turn are pumped by the peptide transporters across the membrane of the endoplasmic reticulum, where newly synthesized HLA class I molecules, peptides, and β_2 -microglobulin associate to form the HLA molecules, which are then routed to the cell surface.

Minor Transplantation Antigens

Rejection episodes documented between HLA-identical siblings support studies in experimental animals that indicate that there are minor transplantation antigens (28,29).

FIGURE 72.2. Map of the human major histocompatibility complex.

FIGURE 72.3. Structure of HLA-A2. The α_1 and α_2 domains (dotted) form the peptide-binding site, with the groove in which the peptide binds and the face with which the T-cell receptor is thought to interact indicated at the top. β_2 -Microglobulin (hatched) and α_3 (heavily shaded) are immunoglobulin-like domains adjacent to the cell membrane. The diagram does not show the membrane anchor and cytoplasmic domains, which are at the carboxy end of the α_3 domain. N and C denote the amino and carboxy ends, respectively. The putative CD8 binding region is indicated in black. (Adapted from Bjorkman PJ, Saper MA, Samraoui B, et al. Structure of the human class I histocompatibility antigen, HLA-A2. *Nature* 1987;329:506–512; and Krensky AM, Weiss A, Crabtree G, et al. T-lymphocyte-antigen interactions in transplant rejection. *N Engl J Med* 1990;322:510–517.)

Numerous minor systems, all with limited polymorphism, have been identified in mice and can result in vigorous rejection between HLA-identical individuals. Because minor histocompatibility antigens are recognized as peptides in association with HLA molecules, rather than as intact antigens, it proved difficult to raise antibodies against them. The generation of T-cell clones and elution of peptides from HLA molecules, however, has allowed the molecular characterization of at least some of these antigens (30,31). Peptides derived from self-proteins that vary among members of the same species function as minor histocompatibility antigens. Examples include mitochondrial proteins and gender-associated antigens (e.g., H-Y) (30,31). The large number of single-nucleotide polymorphisms identified in humans suggests the theoretical opportunity for a very large number of minor histocompatibility mismatches.

ALLOGENEIC RESPONSE

Molecular Basis of the Alloresponse

The immune response between genetically unrelated individuals of the same species, designated the alloresponse, is largely due to the proliferative response induced by HLA class II molecules and cytolytic response directed at HLA class I molecules (4,7). The process by which HLA differences lead to graft rejection is a variation on the normal function of these molecules as described earlier, although the precise role of HLA-associated peptide in the alloresponse remains incompletely defined (4,32).

The allogeneic response is stronger than the T-cell response against nominal antigens, such as viruses. There are at least 100-fold more peripheral T lymphocytes primed to react to nonself HLA than there are T lymphocytes capable of recognizing self HLA plus a particular antigen, such as influenza. The explanation for this probably lies in the natural high affinity of T-cell receptors for HLA antigens. T cells must go through the thymus before they appear in the periphery. It is in the thymus that T cells with appropriate self-reactivity are selected (educated to self). T cells with too high an affinity for self HLA are deleted (negative selection), whereas those with “proper” affinity are selected (positive selection) (Fig. 72.5) (33,34). T cells with too low an affinity die due to a lack of positive selection. Because T cells do not know in advance what the particular self HLA polymorphism will be, the T-cell repertoire must cover the entire spectrum of HLA types. In organ transplantation across an HLA barrier, T cells that escaped negative selection in the thymus may now (in the periphery) encounter donor HLA antigens for which they have very high affinity. This natural affinity of T-cell receptors for HLA molecules may in part account for the magnitude of the allogeneic response. An alternative explanation is that there is “molecular mimicry” between HLA-plus-peptide combinations such that nonself HLA plus X is recognized as self HLA plus Y (35).

FIGURE 72.4. Antigen-processing machinery. It is postulated that antigens are proteolyzed into peptide fragments in proteasomes located in the cytosol. Peptides enter the endoplasmic reticulum via specialized transporters and associate with HLA class I molecules. β_2 -Microglobulin associates with the peptide-HLA heavy chain complex, and mature HLA molecules are routed to the cell surface. (Adapted from Parham P. Transporters of delight. *Nature* 1990;348:674–675; and Robertson M. Proteasomes in the pathway. *Nature* 1991;353:300–301.)

FIGURE 72.5. Positive and negative selection. T lymphocytes are selected in the thymus for proper affinity to self HLA. T cells with too low an affinity for self are not positively selected; T cells with too high an affinity for self are deleted by negative selection. Only T cells with receptors with “proper” affinity for self are positively selected and emerge from the thymus. TCR, T-cell receptor. (From Krensky AM. Immunologic tolerance. *Pediatr Nephrol* 2001;16:675–679, with permission.)

There remains the question of the precise molecular nature of the alloantigen. Is the strong allogeneic response directed at the HLA molecule devoid of peptide, with a particular peptide, or with any peptide? Rammensee and his colleagues shed light on this important question (36,37). Anchoring pockets in the HLA molecule restrict the peptides that can fit into a given HLA molecule. HLA-A2, for instance, tends to bind peptides with a leucine or methionine at position 2 and a valine or leucine at position 9 (36). HLA-B27, on the other hand, contains peptides that have an arginine at position 2 and an arginine or lysine at position 9 (38). Thus, HLA molecules have a restricted pattern of peptides that they are capable of binding. In some cases, it appears that the T cell recognizes these anchor positions in the context of the HLA molecule, whereas in other instances one particular peptide or perhaps an empty molecule may be recognized (32,35–39). Thus, the robustness of the allogeneic response depends not only on the natural affinity of T-cell receptors for HLA molecules but also on the variety of different T cell–peptide–HLA interactions that can result in allorecognition.

Cellular Basis of the Immune Response

The immune response in general, and allogeneic response in particular, are orchestrated by T helper cells, which recognize HLA class II antigens (Fig. 72.1) (4,40,41). A T lymphocyte has on its surface a clonally restricted T-cell receptor (42,43). These T-cell receptors structurally resemble immunoglobulin molecules with variable, constant, and joining regions. The variable and joining regions determine antigen specificity and account for the specificity encoded in the T-cell repertoire. In addition, T cells express other

invariant cell-surface molecules that are associated with the antigen-specific T-cell receptor. These include the CD3 complex (42,44) and the CD4 and CD8 molecules (45) (Fig. 72.6). The CD3 complex consists of three invariant dimers, CD3 ϵ - γ , ϵ - δ , and ζ - ζ , that transduce signals from

FIGURE 72.6. The T-cell receptor complex. The T-cell receptor α and β chains are linked by disulfide bonds to form a heterodimer that recognizes peptides associated with HLA molecules on the target cell membrane. CD3 polypeptides form invariant dimers that are thought to function in signal transduction. The CD8 molecule transiently associates with the T-cell receptor complex and recognizes invariant sequences of the HLA class I α_3 domain. P, phosphorylation sites. (Adapted from Krensky AM, Weiss A, Crabtree G, et al. T-lymphocyte-antigen interactions in transplant rejection. *N Engl J Med* 1990;322:510–517.)

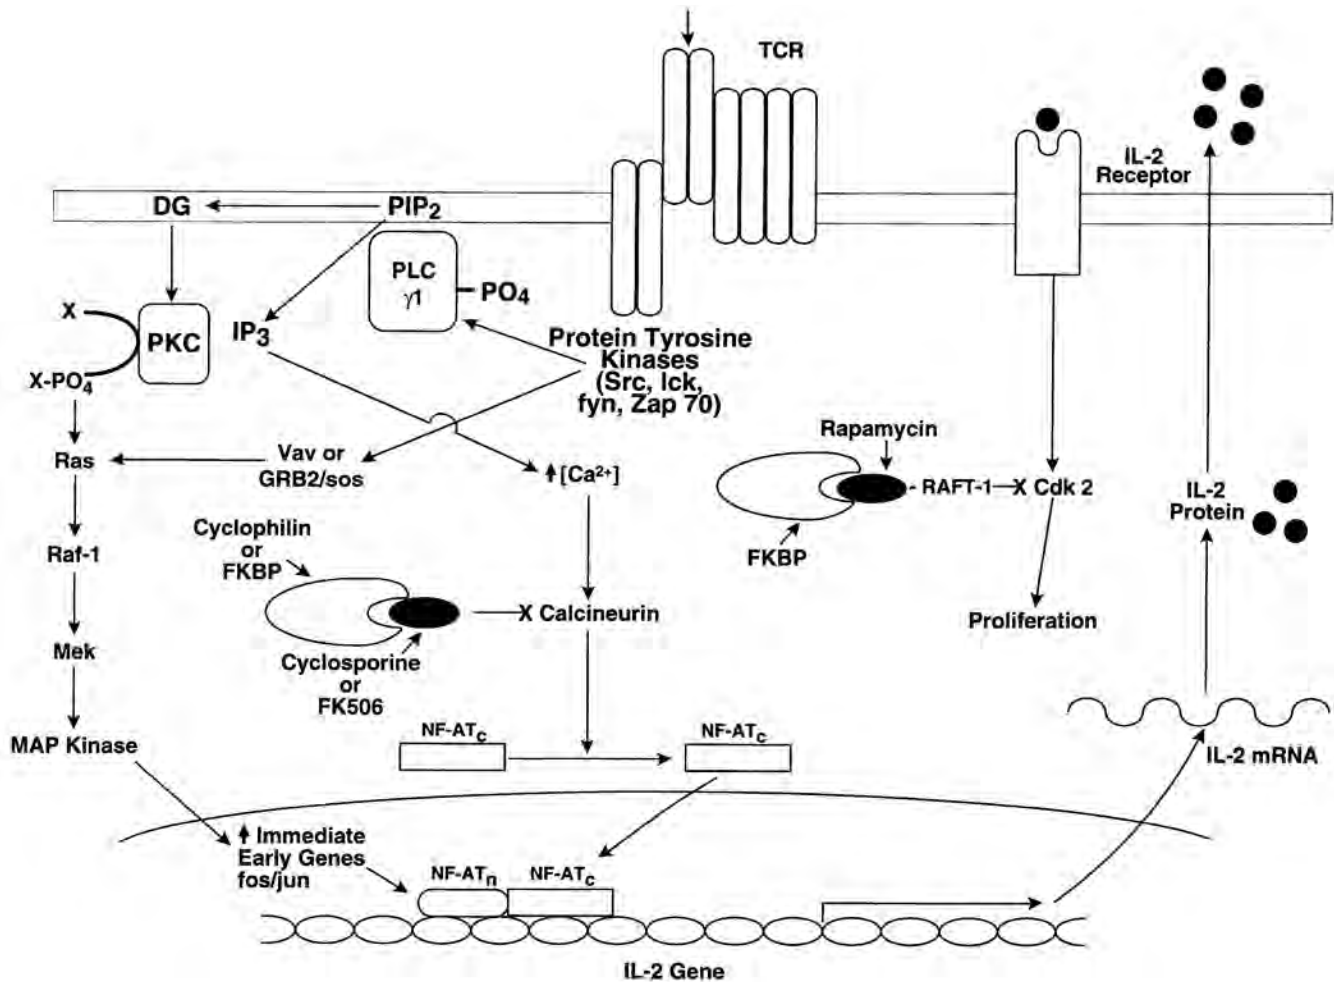

FIGURE 72.7. Cytoplasmic and nuclear events in T-cell activation. Triggering of the T-cell receptor (TCR) complex by specific antigen activates phospholipase C (PLC), tyrosine kinase, protein kinase C (PKC), and calcium ion flux. Through as yet undefined pathways, these cell surface biochemical events induce the transcription of activation-associated genes in the T-cell nucleus. For details, see references 4, 48, and 49. DG, diacylglycerol; FK506, tacrolimus; FKBP, FK506-binding protein; IL, interleukin; IP₃, inositol 1,4,5-triphosphate; MAP, mitogen-activated protein; mRNA, messenger RNA; NF-AT_c and NF-AT_n, cytoplasmic component and nuclear component, respectively, of nuclear factor of T-cell activation; PIP₂, phosphatidylinositol 4,5-bisphosphate. (From Clayberger C, Krensky AM. Mechanisms of allograft rejection. In Neilson EG, Couser WG, eds. *Immunologic renal diseases*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2001:321–346, with permission.)

the antigen-specific T-cell receptor into the cell (see later) (42,46). The CD4 and CD8 molecules, on the other hand, function as “co-receptors” in antigen recognition (45,47). Most mature peripheral blood lymphocytes express either CD4 or CD8. CD4 binds and recognizes HLA class II molecules, whereas CD8 interacts with HLA class I. Therefore, most helper T lymphocytes, which tend to recognize HLA class II molecules, are CD4⁺; most cytotoxic T lymphocytes recognize HLA class I antigens and express CD8.

Thus, when specific T-cell receptors on CD4⁺ helper T lymphocytes of a transplant recipient encounter foreign HLA-DR antigens on a transplanted organ, the helper T lymphocytes are triggered (4,48,49). Signals are sent from the T-cell receptor complex into the T cell (46,48). Several

pathways are activated, including the flux of calcium across the T-lymphocyte membrane, a phosphatidylinositol signaling pathway, protein kinase C, and tyrosine kinases (Fig. 72.7) (46,48). The connections between these biochemical events near the cell surface and the ensuing functional events have become increasingly clear. The cytoplasmic domains of the T-cell receptor invariant chains contain a common motif that couples these proteins to intracellular protein kinases. *Src* family members, *lck* and *fyn*, interact with these antigen recognition activation motifs, which results in the phosphorylation of the motifs and recruitment of ZAP70 kinase to the membrane receptor complex. Both CD4 and CD8 bind *lck* through a common cysteine-containing motif, bringing *lck* into proximity of the T-cell receptor complex

TABLE 72.1. LYMPHOKINES

Name	Biologic activities
IL-1	Activates resting T cells, stimulates lymphokine synthesis, activates macrophages and endothelial cells, has multiple other effects
IL-2	T-cell growth factor; induces lymphokine synthesis, activates cytotoxic T cells
IL-3	Multicolony-stimulating factor, mast cell growth factor; shows histamine release activity
IL-4	B- and T-cell growth factor; induces HLA-DR; enhances cytotoxic T-cell activity, immunoglobulin isotype regulation (induces IgE), mast cell growth factor
IL-5	B-cell growth and differentiation factor; enhances IL-2-mediated killer cell induction, eosinophil colony-stimulating factor
IL-6	B-cell growth factor; myeloid growth factor; T-cell costimulatory activity; induces HLA class I expression, immunoglobulin secretion, and hepatic acute-phase proteins
IL-7	B- and T-cell growth factor (stromal cell factor)
IL-8	Neutrophil chemotactic and activating factor
IL-9	T-cell, mast cell, erythroid (hematopoietic) growth factor
IL-10	Cytokine synthesis inhibitory factor, B-cell-derived T-cell growth factor, mast cell growth factor; increases MHC class II expression
IL-11	Megakaryocyte stimulatory factor
IL-12	NK (natural killer) cell stimulatory factor
IL-13	B-cell growth and differentiation factor; inhibits macrophage inflammatory cytokine production
IL-15	T-cell growth factor; IL-2-like in action
GM-CSF	Granulocyte, eosinophil, and macrophage colony formation, histamine release activity
IFN- γ	Induces MHC and other cell surface antigen expression; activates macrophages and endothelial cells; antiviral
TNF- α	"Cachectin," direct cytotoxin for tumors; induces acute-phase responses, induces lymphokines, stimulates macrophages and endothelial cells, mediates inflammation
TNF- β	"Lymphotoxin"; induces MHC expression, B-cell growth factor, antiviral; activates endothelial cells, granulocytes, and osteoclasts

GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IgE, immunoglobulin E; IL, interleukin; MHC, major histocompatibility complex; TNF, tumor necrosis factor.

and perhaps stabilizing the interaction. The role of interacting nonenzymatic proteins as the structural core of T-cell receptor signaling has been elucidated (49). Scaffolds, adaptors, and linkers, including linkers of activated T cells (LAT), SH2 (*src* homology 2)-containing leukocyte-specific protein of 76 kDa (SLP-76), and SLP-76-associated phosphoprotein of 130 kDa (SLP-130), are thought to coordinate signaling pathways by performing anchoring, targeting, and kinetic thresholding functions (49).

In a related but separate pathway, tyrosine phosphorylation of *vav* activates the *ras* signal transduction pathway. The oncogene *ras*, a guanosine triphosphate-binding protein with guanosine triphosphatase activity, interacts

directly with Raf-1, a serine-threonine kinase, which regulates a cascade of kinases, including Mek and MAP (mitogen-activated protein) kinase. These events lead to the binding of c-fos and c-jun transcription factors to the interleukin (IL)-2 promoter. With the nuclear factor of activated T lymphocytes (NF-AT), these factors lead to the transcription of new genes, such as IL-2, in T lymphocytes (50). Immune cells are triggered to make soluble mediators (cytokines or, when made by leukocytes, ILs), which in turn trigger specific effector arms of the immune system (Fig. 72.1) (48,50). For example, activated helper T lymphocytes make IL-2, a potent inducer of lymphocyte proliferation, as well as upregulate IL-2 receptors on their surfaces. These cells then induce themselves to proliferate and differentiate (autocrine stimulation) as numerous other well-characterized factors are elaborated by the helper T lymphocytes (Table 72.1) (51–53). These include interferon-gamma, which induces both the de novo and increased expression of HLA class II antigens, which in turn amplify the stimulation, as well as families of chemoattractants, growth and differentiation factors, and lytic effector molecules (51–53) (see later).

When a CD8⁺ precytolytic T lymphocyte recognizes an HLA class I molecule and receives stimulation by growth factors, including IL-2, IL-4, and IL-5 from nearby helper T lymphocytes, it too proliferates and differentiates (54). These cells in turn are capable of damaging and eventually killing target cells by at least two processes (Fig. 72.8) (55–57). In one process, cytolytic T lymphocytes release granules that contain perforin, granzymes, and granulysin. Perforin is a complement C9-like molecule that makes pores in target cells, which results in osmotic lysis within minutes (55). Granzymes are serine esterase molecules that enter through the pores and rapidly induce the disintegration of target cell DNA and cell death (56). Granulysin is a member of the saposin-like family of proteins and induces apoptosis via caspase-dependent and caspase-independent mechanisms (57). The second process results in apoptotic cell death after interaction of cell surface molecules Fas and Fas ligand. Fas is a transmembrane 48,000-d glycoprotein that shares homology with tumor necrosis factor (TNF)- α . Cross-linking Fas by antibody or binding to its natural ligand (Fas ligand) induces cell death characterized by DNA fragmentation (58).

Some of the factors produced by the CD4⁺ helper T lymphocytes (IL-4, IL-5, and IL-6) induce resting B cells, which express cell surface immunoglobulin specific for donor antigens, to proliferate and differentiate (59,60). Fully differentiated B cells become plasma cells and make large amounts of specific antibody. Antibody in turn binds target tissues, leading to direct destruction by binding complement or directing cell-mediated cytotoxicity by K cells (61) (Fig. 72.1).

Natural killer (NK) cells, macrophages, eosinophils, and granulocytes also respond to factors made by helper T lymphocytes.

FIGURE 72.8. Mechanisms of cytotoxic T lymphocyte-mediated cytotoxicity. Granules containing perforin and granzymes mediate a secretory pathway for target cell lysis. A nonsecretory pathway involves the interaction of Fas (CD95) on target cells with Fas ligand on cytotoxic T lymphocytes. MHC, major histocompatibility complex.

phocytes and contribute to graft dysfunction and rejection (50–53).

TRANSPLANT REJECTION

The cellular and molecular events described earlier account for only some of the well-characterized pathologic and clinical patterns of rejection (62,63). The rejection process is more complex than the classical patterns of (a) hyperacute rejection associated with preformed antibodies (Fig. 72.9A,B) and (b) acute/subacute to chronic rejection associated with cellular infiltrates (Fig. 72.9C–E). Increasingly, chronic forms of rejection associated with vascular and interstitial changes (Fig. 72.9F) have been appreciated (64). These may result from the elaboration of cytokines and other factors that are still poorly understood. Both immunologic and nonimmunologic factors contribute to chronic allograft rejection (65).

Hyperacute rejection is characterized by immediate and massive damage to the allograft (66). Preexisting antibodies to ABO, HLA, and other polymorphic antigens bind the allograft endothelium and activate complement. The result is fibrinoid necrosis of the vessel walls, platelet and fibrin thrombus formation, mononuclear and polymorphonuclear cell infiltration, and ischemic necrosis within minutes to hours. Although the cause of sensitization (pregnancy, transfusion, previous transplants) is not always apparent, routine crossmatching has virtually eliminated this fulminant type of rejection.

The histologic hallmark of acute/subacute rejection is the infiltration of the graft with T cells and injury to parenchymal cells (67). Macrophages, NK cells, and granulocytes are also variably present. Foreign HLA class II antigens in the graft are recognized by circulating immune cells. This

antigen-presenting function may be performed by “professional” antigen-presenting cells, resident macrophages, dendritic cells, or passenger leukocytes. There is now considerable evidence, however, that B cells (and even endothelial and epithelial cells), once induced to express HLA class II antigens, can perform this function, which triggers CD4⁺ helper T lymphocytes and activates the cascade of events described earlier (Fig. 72.1) (68).

Almost immediately after triggering, T cells upregulate the expression of several cell surface receptors that are important in cell adhesion and intracellular signaling (Table 72.2) (69–75). As these molecules are expressed or increased in expression, cells begin to adhere to the vascular endothelium (margination) (Fig. 72.10). After a brief period of “rolling” (weak attachment), they adhere firmly and eventually invade the endothelium and enter the renal parenchyma (76). Like immune cells, endothelial and parenchymal cells regulate expression of various cell surface receptors on activation or injury (74). Vascular endothelial cells downregulate certain receptors and upregulate others. These new molecules serve as ligands for the receptors newly expressed on T lymphocytes (Table 72.2), and these new adhesive interactions control immune cell adhesion to the vessel wall and entry into the graft tissue (76,77). New receptors, many of which are members of the integrin family of cell surface α - β heterodimers (Table 72.3), are expressed on T cells and bind to extracellular matrix components, thereby regulating immune cell movement through the tissues (75–81).

Chemoattractant cytokines (chemokines) are pivotal in attracting immune cells into the allograft (Fig. 72.10) (82). Stressed tissues in the allograft release proinflammatory cytokines, such as IL-1 and TNF- α , which in turn activate parenchymal cells to release chemokines that bind to glycosaminoglycans on the vessel wall and serve as signposts to attract immune cells. Immune cells bind to the vascular

Pathology of transplant rejection. **A:** Hyperacute rejection with edema of stroma, focal hemorrhage, thrombus formation, polymorphonuclear cell infiltration, and mesangiolysis. **B:** Hyperacute rejection 1 hour later, with tubular and epithelial cell necrosis and increased polymorphonuclear cell infiltration. **C:** Acute cellular rejection with inflammatory cell infiltration. **D:** Acute cellular rejection with "endotheliitis," inflammatory cells permeating the vascular intima. **E:** Acute cellular rejection with vessel wall infiltration. **F:** Chronic rejection with dense intimal fibrosis. (Courtesy Dr. Robert Colvin, Massachusetts General Hospital, Boston, Massachusetts.)

endothelium by haptotaxis and enter the tissue along a chemotactic gradient. Once T cells reach the site of antigen-specific triggering, they release additional chemokines, most notably RANTES (regulated upon activation, normal T cell expressed and secreted), which is expressed late (3 to 5 days) after T-cell activation and prolongs the process in time and space. The regulation of these events is complex

and, until recently, it was difficult to dissect the relative roles of the numerous chemokines present, because many chemokines and G-protein-associated chemokine receptors appeared redundant. Studies using "knock-out" mice, however, have begun to shed light on the relative roles, and specific inhibitors show dramatic therapeutic activity in preclinical animal models (83).

TABLE 72.2. RECEPTOR-LIGAND PAIRS IN THE INTERACTION BETWEEN T LYMPHOCYTES AND TARGETS

Receptor	Counterreceptor (ligand)	Reference
T-cell receptor	HLA and peptide	42
CD4	MHC class II	45
CD8	MHC class I	45
CD11a, 18 (LFA-1)	CD54 (ICAM-1), ICAM-2	70
CD43	CD54 (ICAM-1)	71
CD2 (LFA-2)	CD58 (LFA-3)	70
CD5	CD72	72
CD44 (Hermes)	Glycan bearing addressin	73
Leu 8 (Mel 14)	Glycan bearing addressin	74
ELAM-1	Glycan sialylated Lewis X antigen	74
VCAM-1	VLA-4	74

ELAM, endothelial-leukocyte adhesion molecule; ICAM, intercellular adhesion molecule; LFA, lymphocyte function-associated antigen; MHC, major histocompatibility complex; VCAM, vascular cell adhesion molecule; VLA, very late antigen.

As described earlier, CD4⁺ helper T lymphocytes orchestrate the further recruitment, activation, and functional differentiation of a variety of effector cells. They produce IL-2 and IL-4, which induce the proliferation and differentiation of T cells. Interferon-gamma, TNF- β , and IL-6 cause increased expression of HLA molecules. IL-4, IL-5, and IL-6 activate B cells, which in turn differentiate and divide. Some cytokines, including IL-1, TNF- α , and TNF- β , can directly cause cell damage. These events result in increased inflammatory infiltrate and upregulation of HLA expression. Extracellular matrix is damaged and destroyed by inflammatory proteases, and debris is phagocytosed by macrophages and granulocytes (84,85). Fibroblasts undergo morphologic changes and begin to produce large amounts of

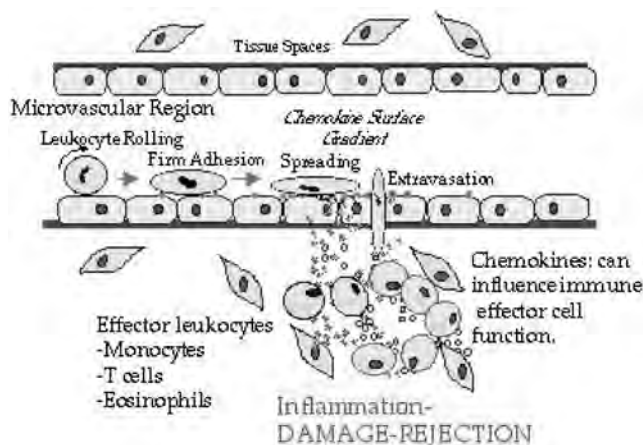

FIGURE 72.10. Chemokine gradients facilitate recruitment of inflammatory cells from peripheral circulation into sites of inflammation. This multistep process is central to the generation of inflammatory infiltrate in kidney transplant rejection. (From Nelson PJ, Krensky AM. Chemokines and allograft rejection; narrowing the list of suspects. *Transplantation* 2001;72:1195-1197, with permission.)

TABLE 72.3. EXTRACELLULAR MATRIX RECEPTORS ON LYMPHOCYTES

Name	Structure	Putative ligand(s)
Integrins		
VLA-1	<i>alpha</i> CD49a	<i>beta</i> CD29 Collagen, laminin
VLA-2	CD49b	CD29 Collagen, laminin
VLA-3	CD49c	CD29 Collagen, laminin, fibronectin
VLA-4	CD49d	CD29 Fibronectin
VLA-5	CD49e	CD29 Fibronectin
VLA-6	CD49f	CD29 Laminin
	CD51	CD61 Fibronectin, vitronectin, fibrinogen
Others		
CD26	Dipeptidyl peptidase	Fibronectin, collagen
CD44	Cartilage link protein	Hyaluronic acid
CD73	Ectoenzyme 5' nucleotidase	Fibronectin, laminin

VLA, very late antigen.

collagen, fibronectin, and proteoglycans; these are organized into new extracellular matrix, which results in scar formation (86). These highly regulated events are designed to maintain the structural integrity of the organ despite considerable parenchymal injury, but invariably, if not halted, they result in progressive loss of graft function.

The major problem associated with kidney transplantation is long-term graft loss, and this is usually due to an incompletely understood constellation of pathophysiologic events that have been collectively called chronic rejection or chronic allograft nephropathy (CAN). It is accepted that this entity is the end result of both immune-mediated and non-immune-mediated events (87), including elements of chronic rejection, chronic calcineurin inhibitor nephrotoxicity, and renal lesions resulting from multiple insults related to transplantation. Despite improvements in immunosuppression and a decrease in the incidence of acute rejection, the incidence of late graft loss due to CAN has remained essentially unchanged over the last decade. Clinically, CAN is defined as progressive and persistent renal allograft functional impairment not attributable to known entities such as recurrence of primary renal disease, vascular complications, overt drug toxicity, or acute rejection. The process is marked by a gradual rise in serum creatinine levels 90 days or more after renal transplantation and is accompanied by pathologic findings, including (a) fibrous intimal thickening that results in renal vessel occlusion and ischemic transplant glomerulopathy, (b) tubular atrophy, (c) interstitial fibrosis, and (d) mononuclear cell infiltration (88). Retransplantation is the only available therapy.

The pathogenesis and molecular events leading to CAN remain poorly characterized. Evidence to support the presence of underlying immune triggers to the development of CAN are the following: There is a correlation between the development of CAN and (a) the incidence of acute rejection (more than two acute rejections have been associated with a 12-fold increase in the incidence of chronic rejec-

tion), (b) the degree of HLA disparity, (c) the recipient's pretransplant sensitization state as reflected by panel-reactive antibody, and (d) a history of underimmunosuppression as reflected by low drug levels of immunosuppressives (88–90). In the absence of obvious immune-mediated injury, however, CAN sometimes still develops. There is an association between development of CAN and preexisting hypertension, hyperlipidemia, obesity, smoking, donor age, organ ischemia time, delayed graft function, cytomegalovirus infection, and bacterial infection (91–93).

Although it was originally believed that CAN was not impacted by current immunosuppressive protocols, more recent analyses of adult renal transplant cases indicates that long-term outcomes are improving, which suggests that better early immunosuppression and decreased acute rejection episodes do somewhat protect from CAN (94). Administration of mycophenolate mofetil (MMF) decreased the relative risk of chronic allograft failure by 27% (risk ratio, 0.73; $p < .001$) and improved censored graft survival (85.6% vs. 81.9% at 4 years) (95). In other studies, patients who experienced gradual loss of renal function while taking cyclosporine A, prednisone, and azathioprine therapy were transferred to alternate protocols in which azathioprine was replaced with MMF (96) or the dose of cyclosporine A was reduced in combination with MMF replacement of azathioprine (97). In both studies, there was a beneficial effect of replacing azathioprine with MMF, but reduction of cyclosporine A alone appears to slow the rate of renal deterioration (98).

IMMUNOPHARMACOLOGY OF GRAFT REJECTION

Although most of the drugs approved for use in organ transplantation have been developed as a result of drug screening and optimization by pharmaceutical companies, elucidation of the cellular and molecular events underlying the allogeneic response allows a better understanding of the mechanisms of action of existing therapies and potentially helps in the design of new immunotherapies.

Drug Therapy

General Approach to Organ Transplant Therapy

Organ transplant therapy is organized around five general principles:

1. Careful patient preparation and tissue matching are performed.
2. A multitiered approach is taken to immunosuppression, much like combination therapy in cancer chemotherapy. Several agents are used simultaneously, each directed at a different molecular target. Because the various immunotherapies described later inhibit rejection at different points, combination therapies can

provide additive or even synergistic immunosuppression without added toxicity (99,100). In addition, when therapies are combined, dosages can be decreased and toxicities further reduced.

3. Greater immunosuppression is required for promotion of early engraftment and/or treatment of established rejection than for maintenance. Therefore, more intensive induction and tapering maintenance therapies are used.
4. Careful evaluation of each episode of transplant dysfunction is required to clarify whether the cause is rejection, drug toxicity, infection, or some combination of these.
5. Drugs are reduced or withdrawn when toxicity exceeds the therapeutic benefit.

Current protocols often involve three or four different drugs in combination. Future protocols will undoubtedly use combinations of therapies to further alleviate the various side effects associated with current approaches.

Adrenocortical Steroids

Corticosteroids were the first drugs to prove efficacious for reversal of acute rejection. Steroids are currently used at moderate dosages for prevention of rejection and at high dosages for treatment of acute rejection (101). Steroids lyse and possibly redistribute lymphocytes, causing a rapid, transient decrease in peripheral blood lymphocyte counts. Longer term effects are due to the binding of either glucocorticoid receptors or glucocorticoid-induced proteins to DNA in the vicinity of response elements that regulate the transcription of numerous genes (Fig. 72.11) (102,103). Glucocorticoid-receptor complexes increase inhibitor of κ B expression,

FIGURE 72.11. Mechanism of action of steroids. Glucocorticoids bind receptors in the cytosol and are transported to the cell nucleus. These receptors and/or glucocorticoid-induced proteins bind to DNA in the vicinity of response elements that regulate the transcription of numerous genes. mRNA, messenger RNA.

decrease nuclear factor- κ B levels, and cause apoptosis of activated T cells (104). Of great significance is downregulation of important proinflammatory cytokines, such as IL-1 and IL-6, which are important factors in macrophage activation of T cells (51–53,105). T cells, in turn, are inhibited from producing IL-2 and proliferating. Neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release (106). Thus, steroids have broad immunosuppressive and antiinflammatory effects on T cells, monocytes, and neutrophils. Steroids have little effect, however, on humoral immunity (107). Because there are numerous responsive tissues and genes, steroids have multiple side effects, including growth retardation, avascular necrosis of bone, osteopenia, increased risk of infection, poor wound healing, cataract development, hyperglycemia, and hypertension. For these reasons, steroid-sparing and now even steroid-avoidance protocols are being evaluated (108,109).

Calcineurin Inhibitors

The most effective immunosuppressive drugs in routine clinical use are the calcineurin inhibitors cyclosporine and tacrolimus, drugs that target intracellular signaling pathways downstream of T-cell receptor triggering (110). Although these two drugs are structurally unrelated and bind to different (but related) molecular targets, their general mechanisms of action are similar (Fig. 72.12).

Cyclosporine

The discovery of cyclosporine and its application to organ transplantation was an important milestone (111). It improved graft survival for kidneys and made other types of organ transplantations a clinical reality. Cyclosporine, an 11-amino-acid cyclic peptide of fungal origin, is highly immu-

nosuppressive (112). Importantly, cyclosporine appears to be highly specific for helper T lymphocytes, while having little if any effect on other arms of the immune response (113). Cyclosporine inhibits transcription of IL-2 and other lymphokines (114). Because it acts early in T-cell activation, it has broad secondary effects on other cell types dependent on T-cell products, as well as late functions of T cells. Cyclosporine inhibits the DNA-binding activity of several proteins involved in regulation of early T-cell activation genes. Cyclophilin, a cyclosporine-binding protein, is identical to a peptidylprolyl *cis-trans* isomerase, which is required for the proper folding of many proteins (115). When it was discovered that another potent drug, tacrolimus (FK506), inhibits a similar isomerase (designated FKBP for FK506-binding protein), it was suggested that this was the mode of action of these most potent immunosuppressives (116). Subsequent data, however, demonstrate that the mechanism of action is more complex. The isomerase activity may not be involved; rather, it may be the proline-binding tendency of the various cyclophilins that is relevant.

A current model is shown in Figure 72.12 (117). The inhibitory drug-immunophilin complex blocks transcription regulated by a T-cell-specific activation factor, NF-AT (nuclear factor of activated T cells). NF-AT is composed of at least two subunits; one is widely expressed and localized in the nucleus, whereas the other is T-cell specific and is found in the cytoplasm of resting T cells. These subunits must associate for transcription of early T-cell-activation genes, including IL-2 and other cytokines, to occur. Cyclosporine or FK506 binds to its particular intracytoplasmic immunophilin (cyclophilin or FKBP), and, in turn, this complex binds a phosphatase, calcineurin, which is required for translocation of the cytoplasmic portion of NF-AT to the nucleus (118). If the NF-AT cytoplasmic component is not translocated to the nucleus, it cannot bind to the enhancers-promoters of IL-2 and other early activation genes, thus preventing T-cell activation and helper T-cell function.

When little or no IL-2 is secreted, T cells do not proliferate and the immune response is not amplified, interferon- γ is not secreted, HLA class II antigens are not induced, and macrophages are not further activated. Although such helper functions are potentially inhibited, cyclosporine therapy appears to spare or even support suppressor T cells (119). Cyclosporine also increases expression of transforming growth factor β (TGF- β), a potent inhibitor of IL-2-stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (120). Although cyclosporine is remarkably nontoxic to other hematopoietic lineages, its use is limited by its marked nephrotoxicity (121). The precise mechanism of nephrotoxicity is unknown, but it is clear that cyclosporine interferes with intrarenal blood flow (122) and that certain cyclosporine-binding proteins are expressed in high amounts by kidney cells (123). Other side effects of cyclosporine include hyperkalemia, hypertension, hepatotoxicity, hirsutism, and gingival hyperplasia.

FIGURE 72.12. Mechanism of action of cyclosporine. In the presence of cyclosporine, a cytoplasmic component of the nuclear factor of T-cell activation (NF-AT_c) is unable to gain access to the nucleus. As a result, the nuclear component of NF-AT (NF-AT_n) is unable to bind DNA, and there is no interleukin-2 (IL-2) gene transcription (117). *, activated.

Tacrolimus

Tacrolimus (FK506) is a macrolide that blocks T-cell activation by mechanisms similar to those of cyclosporine. Tacrolimus binds to binding proteins (FKBP). This complex, in turn, binds calcineurin and interrupts NF-AT translocation to the nucleus and IL-2 production (Fig. 72.12). Tacrolimus is more potent than cyclosporine on a molecular-weight basis (124) but appears to have similar limiting side effects, particularly nephrotoxicity (125). Other side effects include neurotoxicity (tremor, headache, motor disturbances, and seizures), gastrointestinal complaints, impaired glucose tolerance, and hypertension. Tacrolimus has slowly gained market share with cyclosporine over the past several years, largely due to ease of use and some differences in toxicity.

Antiproliferative and Antimetabolic Drugs

Sirolimus

Like tacrolimus, sirolimus is a macrolide that binds FKBP, but it does not block the transcription of cytokine genes. Rather, it inhibits signal transduction mediated by IL-2 and other growth factors, thereby blocking cell cycle progression from G₁ to S phase (126). One or more cellular proteins, mammalian target(s) of rapamycin (mTOR), bind the rapamycin-FKBP complex (127). These proteins have sequence homology to the catalytic domain of the P-110 subunit of phosphatidylinositol 3 kinase. Sirolimus and tacrolimus are pharmacologic antagonists, whereas cyclosporine and sirolimus may act synergistically. In addition, sirolimus blocks the transcription of a molecule required for cell cycle progression, PCNA (proliferating cell nuclear antigen) (128). In animal models, sirolimus inhibits both transplant rejection and autoimmune disease, as well as chronic vascular disease associated with rejection (129). Sirolimus causes diabetes in rats, but not in primates, and is reported to be less nephrotoxic than cyclosporine. Severe gastrointestinal and testicular toxicities described in animals (130) do not yet appear limiting for use in humans. The major limiting toxicity in humans is dose-dependent increase in serum lipid levels (131). Although sirolimus is not nephrotoxic on its own, in combination with cyclosporine, it carries an increased incidence of nephrotoxicity compared to the use of cyclosporine with azathioprine or placebo. Anemia, leukopenia, thrombocytopenia, hypokalemia, hyperkalemia, fever, and gastrointestinal complaints have also been associated with sirolimus use.

Azathioprine

Azathioprine (Imuran) was first introduced as an immunosuppressive agent in 1961 and continues to prove useful for the prevention of organ transplant rejection (132). It is a thiopurine, the *S*-imidazolyl derivative of 6-mercaptopurine, and is metabolized *in vivo* to 6-thioinosinic acid and other 6-mercaptopurine derivatives that become incorporated into DNA, inhibiting purine synthesis and metabo-

lism, hindering RNA and DNA synthesis, and blocking gene replication and cell proliferation (133). It is a powerful inhibitor of primary responses but does not block secondary responses and therefore is not useful for treatment of ongoing rejection (134). Early withdrawal of azathioprine increases the likelihood of rejection, whereas late withdrawal has less effect (135). Azathioprine inhibits most T-cell functions, including the mixed lymphocyte response, cytotoxic T lymphocytes, suppressor phenomena, NK cells, and antibody-dependent cellular cytotoxicity (136–138). In addition, it inhibits primary antibody synthesis and decreases circulating granulocytes and mononuclear cells. Its major side effect is bone marrow suppression, with leukopenia and (less frequently) thrombocytopenia or anemia. Other important side effects include increased susceptibility to viral infection (especially varicella or herpes simplex), hepatotoxicity, alopecia, and increased risk of neoplasia.

Mycophenolate Mofetil

MMF (CellCept) is the 2-morpholinoethyl ester of mycophenolic acid (139). Mycophenolic acid, like azathioprine, inhibits nucleotide biosynthesis (140). It is a selective, non-competitive, and reversible inhibitor of inosine monophosphate dehydrogenase, an important enzyme in the *de novo* pathway of guanine nucleotide synthesis (141). B and T cells are highly dependent on this pathway for proliferation, in contrast to other cell types that use salvage pathways. Mycophenolic acid, therefore, selectively inhibits lymphocyte proliferation and other functions, including antibody formation, cell adhesion, and migration (142). This drug is more potent and efficacious than azathioprine and reduces the incidence of acute rejection in combination therapy (143). In rodent models, it prolongs allograft and xenograft survival, reverses advanced rejection, prevents graft vascular disease, and induces alloantigen unresponsiveness (142). Its use, however, is limited by gastrointestinal and hematologic side effects, including diarrhea, constipation, nausea, vomiting, leukopenia, anemia, thrombocytopenia, and hypochromic anemia (144). There is also an increased incidence of some infections, especially cytomegalovirus-associated sepsis.

New Drugs

Although the rate of development of new drugs (corticosteroids, azathioprine, and cyclosporine) was relatively slow from 1950 to 1990, the profound success of cyclosporine provided additional impetus for pharmaceutical companies to develop new immunosuppressives. Several are currently in clinical trials and may become available for use. For the most part, however, these new drugs are merely variations on those previously developed. In general, they fall into the same families and have similar mechanisms of action. One drug with an apparently novel mechanism of action is FTY720. This drug has been shown to prolong allograft survival in a variety

of preclinical models and is being evaluated in several clinical trials (145). It is reported to alter lymphocyte recirculation and homing after modulation of chemokine G-protein-coupled receptors (146,147). Other drugs affecting chemokine function have shown promising results in preclinical models and may soon be evaluated clinically (83).

The relative efficacies, mechanisms of action, pharmacokinetics, and toxicities of these new drugs are currently being assessed. Preliminary results with all of these drugs are encouraging, and at least some will probably come into general use. There is hope that they may prove more efficacious than current drugs, but the potential for steroid-sparing, additive combinatorial effects and decreased myelotoxicities (azathioprine) and nephrotoxicities (cyclosporine and tacrolimus) make these new drugs potentially important. Perhaps the most exciting of the new drugs are those capable of inducing and maintaining immunologic tolerance (see later).

Antibody Therapy

Both polyclonal and monoclonal antibodies against lymphocyte cell-surface antigens are widely used for prevention and treatment of organ transplant rejection.

Polyclonal Immune Globulins

Purified gamma globulin fractions from polyclonal antisera generated by immunizing horses or rabbits with lymphocytes [antilymphocyte globulin (ALG)] or thymocytes [antithymocyte globulin (ATG)] are useful for preventing and/or treating acute allograft rejection (148,149). These preparations contain a heterogeneous group of antibodies that eliminate circulating T cells by several mechanisms, including clearance of lymphocytes by the reticuloendothelial

system, blocking of lymphocyte function by binding to important T-cell surface receptors, antibody-dependent cellular cytotoxicity, and classical antibody- and complement-mediated lympholysis (148–150). In addition, some reports suggest that these sera expand suppressor cell populations *in vivo* (151). Because each polyclonal immune globulin preparation varies in its constituent antibodies, variable and sometimes unpredictable efficacy and side effects are seen across batches. The lack of standardization has hampered assessment of various polyclonal antisera, but in general, they are highly efficacious for induction immunosuppression and treatment of acute rejection in combination with other drugs (152–154). A course of ALG is often used in patients with delayed graft function to allow withdrawal of nephrotoxic calcineurin inhibitors and thereby aid in recovery from ischemic reperfusion injury. Side effects vary among different preparations but include thrombocytopenia, granulocytopenia, serum sickness, and glomerulonephritis. Local pain, fever, urticaria, and hypotension are generally controlled by steroids and other premedications. Increased susceptibility to infection, particularly viral infections, has also been described.

Monoclonal Antibodies

Many of the problems associated with the lack of standardization of the polyclonal antisera were overcome with the advent of monoclonal antibodies. Kohler and Milstein described methodologies to generate essentially unlimited amounts of antibodies of a single specificity (Fig. 72.13) (155). Mice are immunized with human T lymphocytes, and the murine spleen cells are harvested and fused with a suitable B-cell myeloma that has been selected for the inability to grow in a medium supplemented with hypoxanthine, aminopterin, and thymidine (HAT). Only B-cell

FIGURE 72.13. Generation of monoclonal antibodies. Mice are immunized, and spleen or lymph node B cells are harvested and fused with a suitable B-cell myeloma that has been selected for the inability to grow in a medium supplemented with hypoxanthine, aminopterin, and thymidine (HAT). Only B-cell myeloma cells that fuse with mouse B cells can survive in a HAT-supplemented medium. After these hybridomas have expanded, those of interest are identified and cloned. Monoclonal antibodies can be used directly as culture supernatants or purified from supernatants or ascites fluid from mice injected intraperitoneally with the hybridoma. HPRT, hypoxanthinephospho-ribosyltransferase; Ig, immunoglobulin (155).

TABLE 72.4. SELECTED MONOCLONAL ANTIBODIES AT LEAST PARTIALLY EFFECTIVE AS IMMUNOTHERAPY FOR TRANSPLANT REJECTION

Target antigen	Reference
CD3	160
CD4	162
CD6 (T12)	163
CD8	164
CD11a, CD18 (LFA-1)	165
CD25 (IL-2 receptor)	166
CD45	168
CDw52 (Campath-1M)	169
CD54 (ICAM-1)	170

ICAM-1, intercellular adhesion molecule-1; IL-2, interleukin-2; LFA-1, leukocyte factor antigen-1.

myeloma cells that have fused with splenic B cells can survive in a HAT-supplemented medium. Once these hybridomas have expanded, those of interest can be identified and cloned. Many T-cell-specific and more broadly expressed antigens have been identified and characterized using such monoclonal antibodies, and many of these have been tested therapeutically (Table 72.4) (156–170). The two major groups of monoclonal antibodies used clinically are against the CD3 antigen and the IL-2 receptor.

OKT3

OKT3 was the first U. S. Food and Drug Administration–approved monoclonal antibody available for therapeutic use in transplantation in the United States (171,172). OKT3 antibody binds the 20,000-d δ chain of the CD3 complex. This antibody is a potent inhibitor of virtually every T-cell function. When the antibody binds to the T-cell receptor complex, this all-important recognition complex is shed from the cell surface and/or is internalized. Many CD3⁺ cells are destroyed (T-cell depletion). As a result, the T lymphocytes are unable to recognize the offending (allo)antigen, and the rejection process is blocked. Although OKT3 therapy is highly efficacious for reversing acute rejection (173), its use is limited by the propensity of the recipient to develop antiimmunoglobulin responses to the mouse portions of the antibody (174,175). Chimeric or “humanized” antibodies containing largely human sequences (176,177) still elicit antibody responses to the antigen-specific portions of the immunoglobulin molecule (antiidiotypic responses) (178) but in general are better tolerated. The major side effects associated with OKT3 therapy include fever, shaking chills, nausea, vomiting, diarrhea, headache, anorexia, weakness, and a capillary leak syndrome (179). This constellation of symptoms is thought to be due to T-cell activation and cytokine release induced by the OKT3 antibody. In general, this syndrome can be controlled with prednisone (180). In addition, treatment with “nonmitogenic” anti-OKT3 is less frequently

associated with such side effects. In any case, a decrease in the incidence of acute rejection episodes as a result of the use of mycophenolic acid, anti-IL-2 receptor monoclonal antibodies, and other therapies has resulted in decreased use of anti-OKT3 in general.

Anti-Interleukin-2 Receptor Antibodies

Monoclonal antibodies recognizing other T-cell surface molecules have been evaluated for use in transplantation but only anti-IL-2 receptor antibodies have gained general use. Daclizumab (Zenapax), a humanized murine complementarity-determining region/human immunoglobulin G1 chimeric monoclonal antibody, and basiliximab (Simulect), a murine-human chimeric antibody, have been produced by recombinant DNA technology (181). Both antibodies bind to the α subunit (CD25) of the IL-2 receptor present on activated, but not resting, T lymphocytes. They block IL-2-mediated T-cell activation. Both are used for prophylaxis against acute rejection as part of combination (induction) therapy (182).

Nonpharmacologic Immunosuppression

Nonpharmacologic immunosuppression can be provided in several forms. Plasmapheresis to remove antibodies has been attempted for acute vascular rejection, but this approach does not appear to be generally effective for treatment of acute rejection episodes (183,184). Splenectomy is controversial and is rarely performed. Although the immunosuppressive effects of pretransplantation splenectomy are clear, the risk of overwhelming infection outweighs the potential benefit (185). Irradiation is an effective immunosuppressive therapy (186). Although total-body irradiation was originally abandoned because of the high risk of infection, studies suggest that it may be a useful adjuvant, especially in the development of immunologic tolerance (187) or as rescue therapy for intractable rejection (188). Lastly, retrospective and prospective studies showed that blood transfusions were once beneficial for graft survival (189,190). The effect has diminished or disappeared in the cyclosporine era (191), however, and donor-specific or other transfusion protocols are seldom used today. Although the mechanism of the blood transfusion effect remains unknown, evidence suggests that donor cells, even blood cells, may be effective tolerogens for the induction of specific immunologic unresponsiveness (192) and may be useful in inducing tolerance.

TOLERANCE

Immunosuppression is predicated on blocking the immune response and is therefore associated with multiple unwanted side effects, including the occurrence of opportunistic infections and secondary tumors. It would be pref-

erable to work with the immune response rather than against it. Immunologic tolerance, then, defined as the active state of antigen-specific immune unresponsiveness, is the ultimate goal of transplant biologists.

Mechanisms

An individual who encounters a new antigen must constantly discriminate self from nonself, destroying harmful invaders while leaving self tissues unharmed. Owen first showed that immune responsiveness was an active process when he noted that freemartins, bovine twins who shared a common placenta, became hematologic chimeras and did not recognize their sibling's blood cells as foreign (193). This experiment of nature led Burnet to hypothesize that there was a critical period in development when the fetus learned to discriminate self from nonself and developed tolerance to self (194). Medawar and his colleagues showed that freemartins could in fact accept skin grafts from each other but would reject grafts from third parties and that similar "neonatal tolerance" would develop in mice that received allogeneic skin transplants (195). In fact, mice injected with foreign cells in the neonatal period maintained lifelong tolerance of the foreign-donor transplant antigens but still rejected third-party grafts. These seminal observations, which showed that the immune response could be manipulated to lose reactivity with a transplanted organ, laid the foundation for modern transplantation immunobiology.

There are several theories to explain immunologic tolerance. In clonal deletion, all of the T cells capable of recognizing a particular antigen are deleted from the T-cell repertoire. For example, mice expressing a certain HLA class II molecule (I-E) delete all T cells expressing a particular T-cell receptor variable region (V β 17) (34). This type of tolerance is induced while thymocytes are maturing in the thymus. Experiments in which tissues (glomeruli, pancreatic islets, or spleen cells) injected directly into the thymus induce transplant tolerance may work by inducing clonal deletion of recipient T cells capable of recognizing the injected cells (196,197).

Although T-cell deletion during ontogeny leads to immune tolerance, T cells that have exited the thymus can also be deleted. In the periphery, mature T cells can undergo apoptosis by two distinct pathways: activation-induced cell death (AICD) and passive cell death. AICD occurs in repetitively stimulated T cells and acts to limit the extent of the immune response. AICD is largely mediated through Fas and other members of the TNF receptor family and appears to require IL-2. Once activated, T cells upregulate expression of Fas and Fas ligand, and when these cells are brought together, as would occur on an antigen-presenting cell, the interaction of Fas and Fas ligand results in apoptosis. Interestingly, certain tissues such as testis and the anterior chamber of the eye are characterized by a state of immune privilege. These tissues constitutively express

Fas ligand, which triggers apoptosis in invading Fas⁺ T cells (198). Thus, these tissues are not rejected on transplantation into HLA-mismatched recipients. Passive cell death occurs when activated T cells are deprived of growth factors, perhaps due to the action of regulatory T cells. In addition, phagocytosis of apoptotic cells by macrophages often leads to production of IL-10 and TGF- β (199), which contribute to the development of tolerance (200).

Studies have shown that, once induced, tolerance can be "infectious"; that is, T cells from a tolerant animal can transfer tolerance to another animal. This observation led Gershon and Kondo to hypothesize that there were cells (which they called suppressor T cells) actively involved in dampening the immune response (201). Therapies such as cyclosporine (202), ATG (203), and total lymphoid irradiation (204) may induce suppressor cells. Moreover, it now appears that long-term maintenance of peripheral tolerance depends on self-perpetuating immunoregulatory mechanisms that actively inhibit alloreactive T cells. CD4⁺ regulatory T cells, first identified in 1990 (205,206), are now recognized as critical effectors in both the control of autoimmunity (207–209) and the maintenance of peripheral tolerance (210,211). The mechanisms by which CD4 regulatory T cells exert their effects remain controversial, however. Regulatory T cells inhibit production of IL-2 by the responding T cells (212,213). Suppression of T-cell proliferation by regulatory T cells appears to involve secretion of antiinflammatory cytokines such as IL-10 (214) and TGF- β (215), whereas in other cases suppression requires direct cell contact, possibly through cell-surface molecules such as cytotoxic T lymphocyte A4 (CTLA4) (216) or TGF- β (217).

Tolerance can occur during T-cell selection (central tolerance) or after T cells have moved into the blood and lymphoid organs (peripheral tolerance). Anergy is an important mechanism by which mature T cells are rendered tolerant. The interaction of the T-cell receptor with specific antigen in the context of self HLA activates the T cell only if a second signal is also provided (Fig. 72.14) (218,219). Thus, a T cell that does not receive the second signal will not be activated, proliferate, or differentiate into an effector T cell. Furthermore, these cells become anergic; that is, for a prolonged period of time, they will not respond to the appropriate antigenic stimulus even in the presence of the second signal. Addition of exogenous IL-2 can sometimes overcome this anergy, and, therefore, triggering the IL-2 receptor is one means of providing a second signal. Clinically, anergy appears to be inducible with soluble antigens, through either donor-specific transfusions (220) or soluble HLA molecules that seem to be released in liver transplantation (221). Provision of such first signals (tolerogens) without an accompanying second signal may be a potent and general means of inducing tolerance.

Several observations suggest that there may be different ways to provide a second signal. One of the best-defined pathways involves the interaction of the T-cell surface mol-

FIGURE 72.14. Two signals for T-cell activation. T cells require two signals to be activated to make interleukin-2 (IL-2) and proliferate. If the T-cell receptor complex is engaged without simultaneous provision of a second signal, the T cell is anergic, does not secrete IL-2, and does not proliferate (218,219).

ecule, CD28, with its ligands, B7-1 (CD80) and B7-2 (CD86), expressed on antigen-presenting cells (Fig. 72.15) (222,223). In humans, CD28 is constitutively expressed on 95% of resting CD4⁺ cells and 50% of resting CD8⁺ peripheral blood T cells. Its expression increases after T-cell activation. It has been known for some time that monoclonal antibodies to CD28 could activate T cells (222); in addition, B7 molecules are natural ligands capable of sending this intracellular signal (223). CD28 triggering activates a response element present in the promoter of the IL-2 gene, triggering IL-2 expression (224). CTLA4, another molecule highly homologous to CD28 but restricted in expression to activated T lymphocytes, is capable of binding B7 with even higher affinity (225). The signaling consequences of CTLA4 binding are quite different, however. CTLA4 “knock-out” mice die within 4 weeks of birth from uncontrolled activation and accumulation of T lymphocytes (226). This definitive experiment complements earlier studies that suggested that CTLA4 engagement sends a negative signal into the T cell, turning off activation. In contrast, CD28 “knock-out” mice lack a positive second signal, and T-cell responses are diminished (227). Thus, a pair of related ligands (B7-1 and B7-2) interact with a pair of T-cell surface receptors (CD28 and CTLA4) to dynamically control T-cell activation and deactivation. A soluble, recombinant form of CTLA4, called CTLA4Ig, binds with high avidity to both B7 molecules, inhibits T-cell–dependent antibody responses, prolongs transplant survival, slows autoimmune disease progression, and induces long-term donor-specific tolerance (228,229). Additional novel molecules, identified by mutation of CTLA4Ig, appear more potent and selective in their binding to the B7-1 ligand (230). Although blocking second-signal pathways appears to be an attractive alternative to providing tolerogen, there may be several different ways to provide the second signal, and many approaches may prove clinically useful. Never-

theless, ongoing studies of CD28-B7 and other receptor-ligand pairs will provide new insights into the mechanism of T-cell activation and, reciprocally, anergy.

Therapeutic Approaches

Based on preclinical studies in rodents and nonhuman primates, therapeutic approaches for induction and maintenance of immunologic tolerance are being evaluated clinically. These include donor cell chimerism, costimulatory blockade, immune deviation, and soluble HLA molecules.

Donor Cell Chimerism

Chimerism refers to persistence of donor cells in the peripheral blood of the recipient (231). This can be “macro” or “micro” depending on the percentage of donor cells circulating in the periphery. Both forms have been associated with long-term graft acceptance in both animal models and human patients (232). It is unclear whether these cells survive because of tolerance or whether they are responsible for induction and/or maintenance of tolerance. In general, approaches aimed at obliteration of the immune response with immunosuppressive agents is followed by provision of tolerogen as blood, bone marrow, or stem cells. Sachs, Sykes, Cosimi, and their colleagues reported the first deliberate induction of mixed lymphohematopoietic chimerism after a nonmyeloablative preparative regimen to treat hematologic malignancy and to provide tolerance for a kidney transplant (233).

Costimulatory Blockade

Costimulatory blockade is predicated on the two-signal model described earlier. Reagents that block costimulation, including anti-CD28, CD80, CD86, CD40, and CD40L,

FIGURE 72.15. CD28 second-signal pathway. Activation of the CD28 molecule by engagement with its ligand, B7, sends signals to a CD28 response element (CD28RE) present in the interleukin-2 (IL-2) gene promoter-enhancer, which results in transcription (224). NF-AT, nuclear factor of activated T lymphocytes; NF-IL-2B, nuclear factor of interleukin-2B; NF-IL-2D, nuclear factor of interleukin-2D; NF- κ B, nuclear factor- κ B; OAP, octamer binding protein.

as well as the chimeric molecule CTLA4Ig, are therapeutic in a variety of preclinical models and are beginning to be evaluated in clinical trials for immune-mediated diseases. Early studies appear to be limited by unexpected side effects.

Immune Deviation

Immune deviation is based on the concept that the helper T response involves two competing arms (234): the Th1 subset of helper T cells produces IL-2 and interferon-gamma, regulates cell-mediated immunity, and is associated with rejection. The Th2 subset produces IL-4, IL-10, and IL-13, and is associated with humoral immunity and tolerance. Immune deviation, switching from a Th1 to a Th2 phenotype, has been associated with tolerance in a number of model systems, although it is possible to have transplant rejection without IL-2 and transplant tolerance without IL-4 (235). The balance of such responses is dependent on the cytokine milieu, antigen-presenting cells, the strength of the T-cell receptor signal, and the array of costimulatory molecules expressed. The use of monoclonal antibodies against CD3 and other approaches can produce immune deviation experimentally and are being evaluated clinically.

Soluble HLA Molecules

HLA molecules function in antigen presentation to T cells and NK cells but also can inhibit immune responses in soluble form (236). Synthetic peptides composed of HLA amino acid sequences have unexpected regulatory effects *in vitro* and *in vivo* (237). They are antiproliferative, block cell cycle progression, and induce anergy and apoptosis. Such reagents have been evaluated clinically (238) and may

explain the transfusion effects associated with prolonged graft survival in the precyclosporine era (239).

XENOTRANSPLANTATION

As the demand for organs for transplantation increases, alternatives to both organs from living related individuals and cadaveric organs must be sought. One alternative is transplantation of organs from another species, such as other primates or pigs (240–242). Although successful xenotransplantation of primate kidney was accomplished several decades ago (243), most now would avoid using nonhuman primates because the number of organs these species might provide is few and because use of these animals as a source of organs carries the risk of fatal zoonotic disease. On the other hand, nonprimates such as pigs have as one advantage the fact that they can be genetically engineered. The xenoreaction triggers a different set of immune responses than the alloresponse. The first major immunologic hurdle to xenotransplantation is hyperacute rejection. As in allotransplantation, this process is characterized pathologically by interstitial hemorrhage and thrombosis, and the transplanted organ is destroyed within minutes. In pig to primate transplantation, however, this process is almost exclusively attributable to the binding of xenoreactive antibodies and activation of complement on blood vessels in the donor organ. Surprisingly, most xenoreactive antibodies recognize only one structure, Gal α 1-3gal (244,245), a saccharide expressed by lower mammals but not by humans, apes, or Old World monkeys. A variety of methods have been developed to overcome recognition of this sugar moiety. Specific depletion by solid-phase immunoabsorption (246), blocking by polymerized saccharides

or peptide mimotopes (247), and reduction or elimination of expression of the antigen via genetic engineering (248) have prevented (or, in the case of reduction of antigen expression, promise to prevent) hyperacute rejection. The role of complement has similarly been moderated by the administration of complement inhibitors (249) or expression by genetic engineering of cell-associated complement-regulatory proteins, such as decay-accelerating factor (CD55) and membrane inhibitor of reactive lysis (CD59) (250,251). These approaches also have successfully bypassed hyperacute rejection in a variety of models.

The second immunologic hurdle is acute vascular rejection. Endothelial swelling, focal ischemia, inflammation, and diffuse intravascular coagulation may begin within 24 hours of transplantation, but weeks may pass before the graft is destroyed. This form of rejection also appears to be mediated by xenoreactive antibodies and complement, but cellular components, including NK cells, also may be involved. Of particular interest, depletion of antidonor antibodies from the graft recipient results in a state of "accommodation," whereby enduring graft survival ensues even if antidonor antibodies later return to the circulation (252). The mechanism of accommodation is still unclear. Even if these vascular assaults are inhibited, it is possible that cell-mediated responses involving xenoantigen-associated peptides presented in the context of recipient antigen-presenting cells will provide yet another barrier. Perhaps current approaches aimed at immunosuppression or tolerance induction in the alloresponse will also prove useful in this regard. Even if all of these immunologic barriers are overcome, however, additional problems, such as potential zoonoses (infections passed from animals to humans) and animal rights issues, may prove limiting.

CONCLUSION

Clinical organ transplantation is at a crossroad. Progress in tissue typing, clinical care, and immunosuppression has made renal transplantation a safe and reliable therapy. Nevertheless, opportunistic infection, the increased potential for neoplasm, and poorly understood chronic vascular rejection persist. Therefore, although new and better immunosuppressive therapies should and will continue to be sought, the ultimate goal for clinical transplantation remains the attainment of specific unresponsiveness, immunologic tolerance. Although such tolerance can be routinely attained in animal models (253,254) and is occasionally reported in patients (187,255), we still do not understand how to reproducibly obtain this most desired outcome. Current experimental protocols are aimed at a three-step process: (a) obliterating the normal immune response with irradiation, immunosuppressive drugs, and/or antibody treatment (ATG or OKT3) followed by (b) providing donor-specific antigen (tolerogen) as blood or bone

marrow transfusion (256–258), and (c) allowing the immune response to return, now recognizing nonself as self. Such protocols suggest that future approaches to transplantation using organs from living related donors and organs from cadavers will diverge. For transplantation of organs from living related donors, antigen-specific treatments involving pretransplant irradiation and donor-specific tolerogens (transfusions, thymic injections, etc.) may in fact provide immunologic tolerance. Transplantation of cadaveric organs, on the other hand, does not allow sufficient time pretransplantation for such therapies. Without tremendous progress in longer-term tissue preservation, more classical approaches with better donor selection and more potent but less toxic immunosuppression may be the future. Although tolerance-induction protocols are still experimental, there is every reason to expect that we will someday be able to harness the immune response to provide normal protection from foreign invaders while still accepting the transplanted organ as self. When this is possible, transplantation will be a true cure for kidney failure.

PEDIATRIC RENAL TRANSPLANTATION

WILLIAM E. HARMON

INTRODUCTION

Role of Transplantation

Chronic dialysis and renal transplantation are both satisfactory treatments for end-stage renal disease (ESRD). The majority of adults with ESRD are receiving dialysis rather than undergoing renal transplantation, although the number seeking renal transplantation is continuing to rise substantially (1). There is a survival advantage of transplantation for virtually all candidates. Unfortunately, the lack of suitable donors has limited the number of people who can receive transplants. Renal transplantation was recognized as the better form of treatment for children with ESRD some two decades ago (2). Both peritoneal dialysis, delivered as continuous ambulatory peritoneal dialysis or continuous cyclical peritoneal dialysis, and hemodialysis lead to a deceleration of growth. Data from the dialysis component of the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) registry (3) showed that the overall height deficit of -1.8 standard deviation units at initiation of dialysis became more negative, reaching a value of -2.16 standard deviation units at 24 months. In addition, children do not tolerate being dependent on dialysis, and maintenance dialysis induces loss of self-esteem and emotional maladjustment (4). Cognitive achievement test scores may diminish with prolonged time on dialysis (5). In contrast, the mobility and freedom from dietary restrictions afforded by a functioning renal transplant enable children to live nearly normal lives despite complex immunosuppressive regimens. Although renal transplantation has resulted in normal growth for all children, dramatic short-term improvements in height can be seen in many, and final adult height is improving after transplantation (6–9). Most importantly, successful transplantation permits the child to attend school and to develop normally. School function test scores improve dramatically after transplantation (10,11). Importantly, young children now have the best long-term outcomes of all age groups among transplant recipients, which confirms the usefulness of transplantation in this age group (12). For all of these reasons, successful renal transplantation remains the primary goal for children with ESRD.

Incidence and Frequency of Transplantation

NAPRTCS has registered approximately 500 pediatric kidney transplantations each year since its inception in 1987, which account for 75% of all those performed in North America, and that number has remained relatively constant over the time span. In 2002, there were approximately 14,700 kidney transplants performed in the United States, which suggests that pediatric patients comprise approximately 5% of all transplant recipients. Although the number of pediatric transplants performed each year has not varied by more than 10%, the donor origin has undergone substantial changes. Data of the Scientific Registry of Transplant Recipients show that living kidney donation has expanded substantially, and the number of living donors (LDs) exceeded the number of cadaveric donors (CADs) for the first time in 2001 (1). Living donations now account for 43% of all kidney transplants in the United States. In 1987, only 40% of all transplants performed in children were from an LD source; by 1991, the figure had risen to 53%, and since 1998 LDs have accounted for over 60% of all pediatric renal transplants (Table 73.1) (13). Parents comprise 82% of LDs. Mothers comprise the majority of parent donors; fathers account for 46%. There is no outcome advantage to donation from one parent versus the other with the possible exception that infants younger than 1 year of age seem to experience fewer rejections if the mother is the donor (14,15). Due to the fact that children most often have siblings who are too young to donate (younger than 18 years), the NAPRTCS registry has recorded only 305 transplants between siblings. Of these, 150 grafts were from donors younger than 21 years of age. A review of the NAPRTCS registry data identified only 12 LDs under 18 years of age, of which 11 involved transplants between siblings and one a transplant from parent to child. It is quite clear that most programs are very reluctant to use young donors (16,17). However, a review of United Network of Organ Sharing (UNOS) data revealed that, of approximately 40,000 LDs in the United States between 1987 and 2000, 60 were donors younger than 18 years of age (18). Twenty-four of the recipients were children and 36 were adults; only seven of the transplantations were

Adapted from Seikaly M, Ho PL, Emmett L, et al. The 12th annual report of the North American Pediatric Renal Transplant Cooperative Study: renal transplantation from 1987 through 1998. *Pediatr Transplant* 2001;5:215–231.

between identical twins. There has been a substantial interest in organ donation by living unrelated individuals in the adult transplant literature because the outcome of the grafts has been shown to be better than that using cadaver source kidneys (19). NAPRTCS identified 123 transplantations involving living unrelated donors between 1987 and 2001. A preliminary analysis of the first 38 recipients of grafts from living unrelated donors showed that 23 (61%) were male, 30 (79%) were white, 8 were younger than 6 years of age, and 20 were older than 12 years of age (20). This was the primary transplant for 29 of the 38 recipients. Of the 38 donors, 22 were nonbiological parents, and family friends were the donors in 10 of the cases.

The majority of cadaveric kidneys used in children are recovered from adult donors. In the 1980s there was a tendency to preferentially place kidneys recovered from infants into infant recipients, which led to disastrous consequences for patient and graft survival (21). As a result of widespread dissemination of these data (22,23), there has been a marked change in this practice (Table 73.1). From 1987 through 1990, the percentage of CADs older than 10 years of age ranged from 59 to 68%. From 1991 through 1994, these percentages ranged from 78 to 88%. Before 1991, children younger than 2 years of age comprised 3.2% of CADs. In 1991, no pediatric recipient received a kidney from a CAD under 2 years of age; and in 1995 and 1996, there were no such kidneys used in children (24). Between 1991 and 2002, fewer than 1% (23 of 2464) of CADs for children were younger than 2 years of age (13). This change in allocation of kidneys from young donors led to improvement in graft survival (21). Some specialized pediatric programs have reported good results with young donors (25), but many programs reserve grafts from very young donors for en bloc transplantation into older recipients (26).

Primary Diagnosis

Because of the large NAPRTCS database, it is now possible to determine the percentages of each disease category leading to ESRD by age at transplantation as well as by gender and race. ESRD in children is generally due to congenital or inherited diseases. When 7651 transplantations were reviewed, the most common congenital diagnoses were found to be obstructive uropathy and aplastic-hypoplastic-dysplastic kidneys, each representing approximately 16% of

cases (13) (Table 73.2). Among glomerular disorders, focal segmental glomerulosclerosis (FSGS) is the most common; 873 children received a renal transplant for FSGS between 1987 and 2002. The primary diagnosis also varies with the race of the recipient. Overall in the NAPRTCS registry, white children account for 62% of all recipients; however, white children account for less than 50% of the children undergoing transplantation for FSGS. The data regarding the role of FSGS as a cause of ESRD can be better appreciated by observations from the dialysis section of the registry, in which the two most common diagnoses are FSGS and aplastic-dysplastic kidneys, each accounting for 14% of cases. White children make up only 34% of 733 children with FSGS on dialysis, with African American and Hispanic children accounting for 62% of these patients. Twenty-four percent of African American children on dialysis and 30% of those older than 12 years of age have FSGS. Table 73.2 shows the primary diagnoses by gender and race of 7651 children who have received a transplant as recorded by NAPRTCS since 1987, as well as the percentage of biopsy-proven diagnoses. It is important to observe that confirmation of the primary diagnosis by biopsy was made in 94% of patients with FSGS, 93% of those with systemic immunologic diseases, and 90% of patients with congenital nephrotic syndrome. The information regarding primary diagnosis becomes critical in predicting graft survival as well as recurrence of the original disease, as discussed later.

Age at Transplantation

Kidney transplantation in infants younger than 6 months of age or below a weight of 6 kg is exceptional. From 1987 to 2002, NAPRTCS recorded 81 transplantations performed in children younger than 12 months (13). Of these, 5 transplantations were performed in children between 3 and 5 months, 21 were performed in children between 6 and 8 months, and 55 were performed in children between 9 and 11 months of age. Only 12 infants have been reported to have undergone transplantation since 1996. In general, the number of kidney transplantations performed in infants and young children seems to be declining (Table 73.1). Because infants and adolescents have different risk factors for both patient and graft survival, children have been grouped into five age categories: 0 to 1 year, 2 to 5 years, 6 to 12 years, 13 to 17 years, and 18 to 21 years of age. It had been suggested that children 0 to 5 years of age

Adapted from Seikaly M, Ho PL, Emmett L, et al. The 12th annual report of the North American Pediatric Renal Transplant Cooperative Study: renal transplantation from 1987 through 1998. *Pediatr Transplant* 2001;5:215-231.

were at higher risk for graft failure (27,28). In 1987, 25% of all pediatric transplantations were performed in children 0 to 5 years of age (29), whereas in 1995, the same age group accounted for 15%, and in 1995 the figure was 17% (24). Currently the proportion is 17% (13). Whether the decreased number of transplantations in this group is due to an awareness of the vulnerability of these children or to improvements in dialysis has not been established. It is important to note that excellent results have been obtained in very young patients at some centers (30,31). The concept that the immune response is heightened in young recipients is currently controversial (32-34). Thus, the unique problems associated with transplantation in young recipients may be related to infections, technical issues, and differences in immunosuppressive drug pharmacokinetics (14,35-38) rather than immune response. Reports of outstanding long-term graft survival rates in these young chil-

dren seem to indicate that their specific problems can be overcome successfully (12).

Indications for Transplantation

Because of the shortage of donors for kidney transplantation, the evaluation of potential recipients and the indications for transplantation have been reviewed (39,40). Virtually all children reaching ESRD are considered to be candidates for renal transplantation. In some settings, the definition of ESRD is related to the need for chronic dialysis to sustain life. Currently in the United States, dialysis is rarely indicated in adults until the creatinine level has exceeded 8 mg/dL. The definition of dialysis dependency is inadequate in pediatrics, however, because a significant number of children receive a preemptive kidney transplant without ever having been on dialysis (41). In a review of

7053 primary kidney transplantations in children from 1987 through 2002, NAPRTCS noted that 1713 (24%) of the patients had never received maintenance dialysis (13). In the past, growth failure was considered one indication for transplantation, but the success of recombinant human growth hormone therapy in overcoming this complication of chronic renal insufficiency (CRI) in children (8,42) has virtually eliminated growth failure as an absolute indication. A very disturbing result from an analysis of UNOS data was that African Americans in the United States are less likely to be wait-listed for transplantation at any time after their first dialysis treatment than are whites (43). The point at which a child with CRI should be considered for renal transplantation remains controversial.

Preemptive Transplantation

Because preemptive transplantation is an important treatment modality for children, NAPRTCS conducted a special study to determine the frequency and outcome of this approach (41) and has updated it in the annual reports (13). From 1987 through 1992, 26% of the patients were registered as having had preemptive transplantation. The study compared data for those recipients who had been on maintenance dialysis and for patients who had had no previous dialysis. Of 2213 primary transplantations during that time period, 1150 grafts (52%) were from an LD source, whereas in the preemptive group 70% were recipients of an LD kidney. More recently, of 7053 primary transplantations, 1713 (24%) were preemptive. Preemptive transplantation was more common in those receiving LD grafts (33%) than in those given CAD grafts (13%), and was more common in males (27%) than in females (20%). The rate of preemptive transplantation varied among age groups and was 20%, 24%, 28%, 27%, and 20% for the 0- to 1-year, 2- to 5-year, 6- to 12-year, 13- to 17-year, and 18- to 20-year age groups, respectively. It also varied by race, with whites, African Americans, Hispanics, and "other" races showing rates of 30%, 14%, 16%, and 16%, respectively. As noted earlier, African Americans were also less likely than whites to be wait-listed after initiation of dialysis (43). One objection to preemptive transplantation has been that, if the patient did not undergo the rigors of prior dialysis, compliance with the immunosuppressive regimen might be poor. To determine whether this hypothesis was correct, graft survival was compared for the two groups and was determined not to be different at 1 or 4 years (41). When causes for graft loss were analyzed, the preemptive group did not have a higher incidence due to noncompliance. NAPRTCS also surveyed the motives for preemptive transplantation and determined that the primary reasons were parents' desire to avoid dialysis (34%) and the nephrologist's recommendation (18%). Desire for improved growth was considered a contributory factor for 50% of patients (41).

Contraindications to Transplantation

There are few absolute contraindications to transplantation. The concern of further immunosuppressing an already compromised host makes positivity for human immunodeficiency virus (HIV) in children a relative contraindication. Many children who develop HIV nephropathy succumb to the systemic ravages of the virus, either before or very shortly after reaching ESRD status (44). However, marked advances in the treatment of HIV-positive patients, especially treatment with protease inhibitors and other antiretroviral agents, makes consideration of kidney transplantation more likely (45,46). Ironically, initial results from a few centers suggest that HIV-positive patients with reasonable CD4 cell counts may have more problems with rejection than with infection after transplantation.

Another relative contraindication is a preexisting malignancy. The NAPRTCS dialysis registry contains 70 children with Wilms' tumor or Denys-Drash syndrome (47). Thirteen of these did not receive a transplant because of metastatic disease and all 13 died. The transplant registry lists 86 children who have these diagnoses and who have received a kidney transplant, and no recurrences of malignancy have been reported in any of them. The outcome of those who received transplants was similar to that in recipients without Wilms' tumor or Denys-Drash syndrome. Children with already existing metastatic disease are generally not considered transplant candidates, however. Also, children with devastating neurologic dysfunction may not be suitable transplant candidates, but the wishes of the parents, as well as the potential for long-term rehabilitation, must be considered in these circumstances. Potential for recurrence of the original renal disease is of major concern but generally has not precluded at least an initial transplant. Oxalosis, which once was considered an absolute contraindication due to a high incidence of recurrence, can be treated successfully with combined liver and kidney transplantation (48,49), although the complication rate remains high (31,50,51).

PRETRANSPLANTATION PREPARATION

Recipient Preparation

Before a child can undergo transplantation, the problems caused by CRI must be addressed and remedied if possible. In those cases in which ESRD is due to urologic abnormalities, corrective reconstructive surgery should be undertaken, especially to the lower urinary tract, before transplantation. Two of the major consequences of CRI are anemia and growth retardation, which should both be addressed before transplantation. A report of final height in pediatric renal transplant recipients suggests that the current improvement in final adult height after transplantation is related more to improvement of height deficits before transplantation than to any net gains achieved after transplantation (8,9). Uremia

also leads to wasting and undernutrition in the child, and this can compromise the success of the procedure. For example, prophylactic native nephrectomy and reversal of protein wasting and malnutrition improve the outcome of transplantation in children with congenital nephrotic syndrome (52–54). Careful preparation is particularly important in children undergoing preemptive transplantation. Although there are descriptions of evaluation of the adult transplant recipient (39,40), there are no similar published reports for pediatric patients. Nonetheless, Table 73.3 details typical preparation used before surgery for pediatric recipients.

Urologic Evaluation

Children with the diagnoses described in Table 73.4 require a thorough urologic evaluation before transplantation. In the NAPRTCS report, 1878 of 7651 pediatric transplant recipients (25%) were identified as having lower urinary tract abnormalities (13). For all such patients, a history of voiding pattern before development of renal failure is most helpful. Preliminary investigations consist of measurement of urinary flow rate and ultrasonographic estimation of the postmicturition urine volume. Urinary flow rate should be at least 15 mL/sec (55), and the residual volume should be less than 30 mL. Further investigations would include ure-

Vesicoureteral reflux

throcytostomy in patients suspected of a urethral stricture, and a voiding cystometrogram is essential for complete assessment of bladder function (56). This provides information about bladder capacity, pressure rise, and the efficiency of voiding. Still more information can be obtained by combining the urodynamic studies with radioisotope imaging. Routine voiding cystourethrography is not indicated in older patients without lower urinary tract symptoms (57).

A bladder with a very small capacity may not be adequate for a functioning transplant. Occasionally a small-capacity bladder may be seen in patients with prolonged oliguria or anuria. If the bladder is distensible and the bladder wall compliant, however, such a bladder may be used safely in kidney transplantation. Other criteria for a useable bladder are an end-filling pressure lower than 30 cm H₂O and a good flow rate. In patients with a poor flow rate, if urethral and bladder outlet obstruction are ruled out, the problem may be due to detrusor malfunction (55). When a bladder fails to empty completely, infection and obstruction are potential complications that may shorten graft survival. Intermittent, clean self-catheterization, which is widely used in urologic practice, can be safely used after transplantation in patients in whom the primary abnormality is inefficient, uncoordinated detrusor function.

Most pediatric patients have a urinary bladder that will adapt to the new kidney. Although the bladder may not appear to have the capacity, especially in patients on long-term dialysis before transplantation, it will most often distend with usage (48). However, in patients with a truly low capacity or high pressure, bladder augmentation may be necessary before transplantation (58–60). Augmentation cystoplasty consists of adding bowel or gastric wall to the bladder. In substitution cystoplasty, most of the bladder is excised and replaced with bowel. The use of gastric remnants for augmentation has been popular; however, such remnants do tend to cause excessive loss of acid in the urine, which leads to discomfort and metabolic alkalosis. Attempts to reconstruct bladders with bioengineered material are ongoing. There are promising reports of bioengineered bladder material, although these have not yet been tried in transplant recipients (61,62). In those patients in whom augmentation has been performed before transplantation, long-term antibiotic therapy and intermittent catheterization may have to be used to prevent urine stasis and infection. In a very small subset of patients whose bladder is

unusable and in whom augmentation is unsuccessful, some form of urinary diversion may be necessary (48).

Pretransplantation Blood Transfusions

In the precyclosporine era blood transfusions were shown to have a beneficial effect on graft outcome (63), but their effect subsequently diminished (64) and they are currently rarely used. The early beneficial effect of pretransplant transfusions in children was similar to that seen in adults. In the past, donor-specific transfusions were also given to children. Early results from such studies suggested better graft survival; however, more prolonged follow-up with improved immunosuppression showed diminished benefit (65), and the use of donor-specific transfusions has now been largely abandoned in pediatric renal transplantation. However, two reports of the beneficial effects of deliberate pretransplant transfusions have renewed interest in their use (66,67). Because of the theoretical advantages of pretransplant tolerance induction by antigen presentation, their possible use remains intriguing (68).

The role of random pretransplantation transfusions in improving graft survival remains unclear. In 1992, NAPRTCS, in a study of 1667 transplants of which 57% were of CAD origin, did not observe any beneficial or detrimental effect of pretransplantation blood transfusions (29). Subsequently, however, a deleterious effect of pretransplantation transfusion became apparent. For LD source transplants, the use of five or more prior transfusions was associated with graft loss with a relative risk (RR) of 1.8 (22). By 1995, the use of prior transfusions was found to be a risk factor for CAD source transplants as well, and the use of five or more transfusions was associated with graft loss with an RR of 1.3 (3). The 1996 NAPRTCS report, which analyzed 4714 transplants, showed that the use of more than five transfusions was associated with graft loss with an RR of 1.7 for LD grafts and 1.3 for CAD grafts (24). An NAPRTCS special analysis indicated that multiple transfusions have a deleterious effect on graft survival, but fewer than five transfusions may be associated with a decreased incidence of acute rejection episodes (69). Sixty-five percent of pediatric LD renal transplant recipients and 56% of CAD recipients now receive no random transfusions before transplantation, and donor-specific transfusion is rarely performed (13). Pretransplantation blood transfusions would be of only historical interest except for a renewed interest related to tolerance induction and the reports mentioned earlier (66,67). Whether they will be used in the future for this indication is unknown.

Effect of the Age of the Cadaver Donor

For many years there was a tendency to use kidneys recovered from infants and young children for transplantation into young recipients (21). Early studies showed that 25% of all cadaver transplants used in children were recovered from children under 10 years of age (29). A special NAPRTCS

study (70) demonstrated that the preferential placement of small kidneys into infants and very young children had disastrous consequences for graft survival, and this was subsequently confirmed by a larger study (71). As a result, CAD allocation policies for pediatric recipients were changed, which led to improved outcome (21). More recent information shows that this practice has now undergone substantial change (13). Since 1991, fewer than 1% of cadaver kidneys for pediatric recipients have come from donors younger than 2 years of age. During the same time, the percentage of kidneys recovered from donors over the age of 10 years increased from 78% to 88%. Importantly, the kidneys from young donors have not been discarded but have been used for transplantation into adult recipients via the en bloc technique (26,71,72). Single centers have reported better success with grafts from young donors, using carefully controlled protocols (25). Advanced donor age is also associated with diminished long-term graft survival (73,74), and likely should be avoided for young recipients (70,75,76).

HLA Matching Results in Children

For CAD transplants the NAPRTCS registry data indicate that a 2-DR mismatch graft has a relative hazard (RH) of first rejection of 1.27 and an RH of graft failure of 1.21 ($p = .002$) compared to a 0-DR mismatch (13). These outcomes are consistent with the relationship between histocompatibility matching and graft outcome in adults (77,78). Unfortunately, because children have waiting-time preference in the CAD waiting list in the United States, HLA matching is poorer for them than for adults (12). Because most LDs of renal transplants for children are parents, these transplants are mismatched at one haplotype.

ABO Blood Type in Children

NAPRTCS has recorded 27 confirmed kidney transplants across ABO blood group compatibility barriers. Of these, most are O recipients of grafts from A donors. An NAPRTCS special study of 11 of these patients concluded that the procedure could be successful if performed under carefully controlled conditions (79). Evaluation of recipient isohemagglutinin levels may be helpful to identify suitable donor-recipient pairs. A more recent strategy for ABO mismatching entails "donor swaps," either with a complimentary donor-recipient pair or with a recipient on a CAD waiting list (80,81).

TRANSPLANTATION PROCEDURE

Technical Issues in Transplantation

The operative technique for transplantation differs depending on the weight of the child. For small children of less than 15 kg, the transplantation is frequently performed through a

FIGURE 73.1. Technetium 99m–mercaptoacetyl triglycerine radionuclide renal scan for a 9-month-old infant who received a living-donor renal transplant from his father. The graft is intraperitoneal and occupies most of the right side of the peritoneal space. Note the relative sizes of the graft and the heart.

midline incision, and the larger vessels are used for anastomosis with the donor kidney (48). After reflection of the cecum and the right colon, the anterior wall of the aorta and the inferior vena cava are exposed and dissected (82). The aorta is mobilized from above the inferior mesenteric artery to the external iliac artery on the right side. After the lumbar branches are ligated and divided, the iliac arteries and the inferior mesenteric are encircled. Next the inferior vena cava is mobilized from the left renal vein to the iliac veins. After the lumbar veins are ligated, the iliac veins are encircled. The donor renal vein is anastomosed to the recipient vena cava using an end-to-side technique (83). The donor renal artery is then anastomosed to the recipient aorta in an end-to-side fashion. Careful attention must be paid to the recipient hemodynamic response on clamping and unclamping of the major vessels, and it is desirable to maintain a central venous pressure of 15 to 18 cm H₂O before unclamping (48,82). The filling of the transplanted kidney may be slow due to the fact that a large adult kidney takes up a significant portion of the normal pediatric blood volume. Hemodynamic studies suggest that the cardiac output of infants must double to perfuse the adult donor kidney adequately (84). Thus, volume replacement is critical (Fig. 73.1). The ureteral anastomosis is done by implanting the donor's ureter into the recipient's bladder using either a Leadbetter-Politano procedure or a modification of it. Many surgeons now prefer a nonrefluxing extravascular rather than transvesical approach for ureteroneocystostomy because it is faster, a separate cystostomy is not

required, and less ureteral length is necessary, which thus assures adequate distal ureteral blood supply (85–87).

The transplantation technique used in children with a body weight greater than 15 kg is similar to that used in adults. Whereas the transperitoneal approach is necessary in younger children, in older children the procedure is extraperitoneal, with the renal vein anastomosed to the common iliac or the external iliac vein (82). The arterial anastomosis can be to either the common iliac or internal iliac artery. The ureterovesicular anastomosis is done using the techniques described earlier.

Evaluation of Graft Dysfunction

At the completion of the vascular anastomosis and release of the vascular clamps, immediate function of the transplanted kidney is demonstrated by the production of urine. Various causes may prevent initial function, however, and evaluation of immediate nonfunction and the differential diagnosis of this condition is a critical component of the transplant physician's role.

Acute Tubular Necrosis

Acute tubular necrosis (ATN) represents the most frequent cause of immediate graft nonfunction. Data from the NAPRTCS 1996 annual report showed that ATN was observed in 5% of LD and 19% of CAD transplants (24). Because the NAPRTCS definition for ATN is stringent, requiring dialysis in the first posttransplant week, these figures probably underrepresent the actual incidence of ATN. The risk of early ATN in LD kidneys is related to factors such as prior transplantations and use of more than five transfusions. Similarly, the risk factors of ATN in CAD kidneys include prolonged cold ischemia, absence of prophylactic antibody therapy, and the use of more than five blood transfusions. The diagnosis is confirmed in most cases by radionuclide scan (Fig. 73.2). If recovery of graft function is delayed, however, a transplant biopsy may be necessary, because other diagnostic tests cannot distinguish between ATN and rejection (88,89). Importantly, early acute rejection can mimic ATN or coexist with it. The presence of ATN does not auger well for the transplant, particularly those of cadaveric source, because graft failure and death are more common among patients with ATN (50). The NAPRTCS data showed that 71% of CAD grafts without ATN were functioning at 4 years compared to only 51% of those with ATN (90).

Graft Thrombosis

Graft thrombosis is an almost unique complication of pediatric transplantation. Although usually a major cause of immediate graft nonfunction, it can be seen later on in the course and has been recorded to occur as late as 15 days after transplantation after initial engraftment and function. Graft thrombosis has been the third most common cause of graft failure in pediatric renal transplantation (13), and the rate

FIGURE 73.2. Technetium 99m-mercaptoacetyl triglycerine radionuclide renal scan of a cadaveric-donor renal transplant in a 15-year-old boy performed on the first postoperative day. The cold ischemia time exceeded 24 hours, and the recipient experienced oliguric acute tubular necrosis. Note the good perfusion, followed by little excretion and washout of the tracer from the graft.

may rise further if acute rejection rates continue to fall (91). The critical nature of this complication can be appreciated from the fact that it accounts for 11% of graft failures in index transplantations and 13% in repeat transplantations in the NAPRTCS registry. A dreaded event, this condition is irreversible in most cases and necessitates removal of the graft. Graft thrombosis should be suspected in cases in which there has been immediate function followed by the development of oliguria or anuria. The diagnosis is established by a radionuclide scan using diethylenetriaminepenta-acetic acid (DTPA) or mercaptoacetyl triglycerine (MAG-3) (92), which reveals a photopenic defect with no uptake by the transplanted kidney (Fig. 73.3).

Because the outcome of graft thrombosis is uniformly dismal, numerous studies have been conducted in an attempt to understand and anticipate this complication. The etiology of graft thrombosis is multifactorial, but it is more commonly seen in young recipients (93). In a special study of 2060 LD and 2334 CAD kidney transplants (94), NAPRTCS showed that a history of prior transplantation increases the risk, whereas increasing recipient age has a protective effect for LD kidneys. The prophylactic use of antilymphocyte antibody also decreases the risk, and this may be particularly true for the monoclonal interleukin-2 (IL-2) receptor antibodies (91). For CAD kidneys, a cold ischemia time longer than 24 hours increases the risk of thrombosis. The use of antibody induction therapy, the use of donors older than 5 years of age, and increasing recipient age were factors that decreased the risk of thrombosis. A heightened thrombotic state has also been implicated (92,95,96). One study showed that centers that performed fewer infant transplantations had higher rates of graft thrombosis (97), and another suggested that pretransplantation use of peritoneal dialysis increased the risk of thrombosis (98,99). Some centers rou-

FIGURE 73.3. Note the photopenic area in the right abdomen, which indicates thrombosis of the graft with no perfusion.

tinely administer anticoagulants to pediatric recipients at high risk of graft thrombosis, but no clinical studies of their effectiveness have been performed and their use is not without complications (100). The incidence of graft thrombosis has not changed over the past 15 years (13); however, a preliminary report suggests that a new approach to induction therapy may have led to a decrease (91).

Obstruction and Urinary Leak

An uncommon but correctable cause of immediate graft dysfunction is obstruction of the urinary flow, which presents as decreasing urine output and the development of hydronephrosis. An ultrasonographic or radionuclide scan with a furosemide washout enables the clinician to establish this diagnosis. Obstruction can be due to kinking of the ureter, to edema or blockage of the implantation site of the ureter, or to development of a lymphocele. A more ominous cause of immediate nonfunction is the rare case of urinary leak due to disintegration of the distal ureter or rupture of the bladder. This condition is extremely painful due to the extravasation of urine into the pelvis or peritoneal cavity, and its presence is established by radionuclide scan (Fig. 73.4). The appearance of the tracer in the peritoneal cavity or in the scrotal, vulval, or inguinal area clinches the diagnosis. Immediate surgical correction is necessary.

Induction Therapy

T-Cell Antibodies

Prophylactic therapy with anti-T-cell antibody has been used for quite some time to improve graft survival (101). The

FIGURE 73.4. Technetium 99m–mercaptoacetyl triglycerine radiouclide renal scan for an 8-year-old girl who received a cadaveric renal transplant, taken 12 hours postoperatively. Note the good perfusion of the graft and the rapid concentration and excretion from the kidney. Tracer, however, rapidly accumulates in the right lower quadrant, outside of the bladder. Investigation demonstrated a traumatic bladder rupture.

rationale for this practice is to preempt the development of the first rejection, which is injurious to long-term graft survival. Retrospective data from NAPRTCS does show a beneficial effect. In a review of data for LD transplants, 5-year graft survival was 81% in 1041 patients who received T-cell antibody therapy compared to 75% in 1399 patients who did not receive this therapy. Similar figures for CAD kidneys were 66% in 1423 T-cell antibody–treated patients, compared to 56% in 1034 patients who did not receive T-cell antibody therapy (24). A major problem with these analyses is that several different types of T-cell antibodies were used. In the early years a polyclonal antibody was used, the most common form of which was prepared from horse serum and designated as MALG (Minnesota antilymphocyte globulin) (101). A monoclonal antibody directed at subsets of T-cells, called OKT3, was subsequently used (102).

Two polyclonal antibodies currently available are Atgam (Upjohn) and Thymoglobulin (Sangstat). Atgam, due to the sclerosing nature of the preparation, is given intravenously through a central catheter for 10 to 15 days. The dosage used is 15 mg/kg, and calcineurin inhibitors are generally withheld during the administration of the antibody. Thymoglobulin is provided through a peripheral vein at 1.5 to 2.0 mg/kg/dose. A report suggests daily monitoring of CD3⁺ subsets to guide therapy: the daily dose is given only when the CD3⁺ count exceeds 20 cells/mm³ (103). Thymoglobulin therapy has been studied in small groups of pediatric renal transplant recipients and was found to be effective (104). Comparison in the efficacy of removal of circulating T cells suggested that Thymoglobulin may have some advantage over Atgam (105), but no comparisons of clinical outcomes have been performed. The monoclonal antibody OKT3 is administered as a bolus injec-

tion into a peripheral vein daily for 10 to 14 days at a dose of 5 mg for older children and 2.5 mg for children weighing less than 30 kg. Calcineurin inhibitors are also withheld during the use of OKT3. The major problems with these induction therapies include the “first-dose reaction” (106,107), neurologic difficulties (108), and the potential for the development of superimposed infections, such as cytomegalovirus (CMV) or Epstein-Barr virus (EBV) disease. Although retrospective analysis of pediatric kidney transplantation continues to show a clear benefit to the use of prophylactic induction antibody therapy (13), a prospective randomized trial of OKT3 induction showed no clear advantage (109). Currently, fewer than 10% of pediatric renal transplant recipients receive an anti-T-cell antibody for induction therapy (13).

Interleukin-2 Receptor Antibodies

There are two high-affinity chimeric or humanized antibodies that act on the inducible α -chain of the IL-2 receptor on the surface of the activated lymphocyte: basiliximab (Simlect, Novartis) and Daclizumab (Zenapax, Roche). Basiliximab is generally given as a two-dose regimen (generally 10 mg for children weighing less than 40 kg and 20 mg for those weighing more than 40 kg) on days 0 and 4 after transplantation (110). A pharmacologic study showed that basiliximab clearance in children is reduced by approximately half compared with that in adults and is independent of age, weight, or body surface area (111). One study has noted that pediatric recipients receiving basiliximab may have significantly elevated levels of cyclosporine and may require reduced dosages to avoid toxicity (112). Daclizumab is generally given in a dose of 1 mg/kg intravenously on the day of transplantation and every 14 days thereafter for a total of 5 doses (113). Higher doses may be required for saturation of IL-2 receptors in younger children (6). Both antibodies are generally well tolerated without substantial side effects. The use of both antibodies has been studied extensively in children and both have been shown to be safe and effective (6,110,112,114–116). The precise mechanism of action of the antibodies is not known but is presumed to be saturation of the IL-2 receptor and subsequent competitive antagonism of IL-2–dependent proliferation. A novel 6-month dosing schedule of Daclizumab has been reported as part of a steroid-avoidance pilot study program and appears to be well tolerated (6). There are no studies comparing the two antibodies. Up to 65% of pediatric renal transplant recipients are now receiving an IL-2 receptor antibody as induction therapy (13).

Other Induction Therapies

If T-cell antibody is not chosen for induction therapy, one of the calcineurin inhibitors may be used instead. Currently there are two such drugs, cyclosporine and tacrolimus, which have similar mechanisms but act at different sites to

inhibit calcineurin. The major complication of this type of induction, particularly if it is given intravenously, is delayed graft function (117,118). The data in the twelfth annual NAPRTCS report show that approximately 35% of children receive no induction antibody therapy (13).

Maintenance Immunosuppression

Cyclosporine

Cyclosporine was first used in renal transplantation by Calne et al. in 1978 (119). The initial experience was followed by controlled trials in the United States, Canada, and Europe, all of which showed a significant improvement in graft survival over that with existing therapies. The drug was licensed in the United States in 1983 and has been used in all types of solid organ transplantation for over 20 years. There have been no controlled trials in children, but over the years of use a large body of information regarding its dosing and side effects has accumulated (13).

Induction Dosage

For induction purposes cyclosporine is given intravenously at a dosage of 165 mg/m² daily for children under 6 years of age and 4.5 mg/kg daily in children over 6 years. The dosage for younger children is calculated in square meter format because they metabolize the drug differently. The drug is preferably given in a continuous infusion over a 24-hour period starting intraoperatively. If practicality precludes a continuous infusion, the drug should be administered in three divided doses daily but over as long an interval as possible. If possible, induction therapy using intravenous cyclosporine should be continued for only 48 hours and then converted to oral cyclosporine therapy. The recommended starting oral dosage for children younger than 6 years of age is 500 mg/m² daily, administered in three divided doses; for children older than 6 years, it is 15 mg/kg daily, administered in two divided doses. These dosages are higher than those prescribed for adults because experience over the last 10 years has determined that the drug is metabolized more rapidly in children (120). A calcium-channel blocker is typically given with cyclosporine to reduce toxicity (121).

Maintenance Dosage

Because of the drug's irregular absorption and inherent nephrotoxicity, dosage adjustments of cyclosporine are constantly necessary (122). Data from NAPRTCS show that at 1 year after transplantation the mean cyclosporine dose can vary from 5.6 mg/kg to 8 mg/kg (24). It has also been demonstrated that higher maintenance dosages are associated with diminished chronic graft rejection (120). Among cadaveric kidney recipients the rate of rejection was 16% in those receiving doses higher than 8 mg/kg at 1 year after transplantation, compared with 24% in those receiving less

than 6 mg/kg daily (123). The difficulty of maintaining constant dosing has led to several methods of measuring cyclosporine blood levels (118). Either high-pressure liquid chromatography or fluorescence polarization immunoassay techniques are used. Drug adequacy is considered to be a range of 100 to 200 ng/mL high-pressure liquid chromatography whole-blood trough level or 200 to 450 ng/mL radioimmunoassay whole-blood levels for patients more than 3 months after transplantation. Higher levels are necessary in the first 3 months. Newer data suggest that measuring the level 2 hours after the dose is received may allow more accurate dosing, assessment of the true area under the curve, and avoidance of toxicity (124–126).

Side Effects

Treatment with cyclosporine is associated with nephrotoxicity, hypertension, and hepatotoxicity. A major concern in children is hypertrichosis and facial dysmorphism (127). Hyperkalemia is common in patients taking cyclosporine (128) and also responds to dosage reduction. The mechanism is possibly related to diminished tubular excretion. Renal handling of uric acid is also altered, which leads to hyperuricemia (129). Hypomagnesemia is also observed as a result of altered tubular function (130). Tremors, convulsions, and paresthesias have been recorded in patients taking cyclosporine (131). These side effects may be multidrug induced rather than resulting from cyclosporine alone; however, they are often seen with high blood levels of the drug. Both hypertension and hyperlipidemia are observed in patients taking cyclosporine. A worrisome side effect in children is gingival hypertrophy (132), seen more often with higher dosages and in the presence of poor dental hygiene (133). NAPRTCS registry data published in 2001 showed that slightly fewer than 50% of renal transplant recipients were currently receiving cyclosporine as initial immunosuppression (13).

Tacrolimus

Tacrolimus (Prograf, Fujisawa) was introduced as an immunosuppressant for kidney transplantation in the mid-1990s (134–136). NAPRTCS data show that slightly fewer than 50% of children are being maintained on tacrolimus at 31 days after transplantation (13).

Dosage

One method of initiation of tacrolimus therapy is to provide 0.1 mg/kg/24 hr as a continuous infusion, with a switch to oral therapy within 2 to 3 days. However, because of the good absorption of the oral preparation and the concern about nephrotoxicity, many programs begin treatment by mouth or nasogastric tube very early posttransplantation. Initial oral dosages should not exceed 0.15 mg/kg twice daily and should be reduced to 0.1 mg/kg as a maintenance dose. Blood monitoring is necessary as with cyclosporine, and tar-

get whole-blood trough levels, measured by enzyme-linked immunosorbent assay, should be maintained between 5 and 20 ng/mL. Diarrhea, which is common, particularly in infants, may lead to increased tacrolimus levels (137).

Side Effects

Because tacrolimus has a similar mechanism of action, virtually all of the side effects of cyclosporine therapy are also seen with tacrolimus therapy (135). The nephrotoxic effect is similar (138). The hypertrichosis and dysmorphic features noted with cyclosporine are not seen with tacrolimus (139). Neurologic side effects are common and may be seen more frequently than with cyclosporine (140,141). A concern for the use of tacrolimus in pediatric renal transplantation was the development of posttransplantation diabetes mellitus, because in an early Japanese report one-third of patients developed hyperglycemia requiring insulin therapy (142). This has also been reported from other single centers (143,144). The mechanism may be related to a diminished insulin secretion in association with the insulin resistance associated with steroid use (145). The incidence of posttransplantation lymphoproliferative disorder (PTLD) was much higher with the use of tacrolimus than with the use of other immunosuppressants during early experience (136,146). However, a more recent retrospective analysis showed that the use of tacrolimus was not a risk factor for development of PTLT, likely due to the lower dosages currently used (147).

Choice of Calcineurin Inhibitor

Calcineurin inhibitors have been mainstays of immunosuppression in pediatric transplantation for the past decade and likely account for the continuing improvement in graft survival rates (12,148,149). The choice between drugs has often been based on a center preference. An open-label randomized trial of the two drugs with steroids and azathioprine was completed (150). Tacrolimus-treated patients had a lower rate of acute rejection (37%) than cyclosporine-treated patients (59%), although both rates were higher than current standards (13) and not all episodes were biopsy proven. One-year graft survival rates were similar, although the glomerular filtration rate was higher in the tacrolimus-treated group. Rates of hypomagnesemia, diarrhea, and posttransplantation diabetes mellitus were higher in the tacrolimus group, and rates of hypertrichosis and gum hyperplasia were higher in the cyclosporine group. In a retrospective analysis of NAPRTCS data on therapy with the two drugs given with mycophenolate mofetil (MMF) and steroids (139), there was no difference in early rejection rate (29%), risk of rejection, or risk of graft loss. At 2 years, graft survival was no different with the two agents (tacrolimus, 91%; cyclosporine, 95%). Tacrolimus-treated patients were less likely to require antihypertensive medication and had higher glomerular filtration rates at 2 years.

Azathioprine

For pediatric patients azathioprine is given at a dosage of 1 to 2 mg/kg/day. Patients taking higher dosages should be closely monitored for myelosuppression. In the early years of transplantation azathioprine was routinely used in all transplant recipients; when cyclosporine became available it was still widely used as an adjunct drug. In 1989 and 1990, 80% of pediatric patients in the NAPRTCS registry were receiving azathioprine, but as familiarity with MMF has increased, the use of azathioprine has diminished substantially, and it is currently given to fewer than 10% of patients (13).

Mycophenolate Mofetil

As of 1996, the NAPRTCS registry noted that only 6.5% of patients were being maintained on MMF (24), but the figures published in 2001 show that it is used in approximately two-thirds of pediatric kidney transplant recipients (13). Results concerning its advantages over azathioprine have been mixed (151–154). A well-controlled study, however, concluded that it was safe and effective for use in pediatric renal transplant recipients (155). A major difficulty in widespread use of the drug in children has been gastrointestinal disturbance, especially in young children (156). Both nausea and vomiting are common, but in some patients the drug has to be withdrawn due to intolerable diarrhea. An advantage of MMF over azathioprine is that the drug is less likely to induce leukopenia. The current recommended dosage of MMF for pediatric patients is 1200 mg/m²/day, divided into two, three, or four doses (157). It is likely that therapeutic monitoring should be used, but clear standards are not yet available to guide treatment (158–163).

Corticosteroids

The NAPRTCS reports show that 96% of children with a functioning graft are maintained on prednisone (24). The numerous mechanisms of action of steroids lead to side effects and toxicities. The important concern in children is growth retardation. Studies have shown that dosages in excess of 8.5 mg/day impair normal growth (164). Other side effects include increased susceptibility to infection, impaired wound healing, aseptic necrosis of the bone, cataracts, glucose intolerance, hypertension, cushingoid facies, and acne (165). The preparations commonly used are prednisolone, its 11-keto metabolite prednisone, and methylprednisolone. Although the half-lives of these preparations are very short, they can be administered once daily because their effect on inhibition of lymphocyte production persists for 24 hours (166). The dosage is usually high in the period immediately after transplantation, approximately 2 mg/kg/day, with a gradual reduction to 0.2 to 0.3 mg/kg/day within a 6-month to 1-year period. Because of the multiple side effects of maintenance steroid therapy, attempts have been

made to withdraw steroids altogether and have been reported in both adult and pediatric kidney transplantation cases (167). Unfortunately, the majority of these attempts have failed because of the development of acute rejection episodes (168–170). The use of alternate-day steroid therapy, which appears to reduce the growth-inhibiting effect without unduly increasing rejection episodes (171,172), seems reasonable, but only a minority of pediatric renal transplant recipients are receiving steroids in that manner (13). Several ongoing studies are investigating the use of steroid avoidance or steroid withdrawal protocols, and it is likely that steroids will not be used for immunosuppression in the future.

Rapamycin

Rapamycin (sirolimus; Rapamune, Wyeth) is the newest immunosuppressive agent used for kidney transplantation. It is the product of a fungus that was discovered on Easter Island (Rapa Nui) in 1969. It was first investigated for antifungal properties, and its immunosuppressant characteristics were first discovered in 1988. The agent was approved by the Food and Drug Administration in 1999. A similar compound that may be an analogue, SDZ-RAD, is currently undergoing clinical trials. Rapamycin is classified as a TOR inhibitor. TOR is a cytosolic enzyme that regulates differentiation and proliferation of lymphocytes. TOR is then activated as a result of the cascade of reactions in lymphocytes caused by the proliferation of cytokines and initiates production of messenger RNAs that trigger cell-cycle progression from G₁ to S phase. The TOR inhibitors bind to the immunophilin FKBP12 and inhibit the actions of TOR (173–178). TOR inhibitors may be particularly important in long-term immunosuppression because they stimulate T-cell apoptosis. TOR inhibitors also inhibit mesenchymal proliferation, which may prove to be important in graft vascular disease (179,180). Also, because the mechanism of action of rapamycin is different from that of other currently available immunosuppressants, it can be used in combination with all of them. Rapamycin has been found to be effective in combination with calcineurin inhibitors (181–185), in a calcineurin-inhibitor-sparing protocol (186), and in a steroid-free protocol (187). The role of rapamycin or SDZ-RAD therapy in pediatric transplantation is actively being studied (36,188,189).

Dosage

Rapamycin is available as an oral preparation, either as a solid or a liquid. Rapamycin was shown to have a prolonged half-life in adults that allowed once-daily dosing in adults (183–185). However, pharmacokinetic studies in children have demonstrated a much shorter half-life, as short as 12 hours (36,190). Thus, children may require twice-per-day schedules to maintain therapeutic levels. Retrospective analysis of early trials of rapamycin have suggested a relationship between blood levels and risk of rejection (191). Current suggestions for therapeutic levels remain speculative and

range between 25 ng/mL in the early posttransplantation period without use of calcineurin inhibitors (36,186) to 5 to 10 ng/mL later in the course of transplantation.

Side Effects

The major side effects of rapamycin are hyperlipidemia, thrombocytopenia and leukopenia, and possibly delayed wound healing (183). The former complications can respond to the use of lipid-lowering drugs or dosage reduction. The latter complication may require suspension of the drug until the wound heals completely.

Maintenance Immunosuppression Combinations

Most pediatric renal transplant recipients are treated with triple immunosuppressive agents (13). When the number of drugs was limited, the number of possible combinations was small. However, there are at least 20 possible combinations of the six drugs now available, and when the induction antibodies are added, there are over 60 possible reported protocols (192). No “best” protocol for children has been established, although most clinical trials are currently directed at eliminating either steroids or calcineurin inhibitors or both. Currently most children are receiving prednisone, MMF, and cyclosporine or tacrolimus after kidney transplantation (13).

There are many possible targets for immunosuppression strategies for children (193). One promising new protocol of steroid avoidance has been reported (6). This approach consists of 6 months of administration of anti-IL-2 receptor antibody, tacrolimus, and MMF. Short-term patient and graft survival rates have been excellent, and growth rates have been very good. Major complications have included bone-marrow suppression and nephrotoxicity. Other protocols currently under investigation include calcineurin inhibitor avoidance or withdrawal and costimulation blockade with the eventual goal of avoiding both corticosteroids and calcineurin inhibitors.

ALLOGRAFT REJECTION

In the absence of tolerance the renal allograft is destined for loss by some form of rejection. Rejections are classified as hyperacute (occurring immediately on grafting), accelerated acute (occurring within the first week after transplantation), acute (generally occurring within the first year of transplantation), late acute (occurring after the first year), and chronic, for which the time sequence is difficult to establish because it may occur as early as 3 months but generally occurs years later in the course of the transplant.

Hyperacute Rejection

Hyperacute rejection is the result of specific recurrent anti-donor antibodies against HLA, ABO, or other antigens

(194). Irreversible rapid destruction of the graft occurs. Histologically there is glomerular thrombosis, fibrinoid necrosis, and polymorphonuclear leukocyte infiltration. In the early years of transplantation, when the HLA matching techniques were not well developed, hyperacute rejection was more common. In most centers, it occurs very rarely. The latest data from NAPRTCS show the incidence of hyperacute rejection to be less than 0.25% (17 cases) over the last 15 years (13). The only treatment is surgical removal of the allograft.

Acute Rejection

Information regarding the incidence and outcome of acute rejection in pediatric renal transplantation is available from the NAPRTCS data. Because NAPRTCS receives data from multiple sites that use many different diagnostic and treatment protocols, the definition of a rejection episode is based on the patient's having received antirejection therapy, although biopsy confirmation is becoming more common. In a review of 8777 rejection episodes over a 15-year study, there were, on average, 0.89 rejection episodes for each LD transplant and 1.23 for each CAD transplant. A remarkable decrease in the incidence of acute rejection has occurred since 1987 (Table 73.5). In a study of two cohorts of pediatric renal transplant recipients (1469 in 1987 to 1989; 1189 in 1997 to 1999), the rejection ratios dropped from 1.6 per patient to 0.7 per patient (195). Sixty percent of the latter group was rejection free compared to 29% of the former group, and 1-year graft survival was 94% compared to 80%. Historically, over half of patients experienced a rejection in the first weeks after transplantation; now the majority experience a rejection-free first year. Risk factors for CAD transplants include the absence of prophylactic T-cell antibody therapy, donor age younger than 5 years, black race, and no DR matches. Risk factors for LD source transplants are the absence of T-cell antibody, one or two DR mismatches, black race, and presence of ATN. In an earlier study NAPRTCS noted that, when data were reviewed by age groupings, rejection ratios, time to first

rejection, and mean number of rejection episodes were no different across age groups; however, as the initial rejection episode, recipients younger than 6 years of age had significantly increased irreversible rejections leading to graft loss (23). Data are conflicting regarding whether infants and small children have a "heightened" immune response and an increased incidence of acute rejection episodes. Indirect evidence suggested a more vigorous immune response, especially in infants (27). Also, data from the UNOS registry demonstrated a higher rate of acute rejections in young children after both LD and CAD transplantation, although adolescents were noted to have a higher rate of late acute rejections (14). On the other hand, data from surveillance transplant biopsy specimens suggest equivalent rejection responses in all groups (33). Data from one large pediatric transplant program demonstrated that infants have a lower rate of acute rejection than older children (35). A report of the Scientific Registry of Transplant Recipients demonstrated that infants and young children now have the best outcomes of all age groups (12). Thus, either the proposed heightened immune response has been overcome by improved immunosuppression or the previously poor outcomes were related to other factors.

Diagnosis of Acute Rejection

Rejection is suspected when there is decreasing urinary outflow and a rising serum creatinine level. In the past, classical signs of acute rejection included fever and graft tenderness. With the use of calcineurin inhibitors and prophylactic antibody therapy, however, these signs are rarely seen; thus early evidence of graft dysfunction, even without other signs, should initiate concern. The differential diagnosis consists of ureteral obstruction, renal vascular compromise from stenosis, urinary leak, and an infectious process. When rejection is suspected, a urinalysis and urine culture should be performed to assess the possibility of infection. The urinalysis is also helpful if it suggests intragraft inflammation or immune response as evidenced by proteinuria and the presence of leukocytes and other cells in the sediment. Blood or urinary cytokine analysis may also be useful for diagnosing rejection (196,197), and examination of the sediment may be useful in detecting other reasons for graft dysfunction. Ultrasonography is performed to rule out anatomical obstruction. Obstruction can be the result of perirenal fluid collection, a large lymphocele, hematoma, or, rarely, an abscess. The ultrasonographic scan can also provide information about intragraft blood flow and pressure (88). A radionuclide renal scan using a tracer such as MAG-3 is a very helpful tool in establishing some diagnoses (Figs. 73.2 to 73.4) (198). Rejection is suggested by rapid uptake of the tracer by the kidney but a delayed excretion. Unfortunately, radionuclide scans cannot distinguish among various causes of intragraft dysfunction, such as rejection, cyclosporine toxicity, and ATN.

TABLE 73.5. TWELVE-MONTH PROBABILITY OF FIRST REJECTION BY TRANSPLANT YEAR

Transplant year	Living donor		Cadaveric donor	
	%	SE	%	SE
1987–1990	54.2	1.7	69.2	1.4
1991–1994	45.2	1.5	60.8	1.6
1995–1998	34.0	1.4	41.0	1.7
1999–2002	27.2	1.8	31.2	2.5

Thus, a definitive diagnosis of rejection requires a transplant biopsy.

Renal Transplant Biopsy

The renal transplant biopsy procedure is very easy and safe when conscious sedation and ultrasonographic guidance are used. Data evaluating over 150 pediatric renal transplant biopsy specimens, including some in intraperitoneal kidneys and many performed during the first week after transplantation, have demonstrated a very low risk (89). A major factor in reducing postbiopsy bleeding is the use of an automated biopsy "gun" with a small (18-gauge) needle rather than the standard (15-gauge) needle.

A good biopsy core includes glomeruli, tubules, interstitial tissue, and vessels. Obtaining such a sample is facilitated if a dissecting microscope is used at the time of the procedure to identify glomeruli and tubules in the specimen. In acute rejection glomerular changes are restricted to increased prominence of the mesangial stalk. However, it is the presence of tubular changes that is significant in early acute rejection, and tubulitis is considered the hallmark. Semiquantitative analysis and grading of acute rejection biopsy findings is done using the Banff criteria (199). Grade I is the presence of focal interstitial lymphocytic infiltrate with mild tubulitis and normal vessels. In Grade II there is extensive interstitial infiltrate with tubulitis and vacuolation in arterial vessels, whereas Grade III shows extensive interstitial infiltration with tubulitis and lymphocytic infiltration of arterial walls with occasional fibrinoid change.

Treatment of Acute Rejection

Standard treatment for an episode of acute rejection is intravenous methylprednisolone in a single daily dose of 20 to 25 mg/kg (maximum dose: 0.5 to 1.0 g) for 3 consecutive days. Most grade I and grade II rejections respond to steroid therapy. Steroid-resistant rejection episodes are treated with T-cell antibody, either the monoclonal OKT3 or the polyclonal antithymocyte globulin (Atgam or Thymoglobulin). OKT3 is administered in a dose of 2.5 mg for children with a body weight of 30 kg and 5 mg for children over 30 kg for 10 to 14 days. Atgam is given in a dose of 15 mg/kg through a central venous catheter for 10 to 14 days, depending on the white cell and platelet counts, as it frequently depletes all formed elements in the blood system. It is advisable to maintain the white cell count above 2000/mm³ and the platelet count above 20,000/mm³. Thymoglobulin is given in a dose of 1.5 to 2.0 mg/kg for a total of 10 to 14 days. It may be advisable to monitor levels of CD3⁺ cells during treatment and to restrict dosing only to days when the count is higher than 20 cells/mm³ (103). All antibody therapies have several side effects. Of concern are the first-dose symptoms of OKT3 due to cytokine release (106,107). These are clinically observed as fever with chills and, rarely, as pulmonary edema. Defervescents, such as

acetaminophen, should be given every 4 hours, and the administration of the antibody should be preceded by a bolus dose of 500 mg of methylprednisolone 1 hour before administration. Respiratory compromise, in the form of extravasation of fluid into the pulmonary capillary bed, is seen only in patients with fluid overload. Dialytic fluid removal should be considered before the administration of OKT3 in patients whose body weight exceeds 5% of their baseline. Precaution against a potential anaphylactic reaction to polyclonal antibodies consists of administration of 500 mg of methylprednisolone with the infusion of the antibody and administration of an antihistamine, such as diphenhydramine (Benadryl), one-half hour before drug administration.

Reversibility of Acute Rejection

NAPRTCS data demonstrate that among LD kidneys 55% of rejection episodes are completely reversed, 40% are partially reversed, and 5% end in graft failure. Similar figures for CAD kidneys are 48%, 45%, and 7%, respectively (24). When data are stratified by age, young transplant recipients are found to more frequently experience irreversible rejection episodes. Ten percent of acute rejections among infants receiving an LD kidney end in graft failure, compared to 4% for older children. For CAD kidneys the rate of graft failure in infants is 15%, compared to 7% for older children. Not only is rejection frequency decreasing, but complete rejection reversal in pediatric LD recipients seems to be increasing in more recent age cohorts (13). Molecular or genomic characterization of rejection biopsy specimens may be helpful in describing different types of acute rejection (196,197,200–202).

Rescue Therapy

In those patients in whom neither steroids nor antibody therapy successfully reverses a rejection episode, conversion to an alternative calcineurin inhibitor or to other immunosuppressants appears to be warranted. There have been no controlled studies to document reversal of rejection with conversion to tacrolimus; however, anecdotal reports do suggest that in some cases conversion helps stabilize graft function (135,136,170).

Chronic Rejection

The gradation from acute to chronic rejection is gradual; however, many biopsy specimens show features of both, and some characteristic vascular changes of chronic rejection may be seen as early as 10 days after transplantation (203). The clinical picture is that of gradually declining renal function together with varying degrees of proteinuria and hypertension. An ongoing controversy exists as to whether the changes seen in chronic rejection are immune

mediated, ischemic in nature, or nonimmunologic injury due to hyperfiltration (204,205). Data for children have shown clearly that acute rejection is a predictor of chronic rejection (148). In a study of 1699 patients receiving LD grafts and 1795 receiving CAD grafts, NAPRTCS noted that acute rejection was an RR factor for chronic rejection (RR = 3.1), and multiple acute rejections increased the RR to 4.3. Late acute rejections are also clinical correlates of chronic rejection (206). Even if acute rejection is the most critical element in the genesis of chronic rejection, other immune mechanisms may mediate its progression. One possible explanation would be that, in patients who go on to develop chronic rejection, the immune mediators of acute rejection, such as granzyme B, perforin, and Fas ligand, are expressed in a more robust fashion and the responses are quantitatively different from the responses of an acute rejection that does not lead to chronic rejection. Alternatively, the immune mediators of chronic rejection may be qualitatively different from those associated with an acute episode. For example, the multifunctional cytokine transforming growth factor β 1, which has fibrogenic properties, is present in biopsy tissue of patients with chronic rejection (207). Identification of the mechanism of initiation or progression of chronic rejection is vital to any attempts to control it.

Treatment of symptoms is currently the only available method of dealing with chronic rejection. Hypertension should be controlled, and the proteinuria may occasionally respond to angiotensin-converting enzyme inhibitors; however renal function will continue to decline. In children, chronic rejection produces an additional burden, because

decreased renal function results in deceleration of growth (208,209). It is in this context that prevention of chronic rejection by early aggressive therapy in patients who have had an episode of acute rejection may be rewarding. Because currently available immunosuppressive medications have been unsuccessful in preventing or slowing the progression of chronic rejection, the use of immunosuppressive agents other than those currently approved may be reasonable.

GRAFT SURVIVAL

Pediatric renal centers reporting graft survival show varying results. Because the number of patients at any one center is small, such data cannot represent the pediatric transplant population at large. Furthermore, multiple factors affect graft survival, such as donor and recipient age, histocompatibility matching, recipient race, and so forth. Thus, graft survival rates cannot be described accurately without classification of the important variables. To obtain a proper population mix representing gender, age, and racial diversity, the NAPRTCS annual reports have been used (13).

A total of 2201 graft failures occurred in 8399 transplantations (26%). Of index transplantations, 1924 (23%) failed, whereas 277 of 748 subsequent transplantations (37%) experienced graft failure. Among patients whose grafts failed, 1648 (75%) were returned to dialysis and 132 (6%) underwent retransplantation at the time of failure. Table 73.6 provides the distribution of

TABLE 73.6. CAUSES OF GRAFT FAILURE

	Index graft failures		Subsequent graft failures		All graft failures	
	N	%	N	%	N	%

causes of graft failure. With increased length of follow-up, chronic rejection continues to increase in importance. It is now the most common cause of graft failure. Overall, 47% of graft failures are caused by rejection, with chronic rejection accounting for 33% and acute rejection accounting for 14%. Recurrence of original disease as a cause of graft failure was observed 146 times (FSGS, 66; membranoproliferative glomerulonephritis type 2, 13; oxalosis, 10; hemolytic uremic syndrome, 16; chronic glomerulonephritis, 6; other disorders, 35). Vascular thrombosis remains a major cause of failure, and 327 graft failures were attributed to primary nonfunction, vascular thrombosis, or miscellaneous technical causes. These data show that such problems occur in 3.8% of pediatric transplantations (93-95,97-99,210).

Overall 5-year graft survival curves by donor source are shown in Figure 73.5. Current graft survival rates for index transplants at 1, 3, and 5 years are 95%, 90%, and 83%, respectively, for LD kidneys and 91%, 82%, and 73%, respectively, for CAD kidneys. These values are substantially better than previous results (Table 73.7). Table 73.8 shows RHs for graft failure associated with selected transplant characteristics for both LD and CAD kidneys. Five-year graft survival rates by selected variables for LD grafts are shown in Figure 73.6 and for CAD grafts are shown in Figure 73.7. An important trend toward improved graft survival in pediatric LD and CAD renal transplantation has been reported (12,123), and data published in 2001 and 2003 are shown in Figures 73.8 and 73.9.

Registry-based graft survival data can be used to establish risk factors. RRs of graft failure are derived using Cox proportional hazards regression models. For LD kidneys the risk factors for graft failure include black race (RH = 1.88), receipt of more than five prior transfusions (RH = 1.41), and absence of HLA-B matches (RH = 1.39) (Table 73.8). Lack of receipt of induction antibody therapy is also a risk factor (RH = 1.13) as is transplant era (RH = 0.95) (13). A similar risk factor analysis for CAD kidneys has been reported (13,24,211), and data from the twelfth annual report of NAPRTCS are presented in Table 73.8. The risk factors are similar to those seen with LD grafts, with additional hazards such as young age of recipient (RH = 1.80), young age of donor, and prolonged cold ischemia time (RH = 1.20). Some factors that increase the RR of cadaveric graft failure in children, such as recipient age, are

integral to pediatrics. Other factors, such as recipient race, the degree of HLA matching, and prior transplantation, cannot be easily altered. Improvement in cadaveric allograft survival rates can be achieved, however, by judicious choice of donors, appropriate pretransplantation management, changes of induction therapy, and optimization of immunosuppressive therapy (23).

Another measure of long-term graft function is the calculation of graft half-life. An analysis of 8922 pediatric and 78,418 adult renal transplant cases demonstrated superior long-term graft function in young pediatric recipients (14). Infants (aged 0 to 2 years) had worse 1-year graft survival rates (71%) than children 3 to 12 years (83%), adolescents 13 to 21 years (85%), and adults (86%). However, among all grafts that survived at least 1 year, those in infants had the

FIGURE 73.9. Five-year actuarial survival of living-donor (LD) and cadaveric (CAD) grafts in children and adults undergoing renal transplantation by recipient age. Young children currently have the best long-term outcomes of all age groups. [Adapted from Colombani PM, Dunn SP, Harmon WE, et al. Pediatric transplantation. *Am J Transplant* 2003;3(Suppl 4):53-63.]

longest projected half-life (18 years), exceeding that of grafts in children (11 years), adolescents (7 years), and adults (11 years). A similar analysis of UNOS data showed that grafts in young recipients who received adult donor kidneys and had immediate graft function had projected half-lives of longer than 25 years, even better than that in adult recipients of grafts from HLA-identical adult donors (212).

The primary disease causing ESRD can have an effect on graft survival. Children with oxalosis used to have poor outcomes, so that this diagnosis was considered a contraindication to transplantation. However, improvements in outcome related to combined liver-kidney transplantation have been encouraging (31,49-51). Similarly, infants with congenital nephrotic syndrome often had very poor outcomes (50,213), but strategies designed to reduce the risk of thrombosis and improve nutrition before transplantation have led to marked improvements (52-54,96). FSGS can be a devastating disease that recurs very quickly after renal transplantation, sometimes as early as the first day after transplantation (213-217). Although recurrence is no more frequent in LD transplants than in CAD transplants, the graft survival advantage of LD transplantation is lost for children with FSGS (218). Little is known about the pathophysiology of the disorder or the cause of recurrence (219,220). There are several proposed approaches to preventing or treating recurrence, most involving enhanced immunosuppression with plasmapheresis (217,221-226). Lupus nephritis surprisingly does not recur after renal transplantation to any great extent. Patients with lupus have outcomes similar to those of other patients (227,228), except for a slight increase in mortality (228), an increase in incidence of recurrent rejections, and a slight tendency to graft failure in those patients receiving CAD grafts after peritoneal dialysis (227). Children with sickle cell disease and ESRD can receive kidney transplants successfully

(229), as can those with Down syndrome (230,231). Hemolytic uremic syndrome has been variably described as likely to recur or not (213,232). When the etiologic factors are distinguished, data show that epidemic shiga toxin-associated hemolytic syndrome is unlikely to recur after renal transplantation (233,234), whereas atypical or familial hemolytic uremic syndrome may recur with devastating and irreversible consequences (234).

GROWTH AFTER TRANSPLANTATION

A major feature distinguishing pediatric from adult recipients is the need for statural growth and maturation. The growth failure commonly observed in children at the time of transplantation is multifactorial; however, the most important cause is the reduced response to endogenous growth hormone (42), which is related to several mechanisms. Growth failure often begins insidiously early in the course of CRI. In an NAPRTCS analysis of data for 1768 children with CRI (glomerular filtration rate less than 75 mL/min/m²), over one-third had a height deficit of more than 2 standard deviation scores. It has been amply demonstrated that CRI beginning in infancy leads to permanent reduction in growth potential (235). Growth retardation continues in children who are on a dialysis regime, whether the mode of dialysis is peritoneal dialysis or hemodialysis. For several years it has been suggested that a functioning transplant would enable the child to achieve catchup growth (7). Unfortunately, long-term data from registry studies have revealed a more disappointing outcome.

NAPRTCS data show that the mean height deficit at the time of transplantation is -1.88. Males (-1.92) and younger recipients have greater height deficits at the time of transplantation (13). Younger children can show catchup growth (7) with complete inversion of Z-score up to 0.60 at 2 years in those younger than 5 years of age at the time of transplantation. Older children may grow at a normal rate but rarely show catchup growth. The Z-score for 19-year-olds is -1.5. Final adult height for children with ESRD is improving, but all of the improvements seem to be related to the gains achieved during treatment for CRI rather than after transplantation (8).

These studies on long-term growth after transplantation are disappointing; however, they do focus on mechanisms that prevent growth despite a milieu with normal renal function. Studies at individual centers have adopted a variety of techniques, such as discontinuation of prednisone (236,237), alternate-day steroid therapy (171,172,238), steroid avoidance (6), or the use of recombinant human growth hormone (239). It has been known for several years that use of steroids for immunosuppression inhibits growth (167). It has also been demonstrated that steroids affect growth hormone secretion (208,240-242). Measurements of pulsatile and pharmacologically stimulated hormone release reveal that steroids

play an inhibitory role (167,243). Conversion of children to alternate-day steroid therapy has resulted in improvement in growth (171,172); however, the best catchup growth is seen in patients from whom steroids are completely withdrawn (6,136,168). Numerous uncontrolled studies have shown that steroids can be withdrawn from children after transplantation (6,136,244); however, acute rejection tends to occur shortly afterward in many of these patients (169), with marked detrimental long-term effects. An alternative method of attaining catchup growth after transplantation is the use of growth hormone. Recombinant human growth hormone is not approved for use in children after transplantation; however, numerous uncontrolled studies have shown its ability to accelerate growth in this setting (245). Several possible complications of the use of recombinant human growth hormone after transplantation have been identified (245-248), but a controlled trial demonstrated that it could be used safely and effectively (249).

MORBIDITY

Hospitalization

The median duration of hospitalization at the time of transplantation cited in the twelfth annual NAPRTCS report was 13 days, with longer stays required for young patients and for recipients of CAD transplants (13). The mean hospital stay fell by approximately 8 days between 1987 and 2001. Most children require rehospitalization at least once after the initial discharge after renal transplantation. Fifty percent of LD graft recipients and 62% of CAD graft recipients are hospitalized during the first 6 months after transplantation. The hospitalization rate falls with increasing time after transplantation, but 16% require at least one hospital stay in the fourth posttransplant year (24). The most common reason for hospitalization used to be for treatment of rejection. However, an analysis of recent data indicates that treatment of viral and bacterial infections is now the most common reason for hospitalization (250). The most common bacterial infection in children 5 years of age or younger is *Clostridium difficile* diarrhea; in those older than 5 years, it is urinary tract infection (UTI) (35). CMV infection appears to be the most common viral infection in older children. Treatment for hypertension is the cause for hospitalization in 5 to 8% of recipients in the first 6 months after transplantation; the rate falls to approximately 1% 5 years after transplantation (24).

Posttransplantation Lymphoproliferative Disease and Malignancy

Although PTLN has been reported as a complication of pediatric organ transplantation for many years (251), the number of published reports seems to be increasing (252).

It is not clear whether this indicates that the incidence of this potentially lethal complication of immunosuppression is increasing or that it is just more readily recognized. If the incidence is increasing, it may be the unfortunate consequence of "improved" immunosuppression (146). A review of UNOS data indicates that the incidence of PTLD after pediatric renal transplantation is clearly increasing, and age younger than 18 years, white race, and male gender are significant risk factors (253). The current incidence of PTLD is 1 to 2% of all pediatric renal transplant patients.

PTLD often presents within lymph nodes, but it can be extranodal, frequently occurring within the gastrointestinal tract (254), proximate to or within the graft (255), or distant from it (256). Presentation of PTLD within the central nervous system is often devastating and rapidly fatal. PTLD is generally thought to emanate from an EBV infection (254,257,258). Thus, the pretransplantation EBV status of the donor and recipient may be an important determinant of the disease and may explain why the disease is more common in children than in adults (259,260). In several reports, the incidence rate of PTLD for EBV-seronegative recipients was many times higher than that for EBV-seropositive recipients (261,262), and in others, the source was the donor in most of the cases (263). Concomitant primary infection with CMV may increase the risk of PTLD fivefold (261). The intensity of immunosuppression may also predispose the child to PTLD (264). Treatment with antilymphocyte antibodies, such as OKT3, as either induction or antirejection therapy, may increase the risk of developing PTLD substantially (261,262,265). Although PTLD has been reported after both cyclosporine and tacrolimus treatment, the experience of programs that have used both drugs has suggested that the incidence is higher in tacrolimus-treated recipients (146,259,266). However, a registry report indicated that neither MMF treatment nor tacrolimus therapy was an independent risk factor for PTLD; rather, the overall intensity of immunosuppression was most important (147).

The diagnosis of PTLD has generally been made on the basis of characteristic pathologic findings, and the diagnosis cannot be made without biopsy material. Advances in detection of EBV DNA (267–271) and in the outgrowth of transformed lymphocytes (272,273) have permitted early detection of patients at high risk of developing PTLD. Surveillance of blood and prospective adjustment of immunosuppression has been proposed, but there are no universally accepted standards in this area (274). Similar test results have been used also to guide treatment (267), but their absolute value for this function is not established.

The mainstay of treatment of PTLD is the reduction or discontinuation of immunosuppressive therapy (263,275,276). Of interest, in many of these cases, the graft is not rejected despite the marked lowering or discontinuation of immunosuppressive medications. Interferon-alpha and intravenous gamma globulin (277,278), ganciclovir (279), and even chemotherapy have been suggested, but their efficacy has been

variable. In high-risk patients prophylaxis may be useful (280). Treatment with the monoclonal antibody rituximab has shown promising results (281–285).

Other Infections

Immunosuppression renders the recipient susceptible to numerous viral and bacterial infections. Infections account for the majority of complications after transplantation in children and are the principal cause of morbidity. Most centers use prophylactic therapy against the more common infections seen in the context of a renal transplantation.

Cytomegalovirus Infection

CMV is an extremely important cause of infectious complications affecting transplant recipients. Unlike the situation in nonimmunocompromised individuals, CMV infection in renal allograft recipients more often causes serious symptoms. CMV presents as a primary infection in seronegative patients; in seropositive patients the infection is secondary due to reactivation of the patient's own latent virus. Clinically the two types cannot be distinguished, although the former is generally more severe. Because of the high risk to the patient and renal allograft, prophylactic therapy is indicated for all seronegative patients who receive a seropositive kidney, and for all patients who receive induction therapy with a T-cell antibody. Prophylaxis can be carried out either with specific antiviral therapy or with high-titer CMV immunoglobulin, or both. The incidence of virologically confirmed CMV-associated syndromes was reduced from 60% in control subjects to 21% in recipients of CMV immunoglobulin. CMV immunoglobulin is generally given in the first 4 months after transplantation. Both acyclovir (286) and ganciclovir (287) have been shown to be effective as prophylactic therapy; however, the latter should replace the former since the introduction of an oral preparation, which has been shown to be highly efficacious (288,289). The dosage of oral ganciclovir is 500 to 700 mg/m² every 8 hours (290). There have been no controlled trials comparing CMV immunoglobulin to ganciclovir, so the relative merits of and indications for the two preparations are unknown, although the former seems to ameliorate the severity of CMV disease whereas the latter decreases the frequency.

Pneumocystis carinii Pneumonia

Because of their defective cellular immunity, transplant patients are susceptible to respiratory infection by opportunistic organisms that are not of concern to normal children. Pneumonia is a common cause of morbidity in children with a renal allograft, and *Pneumocystis carinii* is the most important cause. *P. carinii* pneumonia occurs in approximately 3% of all renal transplant recipients (291). *Pneumocystis* produces a diffuse pneumonia in which shortness of breath and hypox-

emia are salient features. If it is diagnosed quickly, it can be treated effectively; however, delay can be fatal, and hence prophylaxis is standard therapy in most centers. The risk is highest in the first year, and trimethoprim-sulfamethoxazole (Bactrim), in a dosage of 10 mg/kg three times per week, should be given during the period of highest risk.

Varicella

Chickenpox is one of the constant worries of both the transplant physician and the patient's family, because exposure in the pediatric age range is extremely high (35). The rash in an immunocompromised patient may become confluent, bullous, and hemorrhagic. If the disease becomes systemic, the fatality rate can be high (292). Treatment of varicella in immunocompromised children generally consists of intravenous administration of acyclovir at least until all lesions are crusted (291,293). Prophylaxis, consisting of the administration of varicella-zoster immunoglobulin, is carried out routinely in all transplanted seronegative children on exposure (291). The administration of varicella vaccine (Varivax) before transplantation substantially reduces the frequency and severity of the disease after transplantation (294). The use of varicella vaccine after transplantation has been reported in only a small series (295).

Urinary Tract Infection

UTIs are extremely common during the first 3 months after transplantation and may be seen in as many as 50% of patients (35,296). Beyond the first 3 months, episodes of asymptomatic bacteriuria appear more common. During the first 3 months, however, UTIs may be a common source of bacteremia (297). Chemoprophylaxis through the administration of trimethoprim-sulfamethoxazole as described for *P. carinii* infection should be provided in the first month for all patients and may be continued up to 1 year in patients whose original disease was urologic in origin.

Polyoma Virus Infection

Polyoma BK virus infection may be an increasingly important cause of graft dysfunction and graft loss after renal transplantation (298), but there has been little information about its frequency or severity in children. In one retrospective analysis of 100 pediatric renal transplant patients, BK virus was detected in the urine of 26 patients and in the blood of 5 (299). Those with viremia had elevated serum creatinine levels and evidence of interstitial nephritis in graft biopsy specimens. Screening of susceptible patients by urine analysis for BK messenger RNA has been proposed (300).

Hypertension

The incidence of hypertension after transplantation is demonstrated in an NAPRTCS investigation in which 70% of

patients required antihypertensive medications at 1 month after transplantation; the incidence decreased to 59% at 24 months (301). Hypertension is detected more commonly if ambulatory blood pressure monitoring methods are used (302,303). Hypertension after transplantation is primarily related to the side effects of drug therapy. The two most widely used immunosuppressive agents—calcineurin inhibitors and prednisone—both exacerbate preexisting hypertension. Hypertension has been correlated with multiple complications of transplantation, including reduced graft survival and cardiovascular complications (304–307).

With dosage reduction of prednisone and calcineurin inhibitors, hypertension can be managed in almost all patients, although multiple drug regimens may be necessary in some patients. An effective and safe drug to use is a calcium-channel blocker such as nifedipine, which also reduces cyclosporine toxicity (121,308). Another drug particularly favored for adolescent patients due to concerns of noncompliance is clonidine, which is available in a transdermal patch. Clonidine may induce drowsiness, and sudden withdrawal tends to produce rebound hypertension. In patients who complain of palpitations due to drug-induced reflux tachycardia, prazosin is more effective because it induces the least amount of tachycardia. Minoxidil, an acute vasodilator, should be used only in cases of severe hypertension and for only a limited time because it causes hirsutism. Care must be exercised to restrict the use of angiotensin-converting enzyme inhibitors, because converting enzyme inhibition in a single kidney model leads to reduction in glomerular filtration (309,310).

Hyperlipidemia

Steroids, calcineurin inhibitors, and rapamycin induce hyperlipidemia. A fall in serum cholesterol levels on conversion from cyclosporine to azathioprine has been demonstrated (311). The mechanism by which calcineurin inhibitors might increase plasma cholesterol is unclarified. The drugs are highly lipophilic, and up to 80% is transported in plasma by binding to lipoproteins, particularly low-density lipoprotein (LDL). It is conceivable that the binding to LDL cholesterol results in impaired clearance of LDL from the circulation via cell surface receptors (312). Posttransplantation hyperlipidemia in adults has an adverse effect on cardiovascular morbidity (313,314). NAPRTCS reviewed data for posttransplantation patients maintained under a rigid common protocol of immunosuppression and observed that at 1 year after transplantation they did exhibit significantly higher levels of plasma cholesterol and very low density lipoprotein cholesterol than healthy controls; however, the elevated cholesterol levels (mean of 213 mg/dL) were not high enough to require the use of lipid-lowering agents (315). In patients with higher serum lipid levels (cholesterol level of 250 mg/dL or higher), 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors are particularly effective in reducing total cholesterol levels

(316,317). The use of rapamycin may increase the need for lipid-lowering agents in the future.

Posttransplantation Diabetes Mellitus

Hyperglycemia and posttransplantation diabetes mellitus in children may be increasing in frequency (144). Corticosteroid use leads to peripheral insulin insensitivity and hyperglycemia that is relatively insensitive to exogenous insulin. Steroid withdrawal has led to improvements in this condition (318). An NAPRTCS investigation described an overall incidence of less than 3% among pediatric renal transplant recipients, with African Americans at higher risk (319). Tacrolimus use was identified as a significant risk factor, a finding confirmed by other reports, some of which showed incidence rates exceeding 50% (135,142–144,320). Tacrolimus may diminish insulin secretion (145). Treatment may be aided by reducing the dosage of or eliminating corticosteroids or calcineurin inhibitors (318,321).

Noncompliance with Therapeutic Regimen

Noncompliance with the therapeutic regimen is often cited as a cause of long-term graft loss in pediatric renal transplant recipients, especially adolescents. A major reason for noncompliance is thought to be the alteration in appearance that accompanies the use of immunosuppressive medications, including the cushingoid facies and growth retardation related to long-term daily corticosteroid administration and the hirsutism and gingival hypertrophy associated with cyclosporine use. However, the true incidence of noncompliance is unknown. Noncompliance rates of 22% (322), 43% (323), and as high as 64% in adolescents (324) have been reported. Some factors, such as young age, adolescence, poor socioeconomic status, and family stress, have been associated with increased levels of noncompliance (322,324–326). Importantly, however, health care workers are not able to identify a significant proportion of noncompliant patients (327). Treatments such as educational programs (323) and family-based therapy (328) have been proposed, but these types of programs have not been universally successful in changing motivation.

LONG-TERM OUTCOME

Rehabilitation

Organ transplantation typically results in dramatic improvement of all aspects of physical, emotional, and social functioning. Importantly, cognitive skills improve after successful renal transplantation (11), which suggests stabilization of neurophysiologic functioning. Scores on health-related quality-of-life measures are generally good, especially in older children and adolescents, although all ages report some problems with usual activities (329). Interestingly, the perceived emotional

status of the children was actually better than that of controls, especially during and after adolescence (329).

Long-term survival is generally excellent (330), and measures of quality of life have demonstrated excellent rehabilitation in long-term survivors (331,332). More than 90% have rated their health as good or excellent, and most did not feel that their health condition interfered with normal functioning. Most of them were full-time students or were employed. The majority were below normal in height and up to one-third were dissatisfied with their body appearance. In one report, only a small minority of long-term survivors were married (333), but in another, 50% were married and half of those had children (332).

Mortality

Infection is generally the major cause of death, particularly in the first years after transplantation (13). Other major causes include cancer and malignancy, cardiopulmonary disorders, and dialysis-related complications. The best patient survival results are found in older pediatric recipients and in recipients of LD transplants (50). Risk factors for excess mortality include young recipient age, graft dysfunction (ATN) at 30 days after transplantation, and certain underlying renal diseases (oxalosis, congenital nephrotic syndrome, Denys-Drash syndrome) (50). Mortality after 10 years posttransplantation seems to be related primarily to cardiovascular causes (330), which may be linked to the hyperlipidemia and hypertension associated with chronic immunosuppression. The mortality rate of children, except for the very youngest, is very low and is generally better than that found in adults.

ETHICAL CONSIDERATIONS

MICHEL J. C. BROYER

Many ethical considerations arise in the clinical practice of pediatric nephrology. Issues range from the appropriate use of modern-day molecular genetic technology in renal diagnostics to choice of therapies in children with retracting symptoms and/or progressive renal failure.

PRINCIPLES

Medical ethics is based on three well-established principles. *First*, the benevolence/nonmalevolence interpretation of the *primum non nocere* principle of the Hippocratic corpus must be used. This states that, in any given case, treatment must confer net benefit over harm, a calculation that is not always readily apparent. *Second*, the principle of autonomy mandates appropriate informed consent. This requires that not only the parents but also the child as much as possible have accurate information, knowledge of possible alternatives, and general understanding, and that their comprehension be confirmed. *Third*, the principle of justice must be constantly applied. This means that equal access to optimal levels of care must be available—abrogation of the rights of some to satisfy the needs of others cannot be condoned.

In addition to following these principles, one also must take into account the impact of cultural, religious, and legal factors that may affect medical decisions. The application of these principles is far from straightforward in most clinical settings. In many cases, the answer to an ethical question may be controversial, with well-developed and contrary positions effectively presented.

From a global perspective, it is obvious that ethics must take into account international conventions and existing national laws. Fundamental is the United Nations Convention for the Rights of Children, which reinforces the human dignity of children and seeks respect for children by endorsing the principle of nondiscrimination and always working in the best interest of the child with his or her participation (1).

ETHICS AND CLINICAL RESEARCH

Research involving human subjects must follow strict rules that originated with the Nuremberg Code and the Declaration of Helsinki. Regularly revised guidelines have been adopted and issued by the World Health Organization. In many countries, national laws define the investigator's obligations in clinical research. Besides these regulations, research on humans must also take into account a series of ethical principles well summarized by Beauchamp and Childress in 1979 (2): First, acknowledge the dignity and the autonomy of individuals with special protection for potentially vulnerable populations such as children. Second, ascertain that the risks always be justified by the expected benefits of the research. Third, research should not involve persons from groups that are unlikely to benefit from subsequent applications of the research. These principles carry strong moral imperatives. Difficult ethical dilemmas may arise when they conflict, which appropriately result in the abandonment of the proposed project.

In the United States, the protection of human subjects is defined in the Code of Federal Regulations (3), and the protocol for any federally sponsored research project involving human subjects must first be submitted to the Office for Human Subject Research, which determines if an Institutional Review Board review is required. The protocol is then submitted to the Institutional Review Board, which approves, disapproves, or requests modifications. A similar process is followed in other countries. In France, for example, a law was enacted in 1988 (4) requiring that all research projects involving human subjects be approved by the Committee for the Protection of Persons Submitted to Biomedical Research. Children, in particular, are protected from research not yielding a direct benefit. Such research is permitted only if the following three conditions are met: (a) there is no foreseeable serious risk to subjects, (b) results are potentially useful specifically for children, and (c) the information yielded could not readily be obtained by other

means. In addition, any indemnity is forbidden. The informed consent of the parents (and the child, if possible) is required. In the United Kingdom, the active informed consent of those older than 16 years of age is mandatory.

In conclusion, before any research project involving children is contemplated, the appropriate answers must be given to five questions well formulated by Alderson (5):

1. Are children likely to suffer any harm as a result of the research in the form of emotional distress or intrusion?
2. Do the benefits of the research clearly outweigh these possible risks?
3. Who will benefit from the research: children or only the researchers?
4. Are children given the proper information about the research?
5. Are children offered the opportunity to refuse to participate or to answer particular questions?

ETHICS AND GENETICS TESTING

The application of functional genomics to kidney diseases creates controversies in the assessment of information provided to patients and possible interventions. This is a particularly complex area that has been extensively reviewed (6). National regulations have been developed concerning genetic testing. The intent behind these regulations is to respect the privacy of any tested individual and to limit the practice of testing in children to special situations. Informed consent is mandatory, because results may have serious impact on the individual, especially when asymptomatic disease with possible severe clinical evolution and the risk of transmission to descendants is identified. With regard to children, because no therapies may be available to prevent the development or progression of disease, it may be argued that the negative impact of a "genetic diagnosis" is serious enough to warrant limiting genetic testing to situations in which the child or the child's family may derive a direct benefit from immediate curative or preventive measures. In France, for example, genetic testing of children is legally forbidden if this latter criterion is not fulfilled. It is still debatable, however, whether yearly renal investigation throughout childhood and adolescence is preferable to genetic testing in individuals at risk for an inherited disease such as nephronophthisis. Another important point to emphasize is that the results of genetic tests must not be delivered directly to the patient by a testing laboratory. It is mandatory that a knowledgeable physician provide and interpret test results as part of the physician-patient relationship. In addition, any patient may accept or refuse to know the results; the subject has the right not to know, a consequence of respecting the patient's autonomy. Results concerning other members of the family are protected by medical confidentiality, and test results must be given to each individual separately.

In the area of genetic renal diseases, it is best that a multidisciplinary team (i.e., pediatrician, genetic counselor,

geneticist, social worker, mental health professional) be involved with pediatric patients and their families.

CLINICAL EXAMPLES: ETHICAL DILEMMAS

Antenatally Detected Abnormalities of the Urinary Tract

Routine fetal sonography is able to detect important renal abnormalities such as kidney agenesis, cystic or dysplastic kidneys, or obstructive uropathy (7). Kidney morphology and the volume of amniotic fluid may be assessed. Studies of the composition of amniotic fluid may provide additional information, but further studies are needed to determine the true value of such assessment. Communication with parents requires the constant participation of the several specialists involved: radiologist, obstetrician, and pediatric nephrologist. In the case of urinary obstruction *in utero*, intervention has been extremely disappointing to date. New data concerning the prevention of neonatal death (due to pulmonary hypoplasia) by amniotic fluid infusion deserve comment. In the case of severe oligoaminos, ethical rationale would consider the risk of fetal intervention justified in view of the 93% mortality rate, acknowledging, of course, the futility of such an intervention should exclusion criteria exist, such as chromosomal abnormalities, renal agenesis, or presumed irreversible renal damage (8). This may be particularly true if exclusion criteria such as chromosomal abnormalities, renal agenesis, or presumed irreversible renal damage are met. In these cases, after full information is disclosed, parents may opt for pregnancy termination when legally allowed. Others have argued that the present possibilities of neonatal dialysis and early transplantation may not warrant these exclusions. As is noted later in this chapter, this raises ethical questions regarding renal replacement therapy (RRT) in neonates.

Amnioinfusion with saline or, preferably, lactated Ringer solution to prevent or limit lung hypoplasia, a consequence of oligohydramnios (9), is an extreme approach that seems effective in limiting lung hypoplasia and the development of Potter syndrome. It does not modify the renal disease. Amnioinfusion, an experimental therapy, is performed only with the fully informed consent of the parents in a decision made together with the obstetrician, perinatologists, and pediatric nephrologist.

Renal Insufficiency in Premature Babies

Renal insufficiency is not uncommon in the very-low-birth-weight premature infant. Peritoneal dialysis is best adapted to this situation given the very large ratio of peritoneal surface area to body weight, but in some cases such infants have been treated with hemodialysis or hemofiltration. The ideal case to treat is the very-low-birth-weight infant with acute reversible renal insufficiency without structural renal abnormalities secondary to toxic or ischemic vasomotor nephropathy. An associa-

tion with other major renal parenchymal damage or multiorgan abnormalities clearly represents a contraindication for intervention in most pediatric nephrology centers worldwide. In a review, Coulthard and Vernon (10) reported survival of 13 infants out of 21 with a birth weight lower than 1 kg, and of 2 infants out of 4 with a birth weight between 1.0 and 1.5 kg.

Such expensive and labor- and resource-intensive therapy raises serious ethical issues: Is it considered unacceptable overtreatment, or, if treatment is withheld, is it nonassistance to an endangered individual? As stated by Coulthard, the choice is between certain death and a slight chance of survival, and for many, death will occur at a later date. Is such treatment an act of cruelty for families whose hopes have been raised only to be dashed, or alternatively is it a welcome opportunity to relate, bringing greater meaning to a life, albeit for a brief period? In such cases, the principles of benevolence and nonmalevolence can support either treatment option. In any specific case, the actual course of action is determined only with the active involvement of parents and all members of the health care delivery team, with constant and consistent communication.

ETHICAL PROBLEMS IN THE TREATMENT OF END-STAGE RENAL DISEASE IN CHILDREN

Treatment by dialysis was first selectively applied to adult patients in the mid-1960s. It was difficult at the time even to imagine that children could be treated using this modality. The prospect of performing kidney transplantation with some success and the dramatic technical progress in vascular access and dialysis modalities changed this attitude, and in the 1970s specialized centers started to accept children into dialysis and transplant programs. At the time, this approach was criticized by certain pediatricians, mental health professionals, and others, who considered it unethical to submit children to such difficult treatments. Nevertheless, from that time onward, desperate parents almost always chose to save their children through dialysis, even though the long-term effects (complications, long-term survival, quality of life) were still unknown. With advances in therapy, it is now clear that most if not all children reaching end-stage renal failure may benefit from RRT as routine treatment. Such therapy, although expensive and labor intensive, is usually compatible with survival and a satisfactory quality of life, as measured by a variety of methodologies. Indeed, if parents actively refused such intervention in the United States, they would immediately be subject to acute investigation for possible child endangerment.

End-Stage Renal Disease in Newborns and Infants

End-stage renal disease (ESRD) in newborns still presents a series of ethical challenges. Two possibilities clinically lead

to different courses of action: bilateral renal agenesis and kidney malfunction in the presence of renal parenchyma. In the first case, the decision is usually made not to initiate RRT, but this is not uniform and is discussed later. In the second instance, dialysis may be contemplated when it is believed that renal damage may be reversible; this dialysis should be initiated only with the informed consent of the parents and should continue only long enough for the diagnosis and prognosis to be established.

Newborns with Renal Agenesis or Irreversibly Damaged Kidneys

In the case of newborns with renal agenesis or irreversibly damaged kidneys, there are two possibilities: either withholding all treatment or using an aggressive approach and initiating dialysis. This is always a difficult scenario for both the parents and the medical-nursing team. The decision is made only after the parents have been fully informed. It must be clearly stated to the parents that, although dialysis and/or transplant treatment can be applied to children with some success, their use is much more difficult in an infant (11) and involves serious treatment and frequent hospitalizations during critical stages of development. Treatment is far more intensive than that for older children. In addition, success is not guaranteed, and almost all studies of this age group report significant morbidity and mortality. Long-term home therapy can be challenging for even the more motivated and intensively trained family members, who become “amateur intensivists” in the home. The consequences of this workload are serious. One of the two parents must dedicate himself or herself full time to this occupation. Family life is disrupted, and the impact on siblings, although significant, remains poorly studied. Overall, the quality of life of an infant on dialysis is far from normal due to the connection to the dialysis machine and all the necessary care. In addition to dialysis, patients also need an aggressive approach to nutrition, which usually necessitates tube or gastrostomy feeding. The overall objective is to perform kidney transplantation after 12 to 18 months of dialysis when the infant has reached at least 12 kg of real body weight. There are centers that perform kidney transplantation in very young patients with good results (12), but it must be noted that these single-center results have not been obtained in larger multicenter studies worldwide. Another concern, besides mortality, is the question of long-term quality of life, particularly neurocognitive development (13). Resource allocation becomes a major issue in countries with limited overall medical resources and health care delivery systems. Several reports have been more encouraging (14–17). A study by Warady and colleagues (16) reports the 5-year outcomes of 34 infants who were started on dialysis before 3 months of age: 6 died within the first year, 28 survived, 24 have received grafts, and only 1 had delayed psychomotor development. In this series, of the 16

who were older than 5 years of age, 15 had normal intellectual development and were at age-appropriate schooling levels. A study by Leder mann (17) reports on a series of 20 children starting dialysis within the first year of life (mean = 3.5 months) with a follow-up of 1 to 5 years. Of the 16 survivors in this series, 14 had normal psychomotor and neurocognitive development. The importance of comorbidity is nevertheless stressed: there were a number of peritoneal dialysis catheter replacements, and more than one peritonitis episode in 30% of cases. Nevertheless, the height, weight, and head circumference were not more than 1 standard deviation below the mean normal values. All these publications, however encouraging, deal with a limited number of infants treated in the first days of life and cannot be used as a compelling argument.

Attitudes of Pediatricians to the Management of End-Stage Renal Disease in Newborns and Infants

Several surveys have addressed the attitudes of pediatricians to the management of ESRD in newborns and infants. A multicenter study involving 217 pediatric nephrology centers in eight different countries was published in 1998 (18); by definition, these centers had the capacity to offer dialysis treatment to at least some infants aged 1 to 12 months. The survey asked whether the nephrologists offered RRT to any or all infants with ESRD, and, if parents refused RRT for otherwise normal children with ESRD, whether this was ever acceptable to the nephrologist. Ninety-three percent of the centers stated that they offered dialysis to some infants younger than 1 month of age; 41% offered it to all infants of this age, but 53% offered it to all children 1 to 12 months of age. The opinion of pediatric nephrologists as to the parents' right to refuse RRT for their children was varied: 50% of physicians thought that this refusal was ethically acceptable for infants younger than 1 month of age, but only 25% held this opinion in the case of infants 1 to 12 months of age. For 19% of physicians, this refusal was never acceptable for infants younger than 1 month of age, and for 38%, it was not acceptable for infants 1 to 12 months of age. Among factors influencing the decision to withhold RRT were the presence of coexistent multiorgan defects, the anticipation of morbidity for the child, the family's right to decide, and the medical staff's right to decide. Economic constraints were not an important factor; neither was the socioeconomic status of the family. There were no clear differences in the attitudes of pediatric nephrologists in different countries except for opinions concerning the right of the parents to refuse RRT, which was much less accepted in Italy and in Japan than in other countries such as Germany, the United Kingdom, and the United States.

In an additional study of 37 level 3 university neonatal units, 34 units answered a questionnaire on the attitudes concerning newborns with ESRD or preterminal ESRD who needed RRT within months or a few years (19). With

regard to newborns with ESRD, 23 of 34 units refused any form of RRT, 3 were in favor, and 8 gave no opinion. In the case of newborns with preterminal ESRD, 18 accepted the idea of RRT, 3 refused it, and 13 gave no opinion. Those that did not give an opinion pointed out that the decision rested on several elements and that each case deserved an individual decision.

End-Stage Renal Disease in Children Older Than 12 Months

As mentioned earlier, for over 20 years children with ESRD have regularly received RRT in specialized centers. However, children under 5 years of age have not always been accepted into such programs. Data of the European Dialysis and Transplantation Association registry (20) reveal a progressive increase in the youngest groups of patients receiving RRT: the proportion of new patients under 2 years of age increased from 0.6 to 9.5%, and the proportion of those 2 to 5 years old increased from 4.7 to 14% from the period 1968–1973 to the period 1986–1991. In other words, in most European countries, RRT for children became progressively acceptable as a routine treatment during the 1980s. Despite this, however, initiation of dialysis in children still provokes ethical controversy. The Spanish Society of Pediatric Nephrology conducted a survey in 1998 (21) with the purpose of defining the criteria for starting RRT in children with ESRD. According to this study, 90% of pediatric nephrologists concluded that some patients ought not to receive RRT and that the main criteria for withholding this treatment were a prognosis of a short life and serious physical or neurologic defects. Fauriel et al. (22) studied via "semidirected" interviews the attitude of French pediatric nephrologists toward the decision of withholding or withdrawal of RRT. Of 20 physicians, 19 answered that withholding RRT was sometimes necessary and only 1 was absolutely against the idea. The reasons given for withholding treatment were poor quality of life, protection of the family, and avoidance of "unbearable treatment."

One of the few publications that report the withholding of RRT in children with ESRD deals with a series of patients with primary hyperoxaluria (23). In this study of 78 cases in 24 countries on three continents, 65 patients reached ESRD, and RRT was withheld from 40% for one or more reasons. The reasons were economic and organizational in 10 cases, "ethical" in 17 cases, and based on parental decision in 16 cases. Most of these children were younger than 1 year of age, and ESRD developed before the time that liver transplantation was generally advised for this indication.

Withholding or Withdrawal of Life-Sustaining Therapy: The Decision-Making Process

In the process leading to a decision to withhold or withdraw a life-saving treatment, Steinberg (24) recognized

three major factors: (a) relevant medical facts, such as diagnosis, the various therapeutic options available, the potential complications, and the spectrum of short- and long-term prognosis; (b) the parent-physician relationship, with stress on the importance of an atmosphere of trust; and (c) general sociocultural, ethical, legal, and religious principles, for which consulting experts in these fields is also important. Besides these obvious factors, a number of other issues must be considered.

Quality of Life

The concept of quality of life has replaced the concept of "life at any cost." However, the definition of unacceptable quality of life is difficult to establish (25). An adult individual, even a mature adolescent, may be able to judge that his or her own quality of life is unacceptable, at least to some extent. The case of newborns unable to express themselves is challenging. In this instance, professionals and parents must have reached an agreement that the quality of life of the infant is unacceptable and without future promise. Admittedly, this assessment is subjective and could be biased. Errors are possible with regard to the diagnosis, the prognosis, the possible benefit of a treatment or its adverse effects, the complications of the disease, and the level of suffering of the child and his or her family. Because there is no precise benchmark beyond which quality of life becomes unacceptable, it is possible to imagine slippery slopes toward decisions that would be clearly unethical. Here, mention may be made of the Dutch legislation (26) permitting euthanasia and possibly leading to more or less acceptable decisions.

Parents' Role

The parents are generally in the best position to determine what is in their child's best interest. It is also the parents who bear the consequences of any decisions, more than any professional. Centralizing all decision making exclusively with the parents may lead to problems, however. Parents may sometimes make a decision that is not in the best interest of the child. In addition, an objective decision is sometimes difficult to make in the emotional context of the birth of a child with a severe medical problem. The postpartum period is often accompanied by a decreased ability to make decisions and a transitory deficit of cognitive function (27). Parents may wish to continue a treatment that has been judged as futile by the medical staff (28).

Patient's Rights, When They Apply to an Opinion Expressed by a Minor

The patient's wish may be considered only if formed by a mature adolescent who is judged to be intellectually capable. When dealing with adolescents, it is important to bear in mind the characteristics of their age: the need for privacy,

independence, mobility, schooling, and the company of their peers (29). The request to withdraw from dialysis is considered ethically and legally acceptable when expressed by adults (30). Consequently, there is no formal reason to dismiss *a priori* such a request from a young patient who perceives his or her future as hopeless with no possibility of improvement. Nevertheless, caution must be exercised regarding the idea of competency. Competency should include a basic understanding of the disease and of the different treatment options, the possible hope of a transplantation, and so on. Maturity, which is acquired with age, is an important part of the decision-making capacity, permitting a value judgment on the world and the surrounding social environment so that one can situate oneself despite the handicap. In fact, maturity and competence are extremely variable at any given age. The irreversibility of the decision justifies physicians' hesitation in accepting an adolescent's request for treatment withdrawal. There is first the evaluation of the cognitive ability to give informed consent, which may have been distorted by social and familial history or by psychological trauma leading to behavior regression. Thus a 14-year-old adolescent may refuse treatment irrationally, and the physician must analyze the situation and make the necessary decision, including an eventual appeal to a psychiatrist. There are cases, however, such as one reported many years ago (31), in which a treatment deemed intolerable may be stopped at the request of an adolescent.

In the case of a minor exhibiting his or her wish to die by refusing dialysis without medical reasons, one must carefully review all information on the different modes of dialysis and the possibility and result of transplantation. It is useful to organize meetings with other adolescents in a similar situation who are being treated by dialysis or who have a functioning graft. The strategy must also be based on allowing some freedom and proposing a trial period with one of the modes of dialysis chosen by the patient; this may permit the patient to gain control of the situation and at the same time may constitute an opening toward treatment acceptance.

Professionals

Professionals have a central role in the decision process. They provide the information that is the basis for a patient's decision. It must be remembered that there are different attitudes regarding withholding treatment (32,33). One must bear in mind the obligation to be as objective as possible, to avoid lies of omission, and to provide the essential elements to permit ethical decisions to be made.

Ethics Committee

The multidisciplinary composition of ethics committees may be useful in difficult cases or those that involve conflict. Such committees are composed not only of experts in the medical field but also of psychologists, social workers, jurists, reli-

gious representatives, philosophers, and lay members of the community. Such a committee may be capable of furnishing reasonable advice and may be able to harmonize various views. Existing national advisory ethics committees may also be useful, as was the case in France, where a study examined the problems raised by intensive care of newborns with borderline medical status (34). Responsibility, discernment, and humanity were the key concepts in this report and should guide decisions on whether to withhold or withdraw a life-sustaining treatment, with the role of the parents being central in the decision process.

Legal Field

The legal field is rather complex because of differences in laws among countries. An important body of court decisions is available in the United States, developed to protect the lives of disabled children, for whom one might abandon treatment. The Baby Doe amendment (35) makes it an obligation to administer medical treatment needed by the child with the parents' agreement in all situations except the following: (a) the child is in irreversible coma; (b) treatment merely prolongs dying, does not correct all of the infant's life-threatening anomalies, and is useless in ensuring the infant's survival; and (c) such treatment would be futile in the infant and its pursuit would be inhumane.

To what extent this amendment applies to a newborn with ESRD is worth discussion, because it could be argued that an infant treated by dialysis may suffer not only from the treatment itself but also from its complications, which may render such treatment inhumane. As a matter of fact, dialysis for ESRD in newborns is one of these ambiguous situations in which contradictory points of view may be held. The decision to initiate such treatment remains controversial (35). In Europe there has been no court decision on the subject. Basic medical principles dictate that the physician is obliged to prescribe the treatment needed by the patient or, in cases without any hope, to apply palliative care. In addition, although the legal regulations generally define euthanasia as a crime, they also define as a criminal offense the exposure of a person to a risk of death. It is important to note that courts are not involved in these decisions in countries such as France or Australia (36), because, although a tribunal gives an *a priori* guarantee of objectivity, judges are less sensitive and more remote than health professionals, the latter of whom are closely connected emotionally with the treatment. In Holland, although the law defines situations allowing euthanasia, the withholding of medical treatment for a non-medical reason (e.g., social, economic, or based on quality of life) is illegal; to perform a futile medical act is also illegal.

Economic Factors

Economic factors are not usually considered a determinant among the reasons to withhold or withdraw treatment for

children in developed countries. They were considered unimportant in the study of Geary (18) and are completely absent in the Spanish survey (21). Nevertheless, it remains true that use of a dialysis program in newborns and infants is associated with a number of days of hospitalization, requires more nurses and physicians for a nonguaranteed result, and is associated with a death rate that may be as high as 20 to 30%. This cost is at present covered by many government programs in the Western world but presents severe problems in other countries. In some areas, allocation of resources must be based on priorities (37). It may be argued that in poor countries priority must be given to preventive and therapeutic measures that offer a basic level of health care to large numbers of individuals at low cost and that expensive treatments which benefit only a small number of the population cannot even be considered.

Development of Recommendations Concerning Withholding or Withdrawal of Renal Replacement Therapy

General Case

In recent years, the question of withholding or withdrawing life-support treatment has been discussed largely in neonatology, with the elaboration of a regulated approach, following a consensus, as in the United Kingdom or France.

In the United Kingdom, the recommendations of the Royal College of Paediatrics and Child Health lists five situations justifying withholding or withdrawing treatment (38): (a) brain death, (b) irreversible vegetative state, (c) the no-chance situation, in which treatment will merely delay death and will offer no significant relief from the suffering caused by the disease, (d) the no-purpose situation, in which treatment may be life saving but will leave the child with a degree of mental or physical impairment so great that the quality of life for the child is without hope of improvement, and (e) the unbearable situation, in which additional treatment may only cause further suffering.

Along with these recommendations, some other considerations were noted: first, expert palliative care must be provided when curative treatment is withheld; and, second, good communication with the parents is needed at the time of the decision to withhold treatment. It is also necessary to provide appropriate measures for the parents after the death of their child. A survey of the application of these recommendations (39) showed their soundness.

In France, neonatologists have developed principles concerning withholding or withdrawing treatment in the newborn, simultaneously with the Comité Consultatif National d'Ethique (National Consulting Committee on Ethics) (33). The consensual document published by the Federation of French Neonatologists (40) mainly insisted on the need for an organized process with several steps. The first is discussion of the case, with the participation

of medical and nursing staff and other experts, which may lead to a conclusion. The second step is to inform the parents, with the notion (extremely strong in France) that parents must not be left alone to make a decision and that their agreement to a possible decision to end life by withholding or withdrawing treatment must be obtained over time and with the attempt to avoid a situation in which the parents are obliged to bear the weight of this decision. Third is the final decision taken in a measured way by experienced professionals, with the whole staff participating in or being informed of the decision.

Specific Case of End-Stage Renal Disease in Children

Recommendations for starting dialysis in children with ESRD were elaborated by the Spanish Society of Pediatric Nephrology (41). In what follows, articles dealing with withholding or withdrawal are given in italics.

1. All pediatric patients receiving dialysis must meet the following criteria:
 - The patient must be diagnosed with ESRD.
 - Informed consent must be given by the parents or the legal guardian.
 - The patient must have real possibilities for kidney transplantation.
 - There must be a reasonable expectation that the patient will enjoy an acceptable quality of life during dialysis therapy and after kidney transplantation.
 - The patient and the parent(s) or guardian(s) must demonstrate a willingness to participate in and cooperate with the dialysis procedure and follow medical advice.
2. Patients with irreversible diseases that make survival extremely unlikely will not be considered as candidates for dialysis.
3. Those patients meeting the criteria stated in guideline 1 will not be refused dialysis treatment for economic, social, or psychological reasons, nor will age, sex, race, or physical handicap be taken into consideration.
4. Dialysis treatment will not be withdrawn against the wishes of the parent(s) or guardian(s).
5. The cessation of dialysis will be considered if results are not satisfactory or it is certain that results will not improve. A decision to stop treatment must always be made with the agreement of the responsible physician, the patient, and the parent(s) or guardian(s).

Recommendations for withholding or withdrawing dialysis have been published for adult patients (42); these recommendations are not appropriate for children. Except for newborns with isolated renal failure, it is always in cases where ESRD is associated with other serious medical problems (e.g., malignant disease at the last stage, severe neurologic disease) that the issue is raised. It is not possible to

foresee all the situations in which the question of whether to perform RRT will arise. As was proposed by the Royal College of Paediatrics and Child Health and the Federation of French Neonatologists, it would be reasonable that such a decision follow a stepwise process, with the best interests of the child kept in mind. This process might be summarized as follows:

1. Gather all elements of the medical history and discuss the details with the different relevant experts, especially neurologists, to determine as precisely as possible the life prognosis, as well as the functional prognosis, with consideration of the quality of life in the short and long term and acknowledgment that some subjectivity may enter into the discussion. In this analysis, the participation of the nursing staff is necessary. The conclusion must be noted in the medical file.
2. Discuss the severity of the case with the family and obtain their agreement for withholding or withdrawal of treatment. This is sometimes possible only after several meetings involving other professionals such as the family's general practitioner or a religious representative.
3. In case of disagreement or conflict, propose that a second opinion be obtained from another group or physician in the same specialty.
4. The advice of an ethical committee may be useful at this stage.
5. If the parents continue to ask that treatment be continued against the physician's recommendation, the problem is difficult, and there is no rule that can prevail absolutely. Some physicians stick to their decisions and are ready to stop a treatment considered to be unethical; others believe they should follow the parents' request, even if it opposes their own feelings.
6. Special cases:
 - a. Adolescent requesting withdrawal from dialysis: This request is to be considered in context and cannot be accepted unless the conditions of intellectual competence, possession of appropriate information, and maturity are present.
 - b. Newborn in ESRD: This case is controversial, and the process described earlier can be applied only in a situation involving trained medical and nursing staff and availability of the necessary medical equipment. It could be useful to show the parents other babies receiving dialysis and also to have them meet other parents who have been faced with a similar situation and are willing to discuss their experience.

In conclusion, pediatric nephrologists are sometimes faced with the question of withholding or withdrawing dialysis in children with ESRD in special situations. It is always a difficult decision, given that opposing positions (43,44) may be put forward. This is another example of a common dilemma of medical ethics in which there are no ready-made answers.

SOME ETHICAL ISSUES IN PEDIATRIC KIDNEY TRANSPLANTATION

Among a number of ethical questions related to kidney transplantation, several issues have been selected for discussion in this chapter: indications and contraindications for transplantation, informed consent, the priority of children on the waiting list, the living donor approach, and the use of commercial donors.

Appropriateness of Contraindications

Rereading the textbooks written in the 1980s and 1990s, one finds that contraindication to transplantation in children was considered justified in cases involving disabilities, some diseases such as oxalosis, or infection with human immunodeficiency virus (HIV).

Today, most of these contraindications are disappearing. Disabilities per se are not an ethically acceptable reason for denying access to transplantation. For example, a number of trisomic patients have successfully received grafts (45). The prognosis of primary oxaluria, previously associated with a constant recurrence in the graft and severe associated extrarenal pathology due to oxalate accumulation, has been completely changed by combined liver-kidney transplantation. HIV infection, aggravated by the effects of immunosuppressors and, in any case, having a poor prognosis, today may be treated effectively by means of triple antiviral therapy and thus is no longer an absolute contraindication (46).

In fact, when a possible contraindication to kidney transplantation in a child is discussed, the individual case deserves to be examined in depth from an ethical point of view. The answer should be given after considering the three basic principles of medical ethics: Do the benefits expected from transplantation clearly outweigh the negative effects? Do the parents and, if possible, the patient still agree after full information has been provided? Is distributive justice contradicted? A reasonable balance must be achieved between protecting the health of the patient and not wasting valuable organs. Today, there probably remains only a very small number of cases for which a contraindication persists—those patients with a short life expectancy or those with very severe brain damage, for example.

Pediatric Priority

Pediatricians have worked in many countries to obtain priority for children on transplantation waiting lists. This has been the case in France since 1997 (47).

From an ethical point of view, some are opposed to granting any kind of priority because it would breach one of the basic principles concerning distributive justice. There is a valid reason for violating this principle, however: childhood is a very special time in the life of human beings during which education and socialization are developmentally

necessary for the individual to reach an acceptable adult level. Only a successful transplantation allows completion of these developmental tasks; long periods on dialysis have been associated with the irreversible loss of both education and socialization (48).

Informed Consent

For at least two decades it has been clear that kidney transplantation is the best therapeutic modality for children with ESRD. Nevertheless, the decision to perform this treatment cannot be made without the informed consent of the parents and the child, depending on his or her age. The main potential complications, including the risk of death, must be described, even if they occur relatively rarely these days, and the need for medical follow-up and for indefinite immunosuppressive treatment must be made clear. Provision of a written document that summarizes the oral information is part of good practice. The information given to the child should of course be adapted to his or her level of understanding. Refusal of transplantation, especially by an adolescent, must be respected until the time that he or she may be more willing to accept it, such as after further information is provided or the individual experiences dialysis. Consent during adolescence is especially mandatory, because compliance with the medical treatment is crucial.

Living Donor

First, one must remember that to take a kidney from a healthy individual breaches the basic principle of Hippocratic medicine, the *primum non nocere*. To do so is possible only when the benefits to the recipient are considered to outweigh the harm to the donor. Consequently, physicians must always keep this balance in mind before making such a decision. For this purpose, a strict protocol must be applied. In the process of live donor transplantation, the initial information given by the physicians is of major importance because it greatly influences the individual who receives it. So that complete autonomy is respected, the initial information must be neutral and must not present the use of a live donor as the best approach when a cadaver program is also available. The recommendations of working groups, such as the consensus statement of the National Kidney Foundation and the American Society of Transplantation (49), are useful and stress the fact that the live donor must be competent, must be willing to donate free of any form of coercion, must be medically and psychologically suitable, and must be fully informed of the risks to himself or herself and the risks and benefits to the recipient, as well as of the available treatment alternatives. It is the physician's duty to verify the correct understanding of the information, especially when the family is from another country and does not speak the same language as the medical staff. It is also important to double-check the consent using a multidisciplinary approach involving the nurses, psychologist, and so on. If a risk factor

for the donor is identified at the time of evaluation, the risk-benefit balance must be carefully considered, with the idea that it is better not to take any supplementary risk involving a donor. This point of view is challenged by some “ethicists,” who claim that donor autonomy must be respected nonetheless and that physicians may only act as the service providers. From an ethical point of view, if the risk—even a seemingly suicidal one—taken by the donor might still be considered ethically legitimate in the aim of alleviating the suffering of another, it remains that the intervention can only be accomplished at the hands of the doctor who must obey his or her own moral principles, as well as the professional code of ethics, which states that one can not be the instrument of injury to others.

Nonrelated Living Donor

Recently, a new donor category has emerged, especially in the United States: the altruistic donor (50). The altruistic donor decides to give a kidney to an unknown individual without expecting any reward. He or she may be considered a kind of holy person, and from an ethical point of view there may be no opposition to such a decision. The real issue lies in the certainty of this decision. An in-depth psychosocial evaluation is needed before such donors are used. Very few donors were ultimately retained in the first such series (50). Altruistic organ donation for a child raises the problem of hidden commerce, which it is never completely possible to exclude.

Commercial Donor

Commercial organ donation is universally banned by the Transplant Society, the European Dialysis and Transplant Association, the World Health Organization, and the Council of Europe, and is illegal under national laws almost everywhere because it is ethically unacceptable. Unfortunately, however, commerce in human kidneys exists in several countries and is actively (though on a limited basis) taking place in Europe. Most worrying is the fact that some self-defined ethicists as well as some physicians have recently defended this commerce. Their arguments hold that the principle that “the body cannot be sold” is obsolete because the world is ruled by the marketplace. They respond to the argument that such donors are compelled by abject misery by proposing to let people be free. To the argument that such a practice will benefit mainly the rich, they respond that this is also true for other areas of medical activity and could be solved by creating a central agency. To the risk of hidden viral contaminations, they propose multiplication of screening procedures. And to the suggestion that commercial organ donation may evolve into a criminal activity, they reply that that is the work of the police. It appears easy to supply a reply to all these arguments. Then why is the commerce in organs unethical? Because converting human beings into products will under-

mine the fundamental values requisite both for respect of others and for self-esteem. In addition, the organ trade is likely to take unfair advantage of poor people and poor countries, and will do nothing to solve the problem of poverty. It will alter the attitude of society toward medical professionals, with the development of suspicion and loss of respect (51). Thus, we must remember that the ends (*of increasing kidney transplantation*) do not justify the means (*for obtaining organs*).

CONCLUSION

Although ethical considerations are a part of any medical act, the most significant questions deal with the treatment of ESRD in children. Even if technically feasible, dialysis may not be appropriate, and transplantation may create more harm than benefits. There is no definitive answer to ethical dilemmas, which require multidisciplinary teamwork with the participation of the parents and the child. The best interests of the child must always be the primary consideration.

**PEDIATRIC NEPHROLOGY
AROUND THE WORLD**

OVERVIEW

MATTHIAS BRANDIS
IRA GREIFER

The subspecialty of pediatric nephrology has developed within the last 40 to 50 years. Sophisticated diagnostic and therapeutic standards have been achieved for the care of children with congenital or acquired renal diseases. The technical equipment developed for adults has been adapted to children.

A series of reports entitled “Nephrology around the World” was first presented in the second edition of this book to draw attention to the variation in the clinical spectrum of renal disease in children in various parts of the world, with particular emphasis on differences from the pattern seen in Europe and North America (1). Cameron, reviewing the historical, social, and geographic factors affecting the pattern of renal disease in children, used the challenging phrase “pediatric nephrology in an unjust world” to describe the fact that most contemporary pediatric nephrology arose from and was relevant to only a minority of the world’s children (2). The situation has hardly changed since that time. The only difference is that more and more pediatricians around the world have become interested in this field of patient care and clinical research (3,4). There has been an impressive change in the distribution of competence and knowledge within the recent past. The increase in activities on the South American continent, which has its own regional society (the Latin American Association of Pediatric Nephrology) (4), the productive and efficient organization of the Asian Society of Pediatric Nephrology with steadily rising numbers of participants at the various congresses in that region, and last but not least the establishment of an African Society of Pediatric Nephrology (AFSPN), which has already organized its second congress, are undoubtedly signs of an increasing conscience about the care of children with kidney disease. These signs of increasing interest and motivation on the part of young pediatricians in the field of nephrology are prompted by the sincere desire to provide better care for children with renal disease and to achieve this goal by initiating better and more adequate training.

Many of the old problems remain. The proper management of renal disease in children is expensive, particularly the

provision of renal replacement therapy for end-stage renal disease. Poor countries are doubly deprived: not only is their gross national product low, but also a smaller fraction of it is made available for health care (5). Nevertheless a concern about renal disease in children has developed in all regional societies and working groups. The newest regional society of the International Pediatric Nephrology Association (IPNA), the AFSPN, is trying slowly to reach pediatricians with interest in this subspecialty within the African continent, despite the existence of a wide variety of ethnic and economic issues. The huge distances and differences in social, economic, and political problems between South African and North African countries, and the quite different structures within Central Africa are only some of the tremendous problems that exist, even independent of the difficult economical questions. Notwithstanding these obvious issues, there is an increasing conscience and willingness to launch better care for children. Different incidences and epidemiologic characteristics of diseases in developing and tropical countries than in developed countries reinforce the interest of the field of nephrology in the pathogenesis and outcome of similar diseases in various parts of the world. One can conclude that, in spite of the economic differences and difficult political situations, the pediatric nephrology societies have an increasing professional interest in studying the clinical and pathologic differences in kidney diseases in various parts of the world (6–10).

To address the prevailing problem of economic limitations to the distribution of equitable diagnostic and high-quality therapeutic services in all parts of the world, the community of pediatric nephrologists has a growing conviction that they must help to increase the knowledge of basic care for children with renal disease (11). Sophisticated research or introduction of technical procedures, which for the near future is not achievable, is not on the main worldwide agenda.

Children have a right to treatment every bit as sophisticated and to resources just as well developed as those available to adults; yet in countries in transition to new demographic and economic patterns, children still have difficulty competing with adults for limited resources, as the

reports from Latin America (see Chapter 75F) and Africa (see Chapter 75E) clearly show.

The modern structure of the specialty can be traced to the formation of the International Study of Kidney Disease in Children (ISKDC) in the second half of the 1960s (12,13). Such multicenter studies are of value not only for the power that they bring to the resolution of a clinical problem by virtue of the large numbers of cases available for study, but also for the professional relationships, understanding, and standards that they foster. This study was naturally followed by the formation of several regional pediatric nephrology societies and by the IPNA, which held its first congress in Paris in 1971. In this section the different regional societies are represented to outline the specific geographic, ethnic, and socioeconomic aspects of pediatric renal disease around the world.

The European Society for Pediatric Nephrology (see Chapter 75B) and the American Society of Pediatric Nephrology (see Chapter 75D) have the longest tradition. Both are associated with registries that maintain a database of children on renal replacement programs: the registry of the European Dialysis and Transplantation Association and European Renal Association, and the registry of the North American Pediatric Renal Transplant Cooperative Study (14,15), which in particular developed the best resource of actual data not only on transplantation but on other renal diseases as well. There is no other registry in the world of comparable quality.

The European Society for Pediatric Nephrology is addressing the issues that arise from the harmonization of standards within the European Community with particular focus on the adaptation of the countries in Eastern Europe. Special training courses have been implemented within the Eastern European community in Russia, Rumania, and the Baltic states. This program has been received with enthusiasm by local pediatric nephrologists.

The American Society of Pediatric Nephrology has taken the lead in defining the requirements for pediatric nephrologists in developed countries (16).

The Japanese Society for Pediatric Nephrology is the oldest and largest of the regional pediatric nephrology societies (see Chapter 75C). A unique feature of pediatric nephrology in Japan is that children are screened annually by urinalysis in a nationwide program (17). This screening has provided invaluable epidemiologic information and the opportunity to set up clinical trials involving children in the early stages of disease.

Asia accounts for 57% of the world's population and an even higher proportion of its children because of that region's demographic characteristics. The Asian Pediatric Nephrology Association has developed into a well-recognized society with yearly conferences that are well received. Educational courses have been introduced to extend competence into areas in which there is less access to financial and technical resources. Because of this, generous space has

been allocated to this region in this section of the book (see Chapter 75H). The Asian Pediatric Nephrology Association and the Latin American Association of Pediatric Nephrology (see Chapter 75F) are principally concerned with the problems of delivering health care to children with renal disease in countries in transition to new demographic and economic structures.

The Australasian Pediatric Nephrology Association is a well-organized, smaller regional society that took responsibility for organizing the IPNA congress in 2004 (see Chapter 75G).

The youngest society, the AFSPN, had its first congress in Cairo, Egypt, in 2000 and its second congress in 2002 in Nigeria with participants primarily from Nigeria but also from South Africa and Egypt (see Chapter 75E).

The IPNA provides a coordinating framework for the regional associations. In April 2002, it had a membership of more than 1600. It promotes the specialty of pediatric nephrology by holding a triennial international congress (next scheduled for Adelaide, Australia in the fall of 2004), supporting other meetings and teaching ventures, and publishing the journal *Pediatric Nephrology*.

ANITA AMINA ELGENDI**

OUTLINE

Among European countries there are major differences in the type and quality of medical care given to children. With regard to pediatric renal care, until now only incomplete data have been available on national organization and provision of health care for children with kidney diseases. The European Society for Pediatric Nephrology (ESPN) suggests that the need to improve the availability of pediatric renal care throughout Europe, especially Eastern Europe, is great. Differences throughout Europe concerning pediatric renal care are related to factors such as population size, geographical and political situation, primary pediatric care patterns, and the economic situation. In 1998, the number of pediatric nephrologists per million child population (pmcp) was related to the different European pediatric care systems. Generally, the general practitioner care system had significantly fewer pediatricians involved in renal care than the pediatric or the combined care system. The difference in access to renal replacement therapy (RRT) is related to the different health insurance systems (public, mixed, and private): Although the syllabus for training in pediatric nephrology is defined by the ESPN, the definition of a pediatric nephrologist is different in Eastern European countries than in Western European countries. In Eastern Europe dialysis and transplantation care for children is not always undertaken by pediatric nephrologists.

Europe, at the end of the twentieth century, had far from equal access to RRT for children. In times of financial constraint, national priorities in pediatric care need to be identified and programs agreed upon. The goal of equal access to RRT for children throughout Europe remains a challenge in the early twenty-first century.

INTRODUCTION

The vision of “health for all” (HFA) was born during the World Health Assembly in 1977 and launched at the Alma-Ata Conference in 1978. HFA, adopted by the world com-

munity in May 1998, aimed to realize a vision of providing maximal health care for all by setting out global priorities and targets for the first two decades of the twenty-first century. The regional HFA policy for the European region of the World Health Organization (<http://www.who.org>) in Copenhagen had recognized 21 European targets in 1999 and concluded that this is a vision that could be realized. With the theoretical approach of these targets borne in mind, Europe needs “clearly focused and committed action and strong leadership” to transform the vision of HFA into a practical and sustainable reality (1). At the beginning of the twenty-first century, the reality was far from “health for all” in Europe. Approximately 800 million people live in the European region in more than 40 countries. Europe contains both highly developed, rich countries and economically challenged countries. Some countries are still struggling with the consequences of the democratic, social, and economic transition that began in the early 1990s. During this time the average life expectancy of people in the European region actually declined for the first time since the Second World War. This was due largely to a deterioration in health care systems in the newly independent states and some Central and Eastern European countries, with an actual life-span variation of up to 15 years. According to the human development report of 1997 issued by the United Nations Development Program, poverty-level income has spread from a small part of the population of these countries to approximately one-third, with 120 million people living below the poverty line of US\$4 per day (1). The situation in Europe, therefore, reflects the global situation of widening gaps between countries and within societies (2).

SYSTEMS OF PEDIATRIC CARE IN EUROPE

At the end of the last century there were at least three different systems in Europe offering general pediatric care, defined according to the proportion of the country’s children aged younger than 15 years and seen primarily either

by pediatricians or by family physicians or general practitioners (3):

1. The pediatric system (12 of 34 countries): more than 75% of children were under the care of pediatricians, with 1 pediatrician per 600 to 1250 children, mostly in Eastern European countries.
2. The combined system (16 of 34 countries): both pediatricians and general practitioners offered primary care to almost equal numbers of children ($50 \pm 25\%$), with 1 pediatrician per 1250 to 2500 children, mostly in Central Europe.
3. The general practitioner system (6 of 34 countries): more than 75% of children were under the care of family physicians or general practitioners, with 1 pediatrician per 2500 to 7500 children, exclusively in Western European countries.

HISTORY OF PEDIATRIC RENAL CARE IN EUROPE

The ESPN is the representative body for pediatric nephrology in Europe and is recognized by the Confederation of European Specialists in Paediatrics. The ESPN was founded in 1967, and by the year 2000 had 398 registered members from 35 different countries. The aims of the ESPN include (a) the continuous updating of recommendations for the training of pediatric nephrologists, (b) the development of international standards for all pediatric nephrology centers, and (c) the development of guidelines for quality assessment of clinical care of children with renal disease and for collaborative research in pediatric nephrology. The ESPN is committed to support training courses in Eastern and Central Europe on a yearly basis. Furthermore, training grants for young pediatric nephrologists from Eastern Europe are available from the ESPN, which include coverage of expenses for a 2-month training course at an established pediatric nephrology center in Europe. Travel grants to congresses are also awarded annually by the ESPN. In addition, the ESPN is creating a basis for international cooperation in nationally controlled trials and published a handbook on pediatric nephrology in 2002.

Since 1965, the European Dialysis and Transplantation Association (EDTA) has gathered data on RRT in children and adults with end-stage renal failure. In 1995 there were more than 2000 centers in 36 European and Mediterranean countries reporting to the EDTA registry. Approximately 150 of these centers were pediatric nephrology centers (4,5). Until 1998, data were supplied on a voluntary basis through three types of questionnaire: (a) those gathering data from each center practicing RRT, (b) those obtaining data on each patient on RRT (pediatric questionnaire for patients younger than 15 years), and (c) specific mini-questions generated by working groups on particular topics (6).

In 1998, 70% of 40 European countries reported on their patients to either a national or international registry, or both, on RRT. The percentage of countries not reporting to any registry was higher in Eastern European countries, with only 50% of countries reporting as opposed to 100% of European Union countries. In 1998, it became evident that the EDTA registry could not continue without major changes because it faced a number of unresolved problems, including incomplete data collection, inadequate management of its database, and financial pressures (7). A new EDTA office was set up in Amsterdam and is based in a university department with access to advice on computing and epidemiology. From now on, only a small set of core data will be collected from national registries, which thus increases the possibility of complete data collection and decreases the burden on contributors. Specific questions will be analyzed through mini-questionnaires.

PEDIATRIC NEPHROLOGISTS IN EUROPE

The Union of National European Paediatric Societies and Associations and the ESPN studied pediatric renal care management in Europe with the help of a questionnaire directed to the presidents of national pediatric nephrology societies. In 1998 there were 842 pediatric nephrologists working in 42 European countries with a median of 9 pediatric nephrologists per country (range, 0 to 150). The median number of pediatric nephrologists pmcp was 4.9, ranging from 0 to 15. The median number of children per pediatric nephrologist was 168,480, ranging from 67,130 to 878,940, excluding five European countries with no pediatric nephrologists at all. The situation in pediatric nephrology varied depending on the pediatric primary care system; for example, fewer nephrologists were reported from countries with a combined system or a general practitioner care system than from countries with a pediatric care system.

In addition, there were a total of 1087 general pediatricians with a part-time interest in pediatric nephrology in Europe in 1998. Eastern European countries with a mean number of 16.7 general pediatricians with a part-time interest pmcp had the highest number of those specialists, and countries with a pediatric care system had significantly more than those with a general practitioner care system. There were approximately 170,000 pediatricians in Europe in 1998, and the proportion of pediatric nephrologists among all pediatricians ranged from 1 in 60 to 1 in 200.

The extent to which the staffing of pediatric nephrology units has affected access to and/or quality of pediatric renal care remains unclear. Hörll et al. (8) found differences in the renal care given to adults depending on their different health insurance systems. Public systems (national health service financed through taxes) had fewer doctors involved in treating end-stage renal disease (ESRD) than health insurance systems (personally financed), as well as lower

acceptance rates for RRT, lower prevalence of patients on dialysis, and a higher proportion of patients undergoing transplantation. Eighty percent of countries with a general practitioner care system are countries with a national health service system, and parallels were found concerning the number of doctors involved in pediatric renal care. Chantler (9) stated in 1991 that in many instances there is no shortage of doctors, nurses, and hospital beds but there is a need to change the administrative and academic structures and to introduce appropriate technology.

Boesken et al. (10) described a fragmentation of nephrology services in some Eastern European countries. There were three types of specialists practicing nephrology in countries of the former Soviet Union: (a) "theraputists" (nephrologists treating general nephrology problems), (b) dialysis specialists (often surgeons), and (c) transplant surgeons. Renal biopsies were often performed by urologists. The training to become a pediatric nephrologist in these countries starts in medical school. There are three different types of medical schools: adult, pediatric, and dental. Two to 3 years of postgraduate surgical, medical, or pediatric training normally follow graduation from medical school, and after this only a 4- to 6-month course in nephrology is sufficient to qualify as a pediatric nephrologist. These significant differences lead to the conclusion that most pediatric nephrologists in Eastern European countries would not be considered as such in European Union countries, and therefore the high number of "pediatric nephrologists" in Eastern countries may be based on different definitions of this specialty. In these countries no real subdivision of pediatrics has taken place; rather, pediatric subspecialties have arisen in other disciplines such as surgery (10). The extent of fragmentation is not the same in all Eastern European countries, however, and some countries have changed their organization of medical care (3). The integration process of a "European house" will need time to train pediatricians and to take the necessary organizational steps. The importance of pursuing this goal is strengthened when one considers that the decision-making processes for promoting a better economic and/or medical rationale are seldom in the hands of health care professionals. Although training recommendations do their part in contributing to better care, they are largely developed following the recommendations of national medical organizations.

The goal of achieving specialized pediatric nephrology centers (defined as a center offering general pediatric nephrology, dialysis, and transplantation) and determining how many centers per country to establish is difficult to define and differs according to geographical, social, and financial factors. In 1990 a median of 1.4 centers pmcp provided 24-hour service with a median of four pediatric nephrologists per center (5). It appears that there are enough pediatric nephrologists in most Western, Central, and Eastern European countries to meet the demands of comprehensive renal care. However, an unlimited exchange of pediatric

nephrologists across borders is possible only within the European Union.

AVAILABILITY OF RENAL REPLACEMENT THERAPY

In recent years the incidence of ESRD has been evaluated by the EDTA registry based on the number of patients accepted into dialysis-transplantation programs. Therefore, these figures underestimate the incidence of children with ESRD because they exclude those children who are not treated due to technical reasons, lack of facilities, or health or social policies in countries with limited resources. In Western European countries the incidence of chronic renal failure has remained stable in children, whereas the prevalence has increased steadily as a consequence of improved RRT and prolonged survival of children on RRT (5). The mean number of new pediatric patients pmcp reported in countries with large child populations such as France, Germany, Spain, and Italy was 2.3 in 1973, 5.6 in 1988, and 4.2 in 1991. In countries with a smaller child population such as Belgium, the Netherlands, Finland, Norway, and Sweden, the mean number of new pediatric patients pmcp was 3.3 in 1973, 8 in 1988, and 6.6 in 1991. Thus, despite wide variations in countries and over time, the number of children younger than 15 years of age who need RRT each year is at least 4 to 6 pmcp and may reach 9 pmcp or more. Data for the former Soviet Union were not available for many years, even after the end of the Cold War. Rutkowski et al. (11) on behalf of the Central and Eastern European Advisory Board on Chronic Renal Failure published the first reliable data in 1998; however, there were no separate pediatric data. In 1995 it was estimated that only 3% of all children with ESRD received appropriate treatment in countries of the former Soviet Union (10). With regard to the availability of pediatric RRT in European countries, data show that 92% of all European countries offered pediatric dialysis for acute renal failure, 90% offered pediatric dialysis for chronic renal failure, and 55% offered pediatric transplantation. The availability of pediatric transplantation was associated significantly with the size of the child population and with the gross national product. Only 30% of Eastern European countries offered pediatric transplantation as opposed to 87% of European Union countries. The fact that, according to available data, approximately 90% of European countries provide pediatric dialysis for chronic renal failure but only 55% provide pediatric renal transplantation indicates inadequate care, as does the association of availability of renal transplantation with the GNP, when one considers the clinical and financial long-term superiority of renal transplantation (12). Some of those Eastern countries that did not offer renal transplantation for children at all did offer transplantation for adults (11). These findings unfortunately reinforce the fact that in

numerous developing countries, long-term dialysis and transplantation have been developed for adults but are still unavailable for children. In 1995 in Rumania, for example, only 20% of children younger than 15 years of age with ESRD were treated with RRT, whereas 60% of those in the 25- to 44-year age group were treated (13). Efforts must be undertaken to ensure that children receive equal access to RRT, not only in different European countries but also in the different social groups within a given country.

The discussion of factors contributing to the mode of selection between peritoneal dialysis and hemodialysis in RRT is long-standing. In pediatric patients an expansion of peritoneal dialysis as an effective treatment modality has been increasingly recognized in Europe (14). In European countries, the distribution of the use of peritoneal dialysis as treatment varies significantly (14) despite the absence of major medical differences between the two types of techniques. Nissenon et al. (15) found the cost and reimbursement rate to be the most important factors influencing choice of treatment. In countries with fixed annual health care allocations to hospitals or regions, use of peritoneal dialysis was high, which reflects its lower cost. Vecchi et al. (16) found cost and reimbursement patterns to be similar in the majority of countries and attributed differences in treatment selection to differences in microeconomics of the provider. Hemodialysis is a treatment with high fixed costs (personnel and structure); peritoneal dialysis is a treatment with low fixed costs but high variable costs (supplies) and low need for investments. Differences in microeconomics are one reason why peritoneal dialysis is not only more expensive in most Eastern European countries than in Western European countries but also more expensive than hemodialysis in Eastern European countries. As with most new pharmaceutical products, all necessary supplies, including lines, bags, fluids, connectors, and so on, must be imported from Western countries (10).

COSTS OF PEDIATRIC NEPHROLOGIC CARE

Data on the costs of RRT in Europe are scanty; they mainly evaluate adult services and fail to link outcome with cost and resource use. RRT is known to be more expensive in children than in adults, due to various factors such as the need for psychosocial care and growth therapy, and feeding problems. The total costs for all pediatric patients, however, are much less due to the lower incidence and prevalence of ESRD in children than in adults. Neuhaus et al. (12) evaluated the costs of RRT in children younger than 5 years of age, including costs for erythropoietin, growth hormone, vaccinations, psychosocial support, travel expenses for diagnosis, treatment, and rehabilitation, and costs of nursing support at home. They found the overall costs of medical treatment before initiation of RRT to be similar to the annual costs after successful renal transplantation [30,000 Swiss francs

(SFr) per patient per year]. The highest costs were incurred in the year of transplantation (130,000 SFr per patient per year), followed by dialysis therapy (93,000 SFr). After all, renal transplantation remains the treatment of choice for children with ESRD, not only with regard to survival and quality of life but also with regard to long-term costs.

An effective program for the development and improvement of RRT was implemented in Poland and provides an example of successful enhancement of RRT through targeted health policies. Improvement of RRT in Poland took place due to the enormous effort of the nephrology community, which resulted in a better appreciation of the problem by the authorities on various levels. Their program was prepared by the National Committee for the Promotion of Nephrology and was accepted by the Ministry of Health and the parliamentary health commission. Each year a budget is allocated by the Ministry of Health to cover the expenses of the program. Central purchasing was organized and a major portion of dialysis equipment was purchased in this way and distributed according to patient load. In addition, a new law on transplantation has been passed by the Polish parliament (17).

COOPERATION AMONG EUROPEAN PEDIATRIC NEPHROLOGISTS

“If inequities are to be lessened and the security and cohesion of Europe to be maintained, a much stronger collective effort must be made by Member States to increase their volume, effectiveness and coordination of support to countries in most need in the Region. Receiving countries for their part should give very high priority to the formulation of HFA policies and make health and development plans” (1). According to our data, the cooperation rate among individual European pediatric nephrologists was reported to be high; however, this is not without difficulties. Access to telephone, fax, E-mail, and the Internet is more difficult in developing countries than in developed countries, and there are more obstacles, such as language barriers (i.e., insufficient knowledge of English) and the lack of a history of cooperation in Eastern Europe due to former political policies. Collaboration between national pediatric societies has many facets, and many challenges will need to be met in the global European context. Participation in international meetings is another area of scientific cooperation. Travel grants for scientists with limited financial resources are provided by the ESPN to allow large groups of junior doctors to attend meetings. Because the attendance of a junior doctor at a congress often depends on the acceptance of an abstract, the ESPN studied the acceptance rate of abstracts for the ESPN congress in 1997 in Greece. In actual fact, the acceptance rate varied according to country. For example, Eastern European countries had an acceptance rate of 30 to 45%, whereas 75 to 85% of all abstracts from Western European countries were

accepted (C. Stefanidis, *personal communication*). These differences underline the need for collaborative, multinational research activities. Our analysis also showed that not only the total number of ESPN members per country but also the proportion of membership among pediatric nephrologists was lower in Eastern European than in European Union countries.

Efforts have to be made by the ESPN to implement training courses on a regular basis. Very successful courses were held in Russia, Georgia, and Lithuania. Furthermore, training grants were offered to young pediatric nephrologists in Eastern Europe that covered the expenses for a 2-month training course at an established pediatric nephrology center in Europe.

Another important challenge for the European pediatric nephrology community and others is to effectively meet the needs of emergency situations such as natural catastrophes, epidemics, and armed conflicts (18). Major disasters create emergencies that often require rapid and large-scale foreign aid for the affected country. By their very nature, disasters and complex human emergencies constitute an international concern and provoke responses at an international level. During the 1990s the European region has experienced armed conflicts in ten member states, and earthquakes in Armenia in 1988 and in Turkey in 1999. Responding to this situation, hundreds of organizations and many donor countries have been involved in emergency assistance, often in a very uncoordinated way. The desperate need for a coordinated and multilateral organized approach through a European pediatric nephrology task force is apparent. In the postemergency phase, "action for health" can be used as an effective entry point to strengthen national health concerns and to promote solidarity and social cohesion (18,19).

SCHOOL URINARY SCREENING PROGRAM

One of the unique features of pediatric nephrology in Japan is that children are screened annually by urinalysis in a nationwide program (1), which has provided invaluable epidemiologic information and the opportunity for setting up clinical trials involving individuals in the early stages of disease. Urine screening of elementary and junior high school students in Japan has been mandated by the School Health Law since 1974. One of the major purposes of this program is the detection of glomerulonephritis to allow early therapeutic intervention.

First-voided early morning urine has been tested on an annual basis for each student. Urine samples are collected at home, with participants instructed to empty the bladder on the preceding night and collect a midstream sample on first urination the following morning. The first-voided early morning urine specimen is examined by a simple dipstick method for the detection of proteinuria and hematuria. If a urine test result is positive (± 30 mg/dL or more), a second test is performed in the same manner. A repeat urinalysis is performed 2 weeks later if the initial collection occurred at the time of menstruation (the first examination). Individuals with hematuria ± 30 mg/dL or more and/or proteinuria ± 30 mg/dL or more are referred to family doctors for the second examination. If needed, blood investigations are performed. Those with persistent hematuria + or more and/or persistent proteinuria +15–30 mg/dL or more in the second examination are referred to nephrologists for special follow-up (the third examination).

Table 75C.1 summarizes the findings of the first urine examination in the city of Kobe in 1998. The first urinalysis revealed that elementary school children (aged 6 to 11 years) had proteinuria, hematuria, or both abnormalities at prevalences of 0.17%, 0.30%, and 0.06%, respectively. The corresponding prevalences among junior high school students (aged 12 to 14 years) were 0.69%, 0.57%, and 0.25%, respectively. The prevalence rates of hematuria and proteinuria were higher in girls than in boys, and higher in

junior high school children than in elementary school children as shown in Table 75C.1.

In the second examination, 34 elementary school students (0.04%) and 43 junior high school students (0.09%) showed positive findings.

The school urinary screening program allows the establishment of clinical trials involving individuals in the early stages of disease. As a consequence of this program, in more than half of the patients with immunoglobulin A (IgA) nephropathy, the most prevalent glomerular disease among Japanese children, this disease is detected at an early stage by routine urinalysis (2). The disorder has been detected in 31% of renal biopsy specimens obtained in Japanese hospitals since 1981. IgA nephropathy is the leading cause of chronic renal disease and end-stage renal failure in Japan. The occurrence of end-stage renal failure in adult patients (3) and long-term studies assessing the prognosis in children have challenged earlier views that the condition represents a benign disorder (2). The long-term follow-up of 241 Japanese children indicated that 5% of patients had developed chronic renal failure by 5 years from the onset of the disease, 6% by 10 years, and 11% by 15 years. Thus, IgA nephropathy presents a therapeutic challenge in both adults and children. Because of the variable rate of progression to renal failure and because of the probable multifactorial pathogenesis of the disease, the effectiveness of treatment can be properly evaluated only by means of a controlled trial.

The controlled trial of the Japanese Pediatric IgA Nephropathy Treatment Study Group demonstrated that treatment with prednisolone, azathioprine, heparin-warfarin, and dipyridamole for 2 years early in the course of disease prevents immunologic renal injury and progression of the disease in children with severe IgA nephropathy (4). In this study, 82% of the patients presented with microscopic hematuria and/or asymptomatic proteinuria. This high figure presumably reflects the high detection rate of the school screening program, which revealed a high prevalence of asymptomatic urinary abnormalities, rather than regional variation in the expression of IgA nephropathy. Renal biopsy specimens are

TABLE 75C.1. FINDINGS OF THE FIRST URINE EXAMINATION IN THE CITY OF KOBE IN 1998

Age (yr)		No. students	No. examined (%)	Total no. cases with positive test results (%)	Proteinuria: No. with positive results (%)	Hematuria: No. with positive results (%)	Proteinuria and hematuria: No. with positive results (%)
6-11	Male	44,018	43,825 (99.6)	141 (0.32)	44 (0.10)	81 (0.18)	16 (0.04)
	Female	41,230	41,031 (99.5)	311 (0.75)	103 (0.25)	173 (0.42)	35 (0.08)
	Total	85,248	84,856 (99.5)	452 (0.53)	147 (0.17)	254 (0.30)	51 (0.06)
12-14	Male	23,723	23,120 (97.5)	231 (0.97)	156 (0.66)	50 (0.21)	25 (0.11)
	Female	22,007	21,538 (97.9)	459 (2.09)	161 (0.73)	210 (0.95)	88 (0.40)
	Total	45,730	44,658 (97.7)	690 (1.51)	317 (0.69)	260 (0.57)	113 (0.25)

usually obtained from children with microscopic or macroscopic hematuria and persistent proteinuria.

The long-term effects of the combination therapy on the rate of progression to chronic renal failure was examined. The treated group of children with IgA nephropathy showing diffuse mesangial proliferation (combination therapy group; N = 40) was compared with a historical control group of untreated children with IgA nephropathy showing diffuse mesangial proliferation (control group; N = 48). Renal survival was significantly better in the combination therapy group than in the control group (100% vs. 77% at the twelfth year after initial biopsy).

To determine whether similar results could be obtained with prednisolone alone, the effects of prednisolone treatment were compared with those of treatment with prednisolone, azathioprine, warfarin, and dipyridamole in 78 children with newly diagnosed IgA nephropathy showing diffuse mesangial proliferation. The patients were randomly assigned to receive either prednisolone alone or prednisolone, azathioprine, warfarin, and dipyridamole for 2 years. This study demonstrated that treatment of children with severe IgA nephropathy with prednisolone alone for 2 years early in the course of disease reduces urinary protein excretion and serum IgA concentration but does not prevent increase of sclerosed glomeruli and progression of the disease.

A controlled trial is in progress to compare the effects of a combination of prednisolone, mizoribine, warfarin, and dipyridamole with those of prednisolone and mizoribine alone in children with severe IgA nephropathy.

NATIONAL REGISTRY DATA FOR CHILDREN UNDERGOING PERITONEAL DIALYSIS

The Japanese Pediatric Peritoneal Dialysis Study Group has collected data on pediatric patients younger than 16 years of age from the National Registry of Chronic Peritoneal Dialysis (5,6). In Japan, 84% of the children with all types of end-stage renal disease were introduced to peritoneal dialysis (PD) as the first treatment modality (0 to 4 years, 90%; 5 to 9 years, 84%; 10 to 14 years, 80%).

The database records the patient number, age, outcome, cause of death, reason for terminating PD therapy, type of

PD therapy, occurrence of peritonitis, and catheter survival. From 1981 to the end of 1999, data accrued on 931 patients. Of these 931 patients, 83 patients (8.9%) were younger than 1 year of age and 308 patients (33.1%) were younger than 6 years of age. The duration of PD for these patients was 5 years or longer for 257 patients (27.6%); the number of long-term PD patients increased from 11% in 1991 (5). The number of patients on automated PD increased to 78% in 1999 from 9% in 1991.

The outcome of the total patient population of 931 as of the end of 1999 is as follows: 221 patients (23.7%) were being successfully treated with PD, 99 patients (10.6%) died, 328 patients (35.2%) received a kidney transplant, and 169 (18.2%) were transferred to hemodialysis (HD). The patient survival rate was 92% at 3 years and 87% at 5 years. The technique survival rate (percentage who remained on PD) was 84% at 3 years and 72% at 5 years. Survival rates were compared for 354 patients who began PD before 1990 and 577 patients who began PD after 1990 (Table 75C.2). Although patient survival rate was significantly worse ($p < .0001$) in children younger than 6 years old, technique survival rate showed no significant change. Two major causes of death were infection and cardiovascular disorders. Before 1990, 20 of 62 deaths (32%) were due to infection. Subsequently 8 of 36 deaths (22%) have been due to infection. Cardiovascular deaths increased from 33% to 44% during the same period. Of the 169 patients who were transferred

TABLE 75C.2. PATIENT AND TECHNIQUE SURVIVAL RATE IN CHILDREN ON PERITONEAL DIALYSIS BEFORE AND AFTER 1990

		No. patients	Survival rate (%)			
			1 yr	3 yr	5 yr	7 yr
Patient ^a	Before 1990	354	96	88	82	78
	1990 and after	577	97	93	91	89
Technique ^b	Before 1990	354	92	78	64	55
	1990 and after	577	96	88	78	70

^a $p < .02$ by generalized Wilcoxon method. Patient survival rate for children before 1990 versus that for children in 1990 and after.

^b $p = .01$ by generalized Wilcoxon method. Technique survival rate for children before 1990 versus that for children in 1990 and after.

from PD to HD, 76 patients (45%) were transferred because of peritonitis and 38 patients (22%) were transferred because of ultrafiltration failure. The number of patients who transfer to HD due to ultrafiltration failure has increased, and encapsulating peritoneal sclerosis has been identified as a long-term side effect of PD (7). The rate of peritonitis was one episode over 31 patient months (0.39/year). Both the number of patients with peritonitis and the peritonitis rate were worse in children younger than 6 years of age (0.47/year) than in older children (0.36/year). Double-cuff swan-neck catheters showed significantly better survival and an improved peritonitis-free rate compared to other catheters.

NORTH AMERICA

SHARON P. ANDREOLI

Pediatric nephrologists in North America are a diverse and active group of academic pediatric nephrologists and practitioners, pediatric department chairmen, medical school deans, and physicians employed in the pharmaceutical or biotechnology industry. Pediatric nephrologists are clinicians, basic scientists, clinical and translational researchers, and advocates for pediatric patients with renal disease. Whatever the primary activity of North American pediatric nephrologists, each is likely to participate in at least some capacity as a clinician, teacher, researcher, and mentor to future pediatric nephrologists.

AMERICAN SOCIETY OF PEDIATRIC NEPHROLOGY

The American Society of Pediatric Nephrology (ASPN; <http://www.aspneph.com>) was established in 1969 to promote optimal care for children with renal disease and to disseminate advances in the clinical practice and basic science of pediatric nephrology. A major goal of the ASPN has been to organize an annual national scientific meeting at which pediatric nephrologists and other health care professionals have the opportunity to meet and learn about new advancements in the care of children with renal disease. In 2002, the ASPN initiated a formal partnership with the Pediatric Academic Societies. Since that time, the ASPN annual meeting has been held jointly with that of the Pediatric Academic Societies in a convocation forum at which advances in the clinical and basic science of pediatric nephrology have been presented in the overall context of pediatric academics for trainees, pediatric nephrologists, and pediatric subspecialty colleagues in many disciplines.

A major focus of the ASPN is to promote clinical and basic scientific research in pediatric nephrology and to support training of physicians and allied health care professionals who will provide clinical care to children with kidney disease. In the late 1990s, the ASPN urged the National Institute of Diabetes and Digestive and Kidney Diseases of the National Institutes of Health to develop and implement plans to address the special research needs of children with

kidney disease. The National Institute of Diabetes and Digestive and Kidney Diseases and the ASPN formed a task force of pediatric nephrologists experienced in basic, clinical, and translational research that analyzed the research needs in pediatric nephrology. The task force produced a report that focused on genetics and developmental diseases, acute renal failure, immune-related renal diseases, chronic renal failure, and pediatric transplantation (1). This report has served as a blueprint for the implementation of a number of specific basic research institutes and national multicenter clinical trials for renal transplantation, treatment of focal segmental glomerulosclerosis, and identification of risk factors for progression of chronic kidney disease in childhood.

A major goal of the ASPN is to support training of pediatricians to care for children with kidney disease. As in many pediatric subspecialties in the United States, the number of pediatric nephrology fellows currently in training is inadequate to fill current and projected personnel needs. The ASPN, in association with the other major nephrology societies, commissioned an analysis to determine the number of pediatric nephrologists necessary to meet the clinical needs of children with kidney disease by the year 2010 (2). In addition to documenting a major personnel shortage, the workforce survey identified two major differences between the practice of pediatric nephrology and internal medicine nephrology. First, clinical care of children and adolescents with end-stage renal disease (ESRD) requires a greater time commitment than care of adults with ESRD as a direct result of greater disease acuteness and changing maturational and developmental needs of chronically ill children. Second, the vast majority of pediatric nephrologists are members of full-time academic faculties or maintain significant affiliations with academic medical centers. Their mission includes teaching and other academic activities in addition to patient care. These differences must be taken into account in assessing future workforce needs in pediatric nephrology (3).

The distribution of pediatric nephrologists in North America is quite diverse. According to ASPN data detailing the number of ASPN members in each state, a few states such as Alaska and Montana have no pediatric nephrologists, whereas California has 50 and New York has 57 pedi-

atric nephrologists (active members, emeritus members, and fellow members). Rough per capita data demonstrate state-by-state and regional variability (Table 75D.1).

The ASPN promotes the provision of quality care to children with kidney disease and assists ASPN membership in fostering sound fiscal clinical programs. The Clinical Affairs Committee of the ASPN serves as a liaison with other organizations that have the responsibility of developing clinical practice guidelines and educational and clinical care materials for physicians and families of children with renal disease. Over the past several years, the Clinical Affairs Committee of the ASPN has participated in a review of clinical practice guidelines produced by the Kidney/Dialysis Outcome Quality Initiative (see later) and reviewed fact sheets for the National Institutes of Health and other organizations.

The Public Policy Committee of the ASPN advocates for public policies and programs that promote the interests of children with kidney disease and the educational and research mission of the society. This committee is quite active in representing the interests of the ASPN, patients, and their families in coalition with similar organizations before the U.S. Congress and federal agencies. The Public Policy Committee gathers, analyzes, and disseminates information pertinent to its members and provides advice in the development and evaluation of the ASPN formal positions, initiatives, and responses pertaining to public policy. The research committee and the Public Policy Committee work together in the development and promotion of research policies.

NORTH AMERICAN PEDIATRIC RENAL TRANSPLANT COOPERATIVE STUDY AND SOUTHWEST PEDIATRIC NEPHROLOGY STUDY GROUP

The North American Pediatric Renal Transplant Cooperative Study (NAPTRCS) is a research effort organized in 1987 to obtain data on all pediatric renal transplant recipients in North America (4) (<http://spitfire.emmes.com/study/ped>). Scientific objectives included capture of information about current practice and trends in immunosuppressive therapy with an ultimate goal of improving care of pediatric renal allograft recipients. In 1992, the study was expanded to include pediatric dialysis patients and in 1994 the registry was further expanded to include pediatric patients with chronic renal failure (estimated glomerular filtration rate of less than 75 mL/min/1.73 m² as calculated by the Schwartz formula). The goal is to register and follow more than 80% of the children receiving renal allografts in the United States and Canada and to study the clinical course and natural history of patients with renal dysfunction as they progress to ESRD. At the time of data closure for the 2001 annual report, nearly 12,000 patients had been registered in various arms of NAPTRCS. In addition to the registry components of NAPTRCS, randomized prospective clinical trials were initiated by NAPTRCS in the mid-1990s using a study of OKT3 (muromonab-CD3) induction therapy in children and adolescents undergoing renal transplant. Clinical trials to investigate the use of growth hormone in dialysis patients and in children and adolescents are currently underway. Finally, NAPTRCS is currently carrying out studies to evaluate sirolimus therapy in children and adolescents who have undergone transplantation and experience acute or chronic rejection.

The Southwest Pediatric Nephrology Study Group (SPNSG) was formed in 1980 to develop multicenter collaborative studies of renal diseases in newborns, children, and adolescents (<http://www.spnsg.org>). Over the past several years, the SPNSG has carried out randomized clinical trials of therapy for immunoglobulin A nephropathy, including a comparison of treatment with placebo, fish oil, and alternate-day prednisone. This study is completed and data analysis is underway. The SPNSG has initiated a second study of immunoglobulin A nephropathy using mycophenolate. NAPTRCS and the SPNSG are each participating in the multicenter trial of therapy for focal segmental glomerulosclerosis.

UNITED STATES RENAL DATA SYSTEM

Since 1988, the United States Renal Data System has produced an annual report on ESRD including a report of pediatric ESRD. This report provides valuable information on the demographics, epidemiology, modes of therapy, morbidity, and mortality in pediatric patients with ESRD.

The 2001 United States Renal Data System Annual Report demonstrated that the incidence rates of ESRD in children rose 2 to 3% over the prior decade and revealed unexplained geographical variability in the development of ESRD (5). Overall, congenital and hereditary renal disease and glomerulonephritis are the most common causes of renal failure. However, the age, gender, and racial background of the child are directly related to the cause of renal failure. Glomerulonephritis is the most common primary diagnosis in African American, Native American, and Asian pediatric patients, whereas cystic, hereditary, and congenital disease occurs most often in young white and Native American patients. Interestingly, Asian children are almost twice as likely as children of other races to have a primary diagnosis of glomerulonephritis/vasculitis. Hospitalizations for children with ESRD are directly related to age, and infection is the most important cause of complications requiring hospitalization. Survival rates also differ by age and modality of therapy. For example, by 5 years after the start of ESRD, 69% of children whose end stage began between birth and 4 years of age are still alive on dialysis, compared with 82% of children in other age groups.

KIDNEY DISEASE OUTCOMES QUALITY INITIATIVE GUIDELINES

The Dialysis Quality Initiative Guidelines published in 1997 by the National Kidney Foundation represented the first comprehensive effort to give evidence-based guidance to decrease variations in dialysis practices in the United States. A goal of the Dialysis Quality Initiative Guidelines was to develop concrete plans that could have a measurable impact on improving the quality of life for dialysis patients. The initial guidelines addressed adequacy of hemodialysis, adequacy of peritoneal dialysis, management of vascular access, and management of anemia. Although these guidelines were focused on patients with ESRD, the update of these guidelines was extended to cover patients with chronic renal failure before initiation of renal replacement therapy. This new initiative is known as the Kidney Disease Outcomes Quality Initiative (K/DOQI) (6). Although comprehensive guidelines were targeted to adult patients, specific issues related to pediatric patients are addressed in most of the guidelines.

Several guidelines have covered important aspects of the care of pediatric patients. Pediatric K/DOQI guidelines

addressing nutritional issues including evaluation of protein-energy nutritional status, management of acid-base status, energy and protein intake for children treated with dialysis, and vitamin and mineral requirements were published in 2000 (7). A classification of stages of renal disease in adult and pediatric patients was published in 2002 (8). Specific goals of these guidelines have included the definition and classification of chronic kidney disease irrespective of the underlying cause, the evaluation of laboratory measurement and clinical assessment of kidney disease, the association of the stratification of the level of kidney function with complications of chronic kidney disease, and the risk for loss of kidney function with the development of cardiovascular disease. Guidelines under various stages of development include management of dyslipidemias, management of bone disease, and blood pressure management in chronic kidney disease. Each of these guidelines will address problems specific to pediatric patients with renal diseases. Detailed guidelines published to date are available on the National Kidney Foundation web site at <http://www.kidney.org>.

AFRICA

**BAHIA HASSAN MOUSTAFA
FELICIA EKE
RAJENDRA BHIMMA**

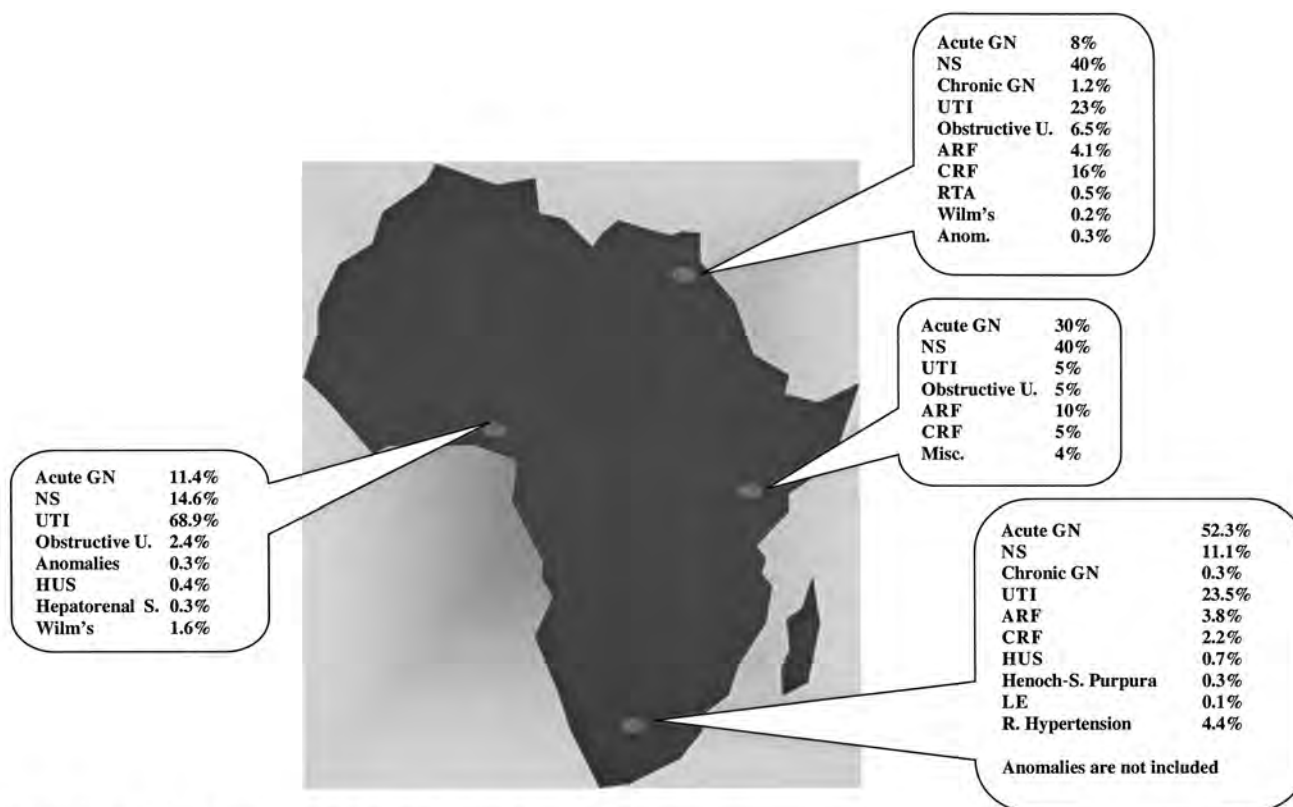

Many children with kidney disease in Africa do not receive proper medical care. Pediatric nephrologists are lacking in many African countries, and even when they are available, their numbers are far below that required for the child population in their areas. In Egypt there is one pediatric nephrologist per 500,000 child population, in Nigeria there is one per 10 million, and in South Africa there is one per 1.5 million. Therefore, pediatricians and general practitioners commonly treat these children (1). In the last two decades pediatric nephrology units have developed throughout the continent. They are concentrated mainly (a) in the northern region in Egypt, Tunisia, Algeria, Libya, and Morocco; (b) in the eastern region in Kenya, Sudan, and Ethiopia; (c) in the western region in Nigeria; and (d) in the southern region in South Africa. Most of these units provide primary and secondary renal care. Some provide tertiary care (i.e., limited dialysis), and very few provide quaternary care (i.e., comprehensive dialysis and transplantation). In the northern region of Africa dialysis and transplantation programs are well developed; however, they are run by internist nephrologists in many areas because of the high ratio of internist to pediatric nephrologists. In Egypt, efficient pediatric nephrology units are university-related units. There are approximately 12 university pediatric nephrology units. They act as regional centers for upper and lower Egypt and provide training and treatment. Over the last 2 years the Ministry of Health has established a number of pediatric hemodialysis units in national hospitals. Medical insurance covers the costs for patients treated in university or national hospital units. Transplantation for children is provided mainly by adult nephrologists. This situation is slowly changing as more pediatric nephrologists are being trained.

In the east, only Kenya has organized renal services including peritoneal dialysis, hemodialysis, and renal transplantation. In the western and central zones, Nigeria is the largest and richest country. There are seven pediatric nephrologists serving a child population of approximately 80 million, among whom 7.5 children per million per year are expected to develop end-stage renal failure. There are 12

adult hemodialysis units of variable quality and reliability. There are no transplantation centers and no pediatric hemodialysis units, but peritoneal dialysis is available for children with acute renal failure (ARF). Continuous ambulatory peritoneal dialysis (CAPD) is not undertaken because of poor socioeconomic and hygienic conditions. Children with chronic renal failure (CRF) whose parents can afford the costs travel to Western countries for dialysis and transplantation. In South Africa, in spite of the deficiency of trained pediatric nephrologists in relation to child population, there are several centers that provide secondary levels of renal care, and most have facilities and expertise for peritoneal dialysis. Care for children with end-stage renal disease who need dialysis and transplantation is centralized in three major centers: Cape Town, Johannesburg, and Durban. In Durban, renal replacement therapy is limited to older children, but with the commissioning of the Inkosi Albert Luthuli Central Hospital, tertiary and quaternary renal care will be offered to all age groups. The policy of the country is to centralize quaternary care to limited designated sites for the entire country, whereas provision of various levels of renal replacement therapy will remain regionalized within a handful of cities.

The profile of renal diseases prevalent in Africa is unique with respect to etiology and clinical presentation. Endemic infections are a major cause of many renal diseases. The low socioeconomic status in many areas, lack of clean water supply, poor sanitation and irrigation systems, and overcrowded housing promote endemic infections such as schistosomiasis, malaria, tuberculosis, hepatitis, and infection with *Streptococcus*, *Salmonella*, *Shigella*, *Filaria*, and human immunodeficiency virus (HIV). The second major category contributing to the unique pattern of renal diseases in Africa includes the overuse of drugs, use of herbal and traditional medicines, toxins from bites, and local environmental pollutants. Obviously the dry environment and tropical climate with inadequate water supply leads to a high incidence of nephrolithiasis in the population.

African children demonstrate unique clinical presentations for various renal diseases. Infection and malnutrition

Data are collected from most developed pediatric nephrology units in Africa:

- ◀ Kenyatta National Hospital Nairobi, Kenya
- ◀ King Edward VIII Hospital Durban, South Africa
- ◀ University of Port Harcourt Teaching Hospital, Nigeria

FIGURE 75E.1. Renal disorders in northern, eastern, western, and southern Africa. Anom., anomalies; ARF, acute renal failure; CRF, chronic renal failure; GN, glomerulonephritis; Henoch-S. Purpura, Henoch-Schönlein purpura; Hepatorenal S., hepatorenal syndrome; HUS, hemolytic uremic syndrome; LE, lupus erythematosus; Misc., miscellaneous; NS, nephrotic syndrome; R., renal; RTA, renal tubular acidosis; U., uropathy; UTI, urinary tract infection.

commonly complicate the picture of the renal disorder. Infection either may be the primary cause of the kidney disease or may be acquired during treatment. The higher mortality and morbidity observed in these children can be attributed in large extent to late diagnosis and late referral to specialized units. Moreover, the poor intradialytic care children receive in some units because of limited resources or insufficient staff explains poor quality of life compared to that of similarly treated children in developed countries. The most prevalent renal disorders in Africa include nephrotic syndrome (NS), urinary tract infections (UTIs), and ARF and CRF (Fig. 75E.1).

NEPHROTIC SYNDROME

NS is the most common childhood renal disorder in Africa. It accounts for 14.6% of renal disorders in eastern Nigeria

(2), 40% in Sudan (3), and 40% in Egypt (4). It has a very diverse profile in the black continent. In northern regions it resembles that in Western countries to a great extent; minimal change NS (MCNS) constitutes the major cause with a prevalence of 88% in Egypt (4), 85% in Libya (5), and 37% in Sudan (3). In Tunisia (6), however, it is not considered the most common pattern. In Egypt, children with nil disease show an excellent response to steroids and a satisfactory outcome. Children experiencing frequent relapse and steroid-dependent children constitute 42% and 36% of children with MCNS in the Cairo unit (4) and 21% and 15% in the Mansoura unit (7), respectively. In most patients, relapse rate correlates with compliance with the steroid therapy regimen. Infection is the main complication commonly reported. Pneumonia, subcutaneous abscesses, UTIs, peritonitis, and septicemia show prevalences of 35%, 22%, 28%, 5%, and 2%, respectively. Hypovolemic shock after infectious diarrhea was reported in 5% of nephrotic

children. Intravascular thrombosis was reported in 2%. The death rate in this study was 2% (4). Among other pathologic types of NS in Egypt, a high prevalence of focal segmental glomerulosclerosis (FSGS) was seen during the 1980s in the Cairo unit (4). Later data from the same unit in the 1990s showed an almost equal prevalence of mesangial proliferative glomerulonephritis (MPGN) (22.7%) and FSGS (21.3%) (8). Subsequently MPGN (34.3%) was prevalent through the next 10 years when data for 394 nephrotic children undergoing renal biopsy were analyzed. Secondary forms of NS are less common in northern Africa than in other parts of the continent. An incidence of 6.6% was reported in Egypt (7). A postinfection pattern is the most common, with schistosomal nephropathy endemic in the north in the Nile delta in Egypt, Ethiopia, and Sudan. The causative parasite is *Schistosoma haematobium* in East, West, and Central Africa as well as the Nile delta. *Schistosoma mansoni* is endemic in the Nile valley, and the western and southern regions of Africa. Such patterns correlate with prevalence of the snail host and poor hygiene. Infected children present with hematuria, glomerulonephritis, NS, or renal failure. Hepatosplenomegaly with the presence of bilharzial ova in urine or stools commonly point to the diagnosis. Patients demonstrate unselective proteinuria, marked reduction in total serum levels of proteins with a characteristic high gamma globulin fraction, normal serum cholesterol level, normal to low serum complement profile, low urine osmolality, and normal to low glomerular filtration rate (GFR). Many such patients are chronic *Salmonella* carriers with intermittent bacteruria, especially those with refractory anemia and persistent fever. Urinary tract imaging may reveal bladder calcification and/or obstructive uropathies and vesicoureteral reflux (VUR); renal biopsy results revealed diffuse MPGN (38%), FSGS (20%), membranous nephropathy (12%), focal MPGN (7%), or mesangiocapillary glomerulonephritis (18%) (9). Different immune mechanisms have been implicated in the pathogenesis of these lesions (10). Current statistics have shown a marked decline in the prevalence of schistosomal nephropathy in many African countries, mainly the Nile delta of Egypt. This has been attributed to aggressive use of chemotherapy among schoolchildren and extensive snail eradication. Trials for manufacture of a new protective vaccine are promising (11).

Hepatitis B is increasingly more prevalent as a cause of NS in northern Africa, with a 44% incidence among secondary forms of NS reported in Egypt (12). Hepatitis C was less commonly reported in the same region (13). Tuberculosis and filariasis are now less prevalent in the northern region. Lupus erythematosus nephropathy is found in 8% of nephrotic children undergoing biopsy (4) in Egypt. Sickle cell nephropathy is rare in North Africa, although the disease is not rare. Ochratoxins and aflatoxins, which are common constituents in foodstuffs in Africa, were detected in urine, serum, and kidney biopsy specimens of

children with NS or renal failure in Tunisia and Egypt (14). Cadmium and aluminum, which are common environmental pollutants in Africa, were recorded as toxic causes for NS in Africa.

In West and Central Africa the profile of NS is unlike that in the Western world. Idiopathic NS is not common. When it affects black children it is often associated with a high rate of steroid nonresponse. This is true in Togo, West Africa (15), western Nigeria (16), northern Nigeria (17), Uganda (18), and Zaire (19). In Port Harcourt (20) and Yaoude, Cameroon (21), however, steroid responsiveness is not uncommon. Infections play a major role in the pathogenesis of NS in West and Central Africa. Quartan malarial nephropathy, first described in Ibadan, western Nigeria, is detected in up to 81% of renal biopsy specimens in children (16). Quartan malarial nephropathy is predominantly associated with *Plasmodium malariae* and also with *Plasmodium falciparum* infection (17). Typically there is focal and segmental glomerulonephritis with thickening of capillary walls but without endothelial cell proliferation. Finding of *P. malariae* or *P. falciparum* antigen in the glomeruli by immunofluorescence is diagnostic. In eastern Nigeria, MCNS is the most common pathologic diagnosis in cases undergoing biopsy (21). Other infections reported in West and Central Africa include hepatitis B with membranous nephropathy (22). NS often complicates poststreptococcal glomerulonephritis in this region. Schistosomiasis, filariasis, and leprosy are also recorded.

In eastern Nigeria, sickle cell nephropathy is common and sickle cell anemia is common with a heterozygous carrier rate of 25%. FSGS and renal papillary necrosis are explained by endothelial damage caused by occlusion by sickled cells and microinfarcts. There are numerous cases of unexplained renal pathology, with NS possibly caused by toxins found in herbal remedies or environmental contamination.

In South Africa, the etiology of NS has undergone considerable change after 1995 as compared to earlier records (Table 75E.1). During the 1970s and 1980s, the pattern in Indian and white children was similar to that seen in the

TABLE 75E.1. HISTOLOGIC PATTERN OF NEPHROTIC SYNDROME BEFORE AND AFTER 1995 IN DURBAN, SOUTH AFRICA

Histologic findings	1976–1994	1995–2000
Minimal change disease	95	11
Focal segmental glomerulosclerosis	41	43
Membranous nephropathy	44	6
Membranous nephropathy (hepatitis B associated)	63	24
Diffuse mesangial proliferative glomerulonephritis	26	1
Focal mesangial proliferative glomerulonephritis	13	2
Mesangiocapillary glomerulonephritis	4	1
Total	286	88

Western world (23). Those of mixed race had a similar histologic pattern of disease but a less gratifying response to steroid therapy. In all of these racial groups, minimal change disease, the presence of which strongly correlated with steroid responsiveness, was the most common lesion. NS among black children in South Africa is characterized by a paucity of minimal change disease, steroid resistance, and a less satisfactory outcome and unidentifiable causative agents in many (24,25). During these two decades the most common histopathologic form of NS seen among black children in the coastal regions was membranous nephropathy, whereas that seen in regions such as Johannesburg was FSGS (26). Membranous nephropathy accounted for 40% of all cases of NS in black children; it was associated with chronic hepatitis B virus carriage in over 86% of cases and showed a strong male predominance (27,28). Minimal change disease accounted for 14 to 25% of all cases of NS; it was less common in coastal regions such as Durban (24,27). Over the last decade there has been a substantial change in the pattern of NS in coastal regions of South Africa. FSGS has increased among Indian and black children, accounting for 50% of all cases of NS in children. More than 95% of these patients are steroid unresponsive. Black patients tend to have more aggressive disease with progression to end-stage disease over a short period of time (29). The introduction of hepatitis B vaccine in April 1995 had a major impact on the incidence of hepatitis B virus-associated NS. In Durban, the number of new cases remained steady up to 1999 with a marked decline thereafter (30). Other secondary causes of NS in South Africa include congenital syphilis, cytomegalovirus infection, and poststreptococcal glomerulonephritis. Schistosomal nephropathy and malarial nephropathy are rare in South Africa. The HIV infection and acquired immunodeficiency syndrome that have overwhelmed Sub-Saharan Africa over the last decade have had little reported impact on the pattern of NS seen in children. There have been no reports on HIV-associated nephropathies in children in South Africa to date.

URINARY TRACT INFECTIONS

UTIs are common in Africa, in both rural and urban areas and among neonates, preschool children, and school-aged children. UTIs show a prevalence of 22% in symptomatic children in Cairo, Egypt. Asymptomatic bacteruria has a recorded incidence of 4.2% in girls and 2.8% in boys among schoolchildren in urban Egypt (31) and 11% in girls and 3.6% in boys in rural Egypt (32). In Central and West Africa, UTIs have an incidence from 8.2 to 72% in symptomatic children (33) and of 48% in an asymptomatic rural community (34). In Cape Town, approximately 1000 cases of UTI are seen yearly. In fact, because of the nonspecific complaints in neonates and young children, many cases are missed, especially in rural areas. The microbiology

of UTIs in Africa is consistent over the continent (35). In the northern region of Egypt, the recorded causative organism is *Escherichia coli* in 70% of cases, *Proteus* in 10%, *Klebsiella* in 5%, and *Pseudomonas* in 5% (36). Schistosomiasis is considered a common predisposing factor for UTI in Egypt (36), Senegal (37), and Cameroon (38). Stones, developmental anomalies of the urinary tract, and VUR are also common structural changes that favor infection in Egypt, with prevalences of 2.5%, 12%, and 17%, respectively (36). VUR is rare in West and Central Africa whereas posterior urethral valves and meatal and urethral strictures are reported to have an incidence of 29.3% among children with UTIs (35). In South Africa, local predisposing factors include malnutrition, congenital anomalies, immunodeficiency states, and VUR. The latter is rare in black children but common in whites (39,40). Adhikari (40) reported 2 Indian children with VUR out of 26 children with anomalies, and 7 cases of PUV out of 14 with obstructive uropathies. Renal growth and GFR are commonly affected in African children with UTI because of late diagnosis and referral, as well as patient noncompliance with treatment. Impaired renal growth was reported in 36% of cases referred to the Cairo University unit, whereas low GFR was reported in 5% of the same patients (36). *E. coli* strains resistant to amoxicillin and co-trimoxazole were reported in Africa with 88% and 86% resistance to these drugs, respectively, in Cape Town.

ACUTE RENAL FAILURE

ARF has unique epidemiology in African children. Infection is the major cause. Bacterial infections commonly reported include streptococcosis, cholera, salmonellosis, shigellosis, leptospirosis, tetanus, and diphtheria. Viral infections include HIV infection, hepatitis B, hepatitis C, hepatitis A, and cytomegalovirus infection. Common parasitic infections are malaria and schistosomiasis. Among all pathogen-related causes, diarrheal diseases, schistosomiasis, and malaria remain the most common. Infection precipitates ARF through immune mechanisms and alteration of kidney hemodynamics (41). Toxins present after snakebites, scorpion stings, or other insect stings, or after ingestion of herbal medicines or overuse of drugs are also unique causes of ARF in Africa. Table 75E.2 summarizes causes of ARF in Egypt (42), Nigeria (43), and South Africa. Septicemia, gastroenteritis, and hemolytic uremic syndrome (HUS) are common causes in the three regions. Epidemic forms of ARF after use of native herbal medicines and holy water were reported in Nigeria (44). In South Africa, an epidemic of *Shigella* dysentery type 1 occurred in 1994 to 1996 in Sub-Saharan Africa, starting in Burudi and progressing to the Cape (45). One hundred fifty-nine cases of HUS occurred in black children after this bloody diarrhea. Among 81 cases of post-*Shigella*-induced HUS in Durban, complications included ARF in 90.1%,

TABLE 75E.2. CAUSES OF ACUTE AND CHRONIC RENAL FAILURE IN SELECTED LOCATIONS IN AFRICA

encephalopathy in 37%, convulsions in 14.8%, hemiplegia in 2.3%, intestinal perforation in 9.9%, protein-losing enteropathy in 32.1%, toxic megacolon in 4.9%, rectal prolapse in 6.2%, hepatitis in 13.6%, myocarditis in 6.2%, disseminated intravascular coagulation in 21%, CRF in 32.1%, impaired renal function in 9.9%, ESRD in 1.2%, and death in 17.3% (46). During the last 2 years *E. coli*-induced HUS, especially coexistent with HIV infection, has been reported in Cape Town.

CHRONIC RENAL FAILURE

The pattern of CRF in African children is unique with respect to its etiology, clinical presentation, and management. Causes of CRF in Egypt (47), Nigeria (2), and South Africa are summarized in Table 75E.2. It is evident that obstructive uropathies and reflux nephropathy are prevalent causes in Egypt, whereas glomerulonephritis is common in Nigeria and South Africa. Late referral of cases explains the preponderance of unknown diagnoses among Egyptian children who already have atrophic kidneys at their first visit to a pediatric nephrology unit.

Signs of CRF in African children are aggravated by three distinct elements: infection (whether causing CRF or acquired during dialysis), malnutrition (especially deficien-

cies of iron, vitamin D, and trace elements), and late diagnosis and poor management (which aggravate anemia, growth retardation, and bone disabilities).

DIALYSIS AND TRANSPLANTATION

Acute peritoneal dialysis is the most common type of dialysis in Africa and is more readily available than acute hemodialysis. Chronic intermittent peritoneal dialysis is the most common technique used in CRF cases in developing countries in Africa. The use of continuous cycling peritoneal dialysis is less common. In developed areas such as Cape Town in South Africa, however, use of CAPD is predominant. Efficiency of dialysis varies among pediatric nephrology centers in Africa. It depends on availability of funds as well as trained staff. African children on regular dialysis demonstrate lack of compliance with the regimen because of psychosocial and economic factors, and most of them experience poor quality of life. Factors that contribute to their poor outcome include deficient dialysis, undernutrition, infection, and lack of appropriate interdialytic care due to nonavailability of erythropoietin, iron, active vitamin D, and growth hormone (1).

Although renal transplantation is more cost effective than dialysis, it is not available in most African countries.

Reported centers are concentrated in the northern region and in South Africa. Ethical and religious factors in each country determine whether cadaveric or living donor grafts are used. In South Africa, cadaver organ-based programs are widely used, whereas in Egypt, only living related donor-based programs are permitted. Morbidity and mortality of patients undergoing renal transplantation are higher in Africa than in developed countries.

Most African countries lack national kidney foundations as well as medical insurance systems. Therefore, funding for ESRD therapy remains a significant handicap for most African countries. Prevention of ESRD is the best strategy when approaching the problem of CRF in Africa. Simple measures include health education to combat unhygienic habits and use of traditional remedies, many of which are nephrotoxic. Additional measures include infection control through antischistosomal and antimalarial campaigns and obligatory vaccination against tuberculosis and hepatitis. Screening for renal diseases among schoolchildren might identify patients early in the disease course and maximize appropriate intervention.

The development of the African Pediatric Nephrology Association (AFPNA) in 1999 with its affiliation to the International Pediatric Nephrology Association carries new prospects for upgrading the practice of pediatric nephrology in Africa. Training programs supported by the IPNA to increase the number of trained pediatric nephrologists are now planned to cover northern, central, and southern regions of Africa. Shortage of specialists and trained staff as well as restricted financial resources remain a major handicap in many areas. Development of regional pediatric nephrology societies such as the Egyptian Society of Pediatric Nephrology and the South African transplantation and pediatric nephrology groups as well as improved education offer promise for dramatic improvements in pediatric nephrology care in Africa over the next decade.

ACKNOWLEDGMENTS

The authors would like to thank Prof. M. Adhikari (Durban) and Dr. M. McCulloch and Dr. P. Sinclair (Red Cross Children's Hospital, Cape Town) for providing valuable data from their centers. The authors also offer special thanks to colleagues in different pediatric nephrology units throughout the continent for their assistance in data collection and collation.

LATIN AMERICA

RAMON ALFONSO EXENI

DEMOGRAPHY

Latin America comprises nations in North, Central, and South America in which the prevailing languages derive from Latin. It encompasses an extensive territory with significant cultural and socioeconomic differences and sharp contrasts. Aboriginal inhabitants live in extremely poor conditions in some regions, and considerable social imbalances characterize urban areas. However, some noteworthy features, such as hospitality, tolerance, and respect for ethnic differences, have arisen from the fusion between the ancient indigenous cultures and the European colonization.

LATIN AMERICAN ASSOCIATION OF PEDIATRIC NEPHROLOGY

The Latin American Association of Pediatric Nephrology (ALANEPE) was created in Buenos Aires, Argentina, in a meeting held by the Sociedad Argentina de Pediatría [Argentine Society of Pediatrics] on November 27, 1981, by 48 founding members. The objective of ALANEPE was to promote knowledge and science in pediatric nephrology and to improve the care of Latin American children with kidney diseases.

ALANEPE is divided in three regions:

- Region 1: Mexico, Guatemala, El Salvador, Costa Rica, Nicaragua, Honduras, Panama, Caribbean islands, Cuba, Dominican Republic, Puerto Rico
- Region 2: Venezuela, Colombia, Ecuador, Peru, Bolivia
- Region 3: Chile, Argentina, Brazil, Paraguay, Uruguay

These regions comprise a population of approximately 457 million (Table 75F.1).

In 2001, the publication of ALANEPE's official journal, *Archivos latinoamericanos de nefrología pediátrica* [Latin American Archives of Pediatric Nephrology], was initiated. This is a teaching journal with reviews, recommendations, practical nephrology items, news, and reports of societal activities. This publication has increased interest in the specialty on the part of pediatricians and has served as continuing medical education for pediatric nephrologists. Like the

triennial ALANEPE congress, it is a symbol of ALANEPE's commitment to its mission.

PEDIATRIC NEPHROLOGY DEVELOPMENT IN LATIN AMERICA

The field of pediatric nephrology in Latin America had the privilege of having two figures that greatly fostered its development in two geographically separated regions. In 1954, Dr. Gustavo Gordillo created one of the first departments of pediatric nephrology in the world in the Children's Hospital of Mexico. Dr. Carlos Gianantonio, in Argentina, championed the specialty in the south. Due to the extremely high incidence of hemolytic uremic syndrome (HUS) in Argentina, Dr. Gianantonio dedicated extraordinary effort to understanding the basic pathophysiology, clinical course, and management of this disease. The influence of these two leaders of the field promoted the creation of pediatric nephrology centers in both countries, which then spread throughout Latin America. Their nephrology departments turned into educational centers for nephrologists from all the regions of the continent. Dr. Renee Habib (France) and Dr. Juan Rodríguez Soriano (Spain) have also promoted and influenced the development of pediatric nephrology in Latin America.

ALANEPE has grown from 48 to 540 members, and the emergence of pediatric nephrology in Latin America is well documented through analysis of the number of Latin American abstracts submitted to the last four congresses of the International Pediatric Nephrology Association (Table 75F.2) and the Latin American papers published in *Pediatric Nephrology*, the official journal of this organization, over the past 15 years (1987 to 2002) (Fig. 75F.1; Table 75F.3).

SPECIFIC AREAS OF CLINICAL AND RESEARCH INTEREST: HEMOLYTIC UREMIC SYNDROME

The world's highest incidence of HUS (see Chapter 47) is reported in Argentina, with 22 cases per 100,000 children younger than 5 years of age. In this country, approximately

TABLE 75F.1. LATIN AMERICA POPULATION (× 1000 INHABITANTS) (1)

Argentina	34,293	Bolivia	7896	Brazil	160,737	Chile	14,161
Colombia	26,200	Costa Rica	3419	Cuba	10,938	Dominican Republic	7948
Ecuador	10,891	El Salvador	5870	Guatemala	11,000	Honduras	5460
Mexico	93,986	Nicaragua	4206	Panama	2681	Paraguay	5358
Peru	24,087	Puerto Rico	3691	Uruguay	3223	Venezuela	21,005

400 new cases are reported annually. Nearly all of them are secondary to infections caused by verotoxin-producing *Escherichia coli* O157:H7. After Gasser's description in 1955, Dr. Carlos Gianantonio and colleagues published a seminal study of 64 cases in 1964 (2). Gianantonio's greatest achievement was the implementation of peritoneal dialysis in these children, which reduced acute mortality from 50% to 5%.

The Nephrology Committee of the Argentine Society of Pediatrics registered 7570 HUS patients in 11 centers in Argentina between 1965 and 2001. In that period, mortality varied between 2 and 5.6% during the acute phase. There were no significant differences between the sexes. Mean patient age of 11 months in 1990 increased to 18 months in 2001. Cases have been observed throughout the year, with a greater incidence between November and March (summer-time). These cases underestimate actual disease incidences, because they reflect data only from public hospitals. A considerable number of children go to private centers and were not included in this report.

The high incidence of HUS in Argentina is related to the high rate of ingestion of bovine meat and its early introduction in young children's diets. Several centers in Argentina have participated in collaborative studies using Synsorb, and many are involved in a multicenter study using therapy with mono-

clonal antibodies. Table 75F.4 summarizes 30 years' experience in the treatment of HUS in two major reference centers: Ricardo Gutiérrez Children's Hospital in Buenos Aires and San Justo Children's Hospital in a Buenos Aires suburb. It was at the Ricardo Gutiérrez Children's Hospital where Dr. Gianantonio performed his research on this disease.

COLLABORATIVE STUDIES

National Collaborative Studies

Venezuela

The Pediatric Nephrology Chapter of the Venezuelan Society of Pediatrics and the Venezuelan Society of Nephrology reported epidemiologic data on renal disorders in children of that country (4). Information was obtained from 14 centers for the period January through December 1998. A total of 3624 patients were evaluated either through a first outpatient consultation or at a first hospital admission.

The patients were grouped into the following categories: (a) urinary tract infections (32%), with detection of abnormalities of the urinary tract in 25%; (b) metabolic disorders (28%), mainly idiopathic hypercalciuria and hyperuricosuria; and (c) glomerulonephritis (9.5%). The remaining 30% included children with urolithiasis (7%), nephritic syndrome (4.5%), primary hematuria (4.2%), acute renal failure (2.8%, with 43% of cases secondary to acute dehydration, 15% due to birth asphyxia, 14% due to secondary septicemia, and 23% due to multiple factors), chronic renal failure

Peritoneal dialysis	1
Tubulopathies	1
Urinary tract infections and uropathies	6

(CRF) (1.6%; secondary to glomerulopathies, predominantly focal glomerulosclerosis, structural abnormalities of the urinary tract, hereditary disorders, and renal hypoplasia and dysplasia), and miscellaneous diseases (4.8%).

Chile: Chronic Peritoneal Dialysis in Chile—A Multicenter Study

Dr. Angela Delucchi coordinated a multicenter study of continuous ambulatory peritoneal dialysis (CAPD) in five Chilean centers: Luís Calvo Mackenna Hospital, Roberto del Río Hospital, Guillermo Grant Benavente Hospital, Exequiel González Cortés Hospital, and School of Public Health—University of Chile, Santiago, Concepción. (5) One hundred and twenty-nine children younger than 18 years of age were evaluated; 97 of them, with at least 6 months of follow-up, were included in the analysis. Causes of disease were renal hypoplasia or dysplasia (26%), glomerulopathies (17%), reflux nephropathy (15%), obstructive uropathy (15%), vascular diseases (15%), and other disorders (12%). Serum calcium levels increased from 8.9 mg/dL to 9.3 mg/dL after CAPD ($p < .05$). Parathyroid hormone and alkaline phosphatase levels were correlated significantly ($p < .0004$). Mean Z score for height and age was -2.2 ± 1.6 . A progressive but not significant impairment of Z score height was found; growth failure was lower in children who started peritoneal dialysis at a younger age.

This study demonstrates that the use of CAPD has progressively increased in Chile in recent years. An increase in the number of children starting CAPD at a younger age was also observed. Hematologic and biochemical parameters improved on CAPD. Poor growth rate was related to a longer mean duration of dialysis. Dialysis doses were inversely related to age.

Staphylococcus aureus accounted for the majority of episodes of peritonitis, and the incidence of this complication was 0.67 episodes per patient per year, a rate similar to that reported in the literature. The mean weekly urea K_t/v was 2.9 ± 1.9 .

TABLE 75F.4. HEMOLYTIC UREMIC SYNDROME: RICARDO GUTIÉRREZ CHILDREN'S HOSPITAL (BUENOS AIRES) AND SAN JUSTO CHILDREN'S HOSPITAL (BUENOS AIRES PROVINCE), 1970–2000

Acute manifestations	
Prodromes	
Diarrhea: mucous-bloody	1249 (96%)
No diarrhea	53 (4%)

Long-term follow-up (3)	
No. patients: 152	
Mean follow-up: 10.3 years (range, 5–27 years)	
Functional status:	
Group A: 107 (70%)—normal renal function without proteinuria or hypertension	
Group B: 21 (13.8%)—normal renal function, proteinuria \pm hypertension	
Group C: 19 (2.6%)—decreased glomerular filtration rate, proteinuria \pm hypertension	
Group D: 5 (5.3%)—end-stage renal disease	

Argentina: National Register of Chronic Renal Disease, Dialysis, and Transplantation

In 1996, Argentina initiated a centralized registry of pediatric patients with end-stage CRF undergoing conservative management, dialysis, and transplantation (6). The coordinator of this national register is Dr. Irene Grimoldi. The 1996 results, which were based on data from 14 centers, were the following.

One hundred and thirty-five patients were registered; 62 (45.9%) were being managed conservatively; 51 (37.8%) were receiving dialysis; and 22 (16.3%) received kidney transplantations. The following were reported as primary renal diseases: glomerulopathies (27.4%), obstructive uropathy (17.7%), reflux nephropathy (16.3%), HUS (10.3%), aplasia-dysplasia-hypoplasia (8.8%), and other (19.5%). Of 51 patients on dialysis, 41.2% received peritoneal dialysis and 58.8% hemodialysis. In the group that was being managed conservatively, the mean age was 8.8 years, whereas for transplantation patients the mean age was 12.3 years. Among transplantation patients, 72.7% received an organ from a living donor and 27.3% from a cadaveric donor.

Mexico: Experience of Ten Years of Kidney Transplantation in Mexican Children

A study reported on 240 children undergoing kidney transplantation between November 1989 and June 1999 who

were admitted to the Service of Nephrology, Urology, and Transplantation at the Pediatric Hospital of Children's Hospital, Department of Nephrology, Occident National Medical Center, from Social Security Medical Institute, in Guadalajara, Jalisco, Mexico (7).

One hundred and thirty-six (56%) were boys and 104 (44%) were girls. Mean age was 11 years (range, 3 to 16). The causes of the renal disorders included glomerulopathies in 59 (25%), obstructive uropathy in 31 (13%), hereditary diseases in 15 (6%), interstitial nephritis in 10 (4%), and unspecified disorders in 125 (52%). Seventy-five percent were receiving CAPD and 25% were on hemodialysis when they underwent transplantation. Ninety-five percent of transplant organ were from living donors (75% from parents, 15% from siblings). One hundred and thirteen (47%) had blood group O, 106 (44%) had blood group A, 16 had blood group B (6%), and 5 (3%) had blood group AB. With regard to HLA, 26 (11%) were identical, 209 (87%) shared one haplotype, and 5 (2%) had different antigens in all their loci. At the end of 1999, 216 (85%) had normal renal function.

International Latin American Collaborative Studies

Epidemiology of Nephrolithiasis in Childhood

The study on the epidemiology of nephrolithiasis (see Chapter 57) was coordinated by Dr. H. Perrone, and 13 centers in Latin America participated (8). Eight hundred and seventy children were recruited; 552 (63%) were boys and 318 (37%) were girls. The age at which the disease was detected ranged from 2 months to 17 years. Only 4% of the subjects were asymptomatic. The initial symptoms reported most frequently were hematuria in 337 (39%) patients, abdominal and/or lumbar pain in 235 (27%), and hematuria associated with pain in 147 (17%). Additional findings were dysuria in 71 (8%), recurrent urinary tract infections in 146 (17%), and elimination of calculi in 28 (3%). Kidney malformations were found in 78 (8.9%).

Epidemiologic Aspects of Chronic Renal Failure in Latin American Countries

Dr. Nelson Orta coordinated a study on the epidemiology of CRF study (9). Its most relevant conclusions are presented in the following paragraphs.

The incidence of CRF shows a wide variability that ranges between 2.8 and 15.8 new cases per 1 million inhabitants (Table 75F.5).

The causes of CRF are glomerulopathies in 36%, obstructive uropathies and reflux nephropathy in 31%, systemic diseases in 9%, and other disorders in 15%. The histopathologic entity most frequently associated with CRF is focal segmental sclerosis. At present, HUS is an important cause of CRF—but not the most frequent one—in Argentina.

TABLE 75F.5. ANNUAL INCIDENCE OF CHRONIC RENAL DISEASES IN LATIN AMERICAN COUNTRIES

Country	Incidence (patients per 1 million inhabitants)
Argentina	15.8
Brazil	6.5
Colombia	2.8
Mexico	3.5
Uruguay	4.4
Venezuela	12.6

Antibodies against Streptococcal Zymogen in the Sera of Patients with Acute Glomerulonephritis—A Multicenter Study

One hundred and fifty-three patients with poststreptococcal acute glomerulonephritis from Argentina, Chile, and Venezuela were studied (10); 140 were male and 49 were female. The source of infection was the skin in 84 patients, the throat in 44, and unknown in the remaining 14. Furthermore, 23 patients with streptococcal infections without glomerulonephritis and 93 healthy controls were also studied.

Antizymogen and antiproteinase titers were determined. The conclusion was that antizymogen antibody titer is the best available marker for streptococcal infections associated with glomerulonephritis.

ORGANIZATION AND RESOURCES

The nephrologic care of children in Latin America varies; countries range from those having medical systems that provide care to all patients who need dialysis procedures to others offering no possibilities to provide dialysis or transplantation to children with end-stage CRF. Even in countries in which hemodialysis, CAPD, and kidney transplantation programs are available, such services are markedly hampered by economic problems. Health authorities appropriately give priority to prevention and treatment of common diseases, and it is difficult to obtain funds for children with chronic renal disease—a small number of patients in need of expensive resources. This is worsened by the current state of devaluation of Latin American currencies, because the relative cost of the materials for treatment of end-stage renal disease, all of which are of foreign origin, constantly increases. To determine the situation in each of these countries, we sent a questionnaire that was answered by nephrologists skilled in these procedures. The assessment was begun in January 2002. Argentina, Brazil, Venezuela, Chile, and Mexico have well-structured programs. CAPD and hemodialysis programs, as well as kidney transplantation programs, have an adequate infrastructure. Uruguay has adequate hemodialysis programs and was a pioneer in CAPD. The program of transplantation in public

hospitals is in its initial phase. Cuba and Costa Rica have adequate programs of hemodialysis and transplantation. CAPD is not used. Other countries, such as Paraguay, Ecuador, and Colombia, are developing new programs for hemodialysis, CAPD, and renal transplantation. We do not have information about national programs in the other countries. Table 75F.6 shows some aspects of the organization of pediatric nephrology services in Latin American countries (11).

MEDICAL EDUCATION SYSTEMS

Pediatric nephrology residency programs exist in Argentina, Brazil, Chile, Mexico, Costa Rica, and Venezuela. Besides the residency in public hospitals, Argentina has developed a postgraduate training program in pediatric nephrology at Buenos Aires University. Currently there are three centers for this postgraduate education: Ricardo Gutiérrez Children's Hospital in Buenos Aires, and Alejandro Posadas National Hospital and San Justo Children's Hospital, both in Buenos Aires Province.

TABLE 75F.7. NUMBER OF PEDIATRIC NEPHROLOGISTS AND POPULATION YOUNGER THAN 14 YEARS

Country	No. pediatric nephrologists	Population younger than 14 yr (thousands)
Argentina	93	104
Brazil	100	518
Bolivia	3	1069
Colombia	14	825
Costa Rica	3	393
Cuba	38	68
Chile	20	216

Paraguay	4	485
Peru	11	769
Venezuela	50	148
Uruguay	15	51

Data from Grunberg J. Pediatric nephrology workforce in Latin America. *Pediatr Nephrol* 1998;12(9):796–798.

The number of pediatric nephrologists varies by country. Table 75F.7 presents such data in the context of the number of children younger than 14 years in each country (12).

In conclusion, there is a great discrepancy in the quality of care available in the different Latin American countries, and many challenges remain. However, dramatic improvement has been made in the care of children with renal disease over the past decade in this area of the world.

ACKNOWLEDGMENTS

The author gratefully acknowledge the questionnaires sent by Dr. Carlos Saieh (Chile), Dr. Michelle López (Venezuela), Dr. Digna Espinosa (Cuba), Dr. Reyner Loza (Peru), Dr. Noemia Perli Goldraich (Brazil), Dr. Gustavo Gordillo Paniagua (México), Dr. Jorge de la Cruz (Colombia), Dr. Jannette Salguero Aparicio (Bolivia), Dr. Cristina Mayado (Uruguay), Dr. Osvaldo Freire Valencia (Ecuador), Dr. Leticia Florentín de Merech (Paraguay), Dr. Mabel Sandoval Díaz (Nicaragua), and Dr. Gilbert Madrigal Campos (Costa Rica).

AUSTRALIA AND NEW ZEALAND

JOHN R. BURKE
WILLIAM WONG

DEMOGRAPHY

Australia and New Zealand have well-established health services giving outcomes comparable to those seen in Europe and North America. Both countries are well served by pediatric nephrologists—25 for the 23 million population of Australia, and 3 for the 4 million population of New Zealand. In Australia, most of the population lives close to the coast, and pediatric nephrology units are confined to five cities that provide outreach services for the appropriate states. In New Zealand, pediatric nephrology is concentrated in the largest center, Auckland, a city of 1.1 million. The service is staffed by two pediatric nephrologists who provide outreach services to other cities in the country and undertake the majority of the end-stage renal failure (ESRF) management. Significant improvement is required in both pediatric and adult health care in New Guinea, however, and for the indigenous people of Australia (Aborigines) and New Zealand (Maoris).

EPIDEMIOLOGY

New Guinea

New Guinea has a population of 4 million, and most people live in remote areas with limited access to a regional hospital. In Papua New Guinea, children die at a rate 20 times higher than Australian children. The mortality rate for children under 5 years of age is 120 per 1000 live births. The major causes of child mortality are streptococcal pneumonia, malnutrition, measles, meningitis, and neonatal sepsis. Less than one-third of women give birth with the assistance of a skilled health worker.

There are no facilities for chronic dialysis or transplantation for adult or pediatric patients, and no adult or pediatric nephrologist resides in New Guinea. A few patients, accompanied by a donor, are sent to Australia for live related donor organ transplantation at considerable cost to their families. There is no health insurance except for employees of some large companies. The process of obtaining informed consent from the kidney donor is often difficult, and follow-up is inadequate because of

the high expense of the immunosuppressive drugs, which must be paid by the families, and the lack of a local nephrology service. Nephrologic disorders seen by local doctors include post-streptococcal glomerulonephritis related to impetigo, urinary tract infections, and nephrotic syndrome that is often steroid resistant. Hemolytic uremic syndrome (HUS) is uncommon. Diagnostic capabilities outside major centers are limited to dipstick testing and urine microscopy. Immunologic services and biopsy facilities are generally not available.

Major improvements in health delivery depend on the return of the village health worker, particularly in the New Guinea highlands and Bougainville; restoration and funding of rural vaccination programs; improvement in maternal education; and economic development (1). Regular teaching and surgical specialty team visits by Australian and New Zealand specialists are coordinated through various organizations, including the International Nephrology Association.

Australian Aborigines

ESRF is a significant problem among adult Australian Aborigines (2). In the Northern Territory, the prevalence is 1 per 3000 of the total Aboriginal population, which is 10 times higher than in the non-Aboriginal population. These patients are more likely to be young adult women and to have renal pathology showing glomerulomegaly and non-immunoglobulin A mesangiocapillary glomerulonephritis. Contributing factors may include genetics, low birth weight, infections, smoking, alcoholism, and type 2 diabetes.

Epidemiologic screening for renal disease in both children and adults has commenced in some Aboriginal communities. People with a history of poststreptococcal glomerulonephritis in childhood have a risk of overt albuminuria more than six times that of those without such a history (3). Skin infections occur in up to 70% of Aboriginal children, with the major pathogens being group A streptococci (4). On Tiwi Island, approximately 10% of children have microalbuminuria by the midteenage years. In some communities angiotensin-converting enzyme inhibitors are prescribed for people who have albuminuria, but controlled studies are not available.

FIGURE 75G.1. Glomerular histologic findings in childhood nephrotic syndrome in New Zealand. CNS, congenital nephrotic syndrome; FSGS, focal segmental glomerulosclerosis; MCGN, mesangiocapillary glomerulonephritis; MCNS, minimal change nephrotic syndrome.

Increased incidence of urate urolithiasis is seen in young Aboriginal children, particularly those living in arid zones (5,6). Development of these stones has been attributed to consumption of a high-cereal, high-protein diet and dehydration. However, some cases occur in breast-fed children younger than 6 months of age, and the disorder is seen occasionally in urban communities. No evidence of a defect in the urate pathway has been identified. These stones tend not to recur and are not a contributing cause of renal failure.

New Zealand Maoris and Polynesians

The incidence of glomerulonephritis in adult Maoris and Pacific Islanders is higher than that in New Zealanders of European descent (7). Histologic analysis in this group shows an increased incidence of mesangiocapillary glomerulonephritis, postinfectious glomerulonephritis, and focal segmental glomerulosclerosis. Among patients with childhood nephrotic syndrome, Maori children are more likely to have mesangiocapillary glomerulonephritis followed by minimal change disease, whereas white and Pacific Island children tend to have minimal change disease followed by focal segmental glomerulosclerosis (Fig. 75G.1). It is also of interest that lupus nephritis occurs predominantly in Maori and Pacific Island children with very few whites represented (8). A prospective national surveillance study currently in

progress will provide a more accurate picture of nephrotic syndrome in New Zealand.

RENAL FAILURE

Hemolytic Uremic Syndrome

In Australia and New Zealand HUS is usually a sporadic disorder. In Australia between 1994 and 1998, 98 cases

TABLE 75G.1. PATIENTS' AGE AND TREATMENT ON DECEMBER 31, 2000

Country	Treatment	Age group				Total
		0-5 yr	5-10 yr	10-15 yr	15-19 yr	
Australia	Hemodialysis	0	2	5	29	36
	Peritoneal dialysis	9	10	6	19	44

	Total	4	9	18	30	61

FIGURE 75G.2. Risk of skin cancer, by age group, in all transplantation patients with surviving grafts (from both cadaveric donors and living related donors).

were identified. Eighty-four were associated with diarrhea (64 cases sporadic, 20 constituting an outbreak), and 14 were atypical. Shiga toxin-producing *Escherichia coli* O111:H- was the most common isolate in sporadic HUS and caused the outbreak. Shiga toxin-producing *Escherichia coli* O157:H7 was not isolated in any case (9). Of five children with T activation caused by pneumococcal pneumonia, all had a complete recovery of renal function (10). The New Zealand Paediatric Society Surveillance Unit study, currently into its fifth year, showed that the most common serotype was *E. coli* O157 and that more than 90% of cases occurred in the North Island.

Chronic Renal Failure

The incidence of ESRF in Australia and New Zealand is 5 to 6 per million population aged 0 to 15 years. In the adolescent age group, the incidence is 13 per million population aged 15 to 18 years (11). Table 75G.1 shows the number of children and adolescents (up to 20 years of age) who commenced treatment for ESRF from 1995 to 2000. The trend in the last 5 years is hospital-based peritoneal dialysis for

TABLE 75G.2. SKIN CANCER IN PEDIATRIC RENAL TRANSPLANTATION PATIENTS

Type of skin cancer	No. cases	Median age (range)		
		At first treatment for renal disease	At transplantation	At cancer diagnosis
Squamous cell carcinoma	22	12.6 (7.8–14.8)	13.3 (8.2–16.7)	28.3 (18.4–45.0)
Basal cell carcinoma	12	12.1 (9.1–14.7)	13.3 (9.8–15.1)	27.8 (14.7–41.3)
Merkel cell tumor	1	14.8	15.2	29.5
Total	35	12.5 (7.8–14.8)	13.3 (8.2–16.7)	28.4 (14.7–45.0)

small children (0 to 4 years) and hospital-based hemodialysis for adolescents. Preemptive renal transplantation occurred in 20% of children.

Australian and New Zealand adult transplant patients have a high incidence of skin cancers relating to the hot climate (12). Figure 75G.2 shows the incidence of skin cancer in different transplant age groups. The risk over 20 years is 10% in children, 30% in adolescents, and 60% in adults. In children the median interval between transplantation and diagnosis of the first skin cancer lesion (basal cell carcinoma or squamous cell carcinoma) is approximately 15 years (Table 75G.2).

The management of adolescent transplant patients continues to encounter difficulties. Analysis by era shows an improvement in graft survival for the 0- to 14-year age group but not the 15- to 19-year age group (Fig. 75G.3). This is most likely related to poor compliance with the medication regimen. Overall patient survival between 1990 and 2000 for the 0- to 19-year age group was 93%.

FIGURE 75G.3. Graft survival in Australian pediatric and adolescent transplant recipients by era.

ASIA

**CARMELO A. ALFILER
HUI-KIM YAP
MAN-CHUN CHIU**

OVERVIEW

The United Nations Population Fund reported that 60% of the world's population of 6.1 billion at the end of 2001 resided in Asia (1). The majority of Asia's people are from developing countries with large populations, which results in major problems in education and health care. This chapter describes the current status of pediatric nephrology in the member countries of the Asian Pediatric Nephrology Association (the report for Japan is in Chapter 78C).

Since the last update (2), there has been a marked increase in the number of postresidency fellowship programs across the region, which has contributed to improvement in care of children with kidney diseases. Better diagnostic and therapeutic facilities in many Asian medical centers have increased the chances of survival and quality of life. The widespread use of oral rehydration solutions has caused a significant decrease in the incidence of acute renal failure due to gastroenteritis-related dehydration. Mass urinary screening programs have been conducted among apparently healthy schoolchildren to help identify kidney and urinary tract abnormalities that can be managed early, in the hope of preventing and retarding progression to chronic renal failure.

EAST ASIA

China

China has more than 1 billion people, of whom nearly one-third are children. In 1979, pediatric nephrologists in China formed a cooperative study group, which led to the establishment of the Chinese Society of Pediatric Nephrology in 1986. In recent years, its membership has reached more than 250. Several projects have been undertaken, including standardization of the clinical classification of glomerular diseases (1979), nationwide investigation of kidney diseases in hospitals (1982, 1992), nationwide urinary screening (1986), and cooperative study of renal biopsy specimens (1995). In 2000,

new clinical guidelines on the diagnosis and management of nephrotic syndrome and other glomerular diseases, based on current practice in China, were formulated by the Chinese Association of Pediatrics and replaced the previous guidelines established in 1982 (3).

In a 1982 survey of 105 hospitals in 20 provinces, acute glomerulonephritis was common, accounting for 54% of renal cases requiring hospital admission (4). Its incidence appears to have declined, as a similar survey done in 1992 showed that such cases constituted only 37% of renal admissions. Acute glomerulonephritis was usually preceded by upper respiratory tract infections in the north and by skin infections in the south. In the 1982 survey, renal diseases requiring hospital admission were nephrotic syndrome (21%), urinary tract infection (8%), and Henoch-Schönlein nephritis (5%). Hepatitis B virus infection was commonly associated with membranous nephropathy, which occurred in 144 of 204 cases.

Renal involvement was commonly seen in Chinese children with systemic lupus erythematosus and commonly affected those in their teens (5). In a review encompassing 105 children with lupus nephritis, the clinical types were nephrotic syndrome (45%), nephritic syndrome (34%), rapidly progressive nephritis (9%), chronic nephritis (2%), and mild proteinuria (10%). Treatment agents included prednisone and cyclophosphamide. Methylprednisolone and cyclophosphamide pulse therapy were used to treat severe cases (6).

A nationwide urinary screening for proteinuria and hematuria was performed in 2- to 14-year-old children in 1986 (7). Of 224,291 children screened, 0.85% were found to have urinary abnormalities, which included asymptomatic hematuria, nephritis, urinary tract infection, asymptomatic bacteriuria, urinary stones, hydronephrosis, and urinary malformations. Urinary abnormalities were more common in girls than in boys (0.85% vs. 0.62%).

In an analysis of the causes of acute renal failure prevalent 10 to 20 years ago (8), acute nephritis was found in 40% of cases; the other causes were progressive glomerulonephritis, infection, septicemia, and congenital renal malformations.

The average mortality was 38%. Peritoneal dialysis is the main modality of dialysis for acute renal failure in many hospitals, but hemodialysis is carried out in a few centers. No data are available on chronic dialysis in children, and few children have undergone renal transplantation.

Hong Kong

Hong Kong has a population of 6.73 million of which 1.55 million (23%) are 0 to 19 years of age. Children with renal diseases are cared for in most major acute-care hospitals. Since 1999, a pediatric renal center for dialysis and transplantation has been in operation, in which children with chronic renal failure are offered treatment in a centralized end-stage renal disease program (9).

The Hong Kong Pediatric Nephrology Society was formed in the 1980s to bring together pediatricians working on pediatric renal diseases to promote nephrology work in children. Several surveillances and a renal registry have been set up for hospital patients. The number of new cases per year of nephrotic syndrome, lupus nephritis, cystic kidney diseases, and hereditary tubular disorders were 57, 10, 12, and 2, respectively (10). An average of seven new cases per year of chronic renal failure with glomerular filtration rates lower than 25 mL/min/1.73 m² were seen in children under 15 years old. A collaborative study on primary nocturnal enuresis involving 100 children was carried out; results showed that combined use of an enuresis alarm and desmopressin was most effective and yielded a lower relapse rate.

The incidence of end-stage renal disease in children younger than 15 years of age was estimated to be 4 per million children in the early 1990s (10). More recently, however, the incidence for those younger than 20 years of age was 34 per million adjusted population (11). The incidence for those between 11 and 20 years of age was six times that of children 10 years old or younger. The common causes of end-stage renal failure were chronic glomerulonephritis (26%), chronic pyelonephritis (18%), hypoplastic or dysplastic kidneys (18%), and hereditary or familial diseases (9%); no cases due to cystinosis or hemolytic uremic syndrome were reported (10).

Chronic ambulatory peritoneal dialysis was started in the 1980s, and since 1996, automated peritoneal dialysis has been provided to nearly all children on peritoneal dialysis. In a review encompassing 24 children on automated peritoneal dialysis, a very low peritonitis rate of 1 in 87.5 patient-months was recorded (9). Chronic hemodialysis was offered to older children or those deemed clinically unsuitable for peritoneal dialysis. In a review involving 12 patients on chronic hemodialysis, no major complications were encountered, and establishment of suitable vascular access remained the main obstacle to overcome in small children (9).

Renal transplantation in children has been available since the late 1980s, and in a review conducted in the mid-1990s involving seven children, all grafts were functioning

after a follow-up period of 37.9 months, with a mean serum creatinine level of 134 μ mol/L (12). In a review of outcomes for 20 transplanted grafts, 1- and 3-year actuarial graft survival rates were 92.3% and 83.1% for cadaveric donor grafts, and 100% and 100% for living donor grafts, respectively (13). The longest graft survival was more than 10 years.

A comprehensive renal registry including both adults and children with end-stage renal disease has been set up in Hong Kong. The 2002 data showed that, of children younger than 10 years of age, four were on peritoneal dialysis, one was on hemodialysis, and three had undergone transplantation. Among adolescents 11 to 20 years of age, 15 were on peritoneal dialysis, 9 were on hemodialysis, and 27 had received transplants (11).

Korea

South Korea had 47,343,000 inhabitants in 2001, and 28.5% were younger than 19 years of age (14). The Korean Society of Pediatric Nephrology, established in October 1994, has over 70 members. There are 45 universities and general hospitals capable of performing renal diagnosis and therapy in Korea. Ten university hospitals have dialysis and transplantation centers for children and offer postresidency fellowship programs in pediatric nephrology.

At the Department of Pediatrics, Seoul National University Children's Hospital, one of the tertiary referral hospitals in Korea, children with renal disease comprised 5.8% of total inpatients in 1999. Urinary tract infection (29%), nephrotic syndrome (22%), and chronic renal failure (17%) were the leading causes of admissions among renal patients (15).

In a review of more than 1400 renal biopsy specimens performed at two tertiary referral centers (16,17), the most frequent pathologic findings were minimal change lesion (26% and 25%), immunoglobulin A (IgA) nephropathy (15% and 10%), focal segmental glomerulosclerosis (14% and 9%), and Henoch-Schönlein nephritis (7% and 14%).

In 2000, a nationwide survey of childhood chronic renal failure was performed by the Korean Society of Pediatric Nephrology (18). The incidence of chronic renal failure was 3.68 per 1 million child population per year and the male to female ratio was 1.73:1. Reflux nephropathy (16%), focal segmental glomerulosclerosis (11%), and renal hypoplasia or dysplasia (9%) were the leading causes of chronic renal failure. The initial mode of renal replacement therapy for end-stage renal disease patients was hemodialysis in 42% of cases, peritoneal dialysis in 35% of cases, and renal transplantation in 23% of cases.

Taiwan

Taiwan is an island of more than 22 million people of whom 6.4 million are between 1 and 19 years of age. A biannual

mass urinary screening of elementary and junior high school students has been in operation since 1990. The first morning urine is tested for pH, protein, occult blood, and glucose. Children whose test results are positive undergo repeat testing 10 to 15 days later, with the addition of sulfosalicylic acid and urine sediment examination. Results from the screening of 2.6 million children showed that 0.10 to 0.35% had proteinuria and 0.07 to 0.21% had hematuria (19). A third examination involves procurement of a blood sample by a public health nurse, which is subsequently tested for 11 substances, including total protein, albumin, globulin, blood urea nitrogen, creatinine, antistreptolysin O, complement C3, cholesterol, hepatitis B surface antigen, IgA, and glucose. The children are classified into grades A to E after analysis of the results. Those in grades D and E are referred to a hospital for further investigation.

In an epidemiologic study of 132,686 schoolchildren screened by renal ultrasonography, 0.5% were found to have renal abnormalities, including hydronephrosis (0.19%), unilateral renal agenesis (0.08%), unilateral small kidneys (0.10%), renal cystic disorders (0.07%), and ectopic kidney (0.02%) (20). Fifty children underwent surgical correction of the abnormality.

Eighty children are registered for chronic ambulatory peritoneal dialysis or automated peritoneal dialysis, and 152 children younger than age 18 are registered for hemodialysis. Dialysis is performed in ten centers throughout Taiwan. Those undergoing chronic ambulatory peritoneal dialysis have peritonitis rates of one episode per 36 patient-months. The first pediatric kidney transplant program was started in Taipei in 1985. To date, 44 children have undergone transplantation, and currently four centers perform pediatric transplantation. More than 90% of transplants were cadaveric organs. Thirty-four patients had prolonged graft function, eight had graft failure, and two died. Common complications in transplantation patients with long-term survival were osteoporosis and cataracts. Although short stature was of great concern, physical and psychosocial rehabilitation has been successful.

SOUTHEAST ASIA

Indonesia

In Indonesia, a country of at least 200 million people in which approximately 30%, or 70 million, are younger than 15 years of age, there are 11 centers for renal diagnosis and therapy; 9 offer dialysis and only 2 perform renal transplantation. One of these centers offers postresidency fellowship training in pediatric nephrology.

Seven university hospitals throughout Indonesia undertook a collaborative retrospective-prospective study from 1984 to 1988 to investigate the spectrum of renal diseases among hospitalized children (21). Of the 104,457 patients admitted to the hospitals over this period, 2892 (3%) had

some kidney or urinary tract complaint. The most common kidney diseases encountered were nephrotic syndrome (35%), acute glomerulonephritis (26%), and urinary tract infections (23%). The study showed that the profile of renal diseases was uniform throughout the country and that no noticeable changes in incidences of disease occurred during the 5-year period.

Between 1991 and 1995, data from the general hospital in Jakarta showed that 688 (or 6.2%) of 11,162 children hospitalized were admitted for renal diseases (22). This was almost double the number of children hospitalized for the same reason between 1984 and 1988, that is, 489 (or 3.3%) of 14,480 children (23). Nephrotic syndrome was still the most frequent cause of renal disease, found in 41.4% of all cases. It was also the main cause of end-stage renal disease (47%), followed by chronic glomerulonephritis (8.8%) and urinary tract infection and/or malformations (44%) (22). In addition, a collaborative study of eight child health departments in teaching hospitals between 1997 and 2001 reported 276 cases of acute glomerulonephritis, mainly poststreptococcal in cause. There were 139 boys (50.4%) and 137 girls (49.6%), aged between 2.5 and 14.5 years, of whom the majority (77.1%) were older than 6 years (24).

Urinary incontinence has been increasingly reported. Between 1989 and 2001, 20 cases were seen in Jakarta, composed of ten boys and ten girls. Seven cases were due to spinal dysraphism, three cases of osteolytic lesion in the vertebrae were due to malignancy, six patients had non-neurogenic bladder, and four had anatomical abnormalities. Eleven out of the 20 children (55%) developed chronic renal failure (25).

Among the causes of acute renal failure in older children, jengkol bean intoxication or poisoning is still the most prominent cause, responsible for 20 out of 64 cases (31%) of children hospitalized with acute renal failure in the general hospital in Jakarta between 1984 and 1993 (26). Jengkol bean is widely consumed in Indonesia, especially in rural areas. The pathophysiologic mechanisms of acute renal failure include obstruction of the renal tubules by jengkol acid crystals, as well as a direct toxic effect on the tubular cells.

Tuberculosis is one of the most common complications in children with nephrotic syndrome. A cross-sectional study of 100 children with nephrotic syndrome revealed that 15% had tuberculosis. The majority of cases (80%) occurred in children with frequently relapsing and steroid-dependent nephrotic syndrome (27).

Malaysia

Malaysia has a total population of 23,795,300, of whom 10,293,000 (43.26%) are in the 0- to 19-year age group. There are currently eight pediatric nephrologists in the country. Dialysis facilities for children with end-stage renal

failure are available in four centers, and pediatric renal transplantation is offered in one center. The 2001 report of the Malaysian Dialysis and Transplant Registry indicated that the dialysis provision rate for children aged 0 to 14 years was 4 per 1 million child population (28), with more than 70 children on dialysis. More than 90% of children on dialysis were on chronic ambulatory peritoneal dialysis. Only two children were on automated peritoneal dialysis. Dialysis treatment for children is subsidized by the Ministry of Health.

More than 90 children younger than 18 years of age have undergone transplantation since the inception of the program in 1986; 90% of donors were living related relatives. The patient and graft survival rates have been comparable to those in other countries.

Singapore

Singapore has a child population (younger than the age of 15 years) of 769,182. Over the last two decades, the pattern of renal diseases in Singapore children has changed drastically. Previously poststreptococcal acute glomerulonephritis was the most common type of glomerulonephritis seen (29). Over the last decade, idiopathic nephrotic syndrome has taken on increasing prominence as a cause of morbidity in children. In a retrospective study of 91 children with steroid-responsive nephrotic syndrome, 61.5% subsequently developed steroid dependency (30). The median age at onset was 3.1 years, and there was no correlation between increasing age at onset and steroid dependency as reported in other studies (31). The incidence of hematuria at presentation of nephrotic syndrome was 31.1%, but this did not correlate with development of steroid dependency. On the other hand, a prolonged duration of treatment before achieving remission was shown to be a significant predictor of steroid dependency (30). In fact, 76.3% of patients who had not achieved remission by day 9 subsequently became steroid dependent, whereas all patients who were still proteinuric at day 21 developed steroid dependency. Of the nephrotic children with steroid resistant disease, almost half had focal segmental glomerulosclerosis, whereas 42% had minimal change disease. Over a period of 10 years, 57.7% of children with focal segmental glomerulosclerosis had progressed to end-stage renal failure. Nonresponse to cyclosporine therapy was a significant predictor of progression to renal failure (32).

Singapore has seen a change in the pattern and modalities of treatment of acute renal failure in children. In an 18-year study of children requiring acute dialysis, it was found that 91% of children underwent dialysis for acute renal failure, whereas the remaining 9% had metabolic disorders (33). The main causes of acute renal failure in this cohort were acute tubular necrosis (62.2%), hepatorenal syndrome (15.1%), acute glomerulonephritis (4.5%), hemolytic uremic syndrome (7.6%), and obstructive uropathy (1.5%).

Approximately one-fourth of children undergoing dialysis for acute renal failure were treated in the first 15 years of the study when acute peritoneal dialysis was the sole modality of dialysis, whereas 75% of them were treated in the last 3 years, when continuous hemodiafiltration was used more frequently in the critical care setting. Despite the implementation of continuous hemodiafiltration for acute dialysis, the mortality rose from 63.9% in the first 15 years to 72.4% over the last 3 years of the study. This increase in mortality was probably related to the changes in patient selection profile because more critically ill children with multiorgan dysfunction syndrome underwent dialysis. Previously, many of these children would have been deemed "undialyzable," especially those with intra-abdominal pathology such as necrotizing enterocolitis and postabdominal surgery, because the sole modality of dialysis was peritoneal dialysis.

The chronic dialysis and transplantation program was first started in 1988 (34). With an annual incidence of end-stage renal failure of 5 to 6 per 1 million children younger than 15 years of age, a total of 46 children have required chronic dialysis, almost half of whom have undergone transplantation. The main causes of end-stage renal failure are chronic glomerulonephritis (43%), renal dysplasia and hypoplasia (27%), and reflux nephropathy (11%). The main modality of chronic dialysis was night intermittent peritoneal dialysis. Although infections remain a major cause of morbidity, the peritonitis rate of 1 case per 17 patient-months was comparable with that in many centers in Europe and North America. Cardiovascular disease has been identified as one of the major causes of morbidity in adults and children on long-term dialysis. Approximately 35% of the children in the chronic dialysis program had evidence of left ventricular hypertrophy, as measured by a left ventricular mass index of greater than 51 g/m^{2.7}. This was shown to correlate significantly with the degree of anemia as measured by the hematocrit in these children.

Pediatric renal transplantation was first performed in Singapore in 1989. Since then, 24 children have received transplants, of whom 67% were given allografts from living related donors. The 5-year allograft survival rate for cadaveric transplants was 58%, whereas the 5- and 10-year allograft survival rates for transplants from living related donors were 92% and 76%, respectively. Viral infections, especially cytomegalovirus infection, occurred in 33% of transplant recipients. Noncompliance with the immunosuppressive treatment regimen was a major problem in 29% of patients.

Screening programs aimed at detecting renal disease and hypertension at an early stage have been initiated in several countries, with the goal of instituting effective interventions to prevent progression to chronic renal failure. In Singapore, a pilot program was launched in 1999 to screen for urinary abnormalities and hypertension in a cohort of 12-year-old schoolchildren (35). Approximately 2000 schoolchildren, or

93.7% of the target population, participated in this program. The prevalence of abnormalities in the target population was high, with hypertension in 13% (predominantly systolic hypertension of 8.4%), proteinuria in 2%, and hematuria in 8%. Increasing weight was found to be a significant predictor for hypertension, which emphasizes the importance of weight control as a potential effective adjunctive strategy for the management of hypertension. On the other hand, low body weight was found to be a significant risk factor for proteinuria in this multiethnic population (36).

Thailand

Thailand has a population of 62 million, of whom 24% are younger than 15 years of age. Common renal problems in children include acute poststreptococcal glomerulonephritis, primary nephrotic syndrome, lupus nephritis, urinary tract anomalies, and infection and urolithiasis. More than 90% of children with primary nephrotic syndrome responded well to corticosteroid therapy (37). Results of renal biopsies performed in selected cases (those with steroid-resistant disease, frequent relapse, and steroid-dependent disease) showed mild mesangial proliferative glomerulonephritis with mesangial immunoglobulin M deposits in 60 to 70%, followed in frequency by focal segmental glomerulosclerosis. Children with immunoglobulin M nephropathy tended to relapse when treated with corticosteroids; however, they were as responsive to oral cyclophosphamide therapy as patients with minimal change disease (38).

Lupus nephritis was the most common secondary cause of glomerulonephritis in Thai children. Diffuse proliferative glomerulonephritis (World Health Organization class IV) was the most common histopathologic finding, identified in more than 50% of the biopsy specimens (39). The prognosis of severe lupus nephritis has improved greatly with the use of intravenous pulse cyclophosphamide therapy (40). IgA nephropathy, as in adults in Thailand, was not a common cause of primary glomerulonephritis in children—only 5% of the biopsy specimens showed mesangial IgA deposits.

Acute renal failure from diarrheal dehydration has been decreasing due to the widespread home use of oral rehydration solution. Hemolytic uremic syndrome as a cause of acute renal failure is rarely seen in Thai children. In the past, bladder calculi were an important problem in the northeast region. With the improvement in nutrition, the prevalence of bladder stones has also been declining. Hence the pattern of childhood renal diseases in Thailand has changed in recent years in association with overall improvement in the socioeconomic climate and health care practices.

Philippines

As of July 2001, the total population of the Philippines was 82,841,518 (41). In 1994, the Pediatric Nephrology Soci-

ety of the Philippines (PNSP) was established. Its mission is the continuing education of pediatricians-trainees, community service, advocacy for children with kidney disease, and research. Currently, the PNSP has 40 certified members. Four accredited centers offer postresidency fellowships in pediatric nephrology.

Ninety-one hospitals in the country with accredited residency training programs offer facilities for diagnosis and treatment of renal disease; 48 of these are located in metropolitan Manila. There are 138 hospital centers for both hemodialysis and peritoneal dialysis, 49 in metropolitan Manila and 89 in other regions. The majority of kidney transplantations are performed in metropolitan Manila hospitals, with the National Kidney and Transplant Institute performing 71% of procedures (42).

Since 1991, kidney disease has consistently ranked among the top ten causes of mortality in the government's registry of diseases. For every 100,000 population in 1998, nephritis and nephrotic syndrome accounted for 10.2 cases or 2.1% of total deaths (43). From January to December 1998, urinary tract infection was the eighth leading cause of morbidity as reported by Philippine Pediatric Society-accredited hospitals nationwide (44). In a 6-year review, the PNSP reported a total of 5861 admissions in four accredited tertiary medical centers with fellowship programs in pediatric nephrology; of these admissions, 1533 patients (26%) had postinfectious acute glomerulonephritis, 1302 (22%) had idiopathic nephrotic syndrome, 812 (14%) were in renal failure for various causes, 335 (6%) had secondary chronic glomerulonephritis, 204 (3.5%) had bladder dysfunction, 188 (3%) had congenital or inherited renal disease, 113 (2%) had IgA nephropathy, 80 (1.5%) had urolithiasis, 79 (1.4%) had tumors, and 415 (7%) had miscellaneous disorders such as hypertension and renal tubular disease (45). The spectrum of renal and urinary tract disease has not changed since the last census. It is interesting to note, however, that the number of reported renal tubular disorders has been increasing through the years and that the incidence of acute renal failure due to leptospirosis has remained high.

The Philippines has one of the highest numbers of kidney transplantations in Asia. From 1983 to 2000, 1829 transplantations were performed at the National Kidney and Transplant Institute, 69 of which were in pediatric patients aged 5 to 18 years of age (3.78%). There were 66 first and 3 second transplantations, mostly with grafts from live donors. The most common cause of end-stage renal disease was chronic glomerulonephritis, representing 88% of cases (R. M. Rosete-Liquete, "Profile of pediatric renal transplant patients in the Philippines," unpublished data, 2002).

In June 1993, the Department of Health, in cooperation with many governmental and nongovernmental agencies, launched the Philippine Preventive Nephrology Project, a mass urinary screening program for apparently healthy public elementary schoolchildren in grades 1 to 6. In 1999,

at the end of the project, 5,758,241 of the targeted 9,800,000 children enrolled in the 1994–1995 school year were tested; 24% of them showed at least one urinary abnormality by dipstick testing. After two formal urinalyses in 361,965 children, the prevalence rate of urine abnormality was 165 per 10,000 cases. Among 19,947 pupils who completed initial and subsequent diagnostic investigations, the following kidney problems were identified, with prevalence rates expressed per 10,000 cases: pyuria, 104; urinary tract infection, 23; benign hematuria, 17; glomerulonephritis, 10; asymptomatic proteinuria, 7; nephrotic syndrome 0.5; and others, 2 (46). The Philippine Preventive Nephrology Project is now known as the Renal Disease Control Program.

SOUTH ASIA

Bangladesh

Bangladesh is the eighth most populous country in the world, with approximately 133 million inhabitants recorded in 2001. Of these, 40% are younger than 15 years of age (41).

A Division of Pediatric Nephrology was established at the Institute of Child Health in the capital city of Dhaka. A masters-level subspecialty program has been started for pediatric nephrology and a Kidney Institute for both adult and pediatric disease has been established.

The pattern of renal disorders and the socioeconomic constraints are similar to those in India (see later). Postdysenteric hemolytic uremic syndrome is a common cause of acute renal failure. A large outbreak of acute renal failure occurred in Bangladesh in 1995 secondary to ingestion of ethylene glycol-contaminated liquid paracetamol preparations. That epidemic was associated with a high mortality rate (47).

India

India had more than 1 billion people in 2001. Children between the ages of 0 and 19 years comprise 46.5% of the population (48). A network of state-managed health centers, and district and referral hospitals has been in place for more than 50 years. The resources available at these centers are often limited, and a large proportion of the population obtains medical care through a parallel private sector.

A nucleus of pediatric nephrology was established in New Delhi in 1969. The growth of the specialty received a further impetus when the Indian Academy of Pediatrics created specialty chapters and instituted training fellowships. The Indian Pediatric Nephrology Group has 210 members, who are pediatricians trained in nephrology. Most of them are located in departments of pediatrics of medical schools and major hospitals. The Indian Pediatric Nephrology Group provides short-term training fellowships in the specialty. A 1-year postresidency fellowship has been started in Bangalore. Consensus recommendations on

the management of idiopathic nephrotic syndrome, urinary tract infections, and antenatally detected hydronephrosis have been formulated by the group (49–51).

Idiopathic nephrotic syndrome is a common problem, although its exact incidence is unknown. The clinicopathologic features and response to therapy are similar to those reported in the developed countries (52). The incidence of serious infections, which complicate the course of the illness, is higher (53). The use of medications like cyclosporin is limited by economic factors. Levamisole has been found effective and is widely used as a steroid-sparing agent for patients with frequent relapses and steroid dependence (54).

The incidence of poststreptococcal glomerulonephritis was high during the 1970s but has gradually declined. Acute renal failure caused by severe hypovolemia from acute gastroenteritis has also decreased due to the widespread use of oral rehydration therapy (55). Acute intravascular hemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency, snakebite in coastal regions and rural areas, and *Plasmodium falciparum* malaria are important causes of acute renal failure in children. A large increase in the number of patients with hemolytic uremic syndrome occurred during the latter part of the 1970s, and hemolytic uremic syndrome was the most common cause of acute renal failure until the early 1990s (56). Clinical and epidemiologic evidence led to the conclusion that most of these cases were associated with *Shigella*-caused dysentery. Over the last 5 to 7 years, the incidence of hemolytic uremic syndrome has declined. Infection caused by verotoxin-producing *Escherichia coli* appears to be rare in the Indian subcontinent. Perinatal asphyxia, septicemia, and injudicious use of aminoglycoside drugs are important etiologic factors in acute renal failure in the newborn period. Peritoneal dialysis is the most commonly used dialysis modality for patients with acute renal failure.

The incidence of hepatitis B nephropathy is very low, although the carrier rate of hepatitis B surface antigen is approximately 3%. IgA nephropathy is also uncommon in children in India. The incidence of familial and genetic disorders, collagen vascular diseases, and renal tubular disorders appears to be similar to that in the United States and Europe. Takayasu's disease (idiopathic aortoarteritis) is an important cause of hypertension in children (57).

The chief causes of chronic renal failure include obstructive uropathy, reflux nephropathy, and chronic glomerulonephritis. Provision of renal replacement therapy is constrained by socioeconomic factors. Facilities for chronic hemodialysis and renal transplantation are available at six pediatric nephrology centers in the country. The use of continuous ambulatory peritoneal dialysis is limited due to its cost and the necessity to import consumable supplies. Although a Human Organ Transplantation Act came into force in 1994, the cadaveric transplant program is not well developed. Neither the state nor insurance companies subsidize the costs of therapy, which are high, particularly in relation to per capita gross national product.

Pakistan

The total population of Pakistan in 2001 was estimated to be 152 million. Of this, the pediatric population younger than 18 years of age is 73.6 million (48.37%) (58). Pakistan has a large rural population (65%) that is served by inadequate medical facilities. Larger cities with university hospitals have well-equipped centers.

In 1997, the Pakistan Pediatric Nephrology Group was formed under the umbrella of the Pakistan Pediatric Association. It has approximately 50 members, including pediatricians with special interest in nephrology. The group provides training in pediatric nephrology to family physicians, undergraduate medical students, and postgraduate students in fellowships in pediatrics. A formal fellowship program in pediatric nephrology has not been developed to date.

In one study, nephrotic syndrome was found to be the most common renal disease (59). Response to steroid therapy and clinical presentation in nephrotic syndrome are found to be similar to those in Europe and the United States. Seroprevalence of hepatitis B virus is high in Pakistan, but its association with nephrotic syndrome has not been demonstrated (60). Poststreptococcal acute glomerulonephritis has shown a decline compared to the level in previous studies, whereas congenital renal anomalies and renal calculi have been recognized more frequently (59). Vesicoureteric reflux and posterior urethral valves are the two most common structural abnormalities and account for 60% of the congenital anomalies.

Urolithiasis is the third most common cause of renal morbidity, particularly in southern parts of the country. The province of Sindh has the highest prevalence of stone disease in the world (61). The high prevalence may be due to multiple factors, such as hot and humid climate with inadequate fluid intake, consumption of a mainly cereal-based diet due to poverty, and recurrent diarrhea in malnourished children. There may also be a genetic predisposition.

Urolithiasis was found to be the most common cause of acute and chronic renal failure (59). Urolithiasis was also responsible for end-stage renal failure in 20% of 75 children who underwent renal transplantation (62).

There are approximately 15 centers in the country that provide peritoneal dialysis and appropriate investigations to manage children with renal problems, although hemodialysis services are limited to 5 centres. The majority of kidney transplants in the pediatric age group are performed at the Sindh Institute of Urology and Transplantation in Karachi. To date the institute has performed 100 transplantations, all with organs from living related donors. The province of Punjab has two centers in the private sector performing kidney transplantation.

COLOR PLATE 14.4. Real-time reverse transcription polymerase chain reaction (PCR). The figure illustrates an actin calibration curve. Total RNA was extracted from HK2 cells and loaded in increasing concentrations in the sample reaction. Fluorescence was measured in real time as primers were incorporated in newly synthesized PCR fragments with an ABI Prism 7700. The number of cycles required to cross a given fluorescence threshold (**A**) is proportional to the initial amount of loaded messenger RNA (**B**).

COLOR PLATE 14.5. Differential display on DNA microarrays. Messenger RNA (mRNA) obtained from two different samples are labeled with two fluorescent cyanine dyes with one round of reverse transcription. The fluorescent targets are then pooled and hybridized under stringent conditions to the clones on the microarray chip. The emission light is measured with a scanning confocal laser microscope at two different wavelengths that are specific for each dye. Monochrome images are then pseudo-colored, combined, and analyzed with suitable computer software.

COLOR PLATE 19.2. Bladders augmented with a collagen matrix derived from bladder submucosa seeded with urothelial and smooth muscle cells [allogenic bladder submucosa (ABS) + cells] showed a 100% increase in capacity compared to bladders augmented with the cell-free ABS, which showed only a 30% increase in capacity within 3 months after implantation.

COLOR PLATE 19.4. Tissue-engineered renal units. **A:** Retrieved tissue-engineered renal unit shows the excretion of yellow fluid in the reservoir. **B:** The engineered tissue showed a clear unidirectional continuity between the mature glomeruli, their tubules, and the reservoir.

COLOR PLATE 19.6. Schematic diagram of therapeutic cloning approach for the isolation of genetically matched tissues.

COLOR PLATE 23.7. Mercaptotriglycine renogram in a 1-month-old boy with antenatal diagnosis of right hydronephrosis and left small cystic kidney. The renogram confirms a nonfunctioning left kidney and a ureterohydronephrosis with response to furosemide (megaureter on magnetic resonance). **A:** Curves corresponding to the function of the right kidney. **B:** Morphologic appearance of the dilated right urinary tract.

COLOR PLATE 23.22. Acute pyelonephritis. Power Doppler ultrasound showing striking area of absent vascularization due to inflammatory involvement (*arrows*). (Courtesy of Dr. Dufour.)

COLOR PLATE 26.2. Immunofluorescence microscopy. Normal distribution of the $\alpha(IV)$ chains in renal and epidermal basement membranes.

COLOR PLATE 26.5. Immunofluorescent microscopy. Distribution of the $\alpha(IV)$ chains in renal and epidermal basement membranes of male (A–C) and female (D–F) patients affected with X-linked Alport syndrome. C: Absence of epidermal basement membrane labelling (arrow). F: Discontinuous epidermal basement membrane labelling (arrows).

COLOR PLATE 26.6. Immunofluorescent microscopy. Distribution of the $\alpha(IV)$ chains in renal and epidermal basement membranes of patients affected with autosomal recessive Alport's syndrome.

COLOR PLATE 30.1. Acute postinfectious glomerulonephritis. The glomeruli show global intracapillary hypercellularity with large numbers of polymorphonuclear leukocytes in the glomerular capillary lumina (hematoxylin and eosin stain, $\times 400$). (Courtesy of Peter Degrell, University of Pécs Faculty of Medicine, Nephrological Center, Pécs, Hungary.)

A

B

C

COLOR PLATE 30.2. Acute postinfectious glomerulonephritis by immunofluorescence. **A:** Garland pattern. Large, subepithelial deposits of immunoglobulin G on the outer side of the glomerular basement membrane ($\times 400$). **B:** Starry sky pattern. There are fine and coarse granular deposits of immunoglobulin G in the glomerular capillary walls and in the mesangium ($\times 400$). **C:** Mesangial pattern. Predominantly mesangial, coarse granular deposits of C3 ($\times 400$). (Courtesy of Peter Degrell, University of Pécs Faculty of Medicine, Nephrological Center, Pécs, Hungary.)

A

B

COLOR PLATE 32.3. Light microscopic appearance of membranoproliferative glomerulonephritis types I and III. **A:** The glomerulus is enlarged, very cellular, and has a lobulated appearance. The mesangium is markedly expanded. The capillary walls are thickened in appearance; frequently, the capillary lumens are obscured by the mesangial expansion. In addition to the increase in mesangial cells, scattered neutrophils are also identified in many of the segments. **B:** The type III glomerulus is less cellular in appearance, and there is less expansion of the mesangium. Most of the capillary loops are patent; however, thickened capillary walls are evident. (Courtesy of Dr. David Witte.)

COLOR PLATE 32.4. Immunofluorescence appearance of membranoproliferative glomerulonephritis type I. The prominent peripheral distribution of immunoglobulin G deposits in the capillary walls results in a fringe pattern. (Courtesy of Dr. David Witte.)

COLOR PLATE 40.2. Schematic view of the antidiuretic arginine vasopressin (AVP) signaling pathway in collecting duct cells and the proteins (microtubule, dynactin-dynein) and vesicle targeting receptors (VAMP-2, syntaxin-4, NSF) that might participate in the specificity of aquaporin-2 water channel (AQP2) targeting to the luminal plasma membrane. AC, adenylyl cyclase; AQP3, aquaporin-3 water channel; AQP4, aquaporin-4 water channel; G, stimulatory guanine nucleotide binding protein; NSF, N-ethylmaleimide-sensitive fusion protein; PKA, protein kinase A; V₂, vasopressin type-2 receptor.

COLOR PLATE 40.3. Schematic representation of the postulated mechanisms in a collecting duct cell to explain recessive and dominant forms of nephrogenic diabetes insipidus (NDI) caused by aquaporin-2 (AQP2) water channel mutations. Normal AQP2 proteins are transported from the endoplasmic reticulum via the Golgi apparatus to the luminal side of the cell. In case of a recessive NDI mutation AQP2 is retained in the endoplasmic reticulum due to misfolding and subsequently broken down by proteasomes. In case of a dominant NDI mutation there is a change in the transport signal of the AQP2 protein and consequent misrouting to the Golgi network or late endosomes/lysosomes. (Adapted from Knoers NVAM, Deen PMT. Van Gen naar Ziekte; van vasopressine-V₂-receptor en aquaporine-2 naar nefrogene diabetes insipidus. *Dutch J Med* 2000;144:2402–2404.)

COLOR PLATE 45.2. Purpuric rash of Henoch-Schönlein purpura over the sides of the buttocks.

COLOR PLATE 45.5. Renal biopsy specimen from a patient with nephritis of Henoch-Schönlein purpura showing expansion of the mesangial matrix and increase in mesangial cellularity (periodic acid-Schiff $\times 250$).

COLOR PLATE 45.7. Immunopathology of Henoch-Schönlein nephritis. Mesangial deposits of immunoglobulin A (anti-immunoglobulin A $\times 250$).

Class I

Class II

Class III

Class IV

Class V

COLOR PLATE 46.1. Class I: Normal glomerulus by light microscopy (*right-hand side*) but mesangial immune deposits by immunofluorescence (*left-hand side*) study. Class II: Purely mesangial hypercellularity and mesangial matrix expansion in glomerulus by light microscopy, with mesangial immune deposits by immunofluorescence study. Class III: Segmental endo- and extracapillary proliferation involving 50% of all glomeruli by light microscopy with mesangial and some subendothelial immune deposits by immunofluorescence study. Class IV: Global endo- and extracapillary proliferation and subendothelial deposits by light microscopy and numerous immune deposits by immunofluorescence study. Class V: Membranous glomerulonephritis, with subepithelial deposits by light microscopy, clearly defined by immunofluorescence study.

COLOR PLATE 61.2. Severe hypertensive retinopathy in a child with long-standing untreated hypertension showing arteriolar narrowing, hemorrhages and exudates, and papilledema.
